VOLUME 1

Keynote lectures

Large scale river morphodynamics: Application to the Mississippi Delta 3
G. Parker, O. Sequeiros & River Morphodyamics Class of Spring, 2006

Rivers and floods: A concern for people, a problem for engineers, a challenge for research 13
Y. Zech, S. Soares-Frazão, D. Bousmar, B. Spinewine, C. Dal Cin & C. Savary

Engineering case studies

Recent training of the lower Rhine River to increase Inland Water Transport potentials: A mix of permanent and recurrent measures 31
H. Havinga, M. Taal, R. Smedes, G.J. Klaassen, N. Douben & C.J. Sloff

Case study: River restoration projects along the Isar (Germany) 51
W. Binder

Sediment transportation in the Yangtze River and impacts of the three gorges project 61
Z.Y. Wang & Y.T. Li

A. River hydrodynamics

A.1. Turbulent open-channel flow and transport phenomena

Unsteady turbulence characteristics in an undular bore 79
C. Koch & H. Chanson

On the definition of the shear velocity in rough bed open channel flows 89
D. Pokrajac, J.J. Finnigan, C. Manes, I. McEwan & V. Nikora

Large eddy simulation of the two phase flow 99
F. Gallerano, L. Melilla & G. Cannata

Turbulent processes at the entrance of a pool using flow visualization 109
G.A. Marquis & A.G. Roy

A laboratory investigation on the advection of free surface fluctuations in turbulent open-channel flows 119
H. Miyamoto

Turbulent wake region of large roughness elements: Combining flow visualization and high frequency velocity measurements 125
R.W.J. Lacey & A.G. Roy

A new perspective on sidewall correction procedures, based on SKM modelling 135
J. Chlebek & D.W. Knight

Copyright © 2006 Taylor & Francis Group plc, London, UK

Open-channel side-cavities: A comparison of field and flume experiments 145
J. Le Coz, W. Brevis, Y. Niño, A. Paquier & N. Rivière

Spatially averaged near-bed flow field over rough armor layers 153
J. Aberle

Parameterisation of the vertical velocity profile in the wall region over rough surfaces 163
K. Koll

Secondary flow and velocity redistribution by bubble screens in open channel bends 173
J.H.A. Wijbenga, R. Schielen, K. Blanckaert & F. Buschman

Detection and reconstruction of coherent structures based on wavelet multiresolution analysis 181
M.J. Franca & U. Lemmin

Equivalent velocity profile for turbulent flows over gravel riverbeds 189
M.J. Franca & W. Czernuszenko

Admissible and inadmissible simplifications of pollution transport equations 199
P.M. Rowiński & M.B. Kalinowska

Fundamental characteristics of high velocity flows in a sinuous meandering channel in the vicinity of resonance 209
T. Hosoda & M. Nishihama

Smoothly limited finite-volume modelling of rapidly varying river flows 219
T. Krámer & J. Józsa

Large eddy simulation of fully-developed turbulent flow through submerged vegetation 227
T. Stoesser, C. Liang, W. Rodi & G.H. Jirka

Experimental characterization and visualization of mass exchange process in dead zones in rivers 235
W. Brevis, Y. Niño & J. Vargas

Coherent structure of horizontal eddies in meandering compound open-channel flow by using multi-layer scanning PIV 243
M. Sanjou, I. Nezu, T. Doi & H. Quang

Large eddy simulation of turbulent structure in meandering compound open-channel flow 253
M. Sanjou & I. Nezu

Emergence of large-scale coherent structures in a shallow separating flow 261
H. Talstra, W.S.J. Uijttewaal & G.S. Stelling

A.2. Flood propagation and channel/floodplain interactions

Finite element hydrodynamic modeling in a river 273
K.-Y. Han, C.-H. Baek & J.-W. Noh

Fourth order balanced WENO schemes for shallow water equations 281
V. Caleffi & A. Valiani

Two-dimensional numerical simulation of flood propagation in presence of buildings 291
C. Costanzo & F. Macchione

A practical approach to estimating the flow capacity of rivers – Application and analysis 303
C. McGahey, P.G. Samuels & D.W. Knight

Diffusion wave based modeling of flood inundation based on sub-grid connectivity 313
D. Yu & S.N. Lane

Experiments on the flow in a enlarging compound channel 323
D. Bousmar, S. Proust & Y. Zech

Copyright © 2006 Taylor & Francis Group plc, London, UK

Stage-discharge modelling in mobile bed compound channel 333
D. Bousmar, S. Atabay, D.W. Knight & Y. Zech

Performance of several hybrid numerical schemes to determine flooding extent 343
I. Villanueva & N.G. Wright

Roughness coefficient for flood plains with macro roughness elements 351
I. Aydin, M.A. Kokpinar & M. Ustaomer

Discretization of the friction term in the shallow water equations 359
J. Murillo, J. Burguete, P. Brufau & P. Garcia-Navarro

Numerical simulations on the Paraná de las Palmas River 367
J.M. Viscardi, A. Pujol, V. Weitbrecht, G.H. Jirka & N.R. Olsen

Selection of interface plane in the assessment of discharge in two stage meandering and straight compound channels 379
K.C. Patra & K.K. Khatua

Mathematical modelling and analysis of river flows in transitional waters 389
M. Santos & J. Hipólito

Modelling the distribution of boundary shear stress in open channel flows 397
M. Omran & D.W. Knight

A methodology for computing non-uniform flows in compound channels 405
S. Proust, D. Bousmar, N. Rivière, A. Paquier & Y. Zech

A coupled 1D to 2D model for flood plain simulation 415
V. Roubtsova, G. Tchamen, J. Abdo & R. Kahawita

1D complex modelling with lateral exchanges coupling two reaches 421
N. Goutal, C. Cheviet & G. Duvivier

A.3. Dam-break and highly unsteady open-channel flow

A marching in space and time solver for the complete 2D shallow water equations: Application to real test cases 429
C. Aricò, C. Nasello & T. Tucciarelli

An application of BGK numerical method to tidal flow 439
D. Jiaquan

A robust implementation of Riemann solvers for one-dimensional free surface flow simulation in natural rivers 445
G.W. Tchamen, T.T. Quach & R. Kahawita

1-Dimensional numerical analysis of tsunami in river 455
H. Yasuda

Analytical solutions of laminar and turbulent dam break wave 465
H. Chanson

Efficient implicit upwind schemes for river flow simulation with or without shocks 475
J. Burguete, P. Garcia-Navarro, P. Brufau & J. Murillo

Numerical and experimental modelling of the generation and propagation of waves caused by landslides into reservoirs and their effects on dams 483
R.F. de Carvalho & J.S.A. do Carmo

High-order finite volume modelling of one-dimensional flows 493
L. Cozzolino & D. Pianese

Copyright © 2006 Taylor & Francis Group plc, London, UK

Nonparallel spatial stability of shallow water flow down an inclined plane of arbitrary slope 503
P. Bohorquez & R. Fernandez-Feria

Dam-break flow experiments in simplified city layouts 513
S. Soares-Frazão, B. Spinewine, A. Duthoit, J.F. Deswijsen & Y. Zech

A.4. Vegetated beds and flow resistance

Evolution of mixing layers in turbulent flow over submersed vegetation: Field experiments and measurement study 525
A. Sukhodolov & T. Sukhodolova

A new 1D-numerical model for flexible vegetated channels 535
D. Velasco, A. Bateman & V. Medina

Steady 1D water surface model of natural rivers with vegetated floodplain: An application to the Lower Biebrza 545
D. Świątek, J. Kubrak & J. Chormański

Experimental investigation of flow characteristics in vegetated channels 555
F.G. Carollo, V. Ferro & D. Termini

A two-dimensional lattice model for describing the open channel flow with vegetation 565
F.J. Jiménez-Hornero, J.V. Giráldez, A.M. Laguna, S.J. Bennett & C.V. Alonso

Depth-averaged flow in presence of submerged cylindrical elements 575
F. Huthoff, D.C.M. Augustijn & S.J.M.H. Hulscher

Turbulent structure and dispersive properties in vegetated canopy open-channel flows 583
I. Nezu, M. Sanjou & T. Okamoto

Influence of aquatic plants on the flow resistance and the hydraulic capacity of vegetated rivers 593
L. De Doncker, P. Troch, R. Verhoeven, K. Bal & P. Meire

Experimental study of flexible and rigid vegetation in an open channel 603
M. Ben Meftah, F. De Serio, D. Malcangio, A.F. Petrillo & M. Mossa

Longitudinal dispersion in vegetated channels 613
E. Murphy, M. Ghisalberti & H.M. Nepf

Turbulent characteristics of flows through emergent vegetation 623
P.M. Rowiński & A. Mazurczyk

Longitudinal dispersion in a lowland river with submersed vegetation 631
T. Sukhodolova, A. Sukhodolov, H-P. Kozerski & J. Köhler

Effects of aquatic and bank-side vegetation on hydraulic performance of small streams 639
V. Nikora, S. Larned, K. Debnath, G. Copper, M. Reid & N. Nikora

Interaction of vegetation, current and sedimentation 647
S. Schneider, F. Nestmann & B. Lehmann

A.5. Interaction with structures

Large-scale motion induced by turbulent plunging jets in pools created by scouring of the riverbed 657
P. Manso, A. Schleiss, J.-L. Boillat & E. Bollaert

Numerical investigation of the turbulent flow around a bridge abutment 667
A. Teruzzi, F. Ballio, S. Salon & V. Armenio

The shallow flow around a single groyne under submerged and emerged conditions 673
A. Kadota, K. Suzuki & W.S.J. Uijttewaal

Copyright © 2006 Taylor & Francis Group plc, London, UK

Diverse riverbed figuration by using skew spur-dike groups 683
A. Tominaga & D. Matsumoto

Turbulence analysis of vertical slot fish pass by in situ measurements and CFD modelling 693
B. Sokoray-Varga, S. Baranya & J. Józsa

Stability analysis of turbulent water jets onto both rigid and mobile beds 701
C. Adduce, M. la Rocca & P. Mele

Investigation of the velocity and pressure fluctuations distributions inside the turbulent horseshoe vortex system around a circular bridge pier 709
G. Kirkil, G. Constantinescu & R. Ettema

The scour-hole problem due to sluice gates: Quadrant analysis of the turbulence characteristics in the presence of Görtler vortices 719
I. Albayrak & U. Lemmin

Temporal flow evolution of sediment embedded circular bridge piers 729
J. Unger & W.H. Hager

A numerical model for local scour at piers according to the unit stream power approach 741
M.E. Cunninghame & N.P. Armitage

Conservative scheme for flow numerical modeling of submerged bridges 747
M. Catella & G. Bechi

Turbulent flow field modeling as an aid to the analysis of scour and for a protection scheme 757
R. Aragão, V.S. Srinivasan, K. Suzuki & A. Kadota

Predictions of turbulent flows around a bridge pier using various numerical models 767
I. Kimura, T. Hosoda & S. Onada

B. River Morphodynamics and sediment transport

B.1. Mechanics of sediment transport

Validation of a new model to account for bed slope effect for prediction of equilibrium condition in loose bed channels with significant suspended sediment transport 779
J. Zeng, G. Constantinescu & L. Weber

A PIV/PTV experiment on sediment transport in a horizontal open channel flow 789
W.A. Breugem & W.S.J. Uijttewaal

Towards a Direct Numerical Simulation (DNS) of particle motion close to river beds 799
A.E. González, F.A. Bombardelli & Y. Niño

Modelling sorting over the lee face of individual bed forms 807
A. Blom & M.G. Kleinhans

Entrapment of fines in coarse sediment beds 817
B.G. Krishnappan & P. Engel

Can a two-layer morphological model compete with common sediment transport formulae? 825
C. Savary & Y. Zech

Wide solid-discharge fluctuations and collective effects in bed-load transport 833
C. Ancey, T. Böhm, P. Frey & M. Jodeau

SETRAC – A sediment routing model for steep torrent channels 843
D. Rickenmann, M. Chiari & K. Friedl

Influence of sand shape to vertical sorting under uniform flow condition 853
E. Harada & H. Gotoh

Copyright © 2006 Taylor & Francis Group plc, London, UK

Investigation of flow hydrodynamics under equilibrium bedload transport conditions using PIV 859
F. Bigillon, G. Couronné, J.Y. Champagne, A. Recking & P. Frey

The resistance of transported sediment 867
G. Smart

Development of a hybrid adaptive neuro-fuzzy system for the prediction of sediment transport 877
M. Valyrakis, P. Diplas, C.L. Dancey, T. Akar & A.O. Celik

Experimental study of bed load on steep slopes 887
P. Frey, M. Dufresne, T. Böhm, M. Jodeau & C. Ancey

Downstream fining of sediments in the Meuse River 895
R. Murillo-Muñoz & G.J. Klaassen

Cohesive sediment removal from a fixed bed 907
R. Della Morte, C. Mucherino, D. Pianese & F. Pirozzi

Modeling granular sediment transport over water worked gravels within a CFD framework 913
R.J. Hardy

The beginning of sediment transport – A different approach 919
R. Aleixo & R. Maia

Marbles in oil, just like a river? 927
S.M. Cameron, S.E. Coleman, B.W. Melville & V.I. Nikora

Bed load fluctuations and channel processes in a braided network laboratory model 937
W. Bertoldi, T. Amplatz, S. Miori, L. Zanoni & M. Tubino

Conceptual model for the bedload layer of gravel bed streams based on laboratory observations 947
R.M.L. Ferreira, J.G.A.B. Leal & A.H. Cardoso

Energy dissipation downstream of dams established in alluvial beds 957
A. Sá Lopes, M.F. Proença & R. Maia

B.2. Bed forms and flow resistance

Modelling morphodynamic evolution of river dunes 969
A.J. Paarlberg, C.M. Dohmen-Janssen, S.J.M.H. Hulscher, J. van der Berg & A.P.P. Termes

Field investigations of sand-gravel bed forms within the Raba River, Poland 979
A. Radecki-Pawlik, P.A. Carling, E. Slowik-Opoka, L. Książek & R. Breakspeare

Semi-empirical model to predict mobile bed evolution in presence of a side overflow 985
B. Rosier, J.-L. Boillat & A.J. Schleiss

Morphology, flow and sediment transport over a natural 3D dune field: Rio Paraná, Argentina 997
D.R. Parsons, J.L. Best, S.N. Lane, R.J. Hardy, R. Kostaschuk, D. Shugar & O. Orfeo

Flow resistance associated to a schematic step-pool pattern 1005
F. Canovaro & L. Solari

Three-dimensional properties of laboratory sand waves obtained from two-dimensional autocorrelation analysis 1013
H. Friedrich, B.W. Melville, S.E. Coleman, T.M. Clunie, V.I. Nikora & D.G. Goring

Spatial development of turbulent open channel flow over bottom with multiple dunes 1023
N.Th. Fourniotis, A.A. Dimas & A.C. Demetracopoulos

Bed forms and transport characteristics of a partly cohesive sediment 1033
R. Banasiak & R. Verhoeven

Bed morphology and flow resistance in steep open channels with varying widths 1039
R.B. Weichert, G.R. Bezzola & H.E. Minor

Copyright © 2006 Taylor & Francis Group plc, London, UK

A vertical two-dimensional morphodynamic model for bedform simulation 1049
S. Giri & Y. Shimizu

Experimental study on steady flow in a channel with macro-roughness at the side walls 1059
T. Meile, J.-L. Boillat, J. Dubois & A.J. Schleiss

Weakly nonlinear analysis on interaction of alternate bars and double-row bars 1069
Y. Watanabe & K. Hasegawa

Three-dimensional numerical modeling of flows over a natural dune field 1077
R.J. Hardy, D.R. Parsons, J.L. Best, S.N. Lane, R. Kostaschuk & O. Orfeo

B.3. Large scale river morphology and morphodynamics

Effect of vegetation growth and unsteady characteristics of water supply on formative condition of mesoscale channel configuration 1087
H. Takebayashi, M. Teraoka, T. Okabe & S. Egashira

Location of hills and deeps in meandering streams: An experimental study 1097
A.M.F. da Silva & T. El-Tahawy

VOLUME 2

B.3. Large scale river morphology and morphodynamics (continued)

On the bed deformation in meandering streams 1119
A.M.F. da Silva & M.S. Yalin

Gravitational effects on river morphodynamics 1129
S. Francalanci, L. Solari & G. Vignoli

Entropy and river meander planform 1137
A.J. Teuling, S.J. van Andel, P.A. Troch & A.J.F. Hoitink

Downstream stable channel configuration: Preliminary analysis 1147
B. Mengoni & E. Paris

Two-layer approach for transcritical flow on mobile bed: Nickpoint migration 1155
C. Savary, M. Bellal & Y. Zech

On the effect of the bed morphology on the river confluence hydrodynamics 1165
D. Đorđević & M. Jovanović

The overdeepening theory in river morphodynamics: Two decades of shifting interpretations 1175
E. Mosselman, M. Tubino & G. Zolezzi

Prevalent morphodynamic regime and short-term dynamics of meandering rivers 1183
G. Zolezzi, R. Luchi & D. Marchiori

Migration of a dredging pit in the Rhone River 1193
J.-L. Boillat, J. Dubois & N. Nilipour

Bed levelling investigations on transverse sloped beds 1203
J.U. Wiesemann, P. Mewis & U. Zanke

Effective use of non-erodible layers for improving navigability 1211
C.J. Sloff, E. Mosselman & J. Sieben

Copyright © 2006 Taylor & Francis Group plc, London, UK

Morphodynamic modeling of sand bar evolution under unsteady flow 1221
K. Kobayashi, Y. Shimizu, S. Giri & Y. Watanabe

Experimental investigation on flow expansions over fans 1231
L. Sittoni, C. Paola, J. Fedele & M. Tubino

Investigation on the dominant discharge in DEZ River and the effect of DEZ Dam on it 1237
M.A. Pourhasan, H.R. Sadeghi, P.S. Mirja'fari & S. Fartoos

Large-scale turbulence and river morphology 1243
M.S. Yalin

Analysis of water and sediment flows over an alternate bar in a gravel bed river 1251
M. Jodeau & A. Paquier

ECOMSED – Three dimensional modeling in rivers 1259
M.A. Mekonnen & B. Dargahi

3D modeling of transient bed deformation in sine-generated laboratory channel with two different width to depth ratios 1269
N. Rüther & N.R.B. Olsen

Morphology and flow structures in a large confluence-diffluence: Rio Paraná, Argentina 1277
O. Orfeo, D.R. Parsons, J.L. Best, S.N. Lane, R.J. Hardy, R. Kostaschuk, R.N. Szupiany & M.L. Amsler

Unsteadiness effects on the morphological behaviour of gravel-bed river bifurcations 1283
S. Miori, R. Repetto & M. Tubino

Sediment dynamics in anabranched channels of the Loire River: The study case of Ingrandes (France) 1293
S. Rodrigues, J.N. Gautier & J.J. Peters

Man-induced morphological processes in Warta river (Poland), and their impact on the evolution of hydrological conditions 1301
T. Dysarz, J. Wicher-Dysarz & B. Przedwojski

Morphological description of river bifurcations in gravel-bed braided networks 1311
W. Bertoldi, S. Miori, M. Salvaro, L. Zanoni & M. Tubino

Study on river change and sediment transportation of Tan Chau reach in lower Mekong river 1319
X.L. Luu, S. Egashira & H. Takebayashi

Morphodynamics of mountain rivers following repeated sediment release from reservoirs 1329
G. Fasolato, P. Ronco & M. Tregnaghi

Analysis of sediment transport during floods in a large river 1337
J.S. Rocha & J.N. Fernandes

The case of the Zambezi River in Mozambique: Some investigations on solid transport phenomena downstream Cahora Bassa Dam 1345
P. Ronco, G. Fasolato & G. Di Silvio

Effect of upstream meanders on bifurcation stability and sediment division in 1D, 2D and 3D models 1355
M. Kleinhans, B. Jagers, E. Mosselman & K. Sloff

Bed Load Management at the River Lech – A physical model 1363
U. Stephan & K. Wibmer

B.4. Debris and hyperconcentrated flows

Intermittency of rheological regimes in uniform liquid-granular flows 1375
A. Armanini, M. Larcher & L. Fraccarollo

Copyright © 2006 Taylor & Francis Group plc, London, UK

Morphological modelling of hyperconcentrated floods in the Yellow River 1383
D.S. van Maren, J.C. Winterwerp, B.S. Wu & J.J. Zhou

Fluctuations in surface granular flow via a PIV-edge detection technique 1393
D. Berzi, L. La Rosa, S. Malavasi & A. Radice

Numerical simulations of the covering a house by a debris flow 1401
E. Harada, T. Hosoda & H. Gotoh

Frictional surface flow of a dry granular medium 1407
D. Berzi & E. Larcan

Experiments on the impact process of dry and saturated mixtures against obstacles of various shapes 1413
P. Ghilardi, M. Pagliardi & B. Zanuttigh

Limiting conditions for the existence of permanent periodic roll waves in stony debris flows 1421
S. Longo

Instability and kinematic for sand-water mixture or dry sand flowing past a circular cylinder 1433
S. Longo, A. Valiani & L. Lanza

B.5. Geomorphic dam-break flows and breach formation

A new approach to solving boundary conditions in shallow water equations using a Riemann solver 1443
V.C. Medina Iglesias, A. Bateman Pinzon & D. Velasco Montes

The role of quasi-conservative form for morphodynamic modelling in river flow computations 1453
A. Siviglia, G. Nobile & M. Colombini

Front dynamics of a water surge at high Reynolds number: Similarity solutions to the Saint-Venant equations 1463
C. Ancey, S. Cochard, M. Rentschler & S. Wiederseiner

Fully-2D and *quasi*-2D modeling of flooding scenarios due to embankment failure 1473
F. Aureli, P. Mignosa, C. Ziveri & A. Maranzoni

Two-dimensional dam-break simulation over movable beds with an unstructured mesh 1483
J.A. Vásquez & J.G.A.B. Leal

Numerical simulation of 2D dam break on mobile bed 1493
M. Greco, M. Iervolino & A. Leopardi

One dimensional modeling of dam break flow over erodible sediment bed 1501
P. Costabile & F. Macchione

Dike erosion – A preliminary outlook 1511
W.H. Hager & J. Unger

Discontinuities in geomorphic dam-break flows 1521
R.M.L. Ferreira, S. Amaral, J.G.B. Leal & B. Spinewine

Experimental study of landslide-induced flooding in open channels 1531
J. Yan, Z. Cao & L. Chen

Dam-break propagation over a movable bed in a non-prismatic channel 1541
J.G.A.B. Leal, P. Silva & R.M.L. Ferreira

Levee breach process of a river by overflow erosion 1547
T. Tsujimoto, A. Mizoguchi & A. Maeda

Copyright © 2006 Taylor & Francis Group plc, London, UK

B.6. Sedimentation in reservoirs

A 3-D numerical investigation of the development of density driven finite-channel lock-release currents at high Grashof numbers 1559
S.K. Ooi, G. Constantinescu & L. Weber

Bedload transport in the case of seepage flow 1569
S. Francalanci, G. Parker & L. Solari

Long-term morphological behavior of Verbois reservoir (Geneva) 1577
E. Bollaert, S. André, S. Diouf, D. Sidler & S. Ferretti

1D Process-based modelling of reservoir sedimentation: A case study for the Barasona reservoir in Spain 1585
G.L. Mamede, A. Bronstert, T. Francke, E.N. Müller, J.C. de Araujo, R.J. Batalla & A. Güntner

Deposition of fine particles varying with their cohesiveness 1595
G. Hillebrand & F. Nestmann

Measurement of flow patterns within an Alpine reservoir 1601
H. Knoblauch, H. Badura & J. Schneider

Reservoir sedimentation: 1D model of turbidity currents and delta deposits 1607
J. González, A. Tamburrino & Y. Niño

Jets opposing flow on inclines 1617
J. Bühler, Ch. Oehy & A.J. Schleiss

Experimental study of suspended sediment transport and deposition in a rectangular shallow reservoir 1623
S.A. Kantoush, E.F.R. Bollaert, J.-L. Boillat, A.J. Schleiss & W.S.J. Uijttewaal

Effects of flushing of two reservoirs in Spain 1633
R. Cobo Rayán & C. Mateos Iguacel

B.7. Local scour and protection

Time evolution of erosion depth and sediment motion for abutment scour in a pressure duct 1639
A. Radice, S. Malavasi & F. Ballio

Local scour at elliptical guide banks in plain rivers 1649
B. Gjunsburgs, R.R. Neilands & E. Govsha

Local scouring at bridge piers and abutments: Time evolution and equilibrium 1657
C. Grimaldi, R. Gaudio, A.H. Cardoso & F. Calomino

Diversity of streambed features caused by open-slot groundsills 1665
C.C. Wu & Y.-C. Lin

Riprap design for spur protection 1673
C. Gisonni & W.H. Hager

Numerical simulation of flow and local scour around hydraulic structures 1683
H. Zhang, H. Nakagawa, Y. Muto, Y. Baba & T. Ishigaki

Dimensional analysis of bridge pier scour and the role of flow intensity 1695
L. Teixeira, G. López, G. Simarro, E. Fernandez & M. Ortega-Sánchez

Maximum scour depth around spur dikes 1701
M. Azarderakhsh, H. Norouzi & M. Ghodsian

Modelling the flow and morphology in groyne fieds 1707
M.F.M. Yossef & R. Rupprecht

Copyright © 2006 Taylor & Francis Group plc, London, UK

Experimental study of the scour regimes downstream of an apron for intermediate tailwater depths 1715
P. Espa & S. Sibilla

Scour protection downstream of block ramps 1725
S. Pagliara & M. Palermo

Temporal patterns of the maximum scour depth around a pier 1731
G. Oliveto & A. Di Domenico

Riverbed scour induced by a long constriction 1737
G. Oliveto, B. Onorati & V. Comuniello

Clear-water scour at bridge piers and abutments 1743
U.C. Kothyari, W.H. Hager & G. Oliveto

Preface

E a cidade,
chamam-lhe Lisboa,
mas é só o rio
que é verdade
só o rio,
é a casa de água,
casa da cidade em que vim nascer.

from "O Tejo", performed by Madredeus,
lyrics by Pedro Ayres de Magalhães

Rivers are embedded into the very fabric of civilization. The knowledge of river hydraulics was passed over different civilizations, being remarkable the Babylonians, Egyptians, Greeks and Romans. Sophisticated irrigation works are reported in China, in the 3rd century BC, and drainage systems were found in cities belonging to the Indus civilization.

In what concerns societies' superstructure, rivers operate as complex and diverse symbols within religious, political or otherwise cultural contexts. Their meaning and usage are often conflicting: in the Hindu, Muslim and Jewish-Christian traditions rivers are endowed with the benign characteristics of pure water, those of cleaning, purifying and regenerating; yet, river waters can be the vehicle of corruption and can even be poisonous, as was the case of the spring waters of River Styx, described by Pausanias the geographer.

Rivers are tokens of fertility; their allegoric use often endorses the world of the Mother, of *natura*. Anqet, the goddess of the Nile in the Old Kingdom, was simultaneously "the embracer" and "the nourisher" of the fields, qualities that evoke the sedimentation of fertile soil during the Nile floods. Sedimentation can be also associated to the death of water streams and used as a metaphor of death and suffering: in Dante's Divine Comedy, the souls of those possessed by wrath and insolence are punished in the muddy marshes along the Styx.

Thoreau, travelling up the Merrimack River, wrote that "rivers must have been the guides which conducted the footsteps of the first travellers". The displacement may be literal but may also be a metaphor of an inner journey or a path to enlightenment. In the pilgrimage of River Narmada, both senses are at use; pilgrims would walk up the river to its spring and, on the other margin, would walk down to its mouth. In the process, the pilgrims could achieve enlightenment and purification. The river is ever present in the journey undertaken by Siddharta, in Herman Hesse's novel. His ultimate synthesis of the world of the senses and the world of pure contemplation is made possible by understanding the message contained in the river, literally by listening to the sound of its waters.

Rivers can also be obstacles in the path. Their crossing may stand for a rite of passage or an act of reconnaissance of owns free will, for instance Siddhartha's crossing of the river into the world of senses. However, crossing the river may also stand for the initiation of an inevitable chain of events; they can represent a mark beyond which free-will matters little, best exemplified by current allegoric use of Caesar's crossing of the Rubicon.

Rivers are political boundaries. However, they can also be attractors that convey identity to the communities that live along their margins. Numerous examples can be drawn, from the community of avieiros of Escaroupim, River Tagus, to the Isis and Oxford canal boat community.

The myth of a great flood, simultaneously destroying all but a small number of chosen living creatures and cleaning the land of all sin, is inscribed in many cultures and religious traditions. Virtually all the civilizations that we acknowledge as ancestors of ours came into being in the fertile valleys of large rivers. It is thus reasonable to believe that they should have experienced, at some point of their development, the devastating effects of river floods.

Generalising, the key concept of experimentation must have certainly guided communities' interaction with rivers. It can be traced in the process by which the heterogeneous and often contradicting allegoric usages of the

Copyright © 2006 Taylor & Francis Group plc, London, UK

river were inscribed in the languages. Conflicting meanings simply reflect the tensions arisen as societies evolve in articulation with their economical base. For instance, rivers have always supported human life by providing water for household consumption, for irrigation and for industry and their flood plains provided nutrients for agriculture. However, misuse of the sources of fresh water and bad agricultural techniques leads to water quality degradation. If the demographic pressure is too intense, river waters may even become the carriers of epidemic vectors.

Hydropower plants were essential to the development of industrial modes of production. Yet, the impacts of large dams are difficult to dissipate and may dramatically reduce rivers' potential to support wildlife and traditional economic activities. Riverbed sand, mud and pebbles have been used in building industry since the dawn of times. Again, overexploitation of these resources leads to oversimplification of their life. Furthermore, river's landscape value, often crucial for the collective identity of riverine communities, is built in permanent tension with its economic value. In particular, navigability requirements and flood defence structures are often seen as aggressions to the river's landscape and to its role as support of diverse biotopes.

In recent years, due to exponential population growth, these conflicting pressures have become more intense. As a result, river management has increasingly been carried out with close attention to the long term impact of river works. There is greater recognition that enforcing quality environments and promoting human development in the river space can be met at one and the same time, by working *with* rather than against nature. In other words, it is necessary to work with a deep knowledge of river phenomena. Such an approach is a clear application of the principles of sustainable development.

In what concerns the knowledge of the river processes, a change from the philosophical science of the Scholastics toward the observational science of the present day came perceptible during the Renaissance. Such change is best exemplified by Leonardo da Vinci's prolific production of drawings depicting flow phenomena. Fluvial Hydraulics is nowadays rooted in engineering practice and scientific research. Recent developments in fluid and sediment mechanics, namely in what concerns turbulent flows and flows of granular material, have provided Fluvial Hydraulics with the formal apparatus to sustain within itself research programs envisaging the integration of basic phenomenological knowledge into practical engineering works. Hence, defined as the discipline, or set of disciplines, geared toward the joint study of the processes of entrainment, erosion, deposition and transport of sediment and the mechanics of open-channel flows with mobile boundaries, Fluvial Hydraulics is more than ever solicited to guide engineering works, evaluate environmental impacts and mitigate hazards. New engineering tools emerge from advances in physical understanding, computation methods and measuring techniques.

River Flow 2006 was organized under the auspices of the Fluvial Hydraulics Section of the International Association of Hydraulic Engineering and Research (IAHR). River Flow conferences are intended to be exceptional forums for scientists and engineers working on Fluvial Hydraulics and river-related disciplines. The hearty spirit of the first edition, in Louvain-la-Neuve in 2002, encouraged the prosecution of the conference series. The ensuing conferences have registered an increasing participation of members of our community of river engineers and researchers, a clear indication of the relevance of such a forum.

The Local Organizing Committee of River Flow 2006 has received 546 abstracts, of which 486 were considered to be aligned with the conference topics. Subsequently, 358 papers were submitted by engineers and researchers of 49 countries from all 5 inhabited continents. The International Scientific Committee has, finally, selected 239 to be included in this proceedings book. Of these, 67% were considered for oral presentation and 33% were selected for the poster sessions. The accepted contributions cover essentially River hydrodynamics, River morphodynamics and sediment transport, and Interdisciplinary approaches for river management.

A distinctive feature of River Flow conferences has been the existence of Master Classes the day preceding the formal opening of the Conference. They are intended for PhD or MSc students or young researchers working on Fluvial Hydraulics or related disciplines. They represent a unique opportunity for students to address senior scientists, meet peers working on similar topics and identify possible collaborations for the continuation of their work. The response to this initiative exceeded the best initial expectations: 7 Master Classes were run, enrolling 41 students from 14 countries and 14 masters. This is an indication of the vitality of Fluvial Hydraulics and a contribution for the continuity of the IAHR.

In 1999, the IAHR added "Engineering" to its official designation. This symbolic gesture signalled IAHR's ever present will to enrol engineering practitioners in the prosecution of its main objective, the promotion of the advancement and the exchange of knowledge in water related subjects. The Local Organizing Committee has decided to implement the new concept of "engineering case studies" in the attempt to encourage practitioners with different approaches and backgrounds to participate in the technical and scientific debate of the conference. Engineering case studies were given the visibility and relative importance of keynote lectures. The initiative was successful and its continuation is recommended: 13 candidate case studies were received for 3 to be presented.

Copyright © 2006 Taylor & Francis Group plc, London, UK

River Flow 2006 introduced a special session dedicated to the Yangtze River, a suggestion made by Professor Zhaoyin Wang. The organizing committee of River Flow 2006 acknowledged the idea enthusiastically and sought to transform it into a perennial trait of River Flow conferences: it was proposed to IAHR that all future editions should have a session dedicated to a particular river. Such river should be chosen on the basis of its symbolic importance for human communities, for the social relevance and impact of engineering works performed upon it or for the innovative aspects shown by the engineering practices led by their managing authorities.

Organising institutions and sponsors

River Flow 2006 was organised by the following institutions.

The following organisations sponsored the conference.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Acknowledgements

River Flow 2006 was jointly organised by the Instituto Superior Técnico (IST) and the Laboratório Nacional de Engenharia Civil (LNEC), both in Lisbon. It took place in LNEC between the 5th and the 8th of September 2006. Its preparation begun much earlier, sometime in March 2004. Over the course of these two and a half years, many people and organisations were directly and indirectly involved in the many tasks that constituted the work program of the conference.

We are first and foremost grateful to all researchers and practitioners working in river-related disciplines that chose to participate in River Flow 2006 by sending their abstracts, papers and case-studies. Their collaboration reiterated the vitality of our rivers community, surely one of the most active groups within IAHR. Special thanks to the students that applied to the Master Classes and whose enthusiasm guarantees a bright future to our community.

The success of the conference was materialized in a record number of contributions accepted for reviewing. The role of the International Scientific Committee was therefore paramount. We are indebted to its members for the in-depth reviewing of the manuscripts, a task carried out with overall excellence, rare in conferences, despite the limited time available.

Such a selective conference, involving so many students at reduced fees, is only financially sustainable with some level of sponsorship. We acknowledge the support of Câmara Municipal de Lisboa (CML), AdP – Águas de Portugal, EDP – Energias de Portugal and FLAD – Fundação Luso-Americana. The support of these institutions has made it possible to attribute five scholarships to participants from developing countries and partly cover the expenses of a large number of Masters.

Complementing the work of the Local Organising Committee (LOC) in IST, there was the dedicated and competent contribution of Mrs. Dulce Fernandes. She was present in all crucial moments of receiving, printing and organizing the manuscripts of all authors and, for that matter, she deserves our deepest recognition.

The preparation of River Flow 2006 benefited, at several stages, from the experience of the organisers of previous editions. For that matter, we are indebted to Didier Bousmar, Yves Zech and Massimo Greco for their ever present willingness to collaborate with us.

The image of the conference was essentially a product of collective work within the LOC. In what concerns the design and the maintenance of the webpage, we acknowledge the valuable contribution of Americo Louro at LNEC. A word of appreciation to Helena Elias for her contribution in the redesign of the logo and for the preparation of the presentation that, in June 2004, in Naples, introduced River Flow 2006.

The involvement of IAHR was fundamental for the divulgation of the conference. For their efforts, we endorse our gratitude to Estíbaliz Serrano and Cristina Moreno. At last, the preparation of the manuscripts often required the intervention of the publisher, Taylor & Francis/A. A. Balkema. Our recognition goes to Léon Bijnsdorp, Lukas Goosen, Maartje Kuipers and remaining staff involved.

ABSTRACT: The delta of the Mississippi River is in jeopardy. It is rapidly subsiding into the Gulf of Mexico. Delta marshland is being drowned and the shoreline is moving northward toward New Orleans. The cause of these problems is the levee system along the Mississippi River, which prevents the replenishment of sediment to the delta. One way to restore the delta is through the use of one or more controlled partial avulsions of the Mississippi River. The design of such diversions represents a monumental task. A natural example of an avulsion in the Mississippi Delta, however, offers an excellent opportunity to test the concept of land building via river diversions. The Atchafalaya River is a distributary of the Mississippi River. During the flood of 1973, part of the Atchafalaya River avulsed into a man-made channel. The Wax Lake Delta at the mouth of the channel has been building seaward since then. Here a morphodynamic model of the Wax Lake Delta is presented and tested against field data. While the model is preliminary, the fact that it captures the process of land building at the Wax Lake Delta suggests that it can be adapted to the design of a major controlled partial avulsion of the Mississippi River into, for example, Barataria Bay.

1 INTRODUCTION

The extensive levees on lower Mississippi River serve an essential role in a) protecting human lives and infrastructure in New Orleans and the Mississippi Delta and b) preventing an avulsion of the river that would render New Orleans useless as a port. These same levees, however, prevent sediment delivery to the Mississippi Delta itself.

Under natural conditions, the delta was maintained by two counteracting processes; sediment deposition and avulsion which cause the delta to build up and prograde seaward, and compaction of fine-grained delta sediment under its own weight, which causes the delta to subside into the Gulf of Mexico. Under present conditions the delta is subsiding without any sediment replenishment. As a result delta marshland is sinking into the sea and the shoreline is rapidly advancing northward (Hallowell, 2001).

Land loss in the Mississippi Delta has resulted in the disappearance of or damage to large tracts of marshland habitat of unique ecological value. It has forced many Delta inhabitants to move elsewhere, and has damaged the livelihood of many more. In addition the northward movement of the shoreline has reduced the land buffer needed to damp hurricane storm surge, and thus placed New Orleans at risk to powerful hurricanes.

This vulnerability is highlighted by the Hurricane Katrina disaster of August, 2005, which caused a public emergency of major proportions, and rendered the city uninhabitable for months. Figure 1 shows satellite images of the Mississippi Delta just before and after the disaster. The damage to the Delta and the increased risk to New Orleans is clear from the images.

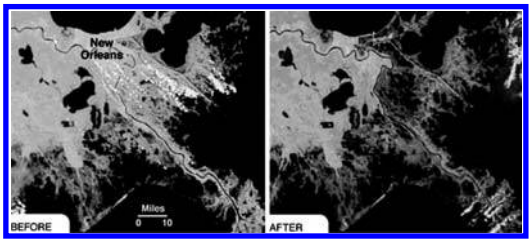

Figure 1. Satellite images of the Mississippi Delta near New Orleans before and after Hurricane Katrina. The image is from the New York Times.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Various proposals have been offered in order to restore the Delta. Among the most attractive of these consists of one or more partial, controlled avulsions of the river either upstream or downstream of New Orleans. These avulsions would be accomplished by means of massive diversion structures of the general type that are already in place at the junction of the Mississippi River and the Old River in northern Louisiana, shown in Figure 2 and located in Figure 3. The Old River Control Structures allow a controlled amount of Mississippi River floodwater to flow into the Old River, and thence into the Atchafalaya River, while preventing a complete capture of the Mississippi River by the Atchafalaya River. Part of the structure nearly failed in the historic flood of 1973; the severe consequences of such a failure are outlined in Kazmann and Johnson (1980). This near failure highlights the importance of careful design of any diversion structures designed to restore sediment to the Delta.

Figure 2. Aerial view of the Old River Control Structures on the Mississippi River, Louisiana. The Mississippi River is to the right; flow in it is from top to bottom.

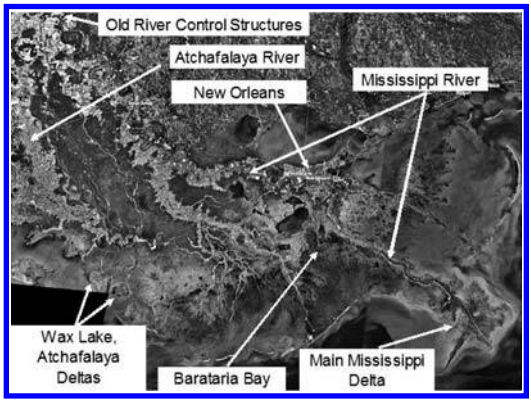

Figure 3. The NASA WorldWind satellite image serves as a locator map for New Orleans, the Mississippi and Atchafalaya Rivers, the Old River Control Structures, the Main Mississippi Delta, the Wax Lake and Atchafalaya Deltas and Barataria Bay circa 2006.

The flood of 1973 also had a consequence that has provided an invaluable case history for restoring the Delta. During that flood, part of the Atchafalaya River near its own delta partially avulsed into a man-made channel known as the Wax Lake Outlet. Ever since that avulsion a new delta at its outlet, the Wax Lake Delta has been building into the Gulf of Mexico. The subsequent growth of the Wax Lake Delta has been monitored by Louisiana researchers (Roberts and Coleman, 1996; Roberts et al, 1997). The locations of New Orleans, the Mississippi and Atchafalaya Rivers, the main mouth of the Mississippi River and the Wax Lake and Atchafalaya Deltas are shown in Figure 3. The Wax Lake Delta itself is shown in Figure 4.

The well-documented growth of the Wax Lake Delta allows an opportunity for "proof of concept" of land building by river diversions. If a morphodynamic model of river-delta evolution can predict the observed evolution of the Wax Lake Delta with a) reasonable accuracy and b) a minimum of "tuning", such a model can be adapted into a powerful tool to aid delta restoration. The tool could be used to study a variety of options for one or more much larger controlled avulsions upstream or downstream of New Orleans, so serving as part of the design of an optimal scheme for land building and delta reconstruction, with minimum negative influence on the economy and habitability of the Delta as a whole and New Orleans in particular.

Here a morphodynamic model of the Wax Lake Delta and the fluvial reach immediately upstream is outlined and compared against available data. The

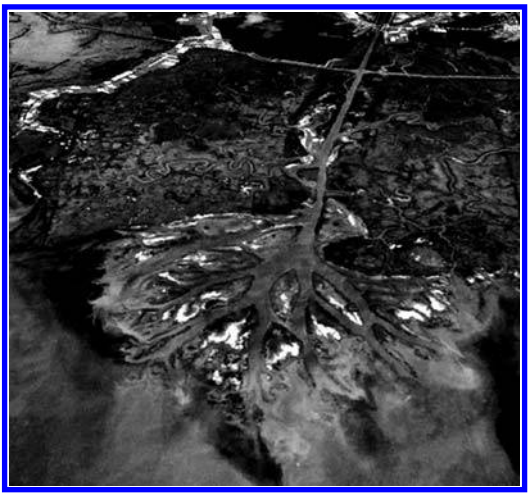

Figure 4. NASA WorldWind satellite image of the Wax Lake Delta, Louisiana as of 2006.

Copyright © 2006 Taylor & Francis Group plc, London, UK

results, while preliminary, are encouraging in terms of the use of controlled diversions to build land.

2 THE WAX LAKE DELTA

The Wax Lake Delta is a fan-delta located at the mouth of the Wax Lake Outlet (Figure 5). The Wax Lake Outlet is a man-made channel that was excavated in 1941. It connects the southeastern corner of Six Mile Lake with Atchafalaya Bay of the Gulf of Mexico. Six Mile Lake is in turn connected to the lower Atchafalaya River (Figure 5; DuMars, 2002).

The Wax Lake Outlet was designed to divert part of the flood flow of the Atchafalaya River. As recently as 1972 the shoreline along Atchafalaya Bay was eroding. The epic flood of the Mississipppi River of 1973 reversed this process (Roberts *et al.*, 1997). A partial avulsion of the Atchafalaya River to the Wax Lake Outlet significantly increased the flow to the Wax Lake Delta.

Subsequent to the flood of 1973 the Old River Control Structures have been used to divert both water and sediment from the Mississippi River to the Atchafalaya River in a prescribed manner. While the design diversion is 30% of the flow of the Mississippi River, as much as 50% of the Mississippi's discharge and over 60% of its suspended load has been flowing into the Atchafalaya River (Roberts *et al.*, 2003a). This delivery of sediment has caused both the Atchafalaya Delta itself and the subsidiary Wax Lake Delta to prograde significantly since 1973. As progressively more flow was captured by the Wax Lake Outlet, a control structure was placed on it in 1988. The structure limited the flow down the Wax Lake Outlet during normal flow, but was less effective at high flows. The structure was finally removed in 1994 (Roberts *et al.*, 2003a).

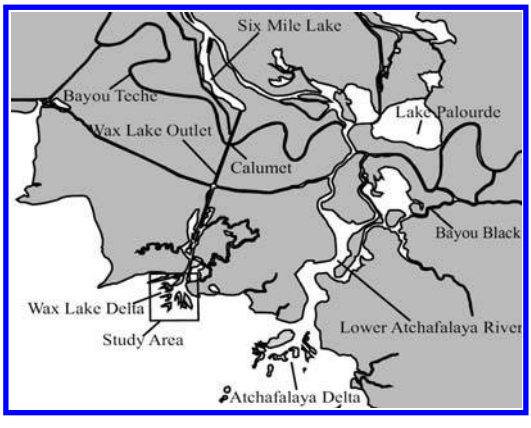

Figure 5. Map showing the Atchafalaya River, Six Mile Lake, the Wax Lake Outlet and the Wax Lake Delta. From DuMars (2002).

As of 2006 the Wax Lake Delta continues to prograde into Atchafalaya Bay (Figure 4). While not specifically intended to do so, it serves to illustrate how the sediment-laden water of the Mississippi River can be used to build land.

3 ELEMENTS THAT MUST BE CAPTURED BY THE MORPHODYNAMIC MODEL

A predictive morphodynamic model of the evolution of the Wax Lake Delta must include at least the following elements:

- account for the flood hydrology of the Atchafalaya River and the Wax Lake Outlet (WLO);
- partition water and sediment in the Atchafalaya River between the WLO and the Atchafalaya River below the outlet;
- discriminate between sand and mud delivered to the WLO;
- account for the Wax Lake Delta as well as a reach of the WLO upstream;
- specify the efficiency of deposition of sand and mud in the WLO, its adjacent "floodplain" and the delta itself; and
- account for the effects of both delta subsidence and sea level rise.

4 MODEL GEOMETRY

The model geometry is illustrated in Figures 6 and 7. A fluvial reach of specified down-valley length L_f and "floodplain" width B_f corresponding to part of the WLO is connected to a fan-delta reach corresponding to the Wax Lake Delta. The downvalley coordinate on the fluvial reach is denoted as x; channel width on the fluvial reach is a variable denoted as B_{fc}.

The fan-delta has specified fan angle θ. The radial coordinate from the fan-delta apex is denoted as r, such that r_u denotes a specified distance to the upstream end of the fan-delta and r_d denotes the distance from the vertex to the topset-foreset break (shoreline). In so far as the delta is prograding, r_d must be allowed to be a function of time t. Under conditions of any given flood flow there may be more than one active channel on the fan-delta; their amalgamated width is a variable denoted as B_{dc}. That part of the fan-delta that is not channelized at any given time is referred to as "floodplain" below. The width of the fan-delta is given as

$$B_d = \theta r \tag{1}$$

River bed elevation on the fluvial reach is denoted as η_f; the corresponding elevation on the fan-delta reach is denotes as η_d (Figure 7). The distance from the fan vertex to the junction between the base of the

Copyright © 2006 Taylor & Francis Group plc, London, UK

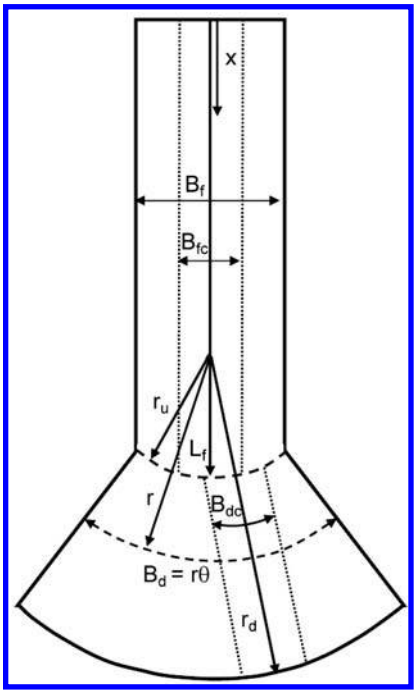

Figure 6. Definition diagram for planform of the fluvial and fan-delta reaches.

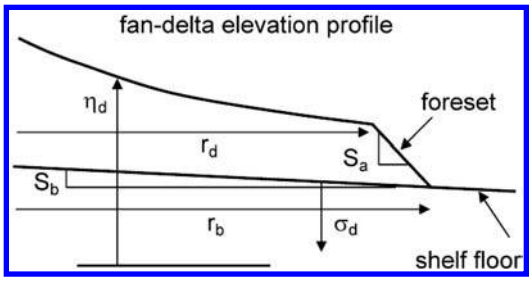

Figure 7. Definition diagram cross-section of the fan-delta reach.

foreset and the shelf floor is denoted as r_b. The shelf floor below the fan-delta reach is taken to have constant slope S_b and to be subsiding at rate σ_d, and the basement below the fluvial reach is subsiding at rate σ_f. Both subsidence rates are taken to be specified parameters. The fan-delta is assumed to prograde with a specified foreset angle S_a (Figure 7).

5 EXNER EQUATION OF SEDIMENT CONTINUITY

Rivers are morphologically active during floods. To capture this in a simple way, the river is assumed to be at bankfull flow Q_{bf} for fraction of time I_f, when it is morphologically active; otherwise the river is assumed to be morphologically inactive. The value of I_f is determined by the constraint that the river transports its mean annual bed material load at bankfull flow sustained for fraction I_f of a year (Wright and Parker, 2005).

Sand-bed rivers such as the Mississippi River and its distributaries carry far more mud than sand. For example, Allison *et al.* (2005) estimate that the Lower Mississippi carries annual loads of 124 Mt/year of mud but only about 6 Mt/year of sand. Here the sand is allowed to exchange with the bed, so constituting bed material load, but the mud is allowed to exchange only with the floodplain.

As the channel progrades, the deposit is spread across the entire floodplain (fluvial reach). Here the following parameters are defined for the fluvial and fan-delta reaches, denoted respectively by the final subscripts "*f*" and "*d*"; total bed material (sand) volume transport rates at bankfull flow Q_{tbff} and Q_{tbfd}, channel sinuosity Ω_f and Ω_d and deposit porosity λ_{pf} and λ_{pd}. It is assumed that for each volume unit of sand deposited in the channel-floodplain complex Λ_f units of mud are deposited in the channel-floodplain complex of the fluvial reach and Λ_d units are deposited in the corresponding complex of the fan-delta reach.

The time-averaged Exner equation of sediment continuity thus takes the following respective forms on the fluvial and fan-delta reaches;

$$(1-\lambda_{pf})\left(\frac{\partial \eta_f}{\partial t}+\sigma_f\right)=-\Omega_f\frac{I_f(1+\Lambda_f)}{B_f}\frac{\partial Q_{tbff}}{\partial x} \tag{2a}$$

$$(1-\lambda_{pd})\left(\frac{\partial \eta_d}{\partial t}+\sigma_d\right)=-\Omega_d\frac{I_f(1+\Lambda_d)}{B_d}\frac{\partial Q_{tbfd}}{\partial r} \tag{2b}$$

6 FLOW AND SEDIMENT TRANSPORT

Channel hydraulics at bankfull flow is described in terms of a quasi-steady backwater formulation. Thus where U = bankfull flow velocity, H = bankfull flow depth, S = bed slope, C_f = a dimensionless bed friction coefficient and g denotes the acceleration of gravity, the shallow-water equation of momentum balance takes the following respective forms on the fluvial and fan-delta reaches;

$$U_f\frac{dU_f}{dx}=-g\frac{dH_f}{dx}+gS_f-C_{ff}\frac{U_f^2}{H_f} \tag{3a}$$

$$U_d\frac{dU_d}{dr}=-g\frac{dH_d}{dr}+gS_d-C_{fd}\frac{U_d^2}{H_d} \tag{3b}$$

where the final subscript "*f*" denotes the fluvial reach and the final subscript "*d*" denotes the fan-delta reach.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Here the bed slopes S are given by the respective forms

$$S_f = -\frac{\partial \eta_f}{\partial x} \quad , \quad S_d = -\frac{\partial \eta_d}{\partial r} \tag{3c,d}$$

In (3a) and (3b) the friction coefficients are treated as constants specified in terms of the corresponding dimensionless Chezy resistance coefficient Cz, such that

$$C_{ff} = Cz_f^{-1/2} \quad , \quad C_{fd} = Cz_d^{-1/2} \tag{4a,b}$$

The boundary condition on (3b) is one of specified elevation of standing water (base level) $\xi_d(t)$ in Atchafalaya Bay. Thus at the delta shoreline $r = r_d(t)$ is the position of the topset-foreset break (shoreline),

$$(\eta_d + H_d)_{r=r_d} = \xi_d(t) \tag{5a}$$

Here tides, which are in any case rather low in the Gulf of Mexico, are neglected for simplicity. The corresponding boundary condition on (3a) is continuity in water surface elevation;

$$(\eta_f + H_f)_{x=L_f} = (\eta_d + H_d)_{r=r_s} \tag{5b}$$

The mobility of bed material load (sand) can be quantified in terms of the Shields number τ_{bf}^* at bankfull flow, here defined as

$$\tau_{bf}^* = \frac{C_f U^2}{RgD} \tag{6}$$

where R denotes the submerged specific gravity of the sand (taken here to equal 1.65 for quartz) and D denotes the characteristic size of the sand in the river bed, here assumed to be a specified constant that is identical in the fluvial and fan-delta reaches. Sand transport is described in terms of the total bed material relation of Engelund and Hansen (1967); where B_c denotes the bankfull width of the channel (taking the values B_{fc} on the fluvial reach and B_{dc} on the fan-delta reach),

$$Q_{tbf} = B_c \sqrt{RgD}\, D \frac{0.05}{C_f} (\tau_{bf}^*)^{5/2} \tag{7}$$

7 DOWNSTREAM VARYING BANKFULL CHANNEL GEOMETRY

A simple way to describe the bankfull characteristics of a channel is in terms of a specified channel-forming bankfull Shields number τ_{bf}^*. Parker *et al.* (1998) and Parker (2004) have found that the following approximate closure is appropriate for sand-bed streams:

$$\tau_{bf}^* = 1.86 \tag{8}$$

Equation (6) can then be rearranged to yield the following relation for bankfull flow velocity U;

$$\frac{U}{\sqrt{RgD}} = \left(\frac{\tau_{bf}^*}{C_f}\right)^{1/2} \tag{9}$$

Thus for constant values of τ_{bf}^*, C_f, grain size D and sediment submerged specific gravity R, (9) specifies a bankfull flow velocity U that remains constant in the downstream direction. Substituting (9) into (3a) and (3b) and reducing, the following forms are found for the fluvial and fan-delta reaches;

$$\frac{dH_f}{dx} = S_f - R\tau_{bf}^* \frac{D}{H_f} \tag{10a}$$

$$\frac{dH_d}{dr} = S_d - R\tau_{bf}^* \frac{D}{H_d} \tag{10b}$$

For a given river profile on the fan-delta $\eta_d(r,t)$ at any time t, (10b) can be solved subject to (5a) to determine the streamwise variation in bankfull depth H_d on the fan-delta. Then (10a) can be solved subject to (5b) to determine the streamwise variation in bankfull depth on the fluvial reach. It is here assumed that the river has no tributaries over the reach of interest, so that bankfull water discharge Q_{bf} is constant in the streamwise direction, taking the same values on the fluvial and fan-delta reaches. Water continuity requires that

$$Q_{bf} = B_c U H \tag{11}$$

in which case the streamwise varying bankfull width is given from (7) and (11) as

$$B_c = \left(\frac{C_f}{\tau_{bf}^*}\right)^{1/2} \frac{Q_{bf}}{\sqrt{RgD}\, H} \tag{12}$$

Once the streamwise variation of H_d and B_{dc} (fan-delta reach) and H_f and B_{fc} (fluvial reach) are computed for a given bed profile, the streamwise variation in total bed material loads Q_{tbfd} (fan-delta reach) and Q_{tbff} (fluvial reach) are computed from (7).

8 SHOCK AND CONTINUITY CONDITIONS

The morphodynamic model has two moving boundaries: the position $r = r_d(t)$ denoting the distance from the fan vertex to the topset-foreset break (shoreline) and the position $r = r_b(t)$ denoting the distance form the fan vertex to the foreset-bottomset break (Figures 6 and 7).

Shoreline migration can be specified in terms of a shock condition (Swenson *et al.*, 2000; Kostic and Parker, 2003). The shoreline is located at $r = r_d(t)$, and

Copyright © 2006 Taylor & Francis Group plc, London, UK

bed elevation there is $\eta_d[r_d(t),t]$. It is assumed that the delta progrades with constant foreset slope S_a. The foreset elevation profile is thus given as

$$\eta(r,t)=\eta_d[r_d(t),t]-S_a[r-r_d(t)] \tag{13}$$

The shock condition is obtained by integrating (2b) from $r=r_d$ to $r=r_b$ subject to (1) and (13). This results in the relation

$$\frac{1}{2}(r_b^2-r_d^2)\theta_f\left[\left.\frac{\partial\eta_d}{\partial t}\right|_{r_d}+\sigma_d+(S_a-S_{dd})\dot{r}_d\right]= \Omega_d\frac{(1+\Lambda_d)}{(1-\lambda_{pd})}Q_{tbfdd} \tag{14}$$

where

$$\dot{r}_d=\frac{dr_d}{dt} \tag{15}$$

denotes the speed of progradation of the shoreline and

$$S_{dd}=-\left.\frac{\partial\eta_d}{\partial x}\right|_{r_d}\quad,\quad Q_{tbfdd}=Q_{tbfd}\big|_{r_d} \tag{16a,b}$$

A relation for the migration speed of the position of the foreset-shelf floor break can be obtained by imposing elevation continuity there. This condition is seen from (13) and Figure 7 to take the form

$$\eta_b(x,t)=\eta_d[r_d(t),t]-S_a[r_b(t)-r_d(t)] \tag{17}$$

Noting that by definition

$$\sigma_d=-\frac{\partial\eta_b}{\partial t}\quad,\quad S_b=-\frac{\partial\eta_b}{\partial x} \tag{18a,b}$$

and taking the derivative of (17) with respect to time, it is found that

$$(S_a-S_b)\dot{r}_b=(S_a-S_{dd})\dot{r}_d+\left.\frac{\partial\eta_d}{\partial t}\right|_{r_d}+\sigma_d \tag{19}$$

where

$$\dot{r}_b=\frac{dr_b}{dt} \tag{20}$$

9 SOLUTION AND TRANSFORMATION TO MOVING BOUNDARY COORDINATES

The specification of the problem is completed by one upstream boundary condition and one more continuity condition. The input volume bed material transport rate Q_{tbfu} must be specified at the upstream end of the fluvial reach;

$$Q_{tbff}\big|_{x=0}=Q_{tbfu} \tag{21}$$

In addition, the bed material transport rate should be continuous at the junction between the fluvial and fan-delta reaches;

$$Q_{btff}\big|_{x=L_d}=Q_{tbfd}\big|_{r=r_a} \tag{22}$$

The solution method can now be described as follows. Time and space must be appropriately discretized to allow a numerical solution, using spatial nodes separated by appropriate spatial steps Δx and Δr and an appropriate time step Δt. At any given time it is assumed that the bed profiles $\eta_d(x,t)$ and $\eta_f(x,t)$ are known. First (11b) is solved numerically by stepping upstream subject to (5a) to determine the bankfull depth profile H_d over the fan-delta reach. Then (11a) is solved by stepping upstream subject to (5b) to determine the bank depth profile H_f over the fluvial reach. Bankfull channel widths B_{fc} and B_{dc} are then solved algebraically from (12). The volume transport rates of bed material load at bankfull flow are computed algebraically from (7).

Equations (2a) and (2b) are then solved numerically to determine the bed elevation profiles η_d and η_f at one time step later. In the fan-delta reach, the volume bed material transport rates are given from (7) at all internal nodes. At the upstream node of this reach the continuity condition (22) is applied. At the downstream node of this reach the shock condition (14) is applied to determine the new position of the delta shoreline. Equation (17) is applied to determine the new position of the foreset-shelf floor break.

The initial conditions for the problem are specified initial bed profiles and shoreline position;

$$\eta_f\big|_{t=0}=\eta_{fI}(x) \tag{23}$$

$$\eta_d\big|_{t=0}=\eta_{dI}(x) \tag{24}$$

$$r_d\big|_{t=o}=r_{dI} \tag{25}$$

Here (23) and (24) are implemented in terms a) specified constant initial bed slopes S_{dI} and S_{fI} on the fan-delta and fluvial reaches, respectively, b) a specified initial delta height $\Delta\eta_I$, where

$$\Delta\eta_I=\{\eta_d[r_d(t),t]-\eta_b[r_b(t),t]\}_{t=0} \tag{26}$$

and c) an initial depth of submergence of the topset-foreset break below sea level;

$$H_d[r_d(t),t]\big|_{t=0}=\xi_d(0)-\eta_d[r_d(t),t]\big|_{t=0}=H_{ddI} \tag{27}$$

The initial elevation of standing water must be specified as well;

$$\xi_d(0)=\xi_{dI} \tag{28}$$

In the present analysis base level is assumed to rise at a specified constant rate $\dot{\xi}_d$.

The fact that the fan-delta reach includes two moving boundaries suggests the utility of solving

Copyright © 2006 Taylor & Francis Group plc, London, UK

the problem within this domain in moving-boundary coordinates. These are introduced as follows;

$$\bar{r} = \frac{r - r_u}{r_d(t) - r_u} \quad , \quad \bar{t} = t \tag{29}$$

Equation (2b), (10b), (14) and (19) thus transform to the respective forms

$$(1-\lambda_{pd})\theta \bar{r} r_d \left[\frac{\partial \eta_d}{\partial \bar{t}} + \sigma_d - \left(\frac{\bar{r}\dot{r}_d}{r_d - r_u} \right) \frac{\partial \eta_d}{\partial \bar{r}} \right] = - \Omega_d \frac{I_f (1+\Lambda_d)}{(r_d - r_u)} \frac{\partial Q_{tbff}}{\partial \bar{r}} \tag{30}$$

$$\frac{1}{r_d - r_u} \frac{dH_d}{d\bar{r}} = -\frac{1}{r_d - r_u} \frac{\partial \eta_d}{\partial \bar{r}} - R\dot{\tau}_{bf}^* \frac{D}{H_d} \tag{31}$$

$$\frac{1}{2}(r_b^2 - r_d^2)\theta_f \left[\left. \frac{\partial \eta_d}{\partial \bar{t}} \right|_{\bar{r}=1} + \sigma_d + S_a \dot{r}_d \right] = \Omega_d \frac{(1+\Lambda_d)}{(1-\lambda_{pd})} Q_{tbfdd} \tag{32}$$

$$(S_a - S_b)\dot{r}_b = S_a \dot{r}_d + \left. \frac{\partial \eta_d}{\partial \bar{t}} \right|_{\bar{r}=1} + \sigma_d \tag{33}$$

10 MODEL INPUT

Input data were gleaned from a) sediment data on the web site of the US Geological Survey, b) information provided by the US Army Corps of Engineers and c) published papers and reports including Roberts and Coleman (1996), Roberts *et al.* (1997), Majersky *et al.* (1997), DuMars (2002), Roberts *et al.* (2003a,b) and Wellner *et al.* (2006). Some poorly-constrained parameters were refined in the course of performing numerical runs, but arbitrary adjustments of the input parameters were kept to a minimum.

The following parameters were used for the results reported here: $D = 0.10$ mm, $R = 1.65$, $Q_{bf} = 4100\ \mathrm{m^3/s}$. $I_f = 0.27$, $Q_{tbfu} = 0.292\ \mathrm{m^3/s}$ (corresponding to 6.58 Mt/year of sand), $\tau_{bf}^* = 1.86$, $L_f = 25{,}000$ m, $B_f = 800$ m, $\theta = 120°$, $S_a = 0.002$, $S_b = 0.00018$, $Cz_f = Cz_d = 20$, $\lambda_{pf} = \lambda_{pd} = 0.6$, $\Omega_f = \Omega_d = 1$, $\Lambda_f = \Lambda_d = 0.49$, $\sigma_f = 0$, $\sigma_d = 5.8$ mm/year, $\dot{\xi}_d = 1.2$ mm/year, $\Delta\eta_I = 2.0$ m, $H_{ddI} = 5.1$ m, $(r_{dI} - r_u) = 4{,}300$ m, $r_u = B_f/\theta = 382$ m, $S_{fI} = 0.000062$ and $S_{dI} = 0.00014$. The modelling was commenced starting in year 1981 rather than 1973, because Majersky *et al.* (1997) suggest that it was in this year that upstream deposition became sufficient to allow the Wax Lake Delta to start prograding in its present rapid mode.

11 PRELIMINARY MODEL RESULTS

Figure 8 shows a plot of the position of the delta front r_d as a function of years since 1980. Both the model predictions and four data points extracted from three sources are shown. Figure 9 shows a plot of delta surface area of time as a function of years since 1980. Both the model predictions and five data points from two sources are shown.

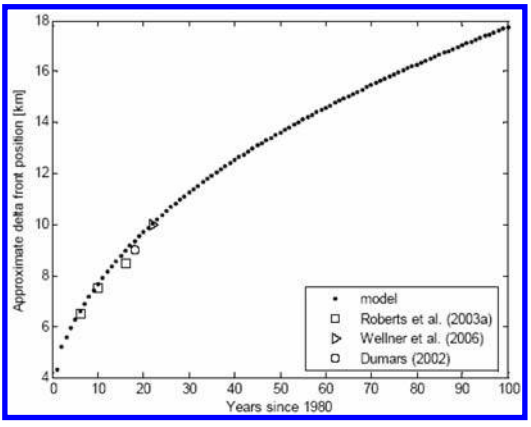

Figure 8. Plot of delta front (shoreline) position as a function of time since 1980.

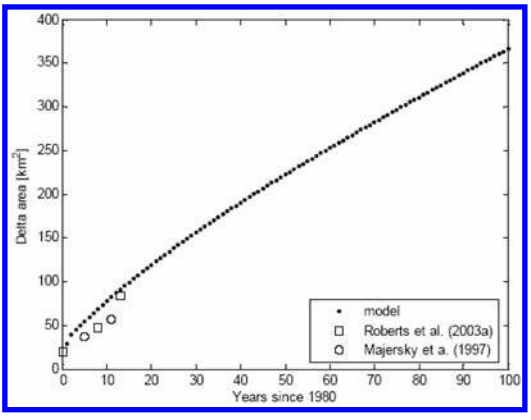

Figure 9. Plot of delta surface area as a function of time since 1980.

The results of these figures are highly preliminary, but they indicate that morphodynamic modeling of land building in the Mississippi Delta is feasible, and can yield reasonable predictions. Figure 10 shows a satellite photograph in which the projected delta front of Wax Lake is estimated out to year 2081. The Wax Lake Delta cannot in fact grow as large as indicated by year 2081, because before then it would partially merge with the Atchafalaya Delta.

12 NOTES OF CAUTION

The morphodynamic model of Wax Lake presented here is preliminary and incomplete in many ways. The

Copyright © 2006 Taylor & Francis Group plc, London, UK

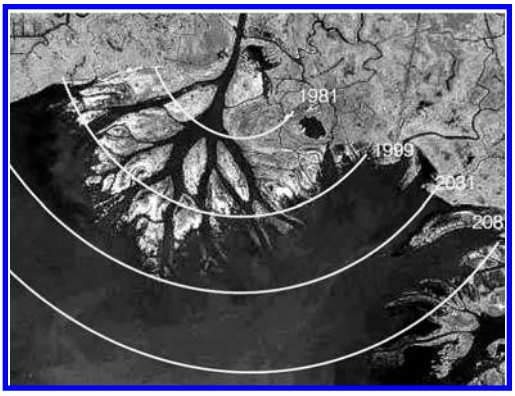

Figure 10. Predictions of the model for the shoreline of Wax Lake Delta overlain onto a satellite image from January 1999.

following revisions and additions need to be made to the model before practical application:

- modification from a single sand grain size to a sand grain size distribution;
- quantitative description of the role of vegetation in increasing the trapping rate of mud in the delta;
- incorporation of removal of delta sediment offshore due to the effect of e.g. cold fronts and hurricanes (Roberts *et al.*, 2003);
- a more detailed description of subsidence, if possible with a link to sediment loading; and
- clarification of the role, if any, of tides on delta dynamics.

It hardly needs pointing out that the morphodynamic model could not have been developed to the present point without the years of patient field campaigns carried out by H. Roberts and colleagues in Louisiana. There are nevertheless important gaps in the data base which need filling by means of further field campaigns.

13 IMPLICATIONS FOR RESTORATION OF THE MISSISSIPPI DELTA

The results of this study, though preliminary, lend support to the concept of building land in the Mississippi Delta by means of one of more controlled partial avulsions. Each such avulsion would involve a) a rigorously-designed diversion structure that would play a role similar to the Old River Control Structures, b) less rigorously designed levees that confine the flow within the diversion channel until the intended depositional zone is reached, and c) the absence of any and all levees and control structures within this depositional zone, to allow the river to do what it does best, in a delta, i.e. build new land.

Figure 11. Possible locations for controlled partial avulsions of the Mississippi River into Barataria Bay.

A primary candidate for such a depositional zone is Barataria Bay (Figure 3). Barataria Bay has been a zone of significant marshland loss in recent years. It is strategically located just south of New Orleans. In addition, it constitutes an area that is relatively sheltered, and thus less subject to the offshore removal of sediment by cold fronts and hurricanes (Roberts *et al.*,2003b).

Two possible sites for diversions are shown in Figure 11. One would divert part of the river into Barataria Bay upstream of New Orleans, and the other would divert part of the river downstream of New Orleans. An extended and refined version of the morphodynamic model presented here combined with extensive field data could be used as part of the design process in selecting a diversion.

There are many issues in regard to such controlled avulsions which need to be considered carefully, but which are beyond the scope of the present model. For example, a partial diversion downstream of New Orleans could cause a wave of degradation to sweep upstream, with potential damage to bridges, pipeline crossings etc. A partial diversion upstream of New Orleans could cause excessive siltation in the Port of New Orleans. If the diversion were sustained during low flow it could allow a salt wedge to move so far upstream as to contaminate the drinking water of New Orleans. In order to address these issues, the morphodynamic model presented here must be linked to purely channel-based models that can predict channel degradation and aggradation such as that of Meselhe *et al.* (2005).

Issues which need to be considered go beyond those involving the channel of the Mississippi River

Copyright © 2006 Taylor & Francis Group plc, London, UK

itself. Any scheme for controlled partial avulsions will require large expenditures of funds. The beneficial results may take decades to realize. In addition, any controlled partial avulsion is likely to have at least some negative consequences. These could, for example include siltation in the Intracoastal Waterway.

In point of fact, Hurricane Katrina was not needed to convince river and delta specialists that the negative consequences of doing nothing in the Mississippi Delta are likely to be far greater, in financial, social and ecological terms (Fischetti, 2001). The time has come to move forward with plans to use the sediment of the Mississippi River to restore the delta. Morphodynamic models of land building have an important role to play in this planning.

ACKNOWLEDGEMENTS

This paper is a contribution to the research effort of the National Center for Earth-surface Dynamics (NCED), a National Science Foundation (NSF) Science and Technology Center. The authors express their sincere thanks to Harry Roberts of Louisiana State University for his generous sharing of data and insight. Robert Twilley, also of Louisiana State University, Chris Paola and Efi Foufoula-Georgiou of NCED and H. Rich Lane of NSF strongly encouraged the pursuit of this research at a time when it appeared as though crucial support was lacking from NSF's Office of Integrative Activities. The cooperation of Mead Allison of Tulane University, John McCorquodale of the University of New Orleans and Ehab Meselhe of the University of Louisiana Lafayatte is gratefully acknowledged. The data collection exercise for the Wax Lake Delta was diligently carried out by the students in the first author's graduate course on river morphodynamics in the first term of 2006. The second author was one of these students: the others are Javier Ancalle, Corrie Bondar, Shane Csiki, Hsi-Heng Dai, Daniel Gambill, Christopher Hamblen, Ciaran Harman, Robert Haydel, Juan Martin-Vide, Stephen McKay, Diego Oviedo-Salcedo, Francisco Pedocchi, James Powell Joy Rexshell and Enrica Viparelli.

ABSTRACT: Practitioners did not wait for a complete achievement of knowledge to design and build flood defence structures, and to prepare emergency plans. As a consequence, research and practice often evolve in parallel worlds, without many interactions. To address end-user needs, research should thus develop adapted models, close to the physics, simple to implement, easy to calibrate, validated against idealised experiments and not too demanding in data. Three examples inspired by this philosophy are proposed: a model accounting for interactions between subsections in compound channels, an analogue 1-D model for a dam-break wave in a sharp bend, and a two-layer model for sediment movement induced by a dam-break wave.

1 INTRODUCTION

Rivers are among the most fascinating creations in nature, closely related to human development and well being. Rivers are involved in essential human activities: irrigation for agriculture, drinking water, energy and transportation.

But rivers also raise a lot of problems: floods and inundation often threaten human activities, rivers may convey chemical or biological pollution, or they may constitute an obstacle to mobility.

Among those problems, floods represent something special. They are a part of the river life and participate to its general equilibrium and evolution. River themselves have organised a natural system to mitigate their excesses. Floodplains may be considered as the most ingenious arrangement of flood regulation. The problem is that riverside areas are so attractive that more than 1.5 billions persons live in a floodplain, often unconsciously.

Modelling floods is thus of primary importance to take the best measures in order to manage their occurrence and mitigate their consequences.

1.1 *Short history of flood modelling*

Mitigation and management of floods and inundation is a very old problem for engineers, well before scientists could propose usable models. Designers could not wait for a complete knowledge and understanding of river behaviour before undertaking protective works. Often, those works were really successful, thanks to the good feeling of the river engineers of the past. But those empirical efforts did not always succeed, and sometimes ill-designed structures may have aggravated the risks of overflow consequences, compared to the natural situation.

In the history of flood defence, action has thus sometimes preceded reflection, at least accurate reflection.

During the 19th century, many works were carried out in rivers (e.g. Rhine, Rhône and Garonne, for Western Europe). These works were not all conducted in a blind way. Sometimes, the main characteristics of the natural river were defined from observation and one of the merits of those practitioners, like Fargue for the Garonne River, was to presume that the natural

Copyright © 2006 Taylor & Francis Group plc, London, UK

behaviour of a river was the best guideline for river works. The first source of knowledge about rivers was thus field observation, but the part of interpretation and empiricism was too large to avoid spectacular failures.

A part of the 20th-century progresses in modelling river floods was thus motivated by the urgency to face the failures in design of the former century. This is an uncommon situation in engineering where fundamental and applied researches generally precede application.

The first theoretical approaches of open-surface hydraulics were developed in a simplified context of straight prismatic channels with very simple geometry. The gap between those assumptions and the complexity of the reality was so large, that mathematical models issued from those pioneering approaches were not, or very approximately applied in real-life rivers.

In the same time, for complex river features or structures, laboratory scale models developed extensively, maybe more than in any other branch of learning. Some major laboratories were built mainly around such models devoted to main river reaches or estuaries.

An unexpected consequence of that was a resistance to mathematical model development and use, compared, for example, to fluid dynamics models in aeronautics. Indeed, during years, in consulting companies, numerical schemes developed by some pioneers (see for instance Miller & Yevjevich, 1975; Abbott, 1979; Cunge et al., 1980) were considered as limited to simplest cases and their feasibility was to be controlled by scale models.

The golden age of large-scale models ended mainly due to the increase of manpower costs, making impossible the construction and the maintenance of those models.

The too expensive physical models were thus rapidly replaced by software suites, generally based on the pioneers' work, developed above all for engineering purposes, with rather simplified reality description, but sophisticated interfaces for friendly use in data introduction and result interpretation.

1.2 *Which future for research in flood modelling?*

The progresses of theoretical and numerical modelling have been slowed down in a first time by the supremacy of physical models, which were the only ones able to account for complex situations. Similarly, the advantages offered by user-friendly packages generated some resistance to new theoretical developments.

This would not be a problem if all the practical issues were addressed by the existing packages. But in river engineering and management, major catastrophic events frequently recall that neither knowledge, nor techniques nor management are yet perfect.

Researchers propose more accurate physical description of the phenomena and more sophisticated numerical formulations. Practitioners are not only interested in accuracy but also in data treatment, user-friendly aspects, aided-interpretation of results, practical design of fluvial structures.

Each one develops as far as possible his own logic, sometimes leading to impossible synthesis. Indeed, why to elaborate a description so complicated that the numerical approach becomes unfeasible? Why to develop a model with so many parameters to calibrate that the usability is compromised? Why to construct a huge data set if this information is too large to be used in practice? Why to build a refined model if the required data are not available? Why to design complex scale models when simple experiments could produce simple results easier to use for calibration?

All the actors of fluvial hydraulics developments should size their own efforts according to the other approaches.

For the last ten years, the hydraulic research team of the *Université catholique de Louvain* (Belgium) had the opportunity to enter most of those aspects of research in river hydraulics and engineering applied to flood modelling. This context of diversified approaches has progressively led to a change in research methodology, privileging simple models, close to the physics, validated against idealised experiments and not too demanding in data for practical use. The present paper aims at sharing some experience gained from this philosophy, without pretending at all that this is the unique efficient approach, or that the presented models are the best ones.

This point of view will be illustrated through three topics of flood hydraulics: flow in compound channels (overbank floods), severe transient flows due to dam- or dike break and interaction between severe transient flows and sediments.

For each of those topics, the paper will organise in the following way: some key problems to be solved, the development of new ideas and models along with simple idealised experiments, and the critique of their applicability in terms of data requirements as well for calibration as for use.

2 OVERBANK FLOODS

The determination of water profile in compound channels is one of the major issues of flood modelling. Indeed, most of the human housing and activity, attracted by the proximity of the river, take place in the floodplains.

2.1 *A key problem to be solved: interactions between subsections*

The determination of the water profile in compound channels is not simple, as the flow behaviour in the

Copyright © 2006 Taylor & Francis Group plc, London, UK

main channel and in the floodplains are distinct. The main channel is deeper, smoother and more uniform, while the floodplain is shallower, rougher and irregular. The typical velocity of various subsections may be very different leading to complex interactions between flows in each subsection.

The simplest assumption is to consider the whole cross section. This could be seen as an interaction between subsections strong enough to force the velocity to be uniform in the whole cross section. In this so-called Single Channel Method (SCM), uniform-flow equations like Manning relation may be used:

$$Q = \frac{AR^{2/3}}{n} S_0^{1/2} = K S_0^{1/2} = K S_f^{1/2} \quad (1)$$

where Q is the discharge, A and R are the cross-section area and hydraulic radius, respectively, both depending on the water level, n the averaged roughness, S_0 and S_f the bottom and the friction slopes (assumed to be equal in uniform flow). The parameter K is defined as the cross-section conveyance, depending on the water depth and on the cross-section geometry and roughness.

The water profile may be computed using the Bernoulli equation (solved for example by the standard step method), assuming that the head loss for a specific reach is equal to the head loss in the reach for a uniform flow having the same hydraulic radius and average velocity (French 1985): the energy slope S_f can thus be expressed from (1):

$$S_f = \left(\frac{Q}{A R^{2/3}/n} \right)^2 = \left(\frac{Q}{K} \right)^2 \quad (2)$$

At the opposite of the SCM, the popular Divided Channel Method (DCM) considers separate subsections, neglecting their mutual interactions. The channel cross section is decomposed into three reasonably homogeneous subsections (Fig. 1) in such a way that the velocity field in each subsection can be assumed to be uniform and the subsection discharge Q_i can be estimated by the Manning formula (Lotter, 1933):

$$Q = \sum_i Q_i = \sum_i \frac{A_i R_i^{2/3}}{n_i} S_0^{1/2} = \sum_i K_i S_0^{1/2} \quad (3)$$

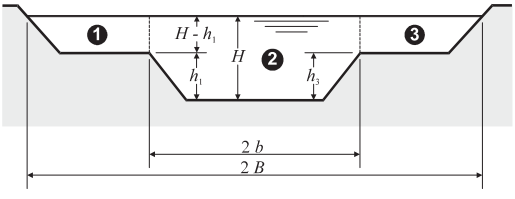

Figure 1. Subsections of compound channels.

where subscript i stands for subsection i. For computing the subsection characteristics A_i and R_i, the limits between the subsections can be vertical, diagonal or horizontal, the most common and practical choice being the vertical ones.

The Divided Channel Method gives better results than the Single Channel one and provides an energy slope value that can easily be included in computational schemes. It is therefore widely used in compound channel packages such as HEC-2 or HEC-RAS (*HEC-2*, 1990). Nevertheless it does not take the momentum transfer into account and thus tends to overestimate the total channel discharge.

A first way to correct the subsection discharges is to consider an apparent shear stress acting at the shear layer between main channel and floodplain. Several empirical shear stress formulae were experimentally established but they generally refer to one particular tested geometry and are difficult to apply to other data (Knight & Shiono, 1996). Moreover, there is no straightforward way to deduce an energy slope value from this kind of models, hindering their exploitation to water-profile computations.

The main progresses have been achieved during the last 20 years in the UK, especially based on large-scale experiments carried out in the Flood Channel Facility (FCF) at Wallingford. Empirical formulae (Ackers, 1993) or analytical methods (Shiono & Knight, 1991) have been developed for prismatic channels.

Those developments significantly improve the prediction of the stage-discharge relationship, but they do not always explicitly represent the physics of the phenomena and require tedious calibrations.

2.2 *A tentative new model: the Exchange Discharge Model (EDM)*

The development of a new model (Bousmar & Zech, 1999) was conducted by some simple guidelines:

(1) to use one-dimensional scheme to reduce the amount of required data and to limit the computation time;
(2) to keep close to the physics by explicitly expressing the momentum exchanges between subsections;
(3) to use a limited number of parameters to be calibrated and to define these physically;
(4) to provide an energy slope value, which can easily be included in computational schemes.

Those principles were dictated by the need to use the new method immediately in real-life applications.

2.2.1 *Physical principles*

In straight compound channels, due to the shear layer at the main channel-floodplain interface, large-scale vortices appear. These vortices can be seen as a turbulent exchange discharge through the interface (Fig. 2).

Copyright © 2006 Taylor & Francis Group plc, London, UK

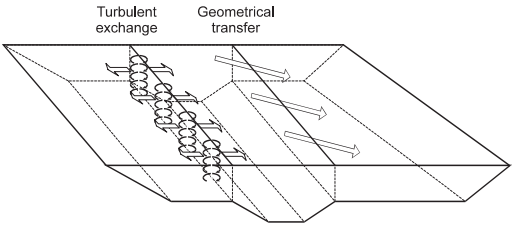

Figure 2. Flow exchange at the interfaces between main channel and floodplains.

Rather than giving an estimate of an apparent shear stress, Bertrand (1994) proposed to model the momentum transfer between subsections by the product of the mass of water flowing through the interface by the velocity gradient at this interface.

This model is easy to extend to non-uniform and/or non-prismatic flows where a lateral discharge occurs through the interface due to a modification of flow distribution in the subsections (Yen et al. 1985). This geometrical transfer discharge (Fig. 2) can be added to the turbulent exchange to get a global estimation of the momentum transfer.

2.2.2 *Governing equations*

Each subsection of a compound channel acts as a channel submitted to a lateral flow per unit length q_l, which consists in an inflow component q_{in} and/or an outflow component q_{out}. Inflow and outflow are normally mutually exclusive, except for turbulent exchanges due to fluctuations, where mass transfer is equal to zero but not momentum transfer. Conservation of *mass* may be written:

$$\frac{\partial A}{\partial t}+\frac{\partial Q}{\partial x}=q_l=q_{in}-q_{out} \tag{4}$$

where A is the cross-section area, and Q the discharge.

On the other hand, the net rate of *momentum* flux into a control volume plus the sum of the forces (gravity, friction, pressure) acting on the control volume is equal to the rate of accumulation of momentum within the control volume (Fig. 3):

$$\frac{\partial}{\partial t}(\rho AU)=-\frac{\partial}{\partial x}(\rho AU^2)+\rho q_{in}u_l-\rho q_{out}U -\rho gA\frac{\partial z}{\partial x}-\rho gAS_f \tag{5}$$

where ρ is the density of water, g is the gravity constant, S_f is the friction slope, estimated for example by (2), $U=Q/A$ is the mean velocity, z the water level; and u_l the lateral-inflow velocity component in the direction of the main flow.

Of course, lateral inflow q_{in} and outflow q_{out} in (4) and (5) may be composed of several parts, which is the case for a main channel flanked by two floodplains.

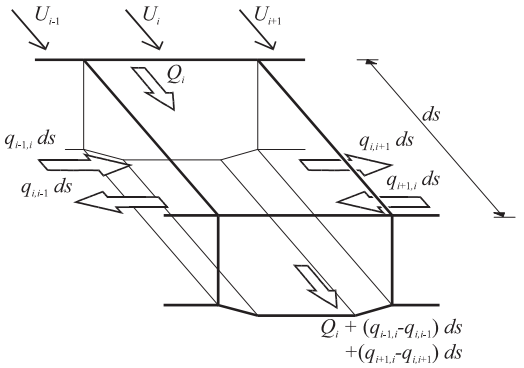

Figure 3. Momentum balance for a sub-section i Developing (5) yields.

$$A\frac{\partial U}{\partial t}+U\frac{\partial A}{\partial t}+AU\frac{\partial U}{\partial x}+U\frac{\partial AU}{\partial x}+gA\frac{\partial z}{\partial x} =q_{in}u_l-q_{out}U-gAS_f \tag{6}$$

which may be simplified, subtracting to (6) the continuity equation (4) multiplied by U:

$$A\frac{\partial U}{\partial t}+gA\frac{\partial}{\partial x}\left(z+\frac{U^2}{2g}\right)=q_{in}(u_l-U)-gAS_f \tag{7}$$

showing that only the lateral inflow influences the momentum, while the outflow effect is implicitly included in the kinetic head variation. An important consequence of this asymmetry between in- and outflow effect is that there exists a momentum transfer due to turbulence even if the average mass transfer is equal to zero.

2.2.3 *Head losses relations*

In case of steady flow, the first term of (7) disappears, and the opposite of the partial derivative of the second term may be defined as a head loss per unit length S_e,

$$S_e=-\frac{\partial}{\partial x}\left(z+\frac{U^2}{2g}\right)=S_f+S_a=S_f(1+\chi) \tag{8}$$

where S_a is an additional head loss due to the exchange of momentum induced by q_{in}. Using (7) generalised to the case of multiple inflows, (8) can be written for a subsection i between a right subsection $i-1$ and a left subsection $i+1$ (Fig. 3)

$$S_{a,i}=S_{f,i}\chi_i=\frac{q_{i-1,i}(U_i-u_{i-1})+q_{i+1,i}(U_i-u_{i+1})}{gA_i} \tag{9}$$

in which $q_{i-1,i}$ is the unit lateral inflow from subsection $i-1$ to subsection i, and u_{i-1} the lateral inflow longitudinal velocity.

Copyright © 2006 Taylor & Francis Group plc, London, UK

2.2.4 *Exchange discharges*

The exchange discharges q is divided in two parts: q^t, due to turbulent exchanges, and q^g, associated to mass transfer due to change in cross-section geometry.

According to Bertrand's proposal (1994), we assume that both lateral discharges q^t_{cf} and q^t_{fc}, respectively from the main channel to a floodplain and from this floodplain to the main channel, are equal to the product of the depth-averaged turbulent part of the transversal velocity by the interface area per unit length,

$$q^t_{cf} = q^t_{fc} = \left|\overline{v'}\right|(H - h_1) = \psi' \left|U_c - U_f\right|(H - h_1) \qquad (10)$$

where H and h_1 are the water and the bank levels above the main-channel bottom (Fig. 1). According to the Boussinesq assumption, the average turbulent transversal velocity is assumed to be proportional to the absolute value of the longitudinal velocity difference between subsections.

If there is a change in geometry (widening or narrowing of floodplain cross-section area) or in water depth (gradually varied flow), the conveyance in the floodplain increases or decreases, forcing through the interface a geometrical transfer discharge q^g_{cf} or q^g_{fc}. For example, if the change in geometry is such that the floodplain conveyance K_f increases,

$$q^g_{fc} = 0 \quad \text{and} \quad q^g_{cf} = \frac{dQ_f}{dx} = \frac{dK_f}{dx} S^{1/2}_{f,f} \qquad (11)$$

neglecting the variation of the friction slope on the floodplain $S_{f,f}$ on the considered interval. This result may be generalised as:

$$q^g_{fc} = \psi^g \kappa_{fc} \frac{dK_f}{dx} S^{1/2}_{f,f} \qquad (12a)$$

$$q^g_{cf} = \psi^g \kappa_{cf} \frac{dK_f}{dx} S^{1/2}_{f,f} \qquad (12b)$$

where κ_{fc} and κ_{cf} take the appropriate values, respectively (0, 1) for $dK_f/dx > 0$ and $(-1, 0)$ for $dK_f/dx < 0$. A proportionality factor ψ^g has also been included to take into account the fact that a change in conveyance does not induce an immediate mass transfer.

2.2.5 *Practical evaluation of flow*

The key assumption is to consider in each subsection i, a distinct friction slope S_{fi}, a distinct additional loss S_{ai}, and thus a distinct ratio χ_i, but a unique total energy slope S_e in all subsections, according to the one-dimensional modelling. This assumption means that the river adjusts its energy budget in such a way that the differences in head are constant between adjacent subsections.

Thus we can write the Manning equation for each subsection:

$$Q_i = A_i U_i = \frac{A_i R_i^{2/3}}{n_i} S^{1/2}_{fi} = K_i S^{1/2}_{fi} = K_i \left(\frac{S_e}{1+\chi_i}\right)^{1/2} \qquad (13)$$

from which the subsection velocity U_i can be evaluated.

Applying (9), for example to the subsection 1 of Fig. 1 (the only connection is with the subsection 2), yields,

$$\chi_1 = q_{2,1} \frac{(U_1 - u_2)}{g A_1 S_{f,1}} = \left(q^t_{2,1} + q^g_{2,1}\right) \frac{(U_1 - u_2)}{g A_1 S_{f,1}} \qquad (14)$$

recalling that $q = q^t + q^g$.

Computing $q^t_{2,1}$ from (10), $q^g_{2,1}$ from (12), and the velocities U_i from (13), (14) reads after some simplifications:

$$\chi_1 = \left[\psi'(H - h_1)\left(\frac{R_2^{2/3}}{n_2}\left(\frac{1+\chi_1}{1+\chi_2}\right)^{1/2} - \frac{R_1^{2/3}}{n_1}\right) + \psi^g \kappa_{21} \frac{dK_1}{dx}\right] \left[\frac{R_1^{2/3}}{n_1} - \frac{R_2^{2/3}}{n_2}\left(\frac{1+\chi_1}{1+\chi_2}\right)^{1/2}\right] \frac{1}{g A_1} \qquad (15)$$

Similar equations may be derived for χ_2 (with interactions between subsections 1 and 3) and for χ_3 (with interactions with subsection 2). For a given depth H, the partial section A_i and hydraulic radius R_i may be computed geometrically for each subsections, and a set of non-linear equations in χ_i results:

$$\chi_1 = f(\chi_1, \chi_2) \qquad (16a)$$

$$\chi_2 = f(\chi_1, \chi_2, \chi_3) \qquad (16b)$$

$$\chi_3 = f(\chi_2, \chi_3) \qquad (16c)$$

which can be solved for example by a Newton-Raphson algorithm.

2.2.5.1 Stage-discharge in uniform flow

Given the values of χ_i, it is possible to compute the subsection discharges Q_i by the adapted Manning equation (13) for an uniform flow at a given depth H with an head slope S_e postulated equal to the channel bottom slope S_0 if the latter may be defined. The total discharge Q in the cross-section is the sum of the corrected subsection discharges,

$$Q = \sum_i Q_i = \sum_i \left(\frac{K_i}{(1+\chi_i)^{1/2}}\right) S_e^{1/2} \qquad (17)$$

The discharge is thus computed in a similar way as the Divided Channel Method, but with corrected conveyance in each subsection.

Copyright © 2006 Taylor & Francis Group plc, London, UK

2.2.5.2 Energy slope for varied-flow computation

Equation (17) also leads to a direct computation of the energy slope for a given discharge, a given water level and the associate cross-section geometry. A coefficient χ may be defined for the whole cross-section as a global correction applied to the friction slope S_f computed from the Divided Channel Method (see Eq. 3 with $S_f = S_0$):

$$S_e = S_f(1+\chi) = \left(\frac{Q}{\sum_i K_i}\right)^2 (1+\chi) \qquad (18)$$

Introducing the discharge (17) into (18) yields,

$$\chi = \left(\frac{\sum_i K_i}{\sum_i \left(K_i/(1+\chi_i)^{1/2}\right)}\right)^2 - 1 \qquad (19)$$

making possible the use of any method to solve (5) or the Bernoulli equation, just substituting the total head loss S_e to the friction loss S_f, in order to compute the water profile in non-uniform flow.

2.3 *Applicability*

Most of the initial objectives are reached: the model is simple and may be easily implemented in common computation procedures as the standard-step method. The method was successfully tested against laboratory data (Bousmar & Zech, 1999).

Only two parameters are to be calibrated: the turbulent exchange coefficient ψ^t, which revealed from comparisons with experimental data to be rather constant ($\psi^t = 0.16$), and the geometrical exchange correction factor ψ^g, whose the value of 0.5 initially adopted (Bousmar & Zech, 1999) has to be refined.

2.3.1 *Validation*

A challenging example is a 4-km meandering reach of River Sambre, Belgium (Fig. 4). Grassland floodplains, on both sides of the main channel were flooded several times during the last years. Accurate topographic data (with cross-section profiles known at intervals of about 100 m, including floodplains) are available. For 18 flood events, discharge was measured together with upstream and downstream water levels, making possible a roughness evaluation in main channel and floodplains.

For each gauged discharge, a water profile was computed from the corresponding measured downstream depth. Three different methods were used: the Single Channel Method, the Divided Channel Method (using HEC-2) and the Exchange Discharge Model. They are synthesised in Fig. 5: each gauged discharge presents

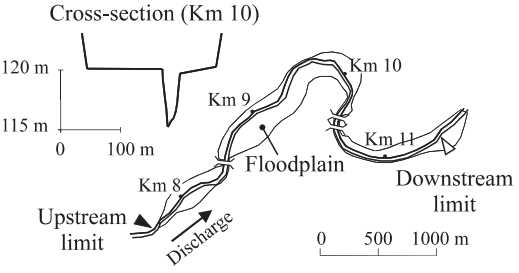

Figure 4. Scheme of River Sambre modelled reach.

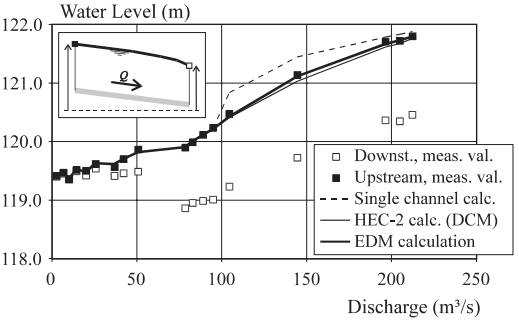

Figure 5. Water-profile computation in River Sambre, Belgium. Measured downstream water levels, measured and computed upstream water levels (lines between points are only drawn for figure legibility). Manning roughness coefficients are, for SCM: $n = 0.026$; for DCM: $n_c = 0.026$, $n_f = 0.100$; and for EDM: $n_c = 0.026$, $n_f = 0.031$.

its specific downstream water level, the upstream calculated levels are shown compared to the measured values.

The results show that the SCM clearly over-estimate the energy slope (difference between up- and downstream levels) for low overflow. HEC-2 (DCM) gives better results, as the energy slope evolution is better estimated. Nevertheless, computations with various floodplain roughness coefficients show that its value can vary in the range $n_f = 0.100 \ldots 1.000$ which are unrealistic.

The Exchange Discharge Model gives better results, with a floodplain roughness coefficient $n_f = 0.031$, which is coherent with field observations on grasslands. For the largest discharge ($Q = 205\ \mathrm{m^3/s}$), the additional loss S_a due to interaction can represent up to 25% of the total losses S_e.

2.3.2 *Application to Meuse River (Belgium)*

The Meuse River, whose the watershed covers 12220 km^2 (73.3% of the Walloon territory in Belgium), has suffered two big floods in 1993 and 1995, with damages partly due to poor information available to decision makers and to population in general.

Copyright © 2006 Taylor & Francis Group plc, London, UK

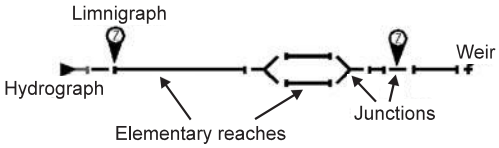

Figure 6. Network scheme of a River Meuse reach.

The Service of Hydrologic Studies (SETHY) of the Walloon Ministry of Equipment and Transport has piloted an ambitious project aiming at giving a real-time forecasting of the water levels and flooded area, with a prediction of 18 hours (Dal Cin et al., 2005). The project is an integration of various techniques:

(1) construction of accurate geometry data base: bed profiles by swath bathymetry, which records depth profiles across tracks from a boat whose motion sensors measure the roll, pitch and heave and DGPS gives position; survey of the floodplains by an airborne laser, yielding a DTM with one measured point per m^2;
(2) prediction of the inflow discharges from the upper valley and from the tributaries: rainfall, non-linear production function, linear transfer function (Moens & Bastin, 1995);
(3) flood propagation in the river, including the effects of control structures (dams and gates);
(4) delineation of flooded areas using GIS tools.

The authors were involved in most of those types of task, except the prediction of the inflows. This multiple involvement naturally imposed an integrated approach. As the river reach was long (one thousand cross-sections for 90 km) and the computation time allowed to obtain real-time prediction was rather short, a one-dimensional model was preferred with a four-point Preissmann implicit scheme.

As the river features some islands and is controlled by several dams (12 in the studied reach), an organisation in sub-reaches was adopted, with "elements" interacting mutually (Fig. 6).

For the determination of cross sections, a simplification of the polylines issued from the DTM and the bathymetry was required to minimise the data size without altering the computation of the characteristics (area A, wetted perimeter P, hydraulic radius R). It was observed that one of the most delicate points was the merging of submerged and emerged data, issued from various sources, not always compatible. In particular the definition of the overbank level is important for the EDM.

The Exchange Discharge Model revealed to improve considerably the results without slowing down too much the computation process (Fig. 7).

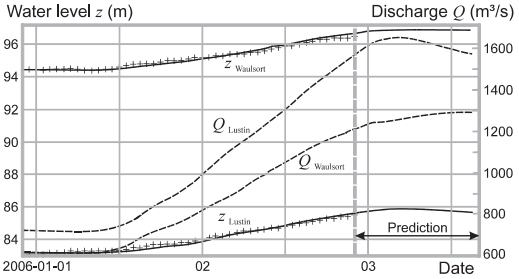

Figure 7. Meuse River: measured (+) and simulated (lines) water levels and discharge (18-hour forecasting).

3 SUDDEN FLOODS

Another challenging problem is the modelling of sudden floods following a structure failure (a dam break or a dike breach) or from an extreme rain-peak.

This kind of flood is fortunately less frequent than overbank floods. However this low probability of occurrence is to be confronted to the magnitude of the associated risk, in terms of casualties and damages to the properties and to the social organisation.

Dam or dike failures are rare but they constitute one of the heaviest threats for the downstream population. People, and thus also decision-makers, less and less accept to consider this event as an uncontrolled fatality. Legal obligations were progressively imposed to the dam owners to investigate the consequences of a potential failure, and to prepare adapted warning systems and rescue plans.

This explains why so many efforts were carried out during the last 20 years, to improve the modelling of such an event. Generally companies in charge of dams developed their own expertise with or without the support of research organisations. Models issued from these developments are often efficient enough to address the legal requirements. In some cases, such models or methods have even become the rule with a trend to fix the procedures.

In parallel, researchers, fascinated by such an interesting problem, have continued to improve their methods. These are more and more accurate but generally heavier to apply. As a consequence, application of such developments in the practice remains limited. A kind of gap has resulted between the practitioners a little reluctant to rerun their computations, and the researchers.

Another difficulty is that the accuracy of new developments has to be confronted to real-life data. Such data are (fortunately) rare and inaccurate, as, in case of catastrophic events, measurements are not the first people's concern. Of course it is sometimes possible to replay the event at a laboratory scale with accurate measurement, but scale models are generally too expensive and also too complex for giving a clear guidance in numerical model calibration.

Copyright © 2006 Taylor & Francis Group plc, London, UK

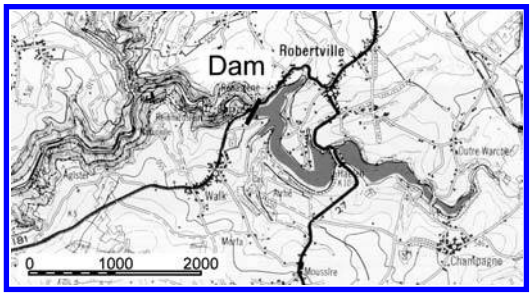

Figure 8. Robertville dam, in the Warche valley (Belgium).

3.1 *An example of key problem to be solved: effect of bends on dam-break waves*

A recent dam-break study on a Belgian valley highlighted important differences in the computed wave arrival time between one- and two-dimensional models: the one-dimensional model, generally preferred for large-scale simulations, predicted a much faster wave than the two-dimensional model (6 minutes instead of 50 minutes to reach the first town downstream).

How to explain such a difference? The valley slope is steep, with multiple sharp bends (Fig. 8), and it was suspected that the important head and momentum losses occurring in the bends, which are not taken into account by the one-dimensional model, were at the origin of the observed difference.

3.2 *A tentative approach: basic experiments and simplified models*

3.2.1 *The basic one-dimensional model*

To represent the dam-break wave in a natural valley, a one-dimensional approach is possible as far as changes in cross-section geometry are accounted for.

The computation is thus founded on an appropriate form of shallow-water equations (Capart et al., 1997; Soares-Frazão, 2002):

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F}}{\partial x} = \mathbf{S} \tag{20a}$$

with

$$\mathbf{U} = \begin{pmatrix} A \\ Q \end{pmatrix}, \ \mathbf{F} = \begin{pmatrix} Q \\ VQ + gI_1 \end{pmatrix}, \ \mathbf{S} = \begin{pmatrix} 0 \\ \frac{\partial}{\partial x}\left(gI_1|_{\bar{z}}\right) - gAS_f \end{pmatrix} \tag{20b}$$

where A is the cross-section area, Q the discharge and I_1 the cross-section static momentum accounting for the hydrostatic pressure (Fig. 9)

$$I_1 = \int_0^h (h-\eta)\, b(\eta)\, d\eta \tag{21}$$

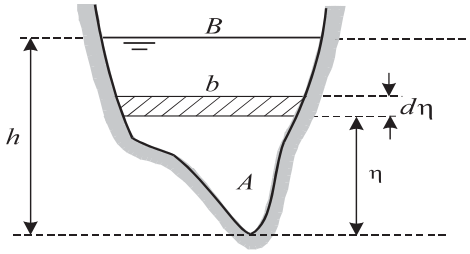

Figure 9. Static moment definition.

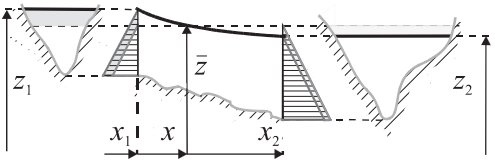

Figure 10. Hydrostatic pressure in non-prismatic channel.

In the source terms, the difference in gI_1 for a given mean water level accounts for the effect on the hydrostatic pressure, as well the effect of the changes in cross-section width as the effect of the bottom slope (Fig. 10).

This formulation, applied to a finite-volume scheme, appeared to be very efficient even for irregular valleys, except if these feature significant changes in direction. Further investigations about this particular point were thus carried out (Soares-Frazão, 2002; Soares-Frazão & Zech, 2002).

3.2.2 *A basic experiment: a 90° sharp bend*

To investigate more deeply the problem posed by sharp bends, and compare the performances of two- and one-dimensional modelling, a simplified case was investigated: a dam-break flow in a channel with a 90° sharp bend. Therefore, an experimental channel with such a 90° bend was built in the laboratory of the Civil Engineering Department of the Université catholique de Louvain, Belgium, and some computations were performed with various levels of sophistication (Fig. 11).

Experiments in the 90°-bend channel showed that the change in flow direction occurs abruptly as depicted on Fig. 12 at various times from a 2-D computation.

The supercritical flow induced by the dam break reflects against the bend, its velocity becomes zero and the water level rises (Fig. 12a). Then, this water column falls down (Fig. 12b) and a new water front propagates both in the downstream and upstream reaches (Fig. 12c). In the upstream direction, this results in a bore receding to the reservoir, with the consequence

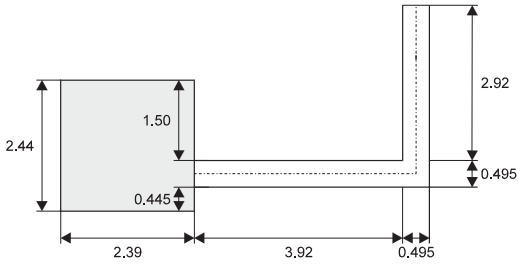

Figure 11. Sharp bend: experimental set-up.

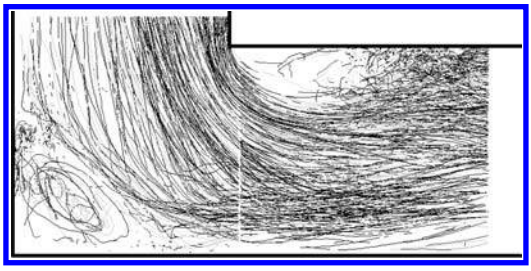

Figure 13. Trajectories in the bend.

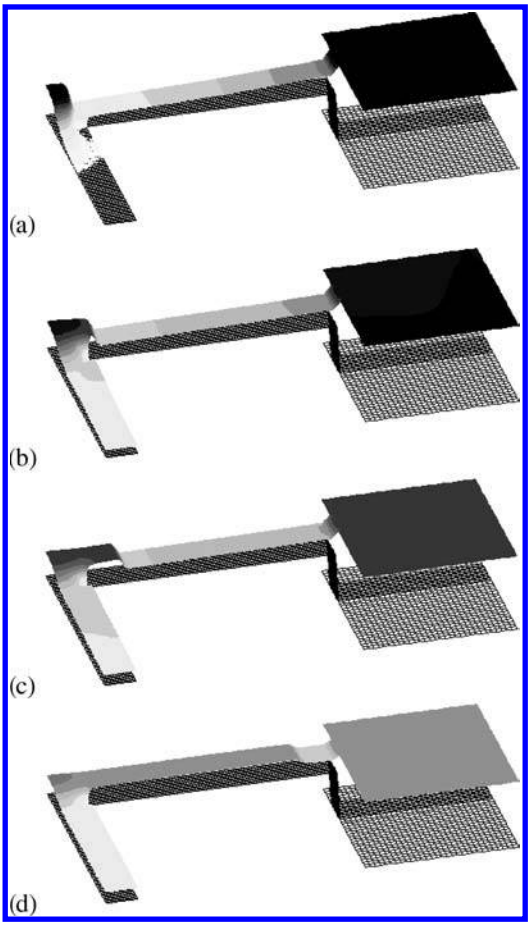

Figure 12. Dam-break flow in a 90˚ bend at times (a) 3 s, (b) 5 s, (c) 7 s, and (d) 14 s.

that the flow at the head of the bore is now subcritical, and thus much slower than the initial supercritical flow (Fig. 12d).

The abrupt change in direction can be explained as follows. In the initial supercritical stage, the kinetic energy is dominant. Then, when the water is suddenly stopped in the bend, its kinetic energy is transformed into potential energy (rise of the water surface) while important head losses occur. Contrarily to kinetic energy, which is associated with velocity vectors with a given direction, the potential energy is purely scalar without any preferential direction. This potential energy then transforms back into kinetic energy, with velocities oriented in the downstream-reach direction.

3.2.3 *An equivalent one-dimensional model for the bend*

Developing the bend channel as a straight one, the water profile along the developed channel shows interesting similarities with the water profile obtained in a case of channel locally constricted. A bore forms just upstream the channel narrowing, similarly to what happens upstream the bend.

Using a digital imaging technique to measure the surface-velocity field in the bend (Capart et al., 2002; Spinewine et al., 2003), it was possible to reconstruct the flow trajectories. Such trajectories measured over the time interval [6 s–7 s] are shown on Fig. 13.

It appears that the active flow region does not extend over the whole channel cross section in the bend: there is a dead zone in the outer corner, and a shadow zone just downstream from the inner corner. The flow thus seems to reproduce a kind of local constriction, supporting the idea of a similarity in the consequences of those two topographical singularities.

Combining the flow trajectories in the bend over different time intervals, it was possible to define an average local constriction in a straight channel corresponding to effect of the bend (Fig. 14).

This fictitious channel was thus used to simulate a dam-break flow under the same initial conditions as for the bend test case. Results show a good agreement between 1-D analogue, 2-D computations and measurements, except regarding the time of the reflected front (Fig. 15a, gauge C2). The water level is exaggerated in gauge C3, but the water release at gauge C4 (Fig. 15b) is even better captured by the analogue 1-D than by the full 2-D model.

Copyright © 2006 Taylor & Francis Group plc, London, UK

3.3 *Applicability*

Of course, equivalent one-dimensional models do not pretend to reach the performance of a complete two- or three-dimensional model, but they may offer to the practitioners an interesting substitute for these, in the frequent case where no complete information is available on the valley topography.

It is clear also that such analogues have to be further investigated to form a usable catalogue, and the only way to do that is a mix of some basic experiments for idealised geometry, and methodical accurate computations with full models in order to scan the whole range of possible situations.

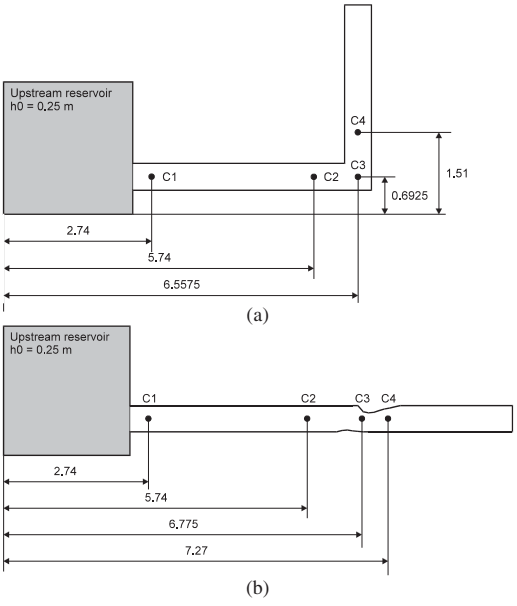

Figure 14. Constriction as an analogue to the bend.

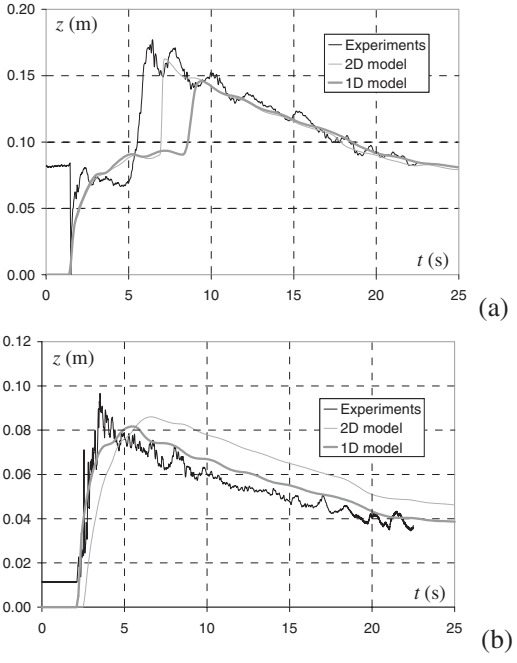

Figure 15. Comparisons between experiments, analogue 1-D model and full 2-D model at gauges C2 (a) and C4 (b).

4 SUDDEN FLOODS AND SEDIMENTS

In a number of ancient and recent catastrophes, floods from dam or dike failures have induced severe soil movements in various forms: debris flows, mud flows, floating debris and sediment-laden currents (Costa and Schuster, 1988). Fig. 16 presents some estimates of the volume of sediment material moved by such flows, gathered from published cases studies (Capart, 2000; Capart et al., 2001). In some cases, the volume of entrained material can reach the same order of magnitude (up to millions of cubic meters) as the initial volume of water released from the failed dam.

Also, this solid transport often causes more damages and casualties than the liquid flood and the means required to restore the devastated area are considerably heavier.

Moreover, presence of solid transport seriously affects the evaluation as well of the maximal water level as of the arrival time of a dam-break wave.

However, at the current stage of development of numerical simulation tools, it is impossible for practitioners to accurately account for such a sediment mobilisation and movement.

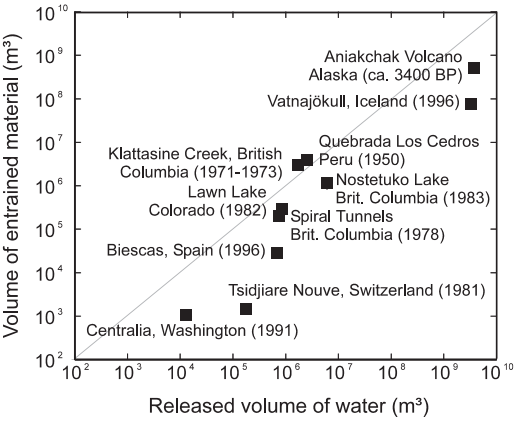

Figure 16. Entrained material from dam or dike failures (Capart, 2000).

4.1 *A key problem: sediment mobilisation and expansion*

Dam-break induced geomorphic flows generate intense erosion and solid transport, resulting in dramatic and rapid evolution of the valley geometry.

Close to the broken dam, rapid and strong erosion accompanies the development of the dam-break wave. The flow exhibits noticeable free surface features: wave breaking occurs at the centre (near the initial location of the dam), and a nearly vertical wall of water and debris overruns the sediment bed at the wave forefront (Capart, 2000), resulting in an intense transient debris flow (Fig. 17).

Behind the debris-flow front, the behaviour appears to be completely different: inertial effects and bulking of sediments may play a significant role.

Common geomorphic models are based on the Saint-Venant – Exner equations, adding to the common continuity and momentum conservation of the liquid phase (see Eqs. 20, for example) an equation for the continuity of the sediment phase. In this approach, the solid transport is not a main unknown and is evaluated externally by a closure equation (for instance a Meyer-Peter – Müller formula).

The main drawback of such a method is that the common solid-transport formulae have been developed in uniform regime, yielding an equilibrium transport capacity, which has no chance to occur under dam-break conditions.

The key point is thus to take into account the complete mechanism of sediment mobilisation, including the inertia of the grains, the momentum required for their acceleration and the expansion needed for their movement.

4.2 *A tentative new description: the two-layer model*

To fulfil the above requirements, the key idea is to consider separately the layer of moving sediments from moving water to make exchanges possible between the two layers.

4.2.1 *Physical description*

The two-layer model presented here is due to Spinewine (2005) and is based on the pioneering work by Capart (2000), progressively improved by Capart & Young (2002), Spinewine (2003).

The sediments are moving in a dense layer, with negligible suspension in the upper layer. The flow is thus represented by the following layers: (a) the upper layer consisting in clear water of depth h_w, (b) the moving sediment layer h_s and (c) the fixed-bed layer, having the bed level z_b as upper limit (Fig. 18).

To give the model the required degrees of freedom the velocities of the two moving layers are distinct: ($u_s \neq u_w$) and the concentrations of the bottom and of the moving layer are not the same ($C_s \neq C_b$) to account for the expansion required by the grain mobilisation.

4.2.2 *Governing equations*

Defining the erosion rate (negative in the case of deposition) as

$$\frac{\partial z_b}{\partial t} = -e_b \tag{22a}$$

it is possible to express the continuity of both the water and the water/sediment mixture layers:

$$\frac{\partial h_w}{\partial t} + \frac{\partial}{\partial x}\left(h_w u_w\right) = -e_b \frac{C_b - C_s}{C_s} \tag{22b}$$

$$\frac{\partial h_s}{\partial t} + \frac{\partial}{\partial x}\left(h_s u_s\right) = e_b \frac{C_b}{C_s} \tag{22c}$$

Those equations can be compared to (4). The right-hand side of (22c) indeed represents the in- or outflow, taking into account the change in concentration of an amount of material passing from the fixed bed to the moving-sediment layer (due to the expansion, the volume is greater in case of erosion), and the call of water from the upper layer to fill the void so-generated, which induces a loss for this upper layer as represented in the right-hand side of (22b).

Using a shallow-water approach, with the assumption of a hydrostatic pressure distribution, the momentum conservation of those moving layers reads:

$$\frac{\partial (h_w u_w)}{\partial t} + \frac{\partial}{\partial x}\left(h_w u_w^2 + \frac{g h_w^2}{2}\right) + g h_w \frac{\partial}{\partial x}\left(z_b + h_s\right) = -e_b \frac{C_b - C_s}{C_s} u_1 - \frac{\tau_w}{\rho_w} \tag{22d}$$

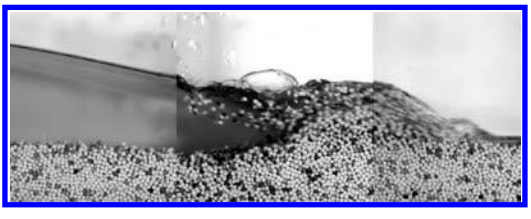

Figure 17. Near-field water/sediment flow (Université catholique de Louvain).

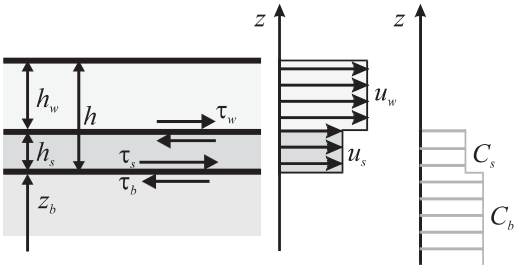

Figure 18. Two-layer model scheme.

Copyright © 2006 Taylor & Francis Group plc, London, UK

$$\frac{\partial(h_s u_s)}{\partial t}+\frac{\partial}{\partial x}\left(h_s u_s^2+\frac{g h_s^2}{2}\right)+g h_s\left(\frac{\partial z_b}{\partial x}+\frac{\rho_w}{\rho'_s}\frac{\partial h_w}{\partial x}\right) = \frac{\rho_w}{\rho'_s}\frac{C_b-C_s}{C_s}e_b\,u_1+\frac{\tau_w}{\rho'_s}-\frac{\tau_b}{\rho'_s} \quad (22e)$$

where $\rho'_s=\rho_w(1-C_s)+\rho_s C_s$ is the volumetric mass of the moving mixture layer h_s. Those equations may be compared to (6).

The asymmetrical exchange of momentum in case of erosion or deposition is taken into consideration in the following way: $u_1=u_w$ if $e_b>0$ while $u_1=u_s$ if $e_b<0$. For details about the above equations see Spinewine (2005)

In this model the five dependent variables are h_w, h_s, z_b, $(h_w u_w)$ and $(h_s u_s)$. The erosion rate e_b (negative in the case of deposition) results from the inequality between the shear stresses τ_s and τ_b on both faces of the bed interface:

$$e_b=\frac{1}{\rho'_b\,|u_s|}\left(\tau_s-\tau_b\right) \quad (23)$$

where $\rho'_b=\rho_w(1-C_b)+\rho_s C_b$ is the volumetric mass of the bottom layer at rest. Closure equations are required for τ_w, τ_s and τ_b. The shear stresses τ_w and τ_s are evaluated from the turbulent friction:

$$\tau_w=\rho_w C_{fw}\left(u_w-u_s\right)^2 \quad (24)$$

$$\tau_s=\rho'_s C_{fs}\,u_s^2 \quad (25)$$

while τ_b depends on the critical shear stress c, and on the internal friction angle ϕ:

$$\tau_b=c+\sigma'\tan\phi=c+\left(\rho'_s-\rho_w\right)g\,h_s\,\tan\phi \quad (26)$$

where σ' is the effective pressure.

4.2.3 *Model calibration*

Some variables in (22–26) are physically determined: ρ_w, ρ_s, C_b, C_s, c and ϕ. The only coefficients impossible to measure directly are the friction coefficients C_{fw} and C_{fs}.

These parameters are not easy to calibrate by means of experiments, as the above model relies on some simplifications: the velocity is considered as uniform in both layers leading to a discontinuity at the interface. This fictitious discontinuity, useful to derive the erosion rate is not really present in the reality, where the interfaces are not so sharp. It is thus difficult to define exactly what and how to measure in order to calibrate (24) and (25).

Fortunately, using the uniform-flow condition as a reference (Zech et al., 2005) it is possible to find a good approximation of the two friction coefficients only by comparison, for one given situation, between results from the model with results from any uniform-flow formula (Manning for example), and any solid-transport formula (for instance Meyer-Peter–Müller).

In uniform-flow conditions, (22d) and (22e) simplify since the partial derivatives $\partial/\partial t=0$ and $\partial/\partial x=0$, except $\partial z_b/\partial x=-S_0$, S_0 being the bottom slope:

$$-g h_w\frac{\partial z_b}{\partial x}=g h_w S_0=\frac{\tau_w}{\rho_w} \quad (27)$$

$$-g h_s\frac{\partial z_b}{\partial x}=g h_s S_0=\frac{\tau_b}{\rho'_s}-\frac{\tau_w}{\rho'_s} \quad (28)$$

In uniform-flow conditions, the solid transport is in equilibrium, which means that neither erosion nor deposition occurs; thus (23) reduces to the condition,

$$\tau_b=\tau_s \quad (29)$$

If we now define the unit liquid and solid discharges,

$$q_w=u_w h_w \quad (30)$$

$$q_s=u_s h_s \quad (31)$$

Equations (24–31) form a set of 8 uniform-flow equations linking 12 parameters: S_0, q_w, q_s, h_w, h_s, u_w, u_s, τ_w, τ_s, τ_b, C_{fw} and C_{fs}. If 4 of them are known, the others may be deduced.

It is thus possible to calibrate the two friction coefficients, C_{fw} and C_{fs}.

For example, for a given discharge q_w in a channel of slope S_0 with mobile bed with a characteristic diameter d, the Manning roughness coefficient n may be evaluated from the Strickler formula,

$$K=\frac{1}{n}=\frac{26}{d^{1/6}} \quad (32)$$

and the water depth h_w may thus be deduced from the Manning uniform-flow relation:

$$q_w=\frac{1}{n}h_w^{5/3}S_0^{1/2} \quad (33)$$

If we now compute the solid discharge q_s from any empirical formula, we obtain the 4 parameters (two imposed: the discharge q_w and the slope S_0; two calculated: the water depth h_w, and the solid discharge q_s) required to compute the 8 others from (24–31) and among them the two coefficients to calibrate: C_{fw} and C_{fs}.

4.2.4 *Some typical results*

Once those coefficients are calibrated, one may investigate the behaviour of the two-layer model in other uniform-flow conditions by considering various combinations of q_w and S_0. For each combination, it is possible to compute q_s, h_w, h_s,u_w,u_s, τ_w, τ_s and τ_b.

Copyright © 2006 Taylor & Francis Group plc, London, UK

To analyse the two-layer model behaviour, an example was computed with the following data: a unit water discharge $q_w = 10\,\mathrm{m}^3/\mathrm{s/m}$ in a channel, whose bed is constituted of uniform grains of diameter d varying from 1 to 10 mm; the density $\rho_s/\rho_w = 2.65$, and the internal friction angle $\phi = 30°$.

For each diameter, the calibration of C_{fw} and C_{fs} was done for a bottom slope S_0 corresponding to the value of the Froude number $\mathbf{Fr} = 1$. The corresponding transport q_s and critical shear stress c are evaluated from Meyer-Peter-Müller formula.

Then, for each diameter a range of bottom slopes is explored. Using the set of equations (24–31), it is possible to compute the various parameters as a function of the Froude number defined as,

$$\mathbf{Fr} = \frac{u_w}{\sqrt{g\,h_w}} \tag{34}$$

Some results about the sediment layer depth h_s and velocity u_s are given in Figures 19 and 20. By increasing bottom slope S_0 (thus by increasing Froude numbers), the solid discharge q_s also increases, due for a part to the increase of sediment velocity u_s but mainly to the development in depth of the sediment layer.

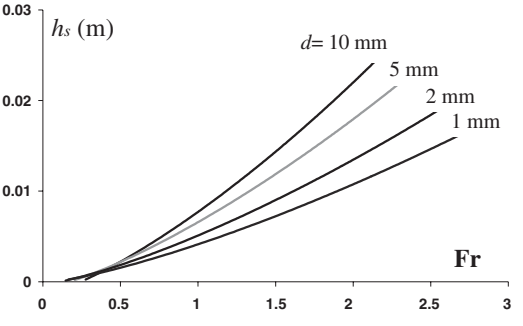

Figure 19. Uniform flow ($q_w = 10\,\mathrm{m}^3/\mathrm{s/m}$): relationship between sediment-layer depth and Froude number (two-layer model).

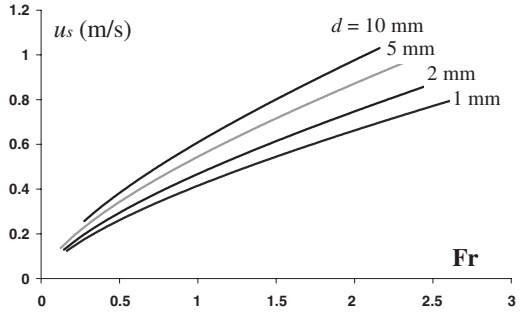

Figure 20. Uniform flow ($q_w = 10\,\mathrm{m}^3/\mathrm{s/m}$): relationship between sediment-layer velocity and Froude number (two-layer model).

4.3 *Applicability*

The two-layer model was tested against experimental data of dam-break induced wave.

Experiments were carried out at the *Université catholique de Louvain* (Spinewine, 2005, Spinewine and Zech, submitted). The set-up is sketched in Figure 21 with the following characteristic dimensions: an initial water layer of depth $h_{w,0} = 0.35$ m in the reservoir, and a fully saturated bed of thickness $h_{b,0} = 0.05$ m. The bed material consisted of cylindrical PVC pellets, with the following measured characteristics: $d = 3.92$ mm, $\rho_s = 1580\,\mathrm{kg/m}^3$, $\phi = 38°$, $C_b = 0.58$. The concentration of the moving layer was estimated from digital imaging measurements: $C_s = 0.22$.

Figure 22 shows a comparison between measurements (obtained from digital imaging techniques, indicated in the background of the figure) and computations by the two-layer model (thick black lines). Regarding the wave front, the agreement is excellent, as well for the arrival time as for the layer thickness. Near the initial position of the gate (abscissa 0), the early stage (Fig. 22a: $t = 0.25$ s) features a zone of fluidisation of the sediments, which corresponds to the sediments mobilised to fill the void created by the gate drop (the gate moves downwards). Of course, this particular phenomenon is not represented in the computation. In the next times (Fig. 22b: $t = 0.50$ s; Fig. 22c: $t = 0.75$ s), bed forms (antidunes-like) appear, probably initiated by the initial fall of the water mass. This phenomenon, involving significant vertical velocity components has no chance to be reproduced by a shallow-water model, where only horizontal velocities are taken into account.

The same experiments (initial water layer of depth $h_{w,0} = 0.35$ m in the reservoir, and fully saturated bed of thickness $h_{b,0} = 0.05$ m) were carried out, with a bed of sand with the following characteristics: $d = 1.82$ mm, $\rho_s = 2680\,\mathrm{kg/m}^3$, $\phi = 30°$, $C_b = 0.53$. The concentration of the moving layer was estimated from digital imaging: $C_s = 0.22$, the same as in the PVC-pellet case.

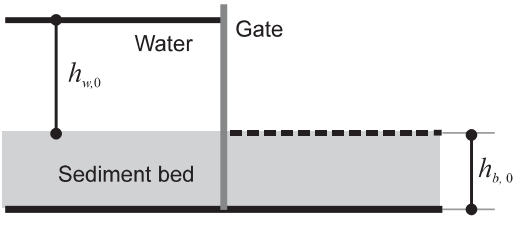

Figure 21. Scheme of the dam-break experiment (UCL).

Copyright © 2006 Taylor & Francis Group plc, London, UK

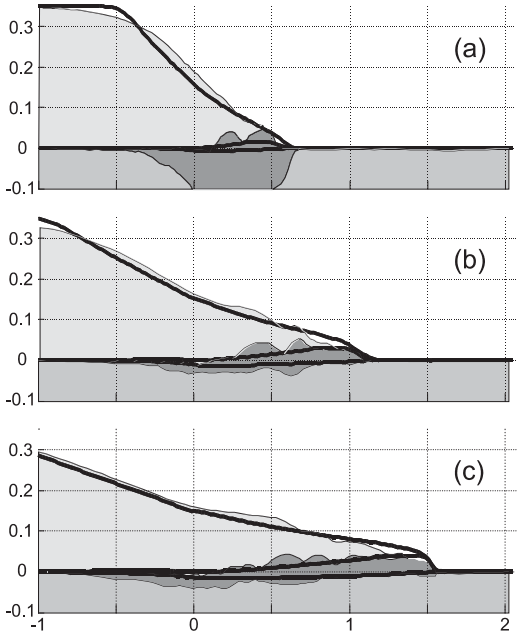

Figure 22. Dam break with PVC pellets: comparison between experiments and numerical results at times (a) $t = 0.25$ s, (b) $t = 0.50$ s and (c) $t = 0.75$ s. Grey-scale zones feature the measurements while the thick lines represent the model result. The dimensions are in metres.

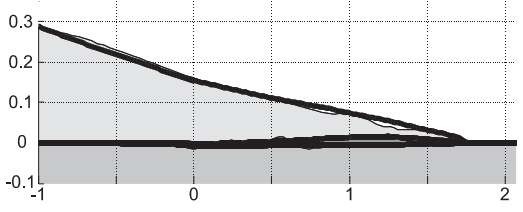

Figure 23. Dam break with sand: comparison between experiments and numerical results at time $t = 0.75$ s. Grey-scale zones feature the measurements while the thick lines represent the model result.

A comparison is presented in Figure 23, for the time $t = 0.75$ s. Due to the higher density, it appears that the erosion is less effective than in the former example. Thus, the thickness of mobilised material is significantly affected.

It is interesting to notice that the two calibrated parameters keep the same value for both experiments ($C_{fw} = 0.005$ and $C_{fs} = 0.04$).

Other experiments were carried out for testing the capacity of the two-layer model in representing the water and sediment movement following a dam-break event (Spinewine, 2005; Zech et al., submitted).

It is clear that all the problems are not solved with this kind of approach. It is clear also that this type of model is far from application in real-life situations, above all if the scale of the problem is large. But, featuring an excellent agreement with basic experiments, the model is really closer to the physics than the common ones and also less demanding in calibration efforts. In that sense, it is promising in terms of generalisation and interpretation.

5 CONCLUSIONS

Fluvial hydraulics, above all in modelling extreme events, is still in progress. Many important phenomena are commonly described in a too rough way. The model based on such rough descriptions may hide some aspects of the reality leading to a false perception of the risks.

All sciences present such a stage of rough description in their history. The danger for fluvial engineering is that so much has yet been designed and realised that inclusion of new knowledge could open an endless and discouraging review of past decisions.

As a consequence, the threat for fluvial science is to progress just for itself, progressively loosing the contact with the practice and the care for applicability.

The few examples developed here show that a median way is possible. Simple models, based on accurate physical description and on basic scale experiments, may seduce the practitioner, as far as those models take care of their concerns.

With such a spirit, fluvial hydraulics remains one of the most exciting fields of research, at the crossing between new knowledge to discover and high responsibility to exert in well being and safety of people.

Recent training of the lower Rhine River to increase Inland Water Transport potentials: A mix of permanent and recurrent measures

ABSTRACT: Inland navigation is very important for national and international transport to and from the Netherlands. River management of the main Dutch Rhine branch, the Waal River, aims at improving navigation conditions, at the same time taking into account other, sometimes conflicting interests. Therefore integrated approaches are demanded to implement improvement measures. This paper focuses on the river improvement measures, executed in the Waal River for the benefit of navigation since 1995. The impact of executed and planned measures for navigation on the morphology of the river is discussed. New in the approach since 1995 is that in addition to (essentially traditional) permanent bend improvement measures, recurrent measures like (systematic) dredging and sediment feeding schemes are becoming increasingly important. This signals a change in policy of the Dutch Public Works Department, which traditionally preferred permanent fixed solutions. Special emphasis is given to the specific in-depth field and mathematical modelling studies, which were carried out to understand the morphological processes in this engineered river, the interaction between structures and the river and the relevant time and spatial scales of effects and impacts of the recurrent methods. The need for a master plan taking into account the autonomic trends to facilitate a sustainable development of the river system is underlined.

1 INTRODUCTION

In the past two centuries the Rhine River has been heavily regulated for the benefit of flood protection and navigation. The Rhine basin has profited enormously from these efforts: the area is one of the world's most prosperous regions. For the Netherlands and Germany Inland Water Transport (IWT) is a very important mode of transport. More than 50% of goods arriving from overseas in Rotterdam seaport are transported to Germany by ship over the Rhine River. The implemented regulation measures, however, caused severe riverbed degradation by the normalization and narrowing of the river channel and the large reduction of natural flooding area (Havinga and Smits 2000). Moreover, bank protection works and the cultivation of the floodplains for cattle breeding and agriculture reduced the bio-diversity in the river (Smits et al 2000). In the last decades, the Rhine bordering governments wish to improve the situation, i.e. to increase bio-diversity, to return some of the river's original resilience and to maintain or even increase the level of flood protection. At the same time the conditions for inland navigation must improve, taking into account an integrated approach to river management. To this end the Dutch Ministry of Transport, Public Works and Water Management, Directorate General Rijkswaterstaat (RWS) presented the Waal project in the mid 1990-ies (Rijkswaterstaat, 1995). New in the approach since 1995 is that in addition to (essentially traditional) permanent bend improvement measures, recurrent measures like (systematic) dredging and sediment feeding schemes are increasingly playing a role. In this paper recently executed measures within the framework of the Waal project are described and results are evaluated.

Nowadays proper river management also takes into account sustainability of measures, beside their effectiveness. In the Netherlands large river improvement schemes are prepared to maintain the level of flood protection (project Room for the River) and to increase the fairway width and depth (project Sustainable

Fairway Rhine delta). To this end reliable predictions of the (morphologic) behaviour of the river system are required to facilitate the necessary decision-making. In view of the character of this paper (an "engineering case study") an overview is presented of the Waal project. Many detailed studies were carried out as part of this Waal project. In a number of boxes the studies, which are of specific interest for fluvial hydraulics, are presented.

2 WAAL RIVER CHARACTERISTICS

2.1 *General lay-out*

The general layout of the Rhine River in The Netherlands is presented in Figure 1. The river enters The Netherlands from Germany. Slightly downstream it bifurcates into two channels, the Waal River and the Pannerdens Kanaal. The latter channel bifurcates again into the IJssel River and the Lower Rhine-Lek River at the city of Arnhem (not named in Figure 1) near Driel. The Waal River is the most important Rhine branch, carrying about 2/3 of the Rhine discharge entering from Germany. This distributary is also the main fairway between Rotterdam (one of the largest sea ports of the world) and the German hinterland. The IJssel is the smallest of the three distributaries (carries about 1/9 of the Rhine flows), but it is important as fairway to the eastern and northern part of The Netherlands.

The two bifurcations in the Netherlands are called Pannerdense Kop and IJsselkop. They are important river features as they determine the flow to the different distributaries. Much effort has been spent to stabilize these bifurcations with their specific flow and sediment distributions. More information on in particular the Pannerdense Kop is presented later in this paper.

The Waal River (see Figure 1) is characterised by some sharp bends between the Pannerdense Kop and Nijmegen and another one downstream of Tiel (here referred to as the bend St. Andries). The reach between Nijmegen and St. Andries is referred to in this paper as the Middle Waal.

2.2 *Waal river data*

The main characteristics of the Waal River are:

- slope about 10^{-4} (0.1 m/km)
- mean depth: 5 m
- width low water bed: 260 m
- discharges: low discharge $Q_{5\%} = 800\,m^3/s$; mean discharge $Q_{50\%} = 1{,}600\,m^3/s$; design flood discharge $Q_{0.08\%} = 10{,}000\,m^3/s$
- bed material composition: $D_{10} = 0.4$ mm; $D_{50} = 1.5$ mm; $D_{90} = 6$ mm
- yearly sediment load $S_{year} = 500{,}000\,m^3$.

Figure 2 shows a schematised cross-section of the Waal River with the following elements: a low-flow channel which is used as fairway, groynes extending into the flow reducing the width of the river and stabilizing the main channel, a floodplain on both sides of the river and in total several kilometres wide, summer dikes to prevent flooding during low summer floods and a main levee designed to withstand the design flood (with a probability of 8% in 100 years).

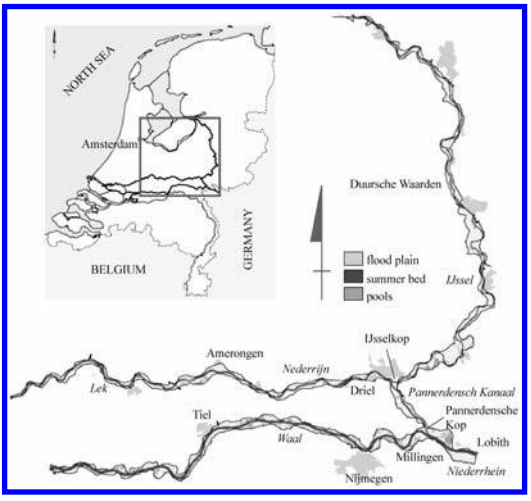

Figure 1. The Rhine River in The Netherlands: two bifurcations, three distributaries of which the Waal River is the most important for inland navigation.

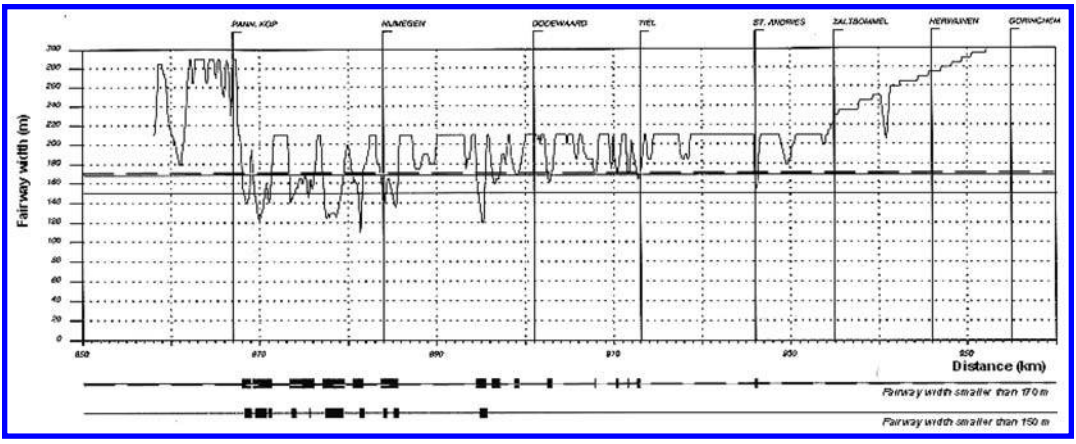

Figure 4. Nautical bottlenecks in the Waal River for 150 and 170 m wide channel, 2.5 m below OLR (1995, flow from left to right).

Table 1. Conflicting interests and different conditions they are posing to the Waal River.

Interest	Preferred geometry	Defences	Preferred hydrological conditions
Safety against flooding	Summer dikes Winter dikes Groynes (to prevent ice jams)	"Fixed" constructions Rock	Guarding maximum design water levels and discharge distributions
Navigation	Summer dikes Deep minor bed (groynes)	"Fixed" constructions Rock	Minimum of 2.8 m water depth: total discharge through minor bed
Agriculture (cattle breeding)	Summer dikes Polder dikes Grass No natural vegetation	"Fixed" constructions	No inundation (at least not in periods that the cattle is in the floodplains)
Ecology	No summer dikes Secondary channels Natural vegetation Islands	No constructions	Frequent inundation

characterize the yearly hydrograph during spring and fall and low-flow periods during the summer with occasional small floods. The summer dikes prevent flooding during summer.

2.3 *Sailing conditions in 1995*

Figure 4 shows the in 1995 present bottle-necks in the Waal River applying the existing fairway dimensions of a navigation channel, which is 150 m wide and 2.5 m deep, referring to the reference of the Agreed Low Water level (OLR in Dutch), which is related to the $Q_{5\%}$ discharge that is exceeded by 95% of the daily discharges. The figure also shows the increase of the number of bottle-necks when the width is increased to 170 m.

2.4 *Conflict of interests*

Several functions of the Rhine branches can be recognized. The primary function of the river is the safe discharge of water, sediment and ice. It is assured by the Dutch system of minor beds and floodplains with elements like summer dikes, winter dikes and groynes. Added secondary functions are navigation, agriculture, sand and gravel mining, recreation and ecology, the latter elements becoming increasingly important in recent years. However, these different functions pose different and often conflicting demands upon the river system (see Table 1). The "traditional" functions, namely safety against flooding, navigation and agriculture go together quite well, considering the nature of required river works. These functions do not pose large policy problems to river administration, apart from optimisation questions (e.g. the Lower Rhine canalisation). However, the ecology function is quite a different matter, which appears to be difficult to integrate into river administration.

Together with the concern to increase ecological values, also emphasis is laid upon using river measures that ensure the resilience of the Rhine river system

Copyright © 2006 Taylor & Francis Group plc, London, UK

(Havinga and Smits 2000). River measures should be designed in such a way that they cause only local effects and do not affect the entire system. This condition turns out to be very decisive in the development of river improvement schemes.

3 RHINE AND WAAL FAIRWAY IMPROVEMENT IN HISTORICAL PERSPECTIVE

3.1 *Introduction*

Since many centuries mankind has been working in and along the Rhine River to improve living conditions. This was done in The Netherlands as well, where the first river regulation works consisted of local dikes for flood protection. Groynes and longitudinal dikes along the riverbed were built, to prevent erosion of the banks and to catch sediment to create farmland in the floodplain. Later also secondary channels were closed and river bends were cut off. These measures were intended to increase and maintain flow velocities in the main channel, thus preventing the formation of sandbanks. In winter periods, these shallows were prone to the development of ice jams at locations where converging flow occurred. These ice jams caused backwaters, which created a serious threat to the dikes sometimes leading, to overflow and breaches (Figure 5).

The river regulation triggered higher velocities in the low water bed, which induced larger water depths and lower slopes, resulting in lower bed levels. Because of this it turned out that these measures had also been beneficial for navigation, because they had deepened the main channel. In order to optimise the navigation channel so-called "width normalisations" were carried out. Width normalisation means that the low water bed is limited to one main channel with a constant (normal) width. Groynes were constructed at regular intervals, which confined the low water bed into a narrower channel and kept the water flow away from the erodible bank. In the 19th and 20th centuries, after many uncoordinated regulations, two large-scale width normalisations were carried out in the Waal River (Figure 6). Until recently the agreed fairway dimensions of the Waal River are 150 m wide and 2.5 m during OLR. If this water depth was not met under these conditions, Public Works Department would carry out local dredging.

3.2 *Rhine bifurcations*

In addition to the regulation works carried out in the different distributaries of the Rhine River, in the past there was also a lot of interest and works carried out in relation to the flow distribution over the three branches. Box 1 provides some details on the bifurcations, the works carried out in the past, and the studies carried

Figure 5. Dike breach by ice dam.

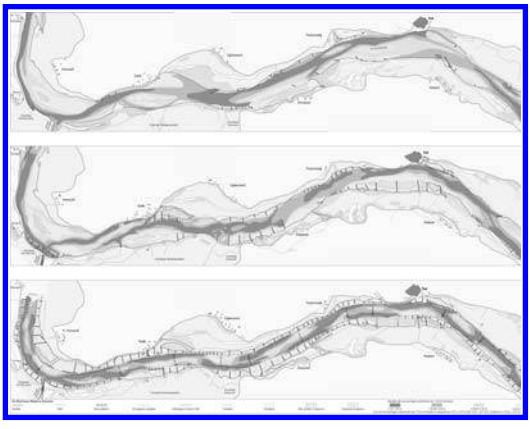

Figure 6. Normalisation of Waal River near Tiel in the 19th century (river planforms from 1831–1835, 1872–1873 and 1888–1989). Note the increasing number of groynes and the decrease of the width of the Waal River.

out recently to better understand the functioning of these bifucations. In principle the distribution could be changed as well, to better serve the different interests, but this can only be done when there is a sufficient undertanding of the consequences. Hence at present many studies are carried out to obtain such a better insight. These include field studies and numerical models with different levels of complexity regarding graded sediment, sorting, and roughness and bed forms. For more details see Sloff et al.(2003).

3.3 *20th century proposals for Waal bend cut-offs*

Between 1960 and 1980, many plans have been devised to cut off the last remaining major bends in the Waal River near Nijmegen and near St. Andries (see Figure 1 and Figure B2 below). Many studies were carried out, both to optimise the layout of the cut-offs, but also the impact of the cut-offs on the flow distribution at Pannerdense Kop bifurcation. Cutting off a bend will lower the upstream stages and this will cause

Box 1. History of the two Rhine bifurcations in The Netherlands

The two bifurcations of the Rhine in the Netherlands are Pannerdense Kop and IJsselkop (see Figure 1). These bifurcations are important river features as they determine the flow to the different distributaries. In the past much effort has been spent to stabilize these bifurcations and the flow and sediment distributions, and many studies have been carried out to better understand their functioning, in the field, in scale models and with mathematical models.

The distribution of Rhine water over the different Dutch Rhine branches (today at the village of Pannerden and the city of Arnhem) caused many problems in the past. Especially the IJssel River showed a strong tendency to aggrade, causing flooding along this river and along the Waal River. The shape of the bifurcations contributed a lot to the unfavourable discharge distributions (see Figure B1a).

Also the waterborne transport to the north suffered greatly from the poor water conveyance of the Nederrijn and IJssel Rivers. In the 17th century there was a lot of (commercial) competition between cities and provinces situated along the Waal en IJssel River. So, when for the military defense of the provinces of Holland (the Spanish armies could cross the northern rivers by foot) a channel was dug between the Nederrijn River and the upstream part of the Waal River, the cities along the Waal River for a number of years obstructed the connection with the Nederrijn River. Finally, after many meetings it was agreed to make an open waterway between the two rivers (Pannerdensch Kanaal), see also Van der Ven, 1976. The shortcut moved the bifurcation further downstream (Figure B1b).

Though this considerably improved the conveyance of the Nederrijn, problems of aggradation and floodings persisted. It took another 75 years before plans were adopted to improve the mouth of the Pannerdens Kanaal. To enable the building of a new bifurcation dam, use was made of a shoal that appeared in front of the bifurcation after a winter with a lot of ice. Also, a new river mouth of the IJssel River had been built (by digging a new canal through the Pley foreland). From the end of the 18th century the discharge distribution had been stabilized, which gave start to the extensive general river training of the Dutch Rhine branches. Leading for the design of river works became the politically agreed waterdivision (1745), according to which the Waal River would convey 2/3^{d} of the total Rhine discharge, and the IJssel River 1/9th. Since then these ratio's have not been changed, so measures for flood defense and navigation have been designed accordingly.

Presently there is a renewed interest in the functioning of the bifurcations. The construction of three barrages in the Nederrijn-Lek and other developments might have had an impact on flow and discharge distribution. Two scale models of the bifurcations were operated in the 1960-ies and 1970-ies. The model study of the IJsselkop was carried out with uniform sediment, but the later model for the Pannerdense Kop was done with graded sediment. Some information on the Pannerdense Kop model is provided in Sloff et al (2003). Recently also attempts have been made to model the Pannerdense Kop with numerical models as well. In the 1980-ies it was found that a 2D

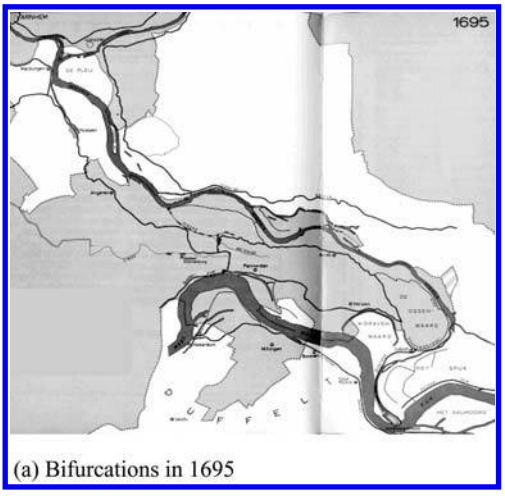

Figure B1. Changes in the two main bifurcations of the Rhine River in The Netherlands.

(depth averaged) model with uniform sediment and a spatially constant Chezy roughness (for a dominant Rhine discharge of 2,400 m^3/s) resulted in a fair reproduction of bed topography and the flow and sediment distribution at the bifurcation.

More recent simulations with Delft3D graded in its depth-averaged mode, but applying recent field data on the bed composition of the bifurcation resulted in poorer results. This model allows for longitudinal and lateral sorting and was expected to yield even better results. Only by including a spatially varying Chezy roughness coefficient, better simulations could be found (Sloff et al, 2003). This suggests that there is a strong interaction between bed-composition patterns, roughness and bed topography. A topic urgently needing more study.

Box 2. Scale model M1278 Waal bend Nijmegen – in retrospect a turning point

In the 1980s it was planned to cut off the two bends upstream of Nijmegen (see Figure B2). The purpose of this measure was to eliminate a number of sharp bends downstream of the Pannerdense Kop bifurcation, and in particular to increase the bend radius of the bend near Nijmegen. This would have had a very beneficial effect on the available draught (=depth available for ships). Although finally these cut-offs were not carried out, in retrospect this model study can be considered to be a turning point in the understanding of 2D river morphology and the use of models in The Netherlands.

To study this possible measure a physical model was constructed which was characterized by:

- distortion 2.5 (horizontal scale 100, vertical scale 40) in line with the roughness condition;
- sand as bed material (particle size scale 4);
- slope about 5 times larger than required when considering only the distortion;
- deviation from the Froude condition (Froude scale 0.4, Froude number model 0.4);
- ideal velocity scale (implying that the Shields number was the same in model and prototype);
- bed load dominant.

For more details on the scaling procedure used see Struiksma (1987). Because the client (RWS = Public Works Department, The Netherlands) was not satisfied with the results of the calibration, WL/Delft Hydraulics was requested to do an investigation into scale effects in mobile bed river models. In the resulting report it is concluded for the first time that in a distorted model (common for mobile bed models) the beginning of a bend is always subject to serious scale effects.

In the same period and by the same researcher and others (as part of a larger group united in the so-called TOW Rivers – long lasting research funded by RWS) extensive research was carried out on

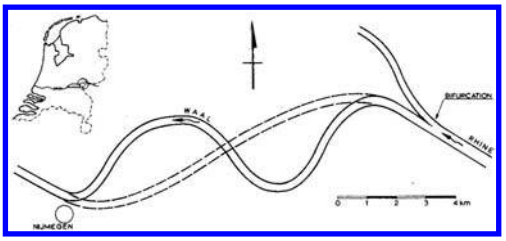

Figure B2. Proposed cut-offs Waal bends near Nijmegen.

morphological phenomena in bends, which culminated in the prize-winning paper by Struiksma et al (1985), in which for the first time the importance of redistribution processes in the beginning of bends was explained and quantified. Using these results Struiksma (1987) managed to fully understand and explain the substantial scale effects in the simulation of bends in mobile bed models with dominant bed load. Based on the understanding on phenomena in bends WL/Delft Hydraulics developed 2D depth averaged morphological models with spiral flow added to arrive at a quasi 3D flow pattern (Struiksma, 1985), which nowadays is included in the Delft3D modelling suite.

In retrospect the study in scale effects in the mobile models turned out to be the transition from the exclusive use of the scale models for 2D morphological problems to the present conditions where most of these studies are done with mathematical models. In these models it is nowadays also possible to consider suspended sediment and the effect of gradation and sorting. Interestingly a similar model was used recently to study scale effects in a scale model with dominant suspended load (Haque et al, 2006), which is a good indication of the changing role of scale and mathematical models in investigations for river engineering projects.

that more flow will enter the Waal River. Eventually none of these plans have been executed, because of an increased awareness of ecological interests and the bad economic situation in the late nineteen-seventies. Box 2 provides more information on this issue.

3.4 *Necessary increased use of IWT potentials*

When it became clear that the anticipated bend cut-off could no longer play part in regulation schemes, bend improvement measures were designed. In 1982 the removal of a bridge pier centred in the fairway of the river bend at Nijmegen gave a start to a general improvement of the Waal River. The admission in 1986 (Anonymous, 1988) of 6-barge push-tows underlined the necessity to increase the fairway dimensions. This triggered a study which was started in the late 1980-ies and which resulted in the so-called Waal project, which is the topic of the remaining part of this paper.

4 OVERVIEW OF RECENT IMPROVEMENTS: THE WAAL PROJECT

In 1994 RWS proposed up the so-called Waal programme, a master plan that combined several different projects to improve navigation conditions on the Waal River (bend improvement, increased fairway

Copyright © 2006 Taylor & Francis Group plc, London, UK

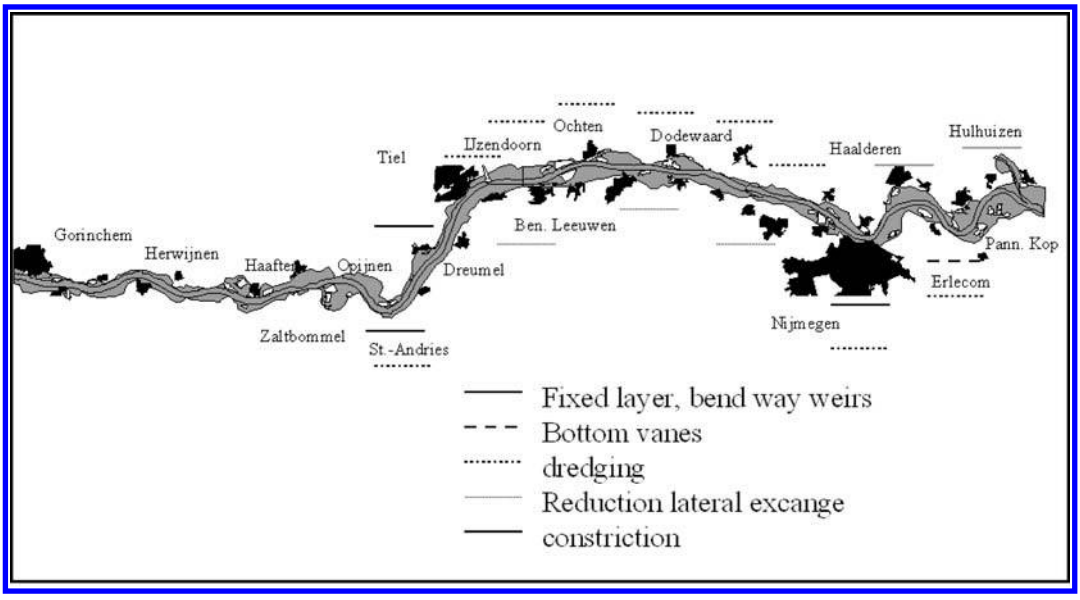

Figure 7. Overview of measures proposed as part of the Waal Project (refugee harbours not indicated).

dimensions, refugee harbours and extended radar coverage). In a visionary report the possibilities to improve the conditions for IWT on the Dutch Waal River were evaluated (Rijkswaterstaat, 1993). Now it was decided to upgrade the fairway substantially. It was also decided to try to stop the ongoing degradation of the bed level, caused by river regulation measures (dikes, groynes, bend cutoffs) that inflicted smaller slopes and larger depth's. This scouring of the bed will 'autonomously' go on for at least another 100 years (Baur, 2003).

The objectives of the Waal programme can be summarized as follows:

- Fairway dimensions of 170 m × 2,80 m available at OLR starting in the year 2004.
- Only apply measures, which do not accelerate the autonomous degradation of the river bed, which in the 1990-ies and also currently amounts to about one cm/year.
- Obtain surplus values for the river's ecosystem by integrating floodplain rehabilitation plans.

Furthermore the different technical solutions had to respect a number of boundary conditions regarding the discharge distributions at bifurcations, besides low water levels and peak flow levels in order to safeguard levels of flood protection and navigation.

Evaluation factors comprised effectiveness (width and depth increase), costs, backwater effects and ecological impact. Any distant response (large scale system effects in place and time) should be prevented.

Evaluation of the solutions led to the application of local river measures (Havinga 1996). The time horizon of the Waal programme was 2010; a study of the conditions beyond 2010 was only recently started (see Chapter 7).

Quite essential in the approach taken is that the engineering measures proposed are *a combination of permanent structures and recurrent measures*. Moreover, nautical bottlenecks that cannot be mitigated by engineering measures are tackled with traffic measures: regulation and traffic control. Also a number of so-called refugee harbours (mutual sailing distance 20 km) have been constructed.

In the original Waal project plan the following technical measures were envisaged (see also Figure 7):

(a) *Permanent measures* (from upstream to downstream)
- Bottom vanes or bendway weirs in the bends upstream of Nijmegen.
- For the reach between Nijmegen and St Andries stabilization of discharge ratio between low water bed and floodplain during peak flows plus width constriction.
- Bottom vanes or bendway weirs in the bend of St. Andries.

(b) *Recurrent measures*
- Dredging in the bend of Nijmegen (fixed layer already constructed in 1986).
- Large-scale dredging in the Middle Waal.
- Dredging in the bend of Opijnen.

Copyright © 2006 Taylor & Francis Group plc, London, UK

In the end certain measures have not (yet) been carried out for different reasons: expected low effectiveness and reduced confidence in a proposed solution (bottom vanes), postponement (stabilizing discharge distribution between low water bed and floodplain plus local width constriction) and awaiting possible integration with measures within the so-called Room for the River project. Upstream of Nijmegen only in the bend Erlecom bendway weirs were placed; the improvement method for the other bends upstream of Nijmegen has still to be decided upon. At present additional dredging is required in all remaining bottlenecks.

5 PERMANENT BEND IMPROVEMENTS

5.1 *General*

In 1990 new research on improvement of river bends was initiated, leaving aside the cut-off option for ecological and landscape reasons and for the possible impact of bend cut-offs on the discharge distribution. This implied that apart from dredging the fairway width in bends could only be increased by measures limited to the low water bed, like fixed layers, bendway weirs (submerged groynes) and bottom vanes (Rijkswaterstaat, 1991).

By now much experience has been gained on measures in bends: fixed layers (Figure 8) were applied in the bends Nijmegen (1985) and St.-Andries (1998), and bendway weirs (Figure 9) were applied in the bend Erlecom (1996).

A fixed layer in the outer bend consists of a partly filled up outer bend with sand and gravel, protected by a layer of riprap. This measure raises the bed level, which initially decreases the overall flow area. The rough surface of the stones increases the hydraulic roughness in the outer bend. Both effects cause water velocities and sediment transport in the inner bend to increase, degrading the riverbed and subsequently increasing the overall flow area again.

Bendway weirs in the outer bend are in fact submerged groynes, constructed with sand, geo-textile and riprap, reducing the spiral flow near the riverbed. They show a slight inclination upstream in order to decrease the spiral flow even further and to direct the sediment transport near the bed to the outer bend. In this way the bed in the outer bend is aggraded and the bed in the inner bend is degraded, yielding a larger fairway width. The resistance to flow of the bendway weirs also redirects the flow to the inner bend, which adds to the eroding effect.

5.2 *Investigations carried out during design phase*

In the design phase the hydraulic and morphological effects of the bend measures were investigated

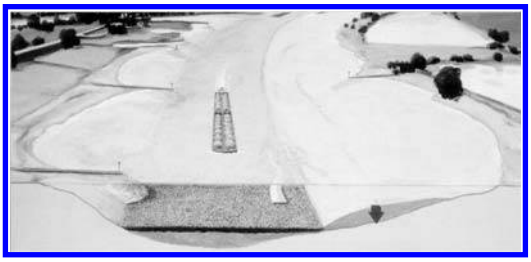

Figure 8. Fixed layer (C. Nuyten).

Figure 9. Bendway weirs (C. Nuyten).

in various ways by WL|Delft Hydraulics. The fixed layer at Nijmegen was designed between 1980 and 1985 using a physical scale model and a numerical 2-D morphological model (SEDIBO, a predecessor of Delft3D). The second fixed layer at St.-Andries was designed using only a numerical morphological 2-D model (RIVCOM, another predecessor of Delft3D), flagging the experience obtained and the increased confidence in numerical models. The bendway weirs have been investigated using a physical scale model and a 2-D morphological model (RIVCOM).

The models have always been used in a comparative way. First a reference situation was calibrated, using prototype data and (if available) scale model data. Cross-sectional velocities and depth contours are the main calibration parameters. Next the new bend configuration is implemented in the model and the relative improvement is measured or simulated. This is interpreted towards improved sailing conditions. The simulated results were so promising that the proposed measures were implemented.

5.3 *Construction*

The fixed layer of St. Andries was built using a rock coverage, consisting of stones with specific specifications, to avoid the use of a separate filter layer. During construction a sandpit was maintained upstream, to avoid immediate coverage of the fixed layer, which would endanger a correct measurement (by multibeam soundings) of the top level of this layer. To obtain

Copyright © 2006 Taylor & Francis Group plc, London, UK

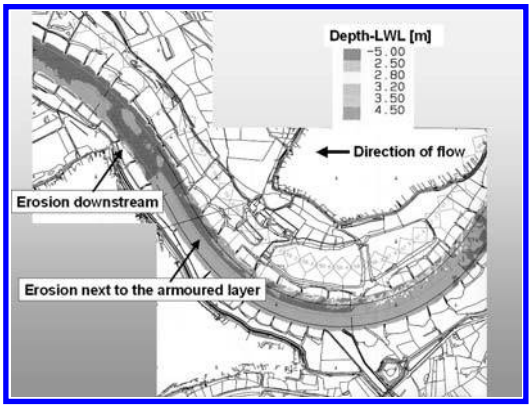

Figure 10. Bed topography in bend St.-Andries after construction of fixed layer (note deep scour hole downstream of the fixed layer and the shoal in the inner bend).

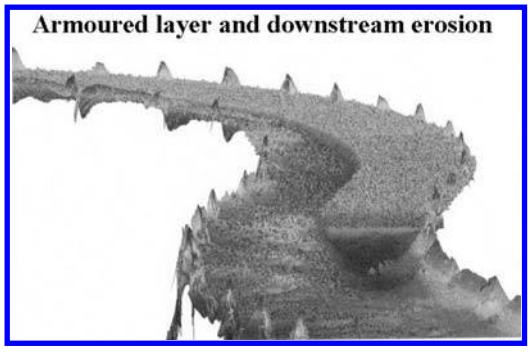

Figure 11. 3D image of fixed layer in bend St.-Andries on the basis of multi-beam soundings (looking upstream).

reliable sounding data, for the first time a multi-beam sounding system was used extensively. This instrument together with GIS techniques offered the possibility to monitor closely the dumping process of sand, gravel and stone. Also the morphologic changes could be followed in detail. Figure 10 shows the final bed topography and Figure 11 shows a 3-D view of the lower end of the construction in the bend St.-Andries.

5.4 *Effect of measures*

In the bend of Nijmegen the increase of the fairway width amounts to about 50 m (with an available depth of 2,50 m at $Q_{5\%}$), while the applied 2-D morphological model had predicted 35 m. The width increase in the bend of St. Andries is about 45 m, while 35 m had been predicted. The fairway width increase in the bend near Erlecom (bendway weirs) appears to be 25 m, which corresponds to what had been predicted. Furthermore it can be noted that the width

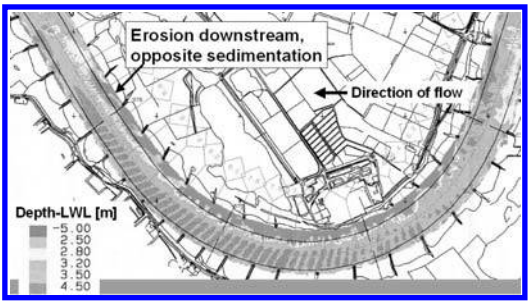

Figure 12. Bendway weirs in bend Erlecom.

changes occurred rather quickly: about 80% of the cross-sectional changes took place within 2 years.

Compared to the impact of a fixed layer in the outer bend the impact of the bendway weirs (in bend near Erlecom) on the navigation width is less, as a consequence the downstream effects are also less (see Figure 12 showing an erosion hole of approximately 2 m downstream of the bendway weirs, and no severe shoaling along the inner bend).

All computations used for the design of fixed layers show severe erosion immediately downstream of the fixed layer and shoaling in the inner bend on the opposite side. However, the prototype data show only about half of the predicted erosion and shoaling (see the Figures 10 and 11). Still this creates a problem and a special study was carried out to understand the cause of the shoaling and to investigate possible mitigating measures (see Box 3).

5.5 *Far field impact of bend measures*

The construction of fixed layers or bendway weirs also has an impact on the bed degradation on a larger spatial and time scale. Figure 13 shows the (moving averaged) bed level development (longitudinal profile) of the Waal River using yearly soundings (cross-sections every 125 m) for the past 20-year period. The three lines refer to the years 1979, 1989 and 1999. The autonomous bed level degradation of about 0.5 m in 20 years clearly can be observed. The armoured layer of Nijmegen, constructed in 1985 locally fixes the bed level, and it causes degradation, which travels downstream. No upstream effect can be deducted. Ignoring the autonomous degradation the conclusion can be drawn that the erosion pit travels downstream with an average rate of 1,5 km/year, which equals the theoretical celerity of a disturbance in the bed (c_b).

Compared to the impact of a fixed layer in the outer bend the impact of bendway weirs on navigation width is less. As a consequence, the downstream impacts are also less. The main concern with fixed layers and bendway weirs is the fact that they create hard points in the river, which with continuing degradation will become a bottleneck themselves in due time.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Box 3. Fixed layer in outer bend near St. Andries and its near-field morphological effect

In the bend near St. Andries a fixed layer in the outer bend was implemented in the year 1998. The purpose of this fixed layer was to fill up the outer bend, which subsequently would lead to erosion of the pronounced point bar in the inner bend. This indeed did occur, resulting in improved sailing conditions in this bend. However, after a few years also some negative morphological impacts were observed. Firstly the unprotected inner bend eroded seriously, endangering the stability of the fixed layer in lateral direction. Secondly downstream of the fixed layer an erosion pit (depth approx. 2,5 m) occurred, threatening the stability of the downstream end of the fixed layer. Finally a shoal developed at the same location but along the inner bend (with a height approx. 1 m). This shoal at St.-Andries has regularly to be removed by dredging. Figure 10 shows an image of the riverbed in the bends at St. Andries, made by multi-beam soundings. This map shows the downstream effects clearly. A study was carried out (van Reen, 2000) to understand the cause of these morphological changes and to propose remedial measures.

The key for understanding these morphological changes is given in Figure B3.1. The dense coverage of sounding data also enabled a good view of the sediment transport over the fixed layer. Figure B3.1 gives an impression of the sediment coverage of this fixed layer, using standard deviations of measured depths. The larger values of the standard deviation indicate uncovered rock, while the smaller values correspond to a fixed layer where the area between the stones is filled in by sediment, which is transported over the fixed layer. From the figure it can be deduced that the sediment on the fixed layer is swept towards the inner bend. This is explained by the effect of the spiral flow, which – because of the fixed layer being horizontal – is not compensated by the lateral slope of the bed, as is the case in alluvial bends. The direction of the near bed flow clearly can be deducted from the pattern. The locations with sediment transport were qualitatively checked using a bed load transport sampler (Wilbers, 2000).

The consequence of the sediment transport pattern, as shown in Figure B3.1, was studied by van Reen (2000) and later by Sloff et al (2006). For axi-symmetric conditions all sediment, which in the reach upstream of the bend is transported over the full width, now is transported in the narrow alluvial strip next to the fixed layer. Applying the improved Lane's balance (Klaassen, 1995) it could be shown that for the conditions in the Waal River near St. Andries the narrow alluvial reach will respond with an increased depth. This explains the deep trough next to the fixed layer, which can be observed in the Figures 10 and 11. Van Reen (2000) developed an analytical model to determine the depth next to such fixed layers as a function of the lateral extent and relative level of the fixed layer. A similar model was later verified by Sloff et al (2006) using field and flume data.

Also the erosion downstream of the fixed layer and the shoaling at the same location but in the inner bend could be explained by the shift of the sediment transport towards the inner bend. Where the fixed layer ends, the reach along the outer bend has a large sediment transport capacity but no sediment is supplied from upstream. Hence this sediment is picked up from the riverbed and causes the serious erosion. The flow in the inner bend is attracted by this deeper part and this causes re-distribution of the flow

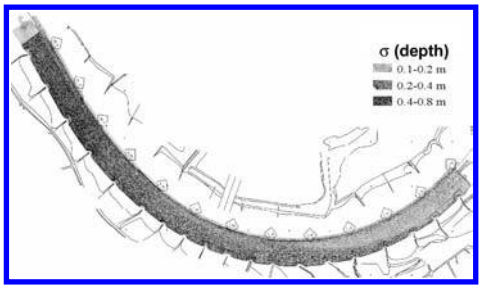

Figure B3.1 Standard deviation (σ) of bed levels of the fixed layer, showing the sediment coverage (large standard deviation = no sediment).

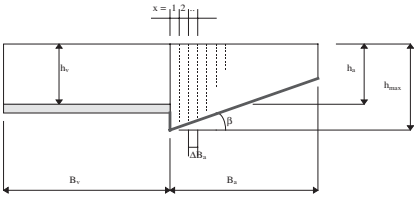

Figure B3.2 Schematised cross-section for axisymmetric conditions with fixed layer in outer bend (van Reen, 2000).

downstream of the termination of the fixed layer. As a consequence the transport capacity along the inner bend reduces and sand is deposited forming a shoal. The re-distribution of flow and sediment is governed by the same process as is dominant in the beginning of a bend. Also the same longitudinal scales (λ_w, λ_s, L_p and L_D), which were introduced by Struiksma et al (1985) are relevant here. Van Reen (2000) applied Delft3D in the depth averaged and quasi-3D mode (with spiral flow added after the flow pattern has been simulated) to show that indeed the re-distribution of flow and sediment is causing the morphological phenomena observed.

In a further step in his study Van Reen (2000) explored possibilities to prevent in particular the shoaling in the inner bend downstream of where the fixed layer terminates. It was shown that one possibility is to extend the fixed layer to the point bar in the next opposite bend downstream. Here the sediment distribution downstream of the fixed layer is in correspondence with the sediment distribution in an alluvial bend. By selecting the termination point of the fixed layer in an intelligent way it is even possible to improve the sailing conditions in this downstream bend as well. It should be mentioned here that initially it was indeed planned to extend the fixed layer in downstream direction, but budgetary problems forced the fixed layer to terminate earlier.

Another option is to try to force the sediment transported in the inner bend to the outer bend. This could be done by bottom vanes, but these may affect the navigability, as they extend into the flow. It could be considered to make the upper part of the bottom vanes flexible, but until now no acceptable solutions have been found. As an alternative the possibility of applying vortex excluders is presently being studied.

6 DREDGING IN THE MIDDLE WAAL RIVER

6.1 *Introduction*

As indicated in Chapter 4 on the Waal programme dredging has been considered, but as a tool that should be used in addition to other constructive measures. Only in the straightened Middle Waal Nijmegen – Tiel – St.-Andries (see Figure 7) systematic dredging has been developed as an alternative for additional normalisation works.

To maintain a fairway for navigation in alluvial rivers dredging might be needed. In principle dredging operations should be planned and executed considering maximal flexibility, because the moment of dredging is not known far in advance. Actual and historical discharges determine bed levels and bedforms, which may hamper navigation. Some forecasting can be done, using the trend of the actual discharges, mean hydrographs and forecasting techniques for water discharge and morphology (see also Section 6.5). As the limitations of the fairway dimensions are of a dynamic nature, also dredging must be dynamic. Dynamic bed level variations will always be present in a river, even in the case that the low water bed width is restricted to the required fairway width. Moreover, every geometrical discontinuity – both in the channel as well as in the floodplain – in principle will generate erosion or sedimentation waves, which will propagate through the river system (Van Vuren 2005). To complicate things even more, also the relation between hydraulic conditions and bedforms is not unique, leading to surprises concerning the Least Available Depth (LAD's) in a reach.

For river management dredging is a measure, which by its nature is recurrent, and that has to be weighed against more structural measures, like normalisation (building groynes, longitudinal dams) and bend regulation measures. Modifying the dimensions of existing groynes and local summer dikes influences the riverbed morphology and consequently the required amounts to be dredged. Dredging can be a good option in situations where the execution of several river training measures is not certain, where the impact of (e.g. Room for the River) measures are not well known, or where funding is too limited to allow for expensive structural measures. However, once the choice for dredging as a systematic recurrent measure has been made, long term future funding is required which may be a problem. A year with reduced budget means a year with hampered navigation. This may have large consequences if transport companies turn to other modes of transport (truck, rail) and do not return to IWT as their preferred mode of transport.

6.2 *Pilot projects*

To gain more experience on dredging on the Middle Waal, several dredging projects have been executed in the reach between Nijmegen and Zaltbommel (see Figure 7) in the period 1998–2002. The aim of these projects was twofold (Groen, 2002 and 2004): (i) maintaining a fairway with dimensions of (at least) 2,5 m depth and 150 m wide at OLR and (ii) gathering experience with systematic dredging as a means to enlarge the fairway. With this in mind between 1998 and 2000 in total four reaches of 2 km were dredged to the standard of 150 m by 2.5 m, and some small reaches slightly deeper (see also Box 4). The development of the bed topography of the river was monitored to identify the response of the river to dredging, both during medium and low flows and during a peak flow. To determine changes in time frequent multi-beam soundings were carried out. The data were analysed in different ways.

Firstly the data were entered into a GIS package (ArcView) and subsequently analysed. This was done at two levels of detail (see the study by Schepman (2000) and Box 4). Locally the re-emergence of shoals was studied and the possible cause identified. Secondly the reduction of the total dredged quantities was studied and also this was tested versus the assumed relaxation behaviour (see also Box 5). These analyses, in combination with additional studies allowed deriving expressions, which predict the development of a dredged reach over time. After a major flood the effect of dredging in the previous period is almost lost and the river is back to its "natural" state before dredging. This implies that dredging is required after every major flood.

The second way of analysing the monitoring results was to study the Least Available Depth (LAD) on the Waal River, which is daily established by measuring the available depth at a number of locations. This is a very relevant parameter as the LAD's are used as a basis for the decision how deep ships will be loaded and it is moreover the basis for compensating the shipping companies when not sufficient draught would be available. For the results of this study see Section 6.7.

It should be noted that in addition to the pilot projects described above also some other pilotprojects

Box 4. Pilot Project Morphology

One of the pilot projects carried out in the preparatory phase of the large-scale dredging of the Middle Waal River (see §6.2) was the Pilot Project Morphology. The aim of the project was to better understand the morphology of the Waal River without and with dredging. Regarding the morphology without dredging, the pilot project was in particular meant to identify the cause of shoals in the Middle Waal and their occurrence and behaviour under variable flow conditions. For the conditions with dredging the interest was how quickly shoals would appear again and which morphological features would be dominant in this respect. This is relevant for the development of a prediction method for how the river responds to dredging. Such a prediction method can help in the decision on where and how much has to be dredged. Over-deepening by dredging can be considered as well.

The Pilot Project covered a period of about two years, from March 1998 to May 2000. During this period two times capital dredging was carried out at in four locations of 2 km in the Middle Waal River (see figure B4.1).

The dredging aimed at lowering the bed level in the whole reach down to OLR – 2.8 m at most places, and at one location down to OLR – 3.2 m. The reaches in which dredging was carried out were monitored by means of multi-beams soundings, resulting in a very dense measuring grid. During the period of slightly more than 2 years, two floods occurred (see Figure B4.2) and in total 23 soundings were carried out (about one sounding every month). These measurements were subsequently entered into ArcView and a number of calculations were carried out in the ArcView environment. To get a better insight into the bed topography of the Middle Waal River without dredging also a number of JDP's (yearly cross-sectional soundings) of 12 previous years were used. The JDP's are single beam soundings at a mutual distance of 125 m, giving only a limited coverage of the riverbed. The effect of dunes, which can be reduced in ArcView by taking a centred average, cannot be eliminated from JDP's. The data collected during the Pilot Project Morphology were elaborated by Schepman (2000). Some results of this study are presented in this box.

Some basic assumptions made during the analysis of the soundings are:

- the bed topography of the Middle Waal River can be divided in a forced bed topography and free moving features,
- the forced bed topography which is hardly varying in time and is determined by the planform of the river,
- the morphological features which can move freely are superimposed on the forced bed topography,
- after dredging the bed topography of the river will return to its natural shape with some delay in time,
- the recovery process is a combination of a pure relaxation and translation.

The major conclusions from the study of Schepman (2000), apart from the observation that this approach using a combination of multi-beam soundings with ArcView is very fruitful, are:

- the forced bed topography is determined by the planform of the river and consists of point bars in combination with the so-called "groyne flames", features linked to the position of the groynes along the low-flow channel,
- the free features are a combination of bedforms and of deposits in the low-water channel, which are generated during periods when the floodplain is flooded and non-uniformity of the floodplains causes deposits (so "forced" by the floodplain geometry), which start to behave as free features once the flow is below bankfull,
- there is a clear difference between the height of the free features in the Northern half of the river (larger) and in the Southern half (smaller), which is most probably caused by navigation (having more draught when sailing upstream),
- the recovery of dredged reaches is faster where much dredging has been carried out: the deeper the dredged reach, the quicker the recovery,
- recovery is fastest in the beginning of point bars (Box 5),
- during low flow conditions the recovery is limited, whereas major recovery takes place during floods,
- the effect of dredging after the previous flood is still noticeable after the next flood,
- in addition to relaxation also translation plays a significant role and has to be taken into account when predicting the response of the river to dredging operations.

Box 5. Prediction of the recovery rate of dredging operations using numerical models

A dredging (and dumping) operation can be considered as a temporary disturbance of the regular cross-section, after which in time the cross-section gradually restores to the undisturbed situation. This process is governed by a one-dimensional propagation process, causing a gradual filling of dredged holes from upstream, and by a two-dimensional process related to transverse flow and transport effects in a (bend) cross-section. If morphological development on the scale of hundred of meters to kilometres is considered the filling process can be approached by an elliptic function:

$$z(t) = z^{+}(0)e^{-t/T_s} + z(t=\infty)\left[1 - e^{-t/T_s}\right]$$

in which t = time, T_s = time-scale of adaptation, z = spatially averaged bed level of a section, z(t = ∞) = long term bed level at low-flow conditions, and z + (0) = average bed level after dredging. Note that to compute the representative bed level additional terms have to be added to include the spatial variations (standard deviation), e.g. by dunes in a section.

To assess the time evolution of dredged holes and fills in the Waal River, a 2-D, depth-averaged morphological model was applied that is capable of reproducing these processes. The aim of these calculations has been to find approximate time-scales for filling of the dredged holes at subsequent sections along the river. As the filling process is highly dependent on the sediment-transport rate, and hence on the expected discharge, these calculations have been carried out for a range of discharges and dredging operations (primarily dredging of point bars).

The 2D model has been calibrated to reproduce the time-average alternately pool and point-bar pattern that is characteristic for the meandering Waal River, and to reproduce the time-scale of propagation of large bed forms which is about 1 km/year. The model has a length of about 84 km, a grid size of about 50 m (length) times 20 m (width), i.e.14 cells in transverse direction, covering only the main channel between the groynes. In the model D_{50} = ca. 1 mm has been used which slightly differs from the average river sediment. Transport rates can be approximated well using the Engelund and Hansen transport

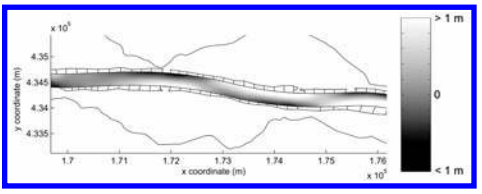

Figure B5.1 2D bed topography of the straightened Middle Waal River.

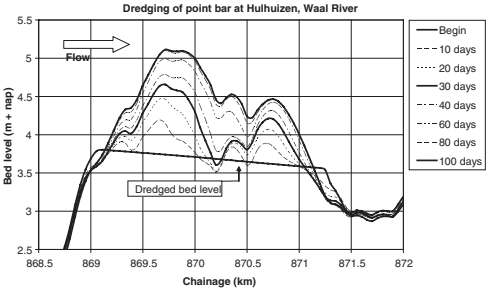

Figure B5.2 Simulated bed levels changes of a point bar after dredging.

formula (1967) for total load. Spiral flow and transverse-slope effects, that essentially determine 2-D effects in the river bends, are computed using the approach of Talmon et al. (1995).

Above figures show some results of the model.

By subtracting the simulated bed levels for the reference situation (without dredging) from the simulated results with dredging, it is possible to construct the elliptic filling process, and derive the time scale T_s. The value of T_s is in the order of 100 days (depending on discharge, dredging depth, section length, etc.).

In many dredging operations the depth-gain is reached by removal of dunes, which gradually grow up again in time. The growth of dunes does not follow from the 2-D simulation, but is derived from relations from observed dune development. The empirically derived development (growth) of dunes is discharge dependent. Its effect on available depths should be superimposed on the effect from the 2D model simulations.

were carried out e.g. to study different dredging methods.

6.3 *Dredging strategy*

In view of the experience gained during the pilot dredging it was decided to differentiate between two main types of dredging: (i) profile dredging and (ii) local spot dredging. When *profile dredging* is applied the exact fairway dimensions are dredged, taking into account 0.4 m extra dredging when OLR–2.8 m is used as reference. Profile dredging in terms of the volume to be dredged can easily be in the order of the yearly sediment transport in the Waal (see Section 2.2).

Copyright © 2006 Taylor & Francis Group plc, London, UK

Profile dredging is done at the beginning of a dredging programme and usually is required after a major flood (in principle every year, although sometimes it is not needed when the flood was low). After having established the fairway, its dimensions are maintained by *local spot dredging*, i.e. the removal of local shoals and dunes. Local spot dredging can be several thousands of cubic meters per year per spot.

6.4 *Dredging and dumping spoils*

In the past ten years various methods of dredging and dumping of the dredged material were tested on the Waal River. In advance it should be noted that in order to slow down the autonomous bed degradation, all the dredged material is dumped in the river again.

Where to dredge is usually easily determined on the basis of soundings and extrapolations of water level and bed level trends. In the dredging/dumping procedure finding a suitable place to dump the dredged material is a much larger problem. At first glance the deeper spots in the river seem logic dumping sites. However, these spots are maintained deep by the river (hydraulics) itself, and as a consequence the dumped sediment eventually will be transported further downstream and settled in locations with low flow velocities, and may increase existing shoals. Spoil dumped in outer bends appeared to stay there for more than 50% until the peak flow occurred, so depending on the hydrograph, dumping in outer bends can be considered an option for temporary storage of dredged material (Groen, 2002). The same holds for dumping in the erosion pit immediately downstream of a fixed layer. If bendway weirs have been applied, dumping in the space between them can be considered as well, as they also temporarily store the sediment.

Dumping in groyne fields is a very attractive method. Here the location of dumping (close to the low water bed or higher on the banks) defines the rate at which sediment will be supplied back to the main channel. In practice application of this method may be hampered by legislation regarding conditions to the possible contamination of the sediments (in particular regarding the receiving sediment in the groyne fields as the dredged material is of good quality). It also requires study of the local flow patterns during peak flows to estimate the supply rate. Nevertheless dumping in groyne fields is considered a sustainable sediment management solution.

To slow down the ongoing bed degradation the dredged material actually is dumped upstream of the dredging location. In this way the extra sediment supply increases the bed slope. Logically this might mean that the volumes to be dredged are increasing. This upstream dumping is subject to criticism and after investigations this procedure may be changed into dumping downstream.

6.5 *Decision support system*

For the determination of when and where to dredge a Decision Support System was developed. More details on the DSS Dredging on the Waal are given in Box 6 and in Douben & Werners (2000). At present the DSS is mainly used for data storage and presentation. This is due to the fact that until now the fairway is still maintained at the dimensions of 150 m by 2.50 m. Available experience is in this case a good alternative for the use of the DSS. It is expected that when the Middle Waal will have to be maintained by dredging to fulfil the required fairway dimensions of 170 m $\times$ 2.80, the DSS will be used again extensively.

6.6 *Effect of dredging on LAD's*

As mentioned before also the impact of dredging on the Least Available Depths (LAD's) was studied. Amazingly it turned out that dredging of the Waal did not increase the available draught for the ships. A number of reasons appear to be responsible for this disappointing result:

- The downstream shoal of the fixed layer in the bend near St Andries presented a fairly constant bottleneck, which constricts the width (and the LAD). This bottleneck is new (and linked to the construction of the fixed layer; studies are carried out to eliminate this new bottleneck. The shoals downstream of the other bend improvement structures in the bends Erlecom and Nijmegen were not critical.
- According to the dredging contract RWS prescribed the dredging locations, which contributed to the fact that the contractor could not respond in time to rapid changes in bed levels.
- Insufficient dredging downstream of the area. prescribed in the contract.

These observations resulted in the decision (i) to find a more permanent solution for the shoaling downstream of the fixed layer at St Andries and (ii) to develop a different form of contract between RWS and the dredging contractor to make the latter responsible for the maintenance of the fairway dimensions (see Section 6.7).

6.7 *Flexible contract*

With help of the experiences described in Section 6.6 it was decided to develop a new form of contract for dredging the Waal River, whereby the contractor is held responsible for every flaw in the required fairway dimensions, i.e. a smaller LAD than 2,5 m at OLR, with accompanying prescribed widths in the contracted river reaches. Early experiences with this new form of contract demonstrate that the cost of dredging decreased in the order of 50% and that the required fairway dimension can be maintained, apart from the known local shoals downstream of the permanent bend regulation measures.

Box 6. Decision support system for dredging

Operational decision-making about maintenance dredging in an engineered river like the Waal is complex; future discharges, water levels and morphological changes remain uncertain. A Decision Support System (DSS) to optimise maintenance dredging has been developed, which is based on the combination of bathymetric monitoring-data and simplified water level and morphological predictions. The DSS facilitates decision-making on dredging activities during critical low-water periods and after the recession of peak flows. In addition, the DSS analyses dredging and dumping strategies, maintains a database with dredging information, determines relative economic benefits and visualises the effects of different strategies.

The DSS contains five main components (modules): (i) data input, (ii) data management, (iii) calculation & analyses, (iv) presentation & interface and (v) assessment & evaluation.

By defining several boundary conditions, the user can compose dredging strategies, focussing on dredging and dumping volumes in time and space, including short and/or long term water level and morphological predictions and estimations of relative benefits. Readjustment of boundary conditions provides the opportunity to set time related priorities and to compare and optimise dredging strategies. Strategies and their consequences can be visualised in the presentation module.

The DSS contains three different prediction methods: (i) water level predictions, (ii) morphological predictions and (iii) estimation of relative benefits. Long-term water level predictions (up to 6 months) are based on the base flow concept (Lyne-Hollick algorithm) in combination with regression equations for the Rhine River. Short-term water level predictions (up to a fortnight) are calculated with an extended version of a Multi Linear Regression (MLR) model, based on statistical relations between several upstream water level gauges and rainfall stations.

Morphological predictions are based on 'conceptualised' empirical knowledge in combination with (weekly) bathymetric measurements, providing the user guidelines for future bed level developments and morphological recovery after dredging. A distinction is made between forced morphological phenomena (as a result of the river geometry) and free moving bed forms such as dunes.

In the DSS also a methodology to estimate relative benefits (comparative transportation costs) of inland shipping is included. It is based on an increasing normative depth as a result of dredging activities, which (theoretically) results in an increasing loading capacity. For more details on this module see Douben and Werners (2000).

7 TOWARDS A MORE SUSTAINABLE APPROACH FOR IWT

7.1 *Long term trends*

The Rhine delta has always been very important for the safety of Holland. For each of the downstream branches the level of flood protection, navigation potential and fresh water supply is determined by the (in principle) unregulated discharge distributions at two bifurcations. Though the discharge distributions appear to be remarkably stable, this is not certain during extreme peak flows. Recent observations of developments of bed levels, water levels and discharge distributions show tendencies that are worrying. The ongoing bed degradation of the upstream reaches of the Dutch Rhine branches leads to less discharge flowing into the Waal River, which is part of the main transport route to the German Ruhr area. Germany tries to stop this degradation by armouring the bed and by sediment feeding. Continued lowering of the water level in the Dutch waters would lead to a gradual reduction of draught near the border and increased upstream bed degradation.

Flood management measures, such as flood channels and lowering of summer embankments, may influence the flow pattern in the main channel during low flow conditions. Lowered water levels or sedimentation in the fairway might hamper navigation or require costly measures like dredging. The reintroduction in the (regulated) river system of unprotected banks, secondary channels and patches of naturally evolving vegetation – all aimed at increasing the ecological potential and biodiversity – will also have an impact on flood levels and navigation.

A large number of flood management projects are in preparation along the Rhine branches. Because these rivers are also important IWT routes, it appears necessary to deal with negative effects of flood management works on navigation and vice versa.

7.2 *Towards a Sustainable Fairway Rhine delta*

The combination of the requirements for navigation with the targets set by the "Room for the River" project has given rise to the Sustainable Fairway Rhine delta (SFR) project which should lead to an integrated solution that allows for a maintainable fairway on the main transport routes. It is expected that measures like local bed armouring, sediment supply schemes, adaptation of normal widths and modifying groyne dimensions will be part of the solution.

Besides the fact that the (autonomous) bed degradation has to be stopped, the main goals of SFR are the following:

- Assure a fairway (170 m wide and 2.8 m deep during low stages) that can also be maintained in the long run (both technically and financially).
- Use of sustainable measures that also in the long run can cope with system developments, so that possible future bottlenecks can be avoided. In this respect sustainability also is related to (financially) maintainability.
- Development of an optimal maintenance program.

It can be stated that the SFR project is a new master plan, which adds sustainability to the original Waal project.

For the choice of a set of measures the impact of the measures on the different user functions should be known. Therefore a prediction tool is being developed, that must be able to simulate the relevant processes with sufficient accuracy. This includes the following aspects:

- Simulation of the supply of sediment consisting of sediment with a different composition than the local alluvial material.
- Simulation of the effect of non-erodible layers in combination with non-uniform sediments.
- Simulation of the morphological development of the river system including the two bifurcations in combination with the flood plain areas on both sides of the river branches (including all above-mentioned aspects of groynes, vegetation and summer embankments).

7.3 *Sediment management*

Measures have to be investigated that contribute to sustainable river management to stop the degradation of both the bed and water levels. An extensive study on possible measures already has been carried out for the reach Emmerich-Lobith at the Dutch-German border (Baur, 2003), which shows the most severe degradation between Duisburg and Werkendam. In this study a 2-D morphologic model has been used to define solutions to stop the autonomous bed degradation and to increase the fairway depth. It appeared from this study that solutions can be found using combinations of engineering measures with bed-load supply, the construction of armoured layers and local groyne adaptation. From a multi-criteria analysis, a combination of measures with the following elements turned out to be the best solution:

- Non-erodible layers in the deep outer bends (see Figure 14).
- Bed-load supply upstream (4000 tons/week, every second year) and a total of 4000 tons/week in the project area, which results in a total supply of approximately 200,000 m^3/year.
- Local dredging.

It was assumed that no sediment is taken out of the river: the material dredged in the fairway is dumped in deep areas. The locations for bed-load supply and dumping of the dredged material only slightly affects

Copyright © 2006 Taylor & Francis Group plc, London, UK

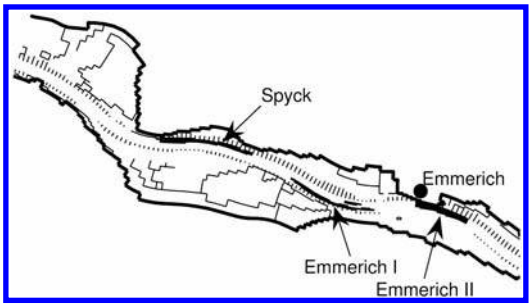

Figure 14. Identified non-erodible layers in border reach.

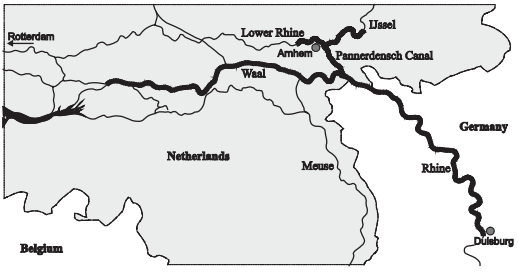

Figure 15. Study reach of the common German-Dutch Rhine.

the scoring of the combinations of measures. The erosion averaged over the whole project area will be reduced by these engineering measures from 50 cm to about 5 cm between 2000 and 2025.

In a recent study on sediment feeding of the Rhine River near the Dutch-German border (Schwerdtfeger, 2004; see Box 7) different feeding strategies related to the grain size distribution and feeding locations were investigated, all of them intended to stop the on-going degradation in this area (no attention was given to maintaining the fairway). A 1-D graded morphologic model was used. It was concluded that the amount of sediment to be fed (around 200.000 m^3/year) was rather independent of the grain size distribution, but that the number of feeding inputs increases as the maximum diameter or the D_{50} of the suppletion also increases. For the effect on downstream areas it is important to note that more sediment is transported downstream when the supplied mixture is richer in fractions near the D_{50}. The addition of finer material may be appropriate if the aim is to quickly stabilize river reaches downstream. A complicating factor can be bedforms, which may develop using finer sediments and the accompanying reduction of the draught.

Though sediment feeding can be applied without great risk a number of aspects need attention. Changing grain size distributions of sediment mixtures cost a lot of money. If feeding material is used which differs from the original bed composition phenomena may be observed that relates to the following aspects:

- Different bedforms.
- Different lateral slopes in bends including point bars.
- Effect on navigability, because of shoals and propagating sand waves.
- Different effect of ship induced currents on bed levels.

These aspects need to be studied carefully.

7.4 *Structural measures*

Though a lot of experience has been collected with dredging as a maintenance tool, experience shows that dredging cannot be used as a means to create and sustainably maintain the targeted fairway with larger dimensions. Taking into account lessons learnt from past training schemes, it is clear that a new round of (traditional) river regulation measures should only be considered with great care. Therefore a large 2-dimensional morphologic model should be used that can show the river system changes also in the long run (Havinga et al, 2005). Figure 15 shows the study reach. Though many measures can be contemplated, with the experience from river measures already carried out in the past or recently investigated, only a few types of measures are convenient to use in a sustainable river training scheme. They are:

- Modification of normal width's to neutralize the increase or decrease in sediment transport capacities.
- Fixed layers: to fix the bed levels.
- Groyne adaptations: to decrease water level set-up and create a better alignment of the fairway.
- Sediment management: to meet the river's sediment demand.

7.5 *Discussion: investigation and the sequence of application of measures and the order of application*

As indicated before each combination of above-mentioned measures should be carefully investigated with morphological models. However, the reliability of such models is limited. Aspects like graded bed material, simulation of flow in groyne fields and correct simulation of cross-sectional slopes, local shoals and bedforms are not yet well represented in these models. Nevertheless they provide interesting information on the effects of measures. Especially a complete 2D morphologic model of the Rhine branches, from Duisburg (Germany) to the tidal area of the Waal River, including the two bifurcations can be very useful, in particular when this model is calibrated with results of measures already carried out. In future more detailed physics can be included to increase the forecasting capability of the model.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Box 7. Simulation of effect of artificial sediment feeding

To reduce or even stop the ongoing degradation of the river bed of the Rhine River different possibilities are available. One possibility is to start feeding sediment to the river. This method has been applied successfully in Germany downstream of the Iffezheim barrage. Presently also more downstream in Germany sediment is supplied to the river. So also in The Netherlands this method is being considered.

When applying sediment feeding as a measure a number of questions have to be answered, notably:

- how much sediment will be supplied?
- where will the sediment be supplied (in one location or over a long reach and in outer bends, in the groyne fields or at other locations?
- when will the sediment be supplied (e.g. only during the flood season?)?
- what should be the size and gradation of the supply material?

The quantities to be supplied each year were determined in a recent study (WL/Delft Hydraulics, 2002/2003) and are about 200,000 m3/year. The experience from Iffezheim will surely be useful, but in Iffezheim great efforts are being made to supply to the river a very accurately composed mixture exactly corresponding to the bed material transported by the river (Droege, 1992a & 1992b; Nestmann, 1992). The preparation of this mixture is very expensive. It would be preferable if a commercially available mixture could be used. Moreover it might be considered to use the artificial sediment feeding to slowly change the bed composition of the river, if this would have advantages.

To study the effect of supplying different types of sediment to the river a study was carried out by Schwerdtfeger (2004), applying the SOBEK package, 1-D software developed by WL/Delft Hydraulics together with RIZA, which is a one-dimensional open-channel dynamic numerical modelling system, including in this application the morphology mode for graded sediments. Morphological changes are simulated by means of bed-material conservation (sediment continuity equation for bed-load material). The changes of composition are computed from the continuity equations per fraction for the separate layers, and by the bed-load transport simulation per fraction. Changes in composition of the active layer are caused by differential transport of the different fractions. The model uses the Hirano active layer approach (see Ribberink, 1987), and the active layer thickness can be selected as a fixed value or can be linked to e.g. the bedform height. The different parameters in the model (roughness, sediment transport formula, etc.) were selected to represent the Rhine River. For more details see Schwerdtfeger (2004).

There was one serious problem with the modelling approach. In the reach modelled the size of the bed material changes rapidly (Figure B7.1). This might be caused by abrasion, but abrasion rates would have to be excessive in this particular reach. Often the modelling approach is that the basis for the model is a base case in which no changes occur. In the case of a graded model with a reduction of grain size in downstream direction, it is not possible to define a base case where no net bed level and bed composition changes are taking place if no feeding is applied. Hence the modelling used the approach of simulating the conditions over a period of 20 years ahead without and with artificial feeding. The differences were used as assessment criterion.

A typical result of the study of Schwerdtfeger (2004) is shown in Figure B7.2. It is proposed to supply the sediment to the river divided over a number of feeding points to reduce

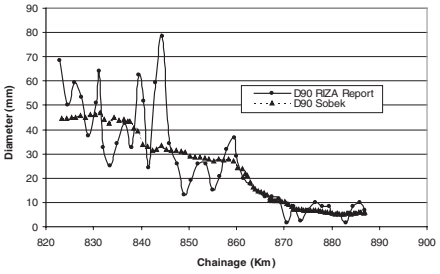

Figure B7.1 Reduction in grain size in the Rhine River in the German-The Netherlands border reach.

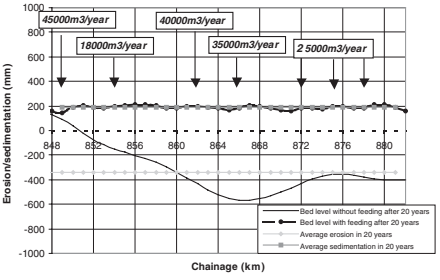

Figure B7.2 Possible feeding strategy and effect on bed degradation.

possible irregularities in the riverbed. Schwerdtfeger (2004), who studied only morphological issues and e.g. not practical aspects as mentioned above, concluded the following:

- Sediment feeding is an attractive and sustainable measure, giving a lot of flexibility (quantities and composition can be changed over the years on the basis of experience).
- It is possible to change the bed material characteristics of the Rhine River by artificial bed material different from the bed material present in the river.
- How quickly these changes in bed material proceed is dominated by the thickness of the active layer (however there is much uncertainty on the thickness of this active layer in a river reach with a very graded bed material consisting of gravel and sand).

More detailed studies are needed to develop appropriate feeding strategies (where, how much, when). Moreover it is proposed to do a number of additional studies related to the impact of possible changes in the composition of the bed material on other aspects of the river. Some aspects to be studied are (i) the effect of sorting on the lateral slope of bands, (ii) the effect of navigation, (iii) the morphological interaction with the groyne fields, etc.

Based on these results it was proposed to develop a pilot project for artificial feeding of sediment to the Rhine River. This project should be accompanied by a properly designed monitoring study including frequent and comprehensive sampling with the objective to monitor the impact of the feeding on bed degradation and bed composition and other aspects and when needed to adjust the feeding strategy. Simultaneously the current existing graded-sediment models could be improved.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Accepting the limited reliability of morphologic models, measures should be applied with care and the sequence of their application must follow a certain order. Modifying the normal widths is done by adapting groyne lengths, which is a very costly procedure (round € 300.000/groyne, in total 400 groynes), so this should be combined with other groyne modifications. As the required normal width to neutralize changes in sediment transport capacity is computed with morphologic models and the measure is far from flexible, this measure should be investigated thoroughly. From experience we know that with the available models the location and dimensions of armoured layers can be defined fairly well, so though these measures are also very costly and non flexible, they could be applied in short notice. Sediment management can be applied immediately as this is a flexible measure, which can be stopped and altered very easily.

7.6 *Long-term developments in navigation*

The transport capacity of the Waal River is already very large. It has been estimated that the actual used capacity can easily be tripled without having to invest large amounts of money in this waterway, maintaining the actual fairway. To further increase the economical use of the river, tools are being developed that can present the actual bed geometry in the wheel house (electronic chart display information system or ECDIS). In this way the skipper can judge better the ship's course. This may result in a more chaotic navigation pattern, when different types of ships choose different sailing routes. So, with the intention not to decrease the safety level of inland navigation, a system of individual guidance of ships (water traffic control) may be necessary. With ECDIS and a water traffic control system the use of the available fairway can be optimised.

However, there is still another way to increase the transport capacity of the river, i.e. to make use of larger water depths. Apparently in case of the Rhine navigation the choice was made to make use of limited draft and several shipping lanes. In this way many types of ships can sail the Rhine River, its tributaries and the smaller feeder canals. Another strategy can be to limit the width of the fairway for the benefit of larger drafts. This can be demanded when a strong increase of transported volumes of goods has to be faced. The actual fairway of the Waal River enables up to 5 shipping lanes. When the number of shipping lanes is reduced to 3 or even less, the draft of the ships can increase substantially. However, the fairway width might decrease to around 100 m. A consequence of such a fairway is the creation of in-line navigation, which is considered a major drawback of this system. Probably additional measures at crossings will be needed.

8 DISCUSSION

In this paper an overview is presented of river measures carried out in the Waal River during the past 10 years to increase navigation potentials. Though a well motivated master plan was available, a number of works have not been executed and/or have been replaced by alternative measures, due to budget problems and growing insecurity about the effectiveness of certain measures (e.g. bottom vanes). This is not a unique situation, neither for the Netherlands, nor for this era; also in the past this situation frequently happened. Nevertheless it can be concluded that for sustainable development of navigation and other river functions, it is essential to have a master plan in which the long-term autonomous development of the river system is leading. Any planned river measures that deviate from measures envisaged in the master plan, should be of a reversible nature. In view of this the relatively extensive dredging operations in the Waal River, which temporarily (or permanently?) replace more structural measures, are a logical step in the implementation of the original Waal project.

The demands on the layout of the Waal River are large: the combination of user functions with ecology and the desire to obtain sustainable (and maintainable) solutions to optimise the user functions, poses complex questions. Answers have to be sought using 2-D simulation models (also with movable bed), utilizing the best understanding available.

River management has to deal with the natural dynamics of the river. The related uncertainties limit flood safety and navigation opportunities. In the past centuries coping with these uncertainties was also translated in a river lay-out in which (most) people could survive flooding and accepted the nuisances, e.g. small draughts or no sailing at all. Today, the situation is quite different: the regulation of the discharge distributions in the 18th century led to a high flood protection standard and to reliable navigation conditions. Further improvements for navigation can be found in reducing the uncertainties in forecasting of navigation depths. This touches upon a whole range of "river flow" subjects related to forecasting of discharges, water levels, bed levels and bedforms, in which uncertainty plays a major role and where probabilistic approaches are appropriate.

Case study: River restoration projects along the Isar (Germany)

W. Binder
Bayerisches Landesamt für Umwelt, Munich, Germany

ABSTRACT: Like most of the larger rivers in middle Europe sections of the Isar, flowing from the Alps down to the Danube, were canalised more than hundred years ago, to improve flood control and the use of hydropower. The floods in the last two decades showed the needs to improve flood protection and accelerated the discussions about more nature and outdoor recreation along the canalised rivers. The basic for restoration projects are regional river concepts. They contain the guidelines for local projects. Such concepts as well each single local restoration project requires teamwork, needs ecological understanding, technical knowledge in hydraulics/ construction and social acceptance. They have to be supported by the public e.g. engaged Non Governmental Organisations (NGO). Engineers, architects and experts of different fields e.g. nature conservation, wildlife, agriculture, forestry and fishery are working together to find win-win-solutions. The case study Isar, includes projects in the city of Munich and outside in the rural floodplains, describing planning steps, river restoration objectives and measurements and also the importance of public participation.

1 INTRODUCTION

More than 150 years of river and drainage works in many parts within Europe and also other places in the world couldn't ban the danger of floods, but brought a loss of nature to rivers, streams and wetlands.

Within the last three decades restoration projects were started and river restoration is finding growing interests in many states in Europe, but also in the USA, in Australia and Japan. Especially the floods in 1995, 1999, 2002 and 2005 in Central Europe pushed programs for flood protection and restoration. Today the objectives are to preserve natural retention areas and to restore rivers beside technical flood control works. River assessment methods where developed, to show how much of the hydromorphological components in our rivers have been altered by river works and where river restoration should be concentrated to improve the ecology.

Many projects were completed in the last two decades dealing with river restoration. Not all of them were perfect, some are already redesigned by floods. But there are many successful projects along streams and rivers, where we can learn by studying the technical solutions and the experiences which were made. Not all restoration projects needs a lot of construction work, also maintenance work, wisely done, can improve the ecological quality of fluvial systems and can meet the demands of the Water Framework Directive and of Natura 2000.

2 SITUATION OF RIVERS AND STREAMS IN MIDDLE EUROPE

Channelled, incised, dammed, most of the rivers and streams in middle Europe have been altered in the last 150 years to improve shipping, the use of hydropower, land drainage and flood control of rural and urban areas. Close connected with these alternations of rivers and streams were the loss of biotops for animals and plants. The floods of the last decade brought heavily damages and losses for urban areas, since there is not enough open space anymore for the water.

The assessment of the hydromorphological feature of rivers and streams in Germany shows that 2/3 of all assessed rivers have strong deficits or are completely unnatural. The surveys for the European Water Framework Directive (WFD) confirm that most of the rivers in Germany are endangered to reach the good ecological status for the biological quality components due to hydromorphological deficits. Bayerisches Landesamt für Wasserwirtschaft et al. (2001).

3 GUIDELINE FOR RESTORATION PROJECTS: THE ECOLOGICAL FUNCTIONS OF RIVERS AND STREAMS

3.1 *Principles*

Rivers and streams are dynamic systems. They are formed by the natural characteristics of the drainage

Copyright © 2006 Taylor & Francis Group plc, London, UK

basin, climate, geology, tectonic, vegetation and land-use. Depending on the precipitation rainfall and storage capacity the discharge is fluctuating. The power of running water and the amount of transported solids influence the morphological process and the geometry of the river channel.

This includes bank erosion and sedimentation, the rebuilding of riffles and pools and the migration of the riverbed within the alluvial plain. The geometric features of the river channel e.g. planform, longitudinal and cross sections as well the substrate in the river channel are depending from the conditions in the watershed area. River and floodplain are an unit. Mangelsdorf et al. (1980).

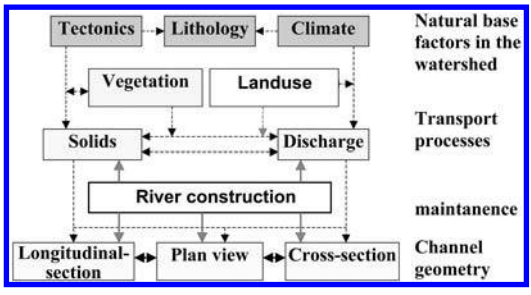

Figure 1. Modification of hydromorphological processes caused by river construction.

The ecological functions are impounded by river construction and regularly maintenance, controlling the morphodynamic processes. They change such dynamic rivers into static systems, causing ecological deficits.

The model for restoration describes the naturally ecological function of a river system. Rivers are called natural, if they are not polluted and can migrate freely in the flood-plain. This is a continuos process in time and space. The transport of water and solids is not interrupted by weirs or bank fixation. The vegetation along the river and in the flood plain is in natural succession, its zonation spans from pioneer vegetation to alluvial woodland. The migration of the river bed, pushed during floods, lead to a continuos replacement of typical structures. Natural river systems flood several times the year. They are housing a mosaic of biotops for animals and plants. This explains why natural river systems offer such a wide range of habitats, if their ecological functions are not affected. Their reference status is equal to the high ecological status of the WFD.

Figure 2. Natural section of the Isar near the alps, showing the alpine character.

Copyright © 2006 Taylor & Francis Group plc, London, UK

3.2 *Planning process*

The basic for river restoration projects are planning concepts for contiguous river sections, mostly done in the scale 1:25.000. Following these concepts restoration projects are done in the scale 1:5.000 to 1:1000. Regional river restoration concepts are helpful for the planning and communication processes with experts, members of the administration, Non Governmental Organisations (NGO) and the public. Such concepts assist the transparency of the planning processes and accelerate the decisions for local restoration projects. There are several planning steps for restoration projects.

Step 1: to develop the reference status for the river landscape.
Step 2: to asses the status quo.
Step 3: to find the deficits by comparison of reference status and status quo.
Step 4: to shows the restrictions for the restoration project.
Step 5: to develop the objectives for the restoration project.
Step 6: to improve the ecological functions of the river system; the measurements have to be placed and the costs estimated.

The objectives for river restoration projects are:

- to improve flood control e.g. in urban areas and outside urban areas strengthen the natural retention capacities
- to enforce the ecological function of the river system and to give more space to the river within the flood plain
- to allow the natural morphodynamics processes
- to find new techniques for mitigation to support or to limit morphodynamic processes
- to win stakeholders, residents and others for river restoration projects by information and participation
- to improve the recreational value of the riverside.

The planning process should be interdisciplinary and should integrate other plans and programs within a county or community related to the restoration project. These can be e.g. programs for city development, for clean water, reducing the pollution from point and non point sources. Interests of stakeholders e.g. fishery, nature conservation and of land owners, especially farmers along rivers and streams have also to be reviewed. Binder (2000).

Public Participation has to be integrated in the planning process to support the restoration projects. Agenda groups on regional and local level are formed to exchange ideas and practical experiences with experts and to accompany restoration projects. This includes to realize the needs for flood control, for natural retention of waters, for the ecological improvement of the system, for nature conservation and the possibilities and limitations for recreation.

4 RESTORATION PROJECTS ALONG THE ISAR, GENERAL INFORMATIONS

There are several restoration projects along the Isar, they include projects in urban areas like the Isarplan Munich and restoration projects north and south of Munich in rural zones.

Before these projects will be described, some general information about the river Isar are given: Bayerisches Landesamt für Wasserwirtschaft et al. (2001).

4.1 *The Isar*

The Isar runs from the Karwendel Alps to the Danube. It watershed covers about 9 000 km with about 2,5 million of habitats, more than 1,5 million in the city of Munich. The length of the river is more than 260 km. The annual precipitation in the mountain areas are more than 2000 mm/a, close to the Danube less than 700 mm/a. Floods occur mainly from spring to fall. The discharges in Munich are:

NMQ	(low flow)	ca. 40 m^3/s
MQ	(medium flow)	ca. 90 m^3/s
HQ	(high flow)	ca. 350 m^3/s
HQ	(Spring 1999)	ca. 870 m^3/s
HHQ	(maximum flow)	1440 m^3/s

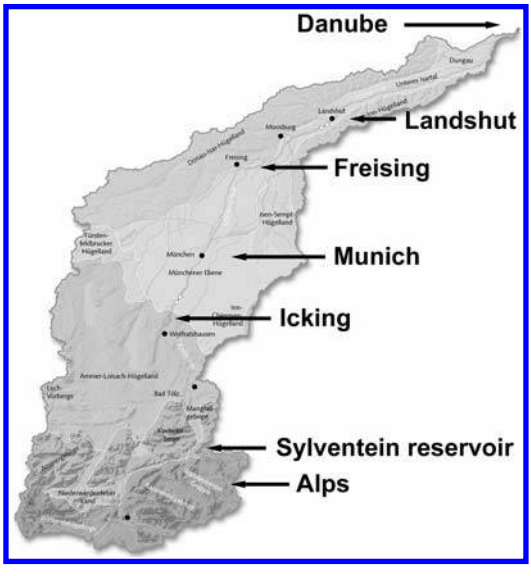

Figure 3. Watershed of the Isar.

Copyright © 2006 Taylor & Francis Group plc, London, UK

4.2 *Isar before canalisation*

Up to the beginning of the 19th century the Isar was a free flowing braided river system from the Alps down to the Danube. During low flow the water gets nearly lost between a corridor of gravel banks within a belt of alluvial woodland. Wetland with oxbows and groundwater streams accompanied the river system. The dynamics processes of erosion and sedimentation provided biotops for alpine plants and special animals. The zonation and the succession of the vegetation were controlled by floods and transport of gravel and sediments.

4.3 *River canalisation*

On the beginning of the 19th century river construction started. The objective was to get the river in a fixed bed, to improve rafting and to reduce flooding. The first construction work was done in the cities of Munich and Landshut. About 100 years later, at the beginning of the 20th century the canalisation of the Isar from Munich down to the Danube was completed, dikes were been built to protect urban and rural land from flooding. Between 1954 and 1959 the Sylvenstein Dam was built as a flood reservoir to improve the flood control in the Isar valley down to Landshut.

4.4 *Hydropower*

Already in the middle age water was used to run mills. Along the Isar only large communities like the cities of Munich and Landshut were able to build and to maintain weirs, which were endangered by each large flood. Water was taken at these weirs in channels to run mills. The streams in the "English Garden" in Munich remember for such systems.

The technical development at the beginning of the 20th century allowed using hydropower to get electricity. This was the start to built weirs and channels at the upper part of the Isar to withdraw the water from the river bed into channels to transport it to Hydropower plants. The riverbed itself remains for the most time of the year mostly dry, only to carry the water during floods. With the renewing of the concessions for this river sections in the last years (1995), minimum discharge in the river bed are guaranteed and restoration projects were started, financed by the hydropower companies.

Between 1948 and 1984 the Isar between Landshut and the Danube were dammed with a chain of hydropower plants, creating an artificial river landscape. Some of these lakes are built with Islands and natural zones. They will reach the good ecological satuts, which is asked for Heavily Modified Water Bodies (HMWB) by the WFD.

Figure 4. The dammed Isar north of Landshut built with islands and natural zones. This HMWB will reach the good ecological status.

4.5 *Natura 2000*

Besides the alternation of the Isar from a free flowing river and the loss of habitats, there are today many protected natural areas, especially from the Alps down to Landshut. In this section a wide corridor of woodland follows the river, only disrupted by the cities of Bad Tölz and Munich. The Isar, as an alpine river, offers a corridor of habitats for alpine animals and plants migrating from the Alps down to the Danube. For this reason more than 100 km of the Isar, flowing in Bavaria are reported for Natura 2000, covering biotops with rare specious of animal and plants, protected at an European level.

4.6 *Program for flood control 2020 in Bavaria*

Restoration projects along the Isar are on the way, to improve the ecological quality of the river and the flood plain. They include taking out bank fixation, where enough land is available, to start again the hydromorphological processes. This includes projects for gravel transport and the construction of By-passes at weirs for the migration of fishes. These restoration projects are parts of the Program "Hochwasserschutz in Bayern" which improves flood control by technical measurements and also by restoring the natural retention capacity of the flood plain, up to the year 2020, spending 2 bn of Euros.

4.7 *Public participation*

For the habitants of Munich and upper Bavaria the Isar is their river. Numerous books and magazines are published describing land and people of the Isar Valley. Isar is synonym for easy life, enjoying outdoor recreation and nature adventures. Already more than 100 years ago, the Isar valley was in the focus of painters and nature oriented people. To protect the beauty of the landscape, organisations were founded like: Isartalverein, Verein zum Schutz der

Copyright © 2006 Taylor & Francis Group plc, London, UK

Bergwelt, Bund Naturschutz in Bayern, Landesbund für Vogelschutz and others. Also the hunters and fisherman were well organised. All these NGO are fighting since decades for the river Isar. Thanks the engagement of these groups the Isar shows especially between Munich and the Alps still its alpine character. Today the NGO are organised in the Isarallianz, a federation of nature, environmental and sports organisations to escort the implementation of the restoration projects along the Isar step by step.

5 CASE STUDY ISAR IN MUNICH, THE ISAR-PLAN

In Munich the Isar get restored for a length of 8 km. The City of Munich and the State Office for Watermanagement put up the ISARPLAN to improve flood control, ecological functions and recreation. For this a planning group was installed with water engineers, landscape architects, city planners and biologist working together. The planning steps included meeting with citizen groups and members of all kind of NGO, like nature conservation-, fisher- and kayak-groups, they all were represented by the Isarallianz. The planning stage of the restoration project was implemented 1995, in fall 2000 the work started. Today 6 km of the project are restored, the last sector of about two km was approved by the city council in spring 2005 and will be finished 2007. The project will cost about 28 Mio Euro; 55% is paid by the State of Bavaria, a part of it is sponsored by the European Commission and 45% covers the city of Munich. Hafner (2001).

Figure 5. Canalised Isar (since 1900) in the city of Munich.

5.1 *Starting position*

The Isar in Munich got canalised about 1900 in a double trapeze profile, with the river bed and a flood plain. The floodplain is limited by walls and dikes. There were no gravel banks. The steep banks got protected with heavy stonework and concrete. To step down to the water was quite dangerous and needed to be sporty, for kids and olds. Small weirs had to prevent the incising in the river bed, they interrupted the longitudinal connectivity for boats and fishes. The flood corridor was grassland, regularly mowed and maintained as green grounds for soccer and other sports. Due to the discharge for floods, there were only a limited amount of trees and shrubs.

The water is taken into a channel to produce electricity, so more than 6 km of the 8 km restoration section has only a minimum flow of 5 m^3/s, but has to take the floods. At the moment there are discussions with the hydropower company to raise the minimum flow up to 15 m^3/s.

5.2 *Reference site*

The reference for the planning group was the "Flaucher" a natural section of the river in the city, where a historic weir widens the river bed with banks of gravel. The idea of the plans is to enlarge the cross sections of the river bed for the 100 year flood, to give the gravel banks back to the Isar by widen the river bed and to improve the longitudinal connectivity by replacing the weirs through ramps. With these principle measurements the objectives of the Isarlpan flood control, ecology and recreation can be covered.

5.3 *Planing approach and public participation*

In urban areas, where available space is limited, river restoration projects are mostly restricted to restore and to maintain the typical structures of the river channel. In Munich the flood corridor offering some space is integrated in the restoration project. From the start of the Isarplan 1995 the public was asked to accompany the planing process. People has been interviewed about the new river and what they would prefer. Their answers were different: The younger people were asking for more gravel banks and an open, easy access to the waterline, the older to keep the grassland. The compromise was to widen the river for 30% to bring back the gravel bank, but keep about 60% of the grassland for playground (soccer) and for the dogs. The main results of these interviews are:

- Bring the alpine character of the Isar back into the city.
- Enlarge the gravel banks along the river, especially wanted by the youngsters.
- Keep the flood meadows wanted by the oldies, (the dogs like grassland).

Copyright © 2006 Taylor & Francis Group plc, London, UK

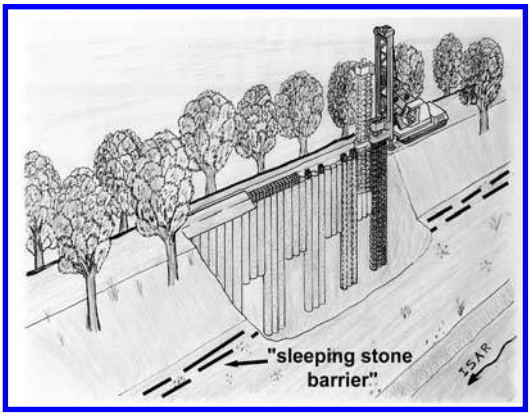

Figure 6. Lack of space to rebuilt the dikes, they got improved by steel pillars and a suspension of bentonit drilled in the dike. The bank fixation was taken out and replaced by a buried stone barrier in front of the dike.

- Keep the tress and the nature vegetation.
- Improve sun bathing along and and bathing in the river.
- Improve the function of the Isar corridor for pedestrian and cyclists, longitudinal north south connectivity within the city along the Isar.
- Improve the lateral connectivity with the quarters east and west the Isar.
- Avoid spectacular attraction along the river, because the area is already under strong pressure of recreation and should not attract additional visitors.

5.4 *Planning competition*

For the last restoration section in the city, south of Deutsches Museum, architects and engineers were invited into a competition to find a acceptable solution. The winner recommended a more formal solution, but this was resisted by the Citizens of the surrounding quarters. After a mediation process a solution now is found, which follows the restoration principles, which were chosen for the sections, already finished.

5.5 *Flood protection measurement*

The main objective of the Isarplan is to improve flood protection for a hundred year flood. To achieve this, the river canal has to be widening, the bank and the adjacent flood corridor were lowered to enlarge the hydraulic section for the discharge of water. The existing dikes have to be improved. For this the bank fixation was taken out and placed by gravel banks. To restrain the river within flood corridor, the fixation of the bank is replaced by and hidden stone barrier, buried in front of dikes, to limit the migration of the river canal and prevent damages of the dike. The dikes have to be improved for the 100year flood. The sections, covered with trees, got enforced by drilling in a mixture of concrete and bentonit, armed with steel pylons into the dikes.

5.6 *Hydraulic modelling*

The widening of the river bed improved the deposits for gravel, so, the gravel banks, a natural part of alpine river systems are back again even in the city, changing their position with each flood. The remodelling of the river canal and the floodplain opens the access for people to the water edge. To make sure that these measurements will resist flood a hydraulic model in the scale 1:30 was built.

5.7 *Ecological and recreational improvements*

Widening the river bed improves the structural variability and with this habitats for plants and animals. The existing vegetation was carefully documented, especially the trees, to avoid losses of natural vegetation and trees. Grassland vegetation with rare species was transplanted to places already restored. Reseeding of grassland was done with a mixture of grass and flowers, harvested on natural grassland along the Isar. Removing weirs and to replace them by ramps brought back the longitudinal connectivity in the river. The bed sediments with the hyporeic interstitial, before stabilised by this weirs, now can be transported during floods; the substrate of gravel and sand, now revived can serve again as spooning places for fishes and other habitants of the riverbed.

5.8 *Recreation*

The opening of the river by widening and lowering the bank, getting islands and gravel banks, improves the recreation facilities along the river in the centre of a city with more than one million of habitants. The new Isar attracts during warm and sunny days ten thousands of visitors, bathing in the sun or in the water, celebrating parties day and night. The restored Isar serves a giant public swimming pool, that also means more public toilets and more maintenance of the river corridor, which is used as a public park during the summer season.

The crowds of people, tied to the river in Munich, will not spoil the more natural sections north and south of Munich with their high value for nature conservation, especially with their habitats for rare and protected species of plants and animals.

5.9 *Hygienic situation*

Since 2005 the Isar in Munich offers in normal days bathing water quality, as this is ask by the Europeandirective for water bathing quality. To achieve

Figure 7. The proposal of the planing competition for the new Isar. Left: a more formal solution. Right: a more nature oriented solution.

Figure 8. The new Isar with an enlarged flood corridor.

this, the sewage treatment plants between the Alps and Munich are running from April to October UV radiation, which treat the outflow. This radiation reduces the bacteria loads during normal flows for about 50%. This is possible, because in the watershed of the upper Isar industrial zones and population is relatively low, compared to some other watershed in Germany. It is covered to more than 50% with woodland and the sewage treatment plants have a very high standard. To keep this high water quality also in Munich, the City of Munich put up a program more than 20 years ago, to enlarge the storage capacity of the sewage system and to reduce the direct discharge of polluted water into the Issuer e.g. stormwater. This high water quality can not be guaranteed during floods, in such times the water is polluted by many non point sources. But since the Isar is a flowing river, it takes only some few days after the flood, that the water quality reaches again a quality, which allows bathing. Bayerisches Landesamt für Wasserwirtschaft (2003).

5.10 *Construction processes*

The planning and construction processes were closely watched by the public. Information was given to the local districts, neighbouring the Isar, the Isar Allianz and to the general public.

The construction time is during October and April, starting 1999. This is the time were the discharge of the Isar, due to snow and ice in the alpine mountains, is low, also the pressure of recreation is during the winter season less.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The first section of the restoration work was done in a pilot project to get experiences with these new steps in river restoration. Especially the design of the new bank and floodplain needs a sensitive understanding. To protect bed erosion the old weirs are replaced by ramps, using a technique, developed for alpine river systems. Workshops and excursions were organised to change experiences and find solutions.

During the construction time are some specialties to mention:

- The problem of removing ammunition and bombs from World War II.
- The removal of contaminated soil, which has to be transported to deposit places outside the city, causing high costs.

5.11 *Flood 9/2005*

For the planners the task was to find a solution, which compromises between the technical standards, the ecological needs and the demands for recreation, and finally which also will resist a one hundred years flood.

This flood took place about 9/2005. The new Isar passed successful this test, with a discharge more than 1100 m^3/s. Damages were especially along one relatively sharp outside curve. Because the trees and the natural grassland vegetation in this sector had to be conserved, it was not allowed to straighten this curve. So the flood did it. The bank, even fixed with heavy stonework, exposed to the high velocity of the water flow, got washed away. The trees along the bank, which were carefully protected during the construction time, were taken by the flood. The river widened the bed. With this additional space, taken by the river, a new bank line could be chosen, which correspondents better with the hydraulic needs.

With this flood gravel was transported without problem through the redesigned sections. But a huge amount of trees, shrubs an wooden debris were deposited at the gravel bank and has to be taken away. But this is has also been always occurred after floods, even before the Isar was restored.

The city of Munich is responsible for the maintenance for the Isar. The cost to maintain the corridor, which is comparable to a public park or a public swimming pool, are slightly higher than before, because the new Isar attracts more guests than before. Binder (2004).

6 RESTORATION PROJECTS OUTSIDE URBAN AREAS

Outside urban areas the objective for restoration projects is to restore the ecological functions with a minimum of intervention. That means: bring back the dynamic processes. An important precondition for this is that enough land is available. In such areas the hydromorphological processes can be started again by taking out the bank fixation. Such restoration projects need space and time and can be done in rural areas. Binder, Hoelscher-Obermaier (2003).

6.1 *Isar near Icking, south of Munich*

South of Munich the Isar flows in the floodplain within a corridor of alluvial woodland. The water of the Isar is taken in cannels to generate electricity. The concession experiences 1997. To get a new concession the power company was asked to raise the minimum flow from and contribute to the cost of river restoration about 50%, based on a river restoration concept. The objectives for river restoration in rural areas are mentioned in chapter 3.

The restoration costs:

- Removing the bank fixations (the concrete stone protection was shredded and given back to the river): approx. 2,5 Mio Euros.
- Building a bypass at the weir in Icking: approx. 200.000 Euros.

Not included in these costs is the land, given back to the river. The land is owned by the state of Bavaria.

Also not included are costs for the loss of energy, since with the new permission since 1997 the minimum discharge in the river is raised from 5 m^3/s to 15 m^3/s.

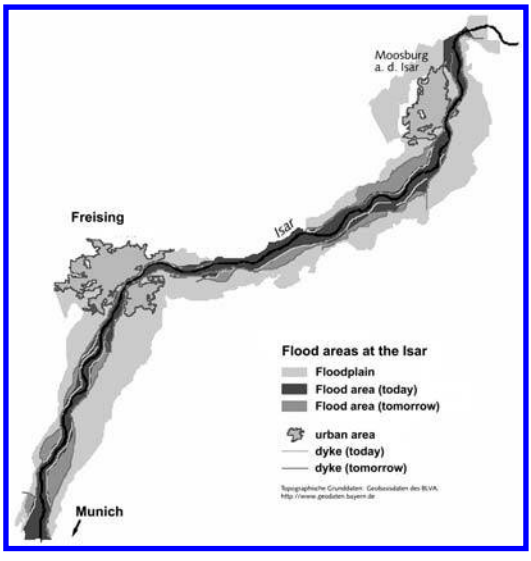

Figure 13. The Isar north of Munich.

6.2 *Isar, north of Munich*

70 km length and about 5000 ha alluvial plan, 3 500 ha woodlands. Most of the area is reported for Natura 2000. The water of the Isar between Munich and Landshut is taken into a channel, for the use of hydropower. The concession expired 2001 and got reviewed. The power company has to keep the minimum discharge in the river between 13 m^3/s and 17 m^3/s and has to pay 20 Million Euros within 10 years for restoration works, which will be done by the state and subsidies by the EU. The basic for this agreement was a river restoration concept. It shows:

- To improve flood control. For this the dikes has to be rebuilt. The old dikes are taken out from and are built at the edge of the woodland with the standards of today. Removing the old dikes, the retention area in causes of floods is enlarged by 1000 ha, from 1600 ha to 2600 ha.
- To replace weirs by ramps to improve the longitudinal connectivity.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Figure 14. Weirs, brought in to stop bed erosion, are replaced by ramps to restore the lateral connectivity.

Figure 15. With widening the flood plain bank protection is withdrawn, the morphodynamic processes can start again, widening the once canalised river bed. The eroded tree improve the structures e.g. for fishes.

- Bank fixations are taken out, so the hydromorphodynamic processes of erosion and sedimentation of the once braided river system can start again. The land is own by the states, who is also in charge for the river.

7 OUTLOOK

There are not many cities in the world with more than a million of habitants, with a river in its middle, were people can bath. And there are also not many rivers in the vicinity of an urban agglomeration like the rural zones north and south of Munich, were the wilderness of a river is coming back by restoration projects. Here flood protection, ecology, recreation and nature conservation (Natura 2000 areas) are combined in win-win projects, done by an engaged team of engineers, landscape architects, supported by stakeholders and public participation through all decision making levels from the beginning. The people in the urban agglomeration of Munich gets back a river, showing again its alpine character, offering recreation facilities and also the beauties and secrets of nature.

Figure 16. River and floodplain as an unit, at least during floods. The Isar-flood 2002 near Freising.

Sediment transportation in the Yangtze River and impacts of the three gorges project

Z.Y. Wang
Professor, Dept. of Hydraulic Engineering, Tsinghua University, Beijing, China

Y.T. Li
Professor, Wuhan University, Luojia Hill, Wuhan, Hubei Province, China

ABSTRACT: The 6300-km long Yangtze River is the largest and longest river in China with a drainage area of 1.80 million km^2. The sediment transportation in the river is complex. Debris flow frequently occurs in the dry and hot valleys in the upstream reaches and has become the main form of sediment transportation from numerous gullies to the tributaries of the Yangtze River. The sediment carrying capacity of the debris flows is 40 times higher than normal sediment laden flows. The total sediment yield from the drainage area of the upper reaches is 2.17 billion tons per year. The sediment carrying capacity of the currents in the tributaries is much lower than load from debris flows and only a small part of the total sediment load from gullies is transported into the Yangtze River. The annual runoff increases from upstream to downstream along the course but the annual sediment load increases from the source to Yichang (the Three Gorges Dam site) reaching its highest amount of about 500 million tons/year. Downstream of Yichang the river flows out of the mountains and enters its alluvial reaches in the middle and lower reaches. Sediment load in the upper reaches is proportional to the flow discharge in flood and low flow seasons. The sediment load in the middle and lower reaches is proportional to the flow discharge in the low flow season but is not related to the discharge in the flood season because a lot of sediment is wash load in the flood season. The sediment load reduced along the course in the middle reaches due to deposition. The riverbed profile in the middle and lower reaches was developing toward the equilibrium profile defined by the minimum stream power but the impoundment of the Three Gorges Reservoir interrupts and modifiers this fluvial process. The Three Gorges Project on the Yangtze River is the largest hydro-project in China, which is regulating the flow for power generation. To mitigate reservoir sedimentation and channel erosion in the downstream reaches, the reservoir is operate in the mode of "storing the clear and releasing the turbid", which is the main strategy for sedimentation control. The sediment transportation in the middle and lower reaches is affected and the middle reaches have changed from siltation to erosion since the impoundment of the reservoir in 2002.

1 INTRODUCTION

The 6300-km long Yangtze River is the largest and longest river in China with a drainage area of 1.80 million km^2, as shown in Figure 1. The figure also shows the locations of hydrological stations, meteorological stations, tributaries, riparian lakes, and debris flow areas. Below the map is the diagram of a cross section through Batang-Chongqing-Poyang lake, showing the elevation of the basin from the origin in the west to the river mouth in the east. The Yangtze Basin has elevation varying from 5,000 m to the 0 m with latitude from N25° to N35°. The river flows through the Qinghai-Tibet Plateau, Yunnan-Guizhou Plateau, Sichuan Basin, Three Gorges, Jiang-Han Plain, Lower Yangtze Plain, and pours into the East China Sea at Shanghai. From the source to Yichang (Three Gorges Dam site) is the upper reach, from Yichang to Hukou (Poyang Lake mouth) is the middle reach, from Hukou to Datong is the lower reach, and below Datong is the estuary. In China, the river is called Changjang (long river), with special names for different stretches: the lower reaches is called Yangtze River; the middle reaches are called Jingjiang River; the reach from Yichang to Yibin is called Chuanjiang River, from Yibin to Batang is called Jinsha River, and from Batang to the origin is called Tongian River (heaven river).

The sediment transportation in the river is complex. Debris flow frequently occurs in many gullies in the dry and hot valleys and has become the main form of sediment transportation from numerous gullies to the tributaries of the Yangtze River. The sediment carrying capacity of the debris flows is more than 40 times higher than normal sediment laden flows. The total

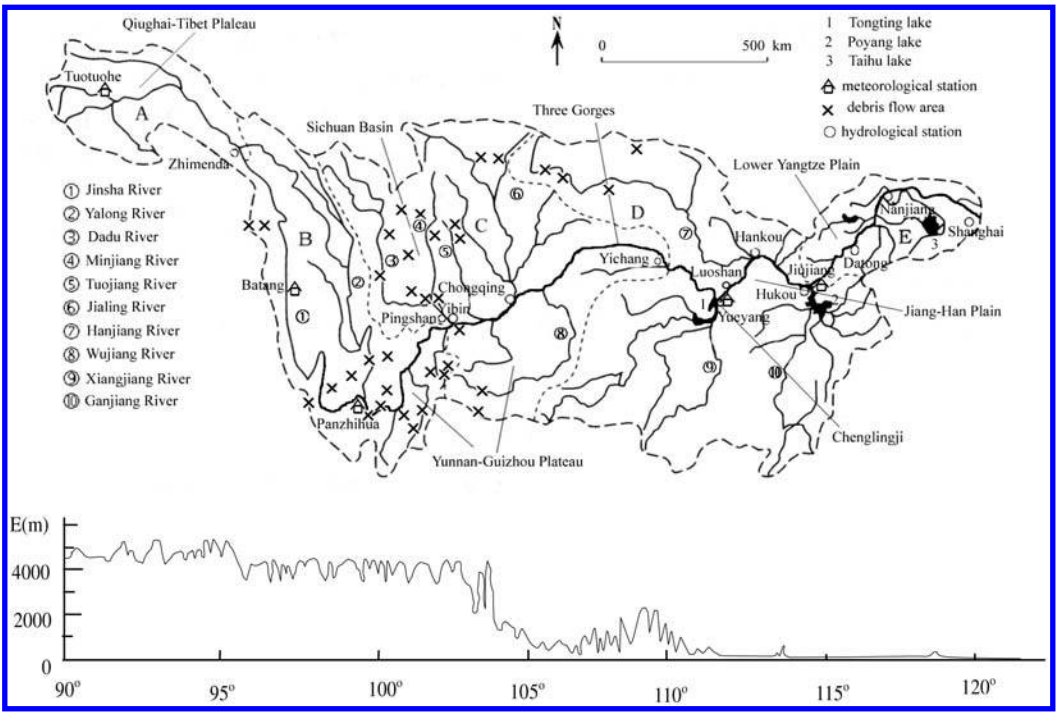

Figure 1. The Yangtze River Basin, showing the locations of the hydrological stations, meteorological stations, tributaries, riparian lakes, and the debris flow areas; and the watershed topography on an east-west line from Batang through Chongqing and Poyang Lake to the East China Sea.

sediment yield from the drainage area of the upper reaches is 2.17 billion tons per year. The sediment carrying capacity of the currents in the tributaries is much lower than load from debris flows and only a small part of the total sediment load from gullies is transported into the Yangtze River. The annual runoff and sediment load varies along its course. The annual runoff increases from upstream to downstream but the annual sediment load increases from the source to Yichang (the Three Gorges Dam site) reaching its highest amount of about 500 million tons/year. Downstream of Yichang the river flows out of the mountains and enters its alluvial reaches. The sediment load reduces from Yichang to Hankou due to deposition.

There have been quite a few studies on the sediment in the Yangtze River. Lu and Higgitt (1998) studied the sediment yield from the tributaries of the upper Yangtze River basin in the period 1956–1987 and indicated that ten stations, mainly located on the Dadu River and Wujiang River have shown increasing sediment yield, and six stations, located on the upper Jialing River and Tuojiang River have experienced decreasing sediment yield. Most of the observed decreases in sediment yield are associated with large reservoirs on these rivers. Zhang and Wen (2004) also studied sediment yield of the upper Yangtze River and illustrated a decrease in sediment yield in the Jialing River and an increase in the Jinsha River during the period from the 1950s to the 1990s. It was apparent that the decreasing sediment yield in the Jialing River was due to construction of reservoirs, reforestation, and soil and water conservation efforts. Land degradation, engineering, and channel activities were responsible for the increase in sediment yield of the Jinsha River. Higgitt and Lu (2001) examined sediment yield and its response to catchment disturbance and environmental variables in the upper Yangtze River basin and illustrated that a significant increase in sediment yield has occurred over about 8% of the catchment area while about 3% of the catchment has experienced decreasing sediment yields.

Investigation of the temporal and spatial variability of sediment transport within the upper Yangtze River catchment leads to the following paradox. There is evidence that the extent and magnitude of soil erosion across southern China has increased dramatically during the last 30–40 years (Smil, 1993; Wen, 1993; Lu and Higgitt, 1999; Edmonds, 1994). But there is no evidence of sediment load increasing at the Yichang Hydrological Station delivered from the upper Yangtze River catchment. Moreover, many studies have indicated that the total soil erosion from the upper reaches

Copyright © 2006 Taylor & Francis Group plc, London, UK

of the Yangtze River is around 2.2 billion tons per year (Tang et al., 2004). But the sediment load measured at Yichang is only about 500 million tons per year. A large volume of sediment is stored somewhere in the upper reaches.

The Three Gorges Dam, which is still under construction, is at Sandouping, 38 km upstream from Yichang (Fig. 1). The main purposes of the project are flood control, power generation and navigation. The dam is 185 m high and the storage capacity of the reservoir is 39.3 billion m^3, in which 17.2 billion m^3 are for sedimentation and 22.1 billion m^3 for flood control. The dam controls 1 million km^2 of drainage area. The hydroelectric station of the TGP will be the biggest in the world, with an installed capacity of 17,680 MW and an annual generation of 84 billion kWH. The project may replace several thermal power stations, thus reduce the consumption of coal by 50 million tons every year and cut carbon dioxide, sulphur-dioxide, carbon monoxide and nitrogen-oxide emissions by 100 million tons, 2 million tons and 10,000 tons and 370,000 tons, respectively. The project will improve navigation conditions from Yichang to Chongqing, by eliminating shoals, deepening and widening the shipping lanes and reducing river currents, and thus enable 10,000-ton tow-boats to sail right up to Chongqing. The annual shipping capacity will increase to 50 million tons from the present 10 million tons and transport costs will be cut by 35–37%.

The Three Gorges Reservoir began to fill in 2002 and the pool level is around 140 m. The water level will rise to the planned normal pool level 175 m in 2009 when the project will be completed. Sedimentation in the Three Gorges Reservoir and erosion of the downstream reaches by the released relatively clearer water from the reservoir has changed the sediment transportation in the river. Operation schemes and management strategies of the reservoir are important to control sedimentation in the reservoir and erosion in the downstream reaches. This paper studies the sediment load in different reaches and the impacts of the Three Gorges Dam on the sediment transportation in the river.

2 SOIL EROSION AND SEDIMENT STORAGE IN THE UPPER YANGTZE RIVER BASIN

There are three different climate patterns in the basin. Figure 2 shows typical climate diagrams for the three zones. It is cold in the source area on the Qinghai-Tibet Plateau and the Tuotuohe Meteorological Station has a typical cold climate pattern (Fig. 2). It is hot and dry in the Jinsha River reach from Batang to Yibin, as shown in the middle of Figure 2 for the Panzhihua Meteorological Station. The area experiences high erosion and is the main source of sediment for the Yangtze River. In the middle and lower reaches it is wet and warm, with the Jiujiang Station shown as an example in Figure 2. The tributaries in the middle and lower reaches contribute little sediment but input 50% of discharge to the Yangtze River.

A parameter is defined to represent the wetness, W, as follows:

$$W = \frac{R}{300mm} - \frac{T}{100^\circ C} \quad (1)$$

in which R is monthly average precipitation in millimeters and T is the monthly average temperature in degree Celcious. A positive W value means a wet climate and well-developing vegetation, but a negative W value implies a dry climate and poor vegetation. At Tuotuohe and Yushu (Zhimenda) the average temperature is low but the wetness is positive, because the evaporation is low. Because of the low temperature and cold climate, vegetation may slowly develop but mainly is herbaceous. The Jinsha River basin (from Batang to Yibin) is called dry and hot valleys, with annual average temperature about 20°C, but monthly average rainfall from December to April is less than 10 mm and the wetness number is negative resulting in poor vegetation. In summer from June to September, the monthly rainfall is more than 120 mm, which causes high soil erosion. The area has experienced extremely high tectonic motions and the rocks have been cut into small pieces. The topsoil layer is thin. Splash erosion, sheet erosion, and rill erosion are moderate but gully erosion is extremely intensive. The rate of erosion per area is very high and the sediment eroded from the area is composed of silt, sand, gravel, cobbles, boulders, and a small amount of clay. More than 50% of the sediment load to the middle and lower Yangtze River are from the Jinsha River basin.

Soil erosion, sediment load, and sediment storage have been measured and the data have been analyzed. There are many hydrological stations and numerous monitored cross sections and gauging stations on the river and its tributaries. Regular measurements are performed daily at the hydrological stations, including stage, velocity, discharge, suspended sediment concentration, and rate of bed load transportation. The later is measured by using bed load samplers. Channel bed deformation is measured occasionally at all stations and at the monitored cross sections on the rivers, ravines, and gullies. The error in bed elevation measurement is less than 5 mm and the error in horizontal positioning is less than 50 mm. The sediment load of the river is calculated with the flow discharge, suspended sediment concentration, and rate of bed load transportation. Because the bed load is less than 1% of the total load, the relatively large error in bed load measurement does not affect the accuracy of the total sediment load measurement. The volume of sediment deposition on the riverbed and reservoirs is calculated with the measured cross sections.

Copyright © 2006 Taylor & Francis Group plc, London, UK

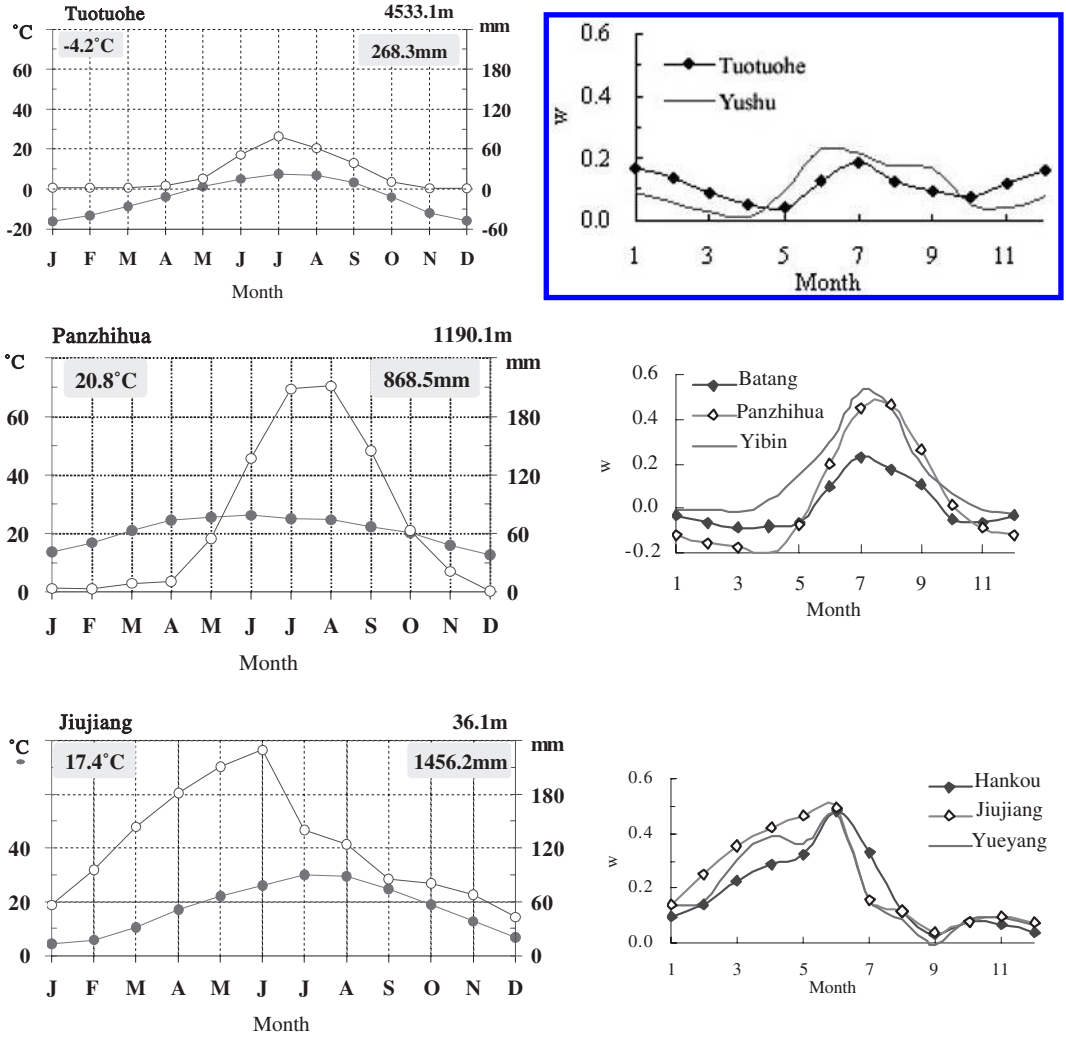

Figure 2. Climate diagrams showing monthly average temperature and precipitation and distributions of wetness number (W) of three typical climate patterns in the Yangtze River basin (note: the climate diagrams also list the elevation, the mean annual temperature and total annual precipitation. Data Source: Climatic Data Center, National Meteorological Information Center, CMA).

Soil erosion is measured in the following ways: (1) the soil erosion areas are determined by field investigations; (2) for each soil erosion area, the rate of sediment load transportation is measured at the downstream end of the small wartershed (generally several tens to a hundred square kilometers); (3) the rate of sediment erosion is calculated with the total load per year over the area of the watershed; or (4) the rate of soil erosion is directly measured by collecting the sediment eroded from a 100 m^2 sample plot, which is isolated by using low steel plate walls during rain falls; (5) the amount of soil erosion from all small watersheds is summed to obtain the total amount of soil erosion from the basin.

The total amount of soil erosion from the upper Yangtze River Basin is reported at 1.6–2.24 billion tons per year, depending on the statistics. Yu et al. (1991) evaluated statistics and reported the total soil erosion from the upper Yangtze River basin as 1.6 billion tons per year. Tang et al. (2004) presented the value of 2.24 billion tons per year. Yu (2003) adopted the value at 2.179 billion tons per year. The ministry of water resources reported the total soil erosion determined by remote sensing performed in 1990, which agrees with

Jiangjia Ravine	48.60	142,200	1965–2002	MWRC, 2000

the value around 2.2 billion tons (ACRS, 1990). Yu (2003) indicated that the Jinsha, Jialing and Minjiang River basins are the main sediment sources for the Yangtze River, with average annual soil erosion 829 million tons, 559 million tons and 253 million tons.

The total soil erosion from the upstream reaches of the Yangtze River is 2.179 billion tons per year. But the long-term average suspended load at Yichang before the impoundment of the Gezhouba Dam – the first dam on the river – in 1980 was 514 million tons, with an additional sum of bed load of 9.54 million tons (sand bed load 8.78 million tons plus gravel bed load 0.758 million tons) (TGP Water Survey, 2005). The difference between the volumes of the total soil erosion from upper Yangtze River basin and sediment load at Yichang is 1.655 billion tons. Where does the huge amount of sediment go?

The Jinsha River basin (upstream Yangtze River basin from the source to Yibin) is the most sediment source of the Yangtze River, with total soil erosion of 829 million tons per year. As shown in Figure 1. there are many debris flow areas in the basin and the slope in the basin is quite high. Table 1 shows the sediment yield from several debris flow gullies measured at the downstream end of the gullies. The sediment yield per area from the debris flow gullies is generally more than 40 times higher than the basin average. For example, the Xiaojiang River is a tributary of the Jinsha River as shown in Figure 3. which is 138 km long and has a drainage area of 3043 km^2. There are 107 debris flow gullies in the small river basin, among which the Jiangjia Ravine is the most well-known because of its high frequency of debris flow events, and they transport huge amounts of sediment into the Xiaojiang River every year. The sediment yield from the Jiangjia Ravine is 142,200 $t/km^2.yr$, of which only 2% can be transported downstream by the Xiaojiang River.

Figure 4 shows the aggradation and degradation of the Jiangjia Ravine in the periods 1957–1985 and 1957–2002 (He et al., 2003). Gully erosion is the main type of erosion, which produces 75–83% of the total sediment yield from the ravine. The eroded sediment from the upstream reaches was transported in debris flows and deposited in the downstream reaches of the ravine. The gully bed aggraded by more than 40 m in the period of 1957–2002. A huge amount of sediment is stored in the downstream reaches and the mouth of the ravine. The same story occurred in numerous debris flow gullies. All the mouths of the debris flow gullies along the Xiaojiang River have been silted up by several tens of meters in the past 50 years.

Figure 5 shows the size distributions of debris flows in the upper reaches of the Yangtze River in comparison with the size distributions of suspended load at Yichang and Datong Hydrological Stations (Kang et al. 2004, Xu 2005, Wang et al. 2001, Xie et al. 2004, & Wan et al. 2003). Only the fine part of sediment eroded from the basin is transported into the Yangtze River. Dividing the sediment into n-fractions with diameter in the ranges $D_1 \sim D_2$, $D_2 \sim D_3$, $D_3 \sim D_4$, … in which the subscript 1,2,3, are the order numbers. If the cumulative percentage corresponding to D_i and D_{i+1} on a sediment size distribution curve in the figure is P_i and P_{i+1}, $\Delta P_i = P_{i+1} - P_i$ is the percentage of the i-th fraction. The amount of sediment of diameter in the range $D_i \sim D_{i+1}$ depositing in a river reach between an upstream section and a downstream section, S_{di}, is given by:

$$S_{di} = S_{up}(\Delta P_i)_{up} - S_{down}(\Delta P_i)_{down} \quad (2)$$

in which the subscripts up and down represent upstream section and downstream section of the river, S_{up} and S_{down} are sediment loads in the upstream section and downstream section.

The sediment eroded from the upper reaches of the Yangtze River is complex and it is difficult to calculate the average size distribution. However, mass sediment transportation in the most upstream tributaries and gullies is in the forms of landslides and debris flows. If the curve of S7 (the Little Haihe River, a tributary of the Xiaojiang River), which is average sediment size distribution of debris flows and hyperconcentrated flows, is used to represent the size distribution of sediment eroded from the upper reaches, the amount of sediment storage of different fractions can be estimated with Equation (2). At the Yichang station, gravel bed load composes only 0.15% and sand bed load 1.7% of the total load, the size distribution curve of suspended load can be approximately regarded as the size distribution of total load. The amount of sediment deposition in the gullies and tributaries can be calculated by using

Copyright © 2006 Taylor & Francis Group plc, London, UK

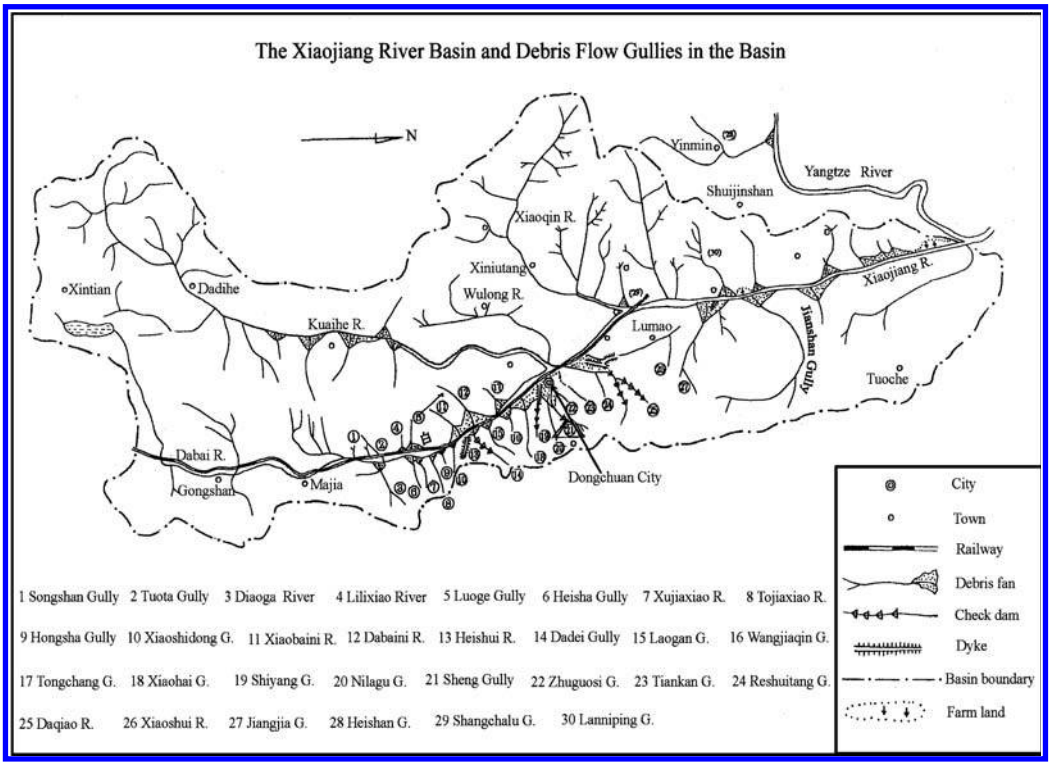

Figure 3. The Xiaojiang River Basin and debris flow gullies in the basin (provided by Zhicheng Kang, Institute of Mountain Hazard and Environment, Chinese Academy of Sciences).

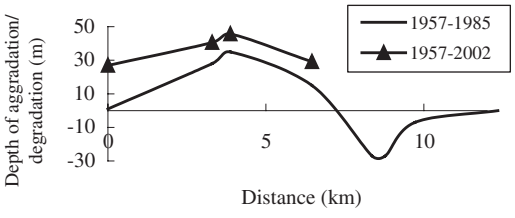

Figure 4. Aggradation and degradation of the Jiangjia Ravine in the periods 1957–1985 and 1957–2002 as a function of distance from the ravine mouth.

Equation (2) and taking figures for the upstream section from S7 and for the downstream section from the size distribution curve of Yichang as follows:

For the fraction coarser than 0.5 mm, $S_d = 2179^* 0.55 = 1198$ million tons

For the fraction in the range $0.05 \sim 0.5$ mm, $S_d = 2179^* 0.22 - 514^* 0.35 = 300$ million tons

For the fraction finer than 0.05 mm, $S_d = 2179^* 0.23 - 514^* 0.65 = 167$ million tons.

In other words, almost all the sediment coarser than 0.5 mm eroded from the watershed deposits in the gullies and tributaries of the upper Yangtze River basin; 300 of the 480 million tons of sediment of diameter in the range of $0.05 \sim 0.5$ mm and 167 of the 501 million tons of sediment finer than 0.05 mm deposit in the gullies and the tributaries of the upper Yangtze River basin.

3 SEDIMENT TRANSPORTATION

The sediment transportation in the river is complex. The sediment carrying capacity of the currents in the tributaries is much lower than the load from debris flows and only a small part of the total sediment load from gullies is transported into the Yangtze River. The sediment load in the river varies along its course because the runoff increases but the energy slope decreases along the course. Figure 6 shows the annual runoff and sediment load in the Yangtze River along its course. The annual runoff increases from upstream to downstream with the annual water at Yichang about 450 billion m^3. The annual sediment load increases from the source to Yichang (the Three Gorges dam site is at 4400 km in Fig. 1) reaching its highest amount

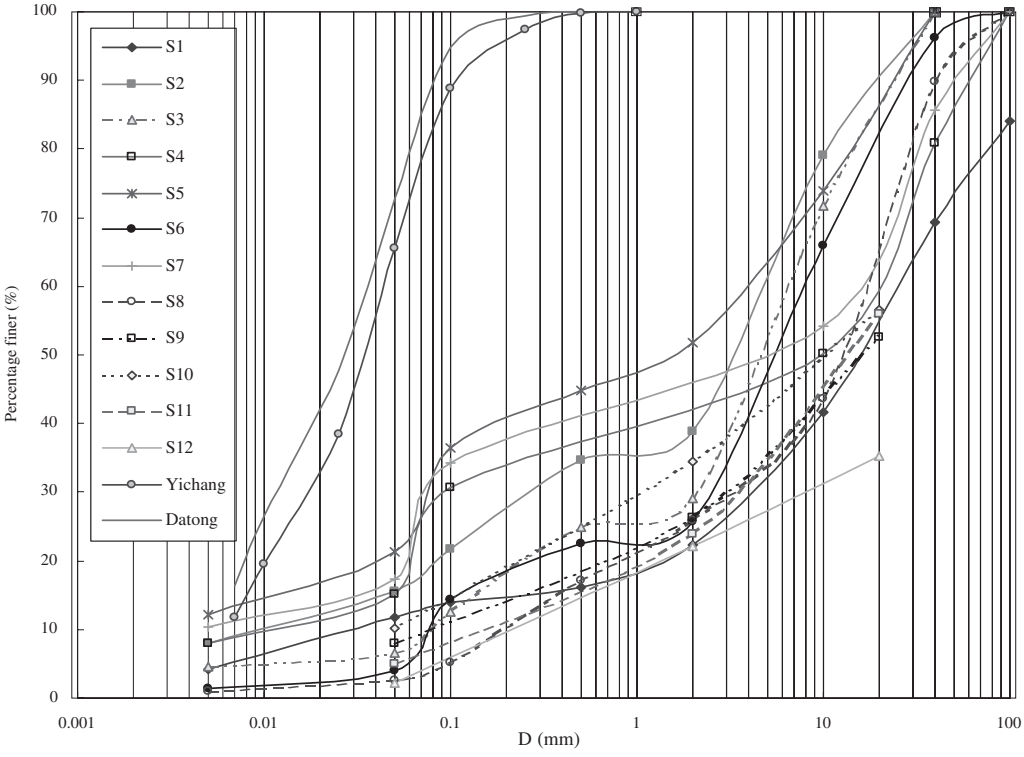

Figure 5. Comparison of the size distributions of sediment transported by debris flow from gullies to the tributaries of the Yangtze River with and those of suspended load at Yichang and Datong stations in the Yangtze River.
Note: S1–S12 are size distributions of debris flows in the upper Yangtze River basin: S1 = Little Xujia River; S2 = Big Baini Ravine; S3 = Tongchangqing Gully; S4 = Dade Gully; S5 = Little Haihe River; S6 = Jiangjia Ravine; S7 = Daduo Ravine; S8 = Xiaojiang River; S9 = Sunshuihe Gully; S10 = Niurihe Gully; S11 = An-Ning River; S12 = Yalong River.

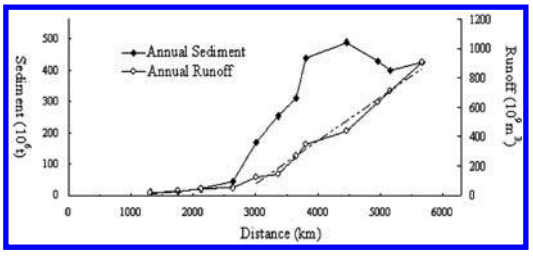

Figure 6. Distribution of annual runoff and sediment load along the course of the Yangtze River (The points are the average value for the period of 1950–2000 with data measured at the stations from left to right: Zhimenda, Batang, Panzhihua, Shigu, Qiaojia, Pingshan, Zhutuo, Cuntan, Yichang, Luoshan,Hankou,and Da-tong).
Note: The source of the data and period of statistics are: Zhimenda 1957–1999 (Wu & Yu 2002), Batang and Shigu, 1954∼1987 (Pan 1999), Panzhihua,1964∼1996 (Zhang & Wen 2002); Qiaojia, 1958∼1992 (Deng 1997); Datong, Hankou, Yichang, Pingshan, 1950∼2002 & Zhutuo, 1950∼2000 (MWRC 2000, 2001 & 2002); Cuntan, 1950∼2000 (Wang & Yi 2003); Luoshan, 1956∼1995(Pan & Lu 1999).

of about 500 million tons/year. The median diameter of suspended load at Yichang is 0.033 mm and the median diameter of bed load is 24 mm. Downstream of Yichang the river flows out of the mountains and enters its alluvial reaches. The sediment load reduces from Yichang to Hankou due to deposition.

Figure 7 shows the water-sediment diagrams at four hydrological stations on the Yangtze River, in which the horizontal axis is the year of the statistics, the left vertical axis is the annual runoff volume and the right vertical axis is the annual sediment load at the given hydrological station. The scales of the two vertical axes are set such that the long term average runoff and the long term average sediment load have the same position for the Datong Station, which is the most downstream station between the lower reaches and the estuary of the river. In the diagram the load and runoff are comparable and mutually convertible. A given runoff also represents the amount of sediment load the runoff can transport into the ocean. For the Pinshan (Yibin) and Yichang Stations, the curve of sediment load is much higher than the curve of runoff,

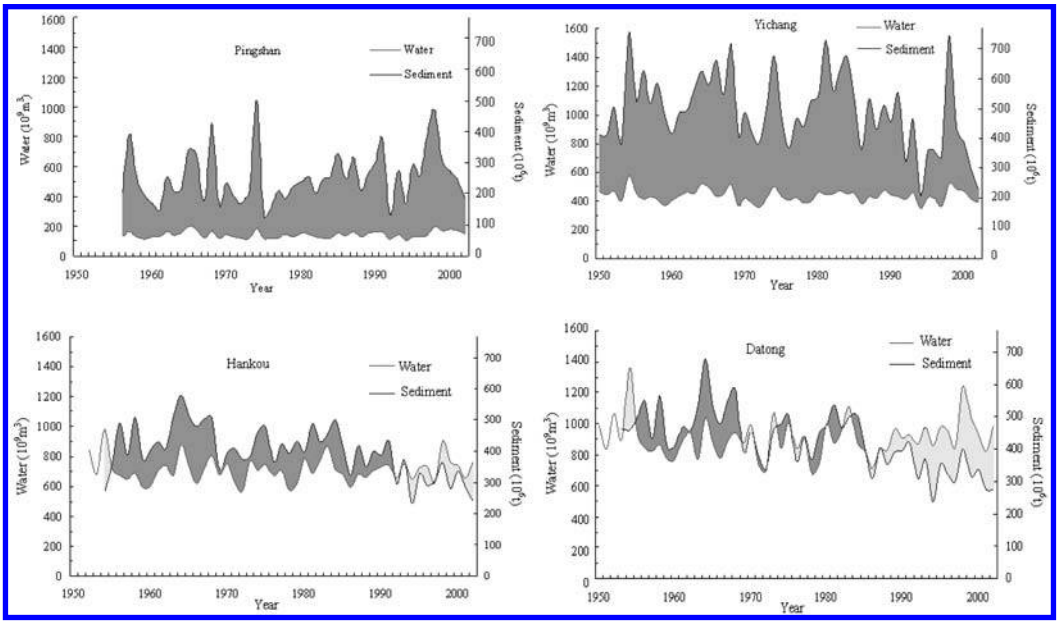

Figure 7. Water-sediment diagrams of the Pingshan (Yibin), Yichang, Hankou (Wuhan), and Datong hydrological stations on the Yangtze River; Beibei station on the Jialing River; Huangzhuan station on the Hanjiang River; Chenglingji Station on Tongting Lake; and Hukou station on Poyang lake.

which implies that the load is more than the capacity of the flow and the difference between the two curves (black area) implies aggradation downstream. Both the runoff and load curves increase from Pinshan to Yichang but the load curve increases more and the black area becomes larger. From Yichang to Hankou (Wuhan), however, the runoff curve increases but the load curve reduces and the black area is much smaller, which implies a huge amount of sediment deposits in the reach between the two stations. At Datong Station the period from the mid of the 1950s to the end of the 1960s is a "black" period, during which more sediment load than the average came to the estuary. Since then the sediment load has been continuously reducing and the load curve is much lower than the runoff curve.

The middle and lower reaches of the Yangtze River are alluvial and the sediment load varies in accordance with the sediment carrying capacity of the flow. Thus, sediment load is related to the flow discharge. Figure 8 shows the relations between the total sediment load and water discharge at the Yichang, Hankou, and Datong stations in different seasons. At Yichang (upper reaches), the sediment load is always proportional to the flow discharge because both sediment and water are from the upper reaches. At Hankou and Datong Stations (middle and lower reaches), however, the sediment load is proportional to the flow discharge in the low flow season from January to June and from October to December, but the load is not related to the discharge in the flood season from July to September. In the middle and lower reaches, sediment consists mainly of bed material load in the low flow season. The higher the flow discharge, the more sediment is eroded from the channel bed, and, therefore, the higher the sediment load. In the flood season, however, a lot of sediment is transported from upstream reaches but half of the water is from the middle and lower reaches. Sediment and water are from different reaches and a huge amount of sediment load is wash load, therefore, the sediment load is not strongly related to flow discharge.

Wang & Dittrich (1992) used the Rouse number Z to differentiate wash load and bed material load, in which the Rouse number is defined as:

$$Z = \frac{\omega}{\kappa U_*} \tag{3}$$

in which ω is the fall velocity of the sediment particles; $\kappa = 0.41$ is the von Karman constant, and $U_* = \sqrt{gsR}$ is the shear velocity, s is bed slope, R is the hydraulic radius of the flow and is equal to the average depth in a wide river channel. Wang and Dittrich analyzed the rate of sediment transportation at high concentrations under different flow conditions and found that some coarse sediment may wash downstream for several hundred kilometers without exchange with the bed sediment at high flow intensities. Thence they

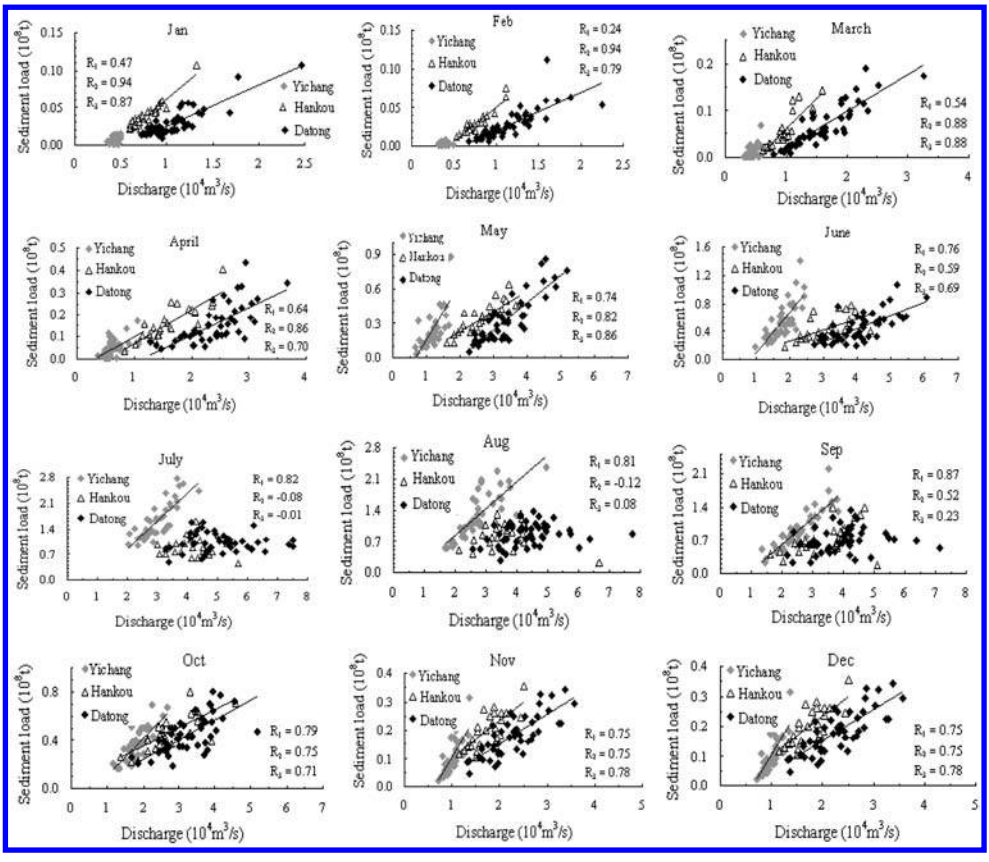

Figure 8. Relations between the sediment load and flow discharge at the Yichang (1, upper reaches), Hankou (2, middle reaches) and Datong (3, lower reaches) stations in different seasons, where Rn is the correlation coefficient of these relations.

proposed the following for identification of bed load, suspended bed material load, and wash load:

$$Bed\ Load > Z = 3 > Suspended\ Bed\ Material\ load > Z = 0.06 > Wash\ Load \quad (4)$$

Figure 9 shows the calculated Rouse number at the Datong station in flood and low flow seasons as a function of the flow depth. In the calculation the fall velocity is determined for the median diameter of the suspended sediment load. In the low flow season, the Rouse number is in the range of 0.1–0.25 and the suspended sediment is bed material load; and in the flood season, however, the Rouse number is mostly smaller than 0.06 and thence the suspended sediment is wash load.

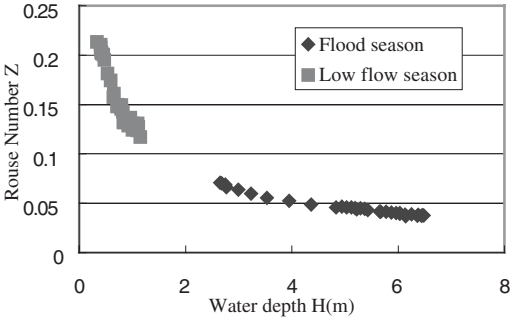

Figure 9. The calculated Rouse number at the Datong station in flood and low flow seasons as a function of the flow depth.

4 FLUVIAL PROCESS IN THE MIDDLE AND LOWER REACHES

The fluvial process and lateral movement of the channel is now constrained by the grand levees in the middle and lower reaches of the river. Sediment deposition and erosion mainly affect the longitudinal profile of the river. According to the minimum stream power theory, the morphology of fluvial rivers develops to reach

Copyright © 2006 Taylor & Francis Group plc, London, UK

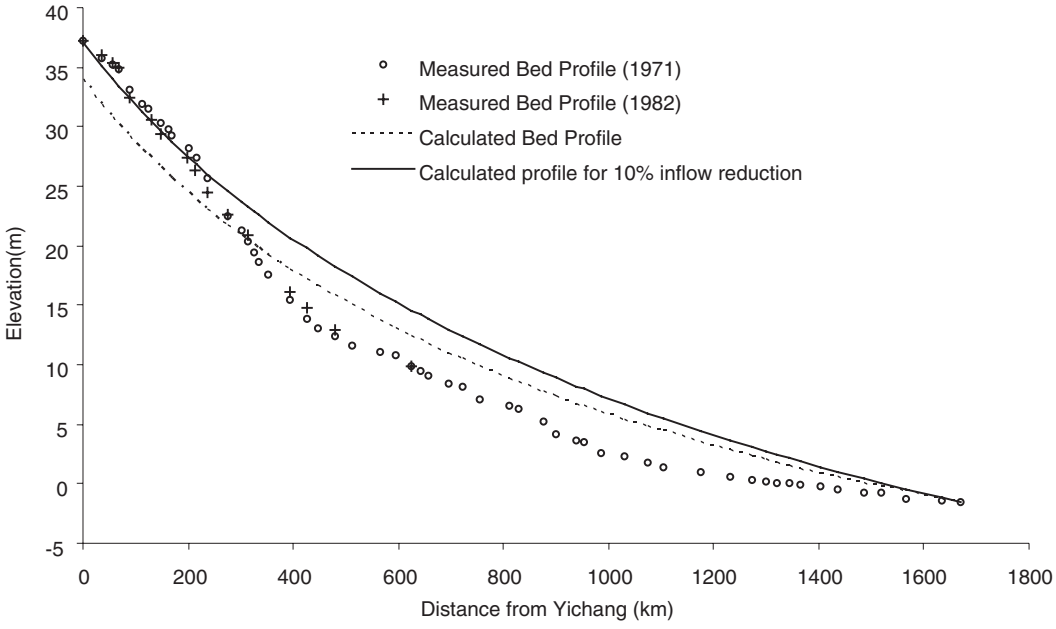

Figure 10. Longitudinal bed profiles of the middle and lower Yangtze River in comparison with the equilibrium bed profile required to reach the minimum stream power.

the minimum stream power (Yang 1996). This can be described by the following equation:

$$\frac{dP}{dx} = \frac{d}{dx}(\gamma s Q) = \gamma(Q\frac{ds}{dx} + s\frac{dQ}{dx}) = 0 \qquad (5)$$

in which Q is the annual discharge, γ is the specific weight of water, s is the bed slope and x is the distance down the river. The equilibrium bed slope can then be calculated with the following formula:

$$s_{n+1} = \frac{s_n}{Q_n}[Q_n - \frac{\Delta Q_n}{\Delta x_n}(x_{n+1} - x_{n-1})] \qquad (6)$$

For the fluvial reaches of the Yangtze River (downstream from Yichang), the discharge increases along the course due to the inflow from tributaries; thus, the equilibrium slope decreases along the course. The river exhibits a concave downward riverbed profile, as shown in the measured profiles in 1971 and 1981 in Figure 10. The fluvial process is developing toward the calculated profile (dashed curve). The inflow of water from the tributaries in the middle and lower reaches is reducing due to water diversion for economic development and agriculture. Assuming a reduction in the reach of about 10%, the equilibrium river bed profile will be different as shown in Figure 10 (solid curve). It is clear that the measured bed profile develops toward the equilibrium profile.

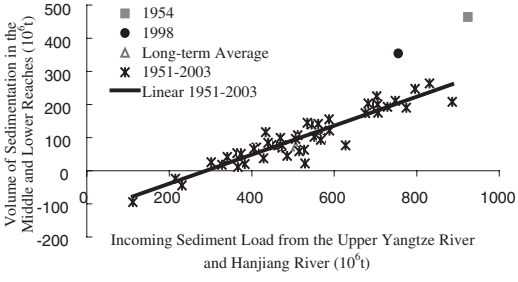

Figure 11. Relation of the net sedimentation in the middle and lower Yangtze River with the incoming sediment load from the upper Yangtze River (measured at Yichang) and the Hanjiang River (sedimentation in Tongting Lake is not included in the net sedimentation).

The equilibrium bed profile is higher than the present profile and sedimentation dominates the fluvial process of the middle and lower reaches. Still a huge amount of sediment is needed for the riverbed to reach the equilibrium profile. Nevertheless, the volume of annual sedimentation in the middle and lower reaches depends on the incoming load. Generally speaking, the higher the incoming sediment load from the upper reaches, the more sediment deposits in the middle and lower reaches. Figure 11 shows the relation between the net sedimentation (the volume of sedimentation minus erosion) and incoming sediment load

Copyright © 2006 Taylor & Francis Group plc, London, UK

from the upper reaches (measured at Yichang) and the Hanjiang River, in which the sedimentation in Tongting Lake is not included in the net sedimentation. The sediment load from Yichang and the Hanjiang River is more than 95% of the total sediment transported into the middle and lower reaches of the Yangtze River, to which the total incoming load refers in the following text. The net sedimentation in the middle and lower reaches increases linearly with the total incoming load. If the total incoming load is more than 280 million tons, sedimentation occurs in the river; if the total incoming load is around 500 million tons, 100 million tons of the sediment will deposit in the river. In the period of 1955–2000, the annual siltation rate of the average riverbed elevation for several reaches is as follows:

Yichang – Chenglingji −2.7 cm/yr;
Chenglingji – Luoshan +1.0 cm/yr;
Luoshan – Hankou +2.0 cm/yr;
Hankou – Jiujiang +3.0 cm/yr;
Jiujiang – Datong +1.8 cm/yr.

If there were no interruption by human activities, the fluvial process to reach the minimum stream power would continue for a long period of time because the present bed profile is still far from the equilibrium profile.

5 SEDIMENTATION IN THE THREE GORGES RESERVOIR

The Three Gorges Reservoir, which is still under construction and will have a storage capacity of 39 billion m^3. The reservoir, located 37 km upstream of the Yichang Station, began to fill in June 2002. The pool level is now around 140 m and will rise to the normal pool level of 175 m in 2009. The filling of the reservoir has caused further reduction in the sediment load to the middle and lower reaches. The reservoir is trapping sediment and releasing flow starving of sediment. The rate of sedimentation in the reservoir depends mainly on the pool levels and operation scheme. The normal pool level (NPL) is set at 175 m, and the flood control level (FCL), to which the pool will be drawn down at the beginning of the flood season generally in June, is set at 145 m. The reservoir is impounded to 175 m after the flood season, usually from the beginning of Oct. and drawn down to 145 m before and during flood. FCL is the major factor affecting the sediment deposition amount in the reservoir.

The main strategy for sedimentation control is "storing the clear and releasing the turbid" (Sedimentation Panel 1988). Sediment transportation in the Yangtze River occurs, of 80–90% of annual sediment load with 50–60% of annual runoff water, in 2–4 months of the flood season. The pool level is drawn down from 175 m to 145 m from June to September when

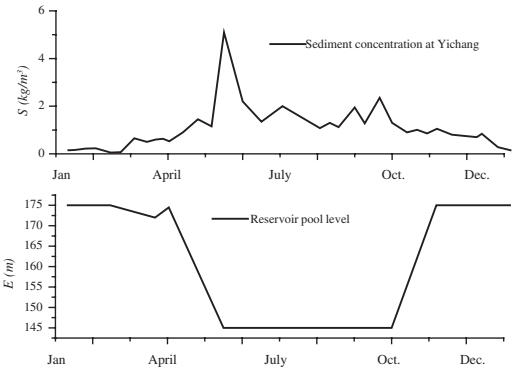

Figure 12. Typical processes of sediment concentration at Yichang and the operational pool level of the reservoir for sedimentation control.

the sediment concentration is high, allowing the turbid water wash through the dam. The reservoir stores water from October when the income water becomes clear. Figure 12 shows the typical seasonal variations of sediment concentration at Yichang and the operational pool level for sedimentation control, in which the distribution of sediment concentration is the average in the 1960s.

By employing the strategy of "storing the clear and releasing the turbid", much less sediment will deposit in the reservoir while the reservoir will be still able to store enough water for power generation in the low flow seasons. Although the pool level is drawn down to FCL, the stage in a 400 km long reach within the reservoir is 10–70 m higher than those without the dam and the average velocity is much slower. For a discharge of 30,000 m^3/s, the average velocity would be 1.5–3.5 m/s if there were no dam, and it is only 0.3–1.3 m/s with the dam. Therefore, sedimentation occurs and the riverbed is silted up.

The sedimentation in the TGP reservoir is calculated with numerical models. Han developed a one-dimensional mathematical model of sedimentation based on the equation of on-equilibrium transport of sediment. In the model Han employed the Manning's formula, the continuity equation and the following sediment equation (Han 1979, Lin et al. 1983):

$$\frac{\partial(hS)}{\partial t}+\frac{\partial(qS)}{\partial x}+\alpha\omega(S-\Phi)=0 \qquad (7)$$

where h is the depth of flow, S the mean concentration of sediment in a cross section, q the water discharge per unit width, ω the fall velocity of sediment, α a variable coefficient. The subscripts x and t denote the independent variables in partial differentiation. Φ is the mean concentration of sediment corresponding to the capacity of sediment transport and represents

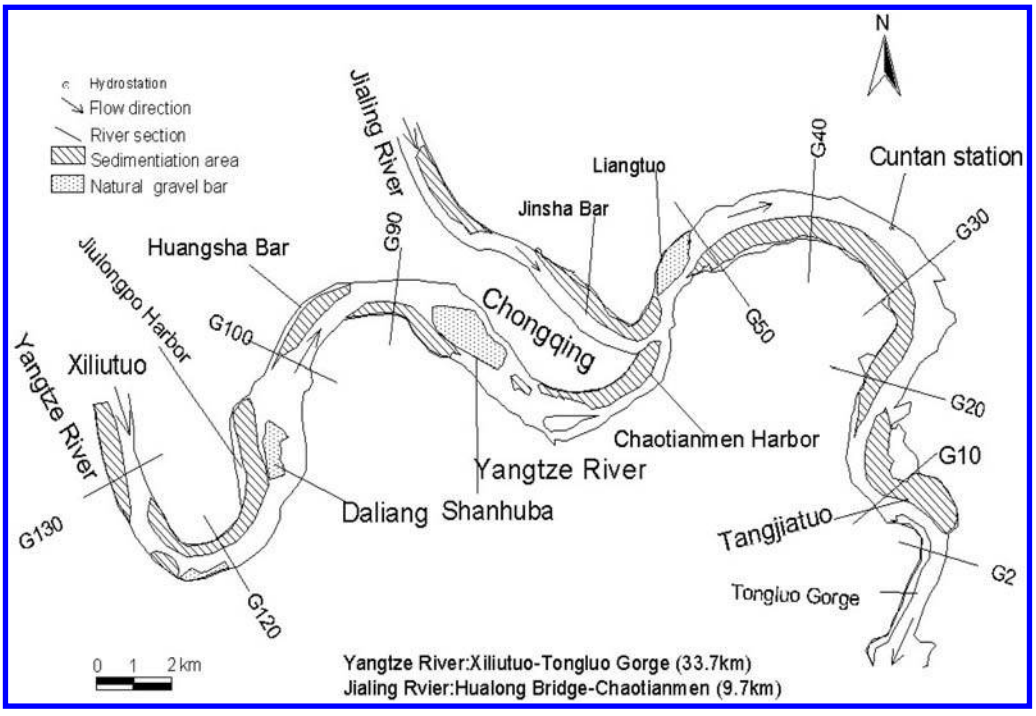

Figure 13. Sedimentation in the Chongqing reach after 80 years operation of the TGP reservoir (Physical model experimental results). The shadowed areas indicate the places where cumulative sedimentation would occur. G2 – G130 represent the measurement cross sections (Wang et al. 1990).

the suspended sediment-carrying capacity of the flow, which is given by:

$$\Phi = 0.03 \frac{Q^{2.76} B^{0.92}}{A^{3.68} \omega^{0.92}} \quad (8)$$

in which Q is the discharge, A is the wet area and B the width of the channel. In this model, Han specifies the values of α to be 0.25 for the case of deposition and 1.0 for the case of erosion on the basis of considerable amount of field data.

Calculation with the numerical model shows that the sedimentation volume in the reservoir will be 8 billion m^3 in 30 years, 14 billion m^3 in 60 years, and 16 billion m^3 in 90 years. Then the accumulative sedimentation amount will approach equilibrium and will increase very slowly thenceforth. The total sedimentation in 120 years will be about 17 billion m^3 (Sedimentation Panel of TGP 2002).

The impoundment of the reservoir also caused sedimentation in the fluctuating backwater region, in which the water level in the low flow season will be higher than before the impoundment but will be the same as before in flood season as the pool level reduces to 145 m. Sediment deposits during the low flow season and can not be scoured down before the flood season, which causes thence problems for navigation and harbor operation. The industrial hub – Chongqing City – is located at about 600 km upstream of the dam and is in the fluctuating backwater region. The Jialing River flows into the Yangtze River at Chongqing. In Chongqing, Chaotianmen harbor is a passenger ship terminal and Jiulongpo Harbor is the most important freight ship terminal in southwest China.

Scale model experiments have been performed to study the sedimentation problems in a 33 km-long section around Chongqing. The experiments showed that impoundment of the reservoir will cause sediment deposition at the apron of the harbors, as shown in Figure 13. The shadowed areas in the figure indicate the places where cumulative sedimentation would occur. There are two channels separated by the Daliang Bar. Water flows in the west channel during low flow season and the main stream flow shifted to the east channel during flood, but the west channel maintains around-the-year a depth over 3 meters, which is necessary for the harbor. After 80 years impoundment of TGP, however, cumulative sedimentation would occur in the west channel, which could result in blockage of the channel eventually. The harbor facilities would not be usable if dredging or other technical measures were not taken. The experiments demonstrated that

Copyright © 2006 Taylor & Francis Group plc, London, UK

the problem can be solved by building spur dykes and groins to regulate the flow. The dykes and groins will narrow the channel and concentrate the flow, so that flow velocity in the west channel can be enhanced, which can prevent sediment from depositing (Wang et al., 1990). With a budget of about $ 100 million, the regulation works will be able to control sedimentation and preserve and improve the navigation and harbor conditions within the Chongqing reach.

6 DEGRADATION OF THE MIDDLE AND LOWER YANGTZE RIVER DUE TO THE THREE GORGES RESERVOIR

Because the TGP reservoir will release clear water to the downstream reaches during non-flood season, the riverbed will be scoured down. The discharge will be higher from January to May but lower from October to November than those without the dam (Fig. 14a). It will remain unchanged during flood season from July to September. Sediment load to the downstream reaches will be less due to trapping in the reservoir. Figure14b shows the calculated annual sediment load released to the downstream reaches, compared with the annual sediment load at Yichang under natural conditions (recycle of the data in the period 1961–1970). The sediment load will be greatly reduced by the trapping of the reservoir in the first 50 years. The load reduction must cause degradation of the downstream reaches (Tsinghua 2002).

The 1-D model by Han calculated the amount of sediment that will be scoured from the riverbed from Yichang to Wuhan. The clear water released from the TGP reservoir will scour 1.7 billion m^3 in the first 20 years, about 2.9 billion m^3 in 40 years, 3.7 billion m^3 in 60 years and 3.9 billion m^3 in 80 years. Thence, resiltation will occur. The scour and reduction of riverbed will cause flood stage reduction, which will be 3 m at Shashi and 0.75 m at Wuhan for a flood of discharge 30,000 m^3/s. The riverbed scour and stage reduction will be more obvious in a reach near the dam. The riverbed of a 150 km long reach from Yichang to Shashi will be scoured down by more than 0.5 m in first 20 years with a total scoured sediment volume of 252 million m^3. Gravel bed section will be scoured down by about 0.5 m and some sand bed sections may be scoured by about 10 m. The flood stage then will be reduced by more than 1.5 m in the reach (Sedimentation Panel 2002).

In the numerical model the data of water and sediment load measured in 1961–1970 were used. In the past 20 years the sediment load to Yichang has remarkably reduced, as shown in Figure 7. This trend is continuing because more and more reservoirs with different scales have been built in the river basin and more and more sediment load is trapped by the reservoirs. There were 45,647 reservoirs of different sizes in the Yangtze

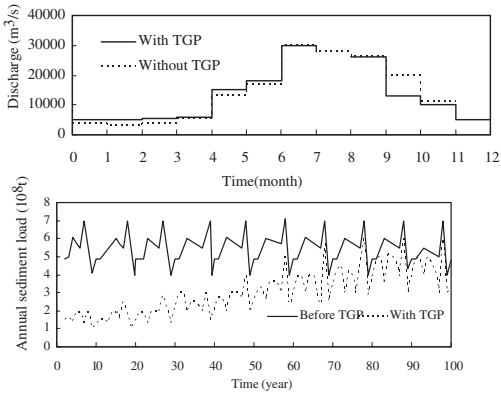

Figure 14. (a) Month-mean discharges under the natural conditions and with the regulation of the TGP reservoir. (b) Variation process of annual sediment load released to the downstream reaches from the reservoir compared with the annual sediment load at Yichang under natural conditions (recycle of the data in the period 1961–1970) (Sedimentation Panel, 2002).

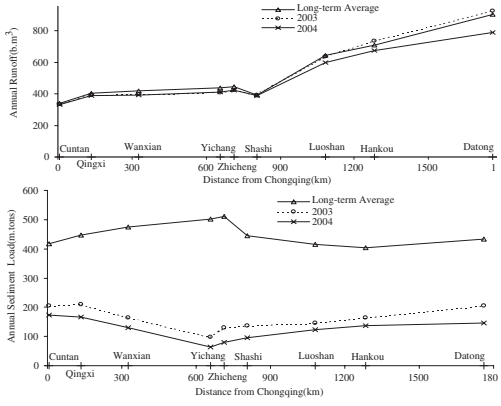

Figure 15. The annual runoff and sediment load after the impoundment of the Three Gorges Reservoir in comparison with the long-term (1951–2001) average values at the hydrological stations along the Yangtze River (after Sediment Panel 2005).

River basin with a total storage capacity of 170.5 billion m^3 up to 2003, among which 143 reservoirs are large with storage capacities over 100 million m^3. The real sediment load entered into the reservoir and released to the middle and lower reaches are less than the calculated values. Figure 15 shows the distributions of runoff and sediment load along the course in 2003 and 2004, in which the long-term average distributions of runoff and sediment load in the period of 1950–2002 are shown for comparison. The distributions of runoff in 2003 and 2004 are almost the same as the long-term average but the distribution of sediment load

Copyright © 2006 Taylor & Francis Group plc, London, UK

changed greatly. The long-term average sediment load reduced from Yichang to Hankou due to sedimentation in the reach; but the sediment load in 2003 and 2004 increases from Yichang to Hankou because the sediment concentration is too low and erosion occurred in the reach. It is predicted that riverbed erosion will dominate the fluvial process for 40 years (Wang et al. 2005). The figure also shows that the released sediment load at Yichang is more than half of the sediment load entered into the reservoir at Cuntan because the pool level was maintained around 140 m. In other words, the strategy "storing the clear and releasing the turbid" may control reservoir sedimentation.

7 CONCLUSIONS

Sediment transportation in the Yangtze River is complex. The total soil erosion from upper Yangtze River basin is about 2.2 billion tons per year, of which 1.7 billion tons deposit in the gullies and tributaries and about 0.5 billion tons are transported into the upper Yangtze River. Debris flow is the main form of sediment transportation from numerous gullies to the tributaries of the upper Yangtze River. The annual runoff increases from upstream to downstream along the course but the annual sediment load increases from the source to Yichang (the Three Gorges Dam site) reaching its highest amount of about 500 million tons/year, and then reduces along the course in the middle reaches. In the upper reaches of the Yangtze River, the sediment load is proportional to the flow discharge because both sediment and water are from upper reaches. In the lower reaches, however, sediment comes from upstream reaches in flood season, but half of the water is from the middle and lower reaches. A huge amount of sediment load is wash load, thence sediment load exhibits a very poor relation with flow discharge. In low flow season, not enough sediment is transported from the upper reaches, and much sediment load is from the riverbed. Therefore, the sediment load in low flow season consists mainly of bed material load and is proportional to the flow discharge. The riverbed profile in the middle and lower reaches is developing toward the equilibrium profile of minimum stream power but the impoundment of the Three Gorges Reservoir interrupts the fluvial process. The annual sediment load in the Yangtze River has reduced due to sediment trapping in numerous reservoirs. And the reduction is even higher after the impoundment of the Three Gorges Reservoir. The middle reaches of the river have changed from siltation to erosion because the sediment concentration released from the Three Gorges Reservoir is too low. It is predicted that riverbed erosion will dominate the fluvial process for 40 years. The first two years operation of the reservoir shows that more than half of the sediment load entered into the reservoir can be released to the downstream reaches.

Unsteady turbulence characteristics in an undular bore

C. Koch
Formerly: Civil Engineering, The University of Queensland, Brisbane, Australia

H. Chanson
Civil Engineering, The University of Queensland, Brisbane, Australia

ABSTRACT: When a river mouth has a flat converging shape with a tidal range exceeding 6 to 9 m, the river may experience a tidal bore. A tidal bore is a positive surge, and the aim of the study is to detail the turbulent field beneath an undular bore. New unsteady experiments were conducted in a large channel. Turbulence measurements were performed with high-temporal resolution using side-looking acoustic Doppler velocimetry. Detailed turbulent measurements were conducted along a vertical profile for a Froude number of 1.4. Instantaneous velocity measurements showed a marked flow deceleration at all vertical elevations. Turbulent stresses were deduced from high-pass filtered data. Maximum Reynolds stresses were observed beneath the whelps, under and just before each crest. The findings suggest that preferential bed erosion takes place beneath each wave crest, and the eroded material is advected in the undular wave motion behind the bore front.

1 INTRODUCTION

In macro-tidal estuaries, a tidal bore may form during spring tide conditions when the flood tide is confined to a narrow channel. The bore is a series of waves propagating upstream as the tidal flow turns to rising (Fig. 1). The occurrence of tidal bores has a significant impact on river mouths and estuarine systems. Bed erosion and scour take place beneath the bore front while suspended matters are carried upwards in the ensuing wave motion. The process contributes to significant sediment transport with deposition in upstream intertidal areas. Tidal bores induce also strong mixing and dispersion in the river mouth, but classical mixing theories do not account for such type of discontinuities. The existence of tidal bores is based upon a fragile hydrodynamic balance which may be easily disturbed by changes in boundary conditions and freshwater inflow (e.g. Chanson 2004a, 2005a).

There are numerous visual accounts of tidal bores. Most occurrences showed well-defined undulations behind the leading wave, that is an undular bore process. The other type of bore is the breaking bore that is rarely seen, but for a few exceptions. Field measurements in tidal bores are very limited and most studies recorded a limited number of parameters with relatively coarse resolutions in terms of time scales, spatial resolutions and velocity magnitudes. All field studies were fixed-point measurements, but a tidal bore is a very dynamic process which extends over several kilometres, sometimes tens of kilometres, and the bore shape and characteristics evolve rapidly with time in response to change in bathymetry. Figure 1B illustrates a tidal bore event in the Baie du Mont Saint Michel, France. The bore front travelled with an average celerity of about 2.7 m/s, but its shape changed constantly with time, sometime disappearing in the deep water channel, while a breaking front was observed in the shallower waters near the banks (Chanson 2005b).

The aim of the study is to detail the turbulence field in an undular tidal bore under controlled flow conditions. New experiments were conducted in a large channel ($L = 12$ m, $W = 0.5$ m). Detailed free-surface and turbulence measurements were performed with high-temporal resolution (50 Hz) using side-looking acoustic Doppler velocimetry and non-intrusive free-surface measurement devices. It is the purpose of this paper to present new compelling evidences on the hydrodynamics of undular bore front.

1.1 *Bibliographic review*

Positive surges and bores were studied by hydraulicians and applied mathematicians. Major contributions included Barré de Saint Venant (1871), Boussinesq (1877), Lemoine (1948), Serre (1953) and Benjamin and Lighthill (1954). Classical experimental investigations of undular bores included Bazin (1865), Favre (1935), Sandover and Holmes (1962), Benet and Cunge (1971) and Treske (1994). Ponsy and

Figure 1. Photographs of undular tidal bores.

Carbonnell (1966) presented superb, detailed three-dimensional free-surface profile measurements in prototype trapezoidal channels. However most experimental studies were limited to visual observations and sometimes free-surface measurements. These rarely encompassed turbulence but a few limited studies (e.g. Hornung et al. 1995).

Field measurements in tidal bores are few: e.g., Lewis (1972) and Huntley (2003) in the Dee river (UK), Wolanski et al. (2004) in the Daly river (Australia), Kjerfve and Ferreira (1993) in Rio Mearim (Brazil). All these studies were limited to a very small number of occurrences.

2 EXPERIMENTAL FACILITIES

2.1 *Channel and instrumentation*

Experiments were performed in a 0.5 m wide 12 m long horizontal flume (Fig. 2). Waters were supplied by a constant head tank. A tainter gate was located next to

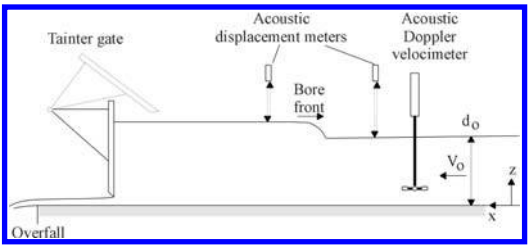

Figure 2. Sketch of experimental channel.

the downstream end of the channel ($x = 11.15$ m). Its controlled and rapid closure induced a positive surge propagating upstream. Steady flow rates were measured with bend meters which were calibrated in-situ with a large V-notch weir. The percentage of error was expected to be less than 2%. In steady flows, the water depths were measured using rail mounted pointer gauges and acoustic displacement meters. Unsteady water depths are measured with acoustic displacement meters Microsonic™ Mic + 25/IU/TC with an accuracy of 0.18 mm and a response time of 50 ms. The acoustic displacement readings were compared with instantaneous free-surface profiles captured with a high-speed camera. The results were found to be within the accuracy of the systems, although a few spurious points were sometimes observed. The displacement meter output was a function of the strength of the acoustic signal reflected by the free-surface. When the free-surface was not horizontal, some erroneous points were recorded. These were relatively isolated and easily ignored.

In steady flows, velocity measurements were conducted with a Prandtl-Pitot tube (3.3 mm Ø) previously calibrated as a Preston tube based upon in-situ experiments (Chanson 2000). Turbulent velocity measurements were conducted with an acoustic Doppler velocimeter Sontek™ 16 MHz micro-ADV at $x = 5$ m. The probe sensor had a two-dimensional side-looking head with a distance to sampling volume of 5 cm. With this arrangement, the closest measurement distance from the bed was 7.2 mm. The V_x velocity component was aligned with the longitudinal flow direction and positive downstream, while the transverse velocity component V_y was oriented normal to the channel sidewall and positive towards the left sidewall. The velocity range was 1.0 m/s, most unsteady flow experiments were conducted with 50 Hz sampling rate and the data accuracy was 1%. The translation of Pitot tube and ADV probe in the vertical direction was controlled by a fine adjustment travelling mechanism connected to a Mitutoyo™ digimatic scale unit. The error on the vertical position of the probe was $\Delta z < 0.025$ mm. The accuracy on the longitudinal position was estimated as $\Delta x < \pm 2$ mm. The accuracy on the transverse position of the probe was less than 1 mm.

Additional informations were obtained with digital cameras Panasonic™ Limux DMC-FZ20GN and Canon™ A85, and a digital video-camera Sony™ DV-CCD DCR-TRV900. Further details on the experimental facility were reported by Koch and Chanson (2005).

2.2 *Tidal bore generation*

For each experiment, the initial steady flow was uncontrolled and gradually-varied. It was established for at least 10 minutes prior to measurements. A bore was generated by the rapid partial closure of the downstream gate. The gate closure occurred in less than 0.1 sec. Flow measurements and data acquisition were started for 2 minutes prior to gate closure. After gate closure, the travelling bore propagated upstream against the gradually-varied flow over the full channel length. Each experiment was stopped when the bore front reached the intake structure. Tests were repeated systematically for different gate closures (Table 1).

Detailed velocity and free-surface elevation measurements were performed with the acoustic Doppler velocimeter (ADV) located at $x = 5$ m from the channel intake and at several transverse positions $y/W = 0.5$, 0.75, 0.90 and 0.95, where x is the distance from the upstream channel end, y is the transverse distance measured from the right sidewall and W is the channel width ($W = 0.5$ m). The acoustic displacement meters were located at $x = 10.95$ m, 7.25 m, 6 m, 5.1 m and 5 m. The latter displacement meter sampled the free-surface elevation immediately above the ADV sampling volume, while the other sensors were placed on the channel centreline.

2.3 *Initial steady flow conditions*

The initial steady flow was partially-developed with $\delta/d_o = 0.6$ to 0.8 at the sampling location ($x = 5$ m). Both ADV and Prandtl-Pitot tube data compared favourably with a 1/7th power law in the boundary layer. The shear velocity was estimated using the Preston-Prandtl-Pitot tube and a match between velocity data and logarithmic velocity law in the inner flow layer. The results were close and yielded: $V_* = 0.044$ m/s. Importantly, the data, including the vertical distributions of Reynolds stresses, showed good qualitative and quantitative agreement with the detailed experiments of Xie (1988) and Tachie (2001) in smooth open channel flows. Further details on the initial flow properties were described in Koch and Chanson (2005, pp. 21–37).

2.4 *Acoustic Doppler velocity metrology*

Acoustic Doppler velocimetry (ADV) is designed to record instantaneous velocity components at a single-point with relatively high frequency. Past and present experiences demonstrated many problems. In steady turbulent flows, the ADV velocity fluctuations characterise the combined effects of the Doppler noise, signal aliasing, velocity fluctuations, turbulent shear and other disturbances (Lemmin and Lhermitte 1999, McLelland and Nicholas 2000, Chanson et al. 2005). For all experiments, present experience demonstrated recurrent problems with the velocity data, including low correlations and low signal to noise ratios. The situation improved by mixing some vegetable dye (Dytex Dye™ Ocean Blue) in the entire water recirculation system. Other problems were experienced with boundary proximity.

In steady flows, detailed comparisons between ADV and Prandtl-Pitot tube data were conducted at $y = 0.473$, 0.450, and 0.375 m (or 27, 50 and 125 mm from the left sidewall) with the micro ADV sensors facing the left sidewall, where y is the transverse distance from the right wall. Experimental data indicated that the streamwise velocity data were not affected by the presence of the channel bed at $y = 0.450$ and 0.375 m as observed at $y = 0.250$ m. But the ADV data underestimated the velocity in the vicinity of a sidewall ($y > 0.455$ mm). This was associated with a drastic decrease in average signal correlations, average signal-to-noise ratios and amplitudes next to the wall (Koch and Chanson 2005).

While several ADV post-processing techniques were devised for steady flows (e.g. Goring and Nikora 2002, Wahl 2003), these post-processing techniques are not applicable to unsteady flows (e.g. Nikora 2004, *Person. Comm.*, Chanson et al. 2005). In the present study, unsteady flow post-processing was limited to a removal of communication errors and a replacement by interpolation. Beneath the undular surge, the ADV probe outputs showed systematically a lower proportion of errors and "spikes" while the bore front passage was associated with some increase in average

Copyright © 2006 Taylor & Francis Group plc, London, UK

signal-to-noise ratios, average signal correlations and to a lesser extent signal amplitudes. Although these observations were not "true" validation, they tended to support the use of Acoustic Doppler devices in such a highly unsteady flow situation.

2.5 *Reynolds stress calculation in rapidly-varied flow motion*

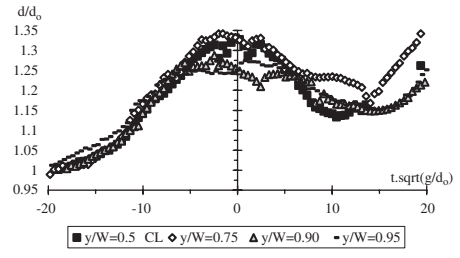
In turbulence studies, the measured statistics are based upon the analysis of instantaneous turbulent velocity data : $v = V - \bar{V}$, where $\bar{V}$ is a time-average velocity. If the flow is "gradually time-variable", $\bar{V}$ must be a low-pass filtered velocity component, or variable-interval time average VITA (Piquet 1999). The cutoff frequency must be selected such that the averaging time is greater than the characteristic period of fluctuations, and small with respect to the characteristic period for the time-evolution of the mean properties.

In undular surge flow, the Eulerian flow properties showed an oscillating pattern with a period of about 2.4 s that corresponded to the period of the free-surface undulations. The unsteady data were therefore filtered with a low/high-pass filter threshold greater than 0.4 Hz (i.e. 1/2.4 s) and smaller than the Nyquist frequency (herein 25 Hz). The cutoff frequency was selected as 1 Hz based upon a sensitivity analysis (Koch and Chanson 2005, pp. A51-A55). The same filtering technique was applied to both streamwise and transverse velocity components, and Reynolds stresses were calculated from the high-pass filtered signals.

3 UNDULAR BORE FREE-SURFACE PROFILES

3.1 *Presentation*

Undular bores were observed for surges Froude numbers less than 1.7, where the surge Froude number is defined as:



$$Fr = \frac{U + V_o}{\sqrt{g\, d_o}} \quad (1)$$

with V_o is the initial flow velocity, U is the bore front celerity for an observer fixed on the bank, g is the gravity acceleration and d_o is the initial water depth (Henderson 1966, Chanson 2004a,b). Measured initial depths and surge celerities are listed in Table 1.

The undular bores propagated upstream relatively slowly and the bore front was followed by a train of well-formed undulations. For low surge Froude numbers ($1 \leq Fr < 1.4$ to 1.5), the free-surface undulations had a "smooth" appearance and no wave breaking wave observed. Some cross-waves were seen developing upstream of the first wave crest and intersecting next to the first crest (Fig. 3A). For intermediate surge

(A) Photograph of advancing undular bore, looking downstream with cross-waves intersecting on the first wave crest

(B) First wave crest free-surface profiles at x = 5 m and 4 transverse locations

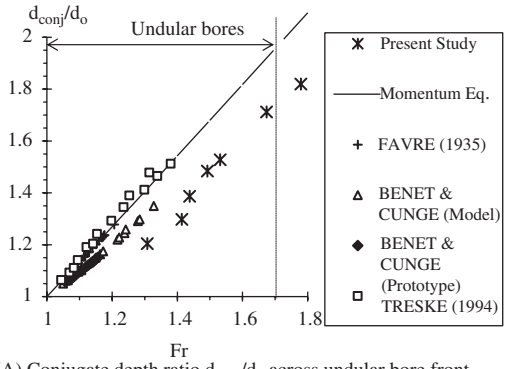


Figure 3. Undular bore free-surface profile ($Fr = 1.4$, $d_o = 0.079$ m).

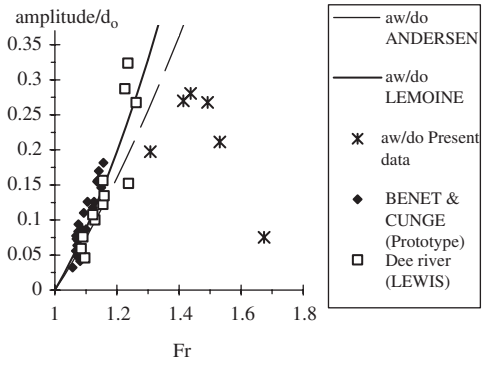
Froude numbers (i.e. 1.4 to 1.5 < Fr < 1.7), some slight wave breaking was observed at the first crest, and the ensuing free-surface undulations were flatter. For larger Froude numbers (i.e. $Fr \geq 1.7$), a breaking surge was seen.



Typical instantaneous free-surface profiles are presented in Figure 3B. Each curve shows the instantaneous dimensionless flow depth d/d_o as a function of a dimensionless time $t\sqrt{g/d_o}$ for the first wave crest. Figure 3B shows data collected at $x = 5$ m for four transverse locations, illustrating the three-dimensional nature of the flow. At the first wave crest, the water levels were higher next to the centreline ($y/W = 0.5$ & 0.75) than next to the sidewall ($y/W = 0.95$ & 0.90) (Fig. 3B).

The data showed a gradual evolution of the undular bore shape as it propagated upstream. It is conceivable that the bore was not fully-developed. However the data tended to suggest a gradual reduction of the bore height with increasing distance from the downstream gate. Such a trend was consistent with a fully-developed bore propagating against a gradually-varied flow with a S2 backwater profiles. In the present study, longitudinal free-surface measurements in steady flows suggested indeed a S2 profile between $x = 5$ and 7 m.

(B) Dimensionless free-surface undulation amplitude (first wavelength) – Comparison between Lemoine's (1948) theory, Andersen's (1978) theory, laboratory data (Present study), prototype data (Benet and Cunge 1971) and tidal bore field observations (Lewis 1972)

Figure 4. Dimensionless properties of undular bores.

3.2 *Undular bore properties*

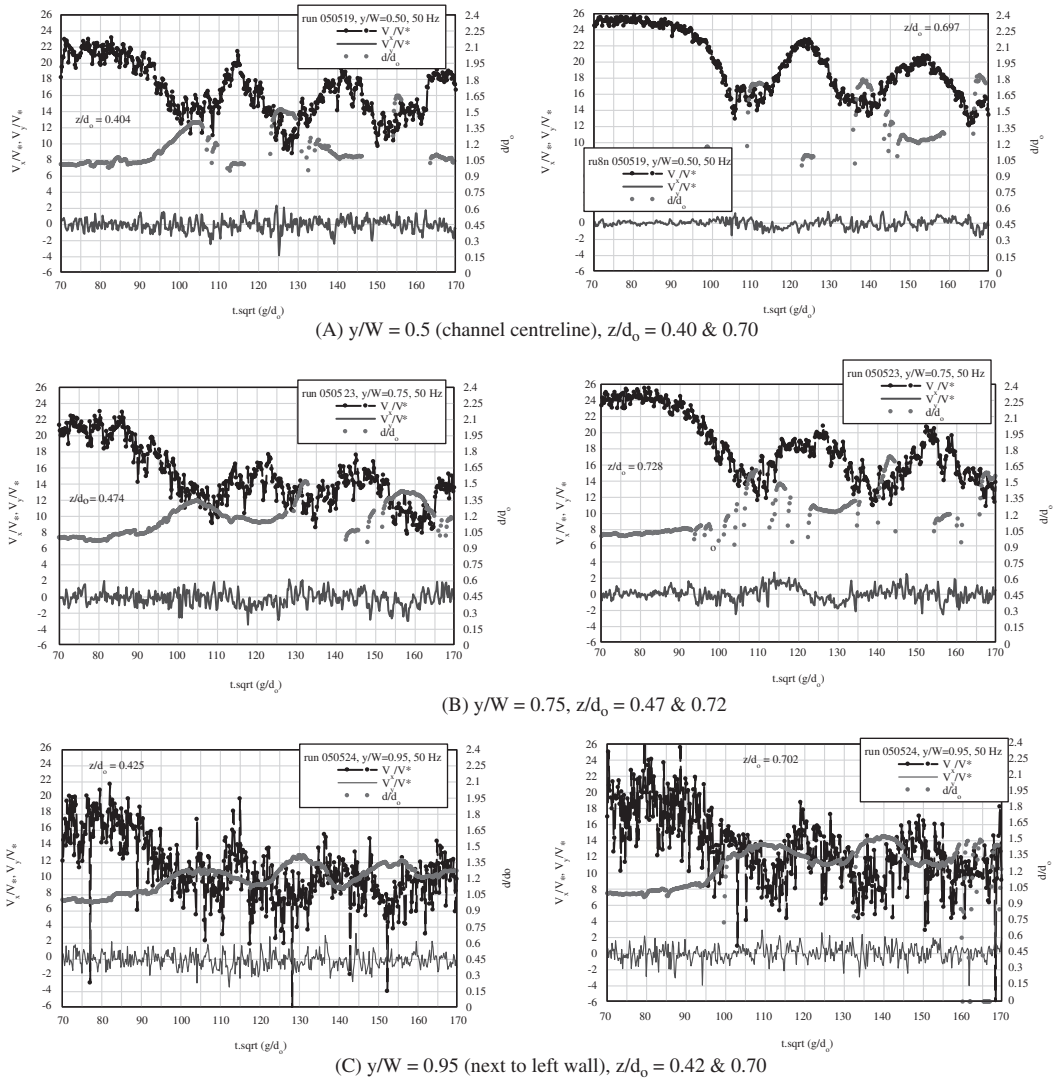
In a fully-developed bore, the ratio of conjugate depths (d_{conj}/d_o) must satisfy the continuity and momentum equations :

$$\frac{d_{conj}}{d_o} = \frac{1}{2} * \left(\sqrt{1 + 8\,Fr^2} - 1 \right) \quad (2)$$

where d_{conj} is the depth immediately behind the bore. Experimental results are presented in Figure 4A, where the ratio d_{conj}/d_o is plotted as a function of the Froude number. Present data are compared with Equation (2) and with past experiments. The data showed slightly lower conjugate depth ratios for $1.1 < Fr < 1.7$. In undular bores, the estimate of the conjugate depth d_{conj} is somewhat arbitrary. For all data the conjugate depth d_{conj} was estimated as the average of wave crest and trough depths. The averaging process assumed a symmetrical wave pattern that was not supported by experimental data.

Undulation amplitude and wave length data were also compared with previous studies and with the theories of Lemoine (1948) and Andersen (1978). Lemoine (1948) assumed that the energy dissipation takes place by radiation of sinusoidal wave train, while Andersen (1978) developed a solution of the Boussinesq equation. Present data showed a good agreement with earlier studies. Interestingly, the data agreed reasonably well with Lemoine's theory although the latter was based upon a sinusoidal wave assumption. Present results do not support claims that cnoidal wave theory yields better agreement with experimental data (e.g. Benjamin and Lighthill 1954).

Figure 4B compares undular wave amplitudes with undular tidal bore observations in the Dee river (Lewis 1972). Note that the wave amplitude (Fig. 4B) decreased sharply immediately before the disappearance of free-surface undulations. Treske (1994) reported a similar trend. It is believed that the flow conditions associated with maximum wave amplitude occurred immediately before the appearance of some wave breaking at the first wave crest: i.e. for Fr ~1.4 to 1.5 in the present study.



4 TURBULENT VELOCITIES BENEATH UNDULAR BORE

4.1 *Instantaneous velocity measurements*

Unsteady velocity measurements were performed beneath an undular bore for a surge Froude number of Fr = 1.4 (Table 1). The acoustic Doppler velocimetry (ADV) system was positioned at x = 5 m and each experiment was conducted at several vertical elevations z and transverse locations y. Figure 5 illustrate the effects of undular bore passage on the turbulent velocity field at a fixed point. Each graph presents the dimensionless velocities V_x/V_* and V_y/V_*, and water depth d/d_o, where d_o is the initial water depth and V_* is the shear velocity measured on the channel centreline in steady flows ($V_* = 0.044$ m/s). The time t is zero at 10 s prior to the first wave crest passage. Figure 5A shows centreline data while Figures 5B and 5C present data at other transverse locations (y/W = 0.75 & 0.95). Figure 6 presents details of the flow field next to the first wave crest.

Experimental results indicated some basic features. The streamwise velocity component decreased rapidly with the passage of the first wave crest and oscillated with time with the same period as and out of phase with the surface undulations (Fig. 5). Maximum velocities were observed beneath the wave troughs and minimum velocities below the wave crests. The trend was seen at all vertical and transverse locations, and it was consistent with irrotational flow theory. Note that the

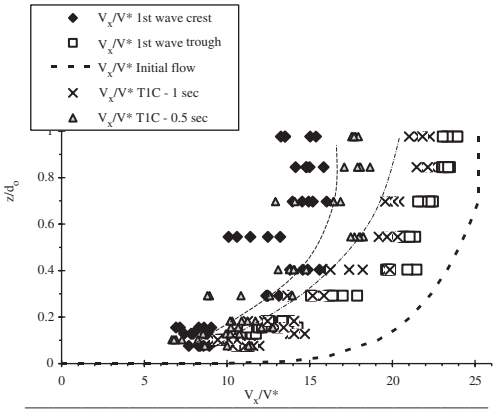
(B) y/W = 0.75, z/d_o = 0.47 & 0.72

(C) y/W = 0.95 (next to left wall), z/d_o = 0.42 & 0.70

Figure 5. Instantaneous dimensionless velocities V_x/V_* and V_y/V_* beneath an undular bore (Fr = 1.4).

streamwise velocities were always positive, although a few negative instantaneous V_x velocities were seldom detected next to the side wall (Fig. 5C).



In the upper flow region ($z/d_o > 0.5$), large fluctuations of velocities were observed beneath the undulations. At a given height, the deviations of instantaneous velocities from an overall data trend were larger than the initial turbulent velocity fluctuations prior to the bore passage. For example, in Figure 5A for $t\sqrt{g/d_o} > 90$ to 100. Since the measurements were Eulerian, the measured fluctuations included the contributions of the velocity deviation from an ensemble average and the time-variation of the ensemble average.

At the highest sampling points (e.g. $z/d_o = 0.7$, Fig. 5A & 5B), the transverse velocity V_y data tended to oscillate with the same period as and in phase with the free-surface.

4.2 *Remarks*

In an undular bore, theoretical considerations and flow net analysis predict significant velocity redistributions between wave crests and troughs associated with

Copyright © 2006 Taylor & Francis Group plc, London, UK

	Initial flow	T1C -1 sec.	T1C -0.5 sec.	1st wave crest	1st wave trough
t(s) =	0	9.0	9.5	10.0	11.05
d/d_o =	1	1.14	1.24	1.80	1.05

Figure 6. Redistributions of dimensionless vertical velocity profiles (V_x/V_*) beneath the first wave crest of an undular surge (Fr = 1.4, centreline data) – At each vertical elevation, 5 instantaneous, consecutive data samples are shown.

pressure gradients greater than hydrostatic beneath wave trough and less than hydrostatic beneath crest (e.g. Rouse 1938, Montes and Chanson 1998). Figure 6 illustrates the redistribution of vertical velocity profiles with time during the propagation of the first free-surface undulation. At each vertical elevation, five instantaneous, consecutive velocity samples are plotted as functions of the vertical elevation. Similarly, five consecutive data samples at each elevation are shown for 1 s before the passage of the first wave crest (T1C–1 sec.), 0.5 s prior to the first crest (T1C – 0.5 sec.), and at the following wave trough. The initial velocity profile is shown in thick dashed line for comparison. Trend lines are shown for (T1C-1 s) and (T1C-0.5 s) also (thin dashed lines).

Present data showed experimental trends that were in agreement with irrotational flow motion theory. But the ideal fluid flow theory is based upon the assumption of frictionless fluid. It does not account for bed and sidewall friction, nor for the initial turbulence flow conditions and turbulence structure. The presence of boundary shear contributes to some energy dissipation as well as the generation of vorticity. When a bore propagates upstream against a current, the average vorticity is positive.

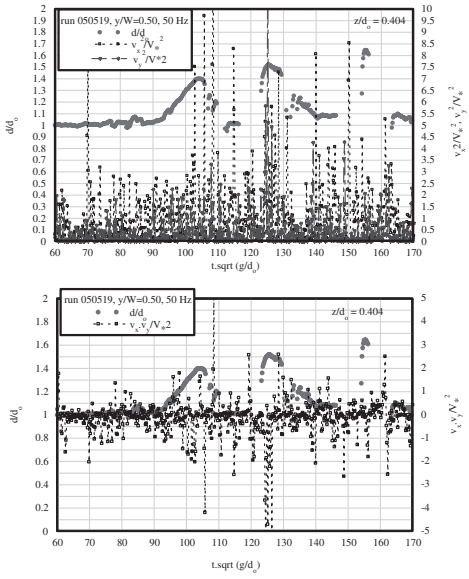
Note also that the velocity redistributions presented a different pattern to that observed beneath undular hydraulic jumps (e.g. Chanson 1995). Several researchers argued that there are indeed fundamental differences between the two types of flows (Montes 1979, Montes and Chanson 1998).

5 TURBULENT REYNOLDS STRESSES BENEATH UNDULAR BORE

5.1 *Instantaneous Reynolds stresses*

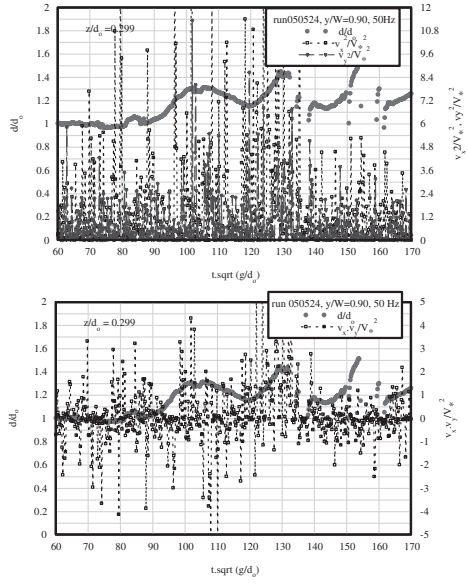
Reynolds stress data showed large turbulent stresses below the surge front and ensuing undulations (Fig. 7). This is seen in Figure 7 for $t\sqrt{g/d_o} > 90$. Figure 7 presents both normal and tangential instantaneous turbulent stresses. Reynolds stresses were significantly larger than in the initial steady flow. In particular, intense normal and tangential stresses were consistently seen beneath wave crests and just before each crest. These turbulent stresses were larger than beneath the adjacent wave troughs (Fig. 7). The data showed also larger Reynolds stresses at the lower sampling locations including next to the bed. Comparatively smaller Reynolds stresses were measured at higher sampling locations, although the Reynolds stress levels were always larger beneath the undulations than in the initial steady flow.

5.2 *Turbulent dissipation and mixing*



In a river, the passage of an undular bore is always associated with very significant turbulence and mixing as demonstrated by field observations. Evidences included repeated impact and damage to field measurement equipments: e.g., in Rio Mearim (Kjerfve and Ferreira 1993), in the Daly river (Wolanski et al. 2004), in the Dee river (Lewis 1972). Further demonstrations covered major damage to river banks, shipping and navigation. Other tragic evidences included numerous drownings in tidal bores and "whelps" (Malandain 1988).

At a point fixed in space, the passage of the bore front and ensuing undulations is associated with rapid fluctuations of vertical pressure and velocity distributions between adjacent wave crests and troughs (e.g. Figs. 5 & 6). This type of mixing is supported by strong turbulence measured in undular bores and sediment advection observations behind bore front.



Second, large volumes of sediments are advected upstream behind tidal bores as observed by numerous researchers (Chen et al. 1990, Tessier and Terwindt 1994). In the Rio Mearim, Kjerfve and Ferreira (1993) reported: "*in shallow areas, the water boiled violently after the passage of the bore and became brownish-black*". All studies showed that the arrival of an undular bore was associated with intense bed material mixing. Chanson (2001, 2005a,b) argued that sediment suspension beneath the "whelps" is sustained by strong wave motion for relatively long periods. In the Dordogne river, he observed some intense wave motion lasting more than 20 minutes after the bore passage.

Third some turbulent energy is dissipated in vortical structures advected behind the surge front. The role of

(B) y/W = 0.90, $z/d_o = 0.30$: (B1) Normal Reynolds stresses (v_x^2/V^{*2}, v_y^2/V^{*2}) (B2) Tangential Reynolds stress ($v_x * v_y/V^{*2}$)

Figure 7. Dimensionless normal and tangential Reynolds stresses beneath undular bore (Fr = 1.4).

these large-scale turbulent structures was highlighted by Hornung et al. (1995). It is thought however that these may be highly dependant upon the initial flow conditions. For example, Hornung et al. (1995) studied positive surges propagating in initially still waters,

Figure 8. Surface on the first wave crest of the Amazon river bore (pororoca) (P. Lespinasse 2005, courtesy of FR3 & TV5 Asie).

while the present study investigated a bore propagating against a steady current.

Present experimental evidences showed that the arrival of an undular bore was characterised by very rapid changes in streamwise velocities and by large fluctuations in transverse velocities at all transverse locations. This was associated with relatively large instantaneous turbulent Reynolds stresses beneath the undulations at most vertical elevations (for Fr = 1.4 and $y/d_o < 1$). In Nature, the initial steady flow conditions are often quiescent. The arrival and passage of an undular bore must be associated with significant bed material scour and pickup. Such a sediment erosion process is an Eulerian problem, and present experimental results are directly applicable. The ensuing sediment suspension and advection behind the bore front is a Lagrangian problem however.

In an undular bore, maximum Reynolds stresses were observed beneath the wave crests (Fig. 7), and the results suggested repeated high shear and scour just before and below each wave crest. Eroded bed material is then placed into suspension and advected in the "whelps" and wave motion behind the leading wave. Such a mechanism was proposed by Donnelly and Chanson (2002,2005) based upon a quasi-steady flow analogy.

Note that the present study was conducted in tidal bores resulting from partial gate closure. The experimental setup was selected to generate under controlled flow conditions a range of undular bores with the same initial conditions. It is acknowledged that these initial conditions might not be typical of tidal bores in natural estuaries (Fig. 8) because there was no complete flow reversal after bore front passage. Further present

Copyright © 2006 Taylor & Francis Group plc, London, UK

results focused on the bore front and the short period immediately after bore passage.

6 CONCLUSION

Limited quantitative information is available to date on the turbulence induced by undular tidal bores because the hydrodynamics and turbulence field were not studied with fine instrumentation under well-defined conditions. In the present study, new experiments were conducted under controlled flow conditions in a large channel. Detailed turbulence measurements were performed with a high-temporal resolution (50 Hz) using side-looking acoustic Doppler velocimetry and non-intrusive free-surface measurement devices. The experiments were designed to study a range of undular bores with a minimum number of dependant variables. Using one set of initial flow conditions, experiments were performed in undular surges resulting from a rapid gate closure at the downstream end of the flume and propagating upstream against the initial flow. The only dependant variable was the downstream gate opening after closure.

Undular bores were observed for surges Froude numbers less than 1.7 although some breaking was observed at the first crest for 1.4 to $1.5 < Fr < 1.7$. Free-surface profiles compared favourably with past measurements in positive surge and tidal bores. The present study demonstrated unique features of tidal bore fronts. Velocity measurements with high-temporal resolution showed a marked effect of the bore passage. Longitudinal velocities were characterised by rapid flow deceleration at all vertical elevations, while large fluctuations of transverse velocities were recorded beneath the front. Turbulent Reynolds stress data highlighted high levels in the lower flow region including next to the bed, and maximum normal and tangential stresses were observed immediately upstream of and at wave crests. Hence bed erosion may take place beneath each wave crest, and the eroded material and other scalars are advected in the "whelps" and wave motion behind the first wave crest. These would be consistent with very-strong turbulence levels observed behind tidal bores in the field (Fig. 8).

While the present study allowed a detailed comparison of the effects of undular bores, it was limited to one set of initial flow conditions. Further works should encompass a wider range of inflow conditions and surge generation, including positive surges propagating downstream and tidal bore flows with complete flow reversal.

ABSTRACT: Shear velocity u_* is a well-known fundamental velocity scale of the wall turbulence, widely used for scaling various flow quantities such as mean velocity and turbulent intensities. The definition of shear velocity is closely related to the universal Logarithmic law of the wall, which was originally derived for constant shear stress boundary layers. Because the shear stress is constant, the momentum flux ρu_*^2 is equal to the wall shear stress, so u_* is often understood as some kind of synonym for the wall shear stress. The universal Log-law is also used for the flows with linear shear stress such as pipe flows and uniform open channel flows. In such flows the turbulent momentum flux delivered to the roughness differs from the wall shear stress, but the difference is negligible for the rough walls where boundary layer thickness (flow depth in case of uniform open channel flow), is much larger than roughness height. In rough wall flows where the flow depth and the roughness height are of the similar order, the difference between the turbulent momentum flux representative of the free outer flow and the wall shear stress may become significant. For such flows it is important to distinguish between the wall shear stress and the shear stress used for evaluation of the shear velocity. This paper highlights the problems associated with the definition of the shear velocity in shallow open channel flows and its use for evaluation of the bed shear stress. The influence of the definition of u_* on the data analysis is illustrated using experimental results.

1 INTRODUCTION

Open channel flows over rough beds are of considerable engineering interest, but there are still some uncertainties about them. One of the difficulties in investigating such flows is that flow properties near the bed are spatially inhomogeneous. Instead of studying time-averaged flow properties which vary in space, it is more convenient to investigate double-averaged flow properties, using the double-averaged (in time/ensemble and spatial domains) Navier-Stokes equations. The idea of spatial flow averaging was first introduced in hydraulics by Smith and McLean (1977). The development of a new methodology based on spatially averaged equations was initiated by Wilson and Shaw (1977) for describing atmospheric flows within vegetation canopies. The atmospheric physicists Raupach and Shaw (1982), Finnigan (1985), Raupach et al. (1991), provided the mathematical basis for a new set of equations.

Double-averaging methodology provides clear definitions of some basic concepts in rough bed open channel flow. For instance, although local flow properties near rough bed always vary in space, globally uniform flow is defined by the requirement that the double-average flow properties do not change in the streamwise direction (Nikora et al., submitted). Furthermore DAM provides strict definitions of the spatially-averaged or macroscopic momentum balance, fluid shear stress and bed shear stress.

However, there is one more question about the rough bed flows that has so far been neglected. Rough beds have complex geometry such that the bed level (height above an arbitrary bed-parallel datum) varies in space. In DAM this variation is expressed by a single parameter – the roughness porosity function, equal to volume of water/total volume within the spatial averaging domain (thin bed-parallel slices). The porosity function varies between one, above the roughness crests, and zero (for impermeable bed), below the lowest roughness troughs. At the level of the roughness crest this variation can be abrupt or gradual, depending on the roughness geometry. In either case it is not clear *a priori* where exactly, between roughness crests

Copyright © 2006 Taylor & Francis Group plc, London, UK

and troughs, is the appropriate position of an equivalent imaginary bed i.e. the idealised sharp interface between turbulent flow and the rough wall. This affects the definition of basic concepts such as flow depth and the shear velocity, especially for flows with small relative submergence (flow depth/roughness height ratio).

The shear or friction velocity is usually defined as the velocity scale of the momentum absorbed by the bed. It can be evaluated either at the roughness crests, where the bed starts extracting momentum from the flow, or at the troughs, where the total momentum is absorbed, or somewhere between them. Various versions are present in the literature and yet called the same name. It introduces confusion and makes it difficult to compare published data.

In this paper we present a case for defining the universal velocity scale u_* in rough bed flows from the shear stress at the roughness crests, rather than from the total momentum extracted from the flow i.e. from the bed shear stress. In order to clearly define the bed shear stress we first use DAM to summarise the momentum balance in uniform flows over rough beds. We then revisit the original derivations of the universal Log-law where u_* was first introduced, and point out that the Log-law was first developed for constant shear stress boundary layers, so it does not answer the question about the appropriate definition of the shear velocity. In case of rough bed open channel flows with linear shear stress only the shear velocity associated with the roughness crest has a potential to be universal, so it is adopted as the appropriate velocity scale for scaling flow properties. The consequences of using the velocity scale based on the bed shear stress instead are illustrated using a case from the literature and our own experiments.

2 DOUBLE-AVERAGED OPEN CHANNEL FLOW

We consider steady uniform two-dimensional open channel flow over a rough bed. A right-hand co-ordinate system is used with $x =$ streamwise, $y =$ lateral and $z =$ bed-normal coordinates, and the velocity components in x, y, z direction are denoted by u, v, w respectively (Fig. 1). Roughness height is denoted by k. and the origin of z is placed at the roughness crest. For simplicity, roughness elements have identical height. In natural sediments, where this is clearly not the case, some statistical property of the bed level e.g. $z_{99\%}$can be used as a global level of roughness crest.

The double-averaged momentum equations are obtained by averaging Reynolds equations over thin bed-parallel volumes dV (Fig. 1). These volumes may intersect with the bed so in general they contain both

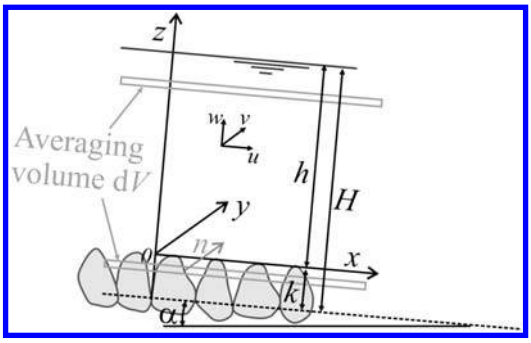

Figure 1. Definition sketch.

water and the grains. The double-averaged momentum equation in x direction is (Nikora et al. 2004)

$$\phi\rho g \sin\alpha = f_x - \frac{\partial \phi \tau_{xz}}{\partial z}, \tag{1}$$

where g = gravitational acceleration, $\rho =$ density, $\alpha =$ angle between the bed and the horizontal datum, $\phi =$ porosity of the rough bed=volume of water/total volume dV, τ_{xz} is the fluid shear stress and f_x is the total drag force exerted by the fluid on the roughness per unit plan area and unit height dz. For an averaging volume above the roughness crests dV contains only water, so $\phi = 1$ and f_x vanishes from the equation. The fluid shear stress is

$$\tau_{xz} = \rho\left\langle \nu \frac{\partial \overline{u}}{\partial z} \right\rangle - \rho\langle \overline{u'w'} \rangle - \rho\langle \tilde{u}\tilde{w} \rangle, \tag{2}$$

where the three terms are the spatially averaged viscous stress, the spatially averaged turbulent stress and the form-induced stress, respectively. The over-bar denotes time average, $' =$ fluctuation, $\langle\ \rangle =$ spatial average and tilde = the deviation of a time-averaged quantity from its spatial average. The drag term is obtained by integrating local pressure and viscous stress over the interface between water and grains, S, within the averaging volume dV:

$$f_x = -\frac{1}{dV}\iint_S \overline{p} n_x dS + \frac{1}{dV}\iint_S \mu\left[\frac{\partial \overline{u}}{\partial x}n_x + \frac{\partial \overline{u}}{\partial y}n_y + \frac{\partial \overline{u}}{\partial z}n_z\right] dS \tag{3}$$

where n_x, n_y, n_z are the components of the unit vector $\boldsymbol{n}$, normal to the surface dS, pointing into the fluid (Fig. 1).

Spatial averaging smoothes spatial heterogeneity of the flow near the rough bed in (x, y) planes, so that all flow variables are represented as profiles in z. The lowest point in such profiles is the lowest point of the bed roughness. Time-averaged flow depth measured from that point is denoted by H, and time-averaged flow depth measured from the roughness crests is h.

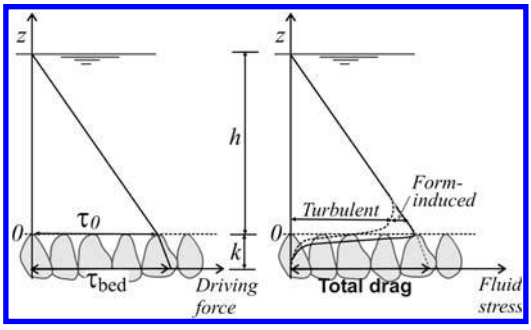

Figure 2. Momentum balance in 2d rough bed flow.

2.1 *Momentum balance*

In boundary layer terminology open channel flow belongs to 'constant pressure gradient' boundary layer flow, because its driving force, gravity, plays a role in the momentum balance analogous to the pressure gradient. In steady uniform flow over a rough bed the terms of momentum balance can be obtained by integrating the momentum equation (1) over z. (Nikora et al. 2001, Nikora et al., submitted). For any bed-parallel plane above the roughness top (Fig. 2) the total driving force or momentum supply (per unit plan area) between the plane and the free water surface is

$$\int_z^h \rho g \sin\alpha \, dz \cong \rho g S (h - z), \tag{4}$$

where $z =$ height of the plane above the roughness top and $S =$ bed slope (Fig. 2 left). It is in balance with the momentum flux through the plane at the height z, $\tau_{xz}(z)$, so τ_{xz} increases linearly, starting from the zero at the free surface. Far away from the roughness both viscous stress and form-induced stress are negligible so τ_{xz} is turbulent shear stress. Near the roughness crest persistent vortices behind roughness elements cause form-induced momentum flux so momentum is transferred from the flow above by both turbulent and form-induced shear stress (Fig. 2 right). At the roughness crest, $z = 0$, the momentum flux from the flow above the roughness is just sufficient to balance ρghS, so the fluid shear stress is

$$\tau_0 = \rho ghS. \tag{5}$$

Below the roughness crest, between the plane $z = 0$ and a bed-parallel plane at level z there is an additional momentum supply of $\phi\rho g(0 - z)S$. The corresponding total momentum supply of $\rho gS[h + \phi(0 - z)]$ is partly transferred further down via fluid shear stress and partly transferred to the roughness via form drag and viscous drag , which act as momentum sinks. At the level of the roughness troughs fluid shear stress diminishes and the total momentum from the flow above is transferred to the roughness:

$$\rho gS(h + \phi k) = \int_{-k}^{0} f_x dz \tag{6}$$

The total momentum flux from the fluid flow is therefore in balance with the total drag. The total drag exerted by the fluid on all roughness elements, per unit plan area of the bed, is the spatially averaged or macroscopic bed shear stress,

$$\tau_{bed} = \rho gh(S + \phi k). \tag{7}$$

Due to the additional momentum supply below the roughness top, the bed shear stress τ_{bed} differs from the fluid shear stress at the roughness top τ_0

2.2 *Flow layers*

In 'deep' rough bed flows, where the influence of the bed roughness is significant only over a small part of the flow depth (less than around 0.15–0.2 h), the following layers can be distinguished:

(i) The *Outer Layer,* similar to the outer layer for flows over hydraulically smooth beds, with the characteristic scales: the shear velocity, u_*, the maximum velocity, U_∞ (assumed to occur at the free surface), flow depth, h, and the distance above the zero-plane. (zero-plane= origin of the Log-law).

(ii) The *Logarithmic layer,* with the scales u_*, and the distance above the zero-plane. A single length scale exists only over a region far away from both the water surface and the rough bed so that it is not influenced by their respective length scales.

(iii) The *Roughness layer,* also called the *Roughness sub-layer,* is strongly influenced by the set of surface length scales L_i that describe bed geometry, including characteristic roughness height, k, so its characteristic scales are u_*, and L_i. This layer may extend up to $4k$ above the roughness crest (Raupach et al. 1991). Flow within the Roughness sub-layer is strongly affected by coherent eddies generated at the top of the roughness. In plant canopy flows the relevant length scale of the Roughness sub-layer is determined by the vorticity thickness $\delta_w = u(0)/(du/dz)(0)$ (Raupach et al. 1996). This was also observed in flows over relatively dense aquatic vegetation canopy (Nepf & Vivoni, 2000, Poggi et al. 2004).

For relatively shallow open channel flows some of the layers may be absent, because the Roughness sub-layer covers the part of the flow profile 'reserved' for the Log-layer, or even extends to the free surface, obliterating the Outer layer as well.

When all three flow layers are present they have a single velocity scale u_*. The Logarithmic layer has only

Copyright © 2006 Taylor & Francis Group plc, London, UK

one spatial scale, so it offers the simplest framework for studying u_*. For that reason the definition of the shear velocity and its application in boundary layer theory are closely related to the universal Logarithmic law of the wall.

3 THE UNIVERSAL LOG-LAW

The universal Log-law was originally derived for constant shear stress (zero pressure gradient) boundary layers over smooth walls. It can be derived in several ways. The two well-known approaches are:

(i) The overlap approach where the dimensional analysis is combined with asymptotic matching (Millikan, 1939, Yaglom, 1979). Asymptotic matching requires a clear scale separation between the boundary layer thickness and the thickness of the Roughness sub-layer. This derivation does not rely on the constant shear stress: the only assumption is that a single velocity scale u_* is responsible for momentum transfer from the outer flow to the wall. This velocity scale is usually called the friction velocity and calculated from the wall shear stress. Due to the scale separation, the difference between the momentum absorbed at the level of roughness crests and troughs, i.e. between τ_0 and τ_{bed}, is negligible.

(ii) The momentum flux approach where the momentum balance equation ($\tau_{xz} = -\rho\overline{u'w'} = \tau_{wall}$) is combined with an assumption about the relationship between turbulent momentum flux (turbulent shear stress) and velocity gradient either directly (Landau, 1944, Monin and Yaglom 1971) or through an assumption on the mixing length or turbulent viscosity. This approach requires that the fluid shear stress and the related velocity scale u_* are constant along z. In such case it clearly makes no difference whether u_* is evaluated at the roughness crests or troughs.

In either of the two approaches the condition for the existence and use of the Logarithmic layer is that it occurs far enough from both boundaries (at sufficient distance from the wall, in terms of wall units z^+, and at the same time at height much smaller than the boundary layer thickness), so that the only remaining relevant length scale is the distance from the wall z. In the 'overlap' approach this assumption is explicit. In the 'momentum flux' approach the assumed relationship between shear stress and velocity gradient is valid only in the vicinity of the wall where the turbulent momentum flux is not affected by the outer flow scales.

The Log-law for boundary layers over rough walls can be stated as

$$\frac{\overline{u}}{u_*} = \frac{1}{\kappa}\log\left(\frac{z+d}{z_0}\right) \tag{8}$$

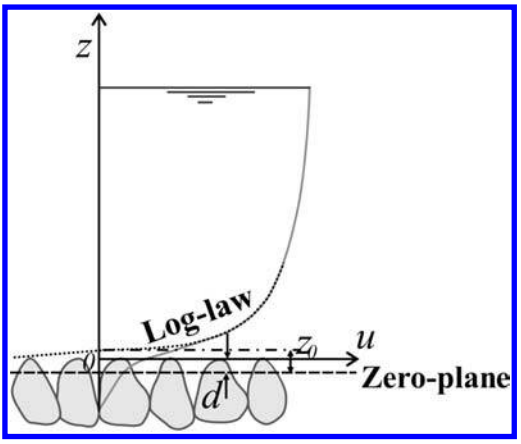

Figure 3. Logarithmic velocity profile above rough bed.

where κ is the universal von Karman constant and d defines the origin of the logarithmic velocity profile (Fig. 3). Due to the complex wall geometry and flow interactions, the position of this origin is not *a priory* known, so it has to be found by fitting. Experimental evidence shows that the origin of the Log-law, called zero-plane, is typically located between roughness crests and troughs and that it moves towards the troughs for more energetic flow and sparse roughness elements (Nikora et al. 2002). The zero-plane position at $z = -d$ implies that the length scale relevant within the Log-layer is $z + d$. If the Log-law is derived for a constant shear stress boundary layer, with the mixing length assumed proportional to the distance from the origin, $\ell = \kappa(z + d)$, the zero plane defines the position where the mixing length is zero.

The roughness length z_0 is formally an integration constant of the Log-law (height above the zero-plane where the velocity obtained from the Log-law is zero, Fig. 3). It depends on the roughness characteristics and is a measure of the efficiency of the surface in absorbing momentum.

The Log layer has to be outside the direct influence of the surface roughness, so it must be located above the Roughness sub-layer. On the other hand, to ensure that the Log-layer is sufficiently far away from the outer boundary of the boundary layer, it is assumed to be limited to some small portion, usually 0.15–0.2 of the boundary layer thickness. In cases where roughness generates a significant Roughness sub-layer which spreads higher than 0.15–0.2 of the boundary layer the Log-layer does not have enough space to develop.

The Log-law is also widely used for boundary layers with linear shear stress such as pipe flows and open channel flows with $h, H \gg k$. The 'overlap' derivation of Log-law explains why it works well with variable shear stress (provided that $h, H \gg k$). It can also be

Copyright © 2006 Taylor & Francis Group plc, London, UK

argued that the shear stress is still approximately constant between the wall and the Log-layer because the Log-layer has to be close to the wall (Monin & Yaglom, 1971),

In shallow open channel flows over rough bed the roughness height is comparable to water depth. Neither the 'overlap' approach nor the 'momentum balance' approach is applicable, since there is no scale separation and the shear stress is not constant. There is no theoretical basis for the universal Log-law and the velocity scale responsible for momentum transfer between the Outer layer and the bed becomes less obvious and Despite that, many investigators present experimental data fitted to the logarithmic equation (8) and scaled with the shear velocity u_*. The choice of u_* in shallow open channel flows is discussed in the remaining part of the paper.

4 DEFINITION OF THE SHEAR VELOCITY

The shear velocity u_* discussed here is a velocity scale expected to universally collapse data for rough bed open channel flows including flows with low relative submergence (with and without the-log layer). In other contexts e.g. sediment entrainment and sediment transport different definitions of u_* are required.

Although the u_* was first introduced in the context of the Log-law, the original derivations of the Log-law do not provide a general definition of the u_* which would be applicable to the boundary layers with variable shear stress where the roughness height is comparable with the boundary layer thickness. They associate u_* with the momentum absorbed by the wall. However this definition does not specify where exactly (along the roughness height k) is this momentum to be evaluated. This is the reason why there is no general consensus in the literature on the appropriate choice of the u_*. The following options exist:

- $u_*^{\text{bed}} = \sqrt{\tau_{\text{bed}}}$, where τ_{bed} is the bed shear stress. This classical approach, which assumes that u_* is an equivalent way of expressing the bed shear stress, is widely used in the open channel flow literature (e.g. Bayazit 1976, Ditrich & Koll, 1997, Katul et al. 2002, Rowinski et al.).
- $u_*^0 = \sqrt{\tau_0}$, where τ_0 is the total fluid shear stress at the roughness crest (at $z = 0$ in Figure 2). This approach is consistently used in the canopy flow literature (e.g. Finnigan 2000, Poggi et al. 2004, Jarvela, 2005), but may be found in open channel flow papers (e.g. Nakagawa 1991).
- $u_*^d = \sqrt{\tau_d}$, where τ_d is the total fluid shear stress extrapolated to the level of zero plane, $z = -d$ (Nepf & Vivoni, 2000, Ditrich & Koll, 1997).
- $u_*^{\log} = \sqrt{\tau_{\log}}$, where $\tau_{\log}$ is the shear stress that corresponds to u_* obtained by fitting experimental data (with the assumed $\kappa = 0.4$) to the logarithmic formula (8). (Wang et al. 1993, Wang & Dong 1996). It is not clear where exactly is $\tau_{\log}$ in the shear stress profile.

The first option clearly cannot yield the universal velocity scale because the bed shear stress depends on the roughness porosity function ϕ, which is not universal. To illustrate this let us assume flow over a bed composed of closely packed rods forming a porous medium with very low permeability, so that only a thin uppermost layer of the porous bed interacts with the mean velocity profile above, while below this layer flow is driven solely by the momentum supplied by gravity within the bed. Increasing height of the rods would not affect the mean velocity profile of the free surface flow above them, they would remain identical. However if we choose to scale them with the shear velocity calculated from the bed shear stress the scaled velocity profiles would differ by a factor proportional to the increase in the height of the rods. Thus we would detect a non-physical suppression of velocities, which is an artefact of the selection of the shear velocity.

Two other options, zero-plane and the Log-layer, rely on the existence of the Log-layer and the universal Log-law. This makes it impossible to use them for shallow flows where the existence of the universal Log-layer is questionable.

The remaining option of defining the u_* from the fluid shear stress at the roughness crest is the simplest and the least ambiguous one. In order to achieve uniform flow, flow depth, the velocity profile and the turbulence structure must adjust to deliver a momentum flux to the roughness that just balances the gravity forcing of the free fluid. This momentum flux is τ_0 and the corresponding velocity scale is u_*^0. At the roughness crest form drag and viscous drag start affecting the flow introducing a major change in flow physics. Below the roughness crest flow adjusts to the microphysics of drag and porosity in the roughness, so that the bed shear stress and the corresponding velocity scale reflect them, rather than solely the characteristics of free fluid. For these reasons we have adopted the shear velocity associated with the shear stress at the roughness crest as the appropriate velocity scale for scaling turbulent flow quantities across the whole flow profile.

5 SHEAR VELOCITY AND THE DATA INTERPRETATION

Shear velocity is widely used as a universal velocity scale, often in the context of the Log-law, but also for scaling the data on shallow rough bed open channel flows where the Log-layer is not present (e.g Katul et al. 2002). In this section we first analyse how the

Copyright © 2006 Taylor & Francis Group plc, London, UK

choice of the shear velocity affects the parameters of the Log-law in its original form (8) and present an example from the literature. We then demonstrate, using our own measurements of turbulent intensities, the general effect of the shear velocity definition on interpretation of data on shallow flows over rough bed.

Only the conventional 'bed shear stress' shear velocity is compared with the adopted 'roughness crest' shear velocity. The effect of other versions of the shear velocity definition, listed in the previous section, can be easily evaluated using an analogous procedure. From the momentum balance explained in the section 2.1 (Fig 2) it follows that the bed shear stress and the fluid shear stress at the roughness crests are related as

$$\frac{\tau_{\text{bed}}}{\tau_0} = \frac{h+\phi k}{h} \tag{9}$$

so that

$$\frac{u_*^{\text{bed}}}{u_*^0} = \sqrt{\frac{\tau_{\text{bed}}}{\tau_0}} \tag{10}$$

Obviously using u_*^{bed} as approximation of u_*^0 always overestimates it. The ratios $\tau_*^{\text{bed}}/\tau_*^0$ and u_*^{bed}/u_*^0 are plotted in Figure 4 as functions of the relative submergence H/k for three typical values of porosity ϕ Porosity 0.3–0.5 is approximately the range that can be expected in natural gravel beds, while 0.9 or higher may occur in aquatic vegetation. In the former case the difference between u_*^{bed} and u_*^0 becomes significant (larger than 10%) for the relative submergences less than 2.5-3.5 while in the latter case it happens for those less than 5. The graphs evaluate the effect of using u_*^{bed} instead of u_*^0 on the quantities scaled with the shear velocity. Two examples are presented in the following text to illustrate the consequences of this effect.

5.1 *Mean velocity and Log-law parameters*

Applicability of the universal Log-law to shallow open channel flows and the alternative formulations of the log-law (adjusted to linear shear stress and flows without clear scale separation) are beyond the scope of this paper. Here we analyse solely a case, often found in the literature, of fitting the conventional logarithmic velocity profile given by (8) to the experimental velocity data for shallow flows with low relative submergence H/k.

For a given set of experimental data, fitting to the log-law produces a single ratio κ/u_*, provided that κ/u_* and d wee both determined by fitting, The most obvious way to demonstrate this is by differentiating the log formula for u with respect to z, which yields (Nikora et al. 2002)

$$\left(\frac{du}{dz}\right)^{-1} = \frac{\kappa}{u_*}(z+d) \tag{11}$$

A given data set has a given set of velocity gradients. The slope of the best-fit line through their reciprocal values gives the ratio κ/u_* and the intercept gives the position of the zero-plane d.

The shear velocity evaluated from the bed shear stress is over-estimated by the factor shown in Figure 4, so that κ is over-estimated by the same factor. This means that for flows with very small relative submergence using the 'bed shear stress' shear velocity instead of the 'roughness crest' velocity can have significant influence on the reported values of the von Karman constant.

Figure 5 shows the results of Bayazit, 1976, who reported gradually increasing von Karman constant as the relative submergence decreased. The values of κ were evaluated by fitting the velocity data to the Log-law, with the position of the zero-plane $d = 0.33\,k$ below the roughness crest for all experiments. In the same paper Bayazit made a comment that these large values of κ for small relative submergences may be due to the wrong choice of the velocity scale u_*, but did

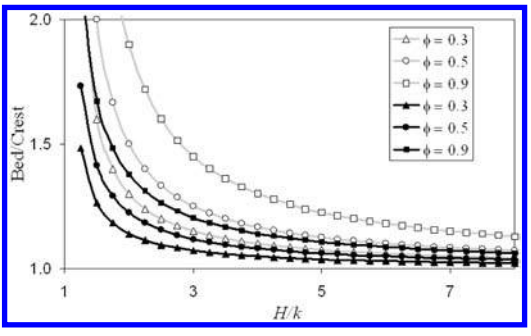

Figure 4. Ratio between the bed shear stress and the shear stress at the roughness crest (white symbols) and between the corresponding shear velocities (black symbols), for a range of relative submergences H/k and 3 different porosities ϕ.

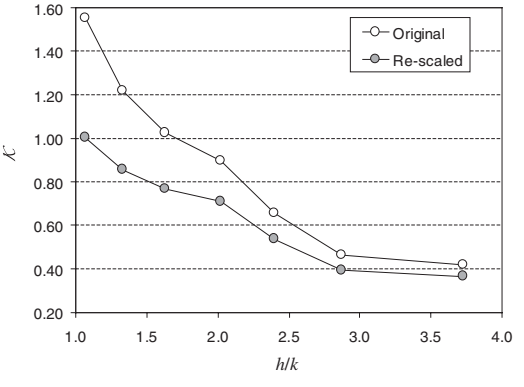

Figure 5. Von Karman constant reported in Bayazit, 1976 and re-calculated with the 'roughness crest' shear velocity.

Copyright © 2006 Taylor & Francis Group plc, London, UK

not attempt to correct it. These values of κ are here re-calculated with the 'roughness crest' shear velocity u_*^0 instead of the 'bed shear stress' u_*^{bed} from the original paper. Figure 5 shows that the correction significantly changes κ values.

This discussion is not aimed at listing all potential problems with fitting the velocity data to the logarithmic law. The aim is to point out just one particular source of error. The literature on shallow rough bed flows contains a range of values of von Karman constant. In cases where the reported values of κ are less than 0.4 the correction for u_*^{bed}/u_*^0 would further reduce them. In flows with small to intermediate relative submergence the universal Log-layer is often not present, so there is no reason for κ obtained by fitting the velocity data to have the universal value. However it is important to realise that without a physically based and consistent velocity scale u_* it is very difficult or impossible to compare different experimental data. Correcting the data for bias introduced by using u_*^{bed} would clarify the genuine influence of the relative submergence and other parameters that affect velocity profiles.

An inverse situation happens when the u_*, determined by fitting the log-law to the measured velocity profile (assuming $\kappa = 0.4$), is used for evaluation of the bed shear stress or the friction factor. This is frequent in field measurements, where using u_* is a simpler and more robust alternative to the direct measurement of the shear stress. In such cases the result of fitting is the 'roughness crest' shear velocity u_*^0, but it is used as if it were 'bed shear stress' velocity u_*^{bed}. Since u_*^0 is always less than u_*^{bed}, this means that, even if the assumed $\kappa = 0.4$ is correct, the bed shear stress and the friction factor are underestimated by factors shown in Figure 4.

The above analysis applies to the cases where κ/u_* and d were both found by fitting. However the position of the zero-plane is sometimes found using the centre-of-pressure method (Jackson, 1981). This method is not applicable to 'constant pressure gradient' boundary layers because the momentum supply below the roughness crest affects the position of the centre of drag. If d was evaluated using this method the error would combine with the error in u_* and further affect the value of κ.

For rough bed open channel flows with small to intermediate relative submergence the use of the Log-law in its original form is questionable and alternative options should be explored. In any case, in future efforts to compile available experimental data it is very important to make a clear distinction between the non-universal 'bed shear stress' velocity scale u_*^{bed}, which depends on the particular roughness geometry and the 'roughness crest' velocity scale u_*^0, which has a potential to universally collapse the experimental data.

5.2 *Turbulent intensities*

The difference between the 'bed shear stress' and 'roughness crest' shear velocity has an important influence on the turbulence characteristics reported for the rough bed shallow open channel flows. For instance turbulent intensities are usually scaled with the u_*, and compared with the corresponding dimensionless turbulent intensities measured in deep rough bed flows or smooth bed flows. Scaling the turbulent intensities for deep flows is not sensitive to the difference between u_*^0 and u_*^{bed}, but for shallow flows the difference becomes significant. Using u_*^{bed} instead of u_*^0 for scaling introduces an artificial suppression of turbulent intensities, caused by the choice of the velocity scale rather than the real physics. The 'suppression factor' progressively increases with decreasing relative submergence. The maximum turbulent intensity (scaled with u_*) is known to decrease when the relative submergence decreases (Wang et al. 1993, Ditrich & Koll 1997). Part of this finding may be the artefact of the choice of the velocity scale.

To explore this possibility we first re-calculated the results from Bayazit (1976), where turbulent intensities were fitted to the formula

$$\frac{\sigma_u}{u_*} = A + B \ln \frac{u_* z}{\nu}. \tag{12}$$

In Bayazit (1976), turbulent intensities scaled with u_* and plotted against $\ln u_* z/\nu$ do not collapse for different relative submergences. Instead, they follow a set of parallel lines, indicating that only the coefficient A from (12) is responsible for the reduction of turbulent intensities as the relative submergence (h/k) decreases. Figure 6 shows the values of A from the original paper and those corresponding to 'roughness crest' u_* as a velocity scale. The re-calculated A values vary much less, indicating very small variation of turbulent intensities with relative submergence. It is

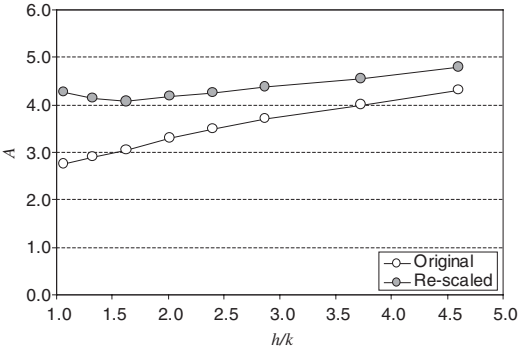

Figure 6. The constant A (eq. 5) defining maximum turbulent intensities σ_u reported in Bayazit, 1976 and re-scaled with the 'roughness crest' shear velocity.

Copyright © 2006 Taylor & Francis Group plc, London, UK

clear that turbulent intensities profiles would collapse much better when scaled with the 'roughness crest' shear velocity.

Further analysis was performed with our own measurements of flow over a single layer of spheres packed in the cubic pattern. All the experiments were carried out under uniform, fully turbulent rough flow conditions. The aspect ratio varied from 18-5.4 for which we can assume that the flow was two-dimensional (Kironoto and Graf 1994). The main hydraulic parameters for the experiments are shown in Table 1. Measurements were carried out using Particle Image Velocimetry along two vertical planes along the flume axis, one plane through the centres of the spheres and another through their connections. The results presented below were obtained by averaging the results for these two planes. More detailed description of the experimental procedures can be found in (Manes et al. submitted). Figure 7 shows turbulent intensities $\sigma_u = \sqrt{\overline{u'^2}}$ and $\sigma_w = \sqrt{\overline{w'^2}}$ measured in the experiments **E1, E2, E3**, once scaled with the 'roughness crest' shear velocity u_*^0 and once with the 'bed shear stress shear velocity u_*^{bed}. The values of the shear stress at the roughness crest and the bed shear stress were determined by the extrapolation of the Reynolds stress

Table 1. Experimental conditions.

Experiment	E1	E2	E3
Bed slope	1:400	1:400	1:200
Sphere diameter, k(mm)	12	12	12
Depth h(m)1.3	22	42	21
Maximum depth H(mm)	34	54	33
Relative submergence (H/k)	2.83	4.5	2.75
Shear velocity u_* (m/s)	0.0235	0.0300	0.0301
Roughness Reynolds number	141	180	181
Average profile velocity (m/s)	0.210	0.340	0.286
u_{bed}/u_*	1.13	1.07	1.14

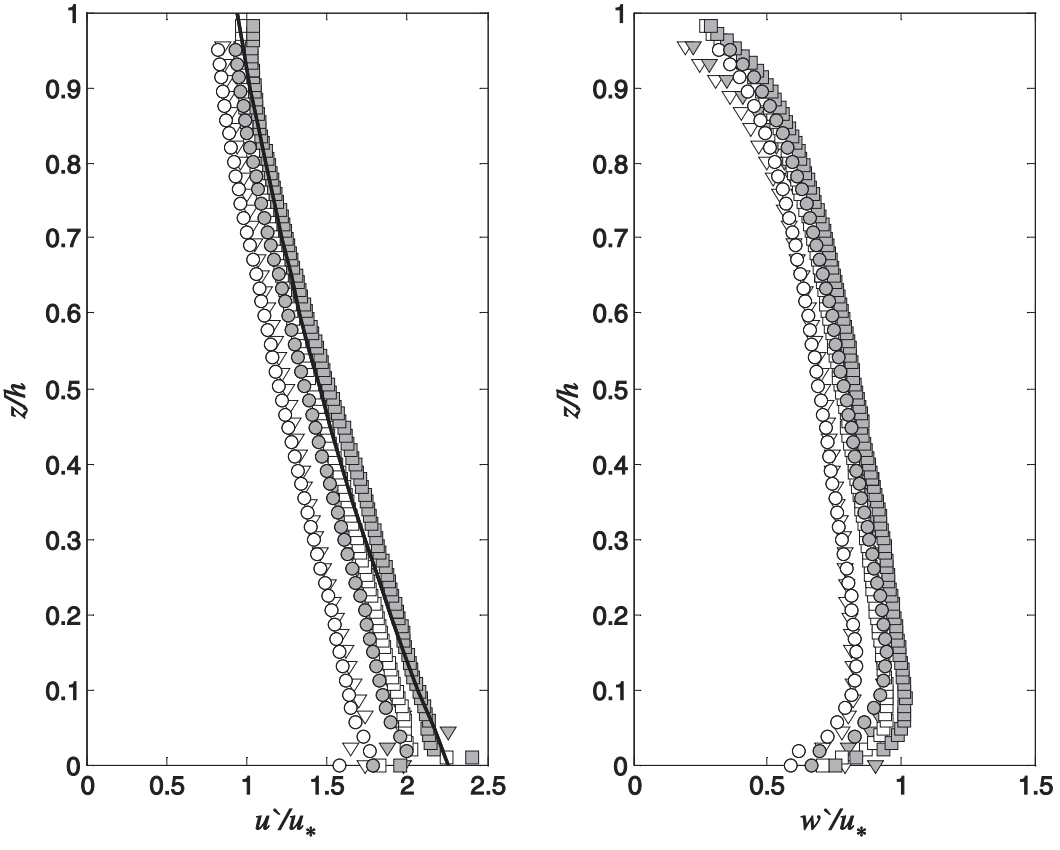

Figure 7. Turbulent intensities σ_u and σ_w scaled with the 'roughness crest' shear velocity (grey symbols) and the 'bed shear stress' shear velocity (white symbols) in experiments E1 (circles), E2 (squares) and E3 (triangles); σ_u is compared with turbulent intensities in flow over smooth bed (Nezu & Rodi 1986, line).

profiles to the appropriate level (the roughness crest and the mean bed level $z = -\phi k$ consequently). The dimensionless profiles of turbulent intensity collapse reasonably well between the experiments when scaled with the 'roughness crest' shear velocity. When scaled with the 'bed shear stress' shear velocity, the turbulent intensities for the two shallower experiments (circles and triangles in Fig. 7) clearly stand out, showing the suppression of the turbulent intensities which is solely the artefact of the choice of the velocity scale u_*. It is interesting to compare the scaled turbulent intensities σ_u with those for the smooth bed flow (Nezu & Rodi, 1986), shown in the same figure. Judging by the data scaled with the 'bed shear stress' velocity scale, the turbulent intensities are suppressed in shallow flow over rough bed compared to smooth bed, while the data scaled with the 'roughness crest' velocity scale indicate that they are similar. As expected, in the experiment **E2** with deeper flow than in other two experiments, this difference vanishes.

These results illustrate how we can reach a different conclusion about turbulent intensities in rough bed shallow flows, solely because of the choice of the shear velocity with which to scale experimental data. For flow over spheres with uniform diameter using the correct velocity scale reveals the similarity of turbulent intensities between smooth-bed and rough-bed flows, while the inappropriate scale causes the non-existent, artificial, suppression of turbulent intensities.

6 CONCLUSIONS

The paper is focussed on the definition of the shear velocity which is to be used, as universal velocity scale, for scaling properties of free-surface turbulent flows over rough bed. In the literature there are several different definitions of the shear velocity, each with the different associated shear stress. The two most common definitions are based on the shear stress at the level of the roughness crest and the bed shear stress. In deep flows, where the water depth is much larger than the roughness height, the different definitions give approximately equal values of the shear velocity. In shallow flows, however, the differences between these values can be significant.

This is the reason why for shallow rough bed flows the definition of the shear velocity requires closer inspection. In this paper we present a case for adopting the shear velocity evaluated from the shear stress at the roughness crest as the universal velocity scale. There are clear reasons against using the bed shear stress, inasmuch as the shear velocity must be interpreted as the universal velocity scale of the free fluid flow in the outer layer. (The velocity scale calculated from the bed shear stress is the appropriate choice in some other context e.g. sediment transport). It was shown that scaling with the velocity scale based on the bed shear stress produces artificially increased von Karman constant and artificially suppressed turbulent intensities. For shallow flows this can significantly affect data interpretation.

ACKNOWLEDGEMENTS

This investigation was carried out as part of an experimental programme funded by the United Kingdom Engineering and Physical Sciences Research Council (Grant GR/R51865/01).

Large eddy simulation of the two phase flow

F. Gallerano, L. Melilla & G. Cannata
Dipartimento di Idraulica, Trasporti e Strade, Università "La Sapienza", Roma, Italia

ABSTRACT: A new LES model is proposed together with a new methodology for the simulation of concentration fields of suspended solids coherent with the LES methodology. The proposed closure relation for the generalized SGS turbulent stress tensor: complies with the principle of turbulent frame indifference; takes into account both the anisotropy of the turbulence velocity scales and turbulence length scales; removes any balance assumption between the production and dissipation of SGS turbulent kinetic energy. In the proposed model the generalized SGS turbulent stress tensor is related exclusively to the generalized SGS turbulent kinetic energy (which is calculated by means of its balance equation) and the modified Leonard tensor. The concentration field is simulated by the spatially filtered equation of the concentration. In this equation the first-order tensor (produced by the correlation between the velocity and the concentration) is related to the gradient of the resolved concentrations according to an original dynamic Germano procedure.

1 INTRODUCTION

The numerical integration of the equations for Large Eddy Simulation (LES) of turbulent flows requires the formulation of closure relations for the generalized sub grid scale (SGS) turbulent stress tensor

$$\tau_{ij} = \tau(u_i, u_j) = \overline{u_i u_j} - \bar{u}_i \bar{u}_j \tag{1}$$

where u_i is the ith component of the instantaneous velocity and the overbar represents the application of the spatial filter.

Breaking down the instantaneous velocity which appears on the right hand side of Equation 1 into filtered (resolved) and fluctuating components,

$$\bar{u}_i \quad , \quad u_i' = u_i - \bar{u}_i ,$$

the SGS turbulent stress tensor can be split into three tensors:

$$\tau_{ij} = L_{ij}^m + C_{ij}^m + R_{ij}^m$$

called, respectively, modified Leonard tensor, modified cross tensor and modified Reynolds tensor and defined as follows (Germano 1992):

$$L_{ij}^m = \tau(\bar{u}_i, \bar{u}_j) = \overline{\bar{u}_i \bar{u}_j} - \bar{\bar{u}}_i \bar{\bar{u}}_j \tag{2}$$

$$C_{ij}^m = \tau(\bar{u}_i, u_j') + \tau(u_i', \bar{u}_j) = \overline{\bar{u}_i u_j'} - \bar{\bar{u}}_i \bar{u}_j' + \overline{u_i' \bar{u}_j} - \bar{u}_i' \bar{\bar{u}}_j \tag{3}$$

$$R_{ij}^m = \tau(u_i', u_j') = \overline{u_i' u_j'} - \bar{u}_i' \bar{u}_j' \tag{4}$$

In this paper a Large-Eddy-Simulation model (which overcomes the drawbacks of the models currently present in the literature) is presented. These include all dynamic Smagorinskv-type SGS models (e.g., Dynamic Smagorinsky Mode DSM (Germano et al. 1991), Dynamic Mixed Model DMM1 (Zang et al. 1993), DMM2 (Vreman et al. 1994), Lagrangian Dynamic Model LDM (Meneveau 1996), Dynamic Two-parameter Model DTM (Salvetti & Banerjee 1995)), in which the generalized SGS turbulent stress tensor is related to the resolved strain-rate tensor by means of a scalar eddy viscosity. It is assumed in these models that the eddy viscosity is a scalar proportional to the cubic root of the generalized SGS turbulent kinetic energy dissipation and that such dissipation is locally and instantaneously balanced by the production of the generalized SGS turbulent kinetic energy (i.e., by the rate of kinetic energy per unit of mass transferred from the large scales, larger than the filter size, to the unresolved ones). Consequently, it is evident that the dynamic Smagorinsky-type SGS models are fraught with three relevant drawbacks. The first drawback is represented by the scalar definition of the eddy viscosity; the second one concerns the local balance assumption of the generalized SGS turbulent kinetic energy production and dissipation, whilst the third drawback is related to the dynamic calculation of the coefficient used to model the eddy viscosity (Smagorinsky coefficient).

The scalar definition (first inconsistency) of the eddy viscosity is equivalent to assuming that the principal axes of the generalized SGS turbulent stress tensor, or the unresolved part of it (represented by the cross and Reynolds terms), are aligned with the principal axes of the resolved strain-rate tensor. This

Copyright © 2006 Taylor & Francis Group plc, London, UK

assumption has been disproved by many experimental tests and by DNS, which demonstrate that there is no alignment between the generalized SGS turbulent stress tensor, or the unresolved part of it, and the resolved strain-rate tensor (Tao et al. 2000, Meneveau & Katz 2000). Moreover, the eddy viscosity is proportional to the product of two terms, of which the dimensions are, respectively, those of a length and a velocity (Tennekes & Lumley 1972). These terms, which represent, respectively, the turbulence length scales and turbulence velocity scales, are, more generally, second-order tensors of which the product is a fourth-order tensor which represents the eddy viscosity (Monin & Yaglom 1972).

The scalar definition of the eddy viscosity, used in the above-mentioned dynamic Smagorinsky-type SGS models, presupposes the existence of a single turbulence velocity scale and a single turbulence length scale. This is equivalent to assuming that the second-order tensors which represent the turbulence length scales and the turbulence velocity scales are isotropic and that, therefore, the turbulence is isotropic. In this manner, the turbulence anisotropy induced by the continuous transfer of energy from the mean flow towards the turbulent fluctuations, which is generally extremely anisotropic, is not considered. Even though the energy cascade process causes a reduction of the turbulence anisotropy, many authors (Speziale & Gatski 1997, Sreenivasan 1991) demonstrated that even in the dissipation range of the smallest turbulent scales, where viscous dissipation occurs, there is a high anisotropy level even at high Reynolds numbers.

The second inconsistency of the Smagorinsky dynamic models is related to the assumption of a local and instantaneous balance between production and dissipation of the generalized SGS turbulent kinetic energy, formulated in the above-mentioned models to obtain the turbulent viscosity expression. This assumption is confirmed statistically and never instantaneously, and only locally at the scales associated with wavenumbers within the inertial subrange, and the latter exists only for isotropic turbulence and at high Reynolds numbers. Moreover, since the dissipation of the generalized SGS turbulent kinetic energy is, by definition, positive, the assumption of local balance implies that also the production of generalized SGS turbulent kinetic energy is positive. However, the assumption that the production is always positive implies that the energy transfer always occurs from the largest to the smallest scales and prevents positive transfers of kinetic energy from the subgrid scales to the resolved ones (backscatter). Since the energy exchange processes between the resolved and unresolved scales generally occur in both directions (forward scatter and back scatter), as has been observed by various authors (Piomelli et al. 1991, Horiuti 1989), the assumption that the production of generalized SGS turbulent kinetic energy is always positive does not enable the complexity of the energy exchange processes which characterize the turbulence to be adequately taken into account.

The third inconsistency of the dynamic models concerns the calculation of the above mentioned Smagorinsky coefficient C_s. It is calculated with variational methods, (e.g. with a least squares minimization method (Lilly 1992) or Lagrangian method (Meneveau et al. 1996)). These methods identify a single value of the scalar coefficient C_s from a system of five independent scalar equations relating the components of the anisotropic part of the generalized SGS turbulent stress tensor to the components of the resolved strain-rate tensor. This procedure does not provide completely acceptable results. Moreover, when simulating confined flows at high Reynolds number, the results of the dynamic procedure are of doubtful reliability in the region close to the wall including both the viscous sublayer and the buffer layer (Sarghini et al. 1999). In this region, the filter width used in the dynamic procedure is larger than most eddies that govern the momentum and energy transfer. Consequently, the dynamic procedure used under these conditions for the calculation of the coefficient C_s is not able to fully account for the local subgrid dissipative processes that affect the entire domain.

Another group of SGS models is made up of models that are based on the assumption of scale similarity, according to which there is a strict analogy between the hydrodynamic characteristics of the scales of motion which are contiguous in wavenumber space. This assumption is evidently justified by the characteristics of the energy cascade process that transfers the turbulent kinetic energy from the mean velocity field towards the largest turbulent scales and then towards the smallest by vortex stretching. The scale similarity models of Bardina et al. (1983) and of Liu et al. (1994) unlike the Smagorinsky dynamic models, assume neither local isotropy of the turbulence scales, nor alignment of the generalized SGS turbulent stress tensor with the resolved strain-rate sensor, nor local balance between production and dissipation of generalized SGS turbulent kinetic energy. In particular, Bardina et al. (1983) use scale similarity and assume that

$$\tau_{ij} = L_{ij} + rL_{ij} \tag{5}$$

in which

$$L_{ij} = \overline{\bar{u}_i \bar{u}_j} - \bar{u}_i \bar{u}_j \tag{6}$$

is the Leonard term and C_b is a dimensionless coefficient.

The scale similarity model of Bardina et al. (1983) and those derived from it, even though they eliminate the main inconsistencies of the Smagorinsky dynamic

Copyright © 2006 Taylor & Francis Group plc, London, UK

models, have the drawback of being insufficiently dissipative, i.e. they are not able to guarantee an adequate energy drain from the grid scales to the subgrid scales.

In this paper a new scale similarity model is proposed in which the SGS stress tensor is related to the modified Leonard stress tensor and the generalized SGS turbulent kinetic energy, which is calculated by its balance equation.

In such a way it is possible to guarantee an adequate energy drain from the grid scales to the subgrid scales without adding an eddy viscosity type term.

In this paper the main drawbacks of the large eddy simulation models present in literature are overcome and a new LES model is proposed, along with a new methodology for the simulation of concentration fields of the solids in suspension, coherent with the LES methodology.

In the proposed model: (a) there is no coefficient which appears in the closure relation for the generalized SGS turbulent stress tensor; (b) the generalized SGS turbulent stress tensor is related exclusively to the generalized SGS turbulent kinetic energy and the modified Leonard tensor; (c) the viscous dissipation ε of the generalized SGS turbulent kinetic energy is calculated directly by its balance equation, thereby overcoming the inconsistencies concerning the modelling of ε. The closure relation at the basis of the proposed Two-Equation Model (TEM): (a) complies with the principle of turbulent frame indifference; (b) takes into account both the anisotropy of the turbulence velocity scales and of the turbulence length scales; (c) removes any assumption of balance between the production and dissipation of the turbulent kinetic energy; (d) allows the use of a filter of which the width is not necessarily associated with the wavenumbers lying within the inertial subrange; (e) assumes scale similarity; (f) guarantees an adequate energy drain from the grid scales to the subgrid scales and guarantees backscatter; (g) overcomes the inconsistencies linked to the dynamic calculation of the closure coefficient used in the modelling of the generalized SGS turbulent stress tensor.

The concentration field is simulated by the spatially filtered concentration equation. In this equation the first-order tensor (produced by the correlation between the velocity and the concentration) is related to the gradient of the resolved concentrations according to an original dynamic Germano procedure.

2 A NEW LES MODEL

2.1 *The turbulence model*

According to Bardina's scale similarity assumption, the generalized SGS turbulent stress tensor can be expressed by

$$\tau_{ij} = (1+r)L_{ij}^m \tag{7}$$

where r is an unknown scalar coefficient and L_{ij}^m is the modified Leonard tensor.

In this paper it is demonstrated that, starting from the scale similarity assumption in 7, (by simple mathematical calculations) a closure relation is reached for the generalized SGS turbulent stress tensor, in which there appears no coefficient to be calibrate or to calculate dynamically and which is given by the following relation:

$$\tau_{ij} = \left(\frac{2E}{L_{kk}^m}\right) L_{ij}^m \tag{8}$$

Such a relation is not present in literature and has never been presented by other authors.

It is easy to verify that as, by definition, the generalized SGS turbulent kinetic energy equal to half the trace of the generalized SGS turbulent stress tensor (Germano 1992),

$$E = \frac{\tau_{kk}}{2} \tag{9}$$

from Equation 7 is obtained

$$\tau_{kk} = (1+r)L_{kk}^m \quad \text{where} \quad r = \frac{2E - L_{kk}^m}{L_{kk}^m} \tag{10}$$

Introducing 10 into 7 gives:

$$\tau_{ij} = \left(1 + \frac{2E - L_{kk}^m}{L_{kk}^m}\right) L_{ij}^m = \left(\frac{2E}{L_{kk}^m}\right) L_{ij}^m \tag{11}$$

The closure relation 11 is obtained without any assumption of local balance between the production and dissipation of generalized SGS turbulent kinetic energy and may thus be considered applicable to LES with the filter width falling into the range of wave numbers greater than the wave number corresponding to the maximum turbulent kinetic energy.

The closure relation 11 for the generalized SGS turbulent stress tensor: (a) complies with the principle of turbulent frame indifference given that it relates only objective tensors; (b) takes into account both the anisotropy of the turbulence velocity scales and turbulence length scales; (c) assumes scale similarity; (d) guarantees an adequate energy drain from the grid scales to the subgrid scales and guarantees backscatter; (e) overcomes the inconsistencies linked to the dynamic calculation of the closure coefficient used in the modelling of the generalized SGS turbulent stress tensor.

The generalized SGS turbulent kinetic energy, E, is calculated by solving its balance equation, defined by the following equation:

$$\frac{DE}{Dt} = -\frac{1}{2}\frac{\partial \tau(u_k,u_k,u_m)}{\partial x_m} - \tau_{mk}\frac{\partial \bar{u}_k}{\partial x_m} - \frac{\partial \tau(p,u_m)}{\partial x_m} + \nu\frac{\partial^2 E}{\partial x_m \partial x_m} + \tau(F_{ok},u_k) - \nu\tau\left(\frac{\partial u_k}{\partial x_m},\frac{\partial u_k}{\partial x_m}\right) \tag{12}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

The 1st and 3rd terms of the right-hand side of Equation 12 express the turbulent diffusion of the generalized SGS turbulent kinetic energy:

$$\frac{1}{2}\frac{\partial \tau(u_i,u_i,u_k)}{\partial x_k}+\frac{\partial \tau(p,u_k)}{\partial x_k}=\frac{\partial (F_E)_k}{\partial x_k} \tag{13}$$

The following equation is used for the calculation of $(F_E)_k$

$$(F_E)_k = D\sqrt{E}\,\overline{\Delta}\frac{\partial E}{\partial x_k} \tag{14}$$

Scalar coefficient D is dynamically calculated by means of a Germano identity applied to the 1st and 3rd terms on the right-hand side of Equation 12

$$\left(F_E^T\right)_k-\widetilde{(F_E)}_k=\frac{1}{2}T(u_i,u_i,u_k)-\frac{1}{2}\widetilde{\tau(u_i,u_i,u_k)} +T(p,u_k)-\widetilde{\tau(p,u_k)} \tag{15}$$

where the first term on the left-hand side of Equation 15 is the turbulent diffusion of the generalized SGS turbulent kinetic energy at the test level, the symbol $\widetilde{(.)}$ indicates the filter operation at the test level and

$$T(f,g)=\widetilde{\overline{f}\,\overline{g}}-\widetilde{\overline{f}}\,\widetilde{\overline{g}} \tag{16}$$

$$T(f,g,h)=\widetilde{\overline{f}\,\overline{g}\,\overline{h}}-\widetilde{\overline{f}}\,\widetilde{\overline{g}}\,\widetilde{\overline{h}} -\widetilde{\overline{f}}\,T(g,h)-\widetilde{\overline{g}}\,T(f,h)-\widetilde{\overline{h}}\,T(f,g) \tag{17}$$

are, respectively, the generalized second and third order central moment at the test level (Germano 1992). According to 16 and 17, Equation 15 reads.

$$\left(F_E^T\right)_k-\widetilde{(F_E)}_k=\frac{1}{2}\widetilde{\overline{u_i}\,\overline{u_i}\,\overline{u_k}}-\frac{1}{2}\widetilde{\overline{u}}_i\widetilde{\overline{u}}_i\widetilde{\overline{u}}_k -\frac{1}{2}\widetilde{\overline{u}}_k T(u_i,u_i)+\frac{1}{2}\widetilde{\overline{u}_k\tau(u_i,u_i)}-\widetilde{\overline{u}}_i T(u_i,u_k) +\widetilde{\overline{u}_i\,\tau(u_i,u_k)}+T(p,u_k)-\widetilde{\tau(p,u_k)} \tag{18}$$

Using Equation 14, the left-hand side term of Equation 15 takes the form

$$\left(F_E^T\right)_k-\widetilde{(F_E)}_k=D\sqrt{E^T}\,\overline{\Delta}^T\frac{\partial E^T}{\partial x_k}-\widetilde{D\sqrt{E}\Delta}\frac{\partial \overline{E}}{\partial x_k} \tag{19}$$

where E^T is the generalized SGS turbulent kinetic energy at the test level. The coefficient D is calculated by introducing 19 into 18.

The last term on the right-hand side of Equation 12 is defined as viscous dissipation:

$$\varepsilon=\nu\tau\left(\frac{\partial u_i}{\partial x_j},\frac{\partial u_i}{\partial x_j}\right) \tag{20}$$

In the proposed LES model a further balance equation is introduced for the subgrid viscous dissipation ε. This equation, expressed in terms of the generalized central moments, takes the form (Gallerano et al. 2005):

$$\frac{\partial \varepsilon}{\partial t}+\frac{\partial \overline{u}_k\varepsilon}{\partial x_k}-\nu\frac{\partial^2\varepsilon}{\partial x_k\partial x_k}+\nu\frac{\partial}{\partial x_k}\tau\left(u_k,\frac{\partial u_i}{\partial x_j},\frac{\partial u_i}{\partial x_j}\right)+ 2\nu\frac{\partial}{\partial x_k}\left(\frac{\partial \overline{u}_i}{\partial x_j}\tau\left(u_k,\frac{\partial u_i}{\partial x_j}\right)\right)+2\nu\frac{\partial}{\partial x_k}\tau\left(\frac{\partial u_k}{\partial x_i},\frac{\partial p}{\partial x_i}\right)+ -2\nu\frac{\partial}{\partial x_k}\left(\frac{\partial \overline{u}_i}{\partial x_j}\frac{\partial \tau_{ik}}{\partial x_j}\right)+2\nu\tau\left(\frac{\partial u_i}{\partial x_k},\frac{\partial u_k}{\partial x_j},\frac{\partial u_i}{\partial x_j}\right) +2\nu\frac{\partial \overline{u}_k}{\partial x_j}\tau\left(\frac{\partial u_i}{\partial x_k},\frac{\partial u_i}{\partial x_j}\right)+2\nu\frac{\partial \overline{u}_i}{\partial x_k}\tau\left(\frac{\partial u_k}{\partial x_j},\frac{\partial u_i}{\partial x_j}\right)+ 2\nu\frac{\partial \overline{u}_i}{\partial x_j}\tau\left(\frac{\partial u_i}{\partial x_k},\frac{\partial u_k}{\partial x_j}\right)+2\nu\frac{\partial \tau_{ik}}{\partial x_j}\frac{\partial^2\overline{u}_i}{\partial x_j\partial x_k}+ 2\nu^2\tau\left(\frac{\partial^2 u_i}{\partial x_j\partial x_k},\frac{\partial^2 u_i}{\partial x_j\partial x_k}\right)-2\nu\tau\left(\frac{\partial u_i}{\partial x_j},\frac{\partial F_{0i}}{\partial x_j}\right)=0 \tag{21}$$

In this paper an original expression is proposed for the "modeled" form of the balance equation for the generalized SGS turbulent kinetic energy dissipation, in which the unknown tensors are modeled by adopting the hypothesis of scale similarity and Equation 21 takes the form:

$$\frac{\partial \varepsilon}{\partial t}+\frac{\partial \overline{u}_k\varepsilon}{\partial x_k}-\nu\frac{\partial^2\varepsilon}{\partial x_k\partial x_k}+\frac{\partial}{\partial x_k}C_{F_\varepsilon}\frac{E^2}{\varepsilon}\frac{L_{kl}^m}{L_{jj}^m}\frac{\partial \varepsilon}{\partial x_l} +2\nu\frac{\partial}{\partial x_k}\left(\frac{\partial \overline{u}_i}{\partial x_j}\left(\frac{C_{F^1_\varepsilon}\dfrac{E}{\varepsilon}\dfrac{\partial \varepsilon}{\partial x_q}\delta_q}{\tau\left(\overline{u}_n,\dfrac{\partial \overline{u}_n}{\partial x_n}\right)}\tau\left(\overline{u}_k,\frac{\partial \overline{u}_i}{\partial x_j}\right)\right)\right) -2\nu\frac{\partial}{\partial x_k}\left(\frac{\partial \overline{u}_i}{\partial x_j}\frac{\partial}{\partial x_j}\left(\frac{2E}{L_{qq}{}^m}L_{ik}{}^m\right)\right)-C_{P_\varepsilon}\frac{\varepsilon(-L^m{}_{ij}\overline{S}_{ij})}{L^m{}_{kk}} +2\nu\frac{\partial \overline{u}_k}{\partial x_j}\frac{\dfrac{\varepsilon}{\nu}\tau\left(\dfrac{\partial \overline{u}_i}{\partial x_k},\dfrac{\partial \overline{u}_i}{\partial x_j}\right)}{\tau\left(\dfrac{\partial \overline{u}_q}{\partial x_n},\dfrac{\partial \overline{u}_q}{\partial x_n}\right)}+2\nu\frac{\partial \overline{u}_i}{\partial x_k}\frac{\dfrac{\varepsilon}{\nu}\tau\left(\dfrac{\partial \overline{u}_k}{\partial x_j},\dfrac{\partial \overline{u}_i}{\partial x_j}\right)}{\tau\left(\dfrac{\partial \overline{u}_q}{\partial x_n},\dfrac{\partial \overline{u}_q}{\partial x_n}\right)} +2\nu\frac{\partial \overline{u}_i}{\partial x_j}\frac{\dfrac{\varepsilon}{\nu}\tau\left(\dfrac{\partial \overline{u}_i}{\partial x_k},\dfrac{\partial \overline{u}_k}{\partial x_j}\right)}{\tau\left(\dfrac{\partial \overline{u}_q}{\partial x_s},\dfrac{\partial \overline{u}_s}{\partial x_q}\right)}+2\nu\frac{\partial}{\partial x_j}\left(\frac{2E}{L_{nn}^m}L_{ik}^m\right)\frac{\partial^2\overline{u}_i}{\partial x_j\partial x_k} +C_{D_\varepsilon}\frac{\varepsilon^2}{E}=0 \tag{22}$$

where $\delta_i = (1,1,1)$ and in which the closure coefficients are calculated dynamically by means of the Germano identities.

2.2 *The spatially filtered concentration equation*

The filtered equation of the concentration of suspended solids is:

$$\frac{\partial \overline{C}}{\partial t} + \frac{\partial \overline{u}_i \overline{C}}{\partial x_i} + \frac{\partial}{\partial x_i}\left(\overline{u_i C} - \overline{u}_i \overline{C}\right) = 0 \tag{23}$$

where $\bar{C}$ represents the spatially filtered concentration field.

The last term of Equation 23 is a first-order tensor given by the generalized central moment relative to the velocity vector and the concentration and is defined as follows:

$$a_i = \tau\left(u_i, C\right) = \left(\overline{u_i C} - \overline{u}_i \overline{C}\right) \tag{24}$$

The above tensor can be split in terms of generalized central moments:

$$a_i = L_i^C + C_i^C + R_i^C \tag{25}$$

where:

$$L_i^C = \tau\left(\overline{u}_i, \overline{C}\right) = \overline{\overline{u}_i \overline{C}} - \overline{\overline{u}_i}\,\overline{\overline{C}}$$

$$C_i^C = \tau\left(\overline{u}_i, C'\right) + \tau\left(u_i', \overline{C}\right) = \left(\overline{\overline{u}_i C'} - \overline{\overline{u}_i}\,\overline{C'} + \overline{u_i' \overline{C}} - \overline{u'}\,\overline{\overline{C}}\right)$$

$$R_i^C = \tau\left(u_i', C'\right) = \overline{u_i' C'} - \overline{u_i'}\,\overline{C'}$$

The sum of the second and third term on the right hand side of Equation 25 represents an unknown first-order tensor. In this paper a new closure relation for this unknown tensor is proposed.

The closure relation between this unresolved tensor and the gradient of the filtered concentration is defined by a second-order tensor which is assumed proportional to the subgrid turbulent velocity scale and the turbulence length scale:

$$v_{ij}^C = c_c \sqrt{E} d_{ij} \tag{26}$$

the above closure relation is:

$$C_i^C + R_i^C = c_c \sqrt{E} d_{in} \frac{\partial \overline{C}}{\partial x_n} \tag{27}$$

Let $T(u_i, C)$ be the generalized central moment at the test level related to the velocity vector and the concentration, the following first-order tensor is defined

$$A_i = T\left(u_i, C\right) = \widetilde{\overline{u_i C}} - \tilde{\overline{u}}_i \tilde{\overline{C}} \tag{28}$$

which in terms of generalized central moments can be split as:

$$A_i = L_i^T + C_i^T + R_i^T \tag{29}$$

where:

$$L_i^T = T\left(\tilde{\overline{u}}_i, \tilde{\overline{C}}\right) = \widetilde{\tilde{\overline{u}}_i \tilde{\overline{C}}} - \tilde{\tilde{\overline{u}}}_i \tilde{\tilde{\overline{C}}}$$

$$C_i^T = T\left(\tilde{\overline{u}}_i, C'\right) + T\left(u_i', \tilde{\overline{C}}\right) = \left(\widetilde{\tilde{\overline{u}}_i C'} - \tilde{\tilde{\overline{u}}}_i \tilde{\overline{C'}} + \widetilde{u_i' \tilde{\overline{C}}} - \tilde{\overline{u'}}\,\tilde{\tilde{\overline{C}}}\right)$$

$$R_i^T = T\left(u_i', C'\right) = \widetilde{\overline{u_i' C'}} - \tilde{\overline{u_i'}}\,\tilde{\overline{C'}}$$

The sum of the last two terms on the right hand side of Equation 29 is an unknown quantity that is modeled with an expression analogous to Equation 27:

$$C_i^T + R_i^T = c_c \sqrt{E^T} d_{in}^T \frac{\partial \tilde{\overline{C}}}{\partial x_n} \tag{30}$$

The calculation of the coefficient c_c is carried out by using the following identity

$$A_i - \tilde{a}_i = \widetilde{\overline{u_i C}} - \tilde{\overline{u}}_i \tilde{\overline{C}} \tag{31}$$

Equation 31, with the use of the closure relations expressed by Equations 27 and 30, becomes

$$c_c \sqrt{E^T} d_{in}^T \frac{\partial \tilde{\overline{C}}}{\partial x_n} - \widetilde{c_c \sqrt{E} d_{in} \frac{\partial \overline{C}}{\partial x_n}} = \widetilde{u_i \overline{C}} - \tilde{u}_i \tilde{\overline{C}} - \widetilde{\tilde{u}_i \tilde{\overline{C}}} + \tilde{u}_i \tilde{\tilde{\overline{C}}} + \widetilde{u_i \tilde{\overline{C}}} - \tilde{u}_i \tilde{\tilde{\overline{C}}} \tag{32}$$

where E^T indicates the SGS kinetic energy relative to the test-filter and d_{in}^T indicates the second-order tensor associated with the turbulence length scales relative to the test-filter.

Equation 32 allows the dynamic calculation of the coefficient c_c.

The numerical integration of Equation 23 for the simulation of the filtered concentration field of suspended solids may be carried out once the boundary conditions have been defined.

The plane, in proximity to the bottom, which defines the boundary for the concentration field is placed immediately above the viscous sublayer, inside the buffer layer: the "Reference Concentration", C_r, is imposed on the plane as a boundary condition.

Copyright © 2006 Taylor & Francis Group plc, London, UK

This reference concentration is calculated as a function of the resolved tangential stress at the bottom and the critical stress representing the threshold beyond which the movement of solid particles from the bottom is produced.

In particular, in the proposed model the value of the local and instantaneous reference concentration, C_r, is related to the resolved velocity field at the bottom by means of the formula proposed by Van Rijn (1985). The aforesaid Van Rijn formula reads:

$$C_r = 0{,}015\left(\frac{D_p}{a}\right)\left(\frac{T^{1,5}}{D_*^{0,3}}\right) \tag{33}$$

in which
a: distance from the bottom at which C_r is calculated
D_p: diameter of the solid particles

$$D_* = D_p\left[\frac{(\delta-1)g}{\nu}\right]^{1/3} \quad \begin{cases} \delta: \text{relative density of the particle} \\ \nu: \text{kinetic viscosity} \end{cases} \tag{34}$$

$$T = \frac{\overline{u}_*^2 - u_{*crit}^2}{u_{*crit}^2} \tag{35}$$

and the quantity $\overline{u}*^2$ which appears in Equation 35 is linked to the tangential stress at the bottom, τ_f, produced at each time step by the tangential resolved velocity component at the bottom, $\overline{u}$, by means of the following relation:

$$\overline{u}_*^2 = \frac{\tau_f}{\rho} = \nu\frac{\partial \overline{u}}{\partial y} \tag{36}$$

3 RESULTS AND DISCUSSION

The symbol $\langle . \rangle$ represents the Reynolds average and the friction velocity based Reynolds number is given by:

$$Re_\tau = \langle u_* \rangle L/\nu.$$

Turbulent channel flows (between two flat parallel plates placed at a distance of $2L$) are simulated with the proposed Large Eddy Simulation model at different friction-velocity-based Reynolds numbers, ranging from 395 to 2,340.

In order to validate the proposed closure relation for the generalized SGS turbulent stress tensor, the numerical results obtained with the proposed model are compared with DNS results and with experimental data.

The proposed model is used to simulate the phenomenon of the re-suspension (from the bottom) of solid particles in a channel flow.

The values of the diameter and the relative density of the solid particles are, respectively, equal to 100 μm and 1.65.

The simulation of the velocity and concentration fields in a channel flow is performed at Reynolds number $Re_\tau = 600$.

In Figure 1 is plotted the profile of the time-averaged streamwise velocity component obtained with the proposed model compared with the profile obtained with DNS (Mansour et al.) and the Dynamic Mixed Model, DMM (Zang et al. 1993), for flows at $Re_\tau = 395$. The figure shows that the profile obtained with the proposed model agrees more the DNS velocity profile than with the profile obtained with the DMM, both in the boundary layer and in the region inside the channel.

Figure 2 shows the profiles of the component $<u_1' u_3'>$ of the Reynolds stress tensor, (where indexes

1 and 3 denote, respectively, the streamwise and wall-normal directions), obtained from the simulations carried out with the proposed model compared with the profiles of the analogous component obtained from DNS and from simulations carried out with the DMM at $Re_\tau = 395$. As can be seen from figure 2, the profile of the component $<u_1' u_3'>$ calculated with the proposed model yields a similar profile to that of the corresponding component of the Reynolds stress tensor obtained by the DNS, whilst the DMM provides values which are greatly underestimated.

Figure 3 shows the profile averaged streamwise velocity component for a channel flow at $Re_\tau = 2340$ obtained with the proposed model compared with the profile of the analogous velocity component measured experimentally (Comte-Bellott). The agreement between the two velocity profiles is very good.

Figure 4 compares the profile of the component $<u_1' u_3'>$ of the Reynolds stress tensor calculated with the proposed model with the profile of the similar component of the Reynolds tensor obtained from experimental measurements, for a channel flow at $Re_\tau = 2340$. Figure 4 shows that at $Re_\tau = 2340$ the proposed model provides a profile of the component $<u_1' u_3'>$ in agreement with that of the corresponding component of the Reynolds stress tensor obtained from the experimental measurements.

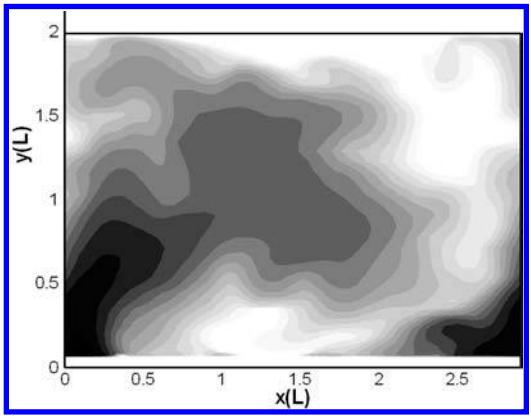

Figure 8. Channel flow: filtered concentration field.

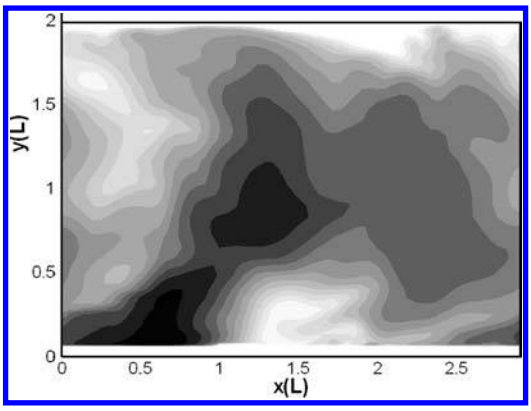

Figure 9. Channel flow: filtered concentration field.

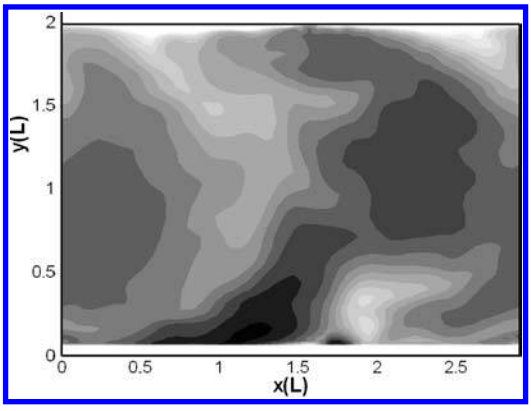

Figure 10. Channel flow: filtered concentration field.

In Figures 5–10 is shown a sequence of longitudinal sections of instantaneous solid particles concentration fields relative to the transitory interval during which the phenomenon of the re-suspension begins and develops from the bottom and the transport of solid particles inside the channel.

Periodic boundary conditions on the velocity and concentration fields in the streamwise direction allow the numerical simulation of the concentration field which occurs in a channel of infinite length having an erodible particle bed.

Figure 5 shows the filtered concentration field (at an instant of the numerical simulation): from the figure it is possible to see how some vortices (characterized by a high content of the turbulent kinetic energy and located between the abscissa $x > 1$ and $x < 1.5$) are able to produce instant values of friction velocity that may generate the re-suspension of the solid particles.

In Figures 6–10 it is shown how the concentration field values change over time: these variations are the result of the streamwise movement of the aforesaid vortices: the increases of the instantaneous friction velocity (associated to the vortices) and the streamwise movement of the vortices with high value of kinetic energy produce an increase of the value of the reference concentration and a streamwise movement of the bottom regions characterized by the re-suspension of the solid particles.

After a high number of iterations a statistically steady condition for both the solid and the liquid phase is verified.

By applying a Reynolds average to the spatially filtered concentration values (for a time higher than the integral time scale of turbulence) a statistically steady vertical concentration profile of the solids in suspension is obtained:

$$\left\langle \overline{C}(y) \right\rangle = \int_0^{T_0} \overline{C}(y,t)\,dt \qquad (37)$$

where y is the vertical coordinate and T_0 the time over which the average is calculated.

The numerical results of the concentration vertical profile, obtained by Equation 37, are compared with the experimental measures concentration of Gallerano & Cioffi (1991) in a channel of rectangular area with an erodible particle bed, in steady conditions.

The theoretical profile of the Reynolds averaged concentration values is also calculated by adopting the following Van Rijn's formula in the same average hydrodynamic conditions and for the same particle characteristics of the LES simulations:

$$\frac{\langle C \rangle}{\langle C_r \rangle} = \left[\frac{a(H-y)}{y(H-a)} \right]^{Z} \qquad (38)$$

where

$$Z' = Z + \tau; \qquad \tau = 2.5 \left[\frac{\omega_0}{\langle u_* \rangle} \right]^{0.8} \left[\frac{\langle C_r \rangle}{0.65} \right]^{0.4} \qquad (39)$$

$$Z = \frac{\omega_0}{K_\beta k u_*} \; ; \qquad K_\beta = 1 + 2\left[\frac{\omega_0}{\langle u_* \rangle}\right]^2 \tag{40}$$

ω_0 : terminal velocity; k: Von Karman constant
$\langle C_r \rangle$: Reference Concentration calculated by means of Equation 33 in which

$$T = \frac{\langle u_* \rangle^2 - u_{*crit}^2}{u_{*crit}^2} \tag{41}$$

and the parameter a, that appears in the Equation 33 and 38, is assumed equal to the distance from the bottom where the plane on which the Reference Concentration is assigned is placed. In this case a is assumed equal to 12 wall units, where the wall unit

$$y^+ = \frac{y\langle u_* \rangle}{\nu} \tag{42}$$

is calculated using the friction velocity obtained with the Reynolds number of the numerical simulation of the channel flow:

$$\langle u_* \rangle = \frac{Re_\tau \nu}{D} \tag{43}$$

In Figure 11 the vertical concentration profile, obtained by averaging (over time) the spatially filtered concentration values (calculated by means of the proposed numerical model), is compared with the vertical concentration profile measured experimentally by Cioffi & Gallerano (1991) in stationary conditions and with the vertical concentration profile calculated theoretically by means of Van Rijn's formula.

4 CONCLUSIONS

In this paper a new LES model is presented together with a new methodology for the simulation of concentration fields of solids in suspension which is coherent with the LES methodology.

A new constitutive equation, relating the generalized SGS turbulent stress tensor to the resolved kinematic quantities, is proposed. The closure relation on the basis of the proposed model (a) respects the principle of turbulence frame indifference (Hutter & Johnk 2004); (b) takes into account both the anisotropy of the turbulence velocity scales and of the turbulence length scales; (c) removes any balance assumption between the production and dissipation of turbulent kinetic energy; (d) assumes scale similarity.

In the proposed model: (a) the generalized SGS turbulent stress tensor is related exclusively to the generalized SGS turbulent kinetic energy (which is calculated by means of its balance equation) and the modified Leonard tensor; (b) the viscous dissipation ε of the generalized SGS turbulent kinetic energy is calculated by solving the ε balance equation.

Turbulent flows have been simulated with the proposed model between two flat and parallel plates (turbulent channel flow) at friction-velocity-based Reynolds numbers ranging from 395 to 2340. The closure relation between the generalized SGS turbulent stress tensor and the resolved kinematic quantities, used in the proposed model, improves the agreement between the results obtained with LES and those obtained with DNS and with experimental measurements and it allows the simulation of high Reynolds number flows.

The concentration field is simulated by the spatially filtered equation of the concentration. In this equation the first order tensor (produced by the correlation between velocity and concentration) is related to the gradient of the resolved concentrations according to an original dynamic Germano procedure.

The vertical concentration profile, obtained by averaging (over time) the spatially filtered concentration values (calculated by means of the proposed numerical model), are in agreement with the experimental data.

Turbulent processes at the entrance of a pool using flow visualization

G.A. Marquis & A.G. Roy

Département de géographie, Université de Montréal, Montréal, Québec, Canada

ABSTRACT: We examine the response of the turbulent flow processes to changes in bed morphology at the entrance of a pool. Flow visualization and high frequency velocity measurements are combined along a transect where depth increases over a short distance. Velocity data revealed an increased spatial coherence of the turbulent flow structures along the transect. Results from the visualization showed a clear transition in the spatial and temporal scales of the turbulent events. As depth increases, there is a transition in the scale of roughness from a clast dominated boundary layer to a large bedform dominance and turbulent events adjust to this change. Turbulent events that develop in the lee of the slope at the entrance of the pool are more regular and they advect less frequently but more powerfully towards the surface. This bedform-turbulent flow structure interaction may be significant for sediment transport and flow mixing within pools.

1 INTRODUCTION

The turbulent structure of the flow in a river is often described by mean parameters such as turbulence intensity and turbulent kinetic energy. However, individual turbulent events may be significant for river processes like sediment transport and water column mixing (Nelson et al. 1995). Turbulent events in a gravel-bed river mainly occur as large-scale turbulent flow structures, which are ubiquitous and dominant features of the fluvial turbulent boundary layer (Roy et al. 2004). Large-scale turbulent structures are composed of alternating high- and low-speed wedges that scale with outer flow variables such as flow depth (Y). Wedges are narrow (0.5 to $1Y$), elongated (2 to $6Y$) and generally occupy the entire flow depth. Low-speed wedges are ejection-like structures with vertical velocity being positive most of the time. In contrast, high-speed wedges are sweep-like structures with a mostly negative vertical velocity. Those two counterparts, the ejection and the sweep, form the well known bursting process.

Evidence to substantiate the presence and role of these large-scale turbulent flow structures has come from high frequency velocity measurements as well as from flow visualization. While high frequency velocity measurements have been extensively used in river flows, visualization has mostly been limited to flume experiments where it is possible to control the conditions. For instance, flow visualization provides very rich spatio-temporal information on the turbulent flow field. In a river, flow visualization measurements are laborious and only a few researchers have chosen this method to investigate flow turbulence. However, the information provided by visualization is complementary to point velocity measurements, mostly used is shallow flows (Roy et al. 1999). Automated quantification of images recorded in the field has not been fully exploited until now, because the complex images require many transformations before being usable. Also, the quantification of turbulence based on the visual analysis is subject to operator errors and is time consuming. Nevertheless, this type of analysis reveals an excellent correspondence with results derived from the velocity measurements. For example, Paiement-Paradis et al. (2003) showed that the two methods result in similar power law scalings of the frequency distributions for individual turbulent event duration. Generally, the qualitative and the quantitative information manually extracted from the images have allowed to confirm and extrapolate the results from velocity measurement (e.g. Roy et al. 1999, 2004). Until now, *in situ* flow visualization has been only used to study small scale turbulent processes in uniform flows above rough beds and not to examine larger scale bedform-flow interactions.

Several researchers have emphasized the necessity of investigating turbulent flow processes to better understand the complex relationships between bedforms, sediment transport and flow in rivers with pool-riffle morphology (e.g. Clifford 1993). These bedforms impose repeated constraints on the flow by

Copyright © 2006 Taylor & Francis Group plc, London, UK

inducing depth changes in the channel, thus affecting flow turbulent parameters as well as individual turbulent events. In a flume experiment, Thompson (2004) found that the acceleration of the flow at the exit of a pool where flow depth is decreasing produced a non-linear increase of the velocity standard-deviation in the downstream direction. He hypothesized that turbulence intensity increases at the exit of the pool thus leading to an increased dissipation of energy, a mechanism that may be critical for sediment transport. Consequently, the length of the pool is optimized to the mean hydraulic conditions. To our knowledge, no study has investigated the effects of a large bedform on individual turbulent events in a pool-riffle river.

In this paper, our aim is to characterize the effects of increasing flow depth on the turbulent processes at the entrance of a pool in a gravel-bed river. Individual turbulent events that correspond to wedges are the focus of this study. We have used a combination of high frequency velocity measurements and flow visualization. We have also developed a new protocol to automate the quantification of the information extracted from the images. This paper will focus on the visualization results. Velocity measurements will mainly be used to confirm visualization analysis and describe the global characteristics of the flow at the entrance of a pool.

2 METHODS

2.1 *Sampling design*

Field work was conducted in the Eaton-Nord River, Estrie, Québec, Canada. This gravel-bed river is characterized by well defined pool-riffle sequences. The study site is a deep forced-pool induced by a bedrock outcrop on one of the river banks (Figs. 1a, 2). The consequence of this morphology is a flow field where depth increases over a short distance from the riffle to the pool. The study section is 10 m wide and depth (Y) varies from 0.3 to 1.0 m. At the study site, the bed is composed of loose gravel and D_{50} of the substrate is 19 mm with a sorting coefficient of 0.89. During field sampling, particles on the bed were at the threshold of mobility. Mean velocity (U) was around 0.90 ms^{-1} along the transect. No flow deceleration trend was observed because the depth increase occurred at the same time as the flow constriction (Tab. 1). However, the standard deviation of longitudinal velocity (s_u) shows a decreasing trend (Tab. 1). As a consequence of the flow high velocity and complex morphology, the Reynolds number is high (Re = 250 000 to 500 000).

Measurements were taken along a transect in the center of the reach at the entrance of the pool, where most of the depth transition between the riffle and the pool is observed (Fig. 2). All the measurements were taken upstream from the entrance of a secondary channel into the pool (Fig. 2). The study site was divided into four zones where similar measurements were taken (Fig. 1b). Bed topography is irregular along the measurement section and depth increases in two steps. Bed roughness also changes along the section and the central zones (B and C) present larger particles than those in zones A and D (Tab. 1). Visualization and

velocity measurements were carried out successively within each zone.

Velocity measurements were recorded with two acoustic Doppler velocimeters (SonTek, 10 MHz ADV). Flow velocities are measured in three dimensions at a frequency of 25 Hz in a sampling volume of 250 mm^3. In each zone of the study site, one ADV was positioned at the downstream end of the zone and one ADV was placed 0.50 m upstream (Fig. 1b). This design was chosen in order to characterize the flow field in the downstream half of each zone where the visualization patterns are well developed. The velocimeters were fixed on wading rods and held by operators. The sampling volume was located at 0.15 m above the bed, an adequate distance to capture the large-scale turbulent flow structures without the local perturbations in the vicinity of the bed (Roy et al. 2004). This strategy allows the comparison of the velocity measurements with the visualization data. In further analysis, only the longitudinal (u) and vertical (v) velocity components were used, as the data obtained from the visualization only concern these two dimensions.

To observe turbulent events, dye (powder milk) was injected at the bed surface and filmed with a video camera (Sony, model DCR-TV18) protected by a waterproof casing (Amphibico). The high flow velocity challenges the quality of the flow visualization measurements as the dye is advected very quickly. The injection of the dye at the bed surface ensures that it will be picked up by the ejection-like events that are characterized by an upward vertical velocity (Roy et al. 1999). These events overlap with the low-speed wedges. The dye was injected at a single point at the upstream limit of each zone. The camera was orientated perpendicularly to the flow direction. The camera captured images of 1.10 to 1.22 m wide at the center of the plane delineated by the dye (Fig. 1b, Tab. 1). The frequency of image acquisition (30 Hz) is similar to the sampling frequency of velocity (25 Hz) thus the measurements can be easily compared.

Three minutes were kept of each film and velocity records for further analysis. Buffin-Bélanger & Roy (2005) suggested that records of 60–90 s were sufficient to estimate the mean and turbulent flow properties in a gravel-bed river. From the films, the frequency of occurrence of turbulent events that reach a height of $0.5Y$ was between 0.4 and 1.0 s^{-1}. Therefore, a three minute record should be representative of the turbulent flow structure in conditions of high flow velocity where turbulent events occur at a high frequency.

Table 1. Characteristics of the sampling sites.

	Zone A		Zone B		Zone C		Zone D	
Width (m)	1.17		1.14		1.12		1.22	
D_{50} (m)	0.017		0.020		0.023		0.016	
ADV	A1	A2	B1	B2	C1	C2	D1	D2
Y (m)	0.35	0.45	0.50	0.52	0.58	0.63	0.64	0.65
y/Y	0.43	0.33	0.30	0.29	0.26	0.24	0.23	0.23
U (ms^{-1})	0.93	0.82	0.77	0.96	0.87	0.91	0.96	0.93
s_u (ms^{-1})	0.19	0.20	0.17	0.15	0.15	0.14	0.16	0.16
s_v (ms^{-1})	0.10	0.11	0.09	0.11	0.09	0.09	0.10	0.10

2.2 *Velocity data validation and analysis*

ADVs are instruments sensible to multiple sources of environmental noise (Voulgaris & Throwbridge 1998, MacLelland & Nicholas 2000, Goring & Nikora 2002). It is therefore necessary to evaluate the velocity data quality and to apply the appropriate corrections. In the present study, mean signal correlations are between 78% and 82% and mean signal to noise ratios are between 35 and 40dB. According to the recommendations of the manufacturer, these values should ensure good data quality (SonTek documentation 2002). Spikes in the series were detected using the method presented by Goring & Nikora (2002) and were removed and replaced by linear interpolation using the nearest neighbors of the deleted points. Noise associated with the Doppler effect in high frequencies was removed with a third order low-pass Butterworth filter as recommended by Roy et al. (1997). This filter affects the slope of the power spectrum in the high frequency region and brings the value closer to $-5/3$, a characteristic value of velocity in the inertial subrange of the turbulent boundary layer (Panofsky & Dutton 1984). For means of comparisons between the different velocity measurements, the averages of the vertical (V) and lateral (W) velocity components should be equal to zero over three minute records. The average angles in the longitudinal/vertical plane were between $-5°$ and $2°$. Such angles are believed to be more attributed to the misalignment of the instruments rather than by secondary currents (Roy et al. 1996a). All velocity signals were therefore rotated to bring the angles to $0°$. Finally, the velocity time series were detrended. For some analysis, the longitudinal (u') and vertical (v') velocity fluctuations were used, where

$$u' = u - U \quad \& \quad v' = v - V \tag{1}$$

The analyses of the velocity measurements are conducted in two parts. Firstly, the coherence of the turbulent flow structure is assessed by a space-time correlation analysis. The spatial coherence is estimated from the maximum value of the cross-correlation function (CCF) between simultaneous pairs of ADV time series in each of the four zones. The CCF is estimated for longitudinal and vertical velocity. The maximum correlation coefficient is indicative of the coherence of the turbulent flow structures maintained between two separated points of measurements (Nakagawa & Nezu, 1981).

Copyright © 2006 Taylor & Francis Group plc, London, UK

Secondly, we analyzed the dynamics of individual turbulent events using the modified U-Level technique developed by Luchik & Tiederman (1987). It detects low- and high-speed wedges solely from the longitudinal velocity component. The detection of a turbulent event begins when

$$|u'| > ks_U \quad \text{and ends when} \quad |u'| < pks_U \tag{2}$$

where k is a threshold value, s_u is the standard deviation and p takes a value between 0 and 1. In this paper, a threshold of $k = 0$ is used so that every portion of the signal is categorized as a low or a high-speed wedge. The U-level with $k = 0$ was chosen for its reliability to be compared with the visualization analysis (Paiement-Paradis et al. 2003, Roy et al. 2004).

2.3 *Visualization data validation and analysis*

Before extracting quantitative data from the films it is necessary to reclassify the images. Most of the information on turbulent dynamics is derived from the spatio-temporal evolution of the cloud formed by the dye. Because the injection point is in the clasts at the bed, the dye elevates within the water column with ejections of fluid from the near-bed region. When the dye remains close to the bed, we assume that it corresponds to the passage of sweeps. Therefore, we have chosen to isolate the dye in order to obtain a film of binary type images as shown in Figure 3. The raw images of the films (Fig. 3a) are composed of three color layers (red green blue, RGB mode). Hence, the first step is to reduce each frame in a single layer to facilitate further handling by saving computer memory space. The addition of the red and blue layers has the advantage of enhancing the brightness of the dye in comparison with the ambient environment (Fig. 3b). Once this is done, only the portion of the images where the dye is visible in the flow field is kept (Figs. 3b, c, d).

The next step is the application of a threshold to all the frames to obtain a film of binary fluctuations of the dye (presence/absence) (Fig. 3c). The value of the threshold is determined from the pixel intensity distribution in the flow field of the whole film. In the absence of dye in the flow, pixel intensity varies little over time. In the presence of dye, the distribution of pixel intensity values for a single pixel time series is skewed to the right. From experience, pixel intensity values higher than the mean of the distribution correspond to the presence of the dye. Thus, the threshold is determined by trial-and-error around the mean value of pixel intensity. The effects of a given threshold is checked by a visual assessment of the goodness-of-fit between the original contour of the dye on the raw image and the contour of the dye cloud delineated at that threshold on the binary image. The value of the threshold for each film varies with the saturation of the images, which is essentially a function of depth, water turbidity and the intensity and orientation of the sun.

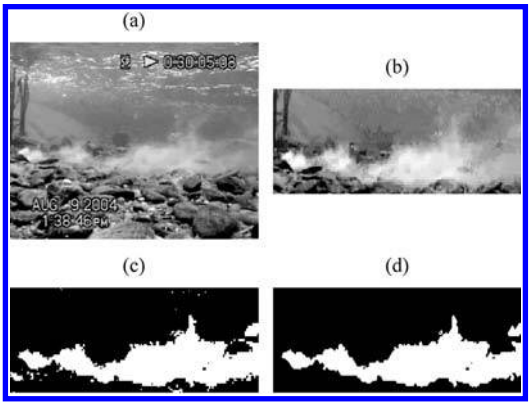

Figure 3. Steps in the reclassification of the images of the flow visualization analysis. Width of the frame is 1.17 m. (a) Raw image. (b) Red and blue layers added. (c) Raw binary image. (d) Filtered binary image.

The last step before the films are ready for quantitative analysis is the filtering of each frame to remove the noise (Fig. 3d). The noise is mainly due to objects that have the same saturation signature than the cloud of milk. This step requires being cautious because the noise has to be removed without affecting the shape of the cloud of dye. Therefore, classical median or mode filters cannot be used. The noise may also be unstable due to the variation of the sun reflection on the bed particles. As the noise is not always located at the same position in the image, the filtering operation cannot be facilitated by applying a mask. The best differentiation criterion is the size of the objects. The noise is always due to objects smaller than the cloud of dye. In order to leave untouched the cloud of dye and to remove the noise at a satisfying level, an algorithm was designed to detect isolated groups of pixels by scanning each frame with a moving window. Finally, all the films are rescaled to allow comparison between each zone.

The first type of visualization analysis consists of extracting time series from strategic and meaningful positions in the flow field. The reclassified images show the occurrence of low-speed wedges when the dye is present and it advects downstream and high-speed wedges when the dye is absent. Time series were built from the variation of a single pixel, which represents roughly 10–15 mm^2. All series were extracted from the downstream half of the images where the dye can reach $0.5Y$ above bed. At a distance of $1Y$ from the dye injection point, the turbulent structures are well developed, enough to characterize their dynamics (Paiement-Paradis et al. 2003). A first set of visualization time series are taken at the location of the ADVs (Fig. 1b). A second set of visualization time series

Copyright © 2006 Taylor & Francis Group plc, London, UK

are extracted from each pixel along a vertical profile between $0.25Y$ and $0.5Y$ located at $1.5Y$ downstream of the injection point. These heights were chosen because below $0.25Y$ the dye is too homogenous and above $0.5Y$ it becomes too sparse and diluted.

In order to describe the spatio-temporal dynamics of the largest individual turbulent events, fifteen wedges were selected visually in each film over the three minute duration. A large turbulent event is defined as a structure that extends vertically above $0.5Y$ and that occupies a large surface in the image. For each turbulent event, three time steps were kept to represent its evolution. One frame is extracted when the turbulent event is the most developed. From that frame, one is extracted 10 frames before (1/3 s) and another one 20 frames before (2/3 s). We chose to analyze 15 major events per film because it is approximately the number of very large turbulent events that occur during three minutes. These few structures may contribute a large part of the Reynolds shear stress because of the important fluctuations in vertical velocity (Lu & Willmarth 1973).

3 RESULTS

3.1 *Reliability of the automated analysis of the turbulent flow structures*

To confirm the reliability of the automated procedure, we compared the results of the image analysis with those obtained from the modified U-level technique applied to the streamwise velocity component as shown in Figure 4a, b, c. The visualization results for the points located where ADV measurements were taken (Fig. 1b) have similar characteristics than the U-level analysis. Along the transect, the mean durations of turbulent events show approximately the same trend for the visualization and velocimetry (Fig. 4a). The main difference between the two methods is in the frequency of occurrence of turbulent events (Fig. 4b). The frequency of occurrence is obtained by dividing the number of events detected by the length of the time series. The visualization analysis underestimates the number of turbulent events. This underestimation is more pronounced for short turbulent events because of the rapid dilution of the dye within the high velocity flow. This phenomenon explains the slight overestimation of the mean duration of events (Fig. 4a).

The frequency distribution of the duration of turbulent events should display a power law scaling as reported by Paiement-Paradis et al. (2003). For example, at the downstream end in zone D, the low-speed wedges detected from the images and from the velocity time series have similar frequency distribution shapes (Fig. 5). The number of events in each class is less for visualization results than for the velocity time series (Fig. 5). The power law slopes of the frequency

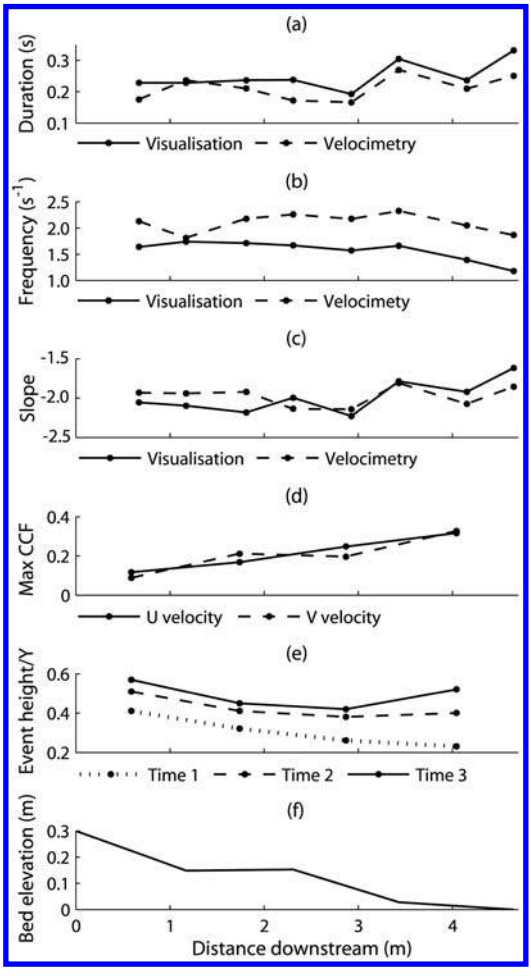

Figure 4. Characteristics of low-speed wedges in each zone as estimated through visualization and ADV measurements (U-level detection), (a) Mean duration; (b) Frequency of occurrence (or number of events per second); (c) Power law slope of the frequency distribution of events duration; (d) Maximum cross-correlation function; (e) Event height normalized on depth (Y) of the 15 largest events in the three minute films at three time steps; (f) Bed topography.

distribution of low-speed turbulent events duration along the transect are shown in Figure 4c. The range and trend of the values are similar for both methods. This means that the ratio between short and long turbulent events is the same even though there is an offset in the number of events detected by the methods. These results tend to show that the data obtained from the protocol to analyze the images yields reliable information even tough flow conditions were challenging for such a visualization experiment. There is a need, however, to be cautious with the absolute values of the

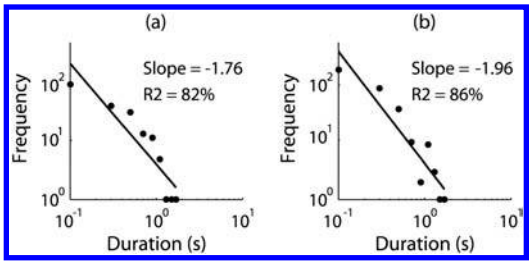

Figure 5. Frequency distribution of the duration of the low-speed wedges for location D2, at the downstream end in zone D, (a) Flow visualization; (b) ADV velocity measurements.

results obtained from the visualization analysis as the procedure is still in development.

3.2 *Flow spatial coherence*

The spatial coherence of turbulent flow is assessed from the correlation analysis in the velocity time series. The maximum correlation coefficients of the CCF between two simultaneous ADV represent the coherence of the turbulent flow structures between two points in the flow. Figure 4d shows that for both the longitudinal and vertical velocity components, the maximum of the CCFs per pair of ADVs increases in the downstream direction. Surprisingly is the value of the maximum of the CCFs of the vertical velocity component is in the same range as the value for longitudinal velocity component (Fig. 4c). Usually, the vertical component of the velocity is less coherent than the longitudinal component (Roy et al. 1996b). Here, there is an enhanced coherence of the vertical velocity component.

3.3 *Events duration, time interval and frequency*

In Figure 4a, b and c, the mean duration of turbulent events, the frequency of occurrence of turbulent events, and the power law slopes of the frequency distribution of the turbulent events duration are similar in zones A and B. A break in these values occurs at the downstream end in zone C showing that the characteristics of the turbulent events are changing with an increasing depth. This effect is still present in zone D where the turbulent events are still adjusting to the increase in flow depth.

The results of the image analysis of the vertical profiles between $0.25Y$ and $0.5Y$ located at $1.5Y$ downstream of the injection point for each zone are shown in Figure 6. The mean duration of events is decreasing from the bed to the surface (Fig. 6a). This result was expected as the dye is injected at the bed and progressively advected towards the surface. The four zones have approximately the same vertical profile of mean turbulent event durations (Fig. 6a). However, the durations of events in zone D have a larger standard deviation than those in the three upstream zones (Fig. 6b). Turbulent events in zone D also display a lower frequency of occurrence in time (Fig. 6c) and consequently, a larger mean time interval between turbulent events (Fig. 6d). The mean time interval between turbulent events is the mean duration between two successive low-speed wedges events. It is shown in Figure 6e that the relationships between the frequency of occurrence of turbulent events and the mean time interval between events have the same trend in the four zones. When relative height above bed is plotted against the ratio between mean events duration and the mean time interval between events, the four zones become distinct from one another (Fig. 6f). The profile in zone A has the highest ratio values, followed by zones C, B and D where the smallest ratio values are observed.

3.4 *Spatio-temporal evolution of turbulent events*

The characteristics of low-speed wedges presented in Figure 6 indicate that turbulent processes at the downstream end of the entrance of the pool, where the flow is deeper, are different than those seen at the beginning of the flow expansion. To investigate further these processes, we examined the spatio-temporal evolution of the shape and size of 15 large turbulent events in each zone. The results are shown in Figure 7. The three first rows in the figure present the superimposition of the 15 frames for each time step in each zone. The darker portions of the images represent the areas where most of the events have passed. Visually, we see that turbulent events in zones A and D are larger and that their shapes are more regular than those in zones B and C. This holds true for the three time steps. The saturated black area is smaller for zones B and C while the gray cloud occupies a larger portion of the image. In other words, the large turbulent events in zones B and C tend to be smaller and their evolution in space is more irregular. The structures do not tend to follow a similar path. Turbulent events in zone D are the most regular and the largest. They are very well defined in space through time for the three time steps displaying a greater consistency in their trajectories as they advect downstream. Visual observation of their evolution on the film showed that the vortices were not only larger than in the other zones but also that they rotated more slowly.

The fourth row of Figure 7 displays all the turbulent structures for the 15 events at the three time steps for each zone, for a total of 45 images superimposed. This superimposition of the temporal evolution reveals a net transition in the turbulent processes. For large turbulent events in zones A to C, the head of the cloud of each time step where the dye has passed quite consistently is visible (Fig. 7). When an ejection-like event forms, it rapidly grows vertically before

Copyright © 2006 Taylor & Francis Group plc, London, UK

being advected downstream. The structures maintain a constant angle of approximately 40° relative to the bed. The structure heads for time steps 1 and 2 of the turbulent events in zone D are not visible in the time superimposed images (Fig. 7). When an event in zone D is initiated, it always grows in the same direction. Even though this speculation remains to be fully demonstrated, the evidence presented here clearly shows a different mode of development for the large turbulent structures. Figure 4e presents the mean maximum height of turbulent events normalized by depth for each time step at each zone. The vertical extent of the large turbulent events is smaller in zone B and C. As we progress into the pool, the vertical development of the structures occurs later but faster. This indicates a dominance of the vertical velocity component which has an enhanced coherence as indicated by the maximum correlation of the CCFs (Fig. 4d).

4 DISCUSSION

The results presented in this paper link the study of individual turbulent events processes to a large bedform such as a pool where a rapid vertical flow expansion is observed in a gravel-bed river. The use of flow visualization has been shown to provide a complementary approach to the analysis of velocity measurements to describe and understand the spatio-temporal characteristics of the turbulent processes. The data show a transition in turbulent processes occurring at the entrance of a pool. In general, the agreement between the two methods is good even tough the number and duration of the detected turbulent events may differ. It is necessary, at this point, to use the results of the new visualization automation procedure with care. The procedure that we have used shows promising results but still needs further refinement.

The measurements where intentionally done in the transition zone between a riffle and a pool because we consider that key processes occur in this zone between these two large bedform features. Most of previous flow measurements in pool-riffle units have been done over representative cross-sections of pools or riffles without covering the transition zones (e.g. Clifford 1993, Clifford & French 1993, Robert 1997). It is well accepted that the turbulent flow structure is different between riffles and pools (e.g. Cliffford 1993, Robert 1997). Thompson (2004) has focused his study on the exit of a pool which is the transition zone between a pool and a riffle. However, he did not explore individual turbulent events characteristics.

The turbulent structures present a range of characteristics at the entrance of the pool because the morphology of the study reach is complex. From the results presented here, three main characteristics of the flow field seems significant to the change of scale of the turbulent processes identified: (1) The spatial flow coherence increases as flow depth expands which favors the maintenance of the structure of the flow. (2) The vertical velocity spatial coherence is as important as that of the longitudinal velocity. This enhanced coherence in the vertical velocity component is induced by the flow expansion. This is visible in Figure 7 where large turbulent events tend to develop very early, mostly in zones A, B and C. The vertical development of large turbulent events in zone D is important also but it occurs much later in the evolution of the structures (Fig. 4e). (3) Even tough there is no apparent deceleration of the flow as depth increases because of the flow constriction induced by the bedrock outcrop, there is a decreasing trend of the standard deviations of the longitudinal velocity (Tab. 1). This is in agreement with the results of Thompson (2004) who found an increase of the standard deviation of the longitudinal velocity component at the exit of a pool. Although the downstream trend of velocity standard deviations may not be statistically significant, it is consistent with the results shown in Figure 7. Lower turbulence intensity at the downstream end of the entrance of the pool may explain that large turbulent events in zone D are larger and more regular than those in the upstream zones.

By a combination of approaches, we have identified changes in the scale of the turbulent processes. There is an apparent shift between particle-influenced turbulent processes to bedform-influenced turbulent processes as flow depth increases. Ejection-like structures occur in zones A, B and C as shown by the intense vertical development of the turbulent events. This vertical motion occurs early and it propagates in the flow field at a constant angle relative to the bed. The mean angle of 40° is similar to that found by Buffin-Bélanger et al. (2000) for low-speed wedges. These events should reflect the development of a turbulent boundary layer over a rough and irregular bed composed of heterometric clasts (Grass et al. 1991). At the downstream end of the transect, in zone D, large turbulent events propagate while maintaining a constant direction in such a way that the angle relative to the bed varies along the turbulent structure. This would be more typical of eddy shedding structures where flow separation induced by the rapid flow depth expansion over a short distance may play a role. This type of turbulent environment has already been identified for obstacles bed features like dunes and pebble clusters (e.g. Bennett & Best 1995, Buffin-Bélanger & Roy 1998). Brayshaw et al. (1983) have speculated that riffles may act as an obstacle in the flow and be considered as giant pebble clusters. As the velocity data were not dense enough along the transect, no shear zone indicating a flow separation could be identified at our site. Furthermore, the ratio between the flow

Copyright © 2006 Taylor & Francis Group plc, London, UK

depth and the bedform radius influencing turbulent processes is lower for riffles than for pebble clusters or dunes. Thus, the role of eddy shedding structures on the turbulent flow is still speculative. On the other hand, all zones show a very consistent pattern in the relationships between the frequency of occurrence of turbulent events and the time interval between successive events. The relationships have similar slope perhaps because they all pertain to low-speed wedges independent of their scale. Thus, the signature of turbulent events in zone D may be more closely associated with the flow environment that develops in the lee of large scale bedforms.

The transition in the scale of boundary roughness influence is detectable by the spatio-temporal evolution of the shape of the large turbulent events in zones B and C. In Figure 4e, their vertical development is less important than in zone A and D. The consequence of the flow expansion seems to create temporarily a zone where turbulent structures are not fully adjusted to the morphologic constraints and their development in the vertical direction is broken in many small vortices (Fig. 7). The ratios between the mean duration of turbulent events and the mean time interval between events for each zone show that there is a slight transition in turbulent characteristics along the transect (Fig. 6f). The shift in the scale of turbulent processes in zone D is confirmed by the results of all analysis. Turbulent events in zone D have a larger standard deviation of durations (Fig. 6b), a lower frequency of occurrence in time (Fig. 6c) and a longer mean time intervals between turbulent events (Fig. 6d). All these characteristics scale more closely to the bedform conditions than with only the local bed roughness. Events of zone D are larger, better organized and they eject powerfully as shown in Figures 4e, 7. This is consistent with a shift from the dominance of the boundary roughness type seen at the entrance of the pool.

5 CONCLUSION

When depth increases in a river channel, as it is the case at the entrance of a pool, the constraint on the average and turbulent flow properties is important and dynamic. Using flow visualization data obtained from an automated protocol for the analysis of the images, we have found a clear transition in the scale of the turbulent processes of individual ejection turbulent events. The flow is characterized by an increasing spatial coherence from the riffle to the pool head and the strong dominance of the vertical velocity component in the evolution of the turbulent structures. As we progress into the pool, the scale of the boundary roughness changes from local bed conditions dominated by heterometric grains to a large bedform condition. This change in boundary roughness conditions seems to lead to a shift in the scale of turbulent processes. As depth increases, there is a shift between more frequent ejections to less frequent but more regular and more powerful ejections. This transition in the scale of turbulent events is forced by the rapid flow expansion at the entrance of the pool. It is difficult to describe the exact nature of this transition and further work is required to understand the interactions between large bedforms and the turbulent flow structure. These interactions may be significant for sediment transport, bedform formation and maintenance and for vertical flow mixing within the pool.

A laboratory investigation on the advection of free surface fluctuations in turbulent open-channel flows

H. Miyamoto
Department of Civil Engineering, Kobe University, Kobe, Japan

ABSTRACT: The advection characteristics of both water surface fluctuations and turbulence in turbulent open-channel flows were experimentally examined in this paper. We used a simultaneous image measurement method to obtain instantaneous velocity vectors and the corresponding water surface profiles in a vertical cross section of the open-channel. Time series of the water surface profiles indicated that the water surface fluctuations were propagated with a constant advection velocity in each experimental case. The space-time correlation analysis of the water surface fluctuations and turbulence disclosed that the advection velocity of the water surface fluctuations was always smaller than the mean bulk velocity, while that of the turbulence above the near-bed region was the same as the mean velocity, well-known as Taylor's hypothesis of the frozen-turbulence approximation. It was also found that the ratio of the advection velocity of the water surface fluctuations to the mean bulk velocity became smaller as the Froude number decreased.

1 INTRODUCTION

Understanding behavior of the water surface in turbulent open-channel flows has become important from the viewpoint of the aquatic environment of rivers because it could affect the turbulence structures that regulate the gas transfer and the momentum exchange across the water surface. In addition, the spatial distributions of the water surface fluctuations in rivers could be used effectively to measure the surface velocity and flow discharge by using their video images and appropriate image processing methods (Fujita & Komura 1994, Fujita et al. 1998). However, we have had little knowledge about physical relationships between the water surface fluctuations and the turbulent flows immediately under the free surface when a Froude number becomes large and the surface fluctuations are considerably pronounced. This lack of knowledge makes us difficult to understand the transport phenomena around the turbulent water surface as well as to evaluate the validity of the river surface images for the velocity measurements. Therefore, fundamental laboratory experiments with a special focus on the free surface turbulence are indispensable for better understanding of the phenomena.

As for the recent experimental approaches on turbulent open-channel flows emphasizing water surface effects, many research works have been carried out. Among them, the authors measured velocity vectors and the corresponding water surface profiles by using a simultaneous image measurement method (Miyamoto et al. 2003a) with a high resolution CCD camera and a YAG laser. Then, by using POD (proper orthogonal decomposition) and space correlation analysis to the measurement data, they revealed that there were the specific correlation structures between the water surface fluctuations and turbulence structures having the same spatial scale (Miyamoto & Shimoyama 2003b, 2004a). Moreover, they found that a surface-influenced-layer existed immediately under the free surface of turbulent open-channel flows and its depth changed with the Froude number (Miyamoto & Shimoyama 2004b). Nezu & Nakayama (1998a, 1998b) measured the water surface fluctuations and turbulence by using a LDA (laser Doppler anemometer) and an ultra-sonic displacement sensor. They reported that the turbulence structures of open-channel flows near the surface region differed much from those of pipe flows through the examination of turbulence statistics and its energy budget (Nezu & Nakayama 1998a) and that there was a relationship between the organized vortices near the channel bed and those near the water surface by applying the space-time correlation analysis (Nezu & Nakayama 1998b). However, the advection characteristics of the water surface fluctuations have not yet been understood in detail because of the lack of the spatial and temporal resolutions of the measurements installed in the previous experimental works.

In this paper, a laboratory experiment was carried out to examine advection characteristics of both the water surface fluctuations and turbulence in open-channel flows by using a space-time correlation analysis in order to evaluate their relations to the mean velocity field. Instantaneous velocity vectors and the

Copyright © 2006 Taylor & Francis Group plc, London, UK

corresponding water surface profiles analyzed here were experimentally obtained by the simultaneous image measurement method (Miyamoto et al. 2003a). Moreover, we investigated the Froude number dependence of the advection characteristics of the water surface fluctuations as well.

2 LABORATORY EXPERIMENTS AND SIMULTANEOUS IMAGE MEASUREMENTS

2.1 *Hydraulic conditions*

The laboratory experiments reported here were conducted in a clear acrylic flume with the length of 10 m and the width $B = 0.25$ m. The measurement cross section was a vertical cross section along with the longitudinal direction of the flow and it was located at 7.5 m downstream from the inlet tank. It was expected that the turbulent boundary layer generated from the channel bed was fully developed at the measurement cross section. The hydraulic conditions are listed in Table 1. In the experiments, we kept the Reynolds number based on the mean bulk velocity $\overline{U}$ and the mean water depth H with the kinematic viscosity ν, $Re = \overline{U}H/\nu$, a constant ($=2.0 \times 10^4$), while we changed the Froude number based on $\overline{U}$ and H with the gravitational acceleration g, $Fr = \overline{U}/\sqrt{gH}$, from 0.81 (subcritical flow conditions) to 2.33 (supercritical flow conditions). In the hydraulic conditions, we choose relatively high Froude number in which the water surface fluctuations were expected to be pronounced. The range of the Froude number examined here was overlapped in half of the Cases with that examined in Nezu & Nakayama (1998a, 1998b). Relatively lower Froude numbers, which correspond to the condition of real river floods, will be examined in the next research step. In addition, we kept an aspect ratio of channel B/H greater than 6.0 throughout the experiments so that we could obtain the two-dimensional flow characteristics in long-term turbulence structures in the central zone of the channel, where effects of the side-wall friction almost disappears (Nezu & Nakagawa 1993).

2.2 *Simultaneous image measurements of water surface profiles and velocity vectors*

A schematic view of the image measurement system used in the laboratory experiments is shown in Figure 1. The image measurement system was composed of several pieces of equipment, i.e., an argon-ion laser with a laser beam expander, a high speed CCD camera, a monitor and a digital video deck, a PC with an image memory board and so forth. We used particles with diameters of 0.075–0.150 mm and with a specific gravity of 1.02 as a tracer for visualization. A flow field, where the tracer particles were seeded, was visualized by a laser light sheet, as shown in Figure 1. On one hand, the visualized images of the flow fields were captured by the high-speed CCD camera and were recorded in the PC. Images of the water surface profiles, on the other hand, were taken through the mirror so that the water surface would not be hidden by a meniscus of a water surface on the front channel wall. As a result, the images of both the flow field and the water surface profile on the vertical laser light plane were simultaneously captured in the same image flame. In the image processing technique, an edge extraction algorism was used to detect the location of the water surface, while a particle image velocimetry (PIV) was applied to measure the velocity vectors (Miyamoto et al. 2003a). In the image measurements, the sampling intervals of the velocity vectors (temporal resolution) were 1/400 seconds (Case 1 in Table 1) and 1/240 seconds (the other Cases in Table 1), and the pixel sizes of the image (spatial resolution) were ranged from 0.18 to 0.36 mm. Calculating statistics of the turbulent open-channel flows, we used measurement data of 6500–10900 images, of which the difference depended on the experimental Cases in Table 1, to converge the statistical values.

With regard to the reference flame introduced in this study, x, y in the Cartesian coordinate denote the streamwise direction (positive downward) and vertical

direction (positive upward), respectively, with the origin at a point on the channel bed. u, v denote the components of the instantaneous velocities in the x-, y-directions, respectively; U, V, the time-averaged (or the ensemble-averaged) mean velocities; and u', v', the velocity fluctuations. The $\overline{U}$ represents the mean bulk velocity ($=Q/BH$). As regards the water surface, the h denotes the profile of the instantaneous water depth, while H and h' are the mean and fluctuation components of the water depth h, respectively.

3 METHOD OF SPACE–TIME CORRELATION ANALYSIS

In this study, we examined the advection characteristics of both the water surface fluctuations and turbulence in open-channel flows by using the space-time correlation analysis. Analyzed here were the water surface fluctuation h' and the x-directional component of the velocity fluctuations u', as will be mentioned later.

The space-time correlation coefficient of a fluctuation $f(x_{\mathrm{ref}}, t_{\mathrm{p}})$ with $g(x, t_{\mathrm{p}}+\tau)$ is given as the following equation.

$$COR_{fg}(x;\tau)=\frac{\sum_{\mathrm{p=1}}^{\mathrm{M}} f(x_{\mathrm{ref}},t_{\mathrm{p}})\,g(x,t_{\mathrm{p}}+\tau)}{(\sum_{\mathrm{p=1}}^{\mathrm{M}} f(x_{\mathrm{ref}},t_{\mathrm{p}})^2)^{1/2}\cdot(\sum_{\mathrm{p=1}}^{\mathrm{M}} g(x,t_{\mathrm{p}}+\tau)^2)^{1/2}}, \quad (1)$$

where x_{ref} and x denote position vectors of the fluctuations f and g, respectively, and the word '*ref*' of the x_{ref} represents the fixed reference position of the correlation calculation. The t_{p} denotes the discrete time; M, the number of the whole discrete time; and τ, the time lag between the fluctuations f and g.

4 RESULTS AND DISCUSSION

4.1 *Instantaneous velocity fields*

Instantaneous velocity vectors and the corresponding water depth obtained by the simultaneous image measurement are shown in Figure 2 (Case 2; $Fr=1.60$). The velocity vectors near the channel bed are fluctuated vertically with certain spatial extent mainly due to the bed shear. Although the water surface is almost horizontal, there exist small ripples with the spatial scales of 3–4 cm. We used these fluctuation data of the measurements with the sampling intervals 1/400 or 1/240 sec to examine their advection characteristics.

4.2 *Instantaneous water surface profiles and their time sequence*

Four successive water surface profiles with the time difference of 1/80 sec are shown in Figure 3 (Case 2;

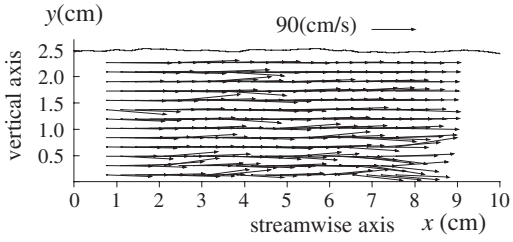

Figure 2. Instantaneous velocity vectors with the corresponding water surface profile. Case 2, $Fr=1.60$.

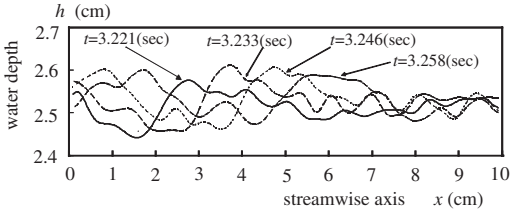

Figure 3. Temporal change of the water surface profiles. Case 2, $Fr=1.60$.

$Fr=1.60$). The instantaneous water depth of the Case 2 is spatially fluctuated with ± 0.1 cm around the mean depth H. The water surface fluctuations are moving downstream with a constant phase speed, although the shape of water surface is slightly changed with time. Moreover, the water surface fluctuations seem to be wave-like motions since a new crest appears at the upstream side of the channel at $t=3.246$ and 3.258 sec.

To examine the advection velocity of the water surface fluctuation as shown in Figure 3, as well as to investigate its relations to the mean bulk velocity and the advection velocity of turbulence, we applied the space-time correlation analysis to the experimental data. Before the correlation analysis, we examined the statistics of both the flow and water surface components in the following subsection.

4.3 *Turbulence statistics of the velocity and water surface*

The distributions of mean velocity U^+ and x-directional turbulent intensity $\sqrt{\overline{u'^2}}/U_*$ are shown in Figures 4 and 5, respectively. Here, $U^+=U/U_*$ and $y^+=yU_*/\nu$ in Figure 4. The vertical axis of Figure 4 is shifted in each Case for the comparison between Cases; the curve of Case 3 represents the original log-law curve for a smooth bed, while the other curves are vertically shifted form it with ± 4 and ± 8, respectively. The experimental values of U^+ are in very good agreement with the calculated log-law curves. In Case 4 of Figure 4, whose Froude number has a near critical value ($Fr=0.96$), there is a specific wake region

Copyright © 2006 Taylor & Francis Group plc, London, UK

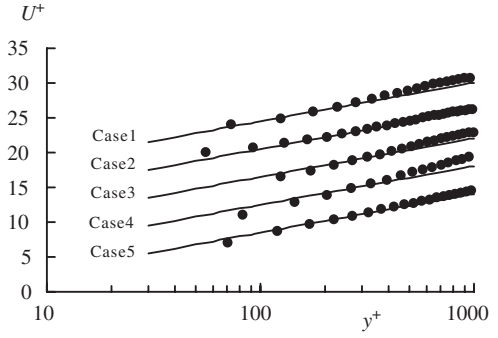

Figure 4. Mean velocity distributions. The experimental values are plotted with the log-law curve. The vertical axis of the figure is shifted for the comparison among the cases; the curve of Case 3 represents the original log-law curve for a smooth bed, while the other curves are vertically shifted form it with ±4 and ±8, respectively.

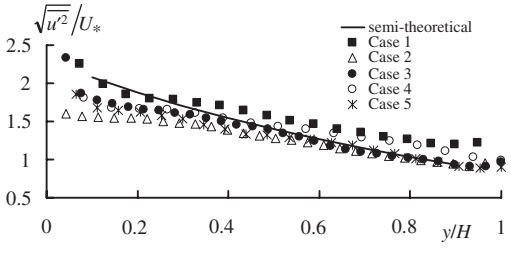

Figure 5. Distributions of x-directional turbulent intensity. The experimental data are plotted with the semi-theoretical curve (Nezu & Nakagawa 1993).

near the water surface. With respect to the turbulence intensity $\sqrt{\overline{u'^2}}/U_*$ shown in Figure 5, the experimental values agree well with the semi-theoretical curves by Nezu & Nakagawa (1993). The values of the intensity decrease toward the water surface region.

The relationship between the intensity of water surface fluctuations $\sqrt{\overline{h'^2}}/H$ and the Froude number Fr is shown in Figure 6. The values of $\sqrt{\overline{h'^2}}/H$ in this study become large as Fr increases. This feature with Fr is almost the same as the results of Nakase et al. (2000). However, a sharp increase around the critical flow condition ($Fr = 1$) reported by Nezu & Nakayama (1998b) is not observed in this study. Since the data of Nakase et al. (2000) also do not have the sharp increase in some cases, it should be necessary to take different approaches that are taken into account interactions of the water surface fluctuations with the turbulence structures under the water surface.

Consequently, from these results of the statistics, the high accuracy of the velocity components and the water surface fluctuations measured by using the simultaneous image measurements is verified.

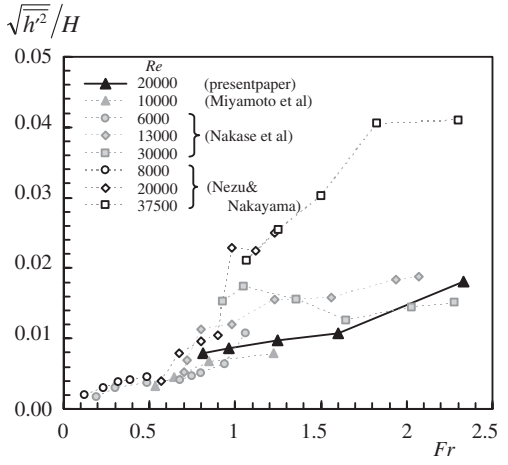

Figure 6. Relationship between the intensity of the water surface fluctuation and the Froude number.

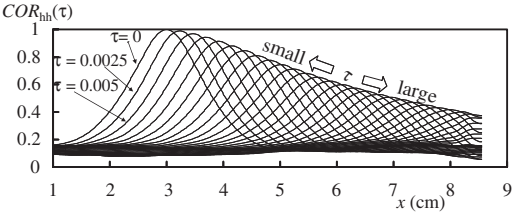

Figure 7. Profiles of the space–time correlation coefficients of the water surface fluctuations in each time lag. Case 1, $Fr = 2.33$. The reference point of the correlation: $x_{ref} = 3.0$ cm.

4.4 *Space–time correlation of the water surface fluctuations and turbulence*

In this subsection, the space-time correlation analysis (Equation (1)) was applied to the experimental data to examine the advection characteristics of both the turbulence and water surface fluctuations.

Figure 7 shows the profiles of the space-time auto-correlation coefficients of the water surface fluctuations $COR_{hh}(x; \tau)$ with the time lag τ in Case 1 ($Fr = 2.33$). These profiles with the time lag $\tau = 0$ to 0.075 sec with the interval of 0.0025 sec are superposed on the figure and the time τ lag becomes large from the left to the right of the figure. The profile of the space correlation coefficients with time lag $\tau = 0$ has a bell-like shape with the maximal value of unity at the reference point $x_{ref} = 3.0$ cm. The maximal values of the profile $COR_{hh}(x; \tau)$ become small and their locations move downstream as the time lag τ increases. The moving rate of the locations of the maximal $COR_{hh}(x; \tau)$ represents the averaged advection velocity of the water surface fluctuations.

Copyright © 2006 Taylor & Francis Group plc, London, UK

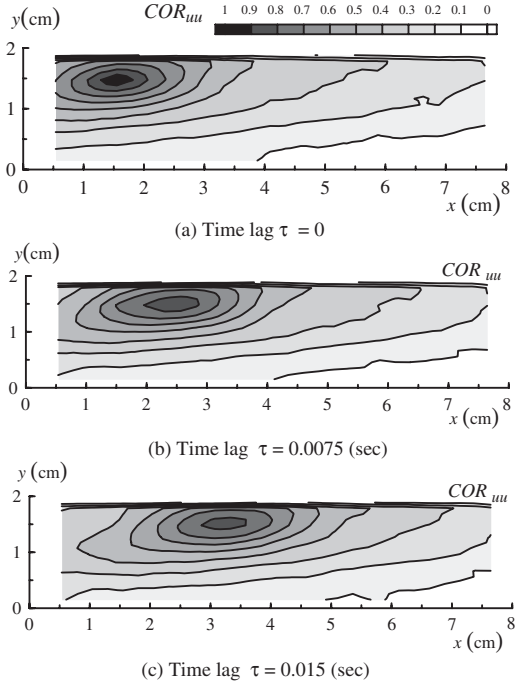

Figure 8. Contour maps of the space-time correlation coefficients of the x-directional velocity fluctuation. Case 1, $Fr = 2.33$. The reference point of the correlation: $(x_{ref}, y_{ref}) = (1.56, 1.47)$ cm.

Figure 8 shows the contour maps of the space-time auto-correlation coefficients of the x-directional velocity fluctuation COR_{uu} in Case 1 ($Fr = 2.33$). The reference point are at $(x_{ref}, y_{ref}) = (1.56, 1.47)$ cm, which is located at $0.75 \times H$ near the water surface. In Figure 8, the maximal values of the correlation coefficients COR_{uu} decrease with time lag τ and their locations move downstream with a constant speed, as same behavior as the cases of the water surface fluctuations.

These characteristics of the correlation coefficients with the time lag τ are qualitatively the same throughout the whole experimental cases both in the water surface fluctuations and the turbulence. Therefore, the advection velocities can be calculated from the movement of the locations of the maximal correlation coefficients.

4.5 *Advection characteristics of the water surface fluctuations and turbulence*

Figure 9 shows the relationship between the advection velocities of the x-directional velocity fluctuation $C_{u'}$ and the time averaged mean velocity $U(y)$. The advection velocity $C_{u'}$ is calculated from the space-time auto-correlation coefficients of the turbulence,

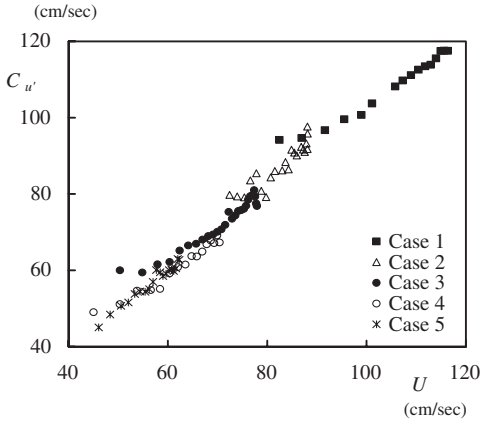

Figure 9. Relationship between the advection velocity of the x-directional velocity fluctuation and the time averaged velocity.

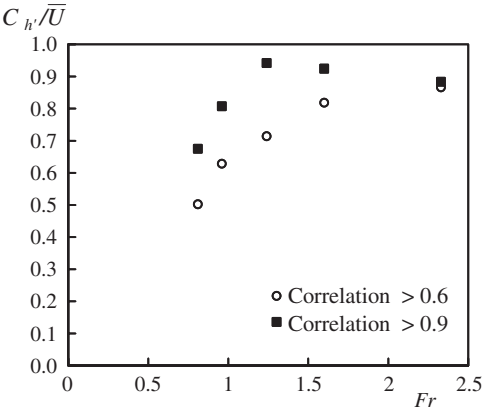

Figure 10. Relationship between the advection velocity of the water surface fluctuation and the Froude number.

as mentioned in the previous subsection. We chose the reference points from near the water surface to near the channel bed and calculate the corresponding advection velocities. It is evident from the Figure 9 that the magnitude of the advection velocity $C_{u'}$ is almost the same as that of the time averaged mean velocity $U(y)$ in whole experiments except near the channel bed region. It indicates that turbulence in the open-channel flows above the near bed region is transported with the time averaged local mean velocity. Therefore, Taylor's hypothesis of the frozen-turbulence approximation (Tennekes & Lumley 1972) is verified above the near bed region. In the near bed region for the Cases 1 to 4, however, the advection velocity $C_{u'}$ is larger than the time averaged mean velocity $U(y)$. Similar result for rough-bed open channel flows was earlier reported in Nikora and Goring (2000). Although our results are for the smooth-bed flows, Nikora and Goring's data and

Copyright © 2006 Taylor & Francis Group plc, London, UK

our data show similar effect in the near bed region. This fact could asserts that the frozen-turbulence approximation is valid only if the turbulence intensity is much smaller than the local mean velocity $U(y)$ not only in grid-generated turbulence (Tennekes & Lumley 1972) but also in both smooth- and rough-bed open channel flows (Nikora and Goring, 2000, present study).

Figure 10 shows the relationship between the non-dimensional advection velocity of the water surface fluctuations $C_{h'}/\overline{U}$ and the Froude number Fr in each Case. The symbols ■ and ○ represent the values calculating from the correlation coefficients larger than 0.9 and 0.6, respectively, implying that the values of ■ represent longer time averaged advection velocity than that of ○. It is found from Figure 10 that the advection velocity $C_{h'}$ has smaller value than the mean bulk velocity $\overline{U}$ in the whole experiments. Since the time averaged local mean velocity $U(y)$ near the water surface has larger value than the mean bulk velocity $\overline{U}$ in general, the advection velocity of the water surface fluctuations $C_{h'}$ has smaller value than the time averaged velocity $U(y)$ near the water surface as well. This evidence with regard to the advection characteristics of the water surface fluctuations is much difference from that of the velocity fluctuations of open-channel flows as mentioned above. Moreover, the value of $C_{h'}/\overline{U}$ decreases as the Froude number Fr becomes small. In the subcritical flow conditions ($Fr < 1.0$), in particular, the advection velocity $C_{h'}$ has considerably smaller value than the mean bulk velocity $\overline{U}$.

5 CONCLUDING REMARKS

The laboratory experiments on turbulent open-channel flows with $Re = 2.0 \times 10^4$ and $Fr = 0.81-2.33$ were conducted to investigate the advection characteristics of both the water surface fluctuations and the turbulence beneath the free surface. The space–time correlation analysis disclosed that the advection velocity of the water surface fluctuations was always smaller than the mean bulk velocity, while that of the turbulence above the near bed region was the same as the mean velocity, which was well-known as Taylor's hypothesis of the frozen-turbulence approximation. Moreover, it was found that the ratio of the advection velocity of the water surface fluctuation to the mean bulk velocity became smaller as the Froude number decreased. It implies from these results and discussion that the simple correlation approaches for the surface velocity measurements of real rivers (e.g. Fujita et al. 1994, 1998) may calculate the velocity relatively smaller than the true value. However, as the examination in this study is limited in the laboratory experiments with the specific hydraulic conditions, further research works should be carried out to evaluate scale effects of the laboratory experiments for the better understanding of the free surface phenomena of real river flows.

ACKNOWLEDGEMENTS

Partial Support from the Ministry of Education, Culture, Sports, Science and Technology, Grant-in-Aid for Young Scientists (B) (No. 18760374, Head Investigator: Dr. Hitoshi Miyamoto of Kobe University) is gratefully acknowledged. I wish to thank to K. Shimoyama and K. Inaoka, my former students of Kobe University, for their assistance on the laboratory experiments.

Turbulent wake region of large roughness elements: Combining flow visualization and high frequency velocity measurements

R.W.J. Lacey & A.G. Roy
Département de géographie, Université de Montréal, Succursale Centre-Ville, Montréal

ABSTRACT: This study characterizes the shear layer and associated shedding properties of an isolated in situ submerged pebble clusters using combined flow visualization and high frequency three-dimensional velocity (acoustic Doppler velocimeter, ADV) measurements. We outline a new method for synchronizing digital video recordings and instantaneous velocity measurements and obtained a precision to within one time step which is a vast improvement over previous in situ methods. The synchronized measurements were used to investigate the behavior of the shear layer and shedding vortices under the influence of large-scale (LS) coherent flow structures. Two scales of shedding structures were observed: small-scale initial shear layer instability vortices and larger-scale coherent structures resulting from the rollup and expansion of the initial small-scale vortices. Dominant frequencies estimated through spectral analysis, visual estimation and the Strouhal relationship were in generally good agreement.

1 INTRODUCTION

Large-scale (LS) flow structures appear to be common features of gravel-bed rivers (Roy et al. 2004) and consist of depth scaled intermittent fronts of high-speed fluid which are mainly directed towards the bed (sweeps) and of low-speed fluid that predominantly move towards the free surface (ejections). Sweeps and ejections have been found to contribute to the bulk of positive Reynolds shear stress and as such exert a considerable influence on local sediment dynamics (Williams et al. 1989). The origin of LS structures is still unclear, and it has been suggested that they are produced by topographic features such as changes in channel geometry and separation of flow over bed forms (Dinehart 1999). LS structures appear to have a strong persistence and have been found to influence the shedding motions of isolated pebble clusters (Buffin-Bélanger & Roy 1998, Roy et al. 1999, Buffin-Bélanger et al. 2001). Large roughness elements such as isolated boulders and pebble clusters are frequent features in gravel-bed rivers (Brayshaw 1984). The wake induced by a roughness element provides an effective means of flow resistance through turbulent momentum exchange. Given previous constraints on the synchronization of field velocity measurements and visualization techniques there is still a lack of understanding of the small-scale shedding processes and behavior of in situ shear layers under the influence of LS structures.

Shear layer behavior has been investigated in laboratory studies of mixing layers (Winant & Browand 1974) and around bluff bodies (Nakamura 1993, Roshko 1993), as well as in situ at stream confluences (Biron et al. 1993, Rhoads & Sukhodolov 2004). Relatively few studies have focused on in situ shear layers around pebble clusters (Buffin-Bélanger et al. 2001). The results from bluff body studies are particularly applicable to the characteristics of pebble cluster shear layers, as all shear layers have identifiable characteristic structures (Fuchs et al. 1980). Bluff bodies like pebble clusters are characterized by a flow separation zone, shear layer instability and the associated shedding vortices (Roshko 1993). The flow around a bluff body is described by two basic length scales, the thickness of the separated shear layer, h_l, and the body size, h_s (Nakamura 1993). The rolling up of the initial shear layer causes a train of small-scale vortices (referred to as a Karman vortex street for low Reynolds numbers). Small-scale instability vortices are a common characteristic of shear layers and have been observed in laboratory experiments on spheres (Taneda 1978). The steady broadening of the initial shear layer gives rise to a new set of larger structures downstream where at some fixed point the dominant frequency scales with roughness element diameter (Fuchs et al. 1980). The shift from small to larger scale vortex structures can under certain conditions be the result of vortex pairing and coalescence (Winant & Browand 1974) which enables the adjustment of the

Copyright © 2006 Taylor & Francis Group plc, London, UK

smaller initial scales to the larger scales at a distance equivalent to several h_s downstream and eventually leads to fully developed turbulent flow (Fuchs et al. 1980).

Using insights from bluff body studies, the current research characterizes shear layer behavior (under the influence of LS turbulent flow structures) and the associated shedding properties of an isolated in situ submerged pebble cluster using combined flow visualization and high frequency three-dimensional velocity measurements. As well, we investigate the use of a promising new technique for synchronizing digital video recordings and instantaneous velocity measurements. Synchronizing field equipment is very challenging at high measurement frequencies. In turbulent studies, the instantaneous velocity can change dramatically over one time step making it very difficult to synchronize video images with specific velocity fluctuations. Past studies, have managed to synchronize video recordings (measured at 30 Hz) and instantaneous velocity measurements (measured at 20 Hz) to within 0.5 s using a sound marker emitted by the laptop computer as the measurements were started (Roy et al. 1999, Buffin-Bélanger et al. 2001). Yet due to the lack of high frequency precision, only large coherent structures could be properly compared and characterized with certainty. The method outlined in the current study allows us to synchronize concurrent measurements at a much higher precision.

2 FIELD SITE AND EXPERIMENTAL PROCEDURES

The study site is located on the Eaton North River in the Eastern Townships, Quebec, Canada. The Eaton North is a gravel-bed river with a $D_{50} = 0.035$ m and a bank full width of 30 m. Several large clast sediments (>0.20 m) are scattered sporadically throughout the reach some of which form the keystones of pebble clusters (Lamarre & Roy 2001). An aluminum 1.5 m square frame was positioned overtop of a naturally occurring pebble cluster. The frame (Fig. 1a) was used to support four SonTek acoustic Doppler velocimeters (ADVs) and an underwater Sony digital video camera (Fig. 1b). The ADVs were arranged along a longitudinal (streamwise, x) transect that crossed overtop of the pebble cluster. The mean water depth (Z) within the sampling area was 0.43 m. The A and B axes of the keystone anchoring the pebble cluster were 0.44 m and 0.30 m respectively. The maximum protrusion, h_s, of the cluster was 0.17 m. The bed topography was measured in detail using a Trimble series 5000 total station and is presented in Figure 2a.

An array of four ADVs was used in this study. The ADVs were deployed along the streamwise transect. During the experiment three ADVs were kept at

Figure 1. (a) ADV and digital video camera support frame on the Eaton North River. Flow is from left to right; (b) digital video camera within underwater case.

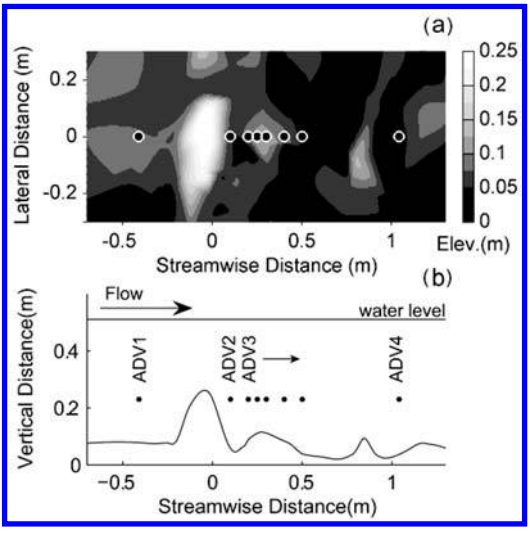

Figure 2. (a) Digital elevation model with ADV sampling locations; (b) Bed profile with ADV sampling volume locations.

stationary positions while one was shifted downstream along the frame to specific measurement locations. The stationary probes were positioned as follows (relative to the lee edge of the pebble cluster): ADV1 at $x = -0.4$ m, ADV2 at $x = 0.1$ m and ADV4 at $x = 1.05$ m. The roving probe ADV3 was located at $x = 0.2$ m for the first set of measurements and was shifted downstream to the positions $x = 0.25$ m, $x = 0.3$ m, $x = 0.4$ m, $x = 0.5$ m for the four subsequent sets of velocity measurements. The centre line bed profile and ADV sampling volume locations are presented in Figure 2b. The array of ADVs was adjusted to a height above the bed to ensure that the sampling volumes of ADV2 and ADV3 were located within the

Copyright © 2006 Taylor & Francis Group plc, London, UK

shear layer in the lee of the pebble cluster. This was accomplished by measuring and analyzing instantaneous velocities in the field at several heights in order to delineate where the shear layer was present. From the velocity time series and spectral density functions it was determined that locating the sampling volumes at a height of 0.02 m below the top of the pebble cluster adequately represented the velocity variations induced by the shear layer.

The digital video camera was housed in a waterproof case and was positioned underwater at a lateral distance of 0.6 m from the ADVs sampling array to give a profile view (x–z plane) which included the lee side of the pebble cluster and the two middle probes (ADV2 and ADV3) directly downstream of the cluster. A neutrally buoyant tracer was prepared by mixing small amounts of non-toxic white latex paint with river water. The tracer was injected continuously into the recirculation zone directly behind the cluster at $x = 0$ m where it could be passively entrained into the overlying shear layer.

Five sets of digital videos were recorded while measuring simultaneously the 3D instantaneous streamwise, u, lateral, v, and vertical, w, velocities. For each subsequent set of measurements the roving probe was shifted downstream along the frame. The video and velocity measurements were initially synchronized by touching the ADVs acoustic transmitter while recording. The ADV responds with large spikes in the signal to noise ratio output and the film captures the hand movement. The sampling frequencies for the ADVs and the digital video camera are 25 Hz and 30 Hz, respectively. Velocity time series were recorded for longer than 6 min, with the exception of the first series which was 4 min in length. Video record lengths were longer than 4 min with the exception of the first film which had a length of 2 min.

3 DATA TREATMENT AND ANALYSIS

The instantaneous velocity time series were visually inspected for irregularities and low signal correlations. With the exception of the velocities measured near the cluster on the downstream side, the majority of the velocity signal correlations were above the 70% rejection limit suggested as a quality control measure by the ADV manufacturer. Failure to remove velocity values with low correlation has been found to introduce bias into both mean velocity values and turbulent statistics (Lane et al. 1998). The velocities measured in the near-shear layer had signal correlations of between 65% and 70%, most likely induced by the high shearing of the flow occurring in the ADV sampling volume. These time series were kept in the analysis in spite of having signal correlations lower than 70% as their velocity spectra indicated an adequate fit with the Kolmogorov $-5/3$ power scale in the inertial subrange. These measurements were also taken at points that were crucial to characterize the dynamics of the shear layer.

The u, v, and w velocity series, u_{i} where i represents the velocity component, were back transformed to beam velocities and obvious spikes from the time series were removed using the Goring & Nikora (2002) phase-space thresholding method replacing them with interpolated values based on adjacent time-step velocities. In order to keep the correlations between velocity signals free of the auto-correlation implicitly added by filters, a low-pass filter was not applied to the time series as is commonly done to remove possible aliasing effects induced by high frequency Doppler noise. Mean lateral velocities were expected to be close to zero given attempts in the field to align the support frame in the streamwise direction. It was found that time averaged lateral velocities, V, were systematically offset. All velocity time series were rotated in the lateral plane, using polar coordinates, by an angle of 8.5° obtained as the mean offset angle of ADV1 and ADV4. These two probes were considered to represent the average flow direction as they are less influenced by the pebble cluster. The rotation angle was selective to give a general downstream orientation to all probes and as such does not bring the V of a single probe to a zero value.

Blue and red hue saturation values, HSVs, were extracted from each digital image of the films to give a time series of the image intensity, I_n, at the estimated sampling volume locations of ADV2 and ADV3 (see Marquis & Roy (2006) for more information on this technique). As the films are recorded at 30 Hz, the I_n, time series were resampled at 25 Hz in order to cross-correlate and compare them with the 25 Hz velocity time series. Using cross-correlation and varying the time lags we were able to precisely synchronize I_n and u_{i}. The correlations between I_n and u_{i} were further improved by adjusting slightly the initial estimate of the ADV sampling volume location on the digital film frames. A roving nine point 15 by 15 pixels window was used to isolate the pixel with maximum correlation with the ADV measurements. Given these cross-correlation methods and the initial field synchronization the ADV time series and the digital films could be matched to within one time step.

To enhance the visualization of the injected tracer, the RGB color levels of the digital films were adjusted and extracted to produce contrasting greyscale films which much facilitate the manual identification and quantification of the coherent turbulent flow structures. The behavior of the shedding structures and the shear layer was compared with the synchronized u_{i} data. The response of the shear layer to the passage of large-scale events was assessed. The frequency, f, of small-scale instability vortices and large-scale

Copyright © 2006 Taylor & Francis Group plc, London, UK

shedding structures was quantified utilizing tracer presence and absence. Identification was based on the characteristic form of a vortex street where vortices contain a much higher level of tracer than the surrounding fluid. While the small-scale instability vortices were easily discerned the detection of LS shedding structures was found to be more difficult due to the complex flow paths and quick dissipation of the tracer. A detection scheme was used, where at a distance of c. $1.5Z$ downstream and at a height of h_s, a structure was detected when an absence of tracer was followed by a large-scale front of rotating fluid with a high tracer concentration. The frequencies of the small and LS shedding structures were compared with the velocity and I_n power spectra and with the shedding frequency predicted by the Strouhal relationship:

$$f = S_r U / h_s \tag{1}$$

where S_r is the Strouhal number. Laboratory and field studies on shear layers have found S_r values ranging from 0.1 to 0.25 (Venditti and Bauer 2005).

Mean turbulent statistics were calculated at each ADV measurement location. These statistics included the root mean squared (RMS), u', v', w'; turbulent kinetic energy $k_e = 0.5(u'^2 + v'^2 + w'^2)$; Reynolds shear stress $\tau_{uw} = -\rho u'w'$, where ρ is the water density.

Space-time correlations (STC) between velocity time series measured simultaneously with each ADV were estimated as follows:

$$r_{u_i u_j}(\Delta x, \Delta t) = \frac{\sum_{k=1}^{n} u_i(x_k, t_k) \cdot u_j(x_k + \Delta x, t_k + \Delta t)}{u_i' u_j'} \tag{2}$$

where r is the space-time correlation between u_i and u_j, Δx is the separation distance between the points where velocity time series i and j were measured, and Δt is the temporal lag between velocity measurements in a series. Equation 2 was also used to estimate the autocorrelation function (ACF) for each velocity component (by setting $\Delta x = 0$). The integral time scale (ITS) of each velocity component was obtained by integrating the ACF up to the time lag at which the correlation is not significantly different from zero ($\alpha = 0.05$).

The digital film I_n time series were cross-correlated with velocity time series by:

$$r_{u_i I_n}(\Delta t) = \frac{\sum_{k=1}^{n} u_i(t_k) \cdot I_n(t_k + \Delta t)}{u_i' I_n'} \tag{3}$$

where I_n' is the standard deviation of I_n.

U-Level event analysis was used to determine the occurrence of high- or low-speed events (Luchick & Tiederman 1987). This is a conditional sampling method that estimates the frequency and duration of the streamwise velocity excursions higher and lower than the mean. As we were interested in determining the occurrence of LS events, we used a threshold (H) of $H = 0$ and a minimum duration of 5 time steps as suggested by Paiement-Paradis et al. (2003).

Velocity spectra were estimated using discrete fast Fourier transforms (fft) of each data series given by:

$$S_{uu}(\omega) = \frac{1}{Tn}\left|\sum_{i=1}^{n} x_i e^{-j\omega i}\right|^2 \tag{4}$$

where T is the sampling interval, n is the number of measurements in the series, x_i is the time domain signal and ω angular frequency. Velocity and I_n spectra were investigated to determine the occurrence of a shedding motion which would appear in a particular range of frequencies.

4 RESULTS AND DISCUSSION

The mean velocities, U, V, W, and turbulent statistics at each sampling location are presented in Table 1. U is reduced in the pebble cluster wake zone and regains its upstream velocities at $x = 1.05$ m ($x = 6.2h_s$) downstream from the cluster. Mean w values show that the flow is directed towards the surface as the flow approaches the pebble cluster and that it is then strongly directed towards the bed in the lee of the cluster. RMS values for all velocity components increase in the wake of the pebble cluster indicating high turbulent energy. The fluctuations in the lateral velocity component, v', are almost equal to those for the streamwise velocity component u', directly behind the cluster. The k_e increases by a factor of 2.5 in the near-wake of the cluster. The increased RMS and k_e values recorded in the wake of the pebble cluster are consistent with other studies investigating the spatial distribution of turbulence around pebble clusters (Buffin-Bélanger & Roy 1998, Lawless & Robert 2001). The integral time scale of all velocity components decreases by a factor of 2 with the exception of the high ITSu at $x = 0.25$ m where the value is larger than what is observed for the upstream measurements ($x = -0.4$ m). The integral time scale gives an indication of the average size of the correlated structures within the flow or the mean life-time of individual eddies (Townsend 1976). Given previous studies where ITSu decreased in the wake of a pebble cluster due to the shedding of smaller scale structures (Buffin-Bélanger & Roy, 1998), the increase of ITSu at $x = 0.25$ is unexpected. This high ITSu value occurs at the same location as the highest Reynolds shear stress recorded. The value of the Reynolds shear stress ($-\rho u'v'$) at $x = 0.25$ m is a factor of 3 greater than the shear stress estimated upstream

of the cluster. Inspection of the film, recorded during the velocity measurements at $x = 0.25$ m did not reveal any insight on the unexpectedly high ITSu estimated by ADV3. The high ITSu value is an indication that through the shedding process the size of the mean vortices measured at $x = 0.25$ m is generally larger than elsewhere in the cluster wake.

The persistence and behavior of coherent turbulent flow structures were investigated through space-time correlation analysis (STC). The maximum correlation coefficients obtained in the STC analysis between pairs of probes for each velocity component are presented in Figure 3. Figure 3a presents the maximum STC of ADV1 velocity time series with the time series measured at the downstream sampling locations.

The u series measured by ADV1 at $x = -0.4$ m show a significant correlation with time series measured at $x = 0.1$ m (located in the wake of the pebble cluster). The correlation decreases at $x = 0.2$ m, yet increases further downstream at $x = 0.4$ m. The robustness of

Table 2. Cross-correlation coefficients between velocity time series and and I_n measurements from the images.

Probe	x m	u	v	w
ADV2	0.1	−0.43	0.10	0.39
ADV3-1	0.2	−0.37	0.06	0.37
ADV3-2	0.25	−0.37	0.18	0.34

ADV3-5	0.5	−0.30	0.15	0.31

the u component correlations is an indication of the very local effect of the cluster on the coherent flow structures advecting from upstream and indicates that some structures persist downstream in spite of having passed the cluster. The maximum correlation coefficients between measurements of ADV2 and the downstream sampling locations (Fig. 3b) indicate an expected trend of decreasing correlations with distance. The correlations for the u and w velocity components are seen to be much higher and the structures more persistent than for v component correlations. This is perhaps due to the formation of vortices that have a weak lateral component that shed from the cluster. Unlike the upstream velocities measured at ADV1, the structures generated in the clusters near wake are less persistent as determined by the near zero correlation between $x = 0.1$ m and $x = 1.05$ m.

Table 2 presents the cross-correlations between the simultaneous velocity and image intensity time series. The values are very well correlated. A strong negative correlation is observed between u and I_n which occurs at a time lag of 0, while a strong positive correlation is seen between the w and I_n occurring at time lag of -1 steps (0.04 s). The strength of the correlations is surprisingly good and the correlations are generally higher than the maximum values of the STC obtained between the measurements of adjacent ADVs. The correlations for the v component are much less than for the other two components and occur at a time lag

Copyright © 2006 Taylor & Francis Group plc, London, UK

of between −3 and −4 steps. The smaller correlation values for v is not surprising as I_n is estimated from two dimensional images of the x–z plane and is therefore much less sensitive to the variations in the lateral direction. A slight decreasing correlation trend is observed with distance from the point of tracer injection ($x = 0$ m), with the exception of the ADV3 at $x = 0.4$ m. The higher correlations values during this set of measurements are perhaps explained by an increased concentration of white paint when preparing the tracer or changing ambient light conditions during the recordings.

The correlation values in Table 2 are fundamental for observing and characterizing the behavior of coherent turbulent flow structures seen in the enhanced film images. The negative correlation of I_n with u indicates that for the same time step an increased image intensity can be directly associated with a slower u. From the positive correlation between I_n and w (at a time lag of −1) we understand that an increased image intensity is followed after one time step by a fluid motion towards the surface.

Preliminary analysis of the shear layer behavior observed in the films has identified two scales of coherent flow structures. Within the shear layer, initial small-scale instability vortices are perceived which are seen to form while still in contact with the lee side of the cluster. As these small-scale structures elongate away from the cluster their behavior differs greatly depending on the surrounding fluid conditions. Under neutral conditions the small-scale vortices seem to shed off from the cluster at regular intervals with or without strong vorticity (clockwise rotation). The passage of a sweep intermittently enhances the rollup and pairing of the instability vortices compressing the vortices against or into the recirculation zone. The rollup and expansion of the initial instability vortices produces the second larger-scale coherent flow structures observed which are much more difficult to discern due to flow complexity and tracer dissipation.

An example of these coherent structure characteristics are presented in Figure 4 along with the simultaneous fluctuating u, w and I_n time series. A sequence of 15 enhanced images is presented, starting at $t = 31.7$ s and ending with $t = 32.3$ s. The images and velocities were measured under the condition where ADV2 and ADV3 were 0.15 m apart, at $x = 0.1$ m and $x = 0.25$ m, respectively. ADV2 is the upstream (left) probe in the image. In the initial frame ($t = 31.7$ s), we see two coherent flow structures advecting downstream with an inclination towards the surface and a positive vertical velocity. The positive vertical velocity is recorded in the ADV2 and ADV3 time series plots at $t < 31.75$ s. Adjacent to the cluster a third coherent structure is forming. Subsequent images show how the forming structure is fed by smaller scale initial shear layer instabilities as observed by Taneda (1978). Three separate small-scale vortices can be observed to shed from the cluster at $t = 31.73$ s, $t = 31.83$ s and $t = 31.93$ s. Detailed comparison of the film images with the I_n plots shows that high I_n is often related to the center the coherent vortices. Visual comparisons with the velocity signals indicates an increased u velocity directed towards the bed as the clockwise rotating vortex approaches and induces slower u directed towards the surface as it exits the sampling volume. In Figure 4, the coalesced vortex structure is shed downstream at $t = 32.10$ s and is recorded with positive u and negative w as the front of the clockwise rotating vortex passes through the sampling volume of ADV3. A spike in the intensity is observed in the I_n ADV3 sampling volume plot at $t = 32.23$ s. These relationships are more difficult to see closer to the cluster as the structures are smaller and pass very quickly through the ADV sampling volume, yet the small scale vortices are represented as fluctuating peaks in the u and w velocity signals of ADV2 and in the I_n values.

The behavior of the shear layer and shedding vortices under the influence of a LS ejection event which is defined as a low-speed wedge, detected using U-level analysis, is depicted in the series of enhanced images presented in Figure 5. The sequence of images from $t = 14.33$ s to $t = 15.27$ s was obtained from the set of measurements where ADV2 and ADV3 were separated by 0.10 m, at $x = 0.1$ m and $x = 0.20$ m, respectively. The synchronous time series of u, w, and I_n are presented below the images from $t = 13.5$ s to $t = 15.5$ s. The average coherent structure advection time between ADV1 at $x = -0.4$ m and ADV2 at $x = -0.1$ m determined through STC analysis is 0.76 s. The LS burst event detected for ADV1 at $t = 13.8$ s reaches ADV2 at $t = 14.56$ s which is consistent with the ADV2 velocity plot. The event is also clearly observed in the ADV3 velocity plot where it occurs at $t = 14.75$ s. The shear layer reacts to the arrival of the burst event by expanding upwards towards the surface as seen in the image at t = 14.60 s. The small-scale instability vortices loose most of their rotation as they are ejected towards the surface. This behavior is demonstrated by the downstream coherent structure seen in the image at $t = 14.87$ s which expands yet retains much of its original orientation as it advects downstream. For the time sequence given here, the peaks in the I_n plots fit well with the peaks in the w plots. A small duration LS sweep event precedes the LS burst event and the shear layer is seen to be compressed towards the bed in the image at $t = 14.47$ s. The results presented here show similar dynamics in the lee of the cluster as what has been reported by Buffin-Bélanger et al. (2001). The shedding motion seemed to expand vertically as a low-speed wedge flowed overtop of the cluster and was suppressed during the passage of a high-speed wedge.

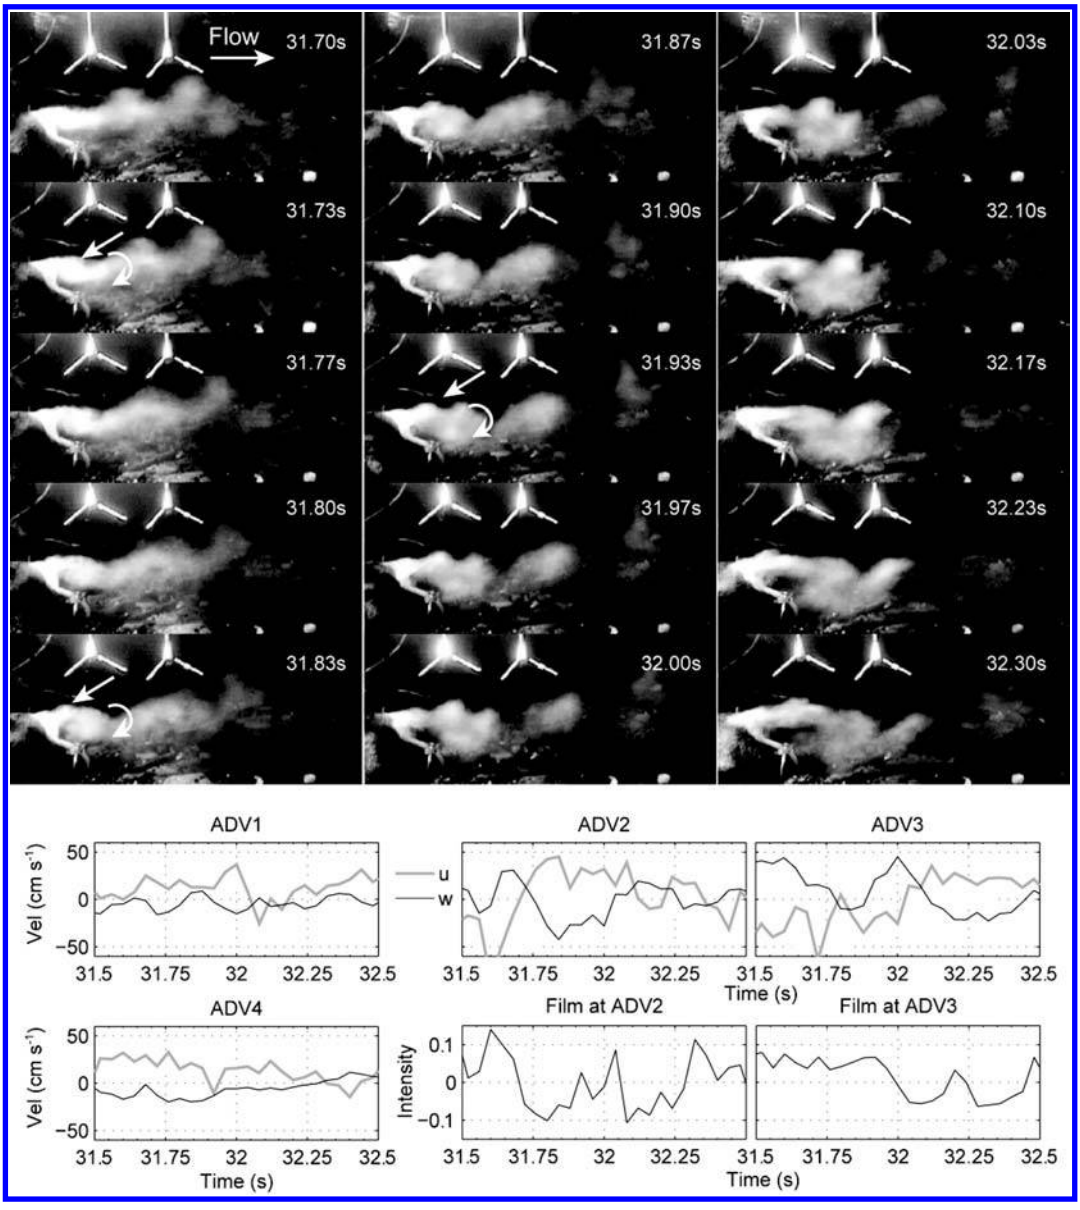

Figure 4. Sequence of 15 enhanced images, starting at $t = 31.7$ s and ending with $t = 32.3$ s. Plots of the simultaneous fluctuating u, w and I_n time series starting at $t = 31.5$ s and ending with $t = 32.5$ are presented below the images. The images present ADV2 and ADV3 (downstream), at $x = 0.10$ m and $x = 0.25$ m, respectively. Arrows highlight shedding of initial instability vortices as well as indicating preferential flow direction.

The peaks in the velocity power spectra for the time series measured by ADV2 at $x = 0.1$ m and ADV3 at $x = 0.25$ (Fig. 6a) compare well with their respective image intensity power spectra (Fig. 6b) and indicate two scales of shedding frequencies. At the $x = 0.1$ m measurement location, a high frequency peak at c. 5.5 Hz is evident in the I_n power spectra. This peak is also seen in the velocity spectra (Fig. 6a) where it occurs over a broader range of frequencies. A second lower frequency peak at c. 1.8 Hz corresponding to the structures that have coalesced into larger scale features is observed in both I_n and the w power spectra although

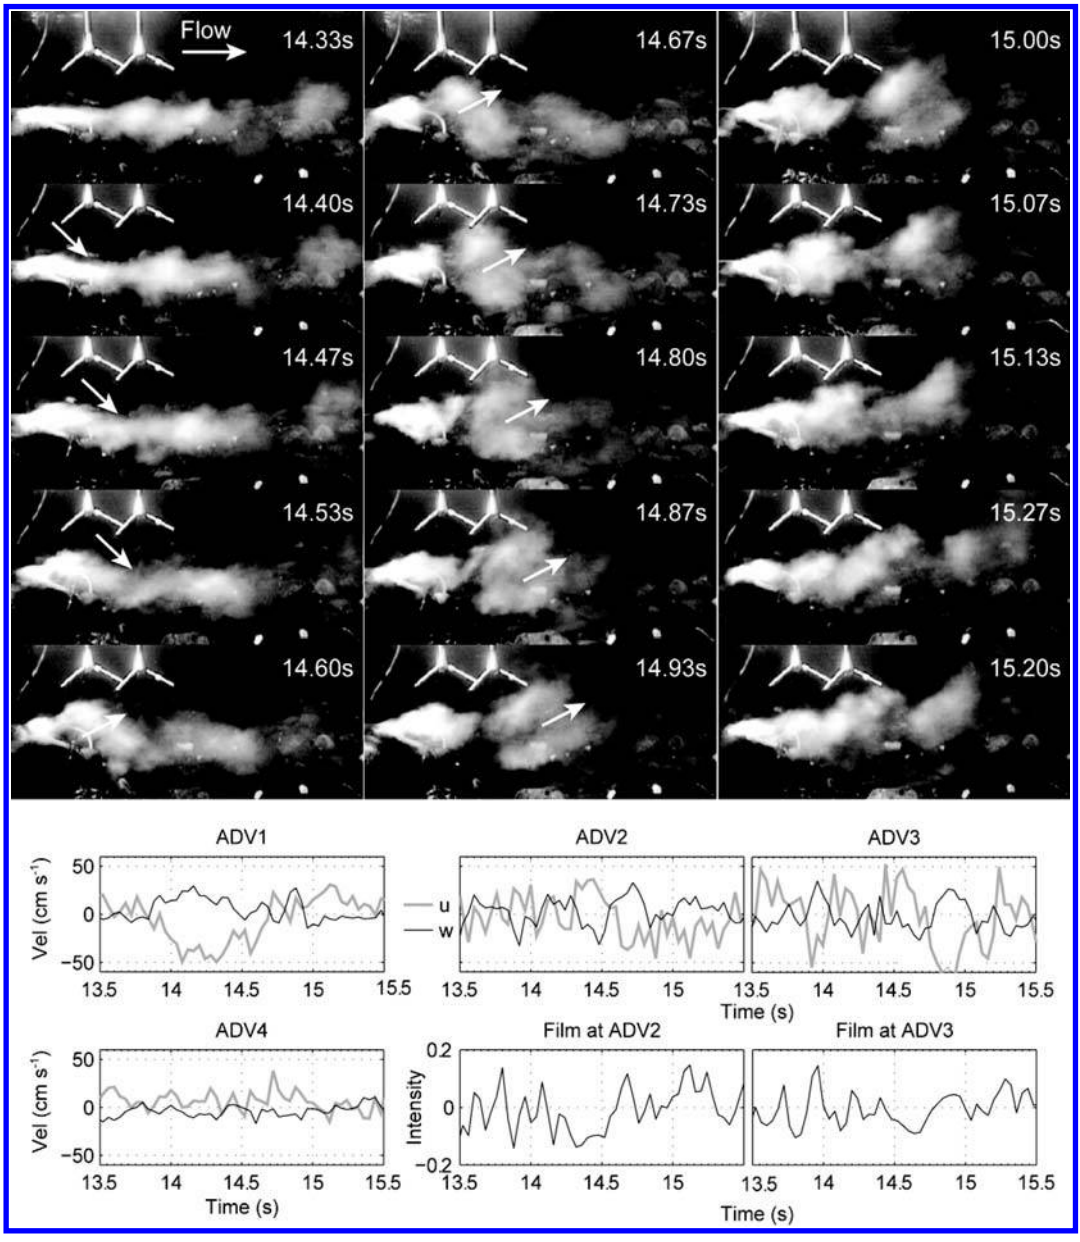

Figure 5. Sequence of 15 enhanced images, starting at $t = 14.33$ s and ending with $t = 15.20$ s. Plots of the simultaneous fluctuating u, w and In time series starting at $t = 13.5$ s and ending with $t = 15.5$ are presented below the images. The images present ADV2 and ADV3 (downstream), at $x = 0.10$ m and $x = 0.2$ m, respectively. Arrows indicate presence and direction of LS flow structures.

it is much less evident in the w spectra. Similar peaks are observed at $x = 0.25$ m, yet they are shifted slightly towards the lower frequency end. The lower frequency w spectral peak is much more evident than at $x = 0.1$ m and occurs at c. 1.2 Hz. The shift in frequency with distance downstream from the cluster may be explained by the intermittent coalescence or dissipation of the smaller-scale vortices. This type of frequency shift has been observed in shallow mixing layer studies and

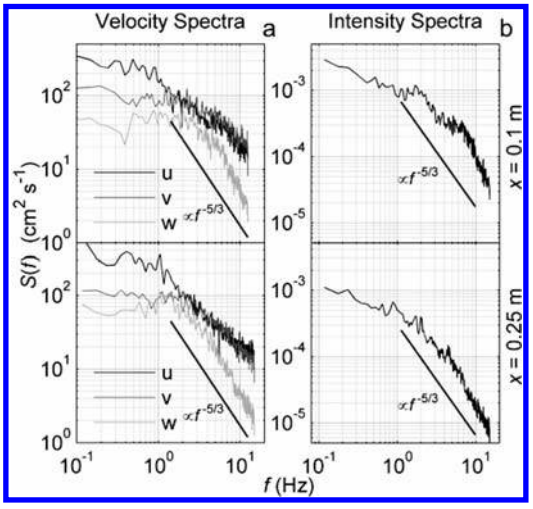

Figure 6. Spectral density functions at $x = 0.1$ m and $x = 0.25$ m for (a) Fluctuating velocity time series (cm^2 s^{-1}); (b) Image intensity time series.

was associated the coalescence and growth of shedding vortices (Uijttewaal & Tukker 1998).

Visual inspection and analysis of the films identified the high frequency observed in the velocity and I_n spectra (5.5 Hz) and could associated it with the formation the small-scale initial shear layer instability vortices. The lower frequency shedding is much more difficult to perceive in the film due to the complexity of the flow paths and the rapid dissipation of the tracer. Using the outlined detection scheme a frequency of *c*. 1.0 Hz was estimated. This frequency is in good agreement with the value predicted by the Strouhal relationship (Equation 1) of *c*. 0.85 Hz.

5 CONCLUSIONS

In order to fully understand the in situ characteristics and processes involved with the shear layer and associated shedding vortices of a pebble cluster at high *Re*, it is important to gain a visual picture of the phenomena. A large benefit is obtained by synchronizing the instantaneous velocity time series with the visualization at the frequency over which the processes are varying. Using the synchronization method presented here, we were able to match the instantaneous velocity fluctuations to within one time step of the concurrent video records and gain a better understanding of the in situ shedding behavior. It was then possible to relate short duration velocity trajectories to the behavior of the small-scale instability vortices. These small-scale vortices were seen to shed from the cluster and intermittently coalesce into larger scale vortical structures. Their intermittent behavior was in part influenced by the passage of LS events. The LS sweep event was seen to compress the shear layer towards the bed and enhance the coalescence of the initial shear layer instability vortices into larger-scale vortices. With the passage of the LS ejection event the small-scale shear layer vortices expanded towards the surface losing some of their clockwise rotating velocities. The LS structures were found to be robust: retaining significant levels of structure coherence after passing overtop of the pebble cluster and the shear layer.

The image intensity showed a strong correlation with the *u* and *w* component velocity time series. Their respective spectral density functions had similar shapes and power law scalings suggesting that I_n could be used as a proxy for detecting the frequency of shedding structures when the peak shedding frequencies in the velocity spectra are less evident.

Due to the intermittent behavior of the shear layer it is difficult to attribute the frequency shift in the velocity and I_n spectra solely to coalescence. The shear layer inherently expands with downstream distance and the shift to lower frequency modes may be more of a measurement of the vortex growth and expansion than to coalescence. Shear layer expansion is a function of *Re* and an area of future work would be to examine if the in situ shear layer behavior characterized in this study occurs in gravel-bed rivers over a range of *Re*.

A new perspective on sidewall correction procedures, based on SKM modelling

J. Chlebek & D.W. Knight
The University of Birmingham, Department of Civil Engineering, Birmingham, UK

ABSTRACT: This paper explores whether a simple depth-averaged flow model, based on the RANS equations, can provide the engineer with a relatively simple tool that can be used to estimate the shear force taken by the sidewalls of rectangular channels for a given aspect ratio. The Shiono & Knight Method (SKM) is used in conjunction with an extensive experimental data set of boundary shear stress measurements to investigate the issue over a wide range of aspect ratios ($0.3 < Asp < 20$). Particular consideration is given to the calibration of the three governing parameters, f, λ and Γ within SKM, bearing in mind the two requirements of simulating both the correct channel discharge and the percentage of the total shear force that is taken by the channel sidewalls. This exploratory attempt, using only one panel to simulate the flow in one half of the rectangular channel, appears to be promising and some equations are presented for the three calibration parameters based on this preliminary analysis. Further work is required to elucidate the physical basis of these equations, to undertake more detailed modelling using multi-panels and to study heterogeneous roughness effects.

1 INTRODUCTION

Sidewall correction procedures are commonly used to process experimental flume or channel data where the influence of the sidewalls is to be excluded from the analysis of bed related phenomena. Typically they reduce an otherwise essentially 3-D flow problem down to a quasi 2-D flow problem.

Although sidewall procedures are well known and have been fully documented by various authors, such as Vanoni & Brooks (1957), Brownlie (1981) and Chang (1992), their application still raises concerns about the underlying physics and level of approximation. Indeed the very number of 'simple' equations for dealing with composite roughness, as illustrated by Table 7 in Yen (1991), or the use of 'shape' effects by Kazemipour & Apelt (1979), indicate the complexity of the physical problem.

The modelling of flow in straight prismatic channels is surprisingly difficult, as shown by Nezu & Nakagawa (1993) and Chiu & Chiou (1986). This is due in part to the nature of the anisotropic turbulence, governed by the channel geometry and roughness distribution, the consequent formation of secondary flow cells and the level of turbulence closure.

This paper explores whether a depth-averaged flow model can provide the engineer with a relatively simple tool that can predict the shear force taken by the sidewalls of a rectangular channel with a given aspect ratio. The flow modelling is based on the Shiono & Knight Method (SKM), described elsewhere by Shiono & Knight (1988 & 1991) and the results are benchmarked against an extensive set of experimental data by Knight et al. (1984), Knight & Patel (1985a & b) and Rhodes & Knight (1994).

2 THEORETICAL BACKGROUND

2.1 *Introduction*

For steady flow in a prismatic open channel, the equation for the streamwise momentum may be combined with the continuity equation to give:

$$\rho\left[\frac{\partial UV}{\partial y}+\frac{\partial UW}{\partial z}\right]=\rho gS+\frac{\partial}{\partial y}(-\rho\overline{uv})+\frac{\partial}{\partial z}(-\rho\overline{uw}) \quad (1)$$

where U, V, W are the mean velocity components in the x (streamwise), y (lateral) and z (normal to bed) directions respectively, u, v, w are turbulent fluctuations of velocity with respect to the mean, ρ is the density of water, and S is the bed slope gradient ($S = \sin\theta$). See Figure 1(a) for notation.

The depth-mean-averaged momentum equation can be obtained by integrating (1) over the water depth, H, provided $W(H) = W(0) = 0$, and is given by Shiono & Knight (1988) in the form:

$$\frac{\partial\left[H(\rho UV)_d\right]}{\partial y}=\rho gHS+\frac{\partial H\overline{\tau}_{yz}}{\partial y}-\tau_b\sqrt{1+\frac{1}{s^2}} \quad (2)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

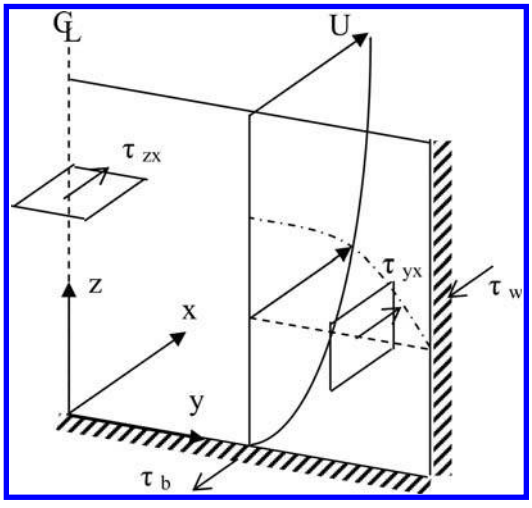

Figure 1(a). Bed and wall shear.

in which τ_b is the bed shear stress, s is the side slope (1:s = vertical: horizontal), and

$$(\rho UV)_d = \frac{1}{H}\int_0^H (\rho UV)dz\,;\ \bar{\tau}_{yx} = \frac{1}{H}\int_0^H (-\rho uv)dz \qquad (3)$$

Using an eddy viscosity approach for dealing with the Reynolds stress term, $\bar{\tau}_{yx}$, then

$$\bar{\tau}_{yx} = \rho\bar{\varepsilon}_{yx}\frac{\partial U_d}{\partial y} \qquad (4a)$$

$$\bar{\varepsilon}_{yx} = \lambda U_* H \qquad (4b)$$

where λ is the dimensionless eddy viscosity coefficient and U_* ($=\tau_b/\rho^{1/2}$) is the local shear velocity. The local boundary shear stress, τ_b, may be related to the depth-mean velocity, U_d, by use of the Darcy-Weisbach friction coefficient, f, giving

$$\tau_b = \rho\frac{f}{8}U_d^{\,2} \qquad (5a)$$

$$U_* = \sqrt{\frac{f}{8}}U_d \qquad (5b)$$

Then, substituting (4) and (5) into (2) yields:

$$\rho gHS - \rho\frac{f}{8}U_b^{\,2}\sqrt{1+\frac{1}{s^2}} + \frac{\partial}{\partial y}\left[\rho\lambda H^2\sqrt{\frac{f}{8}}U_d\frac{\partial U_d}{\partial y}\right] = \frac{\partial}{\partial y}\left[H(\rho UV)_d\right] \qquad (6)$$

Experimental results by Shiono & Knight (1991) show that in overbank flow the shear stress due to secondary flow, $(\rho UV)_d$, varies approximately linearly in certain regions of a channel. Using this concept, the lateral gradient of the secondary flow force per unit length of the channel may then be written as

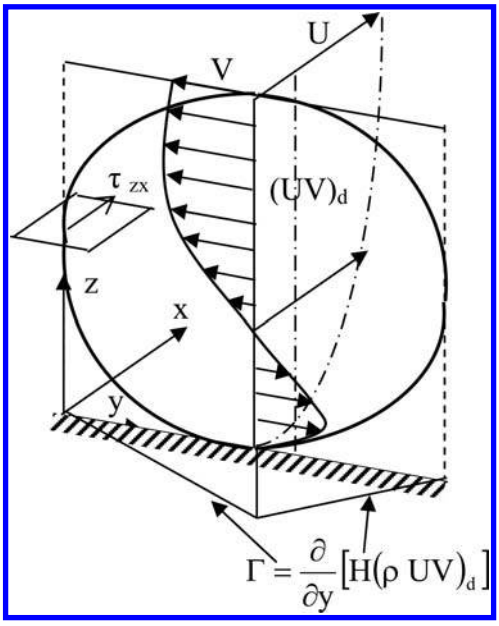

Figure 1(b). Depth-averaged secondary flow term.

$$\frac{\partial}{\partial y}\left[H(\rho UV)_d\right] = \Gamma \qquad (7)$$

where Γ is a dimensionless secondary flow parameter, which is different for different flow regions, as illustrated in Figure 1(b) for a rectangular channel. Thus Eq. (2) may be expressed in a simpler form as

$$\tau_b\sqrt{1+\frac{1}{s^2}} = \rho gHS + \frac{\partial H\bar{\tau}_{yz}}{\partial y} - \Gamma \qquad (8)$$

2.2 *Analytical solution for U_d*

An analytical solution to (6) has been obtained by Shiono & Knight (1988) for two cases, depending on whether the depth is constant or varying across the section. See Knight & Shiono (1996) and Abril & Knight (2004) for further details.

For a sub-area with a constant water depth, H, the analytic U_d distribution has the form:

$$U_d = \left[A_1 e^{my} + A_2 e^{-my} + k\right]^{1/2} \qquad (9)$$

$$\text{where } k = \frac{8gSH}{f}(1-\beta) \qquad (10)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

$$\gamma = \sqrt{\frac{2}{\lambda}}\left(\frac{f}{8}\right)^{\frac{1}{4}}\frac{1}{H} \tag{11}$$

$$\beta = \frac{\Gamma}{\rho g H S} \tag{12}$$

A_1 & A_2 can be determined by considering the relevant boundary conditions of flow continuity and the no-slip condition at the wall, as shown by Knight et al. (2004). For a simple rectangular channel of semi-width, b, with symmetric flow parameters, using just a single panel to represent half the cross-section, the two A coefficients are

$$A_1 = A_2 = -\frac{k\sinh(\gamma b)}{\sinh(2\gamma b)} = -\frac{k}{2\cosh(\gamma b)} \tag{13}$$

Thus for a rectangular channel, Eq. (9) becomes

$$U_d = \left[C_1\cosh(\gamma y) + C_2\right]^{1/2} \tag{14}$$

$$\text{where } C_1 = -\frac{k}{\cosh(\gamma b)};\ C_2 = \frac{8gSH}{f}(1-\beta) \tag{15}$$

2.3 *Analytical solution for* τ_b

The bed shear stress distribution is given via (5a) as

$$\tau_b = \rho\frac{f}{8}\left[C_1\cosh(\gamma y) + C_2\right] \tag{16}$$

The mean bed shear stress, $\bar{\tau}_b$, is then obtained by integration of (16), to give

$$\bar{\tau}_b = \frac{\rho f}{8}\left[\frac{C_1}{\gamma b}\sinh(\gamma b) + C_2\right] \tag{17}$$

and the shear force on the bed, SF_b ($= \bar{\tau}_b \times 2b$) is

$$SF_b = 2b\rho g H S(1-\beta)\left[1 - \frac{\sinh(\gamma b)}{\gamma b\cosh(\gamma b)}\right] \tag{18}$$

The mean wall shear force, SF_w, (both walls) may then be calculated from a force balance:

$$\tau_o P = SF_b + SF_w \tag{19}$$

where P is the total wetted perimeter and τ_o is the mean boundary shear stress ($= \rho g R S_o$). Thus

$$SF_w = \rho g A S - SF_b \tag{20}$$

The percentage of the total shear force that acts on the walls is then given by

$$\%SF_w = 100 \text{ x } SF_w/\rho gAS \tag{21}$$

Eqs (18) to (21) may then be used to produce a theoretical $\%SF_w$ v 2b/H (aspect ratio) relationship for a rectangular channel. This approach is thus different from those given by other researchers such as Guo & Julien (2005) and Yang & Lim (1997).

3 EXPERIMENTAL WORK

3.1 *Open channel flow data*

The open channel flow data used herein were obtained from earlier experimental work by Knight et al. (1984). The experiments were performed in a non-tilting 15 m long flume with a bed slope $S_o = 9.66 \times 10^{-4}$. The flume was 610 mm wide, and 3 smaller flumes were built inside it with widths of 70, 152 & 381 mm, making it possible to conduct 4 series of experiments in 4 flumes at various depths, giving aspect ratios varying from approximately 0.3 to 20. Ancillary experiments were conducted in rectangular ducts, using air as a medium, to investigate a larger range of aspect ratios than were possible with open channels, in some cases up to 50 (Rhodes & Knight, 1994). However, only the flume data are analysed here. It should be noted also that in this paper the aspect ratio, *Asp*, of the rectangular channel (i.e. channel width/depth ratio = 2b/h) is used throughout, although when combining rectangular and trapezoidal channel data together it is more convenient to use the wetted perimeter ratio, $P_b/P_w (= Asp/2)$, as shown by Knight et al. (1994).

3.2 *Experimental procedure*

Prior to every test in a particular flume, ancillary experiments was carried out with M1 and M2 profiles in order to ascertain the precise tailgate setting that gave the normal depth for a given discharge. Once normal depth conditions were established for a given discharge, individual velocity measurements were made within the cross section using a small propeller meter and boundary shear stress measurements made around the wetted perimeter using a Preston tube. The individual readings were subsequently numerically integrated and compared with the overall values, obtained respectively from a Venturi meter or the energy slope ($\tau_o = \rho g R S_o$). Typically, errors of ±3% and ±6% were tolerated in either integrated discharge or boundary shear. These data, along with other data, are available on the website www.flowdata.bham.ac.uk.

4 MODELLING WORK

4.1 *Influence of calibration parameters*

Some initial results are presented in Tables 1 & 2 that illustrate the influence of the 3 calibration parameters, f, λ and Γ used within the SKM. These were undertaken for one particular channel (152 mm wide) at one particular depth (200 mm). The effect of varying λ on the velocity distribution, while holding f and Γ constant, is shown in Figure 2 and the general effect on $\%SF_w$ and Q of varying all 3 parameters is shown in Table 1.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 1. Effect of varying calibration parameters.

Vary	Fixed	+/−	$\%SF_w$	Q
f	λ & Γ	increase f	down	down
		decrease f	up	up
λ	f & Γ	increase λ	up	down
		decrease λ	down	up
Γ	f & λ	increase Γ	up	down
		decrease Γ	down	up

Table 2. Effect of varying parameters on values of $\%SF_w$ & Q for 152 mm wide channel at H = 200 mm.

f	λ	Γ	$\%SF_w$ (%)	Q (l/s)
0.018	0.011	0.047	73.08	13.78
0.040	0.011	0.047	65.23	10.46
0.005	0.011	0.047	83.08	20.52
0.018	0.030	0.047	87.54	9.36
0.018	0.005	0.047	57.44	17.35
0.018	0.011	0.500	79.68	11.97
0.018	0.011	0.000	72.93	13.95

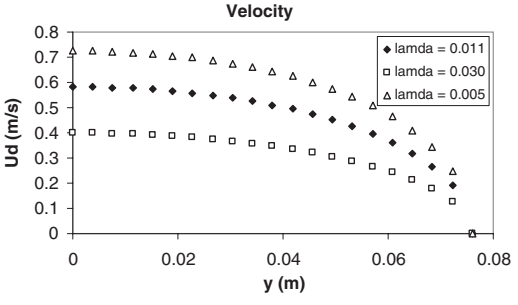

Figure 2. Effect of λ on lateral distribution of velocity in a rectangular channel.

In general, it is found that for a given depth, H, when λ was increased, with fixed f & Γ, it caused $\%SF_w$ to increase and Q to decrease. This is consistent with the results in Figure 2 and physical reasoning. The reverse occurred when λ was decreased. Table 2 illustrates these changes quantitatively, based on this one depth (H = 200 mm) with reference values of $\%SF_w$ and Q of 73.08% and 13.78 l/s respectively.

Table 2 indicates that the effect of varying the 3 parameters is large, as would be expected from physical arguments. Some analysis was therefore undertaken on the sensitivity of each parameter prior to optimising the parameters simultaneously for all flumes over the entire range of discharges and aspect ratios. The 152 mm (= 2b) flume data were selected for this preliminary analysis.

4.2 *Preliminary optimisation and error analysis*

Errors in the modelled values of channel discharge, Q, and the percentage of the total shear force carried by the walls, $\%SF_w$ were determined for each of the 7 depths used in this particular series of experiments, for specific values of the parameters f, λ and Γ. The experiments covered a fairly narrow bandwidth of aspect ratios ($0.99 < Asp < 2.00$) and were undertaken with depths of 153.0, 125.9, 113.6, 102.6, 97.0, 85.8 & 76.0 mm (or $0.50 < P_b/P_w < 1.00$). The discharges ranged from 9.85 l/s to 3.90 l/s and the velocities from 0.424 m/s to 0.338 m/s.

A different procedure was adopted later when optimising the parameters for all data, as in that case 7 pre-selected depths were chosen and the experimental $\%SF_w$ & Q data carefully interpolated in order to make direct comparisons between the data and modelled results at specific aspect ratios.

As the channels being modelled were symmetric, with an assumed constant local friction factor across the channel, it was only necessary to model one half of the cross section. In order to simplify the analysis further in these preliminary tests, only one panel was used to represent this half of the channel. This is known to be inaccurate, especially when modelling the boundary shear stresses, but is not an unreasonable approach when obtaining mean calibration parameters. These mean values may then be used later to undertake more detailed modelling, using 2, 4 and 'n' panels to represent the cross section.

The general approach was to assume values for 2 variables and then vary the other until the modelled values of discharge and $\%SF_W$ were comparable to those measured. The first variable that was calibrated was f, as this has been found to be the most influential. Next, the 'best' value of f was used in conjunction with an initial guess for Γ and λ was varied. Subsequently, the 'best' values of f and λ were used and Γ altered until the optimum solution was found. It should be noted that this order of calibration might not be applicable in all cases, as for example in meandering channels where Γ becomes more significant due to the enhanced secondary flows, as also may occur in overbank flow.

Even though only half the channel was modelled using 1 panel with a given set of f, λ and Γ variables, the panel was sub-divided further into 20 slices and the equations applied to each slice. The velocities from all slices were then laterally integrated to give the discharge for the whole channel.

Initial values of λ and Γ were assumed to be 0.02 and 0.05 respectively, and f values were then varied from 0.010 to 0.046 in increments of 0.002. In some cases the most suitable value for a parameter, f for example, will differ depending on which target variable is being compared, i.e. discharge, Q, or percentage shear force on the walls, $\%SF_w$. This is illustrated in

Copyright © 2006 Taylor & Francis Group plc, London, UK

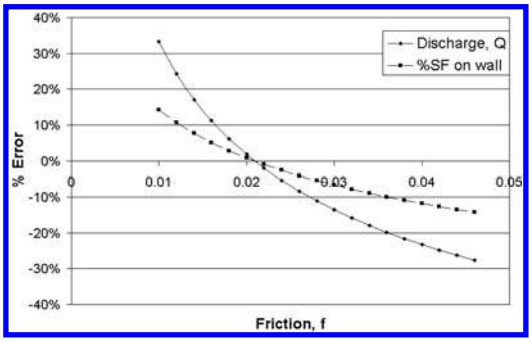

Figure 3. Errors in modelled Q and $\%SF_w$ associated with calibrating f (Experiment 2: h = 85.8 mm & Q = 4.80 l/s).

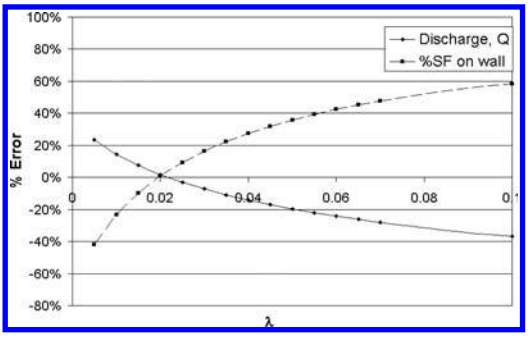

Figure 5. Errors in modelled Q and $\%SF_w$ associated with calibrating λ (Experiment 2: h = 85.8 mm, Q = 4.80 l/s).

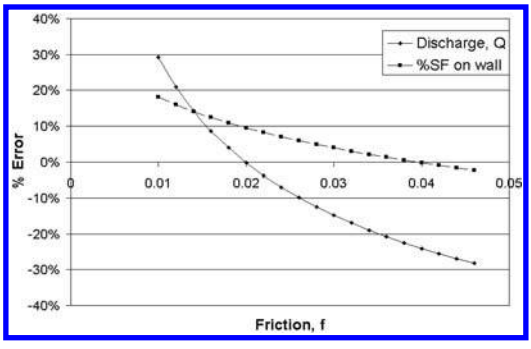

Figure 4. Errors in modelled Q and $\%SF_w$ associated with calibrating f (Experiment 7: h = 153.0 mm, Q = 9.85 l/s).

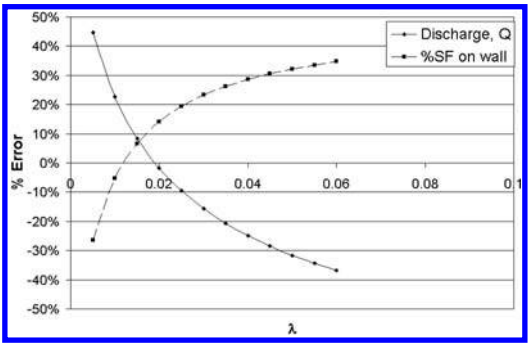

Figure 6. Errors in modelled Q and $\%SF_w$ associated with calibrating λ (Experiment 7: h = 153.0 mm, Q = 9.85 l/s).

Figures 3 & 4 for two particular tests. Experiment 2 had a low depth, with an aspect ratio, *Asp*, equal to 1.77, whereas Experiment 7 had a higher depth and an aspect ratio of 0.99. In Figure 3 it is seen that an f value of 0.021 gives the best result for both Q and $\%SF_w$, whereas in Figure 4 it is seen that the optimum f values are different for each variable ($f \approx 0.020$ for Q and ≈ 0.040 for $\%SF_w$). The errors follow the trends already indicated in Table 1.

Similar problems existed with the calibration of λ but since this parameter had a lower impact on the overall results it was less evident. In cases such as Experiment 7, a decision was made to calibrate λ using all possible values of f. Although this was perhaps tedious, it confirmed that the value of λ changed little. In such cases therefore, a judgement call was required and the combination of f and λ that gave the lowest and somewhat similar errors for discharge and shear force, was selected. In Figure 5 for example, the zero error point associated with discharge coincides with the zero error point for $\%SF_W$, at around $\lambda = 0.020$. However, the same cannot be said of Figure 6, where the zero error points for Q and $\%SF_w$ are again quite distinct, as already seen in Figure 4. In this case (Experiment 7), a λ value of 0.014 was taken as the optimum solution, i.e. in between the two zero error intersection points. This results in errors of approximately 8% in both cases.

A similar procedure was adopted for Γ. The optimum value was again chosen as being the mean value between two zero error intersection points, even though in some cases, the errors were quite large (i.e. ~10%).

Having obtained the optimum values for the 3 calibration parameters that give the best overall discharge and shear force results, the modelled lateral distributions of velocity and boundary shear stress were then compared with the measured ones. It was anticipated that the calculated distributions would not bear much resemblance to the measured ones, on account of using just a single panel in the modelling work, since it is known that then the perturbations that occur in the boundary shear stress due to secondary flow cells cannot be reproduced. An example of these perturbations is shown in Figure 7, taken from the rectangular duct flow experiments of Knight & Patel (1985). In order to model such perturbations accurately, the channel needs to be divided into several panels, each further sub-divided into slices, and the SKM applied to each panel. See Omran & Knight (2006) for further details.

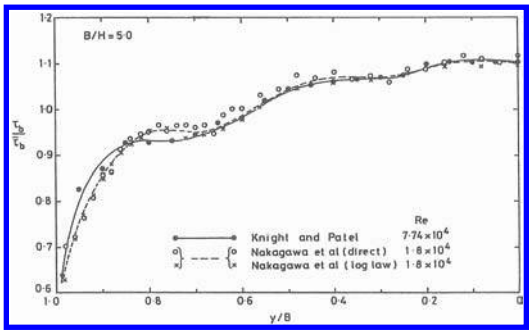

Figure 7. Lateral distributions of boundary shear stress in a rectangular duct (Knight & Patel, 1985).

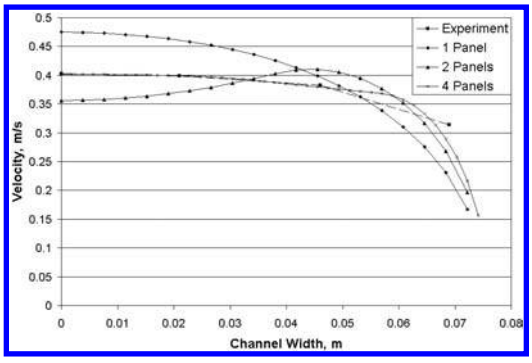

Figure 8. Comparison between modelled and actual lateral distribution of U_d (Experiment 2: h = 85.8 mm, Q = 4.80 l/s).

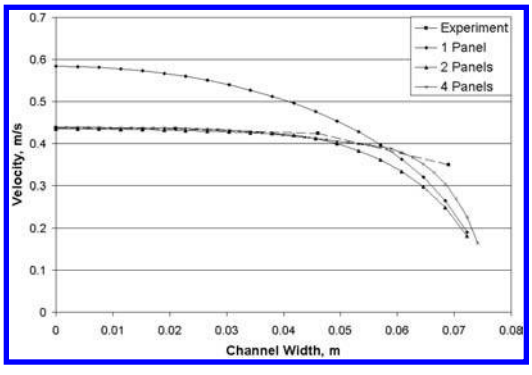

Figure 9. Comparison between modelled and actual lateral distribution of U_d (Experiment 7: h = 153.0 mm, Q = 9.85 l/s).

Two examples of the modelled distributions of depth-averaged velocity, U_d, using just one panel, are shown in Figures 8 & 9. The modelled and actual distributions clearly differ although the general shape of the curves are similar. The model fails to accurately predict the velocity distributions, which then has a knock-on effect on the prediction of the corresponding boundary

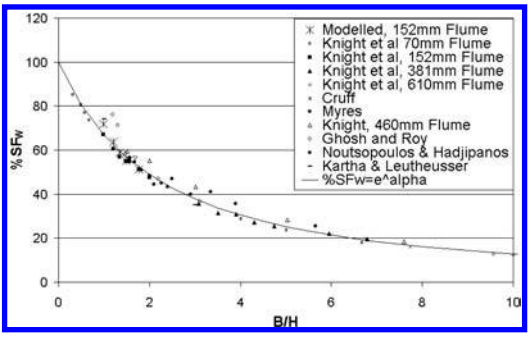

Figure 10. Comparison of modelled results (2b = 152 mm set) with Knight et al's original (1982) equation for $\%SF_W$ (Eq. 23).

shear stress distributions. Despite these obvious shortcomings, these preliminary results compare quite well with the mean shear force results obtained by Knight *et al* (1982), as shown in Figure 10. Also shown in Figure 10 is the original exponential form of equation for $\%SF_w$ v *Asp*, as given by Equations (22) & (23):

$$\%SF_W = e^{\alpha} \tag{22}$$

where, for open channel flow

$$\alpha = -3.230 \log_{10}\left(\frac{2b}{H} + 3\right) + 6.146 \tag{23}$$

In Figures 8 & 9 the one panel solution is shown alongside the 2 and 4 panel solutions. The 2 and 4 panel solutions have a constant λ of 0.07 but the values of f and Γ have been varied between panels. It can clearly be seen though that by increasing the number of panels the user gains more control over the model as each section of the channel can be modelled somewhat independently.

It should be noted that the modelled data in Figure 10 are only those for the 152 mm flume experiments. Although this preliminary analysis serves to show the good agreement between the modelled $\%SF_w$ and experimental results for $1.0 < Asp < 2.0$, data from all 4 rectangular flumes are shown next.

4.3 *Optimisation of parameters using all data*

Having established an understanding of the influence of each calibration parameter, and a procedure for calibration using data from one flume, the data sets from all 4 flumes were then used together. The aim was to obtain an optimized set of calibration coefficients for flow in rectangular open channels for as wide a range of aspect ratios as possible, albeit still modelling them with a single panel.

In order to standardise the modelling results, it was decided to set a maximum allowable error for every

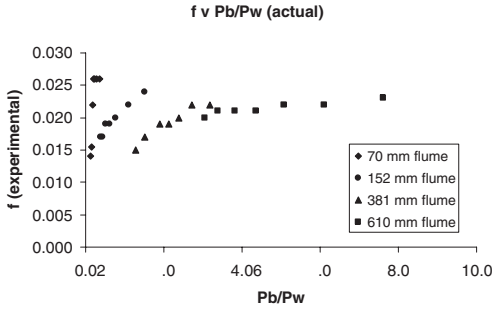

Figure 11. Best-fit f values used in modelling all data from the 4 flumes.

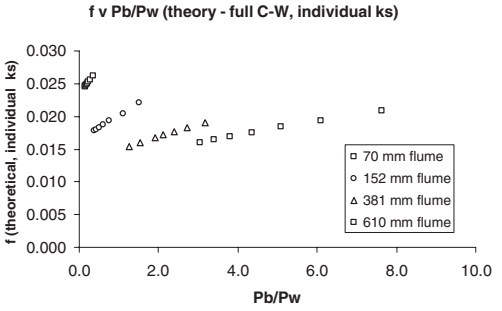

Figure 12. Theoretical f values based on Eq. (25), assuming a rough channel (single optimised k_s value for each flume).

experiment of ±5% for both the discharge, Q, and the percentage of the total shear force acting on the walls, $\%SF_w$. Furthermore, in order to make direct comparisons between different data sets and modelled results at specific aspect ratios, 7 pre-selected depths were chosen for each flume and the experimental $\%SF_w$ & Q data carefully interpolated from the series data for that particular flume. This had the added advantage of smoothing what was already good experimental data, with known errors, into 56 reliable paired $\%SF_w$ & Q target values. For each of these 28 target simulations, each of the f, λ and Γ parameter was varied 10 times over a small optimised bandwidth, making a total of 840 numerical experiments. Conclusions were then made about the choice of parameters.

As an example, the optimized f values are shown in Figure 11, using the wetted perimeter ratio, P_b/P_w as a surrogate for the aspect ratio, Asp ($=2b/H = 2P_b/P_w$), since trapezoidal channel data may then be easily added. It may be seen that each flume, covering a specific range of aspect ratios, produced a discrete curve.

Using the Colebrook-White equation, it is possible to account for the pattern of best-fit f values shown in Figure 11 in the following manner. Since for a rectangular channel $R = A/P = 2bh/(2b + 2h)$ it follows that $R = h/(1 + 2/Asp)$, where Asp = aspect ratio (total width/depth). Inserting these into the standard Colebrook-White equation

$$\frac{1}{\sqrt{f}} = -2.0\log\left[\frac{k_s}{3.71d} + \frac{2.51}{(ud/\nu)\sqrt{f}}\right] \quad (24)$$

and replacing d = pipe diameter by 4R, gives

$$\frac{1}{\sqrt{f}} = -2.0\log\left[\frac{k_s}{14.84\{1+2/Asp\}} + \frac{2.51\nu}{4\sqrt{8gS_f}\{h/(1+2/Asp)\}^{3/2}}\right] \quad (25)$$

where $Asp = 2b/h$ for a rectangular channel of semi-breadth b. Equation (25) thus indicates that the f value

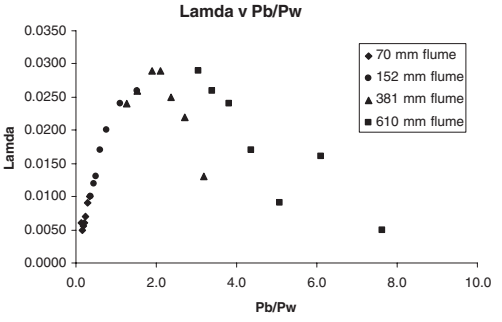

Figure 13. Best-fit λ values used in modelling all data from the 4 flumes.

depends solely on the k_s and Asp values. Equation (25) is illustrated in Figure 12 for a rough channel with the k_s values selected to fit the entire data set from each individual flume. The similarity between the predicted and observed data in Figures 11 & 12 respectively is good. Thus Equation (25) affords a theoretical basis for estimating the friction factors in rectangular channels for all aspect ratios, Asp, once k_s is either specified or known.

A similar procedure was adopted for both the λ and Γ parameters and the optimised results plotted out to observe any underlying trend or relationship. The best-fit results are shown in Figures 13 & 14 respectively. The best–fit equations through the data from all 4 flumes were:

$$\lambda = 6.25x10^{-5}Asp^3 - 0.001625Asp^2 + 0.01145Asp + 0.0032 \quad (26)$$

$$\Gamma = -0.0002Asp^2 + 0.00105Asp + 0.0464 \quad (27)$$

Equations (25)–(26) thus provide the basis for the selection of the 3 calibration parameters, f, λ and Γ for flow in rectangular open channels.

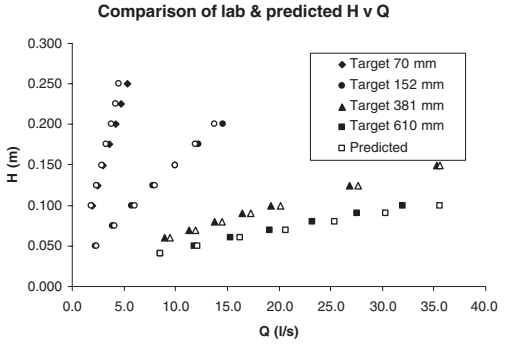

Figure 15. Comparison of laboratory and predicted H v Q values for all flumes.

5 APPLICATION OF MODELLING TOOL

5.1 *Prediction of stage-discharge relationships*

As a check on the optimised calibration coefficients, which were based on interpolated data, Equations (25)–(27) were applied to all the actual flume data. This also illustrates how an engineer might use this novel approach in practice. Figure 15 shows a comparison between the modelled and experimental stage-discharge relationships for the 4 flumes. The agreement is good, despite using a single k_s value for each flume ($k_s = 0.1$, 0.0001, 0.001 & 0.001 mm for the 70, 152, 381 & 610 mm flumes respectively). The predicted curves come from applying the Darcy-Weisbach equations with Eq. (25) supplying the f value, based on the relevant Asp and mean k_s value for each flume. It is apparent that the predicted stage-discharge relationships, using the SKM are in reasonably close agreement with theexperimental ones, indicating that the method is valid over a wide range of aspect ratios ($0.3 < Asp < 20$), as 4 different data sets were used from 4 separate flumes.

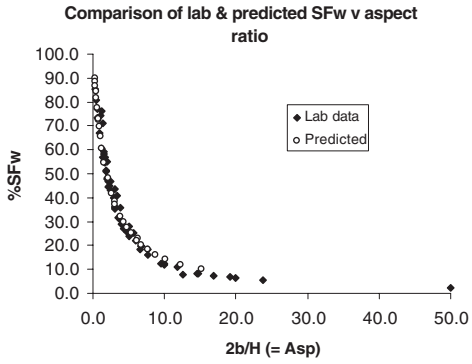

Figure 16. Comparison of modelled results (all data) with Knight et al's (1994) equation for $\%SF_W$ (Eqs. 28–30).

5.2 *Prediction of stage-sidewall shear force relationship*

The sidewall correction procedure outlined in the preceding sections was then tested by applying it to all 4 flumes, using Equations (25)–27) to supply values of the calibration coefficients required in the SKM. Figure 16 shows that the predicted values for the percentage of the total shear force acting on the walls, $\%SF_w$, are in good agreement with the actual experimental data. They are also in agreement with the more general equations for flow in rectangular and trapezoidal channels, provided Knight et al. (1994) for subcritical flow, in the form:

$$\%SF_W = C_{sf} e^{\alpha} \tag{28}$$

$$\alpha = -3.230 \log_{10}\left(\frac{P_b}{P_w C_2} + 1.0\right) + 4.6052 \tag{29}$$

where $C_2 = 1.50$, and $C_{sf} = 1.0$ for $P_b/P_w < 6.546$

$$C_{sf} = 0.5857(P_b/P_w)^{0.28471} \tag{30}$$

It may be noticed in Figure 16 that there is a slight divergence at high aspect ratios ($Asp > 20$), and this is under investigation, using a wider set of data as given in Knight et al. (1994). Figure 17 shows these data, drawn from many open channel flow and duct experiments.

5.3 *Prediction of mean bed shear stress*

Having established the $\%SF_w$ v Asp relationship, it is possible to obtain the mean wall and bed shear stresses via Eqs (20) & (21). The mean bed shear stress may be expressed as

$$\frac{\bar{\tau}_b}{\rho g H S_o} = \left[1 - \frac{\%SF_w}{100}\right] \tag{31}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

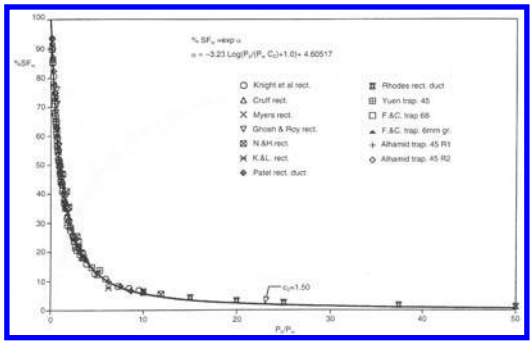

Figure 17. Comparison of channel and duct $\%SF_w$ values in rectangular and trapezoidal channels (Knight et al, 1994).

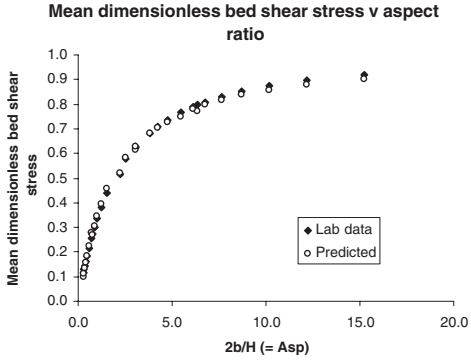

Figure 18. Predicted mean bed shear stress for rectangular channels.

The predicted relationship is shown in Figure 18, together with the experimental data. The agreement is inevitably good on account of the good agreement already shown in Figure 16. Eq. (31) may then be used to estimate how wide a channel will need to be before two-dimensional flow can be assumed. As can be seen, the mean bed shear stress is significantly different from its 2-D value even at large aspect ratios (e.g. $0.95 < \overline{\tau}_b / \rho g H S_o < 1.0$ only when $Asp > 25$.

5.4 *Extension of method to deal with heterogeneous roughness*

The application of this method to channels where there is differential roughness between the bed and the walls, as often occurs in practice in culverts or in flume studies, is not presented herein. However, it should be possible to adjust the λ coefficients and to link them to values of relative roughness, k_{sb}/k_{sw}, where the subscripts *b* & *w* stand for the bed and walls respectively. Some experimental data exist for these conditions, as described by Knight & Alhamid (1992) and shown in www.flowdata.bham.ac.uk.

6 DISCUSSION OF RESULTS

It has been shown elsewhere (e.g. Knight & Shiono (1996) and Abril & Knight (2004)) that the SKM is capable of modelling channels of various cross-sections both accurately and with a minimum of computational effort. This paper has now shown that the SKM is capable of being applied to rectangular channels to give the mean shear force acting on either the bed or the walls. A range of flume data has validated the results over a wide range of aspect ratios ($0.3 < Asp < 20$). Guidance has been given via Eqs (25–27) to the selection of the three calibration coefficients f, λ and Γ. The significance of the calibration values for the 3 parameters lies not so much in the equations, which are based on a preliminary analysis, but in their numerical values.

With regard to the friction factor, f, it is clear from Eq. (25) that the geometric properties of each channel are implicit in the aspect ratio, and therefore the calibrated results show what one might expect, that as Asp increases, f will increase for shallower depths if it is assumed that k_s remains constant for a given surface material. The average k_s values used for each flume were in fact in reasonable accord with experimentally back-calculated values. The 152 mm flume was the first to be tested and built to a high specification, thus having the lowest k_s value. The narrowest flume (70 mm) had the highest k_s value due to the difficulty in assembly. The accuracy obtained for mean values (i.e. <5% error in both Q and SF_w) were not difficult to obtain, and could be improved by simply choosing individual k_s values for each experiment.

The lamda values indicate the lateral shear from the sidewalls and it is instructive to observe that they increase from a low value to a peak at around $Asp = 4$. The discharges are more sensitive to λ than $\%SF_w$ as the velocity distributions show in Figure 2. Since the gradient of velocity is only large near the wall, the influence of λ diminishes as the channel widens. This is also true for large river channels with overbank flow, where the intense shear zone is confined to a relatively small region. However the range of λ values is large, albeit the absolute values used herein are relatively low (typically $\lambda = 0.07$–0.13).

The Γ values are clearly not very significant as using a single panel is not necessarily the best approach, and only used herein as a preliminary modelling experiment. Rectangular channels are actually more difficult to model with a depth-averaged model, by virtue of the fact that in the corner region there are generally two cells present on top of each other, and depth averaging as envisaged in Figure 1 breaks down. Figure 1(b) only shows a single cell operating over the entire depth, as is often conceptualised for wide systems where the cell size scales with the depth and a

Copyright © 2006 Taylor & Francis Group plc, London, UK

pair of contra-rotating cells have a spacing of twice the depth.

Although there are clearly more issues requiring investigation, the modelling approach outlined in this paper does offer an alternative method to obtaining reasonably accurate estimates of mean wall or bed shear, commensurate with the accurate values for the overall discharge. Since many methods give one and not the other, this is offered as a first step in a novel line of attack. The accuracy of the lateral distributions of velocity and boundary shear stress could easily be improved by the incorporation of more panels within the channel.

7 CONCLUSIONS

The SKM has been shown to be applicable to simulating the main physical features of flow in rectangular channels, giving the lateral distributions of both depth-averaged velocity and boundary shear stress.

The method provides a way of determining the proportion of the total shear force that acts on the sidewalls, thus enabling the mean bed shear stress to be determined with the minimum of computational effort. Equations have been given for the general trend in the three calibration coefficients, f, λ and Γ.

Further work is required to elucidate the equations and to undertake more detailed modelling using multi-panels with heterogeneous roughness.

ABSTRACT: Side-cavities are common along natural and channelized rivers. In this paper, results of flume experiments in a rectangular side-cavity (length to width ratio L/W = 2) are compared with field observations of a similar, though topographically more complex, dead zone. The main flow in the flume was kept steady, sub-critical (Fr = 0.36) and turbulent ($Re = 3.9 \times 10^4$). Field measurements were performed during small floods with contrasted discharges. In the river main flow, the Froude number was about 0.5 and the Reynolds number about 2×10^6. In the laboratory, flow structure was investigated at three different depth levels within the side-cavity, by means of PTV (Particle Tracking Velocimetry). In situ, flow dynamics features were explored by acoustic Doppler current profiler (aDcp) and video analysis (LS-PIV). Both experimental and field cases show similar mean flow patterns. Flume experiments offer a detailed view of a two-gyre system: a primary gyre takes up three quarters of the cavity area while a secondary contra-rotating gyre occupies the upstream inner corner of the side-cavity. In the field case, the primary gyre also develops, in close connection with morphological patterns. The secondary gyre, atrophied and non-persistent, is replaced by non-eroded materials that fill in the upper corner of the cavity.

1 SIDE-CAVITIES ALONG RIVERS

Side-cavities or embayments are common along natural and channelized rivers. The physical knowledge of the flow structure developing in these so-called dead zones is important from an environmental point of view. It can also help engineers design hydraulic structures such as groin fields and spur dykes.

Very few detailed field investigations of open-channel flow in side-cavities have been reported (cf. e.g. Sukhodolov et al. (2002), Sukhodolov et al. (2004)). Various flume studies (Kimura and Hosoda 1997; Uijttewaal et al. 2001; Muto et al. 2000b; Langendoen et al. 1994; Nezu and Onitsuka 2002) have stressed the determination of flow patterns by the length to width ratio L/W of the side-cavity: a stable one-gyre system for $L/W \approx 1$, an unstable two-gyre system else. Mass exchange appears to be mainly caused by intermittent inflows driven by shear instabilities at the interface (Kimura and Hosoda 1997; Uijttewaal et al. 2001; Muto et al. 2000b).

In this paper, results of flume experiments in a rectangular side-cavity (L/W = 2) are compared with field observations of a similar, though topographically more complex, dead zone. The natural side-cavity corresponds to the junction between a river and the downstream part of a cut-off meander.

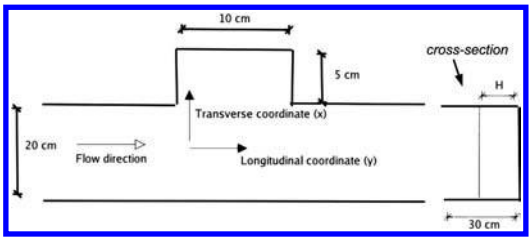

Figure 1. Experimental set-up schematic representation.

2 FLOW PATTERNS IN AN EXPERIMENTAL SIDE-CAVITY

2.1 *Experimental set-up*

Experiments were conducted at the University of Chile, in a 1,200 cm long, 20 cm wide, 30 cm deep flume with a longitudinal slope of 0.001. The side-cavity was located 300 cm upstream from the end of the flume. A schematic representation of the experimental set-up can be seen in Fig. 1. Hydraulic conditions for the experiments, depth (H), flow (Q), mean velocity (U), hydraulic radius (R_h), Reynolds number ($Re = UH/\nu$), and Froude number ($Fr = U/\sqrt{gH}$) are summarized in Table 1.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 1. Experimental hydraulic conditions.

H [cm]	Q [cm^3/s]	U [cm/s]	R_h [cm]	Re	Fr
10.7	7,800	36.4	5.17	3.9×10^4	0.36

The cavity was 10 cm long (L) and 5 cm wide (W) and consequently the aspect ratio was L/W = 2. This configuration was chosen because it is more similar to dead zones in rivers than deep cavities. For instance, it shows some aspects of the flow between river groins, which is interesting from a river engineering point of view (Weitbrecht et al. 2002; Uijttewaal et al. 2001). This kind of cavities (aspect ratio 2) presents a higher mass exchange than cavities with aspect ratios close to 1. The exchange process is dominated by several instabilities in comparison with deep cavities where mass exchange is governed by the main gyre (Shankar and Deshpande 2000).

The implemented PTV-System was composed by a 400 MW two-colour laser beam and by a 30 Hz digital camera. Acrylic particles were used. PTV was employed due to the sensitivity of the cavity flow structure to external perturbations. This phenomenon was observed by Nezu et al. (2005) in a rectangular cavity with the same aspect ratio of 2. This made the use of an acoustic Doppler velocimeter (aDv) inside the cavity unsuitable, so this sensor was employed only for measurements in the channel and at the interface between the main flow and the cavity.

2.2 *Particle Tracking Velocimetry (PTV)*

This method was implemented in Matlab for flow structure determination. The main characteristics of PTV is that information can be obtained from each particle in the flow, which constitutes a clear difference with Particle Image Velocimetry (PIV) where information is averaged over a group of particles. PTV provides velocity samples along particle trajectories, i.e. in a Lagrangian frame of reference. Thus it differs from PIV by the fact velocity is measured at random locations instead of over a regular grid (Cenedese and Querzoli 1997). Flow field determination was obtained by application of a dynamic, binary, spatial cross-correlation analysis between two sequential images, according to an algorithm proposed by Hassan et al. (1992). From the random distribution of samples the velocity field over a regular grid can be obtained by interpolation. Following the results obtained by David et al. (2002), the *Inverse Distance Weighting Method* with a Gaussian adaptive window was used for velocity interpolation. As a conclusion the authors point out that this method gives reliable results for strong velocity gradients. The implemented algorithm was tested on synthetic data obtained by a computational implementation of inviscid flow around a cylinder (Hassan et al. 1992) using standard images provided by the Visualization Society of Japan. Spurious vectors (less than 10%) were eliminated thanks to correlation and direction-magnitude filters.

Musalem (1999) from dimensional analysis and Valdes (1995) from error propagation in the PTV method concluded that errors in velocity and vorticity measurements are about 15% and 20% respectively. To reduce errors the threshold level for light intensity in video images must be chosen carefully and particle density must be high. The three measurements reported here were performed for the same hydraulic conditions by recording 1,000 pairs of frames for planes at 20, 60 and 100 mm over channel bottom.

2.3 *Flow structure*

2.3.1 *Velocity field*

Velocity fields averaged over each image time-series are presented in Figs 2, 3 and 4, for three different cavity depth levels. The origin of coordinates is the upstream cavity corner. As in previous results obtained by Weitbrecht and Jirka (2001) and Uijttewaal et al. (2001) for river groins and Muto et al. (2000a) for river embayment, it is possible to identify a two-gyre system. The main gyre (anticlockwise rotation), which occupies three fourths of the cavity area, is driven by the main channel flow and the secondary gyre (clockwise rotation) is driven by the primary gyre. The primary gyre core (velocity nearly zero) does not change its position at the three levels and it is also possible to recognize a high velocity zone at the interface between both gyres. The low velocity region is maximum at elevation 20 mm. In general, velocity magnitude does not suffer important changes with depth and the maximum magnitude is at most 6 times lower than the main channel mean velocity. From vector fields, the main inflow zone in the cavity can be identified and is located at the downstream corner for all three elevations.

2.3.2 *Vorticity*

Vorticity fields are shown in Figs 5, 6, and 7. A comparison between the three levels suggests that the main change in vorticity occurs in the low velocity region (upstream zone). A displacement of the maximum vorticity area towards the interface is observed as the bottom of the cavity is approached. Besides, there is a zone of high vorticity produced by shear between the cavity and the main channel flow, and another one between the primary gyre and the wall. This is mainly due to the high velocity gradient produced by the high velocity zone, described above.

2.3.3 *Streamlines*

The streamlines (Figs 8, 9, 10) show that there is an evolution of the secondary gyre with depth. The secondary gyre even disappears at elevation 20 mm.

cavity depth level, near the free surface. These pictures show that results obtained by PTV are in agreement with the movement of seeded particles in the cavity. The primary gyre and the secondary gyre as well as the internal shear region between both gyres can be clearly observed.

From image analysis it was possible to detect a displacement of both gyres over time. An important effect of this is the perturbation of the shear layer by the main gyre and a consequent increase of the shear layer instability. This process affects the size of billows allowing a more intense mass exchange from channel to cavity. In Fig. 12 some particles are leaving the cavity in the middle part of the cavity-channel interface, in the outflow region.

Another important observation is the direction of particles coming from the interface between gyres: one part of the particles goes to the secondary gyre, one part to the region close to the upstream corner and the rest remains inside the main gyre or leaves the cavity.

3 FLOW PATTERNS IN A NATURAL SIDE-CAVITY

3.1 *Real case geometry*

The field study area is located at the junction of the Ain river, South Eastern France, and one of its former channels. The "Port-Galand" abandoned channel was a slightly sinuous meander that was artificially cut off in 1964 to protect a bridge. In the vicinity of the abandoned channel's mouth, the river reach between two natural sills is quite straight, with one riffle upstream and the other just downstream the study area. The local gradient is estimated to be 0.4% and the median grain size to $d_{50} = 0.021$ m with low dispersion: $S = \sqrt{\frac{d_{84}}{d_{16}}} = 1.7$ (Rollet 2002).

The left bank of the abandoned channel is made of a rip-rap embankment, while the right bank is made of erodible though vegetalized alluvial deposits. The junction angle is close to 90° (Fig. 14), so that the flow area of interest can be likened to a roughly rectangular side-cavity of length $L \approx 55$ m and width $W \approx 30$ m (aspect ratio $L/W \approx 1.8$, close to that of the flume case).

Copyright © 2006 Taylor & Francis Group plc, London, UK

The particular shape of this natural side-cavity (Fig. 15) stems from:

- the primary morphology of the former river channel;
- the left-side straight unerodible embankment (with a small apex visible on Fig. 14);
- the erosion of the right bank like an upstream pointing triangle;
- the remaining part of the right bank materials, occupying the upper outer corner of the equivalent rectangle.

Furthermore the bottom of the cavity is not flat, mainly because of a central gravel-bar deposit. In spite of a sand deposit partly closing its outer side, the cavity is directly connected to a series of elongated oxbow-lakes, where waters are quite still and suspended sediments can settle down.

3.2 *Flow conditions*

In early 2005, four campaigns of in situ hydrodynamical measurements were carried out: acoustic Doppler current profiler (aDcp) and Large-Scale PIV (LS-PIV) data were acquired and post-processed. The observed velocity fields in the natural side-cavity were compared with 2Dh hydrodynamical modelling outputs (*Cemagref* RUBAR20 code). Further details can be found in Le Coz et al. (2006).

River discharge estimates were provided by the local gauging station by courtesy of the Compagnie Nationale du Rhône (CNR). The pressure gauge is located at the very end of the rip-rap embankment.

As no measurement was performed in the river main flow itself, a 1D hydrodynamic model (*Cemagref* MAGE6 code) was calibrated and used to estimate hydraulic parameters for the four campaigns (cf. Table 2). Upstream boundary condition consisted of discharge time series from the "Pont-de-Chazey" gauging station (DIREN Rhône-Alpes) located 15 km upstream the study site. The experimental rating curve of "Port-Galand" gauging station (CNR) was used as a downstream boundary condition. The model was calibrated against water level series from two *Cemagref* pressure gauges located between "Pont-de-Chazey" and "Port-Galand" gauging stations.

From these simulated results (cf. Table 2), it can be confirmed that close to the study area, the river flow was sub-critical ($Fr \approx 0.5$) and highly turbulent ($Re \approx 2 \times 10^6$).

The reliability of these estimates was checked by analysing an aDcp transect acquired by the CNR on 1998, September 14th, about 100 metres upstream from the study site. Hydraulic condition parameters were: $Q = 290\,m^3/s$, $U = 1.32\,m/s$, $R_h = 1.49\,m$, $Fr = 0.34$ and $Re = 1.97 \times 10^6$. These estimates from experimental aDcp data have the same order of magnitude as 1D-modelling outputs (Table 2). Discrepancies may be explained by differences between the aDcp transect section in 1998 and the interpolated computational geometry from a 2004 topographic survey.

Table 2. Hydraulic conditions during measurement campaigns from 1D simulation (Q river discharge, U mean velocity, R_h: hydraulic radius, Fr: Froude number, Re: Reynolds number).

Campaigns dates	aDcp1 050304	LS-PIV1 050214	LS-PIV2 050408	aDcp2 050425
$Q\ [m^3/s]$	200	325	365	650
$U\ [m/s]$	1.42	1.60	1.63	1.79
$R_h\ [m]$	1.06	1.06	1.11	1.68
Fr	0.44	0.50	0.49	0.44
$Re\ (\times 10^6)$	1.51	1.69	1.81	3.00

As reported in Le Coz et al. (2006), river discharge time series recorded during each measurement campaign show various trends. In particular, the aDcp1 campaign was performed during fairly steady conditions (mean discharge $Q = 200\,m^3/s$, $+0.5\%$ of Q per hour), whereas the aDcp2 campaign was performed during the end of the rising limb of a $700\,m^3/s$ flood (mean discharge $Q = 650\,m^3/s$, $+3.5\%$ of Q per hour).

3.3 *Horizontal flow patterns*

All over the investigated range of discharge values – from $200\,m^3/s$ to $650\,m^3/s$ – the observed mean velocity field organizes according to a clear persistent one-gyre system (cf. Fig. 16 and Le Coz et al. (2006)). A large recirculating flow occupies almost the whole side-cavity, rotating around a central gravel-bar deposit corresponding to low velocities. This primary gyre is distorted as it skirts round the gravel-bar's long apex that points towards the entrance of the oxbow-lake. Velocity intensities in the gyre are close to 0.5–0.8 m/s i.e. about 3 times lower than typical velocities in the main channel.

Averaged velocity fields from March, 4th (aDcp1) and April, 25th (aDcp2) campaigns show quite different patterns (Fig. 16). For aDcp2, the primary gyre is more distorted towards the first oxbow-lake of the abandoned channel. "Input" velocities seem much stronger than "output" ones. Computed discharges from aDcp data are clearly negative, with several m^3/s entering the former channel. This can be explained by severely unsteady conditions due to the several hour rising limb of the flood preceding and including the campaign time span. For aDcp1, input and output velocity intensities are quite balanced and the mean recirculating flow does not seem to enter the oxbow-lake. The computed mean discharges through the 5 aDcp1 transects are quite close to 0 ($|Q| < 1\,m^3/s$) as expected for stationary river discharge conditions. Therefore aDcp1 mean velocity patterns should be

Copyright © 2006 Taylor & Francis Group plc, London, UK

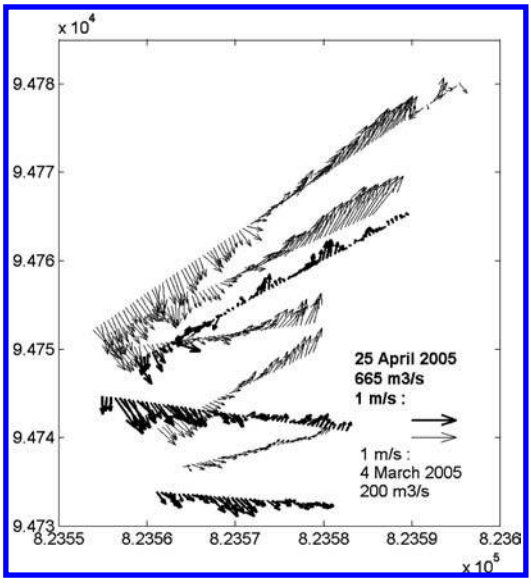

Figure 16. Depth-averaged velocities from interpolated aDcp data. *Equal East and North coordinates in metres*.

considered a reference to be compared with patterns observed in the flume case.

However aDcp instantaneous velocity fields can be quite different from averaged ones (cf. Le Coz et al. (2006)). Non-interpolated data clearly show instabilities that can be compared with fluctuating flow patterns also reported in the experimental side-cavity. Unstable structures connected with intermittent engulfing inflows and water level oscillation were indeed observed in situ (Védie 2005). As a consequence, a secondary contra-rotating gyre intermittently forms in the upstream corner of the cavity (Le Coz et al. 2006). In comparison with the flume secondary gyre, this gyre is very small and degenerated but it causes a local bank erosion (G on Fig. 15).

4 CONCLUSIONS AND PERSPECTIVES

Mean horizontal flow patterns in open-channel side-cavities from flume and field experiments have been depicted and compared. In spite of differences in geometry and hydraulic conditions, the field case may be assimilated to the two-gyre flume case through a so-called "equivalent rectangle" postulate: by means of bank erosion processes, the geometry of the natural side-cavity tends towards a rectangular shape with $L/W \approx 2$ as a morphodynamical equilibrium.

Flume observations show that momentum is transferred from the main flow to the primary gyre through a first unstable mixing-layer, then from the primary gyre to the secondary gyre through a second unstable mixing-layer. What may occur in the field study case is that enough energy is given to the primary gyre to erode the right former-channel bank, but the secondary gyre is too weak to do so. Thus the resulting side-cavity shape would mainly stem from the shape of the primary gyre in the flume case.

From both scientific and engineering points of view, it would be interesting to check this postulate, especially in order to ensure the morphological stability of restored side-cavities. The investigation of different field cases – for instance with both banks erodible – and further flume observations – for instance with variable or erodible walls – would help.

Spatially averaged near-bed flow field over rough armor layers

J. Aberle
Leichtweiss-Institute for Hydraulic Engineering, Technical University of Braunschweig, Germany

ABSTRACT: Results of a laboratory study carried out to investigate the interaction between water worked gravel-bed roughness and the near-bed flow field are presented. Vertical velocity profiles were measured with a 3D-Laser Doppler Anemometer at 24 randomly distributed locations within a defined test section. Bed topography was scanned with a laser displacement meter. The spatial heterogeneity of flow velocities and turbulence parameters in the near-bed region is shown by means of form-induced stresses which follow from the double-averaged Navier-Stokes equations. Form induced stresses are also used to investigate the subdivision of the near-bed flow field into roughness and logarithmic layer dependent on roughness geometry. The influence of the definition of geometrical roughness parameters on hydraulic parameters such as water depth and bed shear stress is discussed.

1 INTRODUCTION

The understanding of the near-bed flow structure over rough natural beds is important for many hydraulic engineering and ecological applications. An abundance of studies have been carried out to explore the theoretical aspects of turbulent structures over rough beds (e.g., Nezu & Nakagawa 1993, Kironoto & Graf 1994, Song & Graf 1994, Nezu 2005). Most of these studies focused on the investigation of the flow field at distances from the bed greater than the roughness height and for flows with large relative submergence. Recent investigations on the near-bed flow structure of flows over irregular rough beds for both, large and shallow water depths resulted in improved approaches for the description of turbulence and the near-bed velocity distribution (e.g., Dittrich & Koll 1997, Dancey et al. 2000, Shvidchenko & Pender 2001, Nikora et al. 2001, 2004, Koll 2002, Tachie et al. 2004, Carollo et al. 2005). However, these approaches still require parameterization and validation.

Most investigations of the flow structure in the near-bed region have been based on the Reynolds equations which were used for both modelling and interpretation of experimental data. However, the near-bed turbulent flow field over rough surfaces is spatially heterogeneous and depends on roughness characteristics. Thus, theoretical considerations based on measurements at a single location cannot be generalized, indicating that the application of the time-averaged momentum equations is inconvenient and impracticable. Giménez-Curto & Corniero Lera (1996) and Nikora et al. (2001, 2005a) concluded that 2D approximations based on the Reynolds equations as well as similarity considerations for time-averaged variables are not possible for the near-bed region. Instead, a detailed analysis of near-bed hydrodynamics requires the consideration of the flow field over a certain spatial scale. Such an approach has been used by researchers to compare flow characteristics at different locations at a small spatial scale (e.g., Lamarre & Roy 2005) or by considering mean velocities and turbulence characteristics to some extent averaged in the space domain, though the averaging operation was not defined explicitly (e.g., Dancey et al. 2000, Lawless and Robert 2001, Carollo et al. 2005).

A methodological approach to investigate rough bed flows is to volume average (within a thin slab) or area average (in planes parallel to the bed) the Reynolds equations. The spatially and temporally averaged Navier-Stokes equations relate to the time-averaged equations as the time-averaged equations relate to the equations for instantaneous hydrodynamic variables. The double averaged Navier-Stokes equations were first introduced by Wilson & Shaw (1977) and further developed by Raupach & Shaw (1982), Finnigan (1985), Raupach et al. (1991), and Giménez-Curto & Corniera Lera (1996). In hydraulics, the idea of spatial flow averaging was first introduced by Smith & McLean (1977) and was recently adopted by various researchers (e.g., Nikora et al. 2001, 2002, 2004, Lopez & Garcia 2001, Righetti & Armanini 2002, Aberle & Koll 2004, Aberle et al. 2004, Campbell et al. 2005, Armanini & Gregoretti 2006). The theoretical background of this methodology and examples of applications for studying rough-bed flows have been described recently in detail in Nikora et al. (2005a, b).

Copyright © 2006 Taylor & Francis Group plc, London, UK

This paper investigates the applicability of the double-averaged momentum equations in order to identify the roughness and the logarithmic layer for flows over gravel beds. The theoretical background of the double averaged velocity distribution in the roughness and the logarithmic layer are briefly discussed. Specifically designed laboratory experiments are described and the data from these experiments are analysed using the double-averaging methodology. The data analysis procedure and the influence of the roughness geometry on flow velocity distribution, form-induced stresses, and layer separation is discussed.

2 BACKGROUND

The double-averaged (in time and space) momentum equations can be written as (Nikora et al. 2005a):

$$\frac{\partial\langle\overline{u}_i\rangle}{\partial t}+\langle\overline{u}_j\rangle\frac{\partial\langle\overline{u}_i\rangle}{\partial x_j}=g_i-\frac{1}{\rho\phi}\frac{\partial\phi\langle\overline{p}\rangle}{\partial x_i}-\frac{1}{\phi}\frac{\partial\phi\langle\overline{u_i'u_j'}\rangle}{\partial x_j}-\frac{1}{\phi}\frac{\partial\phi\langle\tilde{u}_i\tilde{u}_j\rangle}{\partial x_j}+\frac{1}{\phi}\frac{\partial}{\partial x_j}\phi\left\langle\overline{\nu\frac{\partial u_i}{\partial x_j}}\right\rangle+\frac{1}{\rho}\frac{1}{\phi}\frac{1}{V_0}\overline{\iint_{S_{int}}pn_i dS}-\frac{1}{\phi}\frac{1}{V_0}\overline{\iint_{S_{int}}\nu\frac{\partial u_i}{\partial x_j}n_i dS} \quad (1)$$

where $u_i = i$ th component of the velocity vector; $p =$ pressure; $g_i = i$ th component of the gravity acceleration; $t =$ time; $x_i =$ coordinate; $\rho =$ fluid density; $\nu =$ kinematic viscosity; $\phi =$ roughness density function which is defined as V_f/V_0 with $V_f =$ volume of water in the averaging domain and $V_0 =$ total volume of the averaging domain (thin slab parallel to the mean bed); $n =$ inwardly-directed unit vector normal to the bed surface (into the fluid); and $S_{int} =$ extent of water-bed interface. The overbars in Equation 1 denote time averaged variables and angle brackets spatial (volume) averaged variables, respectively. Instantaneous variables are decomposed into time averaged and fluctuating parts according to $\theta_i = \overline{\theta}_i + \theta_i'$ and time averaged variables are decomposed into spatially averaged and spatial fluctuation parts according to $\overline{\theta}_i = \langle\overline{\theta}_i\rangle + \tilde{\theta}_i$. Theoretical considerations related to the averaging procedure are discussed in Nikora et al. (2005a).

The two integrals in Equation 1 characterize form drag f_{pi} and viscous drag f_{vi} per unit fluid volume and are defined only below the roughness crest. Both terms, together with the form-induced stresses $\langle\tilde{u}_i\tilde{u}_j\rangle$ are additional terms when Equation 1 is compared with the conventional time averaged equations. For two-dimensional, steady, uniform flow conditions over a fixed rough bed and a flat water surface, the longitudinal component of Equation 1 reduces to:

$$\rho g S_b+\frac{1}{\phi}\frac{\partial\phi\tau}{\partial z}+f_p+f_v=0 \quad (2)$$

where $S_b =$ bed slope and $\tau =$ total fluid stress. The total fluid stress contains three components, turbulent, form induced, and viscous stresses:

$$\tau=\rho\left[-\left\langle\overline{u'w'}\right\rangle-\langle\tilde{u}\tilde{w}\rangle+\frac{\nu}{\phi}\frac{d\phi\langle\overline{u}\rangle}{dz}\right] \quad (3)$$

For turbulent flows where $-\langle\tilde{u}\tilde{w}\rangle$, f_{pi}, and $f_{vi}=0$ Equation 2 is equivalent to the expression which can be derived from the Reynolds equations. Thus, integration of Equation 2 yields:

$$\rho g S_b\left(z_{ws}-z\right)=-\left\langle\overline{u'w'}\right\rangle(z) \quad (4)$$

In the flow region closer to, but still above the roughness elements, the form induced stresses may contribute significantly to the momentum equation while f_{pi} and $f_{vi}=0$. Thus, integration of Equation 2 yields:

$$\rho g S_b\left(z_{ws}-z\right)=-\left\langle\overline{u'w'}\right\rangle(z)-\langle\tilde{u}\tilde{w}\rangle(z) \quad (5)$$

Below the roughness crest z_c, the drag terms f_{pi}, and f_{vi} must be taken into account and integration of Equation 2 yields:

$$\rho g S_b\left(z_{ws}-z_c+\int_z^{z_c}\phi dz\right)-\phi\left\langle\overline{u'w'}\right\rangle(z)-\phi\langle\tilde{u}\tilde{w}\rangle(z)+\int_z^{z_c}\left(f_p+f_v\right)dz=0 \quad (6)$$

Based on Equations 4–6 it becomes possible to derive relationships for the velocity distribution in the logarithmic layer (above roughness crest) and in the roughness layer. The logarithmic velocity distribution can be derived by Equation 4 and the mixing length approach. Defining mixing length as $l=\kappa(z-d)$ results in:

$$\frac{d\langle\overline{u}\rangle}{dz}=\frac{\kappa}{u_*(z-d)} \quad (7)$$

where $d =$ zero-plane displacement and $\kappa =$ von Kármán constant. The physical background of zero-plane displacement is described in detail in Nikora et al.

Copyright © 2006 Taylor & Francis Group plc, London, UK

(2002) and Koll (2002). Integration of Equation 7 yields the velocity distribution:

$$\frac{\langle \overline{u} \rangle}{u_*} = \frac{1}{\kappa} \ln \frac{(z-d)}{(z_R-d)} + \frac{\langle \overline{u} \rangle_R}{u_*} \quad (8)$$

where z_R = geodetic height of the roughness layer and $\langle \overline{u} \rangle_R$ = double averaged velocity at z_R. Equation 8 shows that the lower boundary of the logarithmic velocity distribution is identical to the upper boundary of the roughness layer. Recent approaches for parameterization of Equation 8 are found, e.g., in Koll (2006).

Conceptual models for an exponential, linear, and constant velocity distribution in the roughness layer have been derived by Nikora et al. (2004). For gravel beds, Nikora et al. (2004) suggested a linear velocity distribution. The prerequisite for a linear velocity distribution is a monotonically decaying roughness density function ϕ towards the lower boundary. Assuming that the total drag term $(f_p + f_v)$ monotonically increases towards the lower boundary, it can be postulated that $\phi(f_{pi} + f_{vi} - \rho g S_b)$ is approximately constant. Shear stress in the roughness layer can be parameterized as $\phi\tau/\rho = k\langle \overline{u} \rangle / u_*$, where k = constant factor. Hence, the following model for a linear velocity distribution is obtained from Equation 6:

$$\frac{\langle \overline{u} \rangle(z) - \langle \overline{u} \rangle(z_R)}{u_*} = \frac{z - z_R}{l_R} \quad (9)$$

where $l_R = \rho k u_*^2 / \phi(f_v + f_p - \rho g S_b)$ corresponds to a shear length scale which characterizes flow dynamics in the roughness layer and does not depend on the vertical coordinate z. Linear velocity distributions in the roughness layer of gravel beds have been identified by, e.g., Dittrich et al. (1996), Nikora et al. (2001), Koll (2002), and Nikora et al. (2004).

3 EXPERIMENTS

Experiments were carried out in a 20 m long, 0.90 m wide and 0.60 m high tilting flume in the laboratory of the Leichtweiss-Institute for Hydraulic Engineering, Technical University of Braunschweig. The experiments were carried out with a constant flume slope of $S = 0.0027$. The discharge Q was adjusted by a valve and measured by an inductive flow meter. Eight piezometers were installed in the flume ($\Delta x = 1.00$ m) and the water surface slope was calculated from linear regression.

A coarse sediment mixture (0.63 mm < d < 64 mm, $d_{50} = 5$ mm) was used as movable bed material for the development of water worked roughness structures. The well-mixed sediment was placed in the flume at the start of the experiments and an armoring discharge $Q_1 = 120$ l/s was then run until the bed-material transport rate became negligible, indicating a stable armored bed surface. The grain-size distribution of the armor layer was determined by using a photographic technique (see Aberle & Koll 2004 and Aberle et al. 2004 for details). Armor layer topography was measured along the 2.40 m long and 0.36 m wide test section with a laser displacement meter. The test section was located 9 m downstream of the flume inlet and its width was smaller than the total flume width to reduce side wall effects. Longitudinal bed profiles were recorded with a sampling interval of $\Delta x = 1.0$ mm and a lateral spacing of $\Delta y = 4$ mm. These data were used to determine the roughness geometry function ϕ. Detailed analysis of the roughness geometry of the different armor layers can be found in Aberle & Nikora (2006).

In a next experimental step, 24 randomly-distributed vertical profiles of 3D velocities were measured for a range of water discharges, less than or equal to Q_1, using a Dantec 3D Laser Doppler Anemometer (LDA). The LDA-system consists of a fully automated traverse system, a 4W Argon-Ion laser, a F80 flow processor and two watertight 27 mm probes with a focal length of 198 mm in water. A 2D probe transmits two orthogonal pairs of beams (514.5 and 488 nm) while the 1D probe, positioned at a 30° angle to the 2D probe, transmits the third pair of beams (476.5 nm) (see Figure 1). Flow velocities (u, v, w) are calculated using coincident LDA-velocity measurements via a transformation matrix (Dantec 2003).

The measurements were carried out with submerged probes to enable flow velocity measurements within the roughness layer. For water depths smaller than the focal length of the LDA probes, the probes were placed in a specifically designed tank with a glass bottom. The tank was filled with water and immersed 1–2 cm in the water body (Figure 1). Flow velocities were measured from 5 cm below the tank bottom

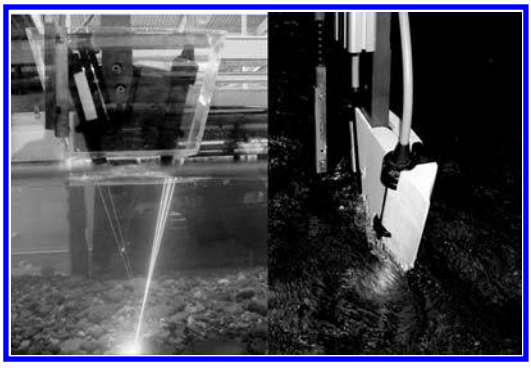

Figure 1. Tank setup for LDA-measurements (left) and measurement situation using submerged probes with aerodynamic housing (right).

to the bed. For flows with water depths significantly larger than the focal length of the probes, the probes were directly immersed. For this setup, a special aerodynamic housing was constructed to minimize flow resistance (Figure 1). Flow velocities were measured until the level of the probes was equal to the water level. Then the LDA-system was changed to the tank setup to measure flow velocities at the upper levels (from 5 cm underneath the tank). Investigations of Beyer (2004) showed that the aerodynamic housing had no influence on the flow field at the level of the sampling volume. For the tank it was found that the flow field was not influenced by the setup for distances to the tank bottom larger than 5 cm.

The vertical sampling resolution of the velocity measurements was $\Delta_z = 2$ mm below roughness crest, $\Delta_z = 4$ mm above roughness crest, and $\Delta_z = 10$ mm in the outer flow field. The sampling time at each point was 1 min (for considerations of sampling time see, e.g., Buffin-Bélanger & Roy 2005) and the sampling frequencies ranged from approximately 20–100 Hz. LDA measurements were performed in planes parallel to the bed slope to simplify the spatial averaging procedure. The spatial averaging procedure was only carried out for planes where 12 or more measurement points were available. All profiles and water levels are referenced to the topography data.

After the LDA-measurements were finished the bed forming discharge Q_1 was increased for the next step to a value $Q_2 = 180$ l/s, so that the existing armor layer was destroyed and a new one developed. The above measurements were repeated and velocity profiles were recorded at the same locations in the $x-y$ plane as for the first run. The procedure was continued for discharges $Q_3 = 220$ l/s, $Q_4 = 250$a l/s, and $Q_5 = 250$b l/s. The bed was armored twice for a discharge of 250 l/s because it was accidentally destroyed in an upstream section during the LDA measurements over the armor layer formed by $Q_4 = 250$a l/s. Therefore, the armoring procedure and measurements were repeated ($Q_5 = 250$b l/s).

In this paper, data from experiments carried out with a measuring discharge of $Q = 90$ l/s are analyzed. Table 1 summarizes the armoring discharges of the successive developed armor layer, the discharge during the LDA-measurements, characteristic grain-size d_{50}, standard deviation of bed elevations s, and water surface slope S. Armor layer topography for the beds formed by $Q_a = 120$, 220, and 250 l/s and the location of the velocity profiles are shown in Figure 2.

4 DEFINITION OF BED LEVELS

Before the velocity data are presented it is necessary to highlight the problem of the accurate definition of geometrical roughness height. In the case of geometrically well defined and identical roughness elements such as cubes or spheres placed on a steel bottom, the definition of roughness height is straightforward. However, in the case of random roughness beds, local effects due to the nature of the bed may significantly influence estimates of roughness height, water depth, bed shear stress, and shear velocity (Rowinski et al. 2005). For example, it is not clear how to unambiguously define roughness trough and crest. One local deep depression in the surface may bias the estimate of the lowermost point of the surface, z_t. Similarly, one single particle protruding significantly through the surface may bias the estimate of the uppermost point of the surface, z_c. Therefore, the effective roughness height does not necessarily equal $(z_c - z_t)$.

A similar problem is encountered when the water depth is defined. Arbitrary definitions comprise the distance from the water surface to roughness crest $(z_{ws} - z_c)$, to mean bed level $(z_{ws} - z_m)$ or to roughness trough $(z_{ws} - z_t)$. Table 2 highlights the influence

$h_{xx} = z_{ws} - z_{xx}$; $\Delta_{xx} = z_{xx} - z_{(100-xx)}$

$$\tau_{xx} = \rho g S(z_{ws} - z_{100}) + \rho g S \int_{z_{xx}}^{z_{100}} \phi dz$$

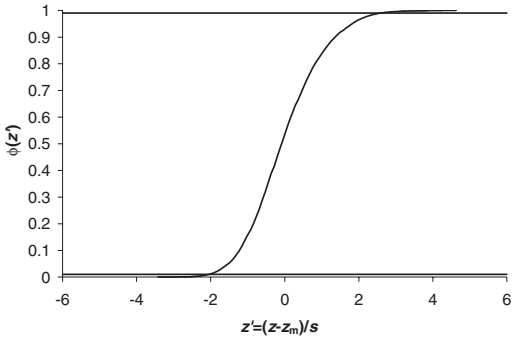

Figure 3. Averaged roughness density function $\phi(z')$ for the bed armored with $Q = 120$ l/s. z is bed elevation, z_m is mean bed elevation and s is standard deviation of bed elevations.

of different definitions of roughness height and water depth on values of relative submergence and bed shear stress. In Table 2, water depth h_{xx} is defined as the distance from the water surface to the level of xx-th percentile of the cumulative frequency distribution of bed elevations, z_{xx}. The frequency distribution can easily be obtained from the bed scans (see Figure 3) and the index xx denotes the upper percentile for which xx % of observed bed elevations are larger than z_t (e.g., z_{100} denotes roughness crest and hence $h_{100} = z_{ws} - z_{100}$). Roughness height Δ_{xx} is defined as the distance between the geodetic height of the upper percentile to its lower counterpart, e.g., $\Delta_{99} = z_{99} - z_{01}$. Bed shear stress τ_{xx} is estimated from depth slope product by taking into account the roughness density function ϕ.

Table 2 shows the influence of the various definitions on relative submergence and bed shear stress. Considering the same flow situation, relative submergence may vary up to 300% and differences in bed shear stress range from 0.6–1.3 N/m^2. Bearing in mind that relative submergence h/Δ is used to classify flows (e.g., large, medium, and small relative submergence) the significance of an appropriate definition of water depth and roughness height becomes apparent.

In the following analysis, roughness crest and roughness trough are defined as z_{99} and z_{01}, respectively. This definition was chosen to minimize local effects due to random nature of the bed and measurement errors. Figure 3 shows the filter defined by z_{99} and z_{01} exemplarily for the roughness density function (which is equivalent to the cumulative frequency distribution) of the bed armored with $Q_a = 120$ l/s. The two horizontal lines indicate the 1st and the 99th percentile. Below the 99th percentile (and above the 1st percentile), the ϕ function is characterized by curvature. Above the 99th percentile (and below the 1st percentile), ϕ does not change significantly. Similar results have been obtained for the ϕ functions of the other armor layers. Therefore it can be concluded that these percentiles are suitable for filtering outliers from the data.

In general, the shape of the ϕ-function reflects a near-Gaussian distribution of bed elevations. In reality, however, ϕ tends to a non-zero value of the bed porosity (0.28 in this case), not to zero. This discrepancy shows a limitation of the laser displacement technique. Additional measurements have been carried out to derive a correction function for ϕ in the lower part of the roughness layer (Aberle, in prep).

5 ANALYSIS OF MEAN VELOCITY PROFILES

Figure 4 shows the double averaged velocity component in flow direction $\langle \overline{u} \rangle$ over the normalized depth $(z - z_{99})/\Delta_{99}$. Above the roughness crest the velocity profiles are characterized by a logarithmic shape. Closer to and below the roughness crest, the curvature of the profiles diminishes and the velocity profiles can be approximated by straight lines. Furthermore, Figure 4 shows that flow velocities above the roughness crest are, at the same dimensionless height, larger for rougher armor layers than for smoother ones. This effect is associated with roughness geometry and (arbitrary) definition of roughness crest.

The parameterization of the velocity distribution according to Equations 8 and 9 requires the subdivision of the flow field in a roughness and logarithmic layer, respectively. Various investigations showed that the geodetic height of the upper boundary of the roughness layer z_R is closely related to the roughness crest

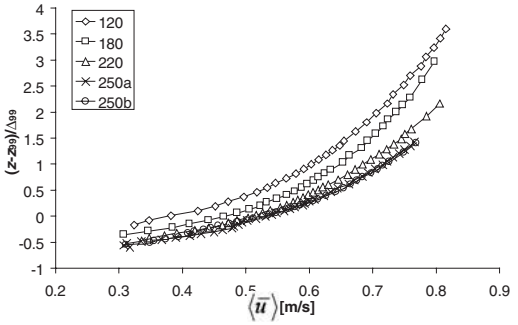

Figure 4. Double Averaged velocity distributions for $Q = 90$ l/s over different armor layers. The legend indicates the armoring discharge of the corresponding armor layer.

(e.g., Dittrich & Koll 1997, Campbell 2005, Carollo et al. 2005, Koll 2006). Therefore, the velocity data were in a first step analyzed in the region close-by z_{99}. Assuming a linear velocity distribution in the roughness layer (Equation 9), the data were fitted by linear regression so that a maximum squared regression coefficient R^2 was obtained. The geodetic height of the uppermost data point from this fit was assigned z_R.

Table 3 summarizes the identified linear ranges with respect to z_{99}, the corresponding ϕ values and R^2 estimates. Table 3 shows that the geodetic height of the roughness layer is located between z_{99} and z_{100} and hence, indeed, closely related to the roughness crest. Only for the experiment over the bed armored with $Q_a = 250$a l/s, z_R was found to be 3 mm above z_{100}. A second linear range within the roughness layer could be found for the flows over the beds armored with 180, 220 and 250 l/s. A second linear range has been suggested also by Dittrich et al. (1996) and Koll (2002). A closer investigation of the slope of the linear velocity profiles revealed a relationship between the shear length scale l_R and the standard deviation of bed elevations s. Such a behavior is expected, since l_R characterizes flow dynamics within the roughness layer and s has been identified as a suitable roughness parameter for gravel-bed rivers (Aberle & Smart 2003, Smart et al. 2004).

The parameterization of the log-range (Equation 8) requires the adequate estimation of the displacement length d. In order to estimate d, the approach of Nikora et al. (2002) is used. Equation 7 can be written as:

$$\left(\frac{d\langle\overline{u}\rangle}{dz}\right)^{-1} = \frac{u_*}{\kappa}(z-d) \qquad (10)$$

Thus, plotting the reciprocal value of the velocity gradient over the vertical coordinate z, it becomes possible to estimate d. The prerequisite for an adequate estimation of d is the knowledge of the lower

Table 3. Ranges of linear flow velocity distribution, corresponding ϕ values, and squared regression coefficient.

Q_a l/s	$z_{R2} - z_{99}$ m	ϕ_{R2} –	$z_R - z_{99}$ m	ϕ_R –	R^2 –

(z_R) and the upper boundary (z_L) of the logarithmic region. The numerical value for d follows then from linear regression coefficients of the relationship in Equation 10. Figure 5 shows the reciprocal values of smoothed velocity gradients as a function of the vertical distance to z_{99}. The gradients were smoothed by applying a moving average procedure over three adjacent points for both, vertical coordinate z and $\langle\overline{u}\rangle$. The smoothing procedure for the gradients became necessary, since estimating velocity derivatives from point velocity measurements belongs to the class of the so-called ill-posed problems (e.g., Bertero et al. 1988).

Figure 5 shows that the gradients, although smoothed, are still characterized by some scatter. The scatter is, especially for larger values of $z - z_{99}$, associated with the distance between measurement points (ill-posed problem), measurement noise, secondary currents and a wavy water surface. Nonetheless, Figure 5 provides the possibility to verify the estimates of z_R. A linear flow velocity distribution requires a constant velocity gradient. Such constant regions may be identified for the z_R boundaries given in Table 3.

Furthermore, Figure 5 shows that the slope of the reciprocal gradients is not constant over water depth. Thus, to be able to compare the velocity data close to the roughness crest, the data range from z_R to the

Table 4. Parameters of logarithmic range.

Q_a l/s	$z_R - z_{99}$ m	$z_L - z_{99}$ m	R^2 –	ϕ_d –
120	0.002	0.026	0.999	0.584
180	0.014	0.024	0.999	0.108
220	0.011	0.023	0.999	0.010
250a	0.011	0.029	0.995	0.010
250b	0.002	0.026	0.999	0.618

geodetic height $0.2(z_{ws} - z_{99}) + z_{99}$ has been arbitrarily chosen as the upper boundary for the log-range. The lower boundary z_R is known from roughness layer analysis. The upper limit corresponds to approximately 20% of the water depth and was chosen with regard to the limitation of the log-law (see Nezu & Nakagawa 1993).

However, the fit of the data in this region resulted in unrealistically small values for the displacement length d for some of the data sets, i.e., d was located below the roughness trough. The reason for this inconsistency was associated with the scatter of the gradients, and thus the fitting procedure was refined by using the original velocity data. The data were fitted by the function $\langle \overline{u} \rangle = a \ln(z - d) + b$ (with a, b = constants). For the procedure, d was initially set to z_{01} (roughness trough) and then raised by increments of 1 mm. The value of d that provided the highest correlation coefficient was selected as the zero-plane displacement d. The fit region, the corresponding R^2 value, and the value of the roughness density function at the geodetic height of d are presented in Table 4.

All logarithmic fits are characterized by correlation coefficients $R^2 \approx 1$. However, a wide range of d-values may be found which yield $R^2 \approx 1$. This shows that the used procedure with small increments for d is important to avoid subjectively biased choice of d. The identified levels of d vary from the defined lower boundary at z_{01} to z_{60}. Low estimates of d are assumed to be associated with the chosen fit range. This issue will be investigated in more detail in the future.

6 ANALYSIS OF SPATIAL STRESSES

The double averaging approach makes it possible to investigate the spatial heterogeneity of the flow field by examining form induced stresses. In the following, the distribution of form induced and Reynolds stresses are examined in more detail to investigate the relationship between characteristic coordinates derived from the stress-profiles with boundaries for layer separation.

The form induced stresses $\langle \tilde{u}^2 \rangle$ correspond to the variance of the mean velocities in the measurement plane and seem, therefore, to be a suitable parameter to investigate layer separation. The investigations of Koll (2002) and Campbell (2005) showed that, for flows over geometrically well defined roughness elements, layer separation is possible by investigating $\langle \tilde{u}^2 \rangle$. In these studies, $\langle \tilde{u}^2 \rangle$ was approximately zero down to the roughness crest and then rapidly increasing below roughness tops.

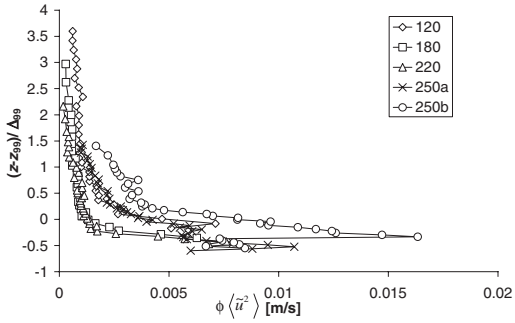

Figure 6. Distribution of form induced stresses $\langle \tilde{u}^2 \rangle$. Note that $\phi = 1$ above the absolute roughness crest. The legend indicates the armoring discharge of the corresponding armor layer.

Table 5. Characteristic vertical coordinates of form induced and Reynolds stresses.

Q_{armor} l/s	$\langle \tilde{u}^2 \rangle_{inc}$ $z - z_{99}$ m	$\langle \tilde{u}^2 \rangle_{con}$ $z - z_{99}$ m	$-\langle \overline{u'w'} \rangle_{lin}$ $z - z_{99}$ m	$-\langle \overline{u'w'} \rangle - \langle \tilde{u}\tilde{w} \rangle_{lin}$ $z - z_{99}$ m
120	0.022	0.056	0.028	0.018
180	0.002	0.026	0.034	0.012
220	0.003	0.029	0.029	0.015
250a	0.015	0.029	0.025	−0.001
250b	0.014	0.042	0.014	0.010

Figure 6 shows the distribution of the form induced stresses $\langle \tilde{u}^2 \rangle$ obtained within this study. The influence of the roughness is taken into account by multiplying the $\langle \tilde{u}^2 \rangle$ values with the roughness density function ϕ (note that $\phi = 1$ above the absolute roughness crest). A closer examination of the $\langle \tilde{u}^2 \rangle$ profiles in Figure 6 reveals that the profiles are characterized by a small but monotonically increase from the outer layer towards the bed. At a certain height $\langle \tilde{u}^2 \rangle$ remains then approximately constant for a certain region before it significantly increases. The corresponding distances of these boundaries ($\langle \tilde{u}^2 \rangle_{const}$ and $\langle \tilde{u}^2 \rangle_{inc}$) to z_{99} are summarized in Table 5. Maximum values occur throughout below z_{99}, i.e. below the roughness crest.

The upper boundary of the constant $\langle \tilde{u}^2 \rangle$-range (column $\langle \tilde{u}^2 \rangle_{con}$ in Table 5) indicates an overlap of this region with the (defined) logarithmic layer for the experiments over the beds armored with 180–250b l/s

Copyright © 2006 Taylor & Francis Group plc, London, UK

(see Table 4). Besides, for the flows over beds armored with 180, 220, and 250a l/s, the upper boundary of the constant $\langle\tilde{u}^2\rangle$-range corresponds approximately to the upper level of the (defined) log-range, i.e. to approximately 20% of water depth. For the flow over the bed armored with 120 l/s, only two data points of the constant $\langle\tilde{u}^2\rangle$-layer overlap with the log-range. The log-range itself falls into the region where $\langle\tilde{u}^2\rangle$ gradually increases (although the values are small, Figure 6). On the other hand, from Figure 6 it would be possible to estimate two more constant $\langle\tilde{u}^2\rangle$-ranges, which would overlap with the log-layer for this particular experiment. However, within this analysis, these "two subjective constant" ranges were interpreted to be part of the rapidly increasing range of $\langle\tilde{u}^2\rangle$.

The rapid increase of $\langle\tilde{u}^2\rangle$ (column $\langle\tilde{u}^2\rangle_{\text{inc}}$ in Table 5) occurs for two beds (armored with 180 and 220 l/s) between z_{99} and z_{100} and for three beds (armored with 120, 250a, and 250b l/s) above z_{100}. The distances to z_{100} range between 0.001 and 0.012 m. Thus, it is not possible to directly relate z_R, estimated from the regression analysis, with the shape of $\langle\tilde{u}^2\rangle$ for the five data sets under investigation. For natural shaped particles glued to a flume steel bottom, the investigations of Koll (2002) showed that the $\langle\tilde{u}^2\rangle$-profiles were characterized by a similar shape as shown in Figure 6. However, in contrast to the results obtained within this study, Koll (2002) concluded that z_R is related to the point of rapid increase. The different results may be associated with roughness density and porosity of the subsurface material. In fact, gluing natural shaped particles onto a steel bottom results, compared to a bed with a porous sublayer, in a different roughness density function and roughness structure. Further data is available to explore this point in more detail in the near future.

Reynolds stresses $-\langle\overline{u'w'}\rangle$ and form induced stresses $-\langle\tilde{u}\tilde{w}\rangle$ are presented in Figure 7. At larger distances to the roughness crest, Reynolds stresses $-\langle\overline{u'w'}\rangle$ are linearly distributed. Below this linear distribution, $-\langle\overline{u'w'}\rangle$ may be approximated by a constant value for a certain range before a decrease becomes apparent. The measurements in the roughness layer covered, as a maximum, the region from the roughness crest to the mean bed level. Therefore it is not possible to discuss the shape of the profiles in the lower portion of the roughness layer in more detail. Table 5 shows the levels to which a linear Reynolds stress distribution $-\langle\overline{u'w'}\rangle$ is apparent from Figure 7. The level was determined by maximizing R^2 values when fitting a straight line to the $-\langle\overline{u'w'}\rangle$-data. The values given in Table 5 indicate that the (defined) log-layer is, in general, part of the constant region of the $-\langle\overline{u'w'}\rangle$-range.

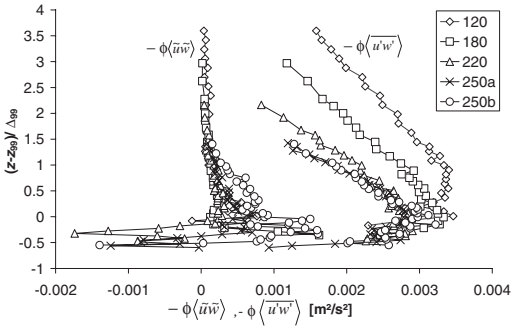

Figure 7. Reynolds stresses and form induced stresses. Note that $\phi = 1$ above the absolute roughness crest. The legend indicates the armoring discharge of the corresponding armor layer.

Figure 7 demonstrates that the form-induced stresses $-\langle\tilde{u}\tilde{w}\rangle$ are not negligible within the roughness layer and, thus, are a significant component in the momentum balance over water-worked gravel beds (see Equation 5). On the other hand, at greater distances from the bed, $-\langle\tilde{u}\tilde{w}\rangle \approx 0$ and the influence of the form induced stresses are negligible. It is interesting to note that closer to the bed, $-\langle\tilde{u}\tilde{w}\rangle$ gradually increases. This increase results in a prolongation of the linearity of the sum $-\langle\overline{u'w'}\rangle - \langle\tilde{u}\tilde{w}\rangle$ compared to the linear portion of $-\langle\overline{u'w'}\rangle$ (see Table 5). The boundaries of the linear portion of $-\langle\overline{u'w'}\rangle - \langle\tilde{u}\tilde{w}\rangle$ (taking into account the roughness density function ϕ) have been estimated using the same procedure as for $-\langle\overline{u'w'}\rangle$. The linear range extends below 20% of the water depth.

Below the linear range, $-\langle\overline{u'w'}\rangle - \langle\tilde{u}\tilde{w}\rangle$ can be approximated by a constant value. Such constant ranges are apparent within or in the vicinity of the range defined by the linear velocity distribution (i.e., close-by z_{100}). The existence of a constant range of $-\langle\overline{u'w'}\rangle - \langle\tilde{u}\tilde{w}\rangle$ below the roughness crest is important, since it justifies the assumption that $\phi(f_{pi} + f_{vi} - \rho g S_b)$ is approximately constant in the roughness layer (follows from Equation 6), and hence the existence of a linear flow velocity profile.

7 SUMMARY AND CONCLUSION

In this paper, the double averaging approach was used to investigate the near-bed flow field of flows over natural gravel bed surfaces. Difficulties concerning the definition of roughness height, water levels, and bed shear stress were discussed with respect to experimental data for flows over different armor layers. This analysis showed that it is important to unambiguously define the datum for roughness crest and trough to make different studies comparable. For gravel beds, the 99th and 1st percentile of the cumulative frequency distribution of bed elevations were suggested as roughness crest and trough, respectively. However, the analysis of the flow velocity data revealed that

Copyright © 2006 Taylor & Francis Group plc, London, UK

by normalizing the vertical coordinate with this definition, the data curves did not collapse. Therefore, the definition of roughness height will be investigated further.

The data were used to investigate the near-bed mean velocity distribution with regard to layer separation. Within the roughness layer, a linear flow velocity distribution could be identified. The shear length scale within the roughness layer was found to be correlated with the standard deviation of bed elevations. The analysis of the form induced stresses indicated that the basic assumption for the linear flow velocity distribution in the roughness layer $[\phi(f_{pi} + f_{vi} - \rho g S_b) = \text{const.}]$ was valid. The upper boundary of the roughness layer, z_R, was estimated from a linear regression of the velocity data and was found to be located between z_{99} and z_{100}.

The zero-plane displacement d was found to be located within the roughness layer. However, the data fitting procedure revealed a strong dependency of d on the data analysis method and underlying assumptions (e.g., roughness trough). Within this study it was assumed that the logarithmic layer commences at z_R and its upper limit was defined to be at the geodetic height $0.2(z_{ws} - z_{99}) + z_{99}$.

The investigation of the spatial terms revealed their importance for the description of rough bed flows and their significant contribution to the momentum equation in the roughness layer. The profiles of the form induced stresses showed a distinct behavior. However, it was not possible to unambiguously relate characteristic levels of the stress profiles (such as sudden increase of $\phi\langle\tilde{u}^2\rangle$) to z_R as estimated from the regression analysis. Therefore, the turbulent intensity $\langle\overline{u'^2}\rangle$ will be included into the analysis of the location of z_R in the future. The next steps will include also the comparison of the parameters of the equations describing the velocity distribution in the linear and logarithmic range. The parameters will be estimated using (i) regression analysis; and (ii) the data identified from characteristic ranges from spatial and turbulent stresses. Further approaches for parameterization of the equations for the velocity distribution will be included into this comparison (e.g., Katul et al. 2002, Koll 2006). For this purpose, further data are available, covering a wide range of discharges, bed slopes, and roughness. Such a consideration will provide deeper insight into the relationship between roughness geometry, form induced stresses and flow velocities.

ACKNOWLEDGEMENTS

The research was conducted under contract DI-651/4-3 from DFG (Deutsche Forschungsgemeinschaft). A. Dittrich and K. Koll provided helpful advice and generous support to this project. U. Ecklebe, G. Beyer, T. Schoneboom, and M. Oppermann provided technical support. The author is grateful for useful discussions and suggestions to V. Nikora, R. Walters, S. McLean, J. Järvelä and to all participants of the 'double-averaging' workshops.

Parameterisation of the vertical velocity profile in the wall region over rough surfaces

K. Koll
Leichtweiss – Institute for Hydraulic Engineering, Braunschweig Technical University, Germany

ABSTRACT: Analyses of vertical velocity profiles over rough surfaces result in parameters which often have no physical meaning, especially if the relative submergence decreases. Assumptions are required which complicate comparative analysis of data sets. A recently published definition of the zero-plane displacement height d allows for the determination of d solely from velocity measurements, instead of fitting it to a fixed value of the von Kármán constant. Based on this definition, a parameterisation of the vertical velocity profile within the wall region was developed as well as a methodology to determine the parameters. The parameterisation and the methodology were tested with a dataset of vertical velocity profiles measured over artificial and natural roughnesses. Dependencies of the parameters on roughness and flow characteristics were investigated. The results support the suggested parameterisation. The methodology is validated for flow over artificial surfaces whereas improvement is required for analyses of flow over natural beds.

1 INTRODUCTION

Since the development of the logarithmic law of the wall for rough beds the meaning and determination of its parameters κ, d, k_S, and B has been discussed. The parameters are related to each other as $\kappa = 0.4$ should be constant, d is used to keep it constant, and k_S results in combination with the assumption that also $B = 8.5$ is constant.

Problems in determining meaningful values of k_S and d as well as κ-values different from 0.4 are reported throughout the literature of the last decades (e.g. Vanoni & Nomicos 1959, O'Loughlin & Annambhotla 1969, Nowell & Church, 1979, Gust & Southard 1983, Nakagawa et al. 1991, Dittrich & Koll 1997, Nikora & Goring 2000). The problems are grounded in the assumed constancy of κ and, thus, in the definition of d.

The re-definition of the zero-plane displacement height (Nikora et al. 2002) allowed for the development of a new procedure to determine the parameters of the vertical velocity profile within the wall region. Assumptions of fixed values are not required, and thus dependencies of the velocity parameters on flow and roughness parameters can be studied.

In the following based on a brief summary of the derivation of the log-law of the wall the new parameters to describe the velocity profile are introduced and the modified formulas are derived. The procedure to determine the velocity parameters is presented and tested with flume data measured over artificial and water-worked surfaces with low and medium relative submergence. Correlations between velocity, and roughness and flow parameters are discussed.

2 VERTICAL VELOCITY PROFILE

Parameterisation of the velocity profile and mathematical description of the velocity distribution require a subdivision of the turbulent flow field into several layers. The layer separation and geometric parameters are shown in Figure 1.

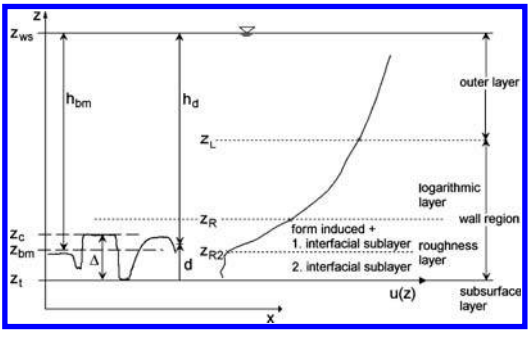

Figure 1. Sketch of layer separation and geometric parameters.

2.1 *Layers of the vertical velocity profile*

The flow field over rough permeable beds can be subdivided into three main layers: the outer layer, the wall region, and the subsurface layer. The wall region includes the logarithmic layer and the roughness layer. The latter contains the form induced sublayer, located just above the roughness crests, and the interfacial sublayer, between the roughness crests and troughs. Velocity measurements over beds with artificial roughnesses indicate that the interfacial sublayer also consists of two parts (Dittrich et al. 1996, Koll 2002).

Following Nikora et al. (2006) the roughness crests z_c and the roughness troughs z_t are defined as the elevations for which 99% of observed bed elevations are smaller than z_c and larger than z_t, respectively. A detailed discussion of roughness geometries can be found in Aberle & Nikora (2006). The height of the interfacial sublayer $\Delta = z_c - z_t$ corresponds to the geometric height of the roughness elements in case of single element roughnesses.

The flow in the form induced sublayer may be influenced by wakes of roughness elements. Thus, the top of the roughness layer z_R -determined from velocity data- is expected to be located above the roughness crests. The height z_{R2}, where the interfacial sublayer is subdivided, results also from velocity data.

The possible minimum height of z_R and, therefore of the lower boundary of the logarithmic layer is z_c. An extension of the logarithmic profile into the layer dominated by characteristics of the roughness is not meaningful, because the derivation of the logarithmic law is based on the assumptions that the shear stress is constant, and that the mixing length increases linearly with the distance from the wall (e.g. von Kármán 1930, Prandtl 1933). The upper boundary of the logarithmic layer z_L is also limited due to these assumptions. According to the conservative limitation of the logarithmic layer the top z_L is set to 20% of the flow depth above the roughness layer. However, discussions about the upper boundary of the logarithmic layer are as yet not conclusive.

2.2 *Equations for the vertical velocity profile in the wall region*

Simplification of the Reynolds equations for two-dimensional, steady, uniform, fully developed open-channel flow results in the basic equation for the derivation of the vertical distribution of the streamwise velocity component (e.g. Nezu & Nakagawa 1993)

$$\frac{\tau_0}{\rho} = u_*^2 = \nu \frac{\mathrm{d}\overline{u}}{\mathrm{d}z} - \overline{u'w'} \tag{1}$$

where $\tau_0 =$ bed shear stress, $\rho =$ fluid density, $u_* =$ shear velocity, $\nu =$ fluid viscosity, $\overline{u} =$ time averaged velocity in streamwise direction, $z =$ vertical coordinate, and $-\overline{u'w'} =$ Reynolds (turbulent) stress with u' and $w' =$ fluctuating part of the velocity components in streamwise and vertical direction, respectively.

By analogy with the viscous stress Boussinesq introduced the turbulent viscosity ν_T to calculate the turbulent stress

$$-\overline{u'w'} = \nu_T \frac{\mathrm{d}\overline{u}}{\mathrm{d}z} \tag{2}$$

Moreover, in rough bed flows the viscous stress is negligible and Equation 1 becomes

$$u_*^2 = \nu_T \frac{\mathrm{d}\overline{u}}{\mathrm{d}z} \tag{3}$$

which is the basic equation to derive the formulas of the vertical velocity profile within the wall region. The problem then to be solved is the determination of ν_T.

2.2.1 *Logarithmic layer*

Prandtl (1933) developed the well known mixing length approach to calculate ν_T within the logarithmic layer

$$\nu_L = l_L^2 \frac{\mathrm{d}\overline{u}}{\mathrm{d}z} \tag{4}$$

where $\nu_L =$ turbulent viscosity of the logarithmic layer considering only time dependent turbulence and $l_L =$ mixing length of the logarithmic layer. Close to the wall it can be reasonably assumed that l_L increases linearily with the vertical coordinate z (von Kármán 1930). Prandtl (1933) used the von Kármán constant κ as constant of proportionality which leads to

$$l_L = \kappa z \tag{5}$$

Substitution of Equations 4 and 5 into Equation 3 and integration results in the formula for the logarithmic profile

$$\frac{\overline{u}(z)}{u_*} = \frac{1}{\kappa} \ln z + const. \tag{6}$$

where *const.* = constant of integration, which depends on the hydraulic roughness of the surface. For hydraulically smooth surfaces it is determined with the boundary condition in the height of the viscous layer. The existence of the buffer layer is neglected.

For hydraulically rough surfaces the viscous layer vanishes in the interfacial sublayer, and thus cannot be used as a boundary condition. Nikuradse (1933a,b), who investigated flow over a surface roughened with a single layer of sand with diameter k_S, chose the top of the roughness elements as lower boundary of

Copyright © 2006 Taylor & Francis Group plc, London, UK

the logarithmic layer, i.e. he determined the boundary condition in the height $z = k_S$. He found the ratio of $\bar{u}(z = k_S)/u_*$ as well as the parameter κ to be constant for hydraulically rough surfaces and formulated the logarithmic law for flow over rough surfaces

$$\frac{\bar{u}(z)}{u_*} = \frac{1}{\kappa} \ln \frac{z}{k_S} + B \tag{7}$$

with $\kappa = 0.4$ and $B = 8.48$.

With increasing geometric roughness height, measured velocities and velocities calculated with Equation 7 correspond less and less. Clauser (1956) attributed this problem to the origin of the vertical coordinate z. He introduced the zero-plane displacement height d and explained it as the height where the logarithmic profile calculated with Equation 7 theoretically becomes zero. Thus, Equation 5 becomes

$$l_L = \kappa(z - d) \tag{8}$$

and Equation 7 becomes

$$\frac{\bar{u}(z)}{u_*} = \frac{1}{\kappa} \ln \frac{(z - d)}{k_S} + B \tag{9}$$

if z starts from below the roughness crests, e.g. from z_t. The parameter d is used to keep κ constant. Nowadays, Equation 9 with $\kappa = 0.4$ and $B = 8.5$ is known as the "log-law of the wall". As aforementioned, the applicability of Equation 9 is limited to a height of 15 to 20% of the water depth due to the assumptions of a linear relation between l_L and z and a constant shear stress.

The equivalent sand roughness k_S became a measure for the hydraulic effect of the bed roughness. Experiments with a further increasing roughness height and, especially, with decreasing relative submergence resulted in k_S-values difficult to explain. For instance, Figure 2 shows the ratio of k_S/Δ as a function of the relative submergence.

Values $k_S/\Delta < 1$ mean that the hydraulic roughness height is smaller than the geometric roughness height, which is not meaningful. Moreover, it implies that the logarithmic velocity profile is valid within the roughness layer. Nakagawa et al. (1991) among others denied this possibility because Reynolds stress decreases below the roughness crests, which contradicts the assumption of a constant shear stress.

Often researchers tried to overcome the problem by using Δ instead of k_S (e.g. Nowell & Church 1979). In that case, k_S is no longer related to the flow, and thus looses its meaning as the hydraulic roughness. Similar problems arise with the zero-plane displacement height d. Consequently, the existence of a logarithmic layer for flow over very rough beds and with low relative submergence often cast in doubt (e.g. Bayazit

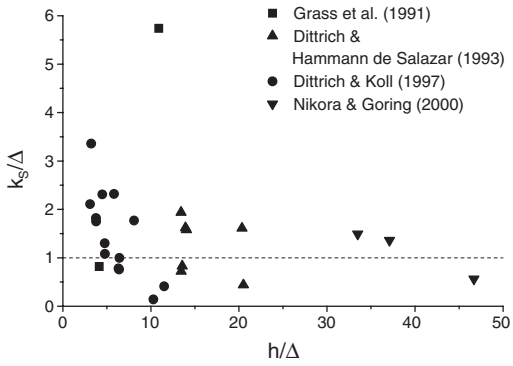

Figure 2. Relation between k_S/Δ and relative submergence h/Δ.

1982). On the other hand, published data (e.g. Bayazit 1982, Dittrich & Koll 1997) show that a region with a logarithmic shape of the velocity profile exists even at low relative submergence.

The problems can be reduced to the requirement that $\kappa = 0.4$ has to be universal – at least in the context considered. It can be shown that κ is not necessarily universal (Koll 2002) but this discussion is however beyond the scope of this paper.

The investigation of the parameters of the vertical velocity profile as a function of roughness and flow requires the variability of all parameters, and thus a re-definition of the zero-plane displacement height d. The new definition introduced by Nikora et al. (2002) explains the physical meaning of d as the level that large-scale turbulent eddies feel as the "bed". It follows that at the height d the mixing length l_L is zero (for more details see Nikora et al. 2002, Koll 2002), i.e.

$$d = z(l_L = 0) \tag{10}$$

Starting again from Equation 6, the constant of integration is determined with the boundary condition $\bar{u}(z = z_R) = u_R$ in the height of the roughness layer z_R. Thus, Equation 6 together with Equation 8 becomes

$$\frac{\bar{u}(z)}{u_*} = \frac{1}{\kappa} \ln \frac{z - d}{z_R - d} + \frac{u_R}{u_*} \tag{11}$$

The parameters κ, d, z_R, and u_R/u_* can be determined from measured velocity profiles without any further assumptions (see Section 3).

2.2.2 *Roughness layer*

The shape of the vertical velocity profile in the roughness layer depends on the geometry of the roughness (Nikora et al. 2004). In case of gravel and comparable artificial roughness elements, the velocity profile follows most probably a linear relation. Using the mixing length concept of Prandtl (1933), linearity implies

Copyright © 2006 Taylor & Francis Group plc, London, UK

that the mixing length in the roughness layer l_R is independent of the vertical coordinate. Assuming that the velocity fluctuation u' scales with $\bar{u}$, and that w' scales with u_* the turbulent viscosity within the roughness layer becomes

$$\nu_R = l_R\, u_* \tag{12}$$

where ν_R = turbulent viscosity within the roughness layer considering turbulence due to roughness.

Substitution of Equation 12 into Equation 3 gives

$$u_* = l_R \frac{\mathrm{d}\bar{u}}{\mathrm{d}z} \tag{13}$$

With the boundary condition $\bar{u}(z = z_R) = u_R$ at the upper boundary of the roughness layer integration leads to the formula for the velocity profile within the roughness layer

$$\frac{\bar{u}(z)}{u_*} = \frac{z - z_R}{l_R} + \frac{u_R}{u_*} \tag{14}$$

Note that it is not distinguished between the form induced sublayer and the interfacial sublayer.

As mentioned previously, the interfacial sublayer can be subdivided into two parts. Although only very little data is available for the lower part, in a first approach it is assumed that the velocity profile follows a linear distribution, too. The formula is derived in analogy to Equation 14 using the boundary condition at the upper boundary of the lower part, i.e. $\bar{u}(z = z_{R2}) = u_{R2}$,

$$\frac{\bar{u}(z)}{u_*} = \frac{z - z_{R2}}{l_{R2}} + \frac{u_{R2}}{u_*} \tag{15}$$

where l_{R2} = mixing length of the lower part of the roughness layer.

The parameters l_R, l_{R2} and u_{R2} can be determined directly from velocity measurements.

3 DETERMINATION OF THE PARAMETERS OF THE VELOCITY PROFILE

The parameters to be determined from measurements of the vertical profile of the streamwise velocity component are summarised in Table 1.

First, the boundaries of the layers have to be determined. Here, linear and logarithmic regression analyses for the roughness and the logarithmic layer, respectively, are used to obtain z_{R2} and z_R. z_L depends on z_R and is calculated with Equation 16.

$$z_L = 0.2(z_{WS} - z_R) + z_R \tag{16}$$

where z_{WS} = water surface level.

Table 1. Parameters of the velocity profile.

Layer	Parameter	
Logarithmic layer	upper boundary	z_L
	constant of proportionality	κ
	zero-plane displacement height	d
Roughness layer (upper part)	upper boundary	z_R
	velocity at height z_R	u_R
	mixing length	l_R
Roughness layer (lower part)	upper boundary	z_{R2}
	velocity at height z_{R2}	u_{R2}
	mixing length	l_{R2}

The velocities u_{R2} and u_R are the velocities at z_{R2} and z_R, respectively, and consequently result directly from the measurements.

The procedure to determine l_{R2} and l_R is identical and, therefore, is exemplarily shown for l_R. Plotting velocities $\bar{u}$ over the vertical coordinate z and employing linear regression results in a straight line with a gradient $m_R = d\bar{u}/dz$. Comparison with Equation 13 gives the formula to calculate l_R

$$l_R = \frac{u_*}{\mathrm{d}\bar{u}/\mathrm{d}z} = \frac{u_*}{m_R} \tag{17}$$

The shear velocity u_* is calculated with the gravity method

$$u_* = \sqrt{g h_d S} = \sqrt{g(z_{WS} - d)S} \tag{18}$$

where g = acceleration of gravity, $h_d = z_{WS} - d$ = water depth, and S = bed slope. Water depth is used here instead of hydraulic radius because the surfaces under consideration are very rough compared to the walls.

However, the zero-plane displacement height d is required to calculate u_* and, thus, l_R. With Equations 3, 4, and 8 it follows

$$u_* = l_L \frac{\mathrm{d}\bar{u}}{\mathrm{d}z} = \kappa(z - d)\frac{\mathrm{d}\bar{u}}{\mathrm{d}z} \tag{19}$$

and thus

$$\frac{l_L}{u_*} = \frac{1}{\mathrm{d}\bar{u}/\mathrm{d}z} \tag{20}$$

Plotting Equation 20 as a function of z and employing linear regression within the logarithmic layer gives the formula of the straight line

$$\frac{l_L}{u_*} = m_L\, z + b_L \tag{21}$$

where m_L = gradient and b_L = intercept of the ordinate.

Copyright © 2006 Taylor & Francis Group plc, London, UK

With the definition of d (Equation 10) the zero-plane displacement height can be calculated with the parameters of the linear regression

$$d = -\frac{b_L}{m_L} \tag{22}$$

and, thus, u_* can be calculated. Finally, comparison of the coefficients of Equations 8 and 21 gives

$$\kappa = m_L\, u_* \tag{23}$$

4 EXPERIMENTAL DATA

Equations 11, 14, and 15 and the method to determine the parameters of the velocity profile (Tab. 1) are tested with data measured with Laser Doppler Anemometry (LDA) over different kinds of roughnesses.

Artificial surfaces were designed using glass beads and PVC cubes as well as uniformly-sized gravel. A single layer of elements was glued to the steel bottom of the flume (flume width $W = 30$ cm). For more details on the experiments see Koll (2002). In addition to the geometric height of the roughness elements, the spacing between the elements was varied. The roughness density is calculated with Equation 24.

$$c_k = \frac{z_{bm}}{\Delta} \tag{24}$$

where c_k = roughness density, and z_{bm} = volumetrically averaged height of the roughness.

The irregularity of the surface of the bed roughness is described by the parameter σ_k/Δ where σ_k is the standard deviation of the bed elevations obtained by scanning the surface with a laser displacement meter.

Moreover, velocity data measured in flow over a natural surface are used. A coarse sediment mixture (grain diameters between 0.63 mm and 64 mm) was placed in the flume (flume width $W = 90$ cm) and leveled to give a thickness of 20 cm. A static armour layer ($d_{50} = 19.6$ mm) was subsequently allowed to develop by adjusting the discharge to 250 l/s and keeping it constant until the sediment transport rate was negligible. For more details on the flume and the methodology see Aberle & Koll (2004) and Aberle (2006).

The characteristics of the roughnesses are summarized in Table 2.

For each roughness, several discharges were adjusted resulting in a range of relative submergence between 2.9 and 20.3. The Froude number was always well below unity and the Reynolds number with a minimum of 41,333 indicated turbulent flow throughout. The lowest grain Reynolds number Re_* was 450 and the surfaces could therefore be considered as hydraulically rough. The width to depth ratio varied between 1.2 and 5.6. Although this ratio is quite small, it has

Table 2. Characteristics of the bed roughnesses.

*) not available

to be taken into account that the bed surfaces were very rough compared to the walls. Note that the aforementioned values are calculated using $h_{bm} = z_{WS} - z_{bm}$ instead of $h_d = z_{WS} - d$ in order to make them comparable with the ranges of published data. However, the relative submergence h_d/Δ *is* used to characterise the flow when discussing dependencies of the velocity parameters.

The measurements were made at three to five locations in case of the artificial beds. This number appears to be too low to analyse spatial variations. Double averaged velocities (in time and in space) can however be used for analyses, as spatial averaging does not change the formulas derived in Section 2 (e.g. Nikora et al. 2001). Thus, the time averaged velocities $\bar{u}$ are replaced by the double averaged velocities $\langle\bar{u}\rangle$. In case of the static armour layer, measurements were made at 24 locations. Preliminary results of analysis of spatial terms are given in Aberle (2006).

5 RESULTS

The applicability of Equations 11, 14 and 15 as well as of the methodology to determine the accordant parameters can be proofed by plotting the standardised velocity profiles. The plots are shown in Figures 3 and 4 for the logarithmic layer and the upper part of the roughness layer, respectively. Both plots show good matches of the standardised velocity profiles measured over very different bed roughnesses.

However, no good results were obtained for the lower part of the roughness layer, and therefore only the parameters of the logarithmic and the upper part of the roughness layer are discussed in the following.

5.1 *Parameters of the logarithmic layer*

The parameters of the logarithmic layer (Table 1) are expected to depend on flow parameters as well as on

Copyright © 2006 Taylor & Francis Group plc, London, UK

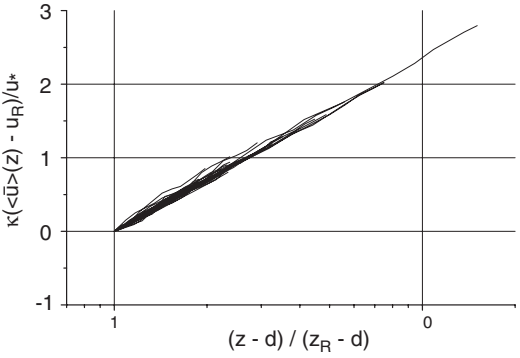

Figure 3. Standardised velocity profile in the logarithmic layer.

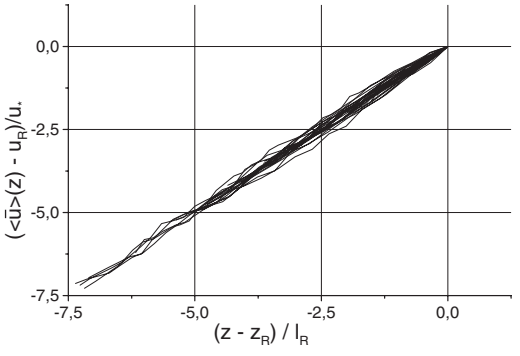

Figure 4. Standardised velocity profile in the upper part of the roughness layer.

roughness parameters. The relative submergence is used to characterise the flow. Geometric roughness height and irregularity of the bed surface are used to describe the roughness.

The zero-plane displacement height d as a function of the geometric roughness height Δ is shown in Figure 5. Considering only the artificial surfaces (beads, cubes, and gravel) d increases with Δ, and a functional relation seems to be inherent. Taking additionally into account the data of the water-worked bed the implication is not supported.

Several reasons for the different behaviour of the armour layer can be suggested. The main differences are that the bed is permeable instead of single layered and that it is water-worked instead of man-made. The roughness elements of the artificial surfaces were glued to the flume bed to avoid erosion. Thus, it was possible to design flow situations which do not exist for water-worked beds. Especially, the determination of the geometric roughness height in case of the water-worked topography contains distinct uncertainties (see Aberle 2006). Moreover, the determination of the boundary between logarithmic and roughness

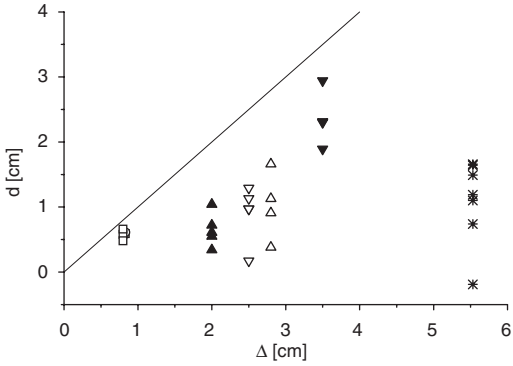

Figure 5. Relation between displacement height d and geometric roughness height Δ (for symbols see Table 2).

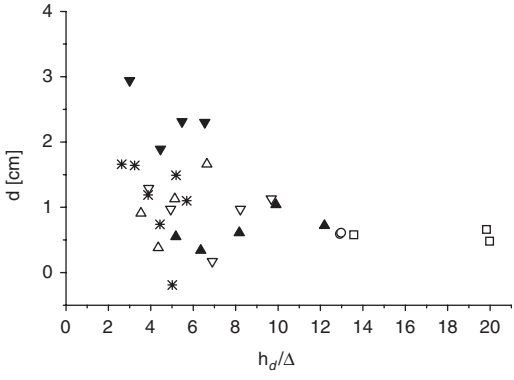

Figure 6. Relation between displacement height d and relative submergence h_d/Δ (for symbols see Table 2).

layer z_R by regression analysis seems to be inappropriate for natural surfaces. Small changes in z_R can change d significantly.

However, d cannot be solely dependent on Δ as the values determined for different flows over the same bed scatter remarkably. Analyses of dependencies on flow parameters show a decrease of d with increasing relative submergence h_d/Δ when looking at the overall shape of the plot (Fig. 6). However, closer examination of the values for single roughness configurations do not support the trend. It has to be considered that the range of relative submergence for each roughness was quite small.

Analyses of κ reveal that it is not a universal constant but depends on the irregularity of the surface σ_k/Δ as well as on the relative submergence. These parameters influence the formation and the expansion, respectively, of coherent turbulent flow structures, and thus the gradient of the velocity profile (e.g. Kirkbride 1993, Sirovich & Karlsson 1997). The relations are shown in Figures 7 and 8.

Copyright © 2006 Taylor & Francis Group plc, London, UK

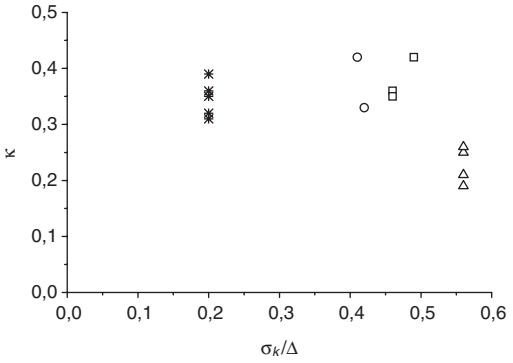

Figure 7. Relation between constant of proportionality κ and irregularity of the bed surface σ_k/Δ (for symbols see Table 2).

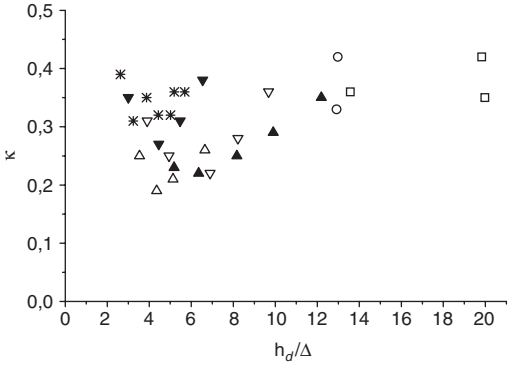

Figure 8. Relation between the constant of proportionality κ and relative submergence h_d/Δ (for symbols see Table 2).

For both, regular surfaces and large relative submergences, κ approaches a value of 0.4. It decreases significantly if the bed surface becomes more irregular and if the water depth related to the roughness height decreases.

Moreover, κ seems to reach a minimum at h_d/Δ between 7 and 4 and increases again for further decreasing relative submergence. This behaviour needs further investigation as an explanation cannot be given at the moment.

5.2 *Parameters of the roughness layer*

In Figure 9 the mixing length of the roughness layer l_R is shown as a function of Δ (note that in the following only the upper part of the roughness layer, i.e. form induced and first interfacial sublayer, is discussed).

For the artificial surfaces the linear increase of l_R with Δ is evident. The values of l_R determined for one roughness and several discharges show only small scatter. This result suggests that l_R is not influenced by flow characteristics.

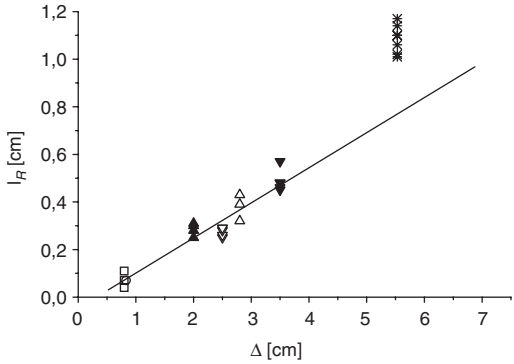

Figure 9. Relation between the mixing length of the roughness layer l_R and the geometric roughness height Δ (for symbols see Table 2).

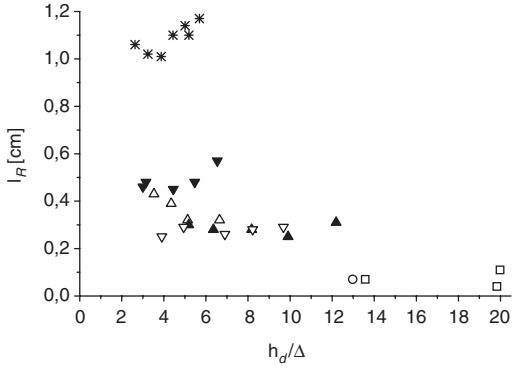

Figure 10. Relation between the mixing length of the roughness layer l_R and relative submergence h_d/Δ (for symbols see Table 2).

The values obtained from the water-worked bed do not follow the linear relation given by the artificial roughnesses but are clearly above the straight line. Moreover, the scatter of l_R is much larger. The most probable explanation for the scatter are the different flow conditions. The mixing length is plotted as a function of h_d/Δ in Figure 10.

The data are grouped according to the preparation of the surface, i.e. man-made and water-worked beds, as well as to the shape of the roughness elements for the flows over artificial surfaces, i.e. gravel, and beads and cubes. The classification cannot be compensated by scaling l_R with another geometric parameter, which indicates the influence of the shape of the roughness elements on the flow field.

The overall shape of the plot shows a decrease of l_R with increasing relative submergence, whereas the trends for single roughnesses are not consistent. Only for the natural bed a dependence on the relative submergence can be observed, but in the opposite

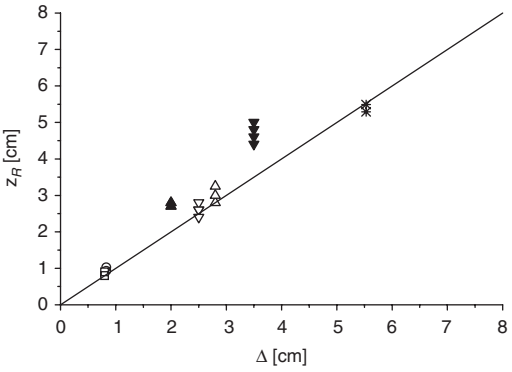

Figure 11. Relation between the upper boundary of the roughness layer z_R and the geometric roughness height Δ (for symbols see Table 2).

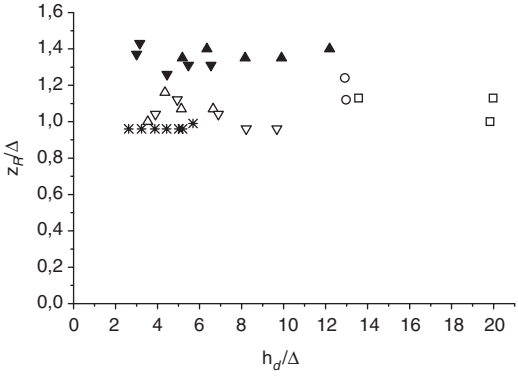

Figure 12. Relation between the upper boundary of the roughness layer normalized with the geometric roughness height and relative submergence h_d/Δ (for symbols see Table 2).

way: l_R increases with increasing h_d/Δ. As mentioned in context with the zero-plane displacement height the findings for the permeable water-worked bed are not consistent with the ones for artificial surfaces.

As the mixing length of the roughness layer also the upper boundary of the layer z_R linearly increases with Δ as can be seen in Figure 11. Again a different behaviour of impermeable man-made and permeable water-worked beds can be observed. As expected, the roughness layer is located at least at the height of the roughness crests in case of the artificial surfaces. z_R is below the roughness crests in case of the armour layer. This finding is not meaningful, as it implements that the logarithmic law would be valid within the roughness layer. Two reasons can be given for the contradiction. First, the definition of the roughness crests z_c as the elevation for which 99% of observed bed elevations are smaller than z_c can be inappropriate. Choosing, for instance, 95% instead of 99% would eliminate the contradiction. And second, as stated above, the determination of the boundary between logarithmic and roughness layer by regression analysis seems to be not sufficiently accurate for natural surfaces.

Plotting z_R as a function of h_d/Δ a plot similar to Figure 10 results. Scaling z_R with Δ and plotting it as a function of the relative submergence (Fig. 12) the classification of the different surfaces almost vanishes.

However, compared to the parameters of the logarithmic layer, the parameters of the roughness layer show only a weak dependence on flow characteristics, if at all. This suggests that it could be possible to parameterise the velocity profile with characteristics of the bed roughness.

The parameter z_R could be treated as the length scale of the bed roughness. It influences the parameters of the logarithmic layer in that way that it defines the lower boundary for analysis of the logarithmic layer. Therefore, thorough determination of z_R is required.

A promising approach to refine the technique of determining the boundary between roughness and logarithmic layer is the adaptation of the double-averaged Navier-Stokes equations (DANS). Due to the spatial averaging the spatial heterogeneity of the flow can be investigated, which then will be related to geometric characteristics of the bed roughness. First results are presented in Aberle (2006).

6 CONCLUSION

Based on the re-definition of the zero-plane displacement height a new parameterisation of the vertical velocity profile within the wall region was developed and a methodology for determination of the parameters was suggested. The parameterisation was tested with velocity data measured over man-made and water-worked surfaces. Dependencies of the velocity parameters on roughness and flow characteristics were investigated.

Scaling of the velocity and the length scale with the appropriate parameters confirmed the parameterisation. Moreover, the study of parameters revealed dependencies for the velocity profiles measured over artificial surfaces. However, the data obtained from the measurements of the flow over a water-worked armour layer show some deviations compared to the data of the artificial surfaces. The inconsistency can be mainly related to the definition of the geometric roughness height and to the determination of the upper boundary of the roughness layer.

The results of the study emphasise the importance of the analysis of the spatial characteristics of the flow field as well as of the roughness density function of water-worked beds, which are under investigation at the moment.

ABSTRACT: In rivers flowing in their own alluvial deposits, the curvature induced circulation results in a cross section with deep outer bends and shallow inner bends, which reduces the depth and width of navigation. In the past various solutions have been proposed to increase the width of navigation through temporary dredging and/or costly non reversible river engineering works. The present paper presents results of preliminary experiments to reduce the influence of the curvature induced circulation by means of a counteracting circulation, generated by a bubble screen along the outer bend. With a bubble screen in operation, two counter rotating circulation cells exist, with a downward flow at the junction of both cells. Due to the presence of the bubble induced circulation, the core of maximum bed shear stress shifts in the direction of the inner bend, while the curvature induced circulation is crushed in inward direction. Increasing the width of navigation seems feasible although many questions still have to be resolved.

1 INTRODUCTION

It is well known that in natural rivers, the bottom configuration is seldom flat. On all spatial scales, bed forms develop, varying from very small ripples to very large alternating bars. For an elaboration of the scale-issue, we refer to Seminara (1995), De Vriend (1999) and Baptist (2005). This paper concentrates on the mega-scale, which is the scale of bars rather than dunes of ripples.

In straight rivers, a pattern of alternating bars is often found, depending on the width-to-depth ratio of the channel. This is a *free* instability, which arises spontaneously due to the fact that there are always small perturbations present on the river bed which grow to finite amplitudes if the conditions are right (for a theoretical analysis of free bars, see for instance Schielen et al 1993).

In open-channel bends, the curvature of the channel gives rise to a *forced* instability which forms the so bar pool bed topography with a point bar in the inner bend and a scour hole in the outer bend (Fargue 1868, Odgaard 1981, etc).

This paper will focus on open-channel bends, although the technique presented can also be applied in straight rivers.

For this paper, it suffices to mention that the bend topography is mainly shaped by the interaction between the velocity distribution, the secondary circulation and the bed topography itself.

This secondary circulation, also called spiral flow or helical flow, is a typical feature of flow in open-channel bends (see Fig. 1, Van Bendegom 1947, Rozovskii 1957, de Vriend 1981, Blanckaert and de Vriend 2003, 2004).

Point bars in the inner bend often cause hinder for shipping because the width of the navigation channel is decreased. This problem is of special importance for the Dutch river Waal (one of the Rhine-branches), which is one of the main shipping routes in Europe. For

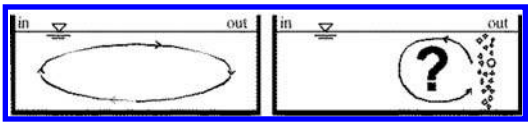

Figure 1. Conceptual sketch of (left) secondary circulation in open-channel bends; (right) the bubble-screen technique.

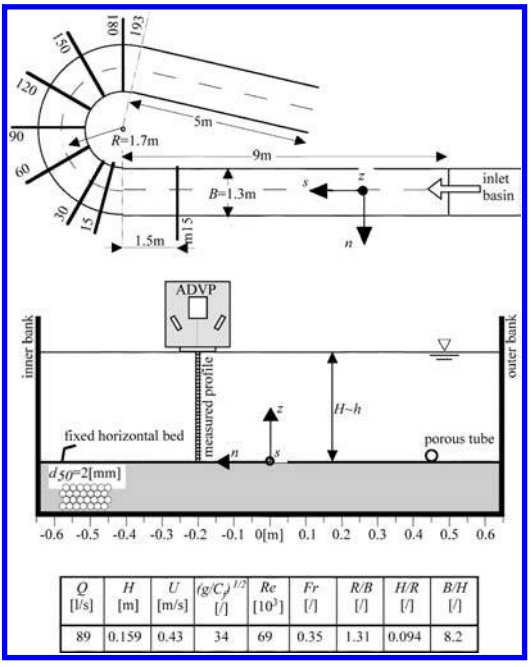
the Waal, the problems are even more pregnant because in the upper reach, there are several sharp bends which induce large point bars. There are in principal two ways to avoid the existence of point bars: influence the flow, or protect the bed.

The flow can be influenced by the construction of bottom vanes, which actually prevent the secondary circulation to develop. A disadvantage of this method is that it is a fixed construction on the bed, and hence it is a possible threat for the ships. Bottom vanes are applied in for instance Bangladesh, see Hossain et al (2005) and Jongeling and Flokstra (2001), and, in the past, have been considered in the Dutch river IJssel. However, due to the aforementioned threat to the ships, they have never been constructed.

A method which acts on the bed is the construction of a fixed layer in the outer bend. The mechanism is that due to the fixed layer, the outer bend can no longer erode, and hence no material can be transported to the inner bend. Thus, point bars can not develop. Disadvantage of this method is again that it is a fixed construction. As the bed-level in the eastern part of the Netherlands is decreasing, the river Rhine cuts itself deeper in the land and hence, a construction like a fixed layer may also become an obstacle for shipping.



A third method to prevent point bars is the construction of groynes with a limited height ('bed-groynes' or submerged groynes). The maintenance of these underwater groynes however, is far from easy and they are often destroyed under high-water conditions.

In this paper, we describe the method and results of a new, and non-permanent way to perturb the secondary circulation. The central idea is to counteract the downward movement of the secondary circulation by releasing rising air bubbles. The bubble screen drags the flow upwards, and hence, the secondary circulation is perturbed. Figure 1 schematically illustrates this technique.

At forehand, it is not clear how the bubble screen will influence the flow pattern. The main research questions of this paper therefore are:

1. Can a bubble-screen counteract the development of the curvature induced secondary circulation ?
2. What are the characteristics of the remaining flow pattern?

This paper briefly describes the laboratory flume and the experimental conditions, presents the results and discusses them with respect to the navigable width.

Q [l/s]	H [m]	U [m/s]	$(g/C_f)^{1/2}$ [/]	Re [10^3]	Fr [/]	R/B [/]	H/R [/]	B/H [/]

2 EXPERIMENTS

To investigate the influence of a bubble-screen on the secondary circulation in a bend, experiments were carried out in the strongly curved laboratory flume at the École Polytechnique Fédérale de Lausanne (EPFL) in Switzerland. The curved flume, see Figure 2, consists of a straight inflow reach of 9 m, a 193° curved reach with a 1.7 m radius of curvature for the centreline and a straight outflow reach of 5 m. The width of the flume is 1.3 m, with a rectangular cross section. The bed slope of the inflow reach is 0.22%, while the bend and the outflow reaches are horizontal. The flume bed and the outer bank were artificially roughened with sand, having an average grain size of 2 mm, glued to the surface, whereas the inner bank was made of Plexiglass.

From earlier experiments in the flume (see Blanckaert 2002a) extensive reference data with respect to the unperturbed secondary circulation, is available for a water depth of 0,159 m. To be able to compare results of the experiments at hand with the earlier experiments similar flow conditions were installed, see Figure 2.

For the bubble-screen, use was made of a porous tube, which was placed from the bend entry till the bend exit at a distance of 0,20 m from the outer wall at the location where the downward velocities were largest in the reference experiments without

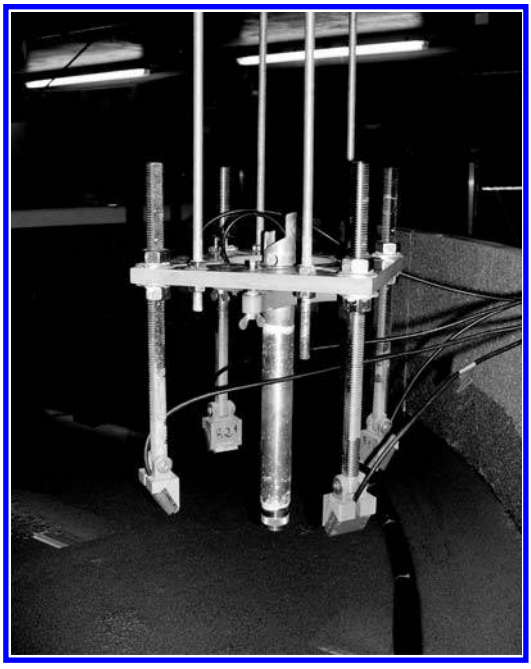

Figure 3. Acoustic Doppler Velocity Profiler (ADVP).

bubble-screen. The holes in the tube are very fine and located on both sides of the diameter, approximately 3 mm apart in longitudinal direction, resulting in bubbles with a diameter of 0.002 m till 0.015 m. The tube was on both sides connected to the same compressor enabling a more or less constant air pressure along the whole length of the tube. The pressure in the tube was measured and could be regulated with a valve. Preliminary tests indicated an optimal pressure of 3 bar, which fortunately coincided with the recommended pressure for the tube.

For the flume a curvilinear coordinate system is defined with s-direction along the centreline of the flume, a transversal axis n, perpendicular to the centreline, positive in outward direction and a vertical z-axis perpendicular to the plane through s and n and positive in upward direction, see Figure 2.

Water levels, bed levels and flow velocities were measured in the cross-sections at an angle of 15°, 30°, 60° 90°, 120°, 150° and 180° in the bend and included the transversal locations, $n = [-0.5, -0.4, -0.3, -0.2, -0.1, 0, 0.1, 0.2, 0.3, 0.4, 0.5]$ m.

The flow velocities, either with or without bubble-screen, were measured with an Acoustic Doppler Velocity Profiler (ADVP), designed at EPFL. Sample time was 180s. The system is based on a central emitter (see Figure 3) which periodically sends an acoustic signal with a frequency of 1 Mhz in the vertical downward direction. From the returning signal of four receivers surrounding the emitter, the time-averaged velocities and velocity fluctuations in the three directions (v_s, v_n and v_z) are derived. The ADVP has the major advantage of measuring entire profiles at one go. Because the flow in the upper 0,02 m of the water column is perturbed by the ADVP, the velocities in this layer were extrapolated by means of procedures outlined by Blanckaert and Graf (2001). For a more detailed description of the ADVP, see Lemmin and Rolland (1997) or Blanckaert and Lemmin (2006).

3 EXPERIMENTAL RESULTS

In general, the flow in river bends is decomposed along the reference axes. The decomposition results in a cross-flow, $U_n = \langle v_n \rangle$ that represents the translatory motion, and the two components (v_n^*, v_z) which represents the circulatory motion, see Bradshaw (1987):

$$\begin{cases} v_s = U_s + v_s^* \\ v_n = U_n + v_n^* \\ v_z \end{cases} \quad (1)$$

To illustrate the effect of the bubble screen on the flow, Figures 4 to 7 compare features of the flow field with and without bubble screen. Figures 4 and 5 show the normalized quantities $(v_n^*, v_z)/U$ and v_s/U in the cross-section at 90° in the bend, whereas Figures 6 and 7 show the evolution around the bend of some depth-averaged flow quantities.

In Figure 4, where the flow velocities for the reference situation without bubbles are given, a curvature induced cell of secondary circulation is clearly visible. It extents over the entire width of the cross-section and reaches maximum transversal and vertical velocities of about $v_n = \pm\ 0.2\ \mathrm{ms}^{-1}$ and $v_z = \pm 0.025\ \mathrm{ms}^{-1}$, respectively. The inclination of the isolines of v_s are illustrative of advective momentum transport by this secondary circulation.

In Figure 5 the flow velocities are given for the same hydraulic conditions and in the same cross section but now with the bubble screen in operation. In the cross section between $n = -0.5$ and $n = 0.4$ two circulation cells can be observed, the curvature induced circulation, smaller in size, more or less equal in strength and direction of rotation and the bubble induced circulation, covering roughly half of the flume width and with a rotation opposite of the curvature induced circulation. The bubble induced circulation is only slightly weaker than the curvature induced one. The vertical downstream velocity at the junction of both cells is amplified and reaches maximum values of about $v_z = -0.055\ \mathrm{ms}^{-1}$. Maximum transversal and vertical velocities are about $v_n = \pm 0.2\ \mathrm{ms}^{-1}$ and $v_z = \pm 0.025\ \mathrm{ms}^{-1}$, respectively.

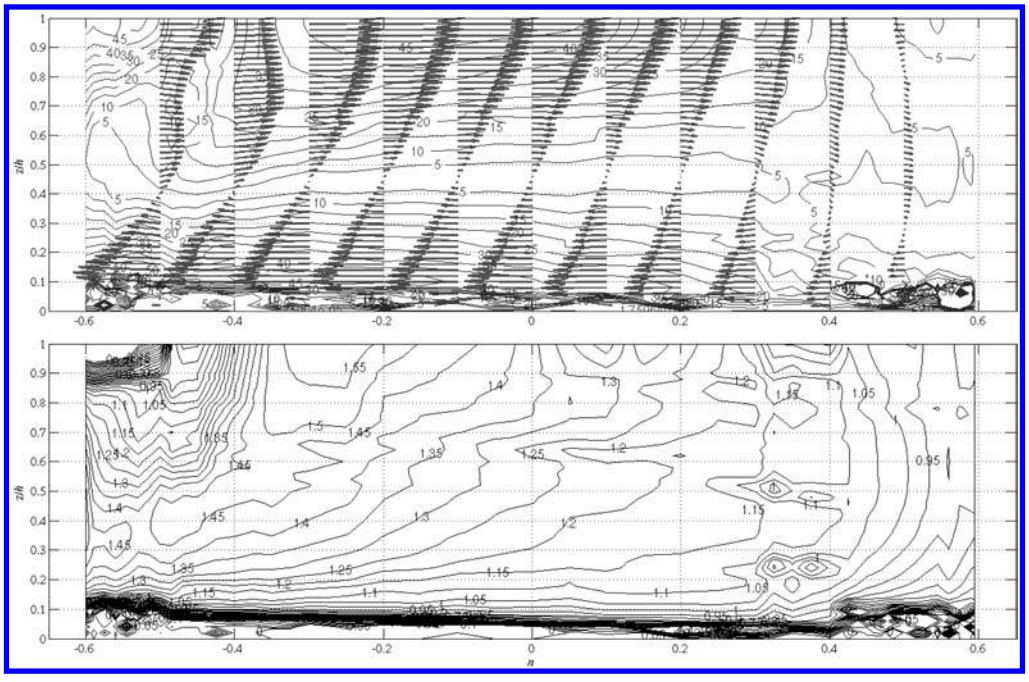

Figure 4. Patterns of normalized secondary circulation, $(v_n^*, v_z)/U$ (isolines show vector magnitude in [%]), and downstream velocity, v_s/U, measured in the cross-sections at 90° without bubble screen. Horizontal axis n, vertical axis z/h.

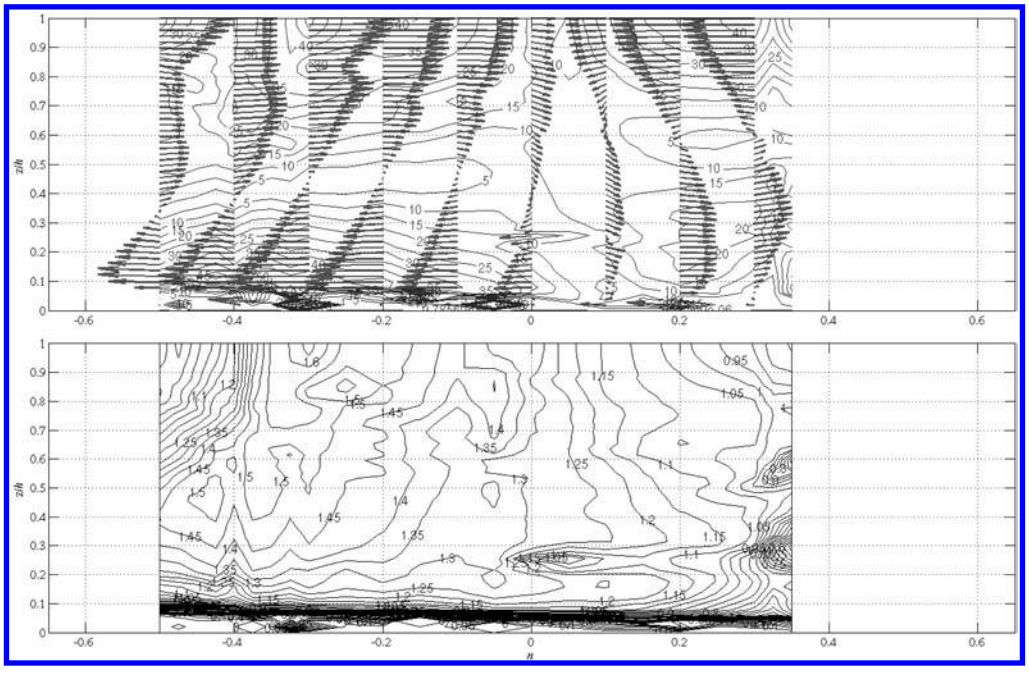

Figure 5. Patterns of normalized secondary circulation, $(v_n^*, v_z)/U$ (isolines show vector magnitude in [%]), and downstream velocity, v_s/U, measured in the cross-sections at 90° without bubble screen. Horizontal axis n, vertical axis z/h.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The secondary circulation pattern is well visualized by means of the functional ψ, defined as:

$$\psi = \frac{1}{2}(\psi_n + \psi_z)$$

$$\psi_n = -(1+n/R)\int_{z_b}^{z} v_n^* dz$$

$$\psi_z = \int_{-B/2}^{B/2}(1+n/R)v_z dn - \langle\langle\psi_z\rangle\rangle + \langle\langle\psi_n\rangle\rangle \qquad (2)$$

The factor $(1+n/R)$ accounts for the divergence of the transversal coordinate axis. $\langle\langle\psi_n\rangle\rangle$ and $\langle\langle\psi_z\rangle\rangle$ represent the grid-averaged value of ψ_n and ψ_z, respectively.

In fully-developed curved flow ($\partial/\partial s = 0$, infinite bend), $\psi_n = \psi_z$ and ψ represents the classical definition of the streamfunction (Batchelor 1967), whence the functional ψ will be called pseudo-streamfunction hereafter.

This pseudo-streamfunction has the advantage of being a scalar quantity, contrary to the secondary circulation vector (v_n^*, v_z). Patterns of secondary circulation measured in the same experimental set-up have been presented by Blanckaert (2002b) by means of a similar pseudo-streamfunction.

Figure 6 shows the strength of the secondary circulation parameterized by the normalized depth-averaged pseudo-streamfunction, $100\langle\psi\rangle/(UH)$. In the experiment without bubble screen, only a curvature induced secondary circulation cell exists, whereas an additional bubble generated circulation cell exists in the presence of the bubble screen. The bubble induced circulation pushes the curvature induced circulation towards the inner bend and reduces its transversal extent, but has hardly any influence on its strength.

In both experiments the secondary circulation develops at the bend entry, reaches its maximum at approximately 90^o in the bend and weakens further downstream.

Figure 7 shows the distribution of the downstream bed shear stress component, τ_{bs}, estimated with the Chézy type relation

$$\tau_b = C_f U_s^2 \qquad (3)$$

and normalized by means of the flume averaged bed shear stress,

$$\langle\langle\tau_b\rangle\rangle = \rho C_f U^2 \qquad (4)$$

where $U = Q/(BH)$ is the flume averaged velocity.

Without a bubble induced circulation cell the core of the high bed shear stress starts at the upstream side at the inner bend and gradually shifts to the outer bend, which is reached at the bend exit. With a bubble induced circulation cell the core of the highest bed shear stress does not migrate further than the junction of both circulation cells, which is found near the centreline of the flume. The bed shear stress decreases towards both banks.

The maximum value of the bed shear stress is higher in the presence of the bubble screen. This maximum value in the bend is about twice as high as the flume averaged value $\langle\langle\tau_b\rangle\rangle$ that would occur in a straight flow.

4 DISCUSSION

The experiments in the strongly curved flume with fixed flat bed show that a bubble induced circulation cell is able to reduce the size of the curvature induced circulation cell.

In case of an alluvial erodible bed, the curvature induced circulation cell would transport the sediment from the outer bend to the inner bend due to the direction of the flow at the river bed. For equilibrium conditions the drag force of the flow in n-direction balances the gravitational force in the same direction. It is expected that, in case of a combination of curvature induced and bubble induced circulation cells, the thalweg would follow the line through the downward junction of both cells and that the cross sectional bed level gradient will be roughly zero along this line. Because of the decrease in size of the curvature induced circulation cell the position of the thalweg would be closer to the centreline. The circulation strength of the curvature induced cell is hardly reduced, so the cross sectional bed slope at the inner bend would be approximately equal to the slope without bubble induced circulation. Due to the shift in thalweg one may nevertheless expect an increase in navigational width, see Figure 8. However, as the experiments so far have only been carried out with a fixed bed, the situation that is indicated in figure 8 remains somewhat speculative. Especially the velocity distribution and shear stress consequences in case of an erodible bed need to be examined.

The main advantage of a bubble screen compared to other techniques, which try to avoid the existence of point bars, is its reversibility. Whenever the compression stops, the bubbles are no longer present, and the flow pattern goes back to normal. In periods of low discharge (and little morphological activity), there is no need for the bubble screen to be present. Only when sediment redistribution is likely to cause problems (this is typically during high discharges) the bubble screen needs to be activated. As a nice side-effect, it may also have an additional positive effect on the ecology in the river. Existing techniques like bottom vanes or fixed layers are always present, and hence do also have an effect at low discharges. This effect is not always appreciated.

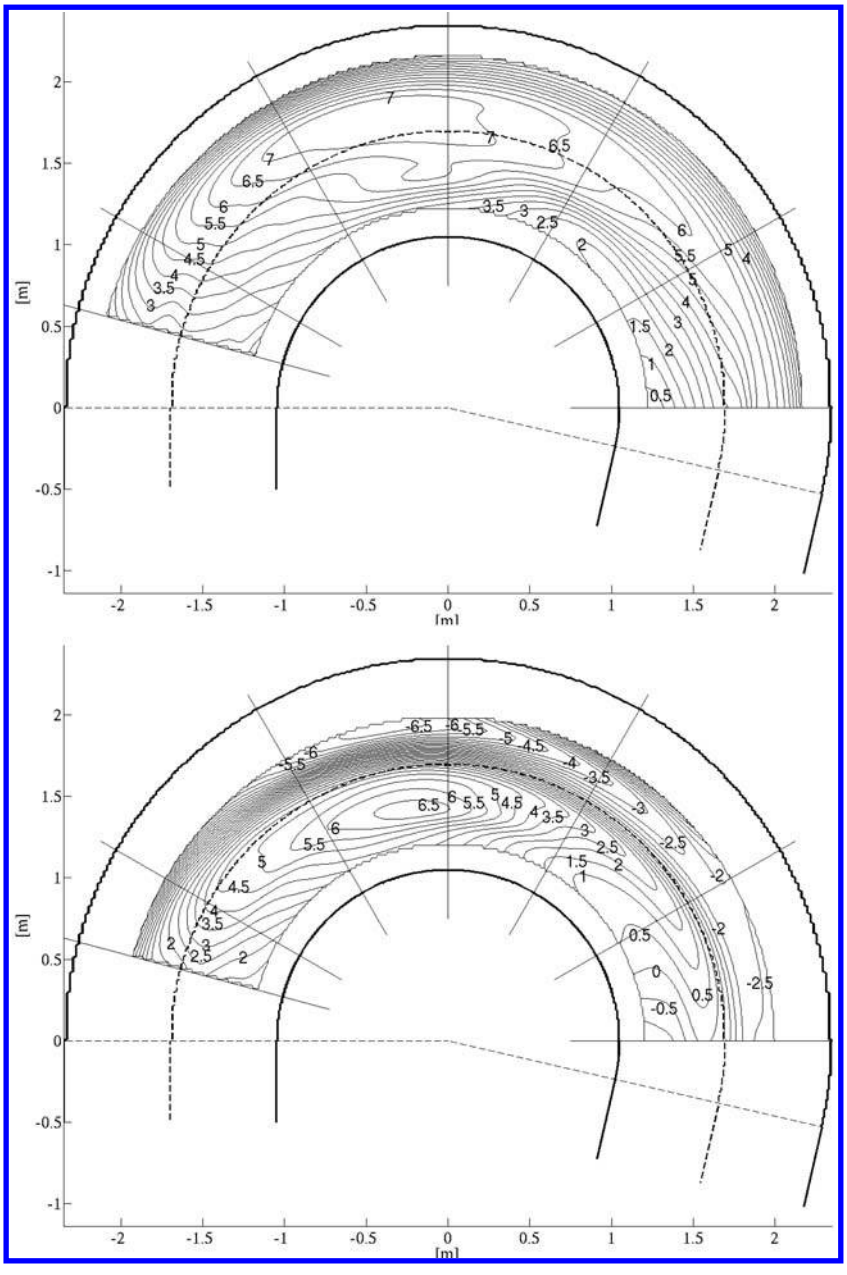

Figure 6. Distribution of the normalized depth-averaged secondary circulation strength $100\langle\psi\rangle/(UH)$ in the bend, (top) Reference situation without bubble screen. (bottom) With bubble screen. Bend entry/exit at the left/right. Measured cross-sections at 15°, 30°, 60°, 90°, 120°, 150° and 180° indicated.

Before applying this technique in practice, further research is needed with respect to technical and economical aspects. The principal seems to work in a flume, but is it also applicable in a real river? The width-to-depth ratio of the flume was about 8.3, while a real river like the Waal has typically width-to-depth ratios over 50. Not only is there a question with respect to the mechanism (will there also appear two cells) but there is also the technical question with respect to the generation of bubbles (which obviously must be an order of magnitude larger than in the experiment) and the energy needed for that.

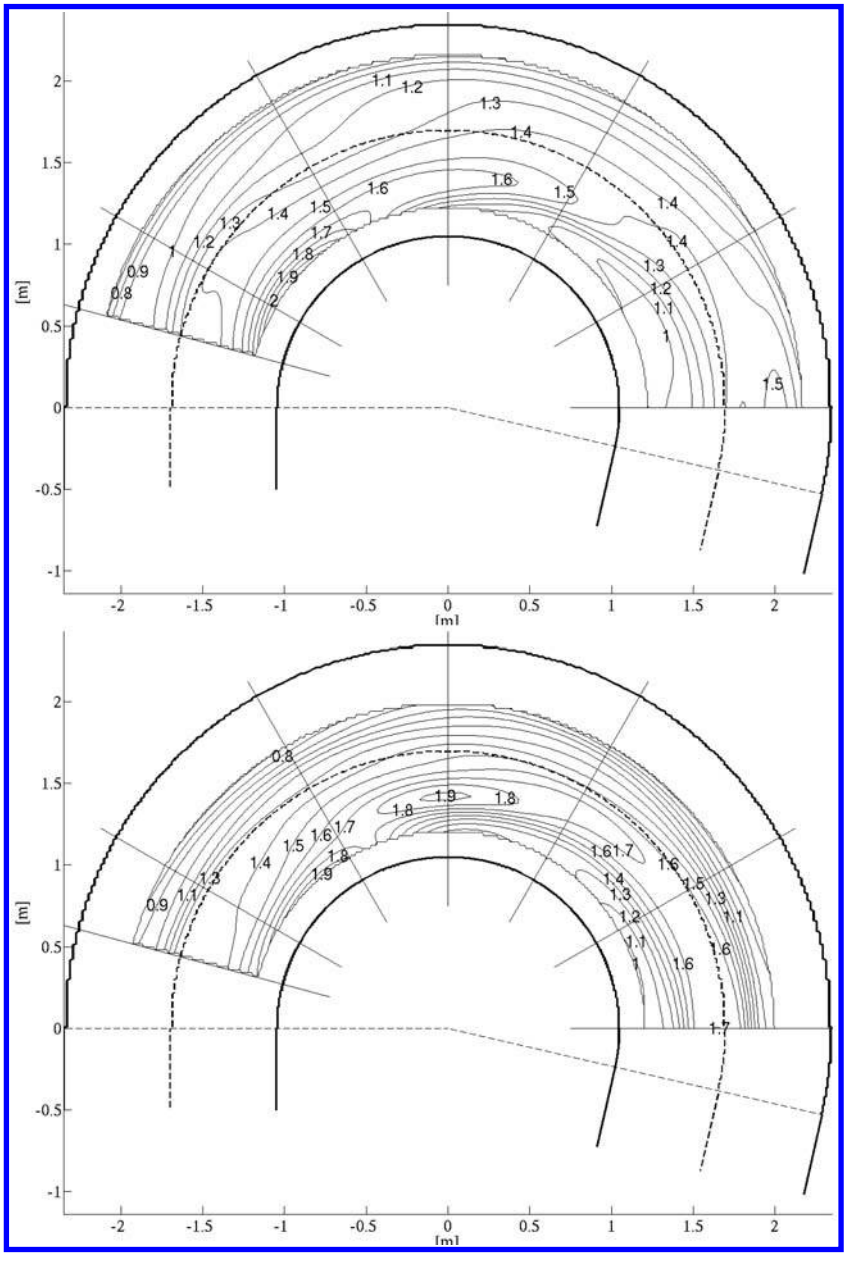

Figure 7. Distribution of the normalized downstream bed shear stress, $\tau_{bs}/\langle\langle\tau_b\rangle\rangle$ in the bend, (top) Reference situation without bubble screen. (bottom) With bubble screen. Bend entry/exit at the left/right. Measured cross-sections at 15°, 30°, 60°, 90°, 120°, 150° and 180° indicated.

5 CONCLUSION

Preliminary experiments in a strongly curved flume convincingly show that a bubble screen reduces the width extent of the curvature induced circulation cell.

A bubble induced circulation cell develops that is roughly similar in strength, but smaller in spanwise extent. It exists next to the counter rotating curvature induced circulation cell, which is shifted in inward direction but hardly reduced in strength. The core of

Copyright © 2006 Taylor & Francis Group plc, London, UK

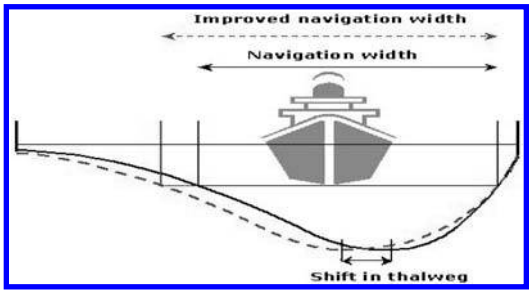

Figure 8. Possible improvement in width of navigation in case of curvature induced and bubble induced circulation cells.

maximum downstream velocities is shifted from near the outer bank in inward direction to the junction of both circulation cells. Over a mobile bed, this would result in a more uniform depth distribution with a maximum depth at the junction of both circulation cells.

Before applying this technique in real life situations however, further technical questions need to be resolved, such as:

- Do the conclusions still hold in the case of an erodible bed?
- During which period of time or during which flow conditions is a bubble screen most effective to increase the width for navigation?
- How much energy is required for such a period?
- Would the navigation be hampered by a bubble screen?
- Will there be an increase in bank erosion at the outer bank?

Besides demonstrating the potential of the bubble screen technique, the measurements provide detailed data on the 3D flow field in open-channel bends, which can be useful for validation of numerical models.

ABSTRACT: In turbulent river flows, coherent structures play a major role in transport and mixing processes. Coherent structures appear as non-stationary randomly distributed singularities in turbulent velocity signals. Wavelet analysis which characterizes signal variability both in time and space is well suited for the analysis of isolated phenomena such as coherent structures. With wavelet decomposition we may represent individual features of the instantaneous signal within a pre-determined scale. We developed a coherent structure detection technique based on wavelet multiresolution analysis, conditioned by event scale and amplitude. The samples are chosen using a correlation threshold condition. 3D reconstruction is made by composite averaging. We assess the relationship between coherent structures and other large- or small-scale flow features and the contribution of individual events to the turbulent flow structure such as velocity profile, Reynolds stress tensor and TKE budget. We apply our method to Acoustic Doppler Velocity Profiler measurements in a gravel-bed river.

1 INTRODUCTION

In geophysical flows, momentary variations of the velocity are related to such processes as the suspension of sediments and the dispersion of pollutants in the water. Coherent structures consist of macroscale "organized" phenomena, belonging to the productive range of the spectral space. In the inertial and the dissipative ranges, turbulence is essentially random and isotropic, composed of fine scale features such as small scale eddies. Coherent structures have a short life cycle. They cannot be identified with a time averaged analysis and require an investigation based on time and space correlation measurements or flow visualization techniques. In laminar and transitional flows, coherent structures occur periodically, whereas in turbulent flows they occur randomly in space and time. Hence, in addition to flow visualization techniques, conditional sampling and statistics techniques have to be used in the detection and characterization of coherent structures. Several authors applied conditional statistics to turbulence studies (Antonia & Atkinson 1973, Nakagawa & Nezu 1977 and Hurther & Lemmin 2000). Adrian et al. (2000) compared Reynolds decomposition, Galilean and LES techniques. In this study we will use Reynolds time-averaged decomposition.

Here we make use of conditional sampling techniques and the wavelet multilevel decomposition of single point instantaneous velocity measurements. Wavelet analysis is a suitable tool for the study of turbulence in geophysical flows. Foufoula-Georgiou & Kumar (1994) presented a compilation of papers dealing with the application of wavelet analysis in geophysics. Turner et al. (1994) examined scales and the location of flow structures related to temperature and flux data of atmospheric flow above a forest canopy. Yoshida & Nezu (2004) used wavelet analysis to study the importance of the bursting process near the free surface for gas transfer in open-channel flows.

We use velocity data obtained with the ADVP instrument in a river in order to develop a detection algorithm for coherent structures. This is based on wavelet multilevel decomposition of 3D instantaneous velocity profiles measured at one location over the whole water depth. A conditioned sample is created with scale, amplitude and cross-correlation threshold methods. Thereafter, the single-point detected structure is reconstructed three-dimensionally by a normalized composite average. We subsequently reconstruct the 3D flow structure over the whole water depth. The reconstructed structure and its time distribution in the instantaneous velocity signal are discussed.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The method is demonstrated for Quadrant II (QII) structures (ejections) but may be generalized to other quadrants. With the detection technique we were able to identify and analyze several sequential bursting packets of coherent structures. The influence of packet dynamics on the velocity profile, Reynolds stress tensor (RST) and TKE production are investigated.

The notation adopted for the Reynolds velocity decomposition is streamwise, $u = \overline{u} + u'$; spanwise, $v = \overline{v} + v'$; vertical, $w = \overline{w} + w'$ (time mean and $'$ instantaneous value). When referring to $v = \overline{v}_i + v'_i$, v is velocity and the subscript i $\{1, 2, 3\} \equiv$ is one of the 3D Cartesian coordinates $\{x, y, z\}$.

2 COHERENT STRUCTURE SAMPLING

2.1 *Wavelet discrete transform and multiresolution analysis*

Wavelet analysis is capable of localizing signal variability simultaneously both in time and scale (scale here refers to time duration) (Kantha & Clayson 2000). Contrary to Fourier based analysis, wavelet analysis can deal with non-stationary signals with randomly distributed singularities, such as the occurrence of coherent structures in turbulent velocity time series. In wavelet decomposition, the wavelet functions are scaled locally (dilation or contraction) in order to represent singularities. Thus, boundaries do not influence the local description of the signal. Fargé (1992) presented an introductory text on the use of wavelet transform in the study of turbulent signals. This paper is based on Fargé (1992), Foufoula-Georgiou & Kumar (1994), Kumar & Foufoula-Georgiou (1997) and Mallat (1999). Only 1D wavelet analysis is used.

In the continuous wavelet transform, the wavelet function $\psi_{\lambda,t}(t)$ is parameterized by the real values of scale λ and time location t, whereas in the discrete wavelet transform $\psi_{m,n}(t)$ it is parameterized by the integers m and n. As in Fourier analysis, we can apply a wavelet transform using appropriate wavelet functions and discrete scale and location parameters (m and n). The process consists of evaluating the signal locally (the wavelet covers all the time locations) in several modes, each corresponding to a defined scale. The scale is defined by the expansion of $\lambda = \lambda_0^m$, where λ_0 is a fixed dilation step and m an integer. The time step to analyze the signal is a function of the chosen scale, $t = nt_0\lambda_0^m$. In this way, the time domain is covered by the discrete analysis.

A wavelet frame, which is characterized by the scale λ corresponds to each of the wavelets $\psi_{m,n}(t)$. The partial reconstruction of the signal conditioned by the wavelet frame defined by m corresponds to one decomposition mode. Wavelet multiresolution consists of the decomposition of the original turbulence signal into one coarse set (the approximation) and several others with progressively smaller scale resolution (the details). Once the multilevel wavelet discretization of the signal is made, each level of the signal is reconstructed resulting in several low-resolution data series corresponding to each wavelet frame scale. A scale resolution higher than the scale of the last lower level of decomposition corresponds to the approximation. The signal may be successively reconstructed by adding the approximation (S) to the consecutive level details (D_λ). Multiresolution analysis allows estimating the energy partition throughout the different scale frames associated with the decomposition modes. We may estimate the contribution of each wavelet frame to the streamwise flow energy by calculating the detail variance:

$$\overline{D_{\lambda,u'}{}^2} = \frac{\sum_{n=1}^{N_{time}} D_{\lambda,u'}(n)}{N_{time}} \qquad (1)$$

where $D_{\lambda,u'}$ = instantaneous detail of the instantaneous streamwise velocity associated with scale λ; n = the integer defining the time step; and N_{time} = total number of time steps (the addition is made for the entire time domain).

We will now introduce a coherent structure detection technique and apply it to a single decomposition mode of the instantaneous 3D velocities measured at one level of the velocity profile. Subsequently the reconstruction of the velocity profile is made taking into account the detected events.

2.2 *Wavelet-frame conditional quadrant analysis*

The statistical distribution of coherent structures in the $\{x\text{-}z\}$ plane may be analyzed by means of the threshold-based conditional sampling of instantaneous shear events $\varepsilon' = u'w'$, combined with their quadrant location (Nakagawa and Nezu, 1977). The quadrant technique consists of analyzing the distribution of the instantaneous shear events ε' in the four quadrants of the $\{x\text{-}z\}$ plane in order to detect coherent motions. For the positive detection of an event, a comparison of the relative amplitude of the instantaneous shear stress with a threshold value H is also required. Events for which the relative shear stress values ($\varepsilon'/\overline{u'w'}$) are lower than a threshold value H are called hole events. Using wavelet multilevel decomposition of the instantaneous signals, we may condition the analysis of the coherent structures to a wavelet frame, by restricting the quadrant analysis to a chosen structure scale:

$$H_{\varepsilon\uparrow\lambda} = \frac{D_{\lambda,\varepsilon'}}{D_{\lambda,u'}D_{\lambda,w'}} \qquad (2)$$

where $D_{\lambda,\varepsilon'}$ = time series of the instantaneous shear stress detail associated with scale λ, defined as

Copyright © 2006 Taylor & Francis Group plc, London, UK

$D_{\lambda,\varepsilon'} = D_{\lambda,u'} D_{\lambda,w'}$. $D_{\lambda,w'}$ is the instantaneous detail of the instantaneous vertical velocity associated with scale λ.

2.3 *Wavelet-frame threshold and cross-correlation conditional sampling*

We discussed how to sample coherent structures according to their scale, quadrant location and shear amplitude. Now we define a time window around the detected structures in a determined wavelet frame centred at the location of the instantaneous shear event detected as relevant (t_ε). Its range ($t_\varepsilon \pm \Delta t_\varepsilon$) is defined by the following window parameter ξ:

$$\Delta t_\varepsilon = \frac{\xi}{2}\lambda \tag{3}$$

The choice for the event reconstruction may be refined with an analysis based on the cross-correlation between individual data windows. A correlation coefficient threshold H_ρ below which the windowed instantaneous velocity data are rejected is defined as:

$$\begin{cases} \rho_{\tilde{v}_i'|\xi, v_i'|\xi} = \dfrac{C_{\tilde{v}_i'|\xi, v_i'|\xi}}{\sigma_{\tilde{v}_i'|\xi}\ \sigma_{v_i'|\xi}} \\ \text{if } \rho_{\tilde{v}_i'|\xi, v_i'|\xi} < H_\rho,\ v_i'|_\xi \text{ is rejected} \end{cases} \tag{4}$$

where $\rho_{\tilde{v}_i'|\xi, v_i'|\xi}$ = correlation coefficient between a windowed instantaneous velocity ($v_i'|_\xi$) and the composite average within the window ($\tilde{v}_i'|_\xi$); $C_{\tilde{v}_i'|\xi, v_i'|\xi}$ = covariance between $\tilde{v}_i'|_\xi$ and $v_i'|_\xi$; and $\sigma_{\tilde{v}_i'|\xi}$ and $\sigma_{v_i'|\xi}$ = standard deviations of $\tilde{v}_i'|_\xi$ and $v_i'|_\xi$, respectively. Appropriate normalization is made for the representation of the identified shear events. The time variable is normalized by the scale corresponding to the wavelet frame used as a basis to identify the structures (t^+). The velocities are normalized by the event amplitude within the time window:

$$v_i'^{+} = \frac{v_i'|_\xi}{\max(v_i'|_\xi) - \min(v_i'|_\xi)} \tag{5}$$

2.4 *Method*

Using the wavelet multilevel decomposition of the signal, a conditional sampling technique is presented that allows detecting and windowing similar coherent motion in a given velocity signal. The main steps of the procedure are:

1) Wavelet discrete transform of the turbulent velocity signal: multilevel decomposition of the signal into several wavelet-frames.
2) Multiresolution decomposition: reconstruction of each wavelet-frame resulting in several low-resolution data series corresponding to different time scales.
3) Scale conditional sampling of the decomposed signal with a chosen reference scale (λ).
4) Quadrant analysis and threshold-based ($H_{\varepsilon'|\lambda}$) sampling of instantaneous shear events conditioned by the chosen scale (λ).
5) Windowing and composite averaging of the detected structures with a defined window parameter (ξ).
6) Correlation coefficient threshold (H_ρ) re-sampling: refinement of the windowed events based on the coherence of different instantaneous events detected within the defined window.
7) Normalization and composite averaging of the windowed events: time normalized by the scale λ, and velocities normalized by the event amplitude (Eq. 5: u^+, v^+ and w^+ respectively for streamwise, spanwise and vertical components).

3 RIVER MEASUREMENTS

This research is based on a timeseries of instantaneous velocity profiles measured in the Swiss river Venoge (canton of Vaud) during the summer of 2004, under stationary shallow water flow conditions. The measuring position was located about 90 m upstream of the Moulin de Lussery. The hydraulic characteristics of the river and of the measured profile are shown in Table 1. where Q = river discharge; S = river slope; h = water depth; $\overline{U}$ = depth-averaged streamwise mean velocity; Re = Reynolds number; Fr = Froude number; u^* = shear velocity estimated using the eddy-correlation method (Monin and Yaglom 1971); D_{50} = bottom grain size diameter for which 50% of the grain diameters are smaller. The riverbed material grain distribution was sampled according to the Wolman (1954) method. The riverbed is hydraulically rough, with coarse gravel and randomly spaced macro-roughness elements scaling with as much as half the water depth (0.5 h). We used the deployable ADVP developed at the LHE-EPFL, which allows measuring 3D quasi-instantaneous velocity profiles over the entire depth of the flow in rivers (Rolland & Lemmin 1997). Data were sampled for 211 s at a frequency of 26 Hz. We implemented a dealiasing method which

corrects the instantaneous Doppler frequencies measured by the four receivers (Franca & Lemmin 2006). The vertical resolution of the measurements is around 0.5 cm. Figure 1 shows the mean velocity (U) profile. The coherent structure analysis was applied to a point which is located in the boundary layer of the logarithmic velocity profile, 1.4 cm above the riverbed (Fig. 1).

4 RESULTS

4.1 *Detection and single point 3D reconstruction*

Coherent structures were sampled according to the method described in Section 2. In Table 2 we indicate the parameters used for the application of the analysis. where N is the number of decomposition levels. The chosen scale ($\lambda = 0.43$ s) corresponds to the most energetic scale in the timeseries. The length of the most energetic coherent structures corresponds to a macro scale with an order of magnitude situated between a characteristic bed grain dimension ($\approx D_{50}$) and the water depth (h). Its value is around $\lambda = 0.43$–0.86 s (in length scale, $\Lambda \approx 0.10$ to 0.20 m). An $N = 8$ level wavelet decomposition with the Daubechies type D4 function (Daubechies 1988) is sufficient to describe the energy partition throughout the different structure scales present in the flow. At this scale, negative shear events situated in QII and QIV are predominant. Restricting our analysis to coherent structures belonging to QII and to a threshold level of $H_{\varepsilon'|\lambda=0.43} = 5,46$ shear events are detected. A high degree of scattering around the mean value is found in the individual windowed data series. By windowing the detected events with a window-parameter $\xi = 2.2$, and a refinement using a correlation coefficient threshold of $H_\rho = 0.5$, this number is reduced to 20 events. Under these conditions we reconstructed a composite 3D normalized

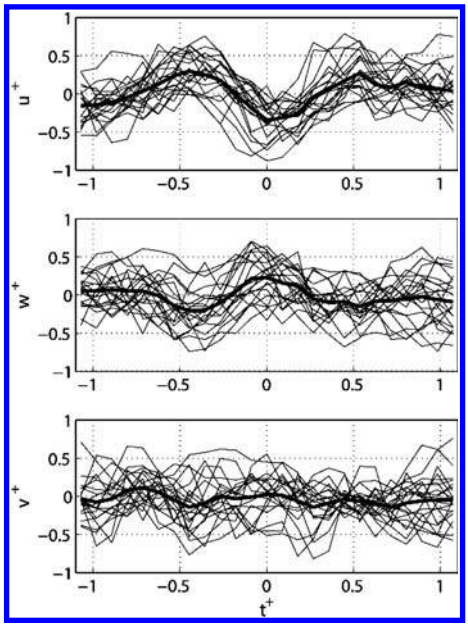

Figure 2. Normalized instantaneous velocity data and composite average (thick line), corresponding to 20 sampled coherent events.

coherent structure at a single-point using the three components of the instantaneous signal.

The windowed composite average ($\tilde{v}_i'|_{\xi=2.2}$) are presented (Figure 2) in the data time series of the corresponding instantaneous streamwise, vertical and spanwise velocity components ($v_i'|_{\xi=2.2}$). In Figure 3 the reconstructed coherent structures from the composite-averaged three velocity components are shown within the selected window.

Coherence exists between the sampled events in the three Cartesian components. Before and after the occurrence of the detected ejection ($t_\varepsilon = 0$ s), lower amplitude sweeps occur (u^+ and w^+ fields). This is a characteristic of the bursting phenomenon. Some in-phase movement is seen in the spanwise velocity data.

The existence of sweeps before and after the detected ejection is a coherent event in all selected structures. Thus, the detection process allows isolating a combined sweep-ejection cycle. In the 3D reconstructed coherent structure, the three velocity components present a statistical coherent structure, mainly in

Copyright © 2006 Taylor & Francis Group plc, London, UK

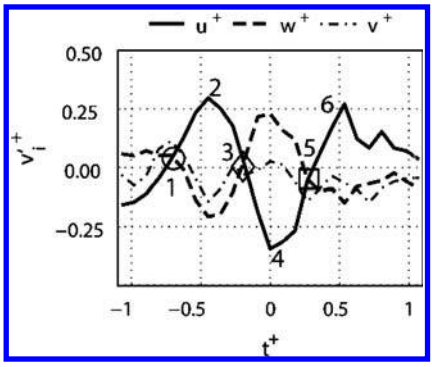

Figure 3. Reconstruction of the detected coherent structure normalized by the local variables. The three velocity components are plotted as a function of time. Symbols ◯ and □ represent the beginning and the end of the sweep-ejection cycle (point 1 and 5 in the figure), and ◇ the beginning of the detected ejection (point 3). Labels are explained in the text.

the $\{x\text{-}z\}$ direction. Six key moments are identified in the process. In chronological order, they are:

1) When all three instantaneous velocity components have low amplitudes;
2) Local maximum amplitude of the u' signal in the first sweep (S1);
3) Before the beginning of the detected ejection when all three instantaneous velocity components again have low amplitudes;
4) High amplitude ejection located in the center of the frame (E1);
5) End of the detected ejection, the three instantaneous velocity components once again have low amplitudes;
6) Local maximum of the u' signal amplitude in the second sweep (S2).

Moments 1, 3 and 5 may be called "stop" points, since all three velocity components simultaneously have low amplitudes and roughly the same value. The spanwise component evolution is in-phase with the vertical component and out-of-phase with the streamwise component, suggesting an interaction between the three components.

4.2 *Reconstruction of the velocity profile*

Having reconstructed one sweep-ejection cycle three-dimensionally in a single point, it is now possible to analyze the remaining water column. The same framing and composite averaging method is applied to the profile, using the time position detected from the single point analysis (the single point analyzed is considered as the detection point for the velocity profile). In Figure 4 the composite averages of the velocity components are represented for the six key moments of the detected cycle indicated in Figure 3.

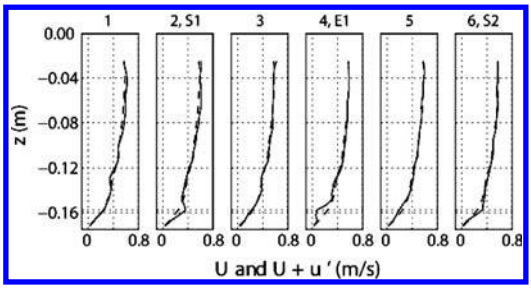

Figure 4. Mean (dashed line) and composite averages (continuous lines) of the streamwise velocity profiles, corresponding to six "key moments" indicated in Figure 3.

The momentary deformation of the velocity profile due to the sweeps and ejections is evident. The streamwise velocity profile acquires its time mean value immediately before and after the events at the so-called "stop" points. The plots of the instantaneous streamwise velocity profiles clearly show the position of the sweep-ejection-sweep cycle detected. The existence of complementary shear events suggest a certain packet behaviour. We are thus in the presence of a bursting packet composed of a sequence of sweeps, S1 and S2 and an ejection, E1.

4.3 *Effect of the passage of the bursting packet on the turbulence intensities*

In this section we analyse the effect of the passage of the bursting packet on the distribution of turbulent intensities (TIs), composite-averaged within the predefined frame. The TIs or normal components of the Reynolds stress tensor (RST) correspond to the variance of the three velocity components ($\overline{v_i'^2}$). The composite-variance calculated within the predefined frame is denoted by $\widetilde{v_i^2}$. The normal stresses define the turbulent energy content of the flow. Since they are production features of the flow, coherent structures are expected to enhance the turbulent energy during their passage. The total mean and composite-averaged (within the frame) TI profiles is presented in Figure 5. The composite-averaged values are denoted by the symbol $\sim$. Both are normalized by the peak values of the mean distribution.

The peak values of the TIs are $\overline{u_{\max}'^2} = 0.0061\ \mathrm{m^2 s^{-2}}$, $\overline{v_{\max}'^2} = 0.0015\ \mathrm{m^2 s^{-2}}$ and $\overline{w_{\max}'^2} = 0.0010\ \mathrm{m^2 s^{-2}}$. As expected, the TIs are enhanced by the bursting packet sequence. Compared with the total time mean, the spanwise TI (Fig. 5b) presents a peak enhancement of about 25 times. This suggests that compared to the background fluctuating field, the component in this direction is particularly strong during these events. The ratio of the peak enhancements for the streamwise (Fig. 5a) and spanwise composite (Fig. 5b) TI is

Copyright © 2006 Taylor & Francis Group plc, London, UK

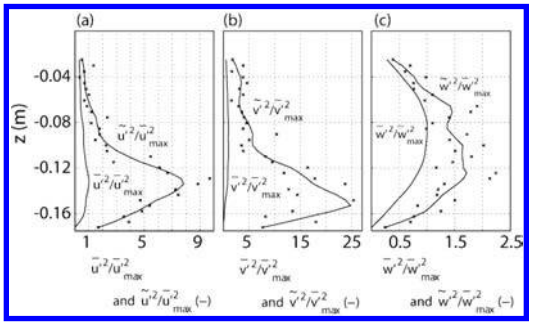

Figure 5. TI profiles, total mean and composite-averaged within the frame defined by $\xi = 2.9$, normalized by the local peaks of the total mean distributions. (a) streamwise, (b) spanwise, (c) vertical TI.

$\frac{\tilde{v}'^2_{max}}{\tilde{u}'^2_{max}} \approx 0.77$. On the average the turbulence structure of the flow is determined by the streamwise velocity component. However, strong short-term processes, such as the sequential bursting packet discussed here, are 3D with an important spanwise component. The determination of streamwise friction velocities by a 2D analysis will thus distort the estimate of the instantaneous bottom drag and provide erroneous information on sediment/mass suspension and transport across the boundary layer.

These results support the observations by Franca (2005) which indicated that 2D friction velocity concepts may not be siutable to determine bottom stress for sediment transport calculations in shallow rough bed rivers. The vertical TI profile (Fig. 5c) is 1 to 2 times greater than the total time average value. The increase is due to the additional vertical momentum introduced into the flow by the packet process. Reynolds shear stress distributions (not shown here) confirm that the strongest transport/suspension processes may occur along both the streamwise and spanwise direction, in agreement with the above observed effect on the friction velocity.

4.4 *Effect of the passage of the bursting packet on the instantaneous TKE budget*

The turbulent kinetic energy (TKE) transport equation, also known as the TKE budget, represents the dynamic equilibrium of the energy terms due to the turbulent motion of the flow. For an incompressible flow of an isothermal fluid, the TKE equation is (Schlichting 1968):

$$\frac{D\overline{k'}}{Dt} = P + D - \varepsilon \tag{6}$$

where $\overline{k'}$ is the temporal mean of the turbulent kinetic energy (TKE: $k' = u'^2 + v'^2 + w'^2$); P is the production rate or generation of TKE by the interaction of Reynolds stress and mean shear; D is the diffusive term; and ε is the dissipation rate. The diffusive term D is negligible for high Reynolds number flows.

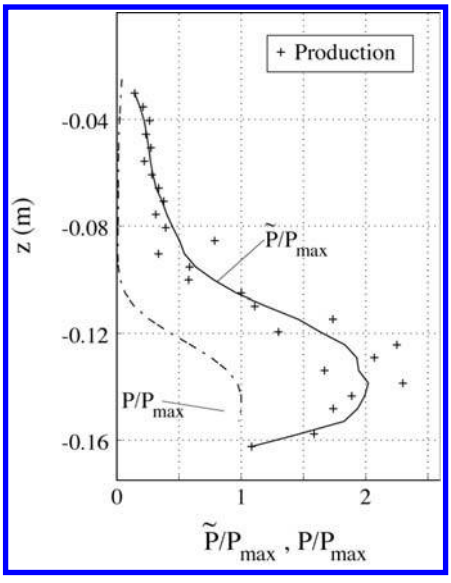

Figure 6. Composite-averaged production $\tilde{P}$, within the frame defined by $\xi = 2.9$, normalized by the peak of the mean distribution.

Background small-scale turbulence present throughout the flow produces dissipation, but production results from individual large-scale events such as the coherent structures described here. The instantaneous production term of TKE, P', is defined by

$$P' = -\overline{v'_i v'_j} \frac{\partial v_i}{\partial x_j} \tag{7}$$

ADVP measurements do not allow direct access to the instantaneous spanwise gradients ($\partial/\partial y$). In order to estimate instantaneous production, we assume that $\frac{\partial u}{\partial y} \approx \frac{\partial v}{\partial x}$, $\frac{\partial w}{\partial y} \approx \frac{\partial v}{\partial z}$, and $\frac{\partial v}{\partial y} \approx \frac{\partial w}{\partial z}$. The streamwise gradients are determined using Taylor's frozen hypothesis. Figure 6 shows the composite-averaged production $\tilde{P}$ profile normalized by the peak of the mean distribution. The maximum increase in the production rate due to the bursting packet is about two times the mean production peak. Despite their short duration, coherent structure packets are highly productive.

5 CONCLUSIONS

Using ADVP measurements in a shallow river, we developed a method for identifying and reconstructing

Copyright © 2006 Taylor & Francis Group plc, London, UK

coherent structures based on a wavelet multiresolution analysis. Coherent structures were detected by analyzing the turbulent velocity signal at one level located in the boundary layer. The reconstruction in time and 3D space was carried out using instantaneous velocity profile measurements. The reconstructed signal provided a visualization of a sequential bursting packet of coherent motion.

The time reconstruction and the phase plots between the three Cartesian components of the reconstruction allowed the following observations:

- The three velocity components present statistical coherent motion.
- A sweep (QIV) was detected before an ejection, with equivalent amplitude and time duration; the compositely reconstructed coherent motion may be a signature of a bursting process.
- A second but weaker sweep (QIV) is observed after the detected ejection.
- Between the sweeps and ejections we observed what may be called "stop" points where all the three components of the instantaneous velocity have low-activity periods simultaneously.
- In summary, the sequence of the movement inside the frame may be characterized by six consecutive key moments: 1) "stop" point; 2) first sweep (S1); 3) "stop" point; 4) ejection, located in the center of the frame (E1); 5) "stop" point; 6) second sweep (S2) (see Figure 3).

We reconstructed the detected coherent motion in the profile, compositely time-averaging the 3D velocity in the water depth. The momentary deformation of the velocity profiles is obvious in the vertical and the streamwise component. The ejection E1 covers a certain scale domain in the water column. An enhancement of the streamwise velocity is limited to the lower layer, whereas the vertical component is affected until $z/h \approx 0.50$. The spanwise velocity profiles are not conclusive. Nevertheless, strong variations of this component occur before the onset of sweeps, suggesting a certain relationship with the shear events in the $\{x\text{-}z\}$ plane. Lateral momentum transfer seems to exist between adjacent ejections and sweeps.

We also analyzed the impact of the passage of the coherent structures packet on the turbulence distribution in the flow, mainly on the RST and on the TKE production. We compared the total time-averaged quantities with frame averages.

The spanwise turbulence intensities are enhanced during the passage of a packet, momentarily equaling the streamwise intensities. Transport and suspension processes, characterized by single or short events, may thus occur in both horizontal directions. The observed packet is highly energetic, and it produces twice the mean peak production during a relatively short period of time.

Based on the present measurements, further systematic research will be conducted in the 3D measuring grid, in order to develop an overall concept of the influence of bursting events on transport and mixing processes in rivers. These extremely energetic events are rare but of great importance in the processes described here. Therefore new approaches are needed in geophysical modeling in order to take their contribution into account.

Equivalent velocity profile for turbulent flows over gravel riverbeds

M.J. Franca
Instituto Superior Técnico – Technical University of Lisbon, Portugal

W. Czernuszenko
Institute of Geophysics, Polish Academy of Sciences, Warsaw, Poland

ABSTRACT: Practitioners need simple estimates of the mean velocity distribution dependent on easy-measurable river characteristics. A simple formulation of the 2D mean velocity profile is thus essential. Recent field measurements obtained with the Acoustic Doppler Velocity Profiler (ADVP) in gravel-bed rivers showed that above the roughness layer the logarithmic law describes the mean velocity distribution fairly well. However, roughness parameters representing local flow conditions differ. It is assumed that the turbulence structure above the roughness layer may be described by the log-law, scaled with height, friction velocity, absolute size of the elements forming the equivalent bed roughness (k) and a coefficient designated by the letter "B". The authors present here a parameterization of the log-law, for turbulent rough flows over gravel riverbeds, where the equivalent roughness is physically based on the bottom roughness protuberances and the coefficient B should represent the bottom geometry.

1 INTRODUCTION

For practical purposes in river engineering it is essential to estimate the flow resistance based in simple measurable quantities. The widely applied logarithmic law to the description of the velocity distribution was object of numerous laboratory studies conducted under idealized conditions of uniform flow and flat beds with fairly homogeneous bed roughness distribution. Conditions like these are rarely found in actual rivers. Field measurements under diverse conditions are desirable for the validation of the existent concepts on river processes with respect to sediment transport, morphology evolution, secondary flows and mixing and transport of matter.

For low values of blockage ratio (h/D, where h is the water depth and D a representative grain diameter), due to the three-dimensionality of the flow, self-similarity of the turbulent flow does not exist inside the roughness layer (Nikora & Smart 1997, Smart 1999, Franca 2005a). Field results show nevertheless that the logarithmic layer is still found on gravel-bed rivers. Franca (2005a) identified three types of velocity profiles for the present measurements: logarithmic, s-shaped and double-logarithmic. The velocity inflection resulting in a s-shaped profile is due to the presence of large scale bed obstacles, whereas the double-logarithmic profiles happen downstream corresponding to the transition to "purely" logarithmic profiles. The extent of the velocity inflection depends on the size of the bed obstacle. Nevertheless, above the roughness layer the flow becomes nearly 2D again and the effects of the bed roughness blend in one single effect causing a linear shear stress with the slope uniformly distributed throughout the river (Franca 2005b). The actual shear in the roughness layer will determine the shear stress distribution throughout the remaining water depth.

If the roughness layer is not too large when compared with the flow depth, it may be possible to parameterize the overall velocity distribution and the flow resistance of gravel river flows over irregular beds (macro-scale roughness), using an equivalent logarithmic 2D velocity profile. Bottom shear would be replaced by the shear at the roughness height.

To both log-law parameters, equivalent roughness and coefficient B, a geometry significance should be attributed, as was the intention since the first studies on the subject (Schlitling 1968). Pitlick (1992) and Baiamonte & Ferro (1997) refer to the equivalent roughness as being 3.0 to 3.5 times the D_{84} (which reflects the deposition of the coarse elements), and Franca & Lemmin (2004) affirm that the mean roughness value is equivalent to D_{84}. The attribution of a physically based value for the equivalent roughness and the definition of the shear or friction velocity resulting from the consideration of uniform flow over a river stretch leaves open the determination of the geometry parameter B. In open-channel rough

Copyright © 2006 Taylor & Francis Group plc, London, UK

turbulent flows, parameter B is commonly attributed the value $8.5 \pm 15\%$ (Monin & Yanglom 1971). Recent developments were made on the attempt to clarify the parameterization of B (Czernusnzenko & Rylov 2004); while the equivalent roughness shall represent the actual confinement introduced by the bed grains in the flow, the parameter B shall be related to the geometry of the bed forms. In gravel-bed rivers, bed forms are typically shaped by the large-scale grains that may under certain circumstances accumulate in coherent regions of the bottom, exerting consequently influence in the flow structure (see Franca & Lemmin 2005). The authors here want to meet up with the idea of physical definition of the equivalent roughness, discussing consequently the geometry signification of the value B.

We will discuss the parameterization of a logarithmic profile for double averaged velocities profiles, in time and space as suggested by Nikora et al. (2001), applied to river velocity measurements. This study is based on field measurements made with the deployable 3D Acoustic Doppler Velocity Profiler (ADVP) in the Swiss rivers Venoge and Chamberonne.

2 THEORETICAL FRAMEWORK

2.1 *Basic hydrodynamic equations*

Three-dimensional, steady and uniform turbulent flow in open channels is governed by the Reynolds – (ensemble) averaged Navier-Stokes (RANS) equations. Continuity and momentum equations for incompressible turbulent flows may be written using the Cartesian tensor notation, respectively:

$$\frac{\partial U_i}{\partial x_i} = 0 \tag{1}$$

$$U_j \frac{\partial U_i}{\partial x_j} = -\frac{1}{\rho}\frac{\partial p}{\partial x_i} + F_i - \frac{\partial}{\partial x_j}\left(\overline{u_i u_j} - \nu \frac{\partial U_i}{\partial x_j}\right) \tag{2}$$

where U_i = i-th component of the time average velocity (i = 1,2,3); p = pressure; ρ = density; F = driving force (F = (g cos α, g sin α, 0), α is the angle corresponding to the river slope) and u_i = i-th component of the instantaneous velocity. A notation of x for horizontal (longitudinal), y for lateral coordinates and z for vertical as well as U, V, W for corresponding velocity components will be used throughout the paper.

However, in open channel flows with irregular beds, these equations are not suitable due to the highly 3D structure of the mean flow. In this case the ensemble averaged flows, at least in the very neighborhood of irregular rough boundary, is strongly spatially heterogeneous. Thus, for any vertical located at (x, y), there is a different local vertical velocity distribution $U(z)$

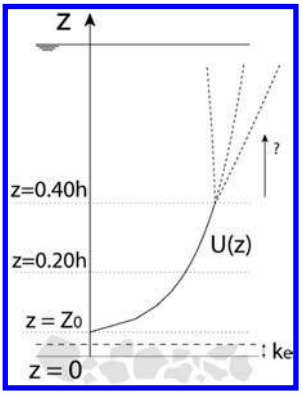

Figure 1. Equivalent logarithmic profile: definition of the roughness length and equivalent roughness.

consequence of the strong spatial variation of the 3D hydraulic conditions. It will be assumed that at some distances from the bed the local profile is defined by the logarithmic law with different parameters (Fig. 1). This assumption is supported by field measurements (Franca 2005b).

Civil and environmental engineers do not need very precise 3D details of the velocity distribution but very often 1D vertical velocity profile description is just enough for their practical applications. This 1D vertical velocity profile should be equivalent to the real 3D in terms of local averaged momentum, i.e., discharges calculated based on these profiles must be the same

$$\int_0^h \int_{y-b/2}^{y+b/2} U(x = const, y, z)\,dy\,dz = b\int_0^h \langle U\rangle(z)\,dz \tag{3}$$

for any x. <> represents spatial averaging. The theoretical level of bed ($z = 0$) is defined as the lowest level of the roughness elements, $U(x, y, 0)$ is not defined to all points belonging to the area of integration. b and h are channel width and depth, respectively.

Double-average velocity (in time and space) is defined as (Nikora et al. 2001)

$$\langle U\rangle(z) = \frac{1}{A}\iint_{D(x,y,z)} \overline{U(x', y', z' = const)}\,dx'\,dy' \tag{4}$$

where the domain $D(x, y, z)$ is a control area located parallel to the plane z = const (assumed parallel to mean bed) centered at the point (x, y). The area of the domain is equal to A, and it is wide and long enough when compared to the characteristic wavelengths of the lateral and longitudinal differences in the velocity distribution.

Longitudinal RANS equations (Eq. 2 to i = 1) may thus be subjected to spatial averaging. First the ensemble average variables (velocity and pressure) are split up into two terms, one double-averaged and

Copyright © 2006 Taylor & Francis Group plc, London, UK

one representing the deviation from this average as follows:

$$\begin{aligned} &U(x,y,z) = \langle U \rangle(z) + \tilde{u}\,(x,y,z) \quad for\ all\ (x,y) \in A, \\ &\langle \tilde{u} \rangle = 0 \\ &p(x,y,z) = \langle p \rangle(z) + \tilde{p}(x,y,z) \\ &\langle \tilde{p} \rangle = 0 \end{aligned} \tag{5}$$

where the tilde denotes the disturbance in the flow variables, i.e., the difference between the double-averaged and time averaged values. One notes that the double-averaged variables are the same in all points belonging to the area of averaging. It is convenient to relate these variables with the location of center of gravity of the area of averaging – A. Choosing appropriate sizes of averaging area, the averaging variables would be only function of the vertical coordinate inside this.

2.2 *Flow above the crest of roughness elements*

Applying Equation 5 to average the momentum and continuity equations over the roughness crests, one can obtain the so called double-averaged (in time and space) (Nikora et al. 2001) equations for conservation of momentum,

$$\langle U_j \rangle \frac{\partial \langle U_i \rangle}{\partial x_j} = g_i - \frac{1}{\rho}\frac{\partial \langle p \rangle}{\partial x_i} - \frac{\partial \langle \overline{u_i u_j} \rangle}{\partial x_j} - \frac{\partial \langle \tilde{u}_i \tilde{u}_j \rangle}{\partial x_j} + \frac{\partial}{\partial x_j}\left\langle \nu \frac{\partial U_i}{\partial x_j} \right\rangle \tag{6}$$

and double-averaged continuity equation

$$\frac{\partial \phi \langle U_i \rangle}{\partial x_i} = 0 \tag{7}$$

It is easy to show that in the z-momentum equation the vertical pressure distribution is close to hydrostatic. The x-momentum equation is simplified to,

$$\frac{\partial}{\partial y}\left(-\langle \overline{u'w'} \rangle - \langle \tilde{u}\,\tilde{w} \rangle + \nu \frac{\partial \langle U \rangle}{\partial z} \right) = g \sin\alpha + \langle W \rangle \frac{\partial}{\partial z} \langle U \rangle \tag{8}$$

After integration of Equation 8 across the boundary layer, one can obtain the formula for distribution of the total shear stresses in the form

$$\begin{aligned} &\frac{\tau_{total}(z)}{\rho} = \left(-\langle \overline{u'w'} \rangle - \langle \tilde{u}\,\tilde{w} \rangle + \nu \frac{\partial \langle U \rangle}{\partial z} \right) = \\ &ghS_f \left(1 - \frac{z}{h} \right) + \int_0^z \langle W \rangle \frac{\partial}{\partial z} \langle U \rangle dz \end{aligned} \tag{9}$$

One can realize that the shear stress in open channel flows includes the contributions of the wall shear stress (caused by pressure and gravity force) and convective inertia. The inertia force disturbs the linear distribution of shear stresses.

The total shear stress in double-averaged formulation comprises three components,: mean Reynolds (τ_t) stresses, a new stress (τ_f) (Eq. 9) called "form-induced stress" or simply "form stress" (Gimenez-Curto & Lera 1996) and mean viscous or laminar stresses (τ_v). The maximum bed shear stress has therefore three components τ_{ov}, τ_{ot}, and τ_{of} and it appears at the roughness height. At this level, the laminar shear stresses are negligible compared with two other stresses. Laminar stresses are essential only in laminar sublayer, which is rather thin in rough turbulent flows. The thickness of laminar sublayer is very difficult to estimate. Omitting the laminar stresses in Equation 9 and considering the convective inertia negligible when compared to the others, the equation of the total shear stresses can be written in the form

$$-\langle \overline{u'w'} \rangle - \langle \tilde{u}\,\tilde{w} \rangle = U^{*}{}_{e}^{\,2} \left(1 - \frac{z}{h} \right) \tag{10}$$

where $U^{*}{}_{e} = (\tau_0/\rho)^{0.5}$ is the friction velocity and $\tau_0 = \rho g h \sin\alpha$ is the bottom shear stresses. Equation 10 says that the total shear stress still varies linearly with the distance from the bed. To solve Equation 10 one has to define the first two terms of the equation. It is assumed that the sum of both terms can be modeled similarly to the Prandtl mixing length theory as follows:

$$\tau_{total} \equiv \tau_t + \tau_f = \rho l_e^2 \left(\frac{\partial \langle U \rangle}{\partial z} \right)^2 \tag{11}$$

where $l_e =$ is defined by analogy with the Prandtl's mixing length.

It is reasonable to assume that the double-averaged velocity profile can be obtained from Equation 10 with the total stresses expressed by Equation 11. Through this equation in similar way as it was done in classical hydraulics, one may get the velocity profile in the logarithmic layer in the form

$$\frac{\langle U \rangle}{U^{*}{}_{e}} = \frac{1}{\kappa_e} \ln \frac{z}{k_e} + B_e \tag{12}$$

where $U_e^* =$ friction velocity for the total shear stresses, i.e., turbulent and form stresses; $k_e =$ equivalent roughness; $\kappa_e =$ equivalent von Karman parameter; and subscript "e" represent equivalent coefficients. The relationship is only valid to flows in rough turbulent regime, i.e. for Reynolds numbers $(U^*k/\nu) > Re^*_{cr} = 70$ (Nezu and Nakagawa 1993).

3 FIELD MEASUREMENTS

The 3D ADVP field measurements were made at two different gravel-bed Swiss rivers, the Venoge and the Chamberonne, in the summer of 2003. The measurements were made on low water periods, during a single day and under stationary flow conditions (confirmed by the data from the Swiss Hydrological and Geological Services). The cross-section locations were: 120 m upstream from the Moulin de Lussery, for the Venoge; 385 m upstream from the last bridge before the lake Geneva, for the river Chamberonne. Table 1 shows the river main characteristics at the time of the measurements: where S = mean river slope; Q = discharge; h = the water depth; b = river width; Re = Reynolds number; Fr = local Froude number; D_{84} = bottom grain size for which 50% and 84% of the grain diameters are smaller. The riverbed material was sampled according to the Wolman (1954) technique.

The aspect ratio of the river (b/h) is 31.5 and 20.5 for the Venoge and Chamberonne rivers, corresponding both to shallow water or wide open-channel flows. The river slopes were determined with topographic data provided by IATE/HYDRAM (1996), for the Venoge, and by "Gesrau system" (SESA – Canton of Vaud), for the Chamberonne. The river slope and the Froude number are within the range specified by Bathurst et al. (1981) to boulder-bed rivers. The riverbed is hydraulically rough, composed of coarse gravel and randomly spaced macro-roughness elements (some of these scale with half of the water depth, $D \approx 0.5\,h$). There was no sediment transport during the measurements.

The profiles were measured across the section starting from the right riverbank ($y/W = 0$). We assumed symmetrical conditions in the river flow, and only measured across half of the river width (Fig. 2).

The 25 velocity profiles were measured in the river Venoge with a horizontal spacing of 10 to 12.5 cm, and 24 velocity profiles in the Chamberonne with a horizontal spacing of 5 to 12.5 cm. For both cases data acquisition was made during 5 minutes, which is sufficient according to Bergeron & Abrahams (1992). The profiles depth varies between 0.12 m and 0.20 m for the river Venoge and between 0.15 and 0.29 for the river Chamberonne. The actual river water depth considered for the present analysis is the correspondent to the deepest profile.

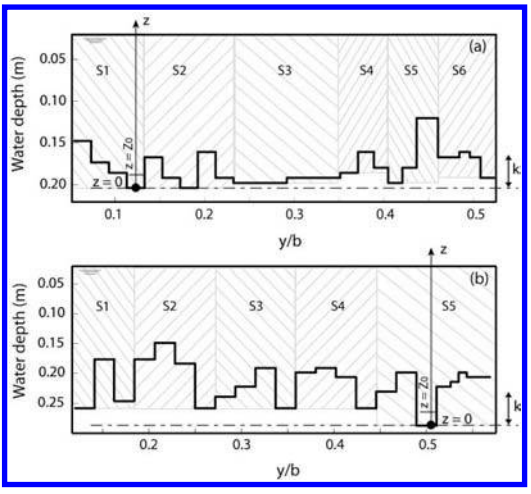

Figure 2. River bottom and length scales for parameterization of the logarithmic law. Definition of the origin of the vertical Cartesian axis. (a) River Venoge, (b) River Chamberonne.

4 INSTRUMENTATION

The deployable 3D ADVP developed at the Laboratoire d'Hydraulique Environnementale (LHE) was used for the present measurements. It allows quasi-instantaneous velocity profiling throughout the water depth, in laboratory flumes and natural rivers. ADVP time and space resolution is enough to quantitatively estimate the main turbulent quantities, within the production and inertial spectral space. A thorough description of the ADVP working principle is given in the literature (Rolland & Lemmin 1997). We used the multistatic configuration of the ADVP, where four different receivers exist to one ultra-sound emitter, providing one redundancy in the conversion of the measured Doppler shift to the 3D Cartesian space velocity components. This redundancy is used to eliminate signal noise and to control the data quality (Hurther & Lemmin 2000). A Pulse Repetition Frequency (PRF) of 2000 Hz and a Number of Pulse Pairs (NPP) equal to 32 was used for the estimation of the Doppler shift and subsequently the flow velocity. This results in an unfiltered sample frequency of 62.5 Hz. Though a low degree of dealiasing was expected on the river data given the PRF used and the flow velocity, a rectifying algorithm based no the signal time history was applied (Franca & Lemmin 2005). A metallic structure was especially conceived to the ADVP displacement in the field (Fig. 3), allowing covering a whole cross-section and the streamwise movement with a relative rapidity.

The instrumentation is kept always at the same vertical distance from the water surface, and the structure

was built to minimize the disturbance of the flow and the vibration of the ADVP.

5 FIELD RESULTS

5.1 *Mean velocity distribution*

Franca & Lemmin (2004) analyzed partially the present data and concluded that the logarithmic layer is found in the lower layers of the majority of the measured profiles. In more than 65% of the profiles, the log law can be applied without apparent deviations up to $z/\delta = 0.4$ (Fig. 4).

Using the distribution of the local Nikuradse equivalent roughness values determined from the log-law, for $B = 8.5$, Franca and Lemmin (2004) concluded that $k_{e,50}$ (defined as the equivalent roughness for which 50% of the values are higher) could be taken equal to the value D_{84} of the gravel diameter distribution (this calculation was made only for the profiles where the logarithmic law could be adjusted). The cross-section averaged values of friction velocity are 0.076 and 0.059 m/s, respectively for the Venoge and Chamberonne rivers.

Above $z/\delta = 0.40$ the mean velocity profiles show deviations from the logarithmic profile in the positive and in the negative direction of the flow. In some profiles a wake effect is detected in the lower layers of the flow, inside the roughness sublayer (Nikora & Smart 1997). This effect corresponds to the s-type velocity profiles observed in gravel-bed streams in the presence of large obstacles (Marchand et al. 1984, Bathurst 1988, Katul et al. 2002, Carravetta & Della Morte 2004, Franca 2005a). The s-profile is a direct result from the riverbed perturbation. Downstream this, a double boundary layer is formed: an inner bottom sheared log-layer exists due to the momentum redistribution throughout the water depth and lateral momentum convection around the bed obstacle. In both flows, there is a large dependency of the flow resistance on the bed forms, thus the local roughness parameterization has a strong cross-section variation. Smart (1999) refers to the dependence of roughness parameters other than grain diameter, namely on the bed forms, bed load, lateral velocity gradients and upstream conditions. Nevertheless, given the field results, the logarithmic law, properly parameterized, is still able to describe the actual velocity distribution to these flows. Franca (2005b) verified that above the roughness layer, the Reynolds shear stress distribution ($\overline{u'w'}$) is nevertheless linear with z.

5.2 *Estimation of the friction velocity from the shear stress measurements to each measured profile*

The ADVP provide us with the 3D instantaneous velocity profiles. The determination of the six Reynolds stress tensor components throughout each measured profile is thus trivial from the measured data. The measurements allow us to compute the local bottom friction velocity from the Reynolds x-z plane shear stress. Turbulent or Reynolds shear stress distribution $\tau_t(z)$ is given by:

$$\frac{\tau_t}{\rho} = -\overline{u'w'} \tag{13}$$

The vertical shear distribution follows a linear trend with slope equal to the bottom shear stress. From the friction velocity definition, the calculation of U^* comes:

$$U^{*2} = \frac{-\overline{u'w'}}{1 - z/h} \tag{14}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

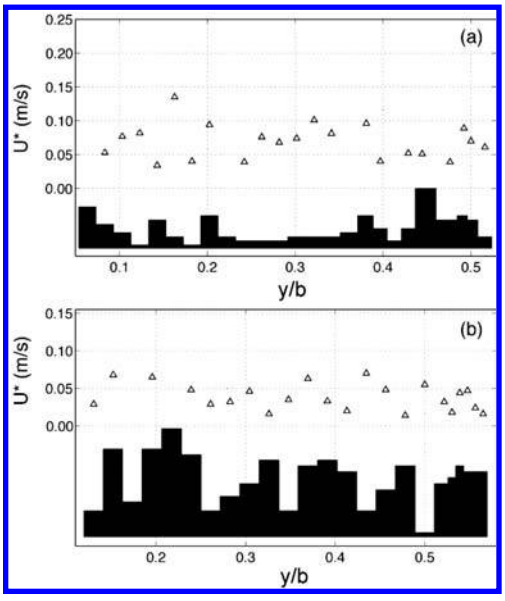

Figure 5. Bottom friction velocity U^* across the sections of the rivers Venoge (a) and Chamberonne (b), estimated from the shear stress distributions.

For both river measurements the shear stress distribution is not always linear due to the three-dimensionality and the presence of large obstacles within the flow. For the bottom friction velocity estimations, we considered only the linear layer closer to the bottom (methodology followed by Wang et al. 2003, for instance), being some of the profiles omitted. In Figure 5 we show the bottom friction velocities results for each profile. The cross-section averaged values of the friction velocity are 0.069 m/s and 0.041 m/s, respectively for the river Venoge and Chamberonne (standard deviations of 0.026 and 0.018 m/s).

In the Venoge case, the averaged friction velocity values, estimated from both the log-law with $B = 8.5$ and from the shear stress measurements, match reasonably well (within an interval error of 10%). In the Chamberonne river, however, the friction velocity estimated from the shear measurements is about 70% of the value determined by the log-law. The discrepancies show the importance of spatial-averaging in the parameterization of turbulent flows over large-scale roughness, as a means to obtain practical information on the flow.

6 PARAMETERIZATION OF THE THEORETICAL LOGARITHMIC PROFILES FOR EACH STRIPE: k_e AND B_e

The spatial averaging of shear stress measurements was made dividing both cross-sections in six and five

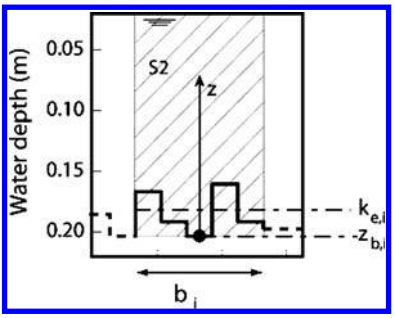

Figure 6. Example of equivalent roughness geometric definition for each cross-section stripe.

Table 2. Parameterization of the logarithmic profiles for each stripe – river Venoge.

Stripe	Profiles	h (m)	k_e (m)	U^* (m/s)	B_e (−)
1	1–4	0.147	0.030	0.071	5.5
2	5–9	0.160	0.022	0.076	5.6
3	10–15	0.191	0.030	0.073	7.0
4	16–18	0.160	0.015	0.068	9.2

Averaged values			0.026	0.069	7.5

lateral stripes, for Venoge and Chamberonne respectively (see Fig. 2). We defined equivalent stripes taking into account the wavelength of lateral changes in the velocity distribution (Fig. 6).

This way we attributed to the roughness parameter k local meaning in terms of flow disturbance. The logarithmic law (Eq. 12) was thus parameterized to each stripe, accounting for the individual parameterization of each individual profile inside the stripe. The equivalent roughness ($k_{i,e}$) was determined as the mean bed level variation inside each stripe. The friction velocity for each stripe ($U^*_{i,e}$) is the average of the several profiles, determined from Reynolds shear stress distributions (in the average process we take into account the spacing between the profiles). The equivalent geometry parameter for each stripe $B_{i,e}$ is determined from regression of Equation 12 against the measured field data (Tables 2 and 3).

The cross-section results were obtained from a weighted average using the stripe width. In Figure 7 we present the results of the logarithmic law parameterization for each stripe across the rivers.

The first noticeable remark is the difference between the B values determined for both rivers. For the river Venoge the parameter B is within the expected interval for hydraulically turbulent rough flows though near the lower limit of the interval defined by $8.5 \pm 15\%$ (Monin & Yanglom 1971). For

the Chamberonne, the value B is within the referred interval, this time near its upper limit. From Figures 5 and 7, we see that the density of the bed protuberances is different in both cases. In our opinion the protuberances density is a factor that should be taken into account in the roughness parameterization of the flow. Further studies shall be carried out where a concept of roughness density is included as a determinant variable.

7 PARAMETERIZATION OF THE CROSS-SECTION EQUIVALENT VELOCITY PROFILE

We intend to discuss the parameterization of the logarithmic law for the description of the velocity profiles, as a function of easy measurable variables to be used by practical engineers. The definition of the water depth

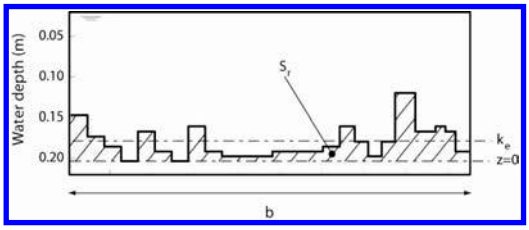

Figure 8. Example of geometric definition of the equivalent roughness using the area occupied by the bed forms – k_{e-4}.

was already referred as corresponding to the deepest measured profile. We parameterized a cross-section equivalent logarithmic profile using the discharge equality as comparison criteria between the theoretical results and the field data. The local discharge values obtained from the measured velocity profiles was compared to the averaged results obtained from the individual stripes parameterization (Tables 2 and 3). Estimates of U^* based in the shear stress measurements (Tables 2 and 3) will be used to our global cross-section parameterization.

To determine the equivalent roughness for the whole river cross-section (k_e) several empirical methods were tested and compared with our data:

$$k_{e,1} = D_{84} \quad (15a)$$

$$k_{e,2} = D_{50} \quad (15b)$$

$$k_{e,3} = S_r / W \quad (15c)$$

$$k_{e,4} = \sigma_{(h_i - h)} \quad (15d)$$

$$k_{e,5} = \sigma_D \quad (15e)$$

where S_r = area occupied by the bed forms (macro-scale gravel) above the reference level (Fig. 8); σ = standard deviation; h_i = depth of each measured profile; and D = bed grain diameter distribution. Several authors refer the value D_{84} being representative for the bottom roughness in gravel-bed rivers (Franca & Lemmin 2004, Smart 1999). Gravel riverbed forms are the result of the individual elements that constitutes the bottom (Fig. 2), hence it is believed that a higher representative diameter as the D_{84} reflect their particular interference on the flow.

The determination of the equivalent velocity profile parameters is made considering the unitary discharge in the river. The real unitary discharge ($q_r = Q/W$, discharge/river width) was calculated directly from the velocity data. The theoretical unitary discharge (q_t) was calculated from the logarithmic model for the velocity distribution, which uses the roughness length as parameter.

$$q_t(Z_0 < z < z_u) = \int_{Z_0}^{z_u} u_t(z)dz = \int_{Z_0}^{z_u} \frac{U^*}{\kappa} \ln\left(\frac{z}{Z_0}\right) dz \quad (16)$$

Table 4. Parameterization of the logarithmic equivalent profiles for each river.

River	q_r (m^2/s)	U^* (m/s)	h (m)	Z_0 (mm)	K_e (mm)	B_e (−)
Venoge	0.016	0.069	0.20	1.4	$K_{e,1} = 74$	9.7
					$K_{e,2} = 40$	8.2
					$K_{e,3} = 24$	6.9
					$K_{e,4} = 20$	6.5
					$K_{e,5} = 23$	6.8
Chamberonne	0.018	0.041	0.29	1.0	$K_{e,1} = 81$	10.8
					$K_{e,2} = 49$	9.6
					$K_{e,3} = 70$	10.5
					$K_{e,4} = 34$	8.7
					$K_{e,5} = 22$	7.7

The roughness length represents the origin of the logarithmic fit to the actual flow velocity and z_u a position near the water level. The integration is made in a layer where the velocity profile is closer to logarithmic ($z_u/h \approx 0.20$). The roughness length can easily be related with other log-law parameters by

$$Z_0 = e^{-B\kappa} k_e \tag{17}$$

Making $q_t = q_r$, we have the non-linear equation which allows the determination of the cross-section equivalent roughness length as a function of the real local unitary discharge:

$$q_r(Z_0 < z < z_u) = \frac{U^*}{\kappa}\left[Z_0 + 0.2h\left(\ln\left(\frac{z_u}{Z_0}\right) - 1 \right)\right] \tag{18}$$

In Table 4 we present the summary of the parameterization of the logarithmic velocity for both rivers.

Considering the parameter B equal to the referenced value of 8.5, the adequate equivalent roughness to be considered would correspond to Equations (15b) and (15d), respectively to the Venoge and Chamberonne rivers. Both correspond to mean values of the variations of the bottom levels. In this case the individual gravel grains are the responsible for the bottom forms. Again we have different conclusions to the different rivers, indicating that an extra parameter representing the bed level variability could be important in the roughness parameterization.

8 SUMMARY

RANS equations are not suitable for irregular rough boundary flows especially in near-bed region where flows are highly 3D and heterogeneous. Boundary irregularities generate perturbations in ensemble-averaged flows, which have been already detected experimentally in steady flows. The velocity profiles are determined by the effects of these disturbances. In order to smooth out the flow irregularities, a special, spatial averaging operation has to be applied to RANS equations. It results in the double-averaged (in both time and space) Navier-Stokes (DANS) equations, which are used to describe the uniform vertical velocity profile. To solve the double-averaged equations we define the so called "form-induced stress" (τ_f). In this text we presented the DANS equations and derived subsequently on equivalent logarithmic law to describe the vertical distribution of the double-averaged streamwise velocity. With field results we discuss the parameterization and definition the equivalent velocity profile.

We estimated cross-section averaged values of friction velocity using both the adaptation of a log-law to the measured velocity profiles, and the shear stress measurements. The results showed discrepancies, especially in the Chamberonne case, emphasizing the practical importance of applying the spatial-averaging techniques to extreme rough cases as the present ones.

The cross-sections were divided in several stripes and to each an equivalent logarithmic velocity profile was derived. From the overall analysis of the results we concluded that the roughness density (or protuberances density) seems to be a determinant factor in the roughness parameterization of the flow.

The use of a variable representing the mean variation of the river bottom constitutes the more indicated estimation for the equivalent roughness. Given the nature of the river, the individual gravel grains are the responsible for the bottom forms.

The original derivation of the time-averaged velocity logarithmic profile was carried out under idealized conditions of open-channel uniform flow and flat beds with fairly homogeneous bed roughness distribution. The analysis of flows with irregular bed as in Venoge and Chamberonne rivers is only possible using space averaged techniques to smooth out the large gradients in the turbulent flow structure.

9 CONCLUSIONS

The presented theoretical background of the equivalent velocity profile allows for adopting the classical log-law to describe the vertical velocity distribution in open-channel flows over irregular bed roughness.

The idea of equivalent velocity profile is supported by river velocity measurements, where beyond a certain distance from the bed the velocity distribution is fairly logarithmic. The velocity distribution is in this case totally defined by the friction velocity and two other parameters characterizing the river bottom, the equivalent roughness k_e, and the dimensionless geometric coefficient B_e.

Equivalent parameters of the logarithmic distribution of the velocities constitute a type of averaged

values of local velocity parameters such as the height of roughness elements disturbing the momentum flux, bed shear stresses and the grain geometry.

Admissible and inadmissible simplifications of pollution transport equations

P.M. Rowiński & M.B. Kalinowska
Institute of Geophysics, Polish Academy of Sciences, Warsaw, Poland

ABSTRACT: In general, pollution transport should be represented by 3D advection-diffusion equations but solution of such equations requires a lot of information which in most cases is not available and is computationally very expensive. Therefore different simplifications have been proposed, they mostly pertain to the reduction of the dimensionality of the problem and omitting of the terms considered as small in comparison to others. In practice very often the assumptions that allow for such simplifications are forgotten and therefore the obtained results may appear to be of disputable validity. An example can be the use of a diagonal dispersion tensor in the governing equations even in geometrically complex (and hence anisotropic) situations. Such treatment introduces unacceptable errors which very often are reduced by artificial manipulation of various coefficients. In this paper different model simplifications are discussed and the emphasis is put on their justification or disapproving, depending on the particular context of problem under consideration.

1 INTRODUCTION

Water quality predictions in rivers require development of a model that is able to capture the basic physical features of the process and depends only on the variables that are available in case under consideration. A very crucial and often made assumption is the limitation to the neutrally buoyant substances. The analysis of such micropollutants like heavy metals (e.g. mercury, cadmium, lead) would go along different line. The reason is that these substances may be present in three states in the system considered: in dissolved form as well as in solid phase mostly present in the suspended solids and in the sediment below. In case when these pollutants are in the solid form the relevant description of their transport should appeal to the dynamics of two-phase flows. The solid grains may move in the form of rolling, saltation and suspension. The manner of their motion depends on many factors, like the position at which the particle initiates to move, its size, shape, density relative to the carrier fluid, as well as turbulent properties of the flow. In general the way in which a particle moves is a direct effect of the role and significance of particular forces acting on a grain and also the variability of other solid particles concentration in its neighborhood. When considering the motion of such particle in a Lagrangian frame all the mentioned forces would have to be considered, namely the drag force, the drifting force due to turbulence, lift force and the combination of the weight and buoyancy of the particle. Additionally some supplementary model of a stochastic nature, responsible for the collision of the considered particle with solid boundaries would have to be built.

Let us assume that the considered mixture is passive that is one, in which the fluid-particle interaction does not affect the dynamics of the flow. Otherwise one would have to include momentum considerations in order to properly represent certain two-phase flows.

Further limitation is the consideration of the fate of solutes only, i.e. the substances that are dissolved in the water. Throughout the paper, we use the macroscopic treatment, i.e. the theory of continuum. Because of practical importance, we do not care about the motion of individual particles of the matter and are interested only in the resultant effects due to the motion of a large number of particles. It is possible because in practical problems the smallest length scales of interest are much larger than the distance between molecules.

In principle the physical processes during the transport of any constituent are three dimensional and should be described by three dimensional (3D) advection-diffusion equation together with the description of 3D velocity field. Advection-diffusion equation (ADE) already imposes so-called one-way coupling, i.e. the particles dispersed in a carrier flow have negligible effect on turbulence. It means that particle spread in this regime depends on the state of turbulence but due to the negligible concentration of the particles the momentum transfer from the particles to the turbulence has an insignificant effect on the flow (Elghobashi 1994). In most cases it is an acceptable assumption. Three dimensional ADE is, however, still too demanding in respect to data and the data for such

Copyright © 2006 Taylor & Francis Group plc, London, UK

models are mainly available for academic purposes. Therefore usually further simplifications are sought in practice.

2 TRANSPORT EQUATIONS

In general three-dimensional case, construction of the mass transport equation for a dissolved quantity requires the application of the Reynolds hypothesis allowing for the decomposition of the velocities and concentrations into mean and fluctuating values, and further additional information about the turbulent mass flux, for example based on a linear relationship between the turbulent flux and the gradient of the mean concentration. The main obstacles to progress in that approach is the lack of reliable theory which relates the spatial variation of turbulent diffusion coefficients to flow and boundary conditions, mathematical difficulties in solving the transport equation for variable diffusion coefficients and realistic spatial domains. Another important problem is the lack of knowledge of the realistic detailed 3D velocity field. 3D approach is probably suitable in the vicinity of the injection point in the river when one is interested in studying the heterogeneity in vertical and lateral directions. Such strong heterogeneity may occur due to the variability of river geometry like meanders, or the ones caused by fairways and weirs.

Various simplifications of the model are necessary to tackle real life problems. One option is to eliminate one or two dimensions in cases where such operation is justified by the conditions in the considered river reach. This elimination may be realized by relevant averaging of the governing equations (both hydrodynamics and mass transfer equation at the same time). It is usually the case that in the mid-field region the governing equations may be averaged over the depth giving two-dimensional models. In the far field, in case when the river geometry allows doing this, one is mostly interested in the cross-sectionally averaged concentrations. The governing equations may be then averaged over the cross-section, which results in a one-dimensional model of the spread of the constituent under consideration. Two-dimensional case will be considered in more detail in the next section. Let us therefore briefly discuss the problem of 1D modeling. A long tradition in the application of the longitudinal dispersion model exists. Such model is very useful for designing outfalls or water intakes and first of all for evaluating risks from, for example accidental releases of hazardous contaminants. 1D models are the easiest in application and not such detailed knowledge about the hydraulic characteristics of the considered reach is required as in case of 2D and 3D approaches. One has to realize, however, about the restrictions that 1D models are burdened (Rutherford, 1994; Sukhodolov et al. 1998, Jirka & Volker 2005). 1D model in the traditional Fickian form applies only in relatively simple river reaches (in terms of the geometry) and only after some initial mixing period (the solute concentration should be well distributed over the channel width). A widely applied criterion for the validity of the equation is that the time from the instant of release t should be greater than $0.4\,B^2/E_L$ where B is the channel width and E_L is the longitudinal dispersion coefficient. The advection-dispersion equation has been successfully applied for many real cases; nevertheless very often the questions about its applicability arise. The tail of a solute tracer pulse is often more pronounced than can be accounted for by the traditional advection-dispersion model. A common method for simulating these long tails has been to allow for storage zones along the stream channel (Czernuszenko et al. 1998, van Mazijk & Veling 2005). These storage zones are assumed to be stagnant relative to the longitudinal flow of the stream and to obey a first-order mass transfer type of exchange relationship. Very often a quicker decrease of the concentration maximum than follows from Fickian equation is observed. Also a nonlinear growth of the concentration distribution variance and dependence of the dispersion coefficient on time has been often manifested in experimental studies.

3 TWO-DIMENSIONAL TRANSPORT EQUATION

As mentioned before, in situations where the concentration is rather uniform along each individual vertical line, the depth averaging of every quantity is made to reduce the dimensionality of the problem. As a result the depth-averaged, two-dimensional advection-diffusion transport equation is readily obtained in the form:

$$h\left(\frac{\partial c}{\partial t}+v_x\frac{\partial c}{\partial x}+v_y\frac{\partial c}{\partial y}\right)= \frac{\partial}{\partial x}\left(hD_{xx}\frac{\partial c}{\partial x}+hD_{xy}\frac{\partial c}{\partial y}\right)+\frac{\partial}{\partial y}\left(hD_{yy}\frac{\partial c}{\partial y}+hD_{yx}\frac{\partial c}{\partial y}\right); \quad (1)$$

where t = time; (x, y) = longitudinal and transverse coordinates; (v_x, v_y) = depth-averaged velocities in x and y directions; $c(x, y, t)$ = depth-averaged solute concentration; h = local depth; D_{xx}, D_{xy}, D_{yx}, D_{yy} = dispersion coefficients. One needs to remember that new dispersion fluxes account for both the non-uniformity of velocities over the depth of flow as well as turbulent diffusion. In general the dispersion coefficients in Cartesian coordinates form a non-diagonal dispersion tensor:

$$\mathbf{D}=\begin{bmatrix} D_{xx} & D_{xy} \\ D_{yx} & D_{yy} \end{bmatrix}. \quad (2)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

In case when the flow direction is parallel to the x-axis, the off-diagonal elements of the dispersion tensor vanish. In such case the transport equation (Eq. 1) can be simplified to the form:

$$h\left(\frac{\partial c}{\partial t}+v_x\frac{\partial c}{\partial x}+v_y\frac{\partial c}{\partial y}\right)= \frac{\partial}{\partial x}\left(hD_{xx}\frac{\partial c}{\partial x}\right)+\frac{\partial}{\partial y}\left(hD_{yy}\frac{\partial c}{\partial y}\right). \quad (3)$$

However, in the realistic cases when an actual river is described, it is impossible to choose a coordinate system with the x-axis parallel to the flow direction for all points of the flow, and hence the full version of the transport equation (Eq. 1) should be used. Literature survey shows that the simplified form of the model is often used, even in very complex situations without any special justification. In the frame where the dispersion tensor is diagonal, D_{xx} element is marked D_L and refers to longitudinal dispersion coefficient, and D_{yy} is marked D_T and refers to transverse dispersion coefficient. D_L and D_T can be measured experimentally. There are numerous phenomenological formulae for calculating dispersion coefficients in literature (e.g. Rutherford 1994). In principle dispersion coefficients depend on channel geometry and turbulent flow structure and their estimation may become a very difficult task.

The use of the same coordinate system for the whole channel may lead to misleading results. To avoid this problem very often transport equations are formulated in a curvilinear coordinate system but it creates other sorts of problems. This matter is discussed e.g. in (Holley & Jirka 1986). In case of Cartesian coordinate systems for some parts of the channel it maybe necessary to use all the dispersion tensor components:

$$\mathbf{D}_D=\begin{bmatrix}D_L & 0\\ 0 & D_T\end{bmatrix}\rightarrow \mathbf{D}=\begin{bmatrix}D_{xx} & D_{xy}\\ D_{yx} & D_{yy}\end{bmatrix}. \quad (4)$$

Mathematically correct way of getting the full tensor $\mathbf{D}$ from the diagonal form $\mathbf{D}_D$ is tensor rotation with the rotation matrix $\mathbf{R}$:

$$\mathbf{D}=\mathbf{R}(\alpha)\cdot\mathbf{D}_\mathbf{D}\cdot\mathbf{R}^{-1}(\alpha); \quad (5)$$

where: $\alpha =$ angle between flow direction and x-axis;

$$\mathbf{R}=\begin{bmatrix}\cos\alpha & -\sin\alpha\\ \sin\alpha & \cos\alpha\end{bmatrix}.$$

It yields:

$$D_{xx}=D_T+D\frac{v_x^2}{v^2};$$
$$D_{xy}=D_{yx}=D\frac{v_x v_y}{v^2}; \quad (6)$$
$$D_{yy}=D_T+D\frac{v_y^2}{v^2};$$

where: $D=D_L-D_T$, $v=\sqrt{v_x^2+v_y^2}$.

For brevity this full method will further be called *rotation*.

Due to the fact that the simplified form of the transport equation is commonly used, a number of approximated methods of the tensor transformation (without off-diagonal components) are reviewed below to reveal under what conditions such simplifications are admissible. The common feature of all these methods is that the tensor stays diagonal after the transformation. A short description of various simplifications used *correctly* or *incorrectly* is given below.

3.1 *Quasi rotation*

As mentioned above a correct way of the rotation of the dispersion tensor is given by Equation 5. To get the diagonal tensor the off-diagonal elements D_{xy}, D_{yx} are often arbitrarily set to 0. Then tensor elements become:

$$D_{xx}=D_T+D\frac{v_x^2}{v^2};$$
$$D_{xy}=D_{yx}=0; \quad (7)$$
$$D_{yy}=D_T+D\frac{v_y^2}{v^2}.$$

3.2 *Vector-like rotation*

D_L and D_T elements are considered to form a vector.

$$\mathbf{D}_V=\begin{bmatrix}D_L\\ D_T\end{bmatrix}\rightarrow \mathbf{D}=\begin{bmatrix}D_{xx}\\ D_{yy}\end{bmatrix}. \quad (8)$$

Such vector is based on longitudinal and transversal dispersion coefficients, D_L and D_T. The resulting vector is rotated according to the vector rotation rule:

$$\mathbf{D}=\mathbf{R}(\alpha)\cdot\mathbf{D}_V. \quad (9)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

If any element of the vector turns out to be negative an absolute value is taken instead. Finally transformed dispersion components are:

$$\begin{aligned} D_{xx} &= \left| D_L \frac{v_x}{v} - D_T \frac{v_y}{v} \right|; \\ D_{xy} &= D_{yx} = 0; \\ D_{yy} &= \left| D_L \frac{v_y}{v} + D_T \frac{v_x}{v} \right|. \end{aligned} \tag{10}$$

3.3 *Identity transformation*

In this case the considered dispersion tensor is not transformed at all. Independently from the orientation of the coordinate system the tensor elements are always the same:

$$\begin{aligned} D_{xx} &= D_L; \\ D_{xy} &= D_{yx} = 0; \\ D_{yy} &= D_T. \end{aligned} \tag{11}$$

This is actually an approach very often applied in practice, usually without consciousness of the committed error. Authors just omit inconvenient terms in transport equations, even if the considered geometry does not allow for that.

Each simplified approach introduces some errors. Further in the paper the differences between the solutions of the simplified equation and the analytical solution for the simple case where the full equation can be solved, will be shown. It allows to judge under what conditions the assumed simplifications are admissible.

4 COMPUTATIONAL TESTS

Computations were performed away from the boundaries for a straight, rectangular channel (Fig. 1) forming different angles α with the axis of abscissa. Respective computer program was created in C++ computing language and compiled under Linux Red Hat operating system. Visualization of results was done with use of an Object-Oriented Data Analysis Framework ROOT – the program created in CERN – European Organization for Nuclear Research (Brun & Rademakers 1996). For numerical solutions of the transport equation various finite differences methods have been applied. Two of them (Crank Nicolson and Upwind schemes) have been compared in (Kalinowska & Rowiński 2004). The results presented herein were obtained by means of Alternating Direction Implicit style scheme (Douglas 1955, Peaceman & Rachford 1955). This scheme is stable, accurate and relatively fast.

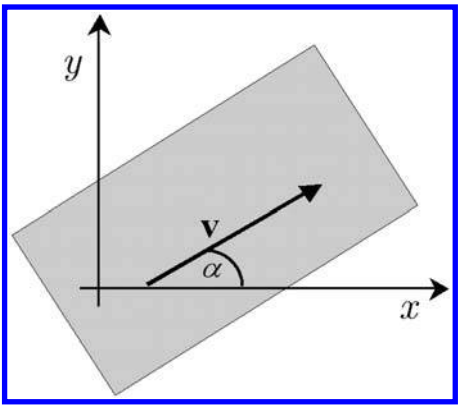

Figure 1. Scheme of straight, rectangular channel, used for computations.

For simplicity in the following tests it was assumed that velocity was uniformly distributed across the channel and equal to $v = 0.15$ m/s, transversal velocity was zero and the depth was constant in the whole channel. The computational time step was assumed as $\Delta t = 1$ s, whereas the grid spacing was $\Delta x = \Delta y = 1$ m. Dispersion coefficients were set as: $D_L = 0.75$ m^2/s, $D_T = 0.1$ m^2/s.

Table 1 provides the values of dispersion coefficients evaluated in the framework of all discussed methods. The differences between those coefficients are small only for angles close to 0° and 90° (with exception of identity transformation). It is worth mentioning the significant values of the "off-diagonal" values of dispersion elements in case of non-trivial angles α.

It is not meaningless how the solute is introduced into the flow and therefore instantaneous and continuous releases will be treated separately in the following numerical tests.

4.1 *Pulse release*

With the initial condition set as a Dirac delta function and with constant velocity and dispersion coefficients, the solution of 2D advection-diffusion equation (Eq. 1), away from the boundaries, is in the form of 2D Gaussian distribution (Smith & Yongming, 2001):

$$c(\mathbf{x},t) = \frac{M}{2\pi\sqrt{4t^2 D}} \exp\left\{ -\frac{(x-\mu_x)^2}{4tD/D_{yy}} \right\} \exp\left\{ -\frac{(y-\mu_y)^2}{4tD/D_{xx}} \right\} \exp\left\{ \frac{(x-\mu_x)(y-\mu_y)}{2tD/D_{xy}} \right\} \tag{12}$$

where: M is the mass released at a point (x_0, y_0) and time $t = 0$; $\mu_x = x_0 + v_x t$; $\mu_y = y_0 + v_y t$; $D = D_{xx} D_{yy} - D_{xy}^2$.

Table 1. Dispersion coefficients for different angles, calculated using different methods.

Angle α	Method of calculation											
	Rotation			Quasi rotation			Vector-like rotation			Identity transformation		
	D_{xx}	D_{xy}	D_{yy}	D_{xx}	D_{xy}	D_{yy}	D_{xx}	D_{xy}	D_{yy}	D_{xx}	D_{xy}	D_{yy}
0°	0.75	0	0.1	0.75	0	0.1	0.75	0	0.1	0.75	0	0.1
5°	0.745	0.056	0.105	0.745	0	0.105	0.738	0	0.165	0.75	0	0.1
10°	0.730	0.111	0.119	0.730	0	0.119	0.721	0	0.229	0.75	0	0.1
15°	0.706	0.162	0.143	0.706	0	0.143	0.698	0	0.290	0.75	0	0.1
30°	0.587	0.281	0.262	0.587	0	0.262	0.599	0	0.461	0.75	0	0.1
45°	0.425	0.325	0.425	0.425	0	0.425	0.460	0	0.601	0.75	0	0.1
60°	0.262	0.281	0.587	0.262	0	0.587	0.288	0	0.699	0.75	0	0.1
90°	0.1	0	0.75	0.1	0	0.75	0.1	0	0.75	0.75	0	0.1

All calculation made for $D_L = 0.75$ and $D_T = 0.1$;
Values are round off to the nearest thousandth.

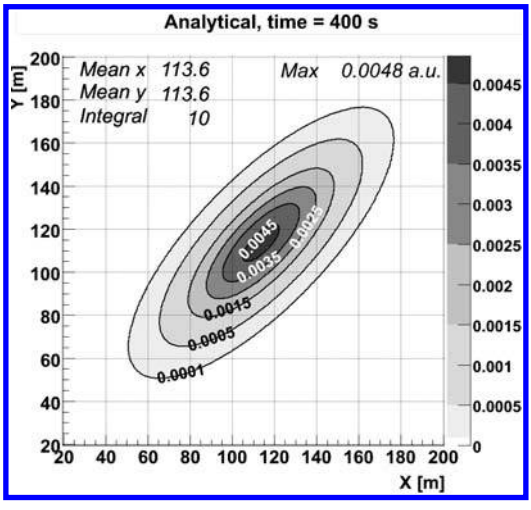

Figure 2. Analytical solution for the pulse release of the substance after 400 s from the release, $\alpha = 45°$.

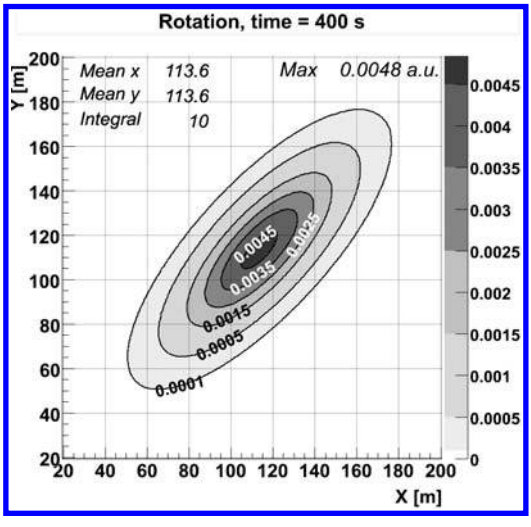

Figure 3. Numerical solution by means of full tensor rotation for the pulse release after 400 s, $\alpha = 45°$.

In our case the mass ($M = 10$ *arbitrary units*) has been injected instantaneously at a point $x_0 = 50$ m, $y_0 = 50$ m. For numerical simulations as an initial concentration (pulse release), the analytical solution after 200 seconds has been taken. In Figures 3 to 10 the results after 400 time steps (after elapsing 400 seconds from the initial time instant) of numerical simulation have been presented. One can compare these results with the analytical solution shown in Figure 2.

All the methods provide identical results as the analytical solution in cases when the angle formed between the channel and the x-axis is equal to 0 or 90° (the only exception is the identity transformation method under 90°). In other cases ($0° < \alpha < 90°$) only the method with the applied full dispersion tensor gives the same result as the analytical method. Figures 3 to 10 reveal most extreme situation when $\alpha = 45°$ – then the differences with the analytical solution are most pronounced. It is worth to note that the difference between the analytical solution and the simplified solutions depend on both the selected method of the transformation of the dispersion tensor and on the angle α. Identity transformation causes that the maximum difference between the analytical solution and the simplified one increases together with the increase of α (Fig. 11) whereas quasi rotation makes that difference symmetrical in relation to $\alpha = 45°$ and that difference diminishes close to $\alpha = 0°$ and $\alpha = 90°$. Vector-like rotation method produces still larger differences (there are small only for angels close to 0° and 90°). That difference for the full tensor rotation method is of the order of 10^{-5} to 10^{-6} and is not visible on the plot.

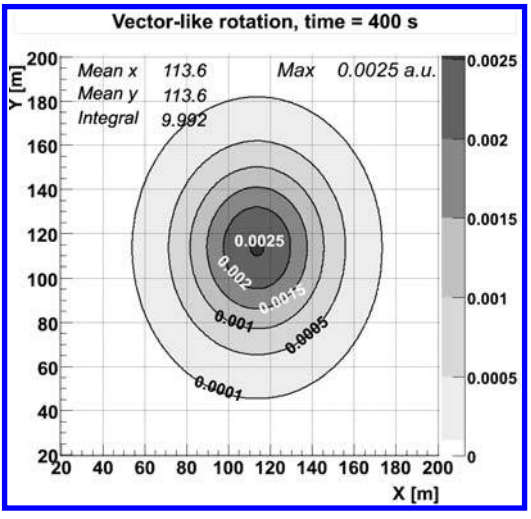

Figure 7. Numerical solution by means of vector-like rotation for the pulse release after 400 s, $\alpha = 45°$.

Environmental criteria cause that information about the maximum concentration of the solute is of special importance. Figure 12 shows the relation between the maxima of concentration obtained with the use of the described methods and the angle α. It is crucial that the maxima of the solute concentration are transformed in a correct way (in respect to their location, not value) independently of the method, which is readily seen in Figures 3 to 10 (note Mean x and Mean y). But the values of those maximum concentrations are very much determined by the method, especially for the angles remote from 0 and 90 degrees. The method with full dispersion tensor as well as the one with identity transformation also provide good estimates of the values of maximum concentration (which in case of the analytical solution for the assumed input data was equal to 0.0048 a.u.). Those observations show that when the investigated problem relates mostly to the maximum values of concentrations, the freedom in the choice of the method is much larger, which may save computational cost. The modeler, however, has to remember that the simplified methods will not provide a reliable pattern of the solute spread in the channel.

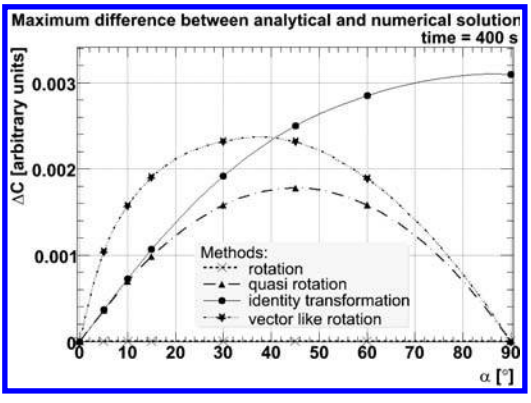

Figure 11. Maximum difference between numerical and analytical solutions for different methods of the dispersion tensor transformations for the pulse release. The difference is plotted as a function of the angle α.

4.2 *Continuous release*

In this case the boundary condition is given in the form of a continuous release at the rate 1[a.u.] per second. The source is located at the point $x_0 = 100$ m, $y_0 = 100$ m. An analytical solution is not achievable in such case so the results of the numerical simulations by means of the simplified methods will be compared with the method in which a complete dispersion tensor rotation is performed. Again the results for the worst case, when the channel forms the angle of 45° with the x-axis, are presented. Figures 13–16 present a snapshot of the numerical results at time instant 1000 s after the discharge of the solute. It is easily seen that all the simplified methods produce much more widespread plume and in case of the so-called identity transformation of dispersion tensor, the plume tends to bend towards one edge. It is again very interesting to judge what information can be gained on the maxima of the solute concentration with use of different methods and for different angles α. As expected, all methods (but identity transformation method) give exact values of the maximum concentration for $\alpha = 0°$ and $\alpha = 90°$ (identity transformation produces true results only

when $\alpha = 0°$). Maximum concentration versus angle α in this case for all discussed methods are presented in Figure 17. Note that the error in case of the identity transformation increases with the increase of the angle α and achieves the largest value when $\alpha = 90°$. The noticeable slight oscillations in the solutions with the full dispersion tensor are associated with the method of discretization of the concentration values in a rectangular mesh. Each method causes that the maximum concentration stabilizes at a different level (Figs. 18a–18c) and the differences with the general method are largest at the angle equal to 45°. It shows that in case of continuous release the information about maximum

concentrations can be misleading when the simplified methods are applied.

5 CONCLUSIONS

A common practice in water quality modeling is the simplification of the original equations in order to

be able to tackle a real-life problem with the achievable data. Simplifications are usually justified under a set of additional assumptions, which very often are ignored in considerations. It very often leads to misleading, loaded with important errors or even totally wrong results. This study clearly shows that care has to be taken when a particular version of a transport equation is applied to a specified problem. Special attention has been paid to the often-encountered practice of neglecting the mixed derivatives in the transport equations independently of the complexity of the domain of computations. In principle such simplified methods are applicable for pulse releases when one is interested in maximum concentrations only or when α is small and varies insignificantly along the channel.

Fundamental characteristics of high velocity flows in a sinuous meandering channel in the vicinity of resonance

T. Hosoda & M. Nishihama
Dept. of Urban Management, Faculty of Engineering, Kyoto University, Kyoto, Japan

ABSTRACT: Fundamental characteristics of high velocity flows in a sinuous meandering channel were investigated theoretically and experimentally. It was shown that the flow characteristics can be classified into two patterns, i.e., out-of-phase and in-phase, by the resonance relation between water surface and channel meandering based on the solutions of the linearized shallow water equations. The experimental results agree well with the theoretical findings within the limited range of flow conditions. We also carried out the numerical simulations by using a shallow water flow model to clarify the non-linear features of water surface profile patterns in the vicinity of the resonance relation. The calculated results of water surface profile were visualized, and compared with the experimental results to verify the numerical model. The calculated results showed some fundamental characteristics such that the phase lag between water surface variations along the side wall and the sinuous channel becomes around 90 degree in the neighborhood of the resonance relation.

1 INTRODUCTION

Fundamental characteristics of high velocity flows in a sinuous open channel (refer to Figure 1) have been investigated by many researchers of hydraulics and river engineering as a typical model for meandering rivers with point bars. Engelund (1974) derived the linear solution of shallow flow equations in a sinuous channel to calculate the erodible bed topography around channel bends. Ikeda, Parker & Sawai (1981) also utilized the solution of the shallow flow equations to investigate the initiation of river meandering. It can be noted that the resonance relation between water surface and channel meandering is not included in the solution that Engelund and Ikeda et al. used, because the inertia terms of the momentum equation in the transverse direction are neglected. Note that resonance in this paper doesn't mean the response between channel meandering and bed topography.

Hasegawa (1980) derived the approximate solution of the linearized shallow flow equations with the inertia terms in the momentum equation along the transverse direction using the Galerkin method to investigate the response of bottom bed to channel meandering. Blondeaux & Seminara (1985) derived the complete linear solution using the same basic equations for the same purpose as Hasegawa (1980). They also derived the solution for the bottom topography combining the sediment transport equation with the shallow flow equations. They claimed that the resonance between channel meandering and bed topography can be explained by the solution and the resonance relation between water surface and channel meandering is also included in the solution. However, since the flow regime near the resonance relation of water surface is super-critical, the flow behaviors near the resonance were not necessary taken into account in the studies of bed topography in meandering channels.

Hosoda (1999) studied the fundamental characteristics of high velocity flows in a sinuous channel using hydraulic experiments. Based on the solutions of the linearized shallow water equations, it was shown that the flow patterns can be basically classified by the resonance relation between water surface and channel meandering. It was shown that the experimental results agreed well with the theoretical findings within the limited range of flow conditions.

In this study, we carried out numerical simulations by using shallow flow equations to clarify the non-linear response of water surface profile near the resonance relation. The calculated results of water surface profile were visualized, and compared with the experimental results to verify the numerical model. It was pointed out that a typical water surface pattern with hydraulic jump appears near the resonance when the inclination of the flume increases.

2 CLASSIFICATION OF FLOW PATTERNS BASED ON THE LINEAR THEORY

2.1 *Summary of linear theory*

For the sake of easy understanding, a summary of derivation process for the simplified linear theory on

Copyright © 2006 Taylor & Francis Group plc, London, UK

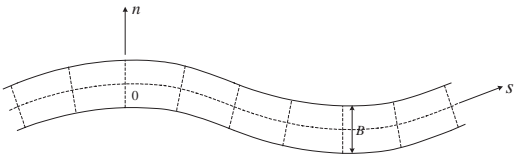

Figure 1. Plan form of a sinuous open channel.

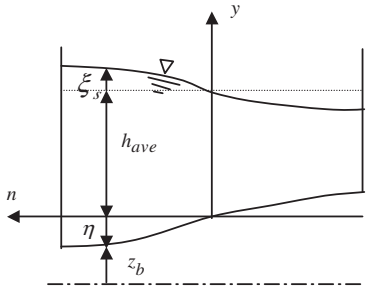

Figure 2. Cross-sectional view of a sinuous open channel.

the response of water surface to channel meandering is presented below.

2.1.1 *Basic equations*

Referring to Figures 1 and 2, the common shallow flow equations, which consist of the continuity equation and the momentum equations, based on the curvilinear orthogonal coordinates are described as follows.

$$\frac{r_0}{r_0+n}\frac{\partial hu_s}{\partial s}+\frac{\partial hu_n}{\partial n}+\frac{hu_n}{r_0+n}=0 \tag{1}$$

$$\frac{r_0}{r_0+n}u_s\frac{\partial u_s}{\partial s}+u_n\frac{\partial u_s}{\partial n}+\frac{u_su_n}{r_0+n}= \frac{r_0}{r_0+n}\left(-g\frac{\partial \xi_s}{\partial s}+g\frac{\partial z_b}{\partial s}\right)-\frac{\tau_{bs}}{\rho h} \tag{2}$$

$$\frac{r_0}{r_0+n}u_s\frac{\partial u_n}{\partial s}+u_n\frac{\partial u_n}{\partial n}-\frac{u_s^{\,2}}{r_0+n}= -g\frac{\partial \xi_s}{\partial n}-\frac{\tau_{bn}}{\rho h} \tag{3}$$

where (s,n): orthogonal curvilinear coordinates, (u_s,u_n): depth averaged velocity vectors in the (s,n) directions, h: depth, ξ_s: water surface elevation, z_b: bottom elevation, (τ_{bs},τ_{bn}): bottom shear stress vectors, r_0: curvature radius along the channel center line.

The sine-generated curve defined by Eq. (4) is assumed as the line of the channel centerline.

$$\frac{1}{r_0}=\frac{1}{R}\cos\left(\frac{2\pi s}{L}\right) \tag{4}$$

where R: minimum curvature radius at the apex of the center line, L: wave length of sinuous channel.

In the previous theoretical studies, the bottom shear stresses are evaluated by the following formulas with friction coefficient.

$$\frac{\tau_{bs}}{\rho}=c_f u_s\sqrt{u_s^{\,2}+u_n^{\,2}},\ \frac{\tau_{bn}}{\rho}=c_f u_n\sqrt{u_s^{\,2}+u_n^{\,2}} \tag{5}$$

where c_f: friction coefficient.

2.1.2 *Linearized equations*

Using the bottom slope along the channel center line as $I_0\approx-\frac{\partial z_b}{\partial s}$, the normal depth, h_0, and the averaged velocity, U, are defined by the following equations.

$$gI_0=c_f\frac{U^2}{h_0},h_0=\frac{q}{U} \tag{6}$$

where q: unit width discharge (discharge divided by channel width).

Firstly, the basic equations are transformed into a non-dimensional form using the following non-dimensional variables.

[definition of non-dimensional variables]

$$u_s'=\frac{u_s}{U},u_n'=\frac{u_n}{U},h'=\frac{h}{h_0},\xi_s'=\frac{\xi}{h_0},\eta'=\frac{z_b}{h_0},$$
$$s'=\frac{s}{h_0},n'=\frac{n}{h_0},\nu=\frac{h_0}{R},\lambda=\frac{2\pi h_0}{L},Fr_0=\frac{U}{\sqrt{gh_0}}$$

Then, the linearized equations, Eqs. (8)–(10), are derived by substituting the expressions in Eq. (7) into Eqs. (1), (2) and (3).

$$u_s'=1+\nu u_1,\ u_n'=\nu v_1,\ h'=1+\nu\left(\xi_{s1}+\eta_1\right) \tag{7}$$

$$\frac{\partial u_1}{\partial s'}+\frac{\partial\left(\xi_{s1}+\eta_1\right)}{\partial s'}+\frac{\partial v_1}{\partial n'}=0 \tag{8}$$

$$\frac{\partial u_1}{\partial s'}+\frac{1}{Fr_0^{\,2}}\frac{\partial \xi_{s1}}{\partial s'}+c_f\left\{2u_1-\left(\xi_{s1}+\eta_1\right)\right\}= -c_f n'\cos\lambda s' \tag{9}$$

$$\frac{\partial v_1}{\partial s'}+\frac{1}{Fr_0^{\,2}}\frac{\partial \xi_{s1}}{\partial n'}+c_f v_1=\cos\lambda s' \tag{10}$$

For simplicity, the prime sign ′ indicating the non-dimensional variables henceforth omitted.

2.1.3 *Approximate linear solutions*

Hasegawa (1980) derived the approximate solutions by using the Galerkin method. Blondeaux & Seminara (1985) derived complete solutions combining the

Copyright © 2006 Taylor & Francis Group plc, London, UK

sediment transport equation with the shallow flow equations. Simpler solutions are shown below to understand the fundamental features of the response of water surface to channel meandering (Hosoda(1999)).

It should be noted that in the bend theory by Ikeda et al. (1981) the first and third terms in the left side of Eq. (10) are neglected and the resonance between water surface and channel meandering is not included in the theory.

Substituting the relations, Eqs.(11a)–(11d), into Eqs. (8)–(10) and setting the coefficients of $\sin(\lambda s)$ and $\cos(\lambda s)$ to be zero, the linear solutions are obtained with the coefficients, $\hat{a} - \hat{l}$, defined below.

$$\xi_{s1} = Fr_0^{\,2} n \cos \lambda s + \xi_{s11} n \cos\left(\lambda s + \phi_{\xi_{s11}}\right) \tag{11a}$$

$$\eta_1 = \eta_{11} n \cos\left(\lambda s + \phi_{\eta_{11}}\right) \tag{11b}$$

$$u_1 = u_{11} n \cos\left(\lambda s + \phi_{u_{11}}\right) \tag{11c}$$

$$v_1 = v_{10}\left(1 - \frac{n^2}{\varepsilon^2}\right) n \cos\left(\lambda s + \phi_{v_{10}}\right) \tag{11d}$$

where ε is defined as $\varepsilon \equiv B/(2h_0)$.

$$\hat{a} = \xi_{s11}\cos\phi_{\xi_{s11}},\ \hat{b} = \xi_{s11}\sin\phi_{\xi_{s11}},$$
$$\hat{e} = u_{11}\cos\phi_{u_{11}},\ \hat{f} = u_{11}\sin\phi_{u_{11}},$$
$$\hat{i} = v_{10}\cos\phi_{v_{10}},\ \hat{j} = v_{10}\sin\phi_{v_{10}},$$
$$\hat{k} = \eta_{11}\cos\phi_{\eta_{11}},\ \hat{l} = \eta_{11}\sin\phi_{\eta_{11}}$$

The coefficients $\hat{a}$ and $\hat{b}$ are calculated by the following relations.

$$\hat{a} = \frac{QS - PR}{P^2 + Q^2},\ \hat{b} = \frac{QR + PS}{P^2 + Q^2} \tag{12}$$

where P, Q, R and S are related to the hydraulic variables defined by the following equations.

$$P = \lambda c_f A_1 + \frac{2}{\varepsilon^2 \lambda}\frac{A_3}{c_f^{\,2} + \lambda^2}\frac{c_f}{Fr_0^{\,2}},$$
$$Q = A_2 + A_3 - \frac{2}{\varepsilon^2}\frac{A_3}{c_f^{\,2} + \lambda^2}\frac{1}{Fr_0^{\,2}},$$
$$R = -\left(A_3 + 2c_f^{\,2}\right)\hat{l} + \lambda c_f\left(1 - \hat{k} - Fr_0^{\,2}\right)$$
$$S = -A_3\left(\hat{k} + Fr_0^{\,2}\right) - \lambda c_f \hat{l} + \lambda^2 + c_f^{\,2}\left(1 + \hat{k} - Fr_0^{\,2}\right),$$
$$A_1 = \frac{2}{Fr_0^{\,2}} + 1,\ A_2 = 2c_f^{\,2} - \frac{\lambda^2}{Fr_0^{\,2}},\ A_3 = 4c_f^{\,2} + \lambda^2$$

The bottom variations, $\hat{k}$ and $\hat{l}$, are given as the boundary conditions. Since the bottom surface of the flume used for the hydraulic experiments is flat, $\hat{k}$ and $\hat{l}$ are set to be zero in this study.

$\hat{i}, \hat{j}, \hat{e}$ and $\hat{f}$ are given by the following equations.

$$\hat{i} = \frac{-c_f\hat{a} - \lambda\hat{b}}{Fr_0^{\,2}\left(c_f^{\,2} + \lambda^2\right)},\ \hat{j} = \frac{+\lambda\hat{a} - c_f\hat{b}}{Fr_0^{\,2}\left(c_f^{\,2} + \lambda^2\right)}$$
$$\hat{e} = -\hat{a} - \left(\hat{k} + Fr_0^{\,2}\right) + \frac{2}{\varepsilon^2\lambda}\hat{j},\ \hat{f} = -\hat{b} - \hat{l} - \frac{2}{\varepsilon^2\lambda}\hat{i}$$

2.1.4 *Resonance relation*

According to the linear theory described above, the flow characteristics are categorized by the following four non-dimensional parameters.

$$\nu = \frac{h_0}{R}, \varepsilon = \frac{B}{2h_0},\ \lambda = 2\pi\frac{h_0}{L},\ Fr_0 = \frac{U}{\sqrt{gh_0}}$$

In this study, since the experiments were carried out using the sinuous channel with constant value of L/B, it is convenient to use L/B instead of λ using the relation $\lambda = \frac{\pi}{\varepsilon}\frac{1}{L/B}$.

Using Eq. (11), ξ_{s1} is described by Eq. (13a) and the variations of water surface along the right side wall, ξ_{sw}, are also given by Eq. (13b).

$$\xi_{s1} = n\left(Fr_0^{\,2} + \hat{a}\right)\cos(\lambda s) - n\hat{b}\sin(\lambda s) \tag{13a}$$

$$\xi_{sw} = Amp \bullet \cos\left(\lambda s + \Phi_{\xi_s}\right) \tag{13b}$$

where Amp and Φ_ξ are defined by

$$Amp = \varepsilon\sqrt{\left(Fr_0^{\,2} + \hat{a}\right)^2 + \hat{b}^2} \tag{14a}$$

and

$$\cos(\Phi_{\xi_s}) = \frac{\varepsilon\left(Fr_0^{\,2} + \hat{a}\right)}{Amp},\ \sin(\Phi_{\xi_s}) = \frac{\varepsilon\hat{b}}{Amp} \tag{14b}$$

If the terms with c_f are neglected from Eq. (12), Amp is reduced to the following equation.

$$Amp = \varepsilon\frac{\frac{2}{\varepsilon^2}}{\left|\lambda^2 - \frac{1}{Fr_0^{\,2}}\left(\lambda^2 + \frac{2}{\varepsilon^2}\right)\right|}$$
$$= \varepsilon\frac{2}{\left|\frac{\pi^2}{(L/B)} - \frac{1}{Fr_0^{\,2}}\left(\frac{\pi^2}{(L/B)} + 2\right)\right|} \tag{15}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

The resonance relation is defined as the relation where the amplitude of water surface variations becomes to infinity, and given by Eq. (16).

$$\lambda^2 - \frac{1}{Fr_0{}^2}\left(\lambda^2 + \frac{2}{\varepsilon^2}\right) = 0 \quad \text{or} \quad Fr_0 = \sqrt{1 + \frac{2}{\pi^2}\left(\frac{L}{B}\right)^2} \tag{16}$$

Figure 3 shows the relation between the amplitude of depth variations along the side wall and the averaged Froude number described by Eq. (15).

The phase lag between the water surface variations along the right side wall and sinuous channel is also determined using Eq. (16). As shown in Figure 4, the variations show in-phase pattern with $\Phi_\xi = 0$ in the region below Eq. (16) and out-of-phase pattern with $\Phi_\xi = \pi$ above Eq. (16). In-phase pattern indicates that maximum depth occurs near an apex of the outer side wall due to the effect of centrifugal force and the minimum depth near an apex of the inner side-wall.

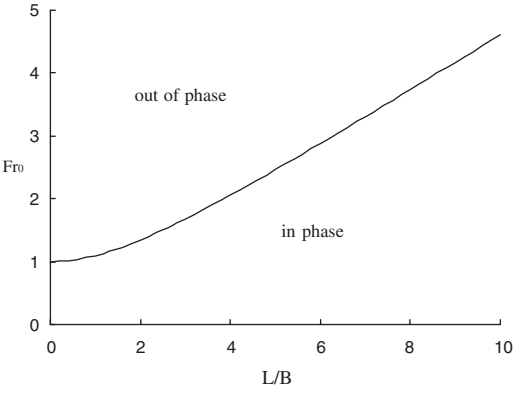

Figure 4. Classification of flow pattern.

3 NUMERICAL MODEL

3.1 *Fundamental equations*

Using the depth averaged shallow flow equations in a generalized curvilinear coordinate, we carried out the numerical simulations of high velocity flows in a sinuous open channel under various hydraulic conditions such as discharge, channel slope, etc.

Common fundamental equations in a Cartesian coordinate, which consists of depth averaged continuity equation and momentum equations, are denoted as follows (refer to Nagata & Hosoda (2000)):

[Depth averaged continuity equation]

$$\frac{\partial h}{\partial t} + \frac{\partial M}{\partial x} + \frac{\partial N}{\partial y} = 0 \tag{17}$$

[Depth averaged momentum equations]

$$\frac{\partial M}{\partial t} + \frac{\partial uM}{\partial x} + \frac{\partial vM}{\partial y} = -gh\frac{\partial z_s}{\partial x} - \frac{\tau_{bx}}{\rho} + \frac{\partial}{\partial x}\left(-\overline{u'^2}h\right) + \frac{\partial}{\partial y}\left(-\overline{u'v'}h\right) \tag{18a}$$

$$\frac{\partial N}{\partial t} + \frac{\partial uN}{\partial x} + \frac{\partial vN}{\partial y} = -gh\frac{\partial z_s}{\partial y} - \frac{\tau_{by}}{\rho} + \frac{\partial}{\partial x}\left(-\overline{u'v'}h\right) + \frac{\partial}{\partial y}\left(-\overline{v'^2}h\right) \tag{18b}$$

where t: time, (x,y): spatial coordinates, (u,v): components of depth averaged velocity vectors in x,y directions, (M,N): components of depth averaged discharge flux vectors in x,y directions, g: gravity acceleration, h: depth, ρ: density of water, z_s: water surface elevation from a datum plane, (τ_{bx},τ_{by}): components of bottom stress vectors, $-\overline{u'^2}$, $-\overline{u'v'}$, $-\overline{v'^2}$: components of depth averaged Reynolds stress tensors.

The bottom shear stresses are evaluated by Manning's formula, Eq. (19).

$$\tau_{bx} = \frac{\rho g n^2 u\sqrt{u^2+v^2}}{h^{1/3}}, \quad \tau_{by} = \frac{\rho g n^2 v\sqrt{u^2+v^2}}{h^{1/3}} \tag{19}$$

The depth averaged Reynolds stresses are evaluated by the following equations.

$$-\overline{u'^2} = 2D_h\left(\frac{\partial u}{\partial x}\right) - \frac{2}{3}k, \quad -\overline{u'v'} = D_h\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right),$$
$$-\overline{v'^2} = 2D_h\left(\frac{\partial v}{\partial y}\right) - \frac{2}{3}k \tag{20a}$$

$$D_h = \alpha h u_* \tag{20b}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

where D_h: eddy viscosity, k: depth averaged turbulent kinetic energy evaluated by Eq. (21), α: constant (=0.3), u_*: friction velocity defined by

$$\sqrt{\sqrt{(\tau_{bx}{}^2+\tau_{by}{}^2)}/\rho}\,.$$

$$k=2.07u_*^2 \tag{21}$$

Fundamental equations (17)–(18a,b) in a Cartesian coordinate are transformed into the equations in a generalized curvilinear coordinate system.

[Depth averaged continuity equation]

$$\frac{\partial}{\partial t}\left(\frac{h}{J}\right)+\frac{\partial}{\partial \xi}\left(\frac{Uh}{J}\right)+\frac{\partial}{\partial \eta}\left(\frac{Vh}{J}\right)=0 \tag{22}$$

[Depth averaged momentum equations]

$$\begin{aligned}
&\frac{\partial}{\partial t}\left(\frac{Q^\xi}{J}\right)+\frac{\partial}{\partial \xi}\left(\frac{UQ^\xi}{J}\right)+\frac{\partial}{\partial \eta}\left(\frac{VQ^\xi}{J}\right)\\
&-\frac{M}{J}\left(U\frac{\partial \xi_x}{\partial \xi}+V\frac{\partial \xi_x}{\partial \eta}\right)-\frac{N}{J}\left(U\frac{\partial \xi_y}{\partial \xi}+V\frac{\partial \xi_y}{\partial \eta}\right)\\
&=-gh\left(\frac{\xi_x^2+\xi_y^2}{J}\frac{\partial z_s}{\partial \xi}+\frac{\xi_x\eta_x+\xi_y\eta_y}{J}\frac{\partial z_s}{\partial \eta}\right)\\
&-\frac{\tau_b^\xi}{\rho J}+\frac{\xi_x^2}{J}\frac{\partial}{\partial \xi}\left(-\overline{u'^2}h\right)+\frac{\xi_x\eta_x}{J}\frac{\partial}{\partial \eta}\left(-\overline{u'^2}h\right)

3.2 *Numerical method*

We used the Finite Volume Method with staggered allocation of hydraulic variables as a numerical method for the numerical simulations. The details and the other basic items on numerical simulations are described in Kimura & Hosoda (1997) and Nagata & Hosoda (2000).

4 RESULTS OF HYDRAULIC EXPERIMENTS

We conducted the hydraulic experiments to investigate the response of water surface profiles with channel slope, discharge, etc. The three types of sinuous side walls, whose curvature radius is given by Eq. (4) (refer to Figure 5), were set on the straight tilting flume with flat bed.

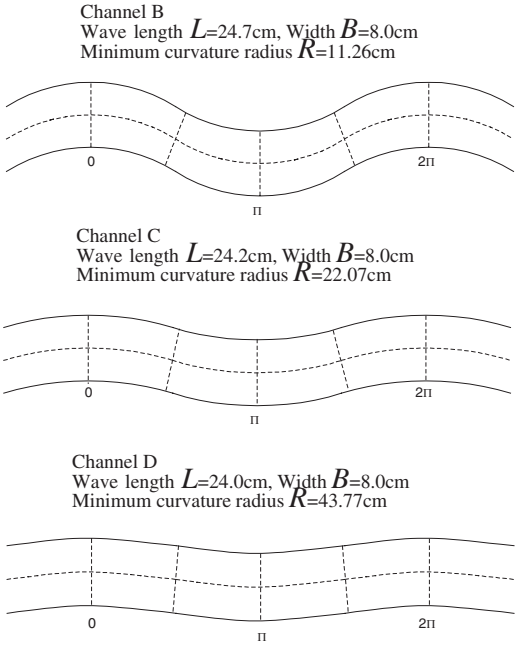

Figure 5. Flumes B, C, D used for experiments.

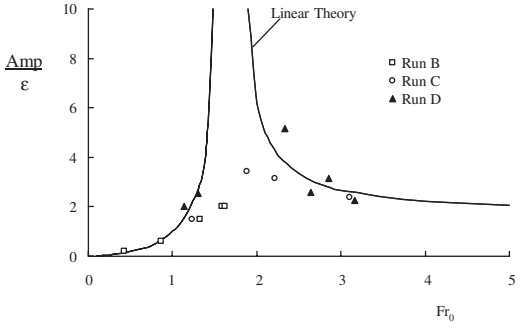

Figure 6. Relation between Amp/ε and Fr_0.

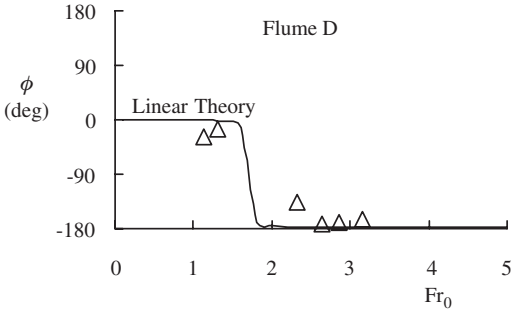

Figure 7. Relation between Φ_ξ and Fr_0 (Flume D).

The hydraulic conditions used in the experiments are listed in Table 1. Plane two-dimensional variations of water surface were measured using a point gage.

Figure 6 shows the relation between Amp/ε and Fr_0 from both the linear solution, Eq. (15), and the experiments. The experimental results are in good agreement with the linear solution in the region a little apart from the resonance relation.

Figures 7 and 8 show the relation of the phase lag, Φ_ξ, and Fr_0 with the linear solution. The results of flume D having the side wall of large curvature radius are in good agreement with the linear solution. But the results of flume B with the side wall of small curvature radius are not compatible with the linear solution due to the non-linear effects.

Some results of the water surface variations along the right side wall are shown in Figures 9, 10 and 11. Figure 9 (Run D1-1) shows in-phase pattern with low Froude number, and Figure 10 out-of-phase pattern with high Froude number. Figure 11 (Run B3-2) shows the pattern with $\Phi_\xi = \pi/2$ under the resonance condition.

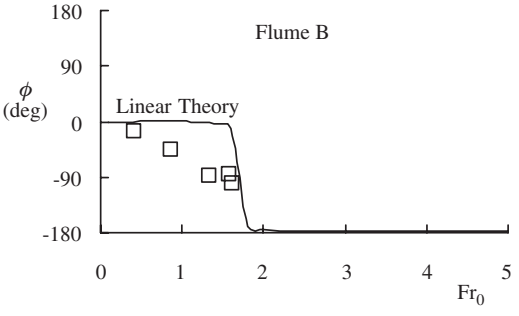

Figure 8. Relation between Φ_ξ and Fr_0 (Flume B).

In the following section, the three dimensional water surface patterns are shown using the numerical results with aid of computer graphics, and the characteristics of the transition of profiles around the resonance relation are discussed.

5 DISCUSSIONS OF CALCULATED RESULTS

5.1 *Verification of numerical model*

In order to verify the numerical model, the numerical simulations were carried out under the same conditions of hydraulic experiments.

Figure 12 shows the comparison of the calculated to the experimental results on the longitudinal variations of water surface profile of Run D2-2, and Figure 13

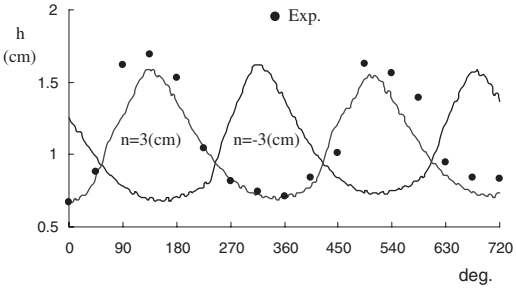

Figure 12. Comparison of longitudinal water surface distributions (Run D2-2).

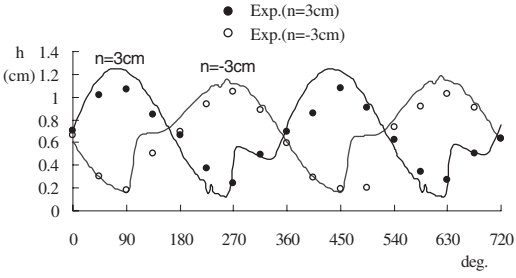

Figure 13. Comparison of longitudinal water surface distributions (Run B3-2).

shows the results of Run B3-2. These two figures indicate that the calculated results are in good agreement with the experimental results.

Figures 14 and 15 show the photographs of the experimental results and the computer graphics created using the calculated results under the same hydraulic conditions. Since the typical features of flow patterns observed in the experimental results are well reproduced in the computational results, the numerical model seems to be applicable to investigate the characteristics of flow response near a resonance relation.

5.2 *Change of flow patterns*

The change of flow patterns from in-phase to out-of-phase are shown in Figures 16 and 17 for flume B and D, respectively. We can observe in these figures that when the Froude number (channel slope) exceeds the value of resonance, the flow patterns are changed from in-phase to out-of-phase. A typical water surface profile with hydraulic jump in the central part of flume is observed at the resonance condition as shown in the middle of Figure 17, which can also be seen in Figures 14 and 15.

Figures 18 and 19 show the water surface variations along the right side wall. Both figures show that the

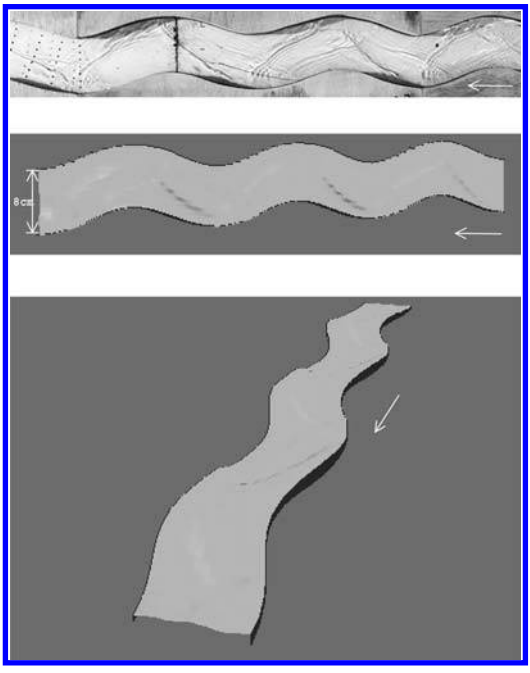

Figure 14. Comparisons of water surface profiles observed in hydraulic experiments with calculated results (Run B3-2, near the resonance condition).

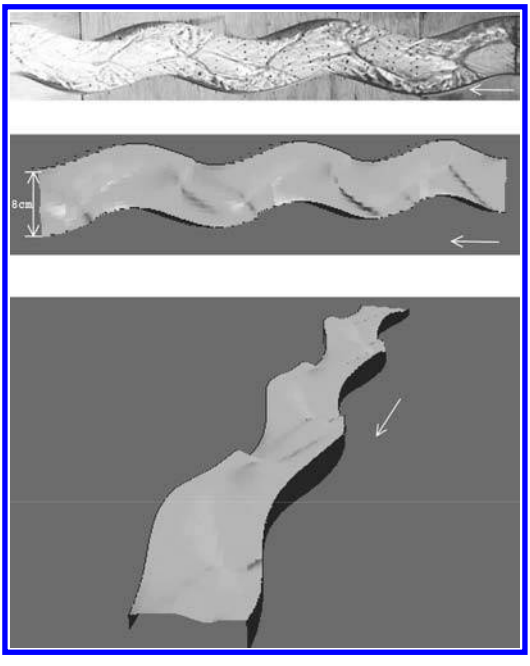

Figure 15. Comparisons of water surface profiles observed in hydraulic experiments with calculated results (Run B3-1, near the resonance condition).

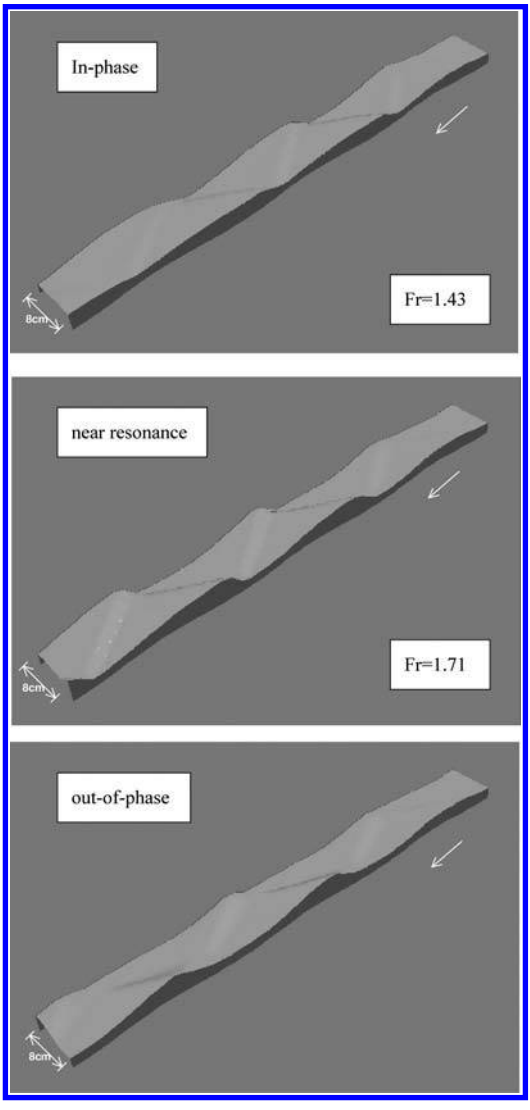

Figure 16. Change of flow pattern with the increase of channel slope (Flume D).

phase lag between water surface variations and sinuous side wall is in-phase for the flows whose Froude number is smaller than the resonance Froude number, and is likely to out-of phase for the flows whose Froude number is larger then the resonance one. The phase lag around the resonance condition is about 90 degrees.

5.3 *Increase of flow resistance*

Figure 20 shows the relation between the calculated averaged flow depth and the bottom slope of the

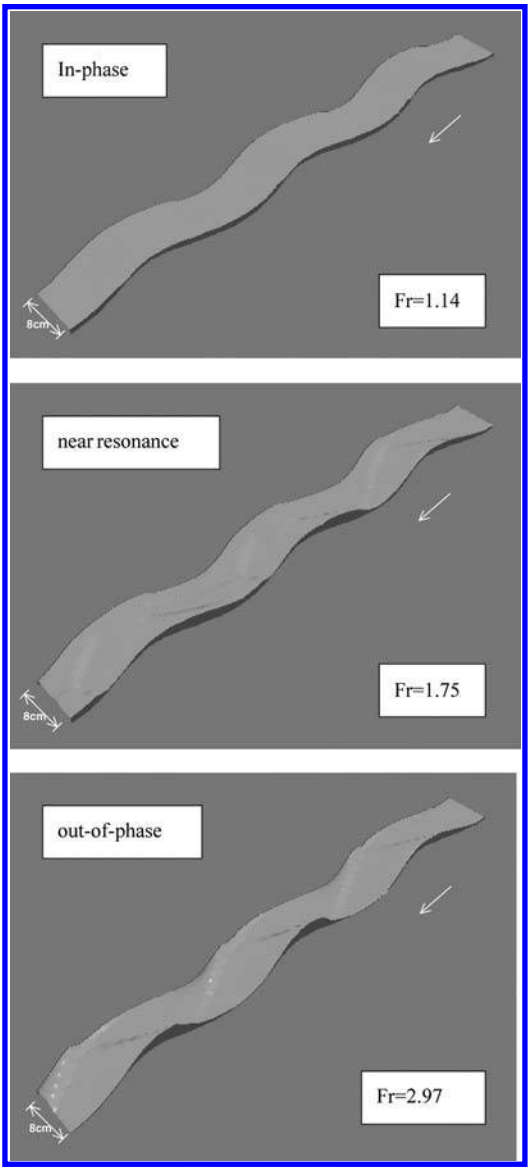

Figure 17. Change of flow pattern with the increase of channel slope (Flume B).

flume B under constant discharges. Here, the uniform flow depth is calculated by the following equation with a value of roughness coefficient as 0.0095 and plotted.

$$h_0 = \left(\frac{nq}{I_0^{1/2}} \right)^{3/5} \tag{28}$$

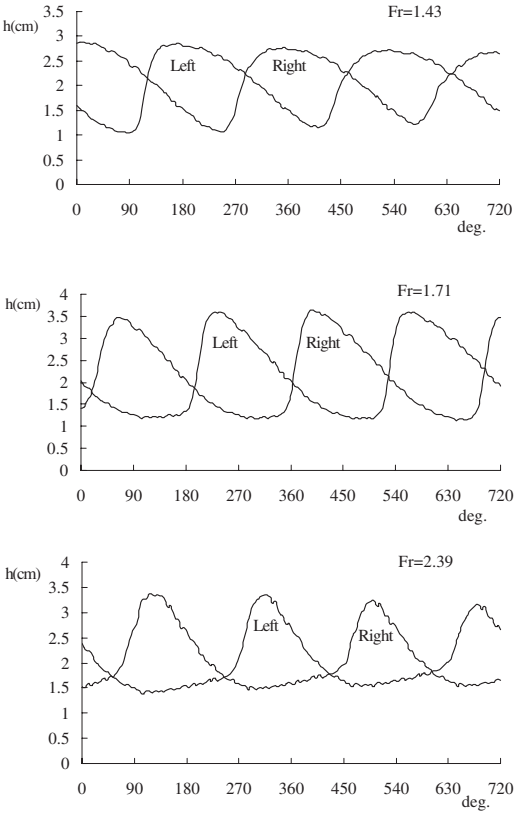

Figure 18. Water surface variations along the right side wall in Flume D.

This figure indicates that the flow resistance increases with the increase of bottom slope and decreases when the slope increases beyond the resonance relation (in this case beyond slope = 1/17).

6 CONCLUSIONS

In this paper, the fundamental flow characteristics of high velocity flows in a sinuous open channel were investigated numerically. It was shown that the flow characteristics can be classified into out-of-phase and in-phase using the resonance relation between water surface and channel meandering based on the solutions of the linearized shallow flow equations. We also showed that a typical water surface profile with hydraulic jump is observed in the central part of flume at the resonance condition. It was found that the flow resistance increases with the increase of bottom slope and decreases when the slope increases beyond the resonance relation.

Smoothly limited finite-volume modelling of rapidly varying river flows

T. Krámer & J. Józsa
Budapest University of Technology and Economics, Budapest, Hungary

ABSTRACT: The Barth-Jespersen (BJ) reconstruction procedure is a well established method to provide oscillation-free, higher-order accuracy to Godunov-type schemes on general unstructured meshes. Their scalar limiter is, however, known to suffer from poor convergence to steady-state with nonsmooth solutions, such as those that occur in rapidly varying river flows. In order to improve convergence, a general smoothing procedure applicable to unstructured limiters is introduced in this paper. In essence, the reconstruction gradually reverts to unlimited gradients for small oscillations in the solution thus reducing the adverse interaction between the limiter and numerical noise. Popular limiters – minmod, superbee, van Leer and van Albada – are also brought to the same BJ formulation so as to suit them to general unstructured meshes and smoothing. The advantage of the new, smoothed BJ limiter is demonstrated by solving a steady, two-dimensional transcritical channel flow problem.

1 INTRODUCTION

A wide variety of rapidly varying open channel flows are successfully simulated using Godunov-type finite-volume schemes. A major advantage of these schemes is their shock capturing capability, which makes them suitable to modelling transcritical flow problems involving hydraulic structures or steep slopes. Much progress has been made recently along this line towards robust, higher-order, two-dimensional modelling in the presence of natural bathymetries.

Limiters used to suppress numerical oscillations are key ingredients of such higher-order schemes. They were originally developed for structured grids. Since then, unstructured mesh techniques have been gaining widespread use, largely because they can be adapted flexibly to complicated boundaries and varying resolution. It is straightforward to formulate the finite-volume framework on general unstructured meshes, where the cell orientation and the number of cell faces may vary arbitrarily. Barth and Jespersen (1989) successfully generalised monotonic polynomial reconstruction to unstructured meshes by introducing a divergence- and a least-squares-based gradient scheme and a multidimensional scalar limiter. Yet the Barth-Jespersen limiter is known to suffer from poor convergence to steady-state due to the overreacted limiting of small amplitude noise. Furthermore, the scalar limiter is stricter than necessary because it affects all components of the gradient uniformly.

The main difficulty with unstructured meshes is to translate directionality and cell neighbour information of proven structured methods. Research focused primarily on triangular meshes: for example Jawahar and Kamath (2000) presented an area-weighted multidimensional method that couples gradient calculation and limiting, but their method is not evidently extensible to arbitrary meshes. To address the diffusive character of the scalar limiter without any presumption on mesh topology, some researchers (Hubbard 1999, Rider and Kothe 1997, Berger et al. 2005) limit the slope in a truly multidimensional fashion at the cost of a multiply constrained, data-dependent minimization problem at each cell and timestep. To cure the convergence problem, van Albada et al. (1982) makes the limiter insensitive to noise by smoothly switching it off as the amplitude of the extremum decreases below a small threshold, thus reverting to the unlimited reconstruction. Venkatakrishnan (1995) interprets Spekreijse's structured limiter concept (Spekreijse 1987) within the Barth-Jespersen limiter, which allows him to implement a smooth limiter similar to that of van Albada.

Finding a non-diffusive and convergent limiter suited to arbitrary meshes was motivated in this paper by the implementation of an adaptive MUSCL-type solver for free-surface flows. The two-dimensional, solution-adaptive quadtree mesh of this model is dynamically restructured during the simulation to describe rapid flow variations, such as hydraulic jumps, with high resolution. We have implemented the technique of Barth-Jespersen and find it robust for unsteady problems, but when the same solver is used in steady-state simulations, nonsmooth solutions are sometimes difficult to achieve with good convergence. Following the procedure of Venkatakrishnan

Copyright © 2006 Taylor & Francis Group plc, London, UK

(1995) in this paper, popular limiters – minmod, monotonized-centered, superbee, van Leer and van Albada – are extended to general unstructured meshes and introduce a simple smoothing technique to improve convergence to steady-state. Results obtained for a transcritical flow in an L-shaped channel with the smoothed version of the Barth-Jespersen limiter demonstrate the merits of the method.

2 FLOW SOLVER

2.1 *Governing equations*

Flow is modelled by the inviscid, Reynolds-averaged shallow water equations, which read (Chaudhry 1993):

$$\frac{\partial}{\partial t}\int_A \mathbf{u}\,\mathrm{d}A + \oint_S \left(\mathbf{f}n_x + \mathbf{g}n_y\right)\mathrm{d}S = \int_A \mathbf{s}\,\mathrm{d}A, \tag{1}$$

where t = time; A and S = area and boundary of the cell, respectively; $\mathbf{n}$:(n_x, n_y) = outward unit normal vector to S, expressed with its horizontal Cartesian components (x, y). The flow state vector $\mathbf{u}$, the flux vectors $\mathbf{f}$, $\mathbf{g}$, and the vector of source terms $\mathbf{s}$ are defined as follows:

$$\mathbf{u} = \begin{bmatrix} \eta \\ p \\ q \end{bmatrix}, \quad \mathbf{f} = \begin{bmatrix} p \\ \frac{p^2}{h} + \frac{g}{2}h^2 \\ \frac{pq}{h} \end{bmatrix},$$
$$\mathbf{g} = \begin{bmatrix} q \\ \frac{pq}{h} \\ \frac{q^2}{h} + \frac{g}{2}h^2 \end{bmatrix}, \quad \mathbf{s} = \begin{bmatrix} 0 \\ -gh\frac{\partial z_b}{\partial x} - \frac{\tau_{bx}}{\rho} \\ -gh\frac{\partial z_b}{\partial y} - \frac{\tau_{by}}{\rho} \end{bmatrix}, \tag{2}$$

where η = surface elevation; $\mathbf{q}$:(p, q) = horizontal volume flux; g = acceleration due to gravity; h = total flow depth; z_b = bottom elevation; $\boldsymbol{\tau}_b$:(τ_{bx}, τ_{by}) = bed shear stress; ρ = density of water. Bottom shear stress is expressed using the Manning formula, $\boldsymbol{\tau}_b = \rho g n^2 h^{-1/3}\,\mathbf{v}|\mathbf{v}|$, where n = Manning coefficient; $\mathbf{v}$ = horizontal depth-averaged velocity.

2.2 *Adaptive quadtree mesh*

Quadtree-based hierarchical meshes are well suited to solution-adaptation, as they can be conveniently created and modified according to the desired local level of detail and solution accuracy. Although neighbours can be identified on a quadtree mesh without having to store cell-edge connectivity information explicitly, the finite volume solver treats it as an arbitrary, unstructured Cartesian mesh. As the simulation progresses, the mesh is refined dynamically based on the estimated truncation error of the velocity

$$\frac{A_i}{n_j}\sum_j \left|\mathbf{v}_j - \left[\mathbf{v}_i + \nabla\mathbf{v}_i \cdot \left(\mathbf{r}_j - \mathbf{r}_i\right)\right]\right|, \tag{3}$$

where $j \in$ neighbours of cell i; n_j = number of neighbours; $\mathbf{r}_i$ and $\mathbf{r}_j$ = position vector to the centre of the respective cell; $\nabla\mathbf{v}_i$ = velocity gradient estimated as for the MUSCL reconstruction (see Section 3). The error indicator is weighted by the cell area A_i to find weaker features in coarser mesh areas of the flow once the stronger features have been sufficiently resolved. To ensure a smooth variation of mesh density, adjacent cell sizes never differ by more that a factor of two. The adaptation procedure is described in more detail elsewhere (Krámer and Józsa 2005, Krámer and Józsa 2006).

2.3 *A Godunov-type scheme*

According to Godunov-type finite-volume methods, the integrals in Equation (1) are discretised around the control volume as

$$A\frac{\partial \mathbf{u}}{\partial t} + \sum_{edges}\left(\hat{\mathbf{f}}n_x\Delta y + \hat{\mathbf{g}}n_y\Delta x\right) = A\mathbf{s}, \tag{4}$$

where Δx and Δy = extents of the boundary edge. The numerical fluxes $\hat{\mathbf{f}}$ and $\hat{\mathbf{g}}$ that arise from a local Riemann problem at each cell edge are approximated in this work by the HLLC Riemann solver (Fraccarollo and Toro 1995). The bed slope source term $-gh\nabla z_b$ is treated similarly to the procedure of Bradford and Sanders (2002), without the second-order flux correction.

The extension of the first-order Godunov scheme to second-order spatial and temporal accuracy is achieved by the MUSCL-Hancock method. With this method, the flow variables are reconstructed at the edges with a piecewise linear distribution in each cell, and time integration is performed explicitly in two stages using a non-conservative predictor step followed by a conservative corrector step (Mingham and Causon 1998). For cell i, the linear reconstruction at its edge e is

$$\mathbf{u}_{e,i} = \mathbf{u}_i + \Phi_i\nabla\mathbf{u}_i \cdot (\mathbf{r}_e - \mathbf{r}_i), \tag{5}$$

where $\mathbf{u}_{e,i}$ and $\mathbf{u}_i$ = flow state vector at the edge and at the cell centre, respectively; Φ_i = Barth-Jespersen-type limiter; $\nabla\mathbf{u}_i$ = gradient of $\mathbf{u}$ approximated at the cell centre; $\mathbf{r}_e$ and $\mathbf{r}_i$ = position vector to the edge midpoint and the cell centre, respectively. In general a different flow state is reconstructed on the two sides of an edge, i.e., for an edge between cells i and j, $\mathbf{u}_{e,i} \neq \mathbf{u}_{e,j}$.

Copyright © 2006 Taylor & Francis Group plc, London, UK

2.4 *Boundary conditions*

The flow state $\mathbf{u}_{in}$ on the inner side of a boundary edge is reconstructed from the interior as usual using Equation (5), except that the gradient in Equation (6) is determined from a closed path that connects only the centroids of inner neighbours (de Zeeuw and Powell 1993). Boundary conditions are assigned to the flow state $\mathbf{u}_{out}$ on the outer side. In supercritical state, η_{out} and $q_{\perp,out}$ are set to the prescribed values at the inflow boundary, and free outfall conditions are used at the downstream boundary: $\eta_{out} = \eta_{in}$, $q_{\perp,out} = q_{\perp,in}$, $q_{||,out} = q_{||,in}$, where $q_\perp$ and $q_{||}$ = volume flux component perpendicular and parallel to the boundary edge. A slip wall boundary condition is prescribed along closed boundaries: $\eta_{out} = \eta_{in}$ and $q_{\perp,out} = -q_{\perp,in}$.

3 MUSCL RECONSTRUCTION

3.1 *Gradient calculation*

The gradient $\nabla \mathbf{u}_i$ is calculated in each cell using surrounding cell-averaged values with a method suited to meshes with arbitrary topology (de Zeeuw and Powell 1993). To this end, a closed path connecting surrounding cell centroids is determined around the cell of interest and the gradient is expressed numerically using the divergence theorem:

$$\nabla \mathbf{u}_i \approx \frac{1}{2A_{path}} \sum_{edges} S(\mathbf{u}_p + \mathbf{u}_n)\mathbf{n}, \tag{6}$$

where $2A_{path} = \sum (x_n - x_p)(y_n + y_p)$ is twice the area enclosed by the path around cell i; S, $\mathbf{n}$ = length and outward unit normal of an edge, respectively. The summation is over all edges of the path, and subscripts p and n refer to the starting and ending cell centres of an edge. The order in which the cell centres are visited is indifferent, but the selection of which cells to connect matters. Here we choose a compact path which connects immediate neighbours, and, unlike in References (Barth and Jespersen 1989, de Zeeuw and Powell 1993), the cell where $\nabla \mathbf{u}$ is calculated is never included in the path and the diagonal neighbours only when a connected edge is on a boundary (Fig. 1).

3.2 *The Barth-Jespersen slope limiter*

Using the slope determined by Equation (6) directly when reconstructing the conserved variables by Equation (5) creates new extrema and therefore corrupts non-smooth solutions with artificial oscillations. To avoid this, Barth and Jespersen (1989) proposed limiting $\nabla \mathbf{u}$ by a factor Φ so that the linearly reconstructed $\mathbf{u}$ satisfies monotonicity requirements, by making no assumption on the directionality or the number

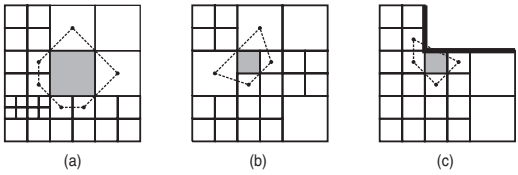

Figure 1. Selection of the closed path for gradient calculation using the divergence theorem.

of neighbours. First we compute $u_{min} = \min(u_i, u_{nbr})$ and $u_{max} = \max(u_i, u_{nbr})$ with all surrounding cell-centered u_{nbr} values, then we seek the maximum admissible limiter that ensures that the flow variable $u_{e,i}$ extrapolated from cell i to the midpoint of each of its edges is bounded:

$$u_{min} \le u_{e,i} \le u_{max} \tag{7}$$

Note that this constraint is more relaxed than the one that requires the reconstructed function $u(\mathbf{r})$ to be bounded at every point within the cell. The monotonicity principle is formulated for each edge as

$$\Phi_e = \begin{cases} \min\left(1, \frac{u_{max}-u_i}{u_{e,i}-u_i}\right) & \text{if } u_{e,i} - u_i > 0, \\ \min\left(1, \frac{u_{min}-u_i}{u_{e,i}-u_i}\right) & \text{if } u_{e,i} - u_i < 0, \\ 1 & \text{if } u_{e,i} - u_i = 0, \end{cases} \tag{8}$$

and the final limiter is determined using $\Phi = \min(\Phi_e)$. In Equation (8), the state at the edge is extrapolated with the unlimited gradient, $u_{e,i} = u_i + \nabla \mathbf{u}_i \cdot (\mathbf{r}_e - \mathbf{r}_i)$.

On regular grids, the Barth-Jespersen (BJ) limiter reduces to the *monotonised-centered* limiter (which is called limited Fromm scheme, double-minmod and MUSCL limiter by some authors). We next follow the procedure of Venkatakrishnan (1995) in order to find the unstructured equivalent of well known limiters. Some of these forms were already derived by Berger et al.(2005), their function $w(f)$ is equivalent to $\Phi(y)$ with $f = y/4$. The analysis is shown in 1D for a sequence of grid indexes $i-1, i, i+1$, whose u values are monotonically increasing or decreasing (otherwise Φ would be 0). Without loss of generality, we assume $u_{min} = u_{i-1}$ and $u_{max} = u_{i+1}$ and consider the reconstruction of the flow variable $u_{i+0.5}$ on the left side of the edge $i + 0.5$ and $u_{i-0.5}$ on the right side of the edge $i - 0.5$. The BJ limiter is in that case

$$\begin{aligned} \Phi_i &= \min(\Phi_{i+0.5}, \Phi_{i-0.5}) \\ &= \min\left[1, \frac{u_{i+1}-u_i}{u_{i+0.5}-u_i}, \frac{u_{i-1}-u_i}{u_{i-0.5}-u_i}\right], \end{aligned}$$

Noting that $u_{i\pm0.5} - u_i = \pm (u_{i+1} - u_{i-1})/4$ and introducing

$$y_i = (u_{i+1} - u_i) / (u_{i+0.5} - u_i),$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

$$\Phi_{BJ}(y) = \min(1, y, 4-y), \tag{9}$$

the reconstruction becomes

$$u_{i\pm0.5} = u_i \pm \frac{1}{4}\Phi_{BJ}(y_i)(u_{i+1} - u_{i-1}),$$

We have brought $\Phi(y)$ to a form similar to the common ψ form of limiters that modulate the one-sided difference on structured grids (Spekreijse 1987):

$$u_{i+0.5} = u_i + \frac{1}{2}\psi(r_i)(u_i - u_{i-1})$$

$$u_{i-0.5} = u_i - \frac{1}{2}\psi(1/r_i)(u_{i-1} - u_i)$$

where

$$r = (u_{i+1} - u_i)/(u_i - u_{i-1}).$$

The Φ and ψ limiters are applied independently on the local flow direction, therefore the following symmetry conditions must hold: $\Phi(y) = \Phi(4-y)$ and $\psi(r) = \psi(1/r)$. The relationship between Φ and ψ can be shown to be

$$\psi(r) = \frac{1}{2}(r+1)\min\left[\Phi\left(\frac{4r}{r+1}\right), \Phi\left(\frac{4}{r+1}\right)\right],$$

$$\Phi(y) = \frac{2+|y-2|}{2}\psi\left(\frac{2-|y-2|}{2+|y-2|}\right),$$

and $r = y/(4-y)$. Additionally, the reconstruction reverts to uniform if u_i is a local extremum, therefore $\psi(r) = 0$ for $r < 0$ and $\Phi(y) = 0$ for $|y-2| > 2$. Now we are ready to express commonly used limiters, *minmod, superbee, van Leer* and *van Albada*:

$$\psi_{MM}(r) = \min(1, r),$$

$$\psi_{SB}(r) = \min[\max(1, r), 2r, 2],$$

$$\psi_{VL}(r) = \frac{2r}{r+1},$$

$$\psi_{VA}(r) = \frac{r^2 + r}{r^2 + 1}$$

in the $\Phi(y)$ formulation:

$$\Phi_{MM}(y) = \frac{1}{2}\min(y, 4-y),$$

$$\Phi_{SB}(y) = \min\left(1 + \frac{1}{2}|y-2|, 2 - |y-2|\right),$$

$$\Phi_{VL}(y) = \frac{y(4-y)}{4},$$

$$\Phi_{VA}(y) = \frac{y(4-y)}{(y-2)^2 + 4}.$$

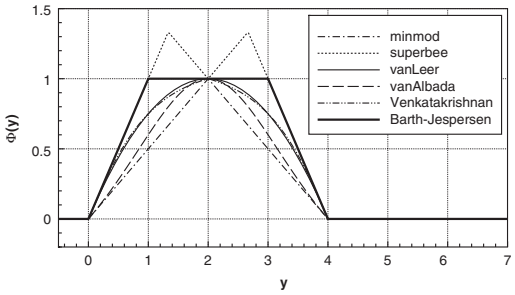

Figure 2. The limiters in $\Phi(y)$ form.

Lastly, the limiter proposed by Venkatakrishnan (1995) is also amenable to a form symmetric about $y = 2$:

$$\Phi_{VKN}(y) = \frac{(|y-2|-3)^2 - 1}{(|y-2| - \frac{5}{2})^2 + \frac{7}{4}}.$$

The $\Phi(y)$ limiters are plotted in Figure 2.

All limiters satisfy $\Phi(2) = 1$, which is required for second-order accuracy. The more diffusive limiters are situated closer to the minmod limiter, and the overcompressive character of the superbee limiter for $y \in (1, 3)$ is also apparent from the figure. The two continuously differentiable limiters (van Leer and van Albada) are convenient in implicit schemes based on a Newton solver.

It is now straightforward to use the new $\Phi(y)$ limiters with the original Barth-Jespersen limiter on unstructured grids: we replace Equation (8) with the more general form:

$$\Phi_e = \begin{cases} \Phi\left(\frac{u_{max} - u_i}{u_{e,i} - u_i}\right) & \text{if } u_{e,i} - u_i > 0, \\ \Phi\left(\frac{u_{min} - u_i}{u_{e,i} - u_i}\right) & \text{if } u_{e,i} - u_i < 0, \\ 1 & \text{if } u_{e,i} - u_i = 0, \end{cases} \tag{10}$$

In the solver presented here, each state variable is reconstructed with its own limiter. For the solution of the Euler equations, it was found preferable (de Zeeuw and Powell 1993) to first calculate Φ_k for each state variable u_k in a cell, then reconstruct all variables in that cell with a common Φ_{min} that is the lowest of the three Φ_k.

3.3 *Smoothing the limiter*

The new limiter is smoothly forced to the unlimited scheme in near-uniform flow regions with a device analogous to that used by van Albada et al. (1982) and Venkatakrishnan (1995). To start, the differences in

Copyright © 2006 Taylor & Francis Group plc, London, UK

the denominator and nominator in Equation (10) are determined separately, denoted by $\Delta_e = u_e - u_i$ and

$$\Delta_m = \begin{cases} u_{max} - u_i & \text{if } \Delta_e > 0, \\ u_{min} - u_i & \text{if } \Delta_e < 0, \\ 1 & \text{if } \Delta_e = 0, \end{cases}$$

respectively. Instead of taking the quotient Δ_m/Δ_e, a smoothed y value is calculated using a small, non-vanishing tolerance ε^2,

$$y' = \frac{\Delta_m \Delta_e + 2\varepsilon^2}{\Delta_e^2 + \varepsilon^2}$$

and Φ_e is evaluated with this modified y'. The modification prevents the clipping of smooth extrema and, more importantly, the wild behaviour of the limiter caused by small numerical fluctuations in near-uniform areas. In fact, if $\Delta_m^2, \Delta_e^2 \ll \varepsilon^2$, then $y' \to 2$ and $\Phi_e(y') \to 1$, that is, we revert to the unlimited slope.

To visualise the effect of smoothing, we fix ε and Δ_e to the same value ($= 1$), and let Δ_m hence y' vary. In this case, the dependence between the non-smoothed y and the smoothed y' is linear,

$$y'(y) = \frac{y + 2\varepsilon^2/\Delta_e^2}{1 + \varepsilon^2/\Delta_e^2},$$

and this has the horizontal stretching effect on $\Phi[y'(y)]$ (Fig. 3). Note that the nonsmooth limiters all revert to the Godunov scheme with zero slope at $y = 0$, whereas the smoothed limiters admit between 50–100% of the unlimited slope there. Smoothing would be of course barely noticeable if ε had a much lower magnitude than the local variation of u. Referring back to Figure 2, $\Phi(y) \le \Phi_{BJ}(y)$ holds for all nonsmooth limiters except the superbee, consequently these limiters also satisfy the boundedness criterion (Eq. 7). Now, if we return to Figure 3, we see that the smoothed $\Phi(y')$ curves exceed the nonsmooth $\Phi_{BJ}(y)$ (denoted by $\varepsilon^2 = 0$ in the legend) for some range of y. In fact, this reflects that the smoothed limiters do not strictly enforce monotonicity.

Next, we fix $\Delta_m = 0.5$ and $\Delta_e = 1$ and plot the functional relationship of y' and $\Phi(y')$ to ε^2 (Fig. 4). As expected, the shape of $y'(\varepsilon^2)$ greatly determines the shape of $\Phi[y'(\varepsilon^2)]$. For low ε^2, the smoothing has no effect and $y' \to y = 1/2$. Only when ε^2 approaches Δ_e^2 and Δ_m^2 does the smoothing become effective. Again, the smoothed scheme reverts to the full, unlimited slopes for large ε^2.

Originally, van Albada et al. (1982) considered setting ε^2 locally proportional to $(\Delta l)^3$, where Δl is the diameter of the circle inscribed into the particular control volume. Wang (2000), who applied Venkatakrishan's limiter on quadtree meshes, found that it was

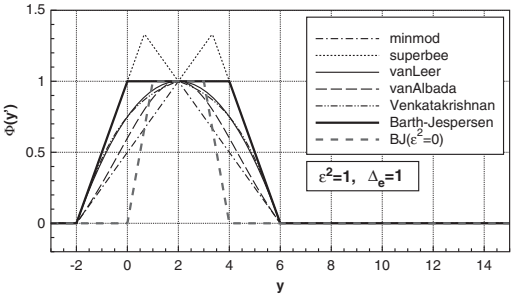

Figure 3. Effect of smoothing the Φ limiters with $\varepsilon^2 = 1$ and $\Delta_e = 1$. The nonsmoothed BJ limiter is also shown.

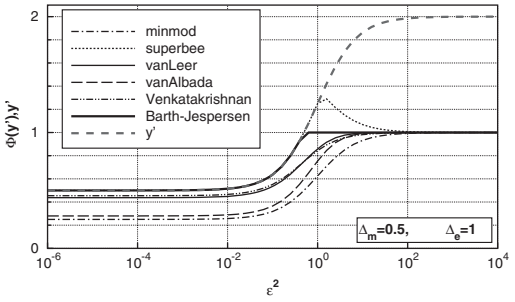

Figure 4. Variation of y' and $\Phi(y')$ to the smoothing parameter ε^2. The differences were fixed to $\Delta_m = 0.5$ and $\Delta_e = 1$.

impossible to find a satisfactory proportionality constant $K = \varepsilon^2/(\Delta l)^3$ that would work well for small and large cells simultaneously and basically set ε^2 constant for each state variable regardless of the local mesh scale. We will pursue the same approach here and set ε^2 a global constant.

4 RESULTS: TRANSCRITICAL FLOW IN A BEND

Steady transcritical flow in a sharp channel bend is modelled in order to highlight the effect of limiter smoothing on convergence. The dimensions of the L-shaped channel as well as the boundary conditions are shown in Figure 5. The prescribed inflow is supercritical with a Froude number of $v/\sqrt{gh} = 3.813$, therefore the normal discharge and the depth are both specified: $q = 0.085\ \mathrm{m^2/s}$, $h = 0.037\ \mathrm{m}$. The bottom is horizontal and its roughness is characterised by a Manning's $n = 0.011\ s/m^{1/3}$. The outfall is free.

The streamlines and the water surface in Figures 6–8 (determined on a fine, adaptively refined mesh with 120,000 active cells) show that the flow separates in the inner corner, recirculates along the top channel wall and makes a sudden transition to subcritical state

through a standing hydraulic jump. In the straight downstream reach, the flow turns gradually back to supercritical and a reflecting shock wave develops. The modelled problem was chosen so that it is similar to the unsteady dam break experiment of Soares Frazão and Zech (2002). A qualitative comparison

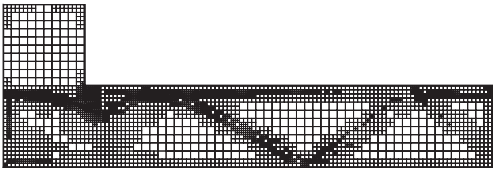

Figure 9. Final adapted mesh consisting of 3500 cells.

reveals the same flow features than in their physical and numerical experiments. Altogether, the genuinely multidimensional character of the flow field, the sharp discontinuities and the arbitrary number of neighbours of the adapted grid provide a good test bed for the smoothed limiters.

The steady-state solution is obtained by explicit time integration. To accelerate the calculation, a near-steady-state solution is first obtained on a uniform, coarse grid with 0.05 m cell size in the first 25 s of model time, then the mesh is adapted to the error indicator in five steps at 1 s interval. The adaptation is limited by the maximum active cell count of 3500 and minimum cell size of 0.00625 m. After the adaptation cycles, the simulation is continued to the final time of 50 s. As the final mesh in Figure 9 confirms, the indicator based on the velocity reconstruction error (Eq. 3) captured the shocks and led to the refinement of the mesh at these places for improved accuracy.

The simulation was repeated for a wide range of values of tolerance ε^2. From the different variants of Φ, only results with the Barth-Jespersen limiter (Eq. 9) are presented. The timestep was dynamically adjusted to yield a maximum Courant-Friedrich-Lewy (CFL) number of 0.8 with local time stepping. The computer program was compiled with 64-bit floating point arithmetic and ran on a desktop PC.

We tracked the L_2-norm of the summed relative residual, defined as

$$\Delta_2 \mathbf{u} = \frac{1}{3}\sum_{k=1}^{3} \frac{\sum_{i \in cells} \left(u_{k,i}^{n} - u_{k,i}^{n-1}\right)^2 A_i}{\sum_{i \in cells} \left(u_{k,i}^{n-1}\right)^2 A_i},$$

where $u_{k,i} \in [\eta_i, p_i, q_i]^T$ are the flow variables for cell i, the upper index n and $n-1$ stand for two successive iteration steps and the inner summations are performed over the whole mesh. The evolution of the residual is plotted for five values of ε^2 in Figure 10 against the number of iterations (time steps).

Residuals decrease rapidly in the startup stage for all schemes but stall at a $\Delta_2 \mathbf{u} = 10^{-3}$ prior to the adaptation, except for the choice $\varepsilon^2 = 10^{-4}$. When viewing the computed flow field, the stalled convergence manifests itself by oscillations in the recirculating zone of bounded, but relatively large amplitude.

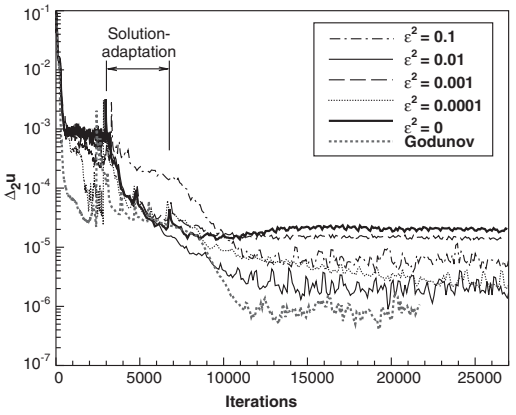

Figure 10. Convergence histories for different values of tolerance ε^2 and for the Godunov scheme ($\Phi = 0$).

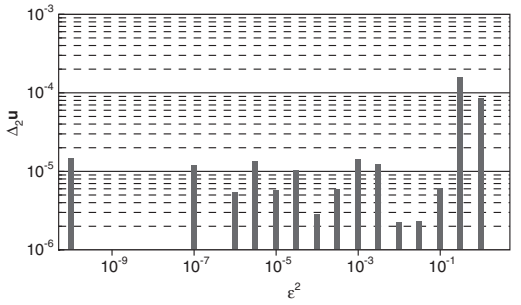

Figure 11. Final value of the summed relative residual vs. the tolerance ε^2.

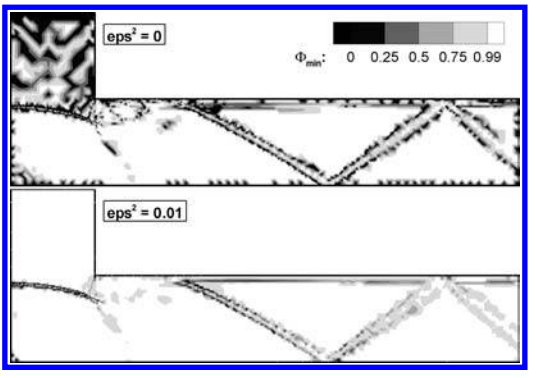

Figure 12. Distribution of Φ using the original BJ limiter (top, $\varepsilon^2 = 0$) and the smoothed BJ limiter (bottom, $\varepsilon^2 = 0.01$).

Solution-adaptation then clearly lowers the residuals by approximately two orders of magnitude. In the later stages of the simulation, limiter smoothing did improve convergence compared to the original BJ limiter ($\varepsilon^2 = 0$, represented by the continuous thick curve) except for the two strongest smoothings ($\varepsilon^2 > 0.1$). Overall, the relationship between ε^2 and the convergence quality is complicated.

Figure 10 also reports the residuals obtained with a first-order Godunov scheme (shown with a thick dotted curve). Due to its excessively diffusive character, the resulting steady-state flow solution lacks the sharp features past the bend. This had the consequence that the adaptive mesh refinement was less concentrated on the standing shocks and more cells of medium size were distributed, affording a larger average timestep and fewer iterations after the adaptation cycles. The Godunov scheme does not use any limiter (it is equivalent to setting $\Phi = 0$ uniformly), so it is insensitive to small-scale oscillations. Nevertheless, convergence stalled at 10^{-6} which is still greater than machine zero and may be attributed the Riemann formulation. This observation allows us to consider the smooth limiter with $\varepsilon^2 = 0.01$ as one that eliminates most of the convergence deterioration caused by MUSCL reconstruction.

Besides the convergence history, the final value of the residual (Fig. 11) also lacks a clear trend with respect to ε^2. Selecting $\varepsilon^2 = 10^{-2}$ or 10^{-4} reduces the residual by almost an order of magnitude compared to the original BJ limiter. Our computational experiments showed that this optimum is not universal: using Roe's approximate Riemann solver with entropy fix instead of HLLC yielded poorer convergence in general and the optimum was with $\varepsilon^2 = 10^{-3}$.

A comparison of the distribution of Φ_{min} for $\varepsilon^2 = 0$ and $\varepsilon^2 = 0.01$ in the last step of the simulation (Fig. 12) shows that smoothing reduces both the extent and the strength of limiting. While the smoothed limiter is active only at the shocks (and near the upper horizontal wall for the transverse flux), the original limiter is also active in the supercritical reach at the inlet. This is an area of near-uniform flow, where machine-level noise produces small extrema and triggers the limiter if these extrema exceed the level set by ε^2. The disturbance propagates downstream and is amplified at the sensitive slip discontinuity between the supercritical main flow and the recirculating eddy. This is reflected in the bumpy water surface of the eddy computed with $\varepsilon^2 = 0.01$ (Fig. 13). In spite of being formally non-monotone, the smoothed limiter yields apparently oscillation-free solutions. For $\varepsilon^2 = 1$, the smoothed limiter becomes so tolerant of oscillations that these visually disrupt the flow field near shocks, though excessive smoothing does not result in improved convergence, which is contrary to expectations.

Similar results were obtained with the van Leer and the Venkatakrishnan limiter (Φ_{VL} and Φ_{VKN}, respectively), whereas the minmod limiter (Φ_{MM}) converged

Copyright © 2006 Taylor & Francis Group plc, London, UK

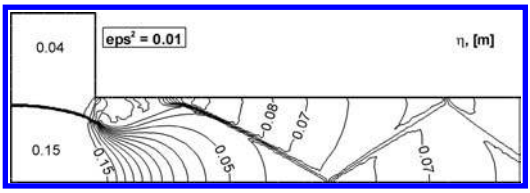

Figure 13. Water surface. Solution using a smoothed limiter ($\varepsilon^2 = 0.01$), contour interval = 0.01 m.

to one order of magnitude less. The poorer performance of the minmod limiter in this case is likely caused by the discontinuity of $d\Phi/dy$ at $y = 2$, i.e., in linearly varying flow field.

5 CONCLUSIONS

We have implemented Barth & Jespersen's (BJ) reconstruction technique into a MUSCL-type solver of the shallow water equations on an adaptive quadtree mesh. Without smoothing, convergence stalled for the steady transcritical flow problem in an L-shaped channel. Hampered convergence associated with slope-limited finite-volume schemes has long been known in the aerodynamic modelling community and was recognised to be due to the interference between small parasitic oscillations and the limiter that is triggered by those oscillations. A simple cure applicable to unstructured meshes is Venkatakrishnan's smooth limiter. We followed the same lines in deriving the smoothed equivalent of popular limiters in the framework of BJ's reconstruction. Among these, the BJ, van Leer and van Albada limiters have the benefit that they are also differentiable for $y' = 2$ (i.e., for linearly varying flow variables) in contrast to Venkatakrishnan's limiter.

The new smoothed BJ limiter is easy to implement and with the optimal ε^2 smoothing parameter, it improves convergence to near the same level as the first-order scheme, one order of magnitude better than the original BJ limiter. The limiter is, however, not as robust as expected, since the convergence history displayed high sensitivity to the value of ε^2. Numerical experiments not reported in this paper indicated that the convergence history is also highly sensitive to the choice of the base limiter, approximate Riemann solver and mesh density.

Further development of the presented technique should consider the analysis of the approximate Riemann solver's role in the scheme's convergence.

Large eddy simulation of fully-developed turbulent flow through submerged vegetation

T. Stoesser, C. Liang, W. Rodi, G.H. Jirka
Institute for Hydromechanics (IfH), University of Karlsruhe, Germany

ABSTRACT: Large Eddy Simulations (LES) are performed for an open channel flow through submerged vegetation with a water depth (h) to plant height (h_p) ratio of $h/h_p = 1.5$ according to the experimental configuration of Fairbanks and Diplas (1998). Fairbanks and Diplas measured longitudinal and vertical velocities as well as turbulence intensities along several verticals in the flow and the data are used for the validation of the simulations. The code MGLET is used to solve the filtered Navier Stokes equations on a Cartesian non-uniform grid. In order to represent solid objects in the flow, the immersed boundary method is employed. The computational domain is idealized with a box containing four submerged circular cylinders and periodic boundary conditions are applied in both longitudinal and transverse directions. The predicted streamwise as well as vertical mean velocities are in good agreement with the LDA measurements. Furthermore, good agreement is found between calculated and measured streamwise *r.m.s* velocities. Large-scale flow structures of different shape are present in the form of vortex rolls above the vegetation tops as well as von Karman type vortices generated by flow separation at the cylinders. In this paper the mean and instantaneous flow field is analyzed and further insight into the complex nature of flow through vegetation is provided based on Large Eddy Simulation.

1 INTRODUCTION

Both aquatic and riparian vegetation have become central to river and coastal restoration schemes, the creation of flood retention space and coastal protection projects. Aquatic and riparian plants obstruct the flow and reduce the mean flow velocities relative to non-vegetated regions, and the additional drag exerted by plants influences strongly the mean and instantaneous flow field as well as transport processes and system morphology. The flow through partially-vegetated channels or submerged vegetation is characterized by significant velocity gradients (both laterally and vertically) and strong secondary currents, which result in shear layer formation between the canopy and the flow region above the vegetation. A greater understanding of the interaction of flow with vegetation will improve our ability to accurately model flow and sediment transport through vegetation. Hence, both conceptually- and physically-based representations of vegetation-flow interactions are sought with the objective to reduce modelling uncertainty in engineering practice.

Most research activities on vegetation effects in the benthic and riparian environment have been devoted to laboratory flumes of simple cross-section, and many researchers (for example: Kouwen *et al*., 1969; Tsujimoto *et al.* 1992; Dunn *et al.,* 1996; Nepf and Vivoni, 1999 to name only a few) have observed that the mean streamwise velocity profile within an emergent or submerged vegetated layer (irrespective of whether the vegetation is rigid or flexible) no longer follows the universal logarithmic law. In the surface flow layer above a submerged vegetation zone, researchers (for example Kouwen *et al*. 1969) have generally assumed that the logarithmic law prevails. However, detailed studies of flow-vegetation interaction and the consequences on the instantaneous flow field are rare.

Presently, steady Reynolds Averaged Navier Stokes (RANS) models are the most practical approaches for high-Reynolds-number-fluvial hydraulics applications despite the rapid advancements in computational power and numerical algorithm development. These steady RANS models allow the resolution of the time-averaged turbulent flow field by adding a subgrid force to the RANS and turbulence transport equations to account for vegetative drag effects. For multi-dimensional flow problems, such methods were used by Shimizu and Tsujimoto (1994), Lopez and Garcia (1997), and Fischer-Antze et al. (2001) together with a k-ε turbulence closure approach to study the mean flow through submerged vegetation. Neary (2003) employed the k-ω model as turbulence closure and

Copyright © 2006 Taylor & Francis Group plc, London, UK

reported results very similar to the studies using a k-ε model. Naot *et al.* (1996) and Choi and Kang (2001) used a Reynold's Stress model (RSM) accounting for the anisotropy of turbulence, to simulate the flow through rigid submerged vegetation elements. However, within the surface-layer region there was only minor improvement in the computed mean velocity, turbulent intensity and Reynolds stress profiles for the RSM relative to the k-ε or k-ω model.

Mean flow features resolved by the steady RANS models include: **(a)** the suppression of the streamwise velocity profile in the vegetated zone, **(b)** the inflection of the velocity profile at the top of the vegetation zone, and **(c)** the vertical distribution of the turbulent shear stress, with its maximum value at the top of the vegetation zone. However, although mean velocities were predicted with satisfying accuracy, RANS models have been less successful at correctly predicting streamwise and vertical turbulence intensities, because these models cannot account for organized large-scale unsteadiness and asymmetries (coherent structures) resulting from turbulent flow instabilities. These coherent structures include: **(a)** the transverse and secondary vortices in the form of rolls and ribs (Finnegan, 2000), which occur at the top of the vegetation layer as a result of a Kelvin-Helmholtz instability due to the inflection of the streamwise velocity profile (Figure 1a), and **(b)** 3D vortices produced by the complex interaction of the approach flow with the stem (e.g trailing or necklace vortices) and the enforced vortex shedding in the wake of the stem due to flow separation (Figure 1b).

Recently, modeling techniques that directly resolve large-scale, organized, unsteady structures in the flow and advanced numerical techniques for simulating flows around multiple flexible bodies were introduced for the simulation of such or similar flow problems, e.g. URANS simulations by Paik et al. (2003) or Large Eddy Simulations by Cui and Neary (2002). Such techniques elucidate the large-scale coherent structures described above, their important role in vegetative resistance, and the interaction and feedback between the region within and outside the vegetation layer. The Large Eddy Simulation of flow through and above vegetation is not new and finds its origins in boundary-layer meteorology. To our knowledge, the first LES for flow over vegetation were presented by Deardoff (1972) in which the atmospheric boundary-layer over a wheat field was simulated. Further LES in boundary-layer meteorology were for the flow and the turbulent structures above forests, a flow problem that has been studied extensively with LES (e.g. Moeng, 1984, Shaw and Shumann, 1992, Kanda and Hino, 1993, Dwyer *et al.*, 1997). The advantage of LES lies in the fact that a highly resolved temporal and spatial picture of the flow field can be obtained. The vertical distribution of Reynolds stresses and turbulent fluctuations

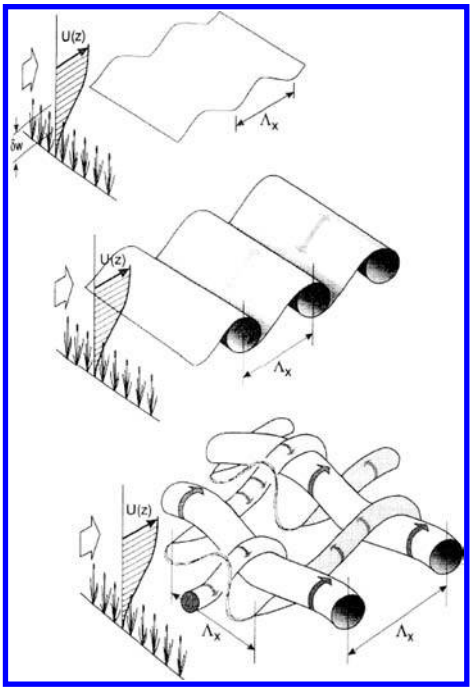

Figure 1a. Kelvin-Helmholtz instabilities resulting in ribs and rolls above vegetation layers (from Finnegan 2000).

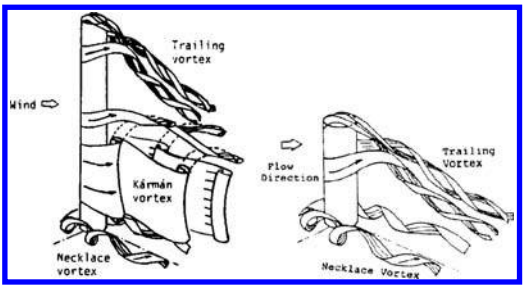

Figure 1b. Vortices originating at tall and short cylinders (from Kawamura et al, 1984).

as calculated with LES were found to be in good agreement with laboratory and field observations. These simulations show the enormous potential of LES in accurately predicting the flow and its associated time-dependent structures.

In this paper we present Large-Eddy simulations of turbulent channel flow through a matrix of cylinders. The flow around the individual cylinders is fully resolved by a high resolution grid and the cylinder-matrix can be regarded as an idealized vegetation layer. The time-averaged velocity field as well as turbulence quantities are presented and compared with laboratory measurements. Moreover, large-scale structures are shown to occur above and within the vegetation layer.

2 NUMERICAL METHOD

The LES code MGLET, originally developed at the Institute for Fluid Mechanics at the Technical University of Munich (Tremblay et al., 2000), was used to perform the Large Eddy Simulations. The code solves the filtered Navier-Stokes equations discretised with the finite-volume method and is based on a staggered Cartesian grid. Convective and diffusive fluxes are approximated with central differences of second order accuracy and time advancement is achieved by a second order, explicit Leapfrog scheme. The Poisson equation for coupling the pressure to the velocity field is solved iteratively with the SIP method of Stone (1968). The subgrid-scale stresses appearing in the filtered Navier-Stokes equations are computed using the Lagrangian dynamic approach of Meneveau *et al.* (1996). The no-slip boundary condition is applied on the surface of the cylinders and the immersed boundary method (e.g. Verzicco, 2000) is employed. This method is a combination of applying body forces in order to block the cells that are fully inside the cylinder geometry with a Lagrangian interpolation scheme of third order accuracy, which is used for the cells that are intersected by the cylinder surfaces to maintain the no-slip condition.

3 FLOW CONFIGURATION

The geometry and the Re number of 15000, based on the channel depth and bulk velocity, are chosen analogous to experimental laboratory investigations undertaken by Fairbanks and Diplas (1998). This allows a comparison between LES and experiments and hence a validation of the LES code as well as the model approximations for the subgrid scale stresses and the treatment of the individual cylinders with the immersed boundary method. In order to investigate the flow through vegetation, Fairbanks and Diplas placed rigid cylinders in a staggered arrangement into a rectangular flume and carried out detailed LDA measurements at the six verticals within the flow as indicated in Figure 2. The Reynolds number based on the bulk velocity u_{bulk} and the cylinder diameter D, Re_D, is approximately *800*. The ratio of cylinder height h_p to water depth is $h_D/h = 2/3$ and the computational box, which is the shaded area indicated in Figure 2, contained four submerged cylinders. The domain spans *20D* in streamwise, *10D* in spanwise and *18D* (which is the full water depth) in vertical direction, respectively. Several simulations with different grid resolutions were carried out, however, in this paper we will only present the results from the finest grid. The grid consisted of $612 \times 308 \times 141$ grid points in streamwise, spanwise and vertical directions, respectively, which sums to a total of approximately

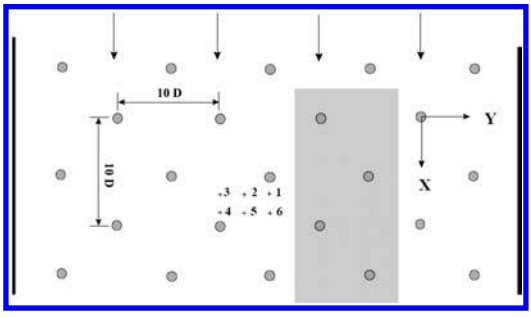

Figure 2. Flow Configuration indicating the positions of the 6 measurement verticals and the computational box.

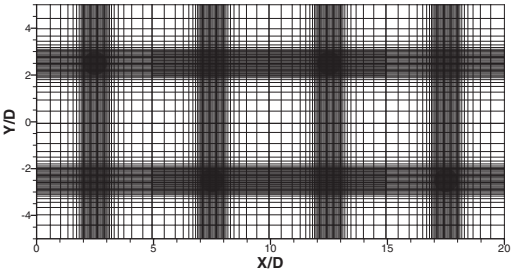

Figure 3. Computational grid for the Large Eddy Simulations (only every 4th grid line is shown).

27 Million grid points. The grid spacings in terms of wall units in streamwise and spanwise direction were $\Delta x^+ = \Delta y^+ \approx 40-60$ in the areas between the cylinders and $\Delta x^+ = \Delta y^+ \approx 1$ near the cylinder surface. In the vertical direction the grid was stretched likewise and values of $\Delta z^+ \approx 60$ near the water surface and $\Delta z^+ \approx 1$ near the top of the cylinders and near the channel bed were obtained. Figure 3 shows the grid in a horizontal plane indicating the refinement of the grid towards the cylinders (note that only every 4th grid line is plotted). Periodic boundary conditions were applied in the streamwise and spanwise directions. At the channel bed the no-slip condition is used and the free surface was set as a frictionless rigid lid and was treated with the symmetry condition. The flow was established over a period of approximately 50 flow through time and circa 80 flow throughs was taken as averaging period. The calculations are still ongoing at the time of the writing and the latest results will be presented at the conference.

4 RESULTS AND DISCUSSIONS

4.1 *Time-averaged flow field*

In Figures 4 and 5, the time-averaged flow field in two selected longitudinal planes (position is indicated in the sketch in the upper right corner) is presented. Due

Copyright © 2006 Taylor & Francis Group plc, London, UK

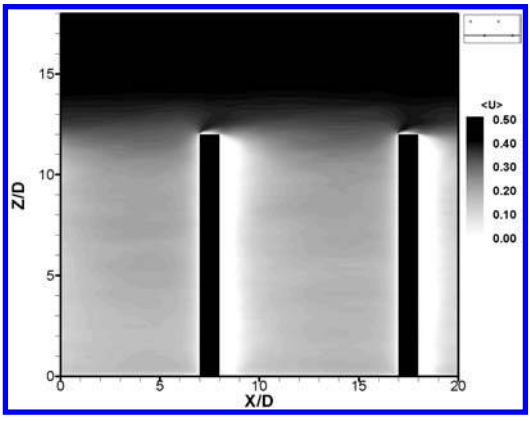

Figure 4. Distribution of time-averaged streamwise velocity in a plane through cylinders (see sketch in the upper right corner).

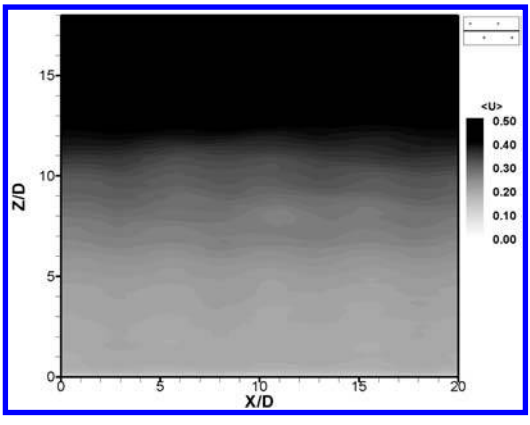

Figure 5. Distribution of time-averaged streamwise velocity in a longitudinal plane midway between cylinders (see sketch in the upper right corner).

to flow separation at several locations on the cylinder walls, e.g. on the top and the rear of the cylinder, the flow develops a number of recirculation zones, due,. The retardation of the flow in the vegetation layer is clearly visible and prevails over the whole width of the channel. Above the cylinders the flow accelerates, causing a strong shear layer. The mean flow field exhibits a wavy shape from the top of the cylinders to the free surface which can be attributed to standing waves forming above the recirculation bubble on the top of the cylinder. In the vegetation layer the velocities are almost constant, though slightly higher in planes where no cylinders are present, except in the rear of the cylinders were recirculation over the whole cylinder height occurs.

Figure 6 presents the comparison of LES with the measurements along the six selected verticals in the flow for time-averaged streamwise velocities. Overall, a good match between the computed and measured quantities could be achieved. Especially the well known vertical distribution of streamwise velocities of the flow through vegetation was reproduced and exists irrespective of the position of the profile. At position #1, which is directly behind the cylinder, the LES underestimates somewhat the streamwise velocities in the vegetation layer. However, this is the region where the highest turbulence occurs, and a longer averaging period is required to obtain a smooth vertical distribution of velocity. Along the Position #6, which is also behind the cylinder but further downstream, the match between measured and computed velocities is very good. Equally good is the agreement at the positions in front of the cylinder (#3 and #4) and along the positions between the cylinders (#2 and #5). Also noticeable is the velocity bulge near the channel bed, resulting from the near bed necklace vortex around the cylinder, which is predicted to a very satisfying degree (see e.g. Positions #1 and #6).

The above mentioned coherent flow structures affect significantly the turbulence intensity distributions along the six verticals. In Figure 7 measured and computed streamwise turbulence intensities are compared. Similar to the comparison of mean velocities, the match between computed and measured *r.m.s* values is very good. As can be seen clearly, the peak in the turbulence intensities appears in the vicinity of the vegetation tops (indicated by the green line). This is the area of highest vertical shear where most of the turbulence production occurs. This region is regarded as the interface between the upper part of the flow and the vegetation layer where momentum transfer between these layers occurs. It should be noted that for a smooth distribution of *r.m.s* velocities a longer averaging time is needed.

Figures 8 and 9 present the distribution of the kinetic energy in two selected longitudinal planes (indicated in the sketch in the upper right corner). In the plane where the cylinders are present (Figure 8), two significant regions of high turbulence can be identified. The highest values of kinetic energy occur in the small recirculation bubble on the top of the cylinder. A second region of high turbulence is the area were the trailing vortex penetrates into the vegetation layer and interacts with the von Karman vortices (see Figure 11) that are shed from the cylinders. In longitudinal planes between the cylinders (Figure 9) the above mentioned shear layer between the vegetation layer and the region above it with elevated levels of kinetic energy is clearly visible and extents between $Z/D = 8 - Z/D = 15$.

4.2 *Instantaneous flowfield*

features of the flow through and above a vegetation layer can be identified. Near the channel bed the necklace vortices cause a more or less strong disturbance of the near bed flow. Near the bottom of the second cylinder (from the left) a necklace vortex, also known as the horseshoe vortex, is visualized and strong vertical accelerations are present. In the middle part of the vegetation layer the von Karman vortices dominate the

flow and instantaneous flow separation occurs. However, the vertical acceleration is fairly small. Near the top of the vegetation layer, the trailing vortices spinning from the top of the cylinder and penetrating the flow within the vegetation layer, is visible. At this instant in time a trailing vortex is present at each of the cylinder tops. Further above the cylinders the flow is characterized by the organized structures in

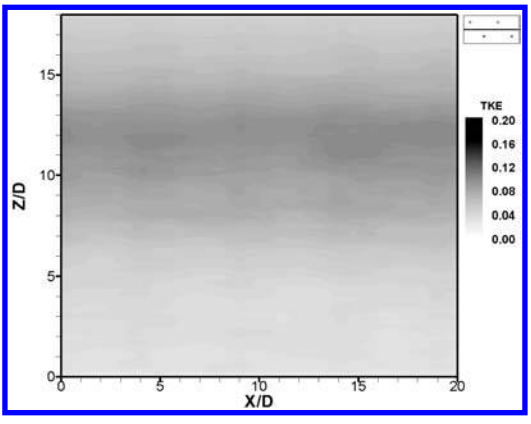

Figure 9. Distribution of time-averaged kinetic energy in a longitudinal plane midway between cylinders (see sketch in the upper right corner).

forms of ribs and rolls, which causes up and downward movement of the flow.

In Figure 11 two dominant flow structures present in the vegetation layer and above the cylinders are visualized. The red isosurfaces of instantaneous pressure fluctuation p' illustrate von Karman vortices shed from the cylinders as a result of alternating flow separation. The vortices travel downstream until they are destroyed by either the trailing vortex that penetrates from the upper region or by interaction with the following cylinder. The upper flow structure, here also visualized by the blue isosurfaces of instantaneous pressure fluctuation, can be identified as vortex rolls that are generated by the shear layer between the vegetation layer and the region above. As can be seen clearly, these two different structures are independent of each other due to the fact

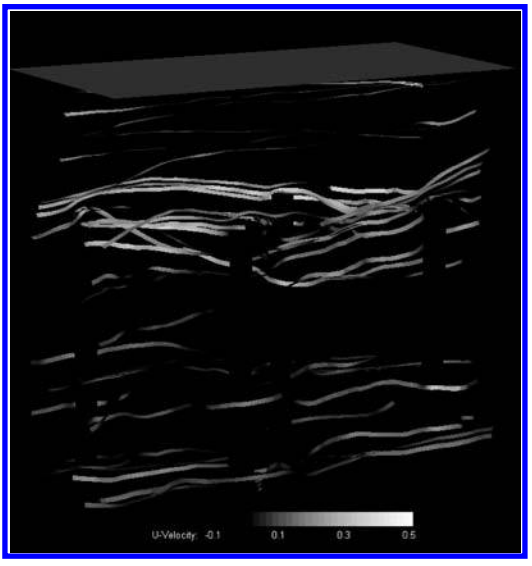

Figure 10. Instantaneous streamtraces colour-coded with instantaneous streamwise velocity.

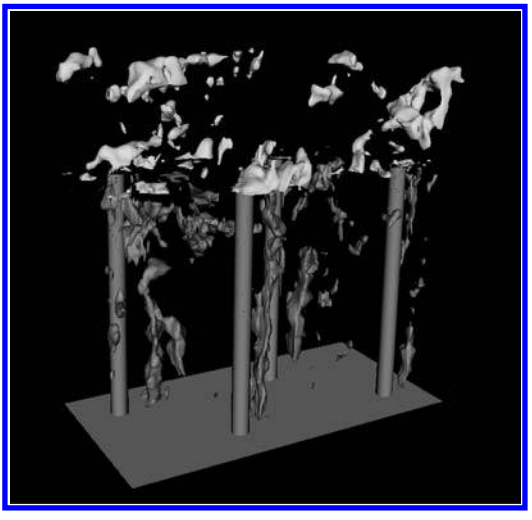

Figure 11. Instantaneous isosurfaces of pressure fluctuations p' visualizing vortex rolls (light grey) and von Karman vortices (dark grey).

that their origin is different. As was shown previously, another flow structure that is responsible for flow interaction is the trailing vortex that disturbs the flow within the vegetation layer transporting momentum from the upper layer of the channel into the vegetation layer and is also responsible for momentum exchange between these two layers as the large-scale ribs and rolls.

5 CONCLUSIONS

In this paper we have presented the results of a Large Eddy Simulation of open channel flow through and above a matrix of cylinders. The time averaged data of the simulations were compared to LDA measurements from laboratory experiments of the same flow. The well known distribution of streamwise velocities was reproduced and the comparison along the six measurement verticals showed good agreement of calculated values with measured data. Furthermore, turbulence intensities were compared and again a good match between computed and measured quantities was found. In addition to the mean flow field the instantaneous flow field was investigated. A strong shear layer develops above the vegetation layer that is responsible for the formation of coherent flow structures being present in the form of vortex rolls. Within the vegetation layer, vortex shedding from the cylinders occurs and von Karman vortices are present. Near the channel bed, the presence of the necklace vortex was confirmed. Also confirmed was the trailing vortex originating at the cylinder tops. It was found that the latter vortex as well as large-scale flow structures in form of ribs and rolls are the main mechanism for flow interaction between the upper part and the vegetation layer.

ABSTRACT: This paper summarizes the results of experimental measurements performed to characterize mass exchange at different depth levels between a simplified dead zone and an open-channel. In the analyzed case the flow in the flume was subcritical, an the dead zone was modelled as a lateral rectangular cavity with aspect ratio, length to width, of 2. It was possible to establish that mass transfer is mainly due to the engulfing process associated to a Kelvin-Helmholtz instability at the channel-cavity interface and that the influence of the gradient of concentration is not important as the one-dimensional Transient Storage Model assumes. The flow within the cavity was dominated by a two gyre system. It was observed that the main gyre modulates the interfacial instability and that there is a marked variation of mass exchange with depth.

1 INTRODUCTION

The presence of large scale recirculation zones in rivers modify the characteristics of the mass transport process in rivers. Normally a difference between the concentration curves measured and modelled by the classical advection-dispersion equation is observed. In order to improve the results several researchers, Chapra and Runkel (1991), De Smedt, et al. (2005), Czernuszenko and Rowinski (1997) have used a first-order model exchange (Transient Storage Model, TSM) between two conceptual zones, a dead zone and a main flow zone. The TSM considers that the exchange process between both zones depends on the concentration gradient and a mass exchange coefficient. However, even with this model the skewness of the observed concentrations does not appear to be decreasing as the theory predicts, (Nordin and Troutman, 1980). On the other hand, even though there is a good fit between the observed and modelled concentrations the information of the real process obtained from its parameters is not enough to understand the physical processes occurring in the recirculation zones and its effects on river mass transport. Equations 1 and 2 show the mass balance equations for main channel and dead zone respectively. In the main channel the model assume that the solute concentration changes because of the advection-dispersion processes and the first order exchange with the dead zone. In the former zone, the model assume that the concentration change is only due to the first order exchange with the main flow.

$$\frac{\partial C}{\partial t}+\frac{Q}{A}\frac{\partial C}{\partial x}=\frac{1}{A}\frac{\partial}{\partial x}\left(AD_L\frac{\partial C}{\partial x}\right)+\alpha\left(C_S-C\right) \tag{1}$$

$$\frac{\partial C_S}{\partial t}=-\alpha\frac{A}{A_S}\left(C_S-C\right) \tag{2}$$

Where C is the solute concentration in the main channel $[M/T]$, Q is the volumetric flow $[L^3/T]$, A the cross sectional areaof the main channel $[L^{-2}]$, D_L the longitudinal dispersion coefficient $[L^2/T]$, C_s the solute concentration in the storage zone $[M/T]$, A_s the cross sectional area in the storage zone $[1/L^2]$, α the mass exchange coefficient $[1/T]$, t time$[T]$, x the longitudinal coordinate $[L]$.

The simplest way to model a real dead zone is by means of a rectangular side-cavity, which is similar to harbours, groyne fields and bottom depressions. There are many investigations related with the flow inside cavities, for example according to Shen and Floryan (1985) in cavities with aspect ratio, length to width, 2 is possible to observe a primary and a secondary gyre. Garrison and Rogers (1994), using concentration determination by image analysis and changing upstream conditions close to the cavity, concluded that

Copyright © 2006 Taylor & Francis Group plc, London, UK

the instabilities generated at the interface are fundamental for mass exchange. As a result of experiments in a cavity located at the bottom of a Odell-Kovasznay channel, Strang and Fernando (2004) conclude that there is an increment of turbulent kinetic energy at the cavity-channel interface, and for cavities with aspect ratio equal or greater than 2, the mass exchange is intermittent. Uijtewaal et al. (2001) who did experiments on river groynes, show that this exchange process can be interpreted as a first-order behaviour and McCoy et al. (2005) using *Large Eddy Simulation* (LES) conclude that this exchange process is three-dimensional and changes with depth.

Muto et al. (2000), as a conclusion of experiments in open-channel side cavities with aspect ratio 1 and 3, show that the mass exchange for large aspect ratio cavities is also mainly due to instabilities on the dominant internal flow. For the same case and based on experimental and 2-D numerical results, Kimura and Hosoda (1997) point out the characteristics of the structures of the interface. These structures can be decomposed into two components due to seiching and shear instability respectively; during one seiche, cycle-velocity variations caused by instability are amplified to the large scale vortex selectively by the interaction between seiche and instability components.

This work presents a characterization of the mass transfer in a rectangular dead zone with aspect ratio, length to width, of 2. Based on the similar patterns of flow in the previous cited investigations and with the aim to describe in a proper way the mass exchange process, a high flow depth was used for this experiments, but even with this assumption the results are comparable with real river cases Le Coz et al.). This study was conducted over different depth levels. The Flow structure was obtained by means of *Particle Tracking Velocimetry* (*PTV*) and spatially-averaged concentration curves and visualizations by means of *Laser Induced Fluorescence* (*LIF*).

2 PREVIOUS OBSERVATIONS IN THE CHILLAN RIVER

In order to understand the influence of transient storage in mass transport, a tracer study was performed in a reach of the Chillán river, Chile. The reach, a sequence of pools and riffles with presence of lateral recirculation zones and a gravel bed, was 1.2 km long, with a flow discharge of 2.7 m^3/s (subcritical regime) and a mean width of 18 m.

The tracer used was Rhodamine WT and the instantaneous injection of the dye was made far enough of the first sample station in order to ensure that the mixing process was completely in the cross-section. Four sample stations (E) were used in this field test. The associated concentration response curves to each station are shown in figure 1. As can be seen the curves

present long tails which is due to the effect of transient storage, i.e recirculation zones and hyporreic flow. Using this measurements, the solution obtained by De Smedt et al. (2005) for the TSM model and an optimization algorithm, it was possible to obtain the value of the exchange coefficent α for the sub-reaches (SR) formed between the sample stations. This values are presented in table 1. The exchange coefficient obtained corresponds to a mean value of the effects of the recirculation zones and hyporreic flow over each sub-reach. These value are small but the total effect over mass transport is clearly observed in the curves showed in 1. From this models it is not possible to understand the importance of the recirculation zones in mass transport and due to this experimental research was developed in the laboratory.

3 DESCRIPTION OF THE EXPERIMENTS

In order to understand the physical processes occurring in a recirculation zone, experiments were conducted in a laboratory flume 1200 cm long, 30 cm width, 30 cm deep and a longitudinal slope of 0.001. A width reduction of 10 cm was set along one side of the flume and the cavity was located 300 cm upstream from the end of the flume. A schematic representation of the experimental set-up can be seen in figure 2. The hydraulic condition for the experiments, depth (H), flow discharge (Q), mean velocity (U), hydraulics radius (R), Reynolds number ($Re = \frac{U H}{\nu}$) and Froude number (Fr) are summarized in table 2.

results (*PTV*) and Laser Induced Fluorescence (*LIF*) were employed. Both systems were composed by a 400 MW two-colour laser beam and by a 30 HZ digital camera. In the case of PTV, acrylic particles were employed and tracked by the implementation in Matlab of a dynamic, binary, spatial cross-correlation algorithm between two sequential images (Hassan et al., 1992). Based on the results obtained by David et al. (2002), the Inverse Weighting Method with a Gaussian Adaptive Window, was used for velocity interpolation. For LIF a green-fluorescent dye was injected instantaneously over the entire cross-section of the flume and to avoid variations in ambient light conditions a dark chamber was built in the channel work area. The response curve at each level was obtained using a previously determined calibration curve. It was found that in the used concentration range, there was a linear relation between the tracer concentration and the graylevel intensities. It was assumed that the dispersion process was not relevant for the determination of the response curves in the cavity, i.e. there was no presence of tracer in the channel after the cavity reaches the spatially average peak concentration.

4 GENERAL CHARACTERISTICS OF FLOW STRUCTURE AND MASS TRANSFER

4.1 *Particle tracking velocimetry results (PTV): flow structure*

PTV measurements were carried out to characterize the flow structure at heights of 20, 60 and 100 mm over the channel bottom. 1000 pairs of frames were averaged in order to get a description of the mean flow properties inside the cavities. In Figures 3, 4, and 5, the mean velocity and streamlines are presented. Two main zones are distinguished, a primary gyre located at

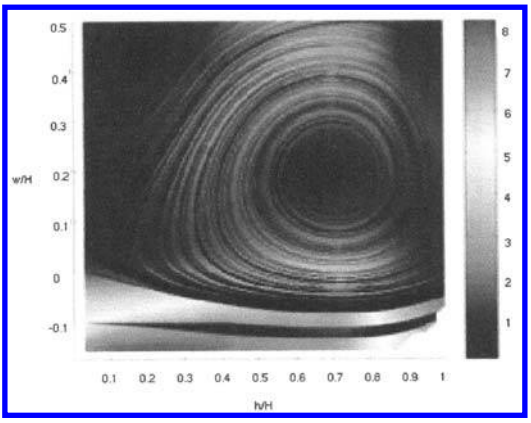

Figure 3. Streamlines over mean velocity 100 mm.

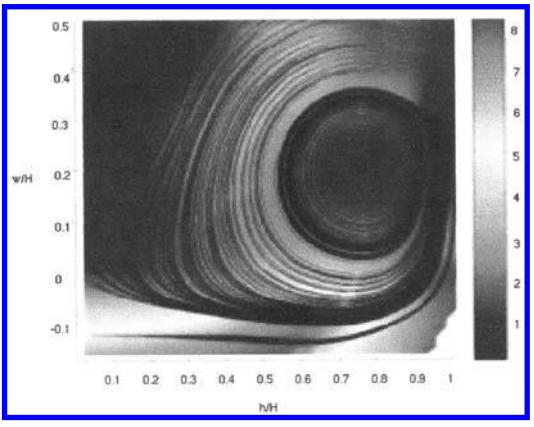

Figure 4. Streamlines over mean velocity 20 mm.

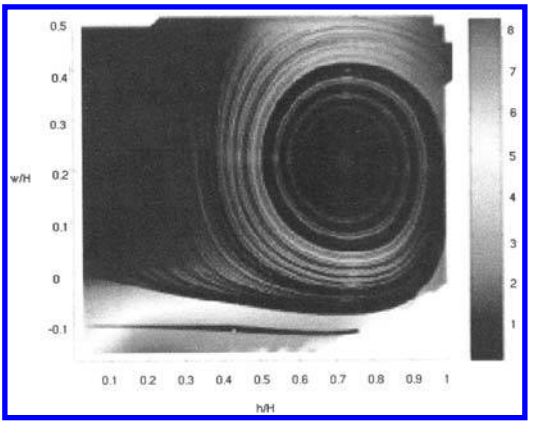

Figure 5. Streamlines over mean velocity 20 mm.

the downstream section of the cavity and a secondary gyre located at the upstream internal corner of the cavity which disappears at 20 mm. From video analysis it was possible to observe an oscillation of the primary

Copyright © 2006 Taylor & Francis Group plc, London, UK

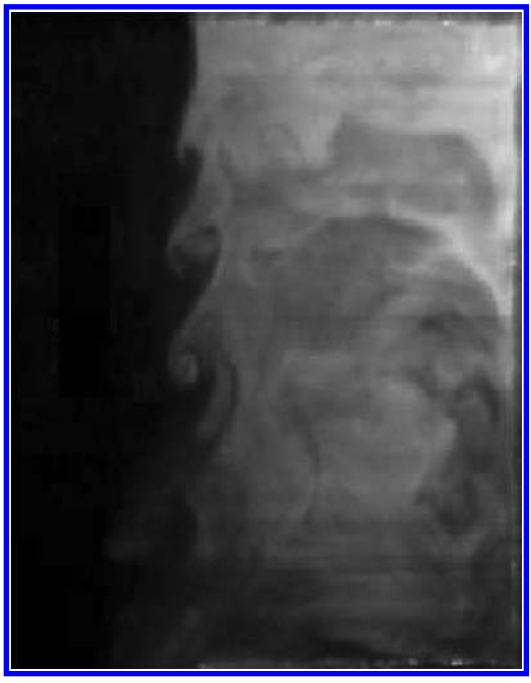

Figure 6. Kelvin-Helmholtz instability at Channel-Cavity interface. The figure show the complete cavity area.

gyre. In general, the velocity magnitude does not suffer important changes and the maximum is at the most six times lower than the main channel flow mean velocity.

4.2 *Laser induced fluorescence (LIF): general observations*

Because of the strong velocity gradient located at the channel-cavity interface, a Kelvin Helmholtz instability is formed. These structures are responsible for the mass exchange between cavity and channel (Garrison and Rogers (1994), Uijtewaal et al. (2001)). This kind of structure depends on the velocity difference between cavity and channel. This means that differences in the vertical flow structure in the channel could affect, in theory, mass exchange. In general, Kelvin-Helmholtz instability allows the exchange from cavity to channel by means of convective patterns called Kelvin billows, and from channel to cavity by means of the engulfing process, these coherent structures will be described below.

From video analysis the velocity of the Kelvin billow was estimated. The advection of these structures was approximately 3 times lower than channel mean velocity, independent of the vertical position, but their frequency of generation changes with elevation: $\simeq$1.1 s at 100 mm, $\simeq$0.7 s at 60 mm, and $\simeq$0.7 s 20 mm.

An intermittent relation between shear layer and primary eddy (shear layer perturbations) has been

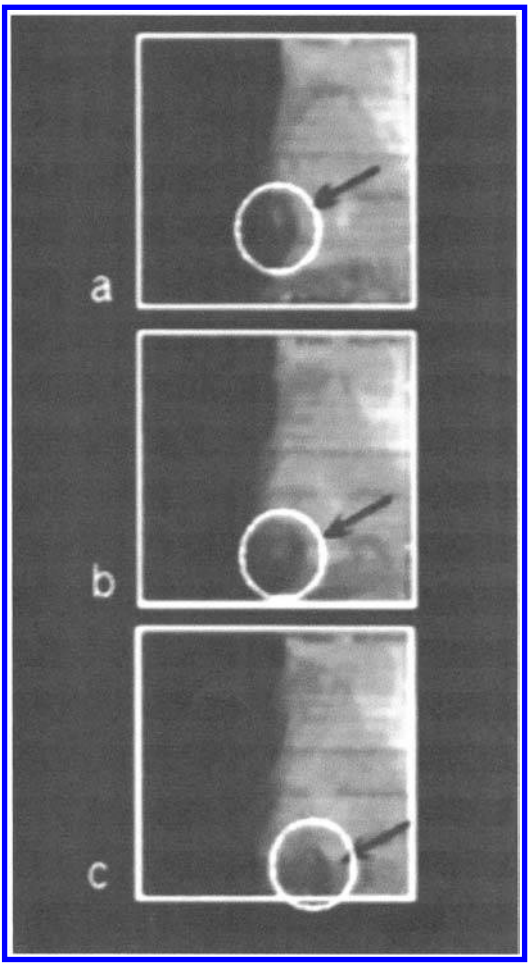

Figure 7. Engulfing process. The picture shows the total cavity area: (a) The Kelvin billow is transported downstream. (b) The billow hits the downstream corner of the cavity. (c) A new volume of water is directly incorporated into the cavity.

observed previously by Strang and Fernando (2004) and Uijtewaal et al. (2001) and they point out that this is the most important mechanism to improve exchange. According to Uijtewaal et al. (2001) the flow is far from stationary and the large turbulence structures in the mixing layer play a prominent role in the exchange process, which is validated by the present experiments. The diffusion process, that occurs preferably in the billows, is fast but does not allow a high volume of exchange in comparison with the observed volume associated to the engulfing process. Figures 8, 9, 10 show the fast diffusion mechanism occurring on Kelvin billows. These figures describe the movement of the upstream billow in figure 11. Due to the camera definiton was not possible to obtain a better resolution for these images. Because of this an investigation

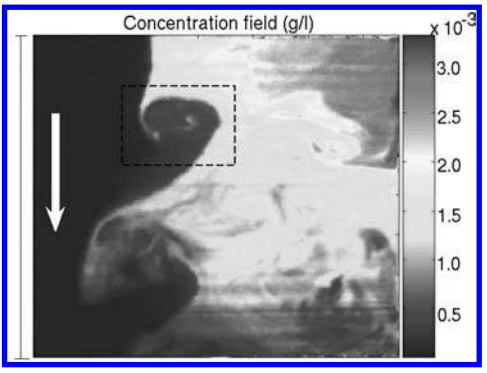

Figure 11. Instantaneous Concentration field at 60 mm. The figure shows the complete cavity area.

conducted to quantify the exchange of these structures will be performed in a future work.

An instantaneous distribution of concentration in the cavity is shown in Figure 11, in this figure it is possible to observe that in the region of the secondary gyre there is an internal recirculation zone of high concentration compared to the concentration in the primary gyre.

4.3 *Engulfing process*

This process is mainly responsible of mass inflow to the cavity. When Kelvin billows are transported, they hit the downstream corner, surrounding fluid that is incorporated into the cavity. The dynamic is presented in figure 7. This process takes relevance when a perturbation acts over the shear layer. In that case the size and direction of the Kelvin billows changes producing a pulse of fluid that is taken inside the cavity.

5 CONCENTRATION RESPONSE CURVES IN THE CAVITY

Using LIF measurements, a mean concentration (spatially averaged over the area) in the cavity was calculated at 5 depth-levels, 20, 40, 60, 80 and 100 mm over the channel bottom. The results are presented in Figure 12, where it can be observed that the lowest exchange takes place at 40 and 20 mm, a medium exchange at 60 and 80 mm and the highest exchange at 100 mm. A similar observation was obtained by Wallast et al. (1999) who compared the exchange integrated over the entire depth with that estimated only at the surface level. They point out that this is due to secondary flow and three-dimensional structures in the flow. The similitude of the mean concentration curve inside the cavity with the previously concentration response curve measured in the Chillán river, shows that the effect of the secondary gyre in the averaged

Copyright © 2006 Taylor & Francis Group plc, London, UK

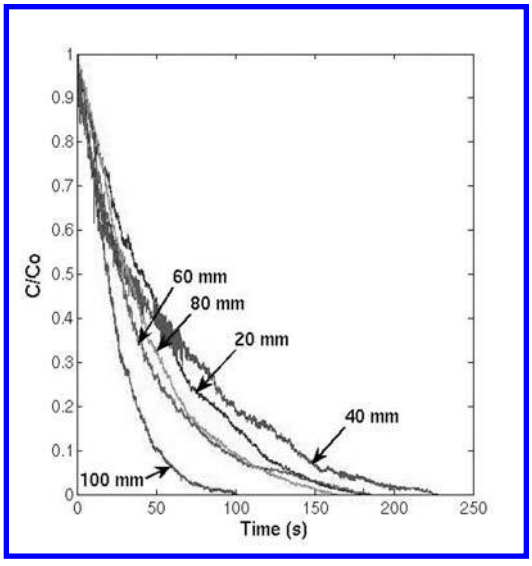

Figure 12. Spatially-averaged concentration response curves in the complete cavity area for 20, 40, 60, 80 and 100 mm over channel bottom.

cavity concentration is the same effect of dead zones over open-channel flows.

5.1 *Evolution of the exchange coefficient with depth*

It is clear from LIF analysis that mass exchange between main channel and cavity do not depend importantly on the concentration gradient, but on the coherent structures formed at the channel-cavity interface. Maybe, due to that assumption the TSM does not allow a physical understanding of the influence of recirculation zones. However, the averaged concentration curves show a first order decay and can be calculated by fitting concentration modelled by equation 3 to experimental data.

$$C(t) = C_0 e^{kt} \tag{3}$$

Where C $[M/L^3]$ is the cavity concentration, C_0 $[M/L^3]$ the initial concentration, k $[1/T]$ the exchange coefficient and t, the time.
Because of the variation of the internal velocity in the cavity with the longitudinal coordinate, the shear velocity (U_*) in the channel flow was used as velocity scale. The spanwise length of the cavity (H) was used as length scale. Using this variables a dimensionless exchange coefficient can be defined as:

$$K = \frac{kH}{U_*} \tag{4}$$

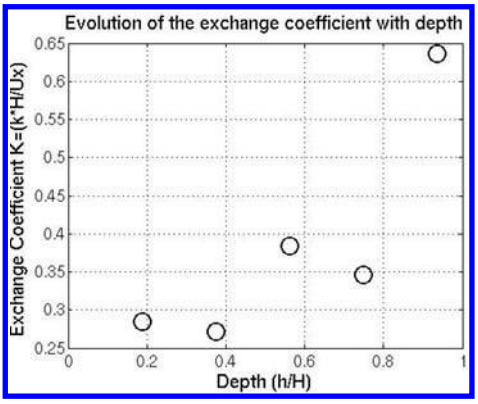

Figure 13. Dimensionless exchange coefficient at different depth levels.

Table 3. Exchange coefficient at different depth levels (1/s).

20 mm	40 mm	60 mm	80 mm	100 mm
0.0187	0.0178	0.0252	0.0227	0.0418

The dimensionless exchange coefficient calculated for each level is presented in figure 13. The corresponding dimensional value for exchange coefficient at each level is presented in Table 3. Clearly, the exchange coefficient increases towards the surface, indicating that the highest mass exchange takes place near the surface.

6 REGIONS ANALYSIS

In order to understand the influence of the primary and secondary gyres on mass transfer, the cavity was divided in two regions: a high velocity region and a low velocity one. The low velocity region was defined arbitrarily as the zone located at the upstream end of the cavity with velocities lower than 1 cm/s. The definition for levels at 40 and 80 mm was obtained by interpolation of the adjacent levels. The low and high velocity regions definition for each level are shown in Figure 14.

6.1 *Peak concentrations in the high and low velocity regions*

Figure 15 shows the influence of low and high velocity regions on mass exchange. The local peak concentration was made dimensionless by means of the maximum mean concentration in the cavity. At the 20 mm level, the low and high velocity regions have almost the same behavior than the complete cavity.

Copyright © 2006 Taylor & Francis Group plc, London, UK

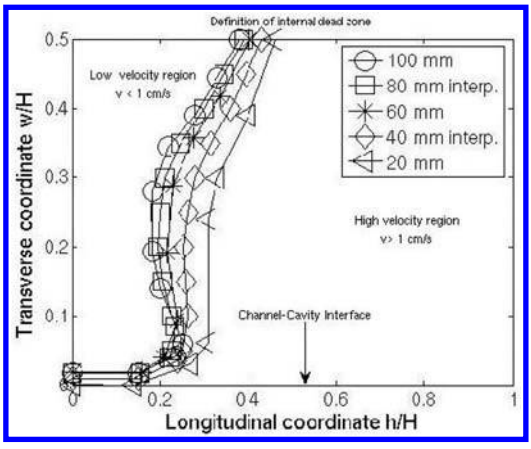

Figure 14. Definiton of low and high velocity regions.

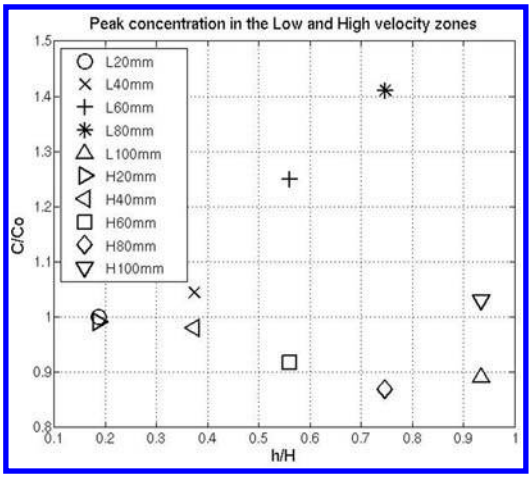

Figure 15. Peak concentrations in low and high velocity regions.

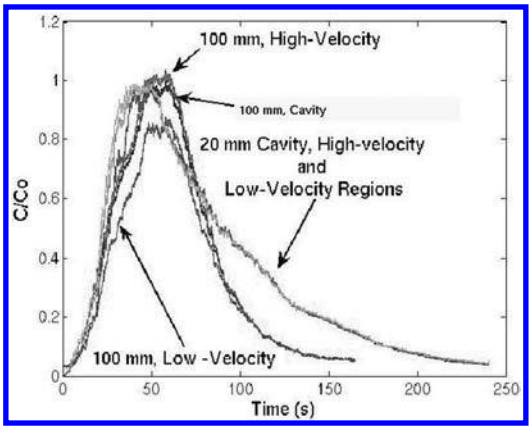

Figure 16. Concentration response curves at 20 and 100 mm. The figure show the concentration curves for each of the three analyzed areas: the complete cavity area, the low velocity region and the high velocity region.

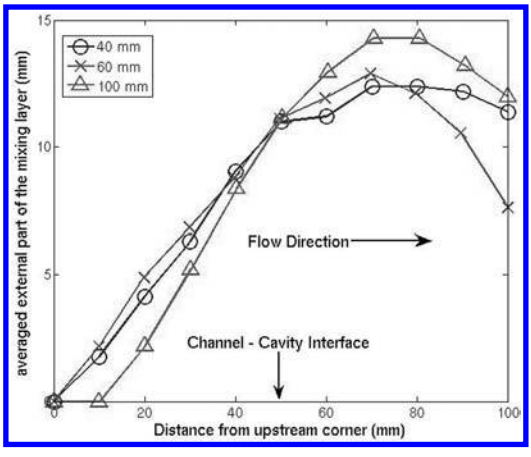

Figure 17. Mixing layer growth out of the cavity.

This is because of the disapearance of the secondary gyre at that level. From 40 mm to 80 mm the importance of the internal recirculation zone (secondary gyre) increases, but at the 100 mm level the primary gyre has the same behavior as the cavity, but the concentration in the low velocity zone is somewhat lower. This situation can partly explain the higher mass exchange obtained at the 100 mm (where also the generation of billows is higher), and as a consequence a three-dimensional characterization of flow structure is needed in order to explain this behavior.

As an example, concentration response curves for the three analyzed regions (the complete cavity, the low velocity region and the high velocity region) at 20 and 100 mm are presented in Figure 16.

7 GROWTH OF THE MIXING LAYER OUT OF THE CAVITY

In order to clarify the differences in mass exchange between the 100 mm level and the others ones, an averaged estimation of the mixing layer structures outside the cavity was developed with the aim of finding possible differences in the billows size. The calculation of the external mixing layer growth was obtained using an over-exposition of the images frames in a period of 20 (s) for the levels located at 40, 60 and 100 mm over channel bottom. Figure 17 shows that mixing layer growth is similar in all the cases, but slightly greater extension of this structure is observed near the surface. The decrease in size in the downstream corner is due to the influence of the primary gyre (main inflow zone).

Copyright © 2006 Taylor & Francis Group plc, London, UK

8 CONCLUSION

Based on *Particle Tracking Velocimetry* (PTV) and *Laser Induced Fluorescence* (LIF) results, it is concluded that the flow structure inside the cavity stays almost constant across the water column, with the exception of the plane located at 20 mm. There are two main regions dominated by a primary and secondary gyre, respectively. The main source for turbulent mass exchange is located at the channel-cavity interface, where Kelvin-Helmholtz instabilities are generated. These structures are responsible for the main mass exchange process from channel to cavity: the engulfing process. The exchange from cavity to channel is carried out by means of the Kelvin-Helmholtz structures, but mainly by intermittent instabilities in the flow inside the cavity that change the size of the Kelvin billows.

The concentration response curves showed a marked variation of exchange with depth. The mean concentration curves show that the exchange process is higher at 100 mm and lower for the range located between 20 and 80 mm levels. The over-exposition images obtained for mixing layer growth characterization show that there are no important differences in billow sizes at different levels, although there is a tendency for the maximum size of them to be close to the surface. The internal recirculation zone which disappears at the 20 mm level, increases its mass retention with depth, but decreases this retention at the 100 mm level. As a conclusion a three-dimensional characterization of the flow structure must be done in order to understand the behavior observed in this study. These experiments must be conducted parallel to surface oscillation measurements in order to better understand the three-dimensional effect of perturbations in the mixing layer.

Coherent structure of horizontal eddies in meandering compound open-channel flow by using multi-layer scanning PIV

M. Sanjou, I. Nezu, T. Doi & H. Quang
Dept. of Civil Eng., Kyoto University, Kyoto, Japan

ABSTRACT: It is necessary to investigate coherent eddy structure in meandering compound open-channel flows for predicting the transport and distribution of suspended sediments in actual rivers. However, in previous studies, flow-visualization techniques such as PIV and PTV, have not sufficiently been applied to such flows, and thus, there is almost no detailed information of coherent turbulence in meandering compound open-channel flows. Therefore, in this study, we conducted innovative flow-visualization measurements by using a multi-layer scanning PIV system, and analyzed instantaneous velocity vectors on horizontal planes at several different elevations simultaneously. As the results, the vortex-existing probability and space-time correlations between the different elevations were revealed in meandering compound open-channel flows.

1 INTRODUCTION

Two-stage free-surface flows can be often observed in rivers in flood, and they consist of the inbank and overbank areas. Since such a compound open-channel flow causes significantly the inflectional instability near the junction region between the main-channel and flood-plains, the coherent horizontal vortices are generated and advected downstream. These eddies induced mass and momentum exchanges significantly between the high-speed inbank flow and the low-speed overbank flow, and thus, such compound open-channel flows have been studied intensively in river management and hydraulic engineering.

With an innovative development of measurement instruments, turbulent structures have been revealed even quantitatively in the past decade. For example, Tominaga & Nezu (1991) have conducted some accurate turbulence measurements with a laser Doppler anemometer (LDA), and they revealed the distributions of primary velocity and secondary currents in compound open-channel flows. Nadaoka & Yagi (1998) developed a two-dimensional (2-D) LES model in order to investigate the developing and merging processes of coherent horizontal eddies in the compound open-channel flows. Nezu *et al.* (2004) have developed a dual-layer PIV system and revealed the unsteady motion of 3-D vortex-tube structure in a depth-varying compound open-channel flow. As mentioned above, there are a lot of previous studies that offer the detailed information on the hydrodynamic properties, turbulence structure and coherent motions.

On the other hand, actual rivers generally have many bending and meandering sections. Several researchers had a great interest in meandering compound open-channel flows. For example, Fukuoka *et al.* (1997) have measured all three components of velocities by using an electromagnetic velocimetry (EMV) in a large-scale laboratory flume with two-stage meandering zone in order to examine the birth and decay processes of secondary currents. Shiono & Muto (1998) conducted some turbulence measurements in a meandering compound open-channel flow by using LDA. They revealed the distributions of secondary currents, primary velocity and turbulence in the fully-developed bend regions. Wormleaton, *et al*. (2005) have measured the velocity distributions, depth variations and sediment transport under the overbank condition in meandering large-scale channels with graded sand bed.

Recently, Nezu *et al.* (2005a) highlighted the channel-transition zone from the straight toward meandering compound open-channel flow. They investigated experimentally the developing process of secondary currents and turbulence structure along the curved main-channel by using 3-D EMV.

However, detailed information of 3-D structure of horizontal vortices in meandering compound open-channel flows is not available sufficiently, because it is difficult to conduct simultaneous measurements with a lot of LDAs. Therefore, in the present study, we tried to conduct the innovative multi-layer PIV measurements for both of the inbank layer and overbank layer in the meandering compound open-channel flows.

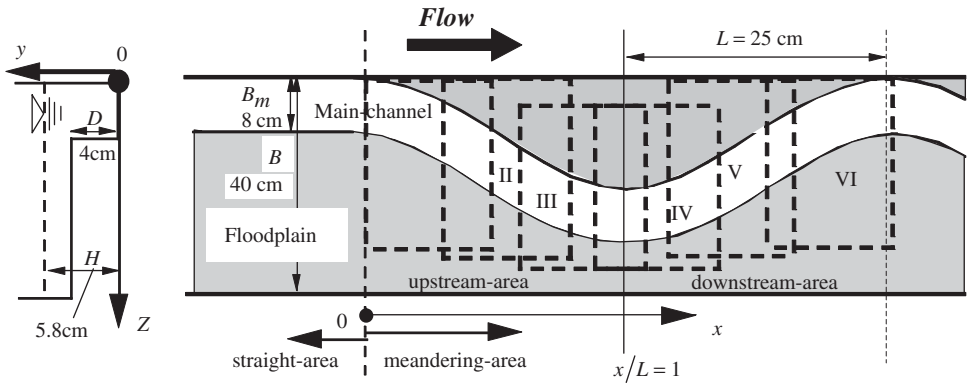

Figure 1. Coordinate system in measurement area.

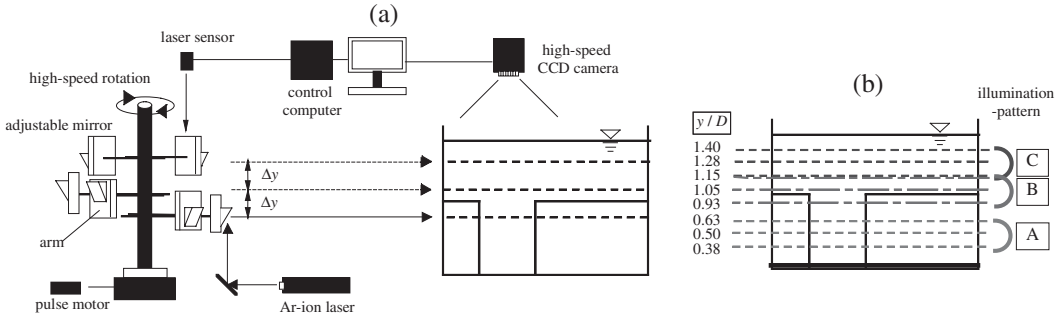

Figure 2. Multi-layer PIV system and illumination patterns of LLS.

2 EXPERIMENTAL PROCEDURES

2.1 *Hydraulic condition and coordinate system*

Figure 1 shows the coordinate system of a glass-made flume, in which the streamwise flow shape of the main-channel is defined as a sine curve, i.e., the sine-generated curve from the straight channel, $x \geq 0$; x is the streamwise coordinate (Fig. 1). The curved side walls are made of transparent 1 mm thick acrylic board in order to project the laser light sheet even into the inbank layers, i.e., $y/D \leq 1$, (see Fig. 1). L is a half of the streamwise length, and y and z are the vertical and spanwise directions; $y = 0$ is at the main-channel bottom-bed and $z = 0$ at the left-side bank of the floodplain. B is the width of the present flume and B_m is the width of the main-channel. D is the floodplain height and H is the main-channel depth.

U, V and W are the time-averaged velocity components in the streamwise, vertical and spanwise directions, respectively. u, v and w are the corresponding turbulent fluctuations. The time-series of horizontal components of velocities, i.e., (u, w), were obtained by PIV measurements, in which six illuminated areas (I–XI) were shown for close-up pictures as shown in Fig. 1

The sinuosity $s \equiv L_s/L$ was chosen to be 1.09 and 1.22 in the present experiments that are in the same order of magnitude as observed in actual rivers. The bend effects are of course larger with an increase of the meandering sinuosity.

2.2 *Measurement instrument*

Figure 2(a) shows the present multi-layer illumination system. In this specially designed beam rotation instrument, three laser-light sheets (LLS) that have different adjusted elevations were projected into the tilting flume by using a rotating beam splitter, which was developed originally for the present study. This beam splitter has three pairs of two arms including with adjustable plane mirrors. PIV analysis of each illuminated layer was conducted on the basis of two set digital images illuminated by the neighboring same elevated mirrors. 2W Ar-ion laser light was projected into the flume as three different elevated LLSs at the almost same time as shown in Figure 2(a).

In this study, these total six arms with each mirror were placed with a constant angle span of $60° = 360°/6$. The speed of the beam rotation was 10 Hz, and thus the time lag of the neighboring LLS was

$1/(6 \times 10) \cong 0.0167$ sec. The seeding particles, which have a diameter of 100 μm and are made of Nylon 12(specific density is 1.01), were uniformly scattered in the circulating water of the flume. The distance Δy between the neighboring LLSs was adjusted accurately as $\Delta y = 5$ mm (Fig. 2). The digital images on the horizontal planes at different elevations were taken simultaneously by a high-speed CCD camera (maximum flame rate: 250 Hz) which was placed above the free surface. As the results, 3-D flow volume, in which LLS were projected, was measured by the PIV method. When more laser light sheets are split and projected, more detailed 3-D PIV is available; the maximum number of the beam splitters is 16 in the present system.

2.3 *Hydraulic condition*

Table 1 shows the hydraulic condition, in which U_m is the bulk-mean velocity in the straight channel region. Two kinds of sinuosities were chosen in order to examine the meandering effects. Figure 2(b) shows the measured patterns of the present multi-layer PIV. We chose three patterns of LLS illumination, i.e., the pattern A ($y/D = 0.38$, 0.50, 0.63) for the inbank layers, the pattern B ($y/D = 0.93$, 1.05, 1.17) for the inbank and overbank layers, and the pattern C ($y/D = 1.15$, 1.28, 1.40) for the overbank layers.

3 RESULTS AND DISCUSSIONS

3.1 *Horizontal distribution of time-averaged velocity components*

First of all, we have to inquire into the horizontal distribution of the time-averaged velocity components (U, W) in the whole measured area indicated in Fig. 1.

3.1.1 *Streamwise velocity*

Figure 3 shows the all component of horizontal distributions of the time-averaged streamwise velocity $U(x, z)$ at eight measured elevations of $y/D = 0.38$, 0.50, 0.63, 0.93, 1.05, 1.15, 1.28 and 1.40, in which the sinuosity was $s = 1.22$. These results were obtained from overlapping the six illuminated areas (I-XI) shown in Figure 1 The streamwise and spanwise coordinates were normalized by L and B_m, respectively. We consider the distributions into two kinds of layers, i.e., the overbank layer ($y/D > 1.0$), and the inbank layer ($y/D \leq 1.0$) in the following way.

Overbank layer

In the straight region, there is a noticeable velocity gradient $\partial U/\partial z$. In particular, a remarkable velocity shear is generated by the high-speed fluid over the main-channel and the low speed fluid on the right-hand side floodplain at $y/D = 1.05$ and 1.15. In the cross-flow area ($x/L = 0.0 - 0.4$), a high-speed stream crosses over the main-channel and attains the maximum at the left-hand side junction. It should be noticed that the high-speed stream zone is observed clearly on the left-side floodplain from $x/L = 0.4$ to 1.2. This is the inbank flow in the straight channel is accelerated due to the up-step impinging effect. In the counter cross-flow region from $x/L = 1.2$ to 1.8, this high momentum fluid is advected over the main-channel with a gradual deceleration. In contrast, we can see the low-speed stream along the right-side junction in the counter cross-flow region ($x/L = 1.0 - 1.5$) at $y/D = 1.15$, 1.28 and 1.40. This result indicates an existence of significant velocity shear $\partial U/\partial z$ in the same manner as observed in the straight channel section. It is therefore inferred that the horizontal vortex may be generated violently in the meandering compound region.

Inbank layer

In the straight region ($x/L < 0$), there is a parabolic profile due to the both side walls. In the cross-flow region ($x/L = 0.5$), we can see that a maximum stream is affected by the meandering boundary walls, that is to say, the maximum region is shifted toward the left-side junction. Of particular significance is that the high-speed zone is seen near the left-side junction of the inner curve. This property is caused by secondary currents as pointed out by some previous researchers, e.g., Fukuoka *et al.*(1997).

3.1.2 *Spanwise velocity current*

Figure 4 shows the distributions of the time-averaged spanwise velocity $W(x, z)$ at $y/D = 0.38$, 0.63 and 1.15, in which $s = 1.22$.

Overbank layer

At the cross-flow region of $x/L = 0.5$, there is a positive zone near the left-side junction. In contrast, at the counter cross-flow region of $x/L = 1.0 - 1.5$, there is a negative zone near the right-side junction.

Inbank layer

There is a positive zone in the cross-flow region, whereas a negative zone in the counter cross-flow region. These values are much larger than the overbank values. It is therefore found that there is much greater effects of the meandering boundary on the inbank layers. These maximum values are distributed in the wider range of the meandering main-channel area.

3.1.3 *Vertical velocity component*

Unfortunately, the vertical velocity component $V(x, z)$ which is associated significantly with secondary

Copyright © 2006 Taylor & Francis Group plc, London, UK

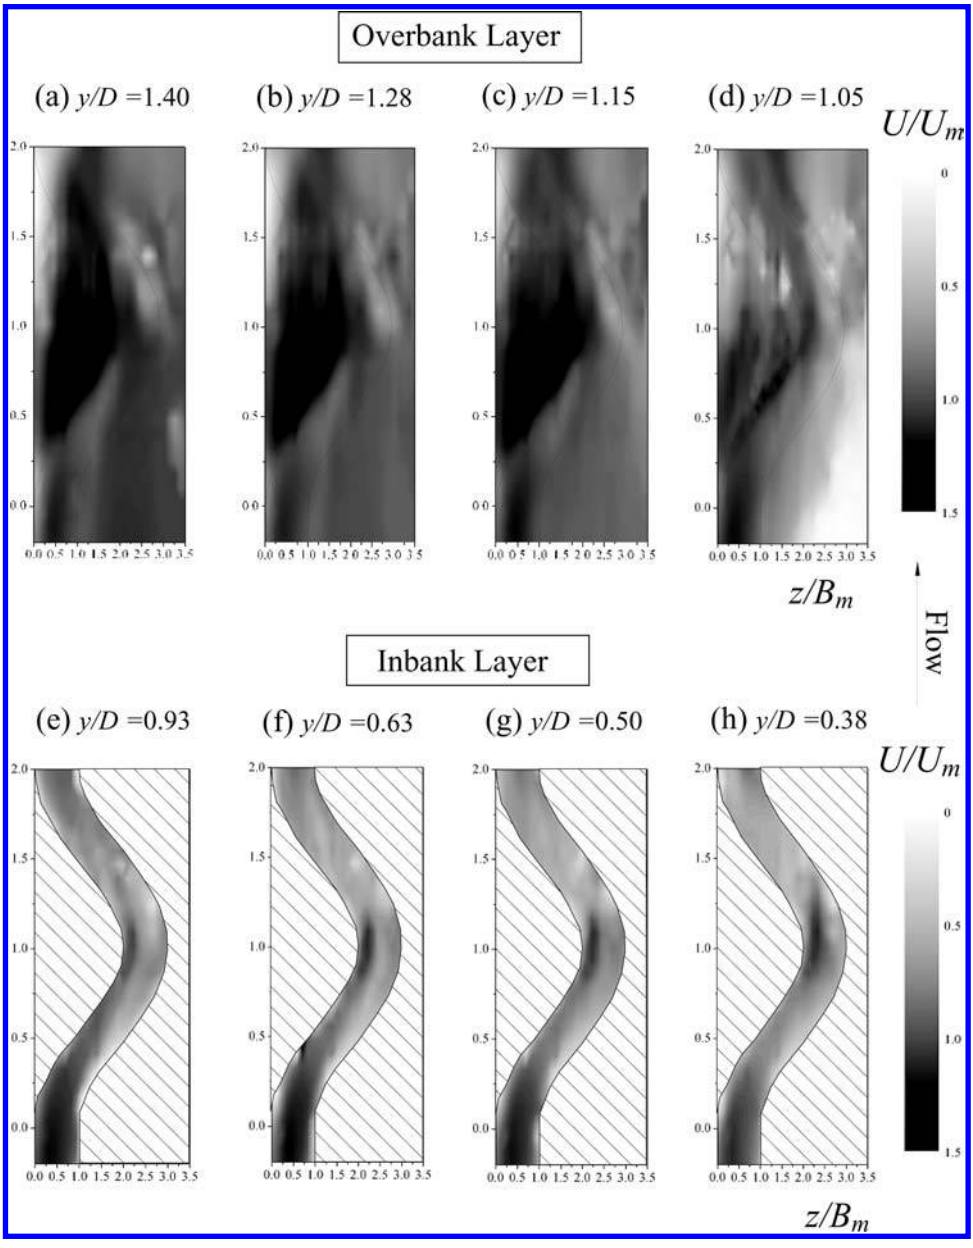

Figure 3. Horizontal distributions of streamwise velocity component ($s = 1.22$).

currents, cannot be measured directly by a single-camera based PIV. In order to overcome these difficulties, we tried to evaluate the time-averaged vertical velocity V by using the following continuity equation:

$$\frac{\partial V}{\partial y} = -\left(\frac{\partial U}{\partial x} + \frac{\partial W}{\partial z}\right) \quad (1)$$

, in which $V = 0$ is given at the free-surface boundary. The validity of this evaluation technique of V was examined by Nezu *et al.* (2005b) who compared them with LDA measurements.

Figure 5 shows the horizontal distributions of $V(x,z)$ at $y/D = 0.38$, 0.63 and 1.15 in the case of $s = 1.22$. Similar positive and negative patterns are seen in these layers, although maximum vales are

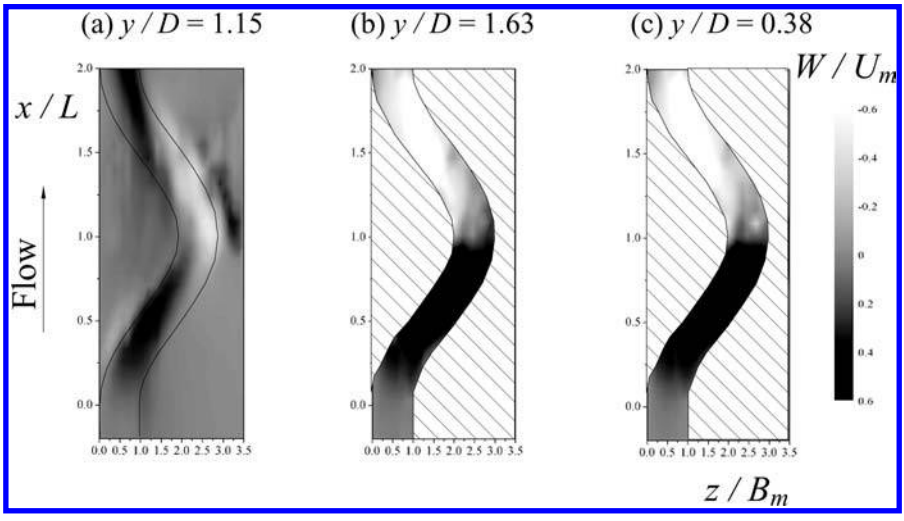

Figure 4. Horizontal distributions of spanwise velocity component ($s = 1.22$).

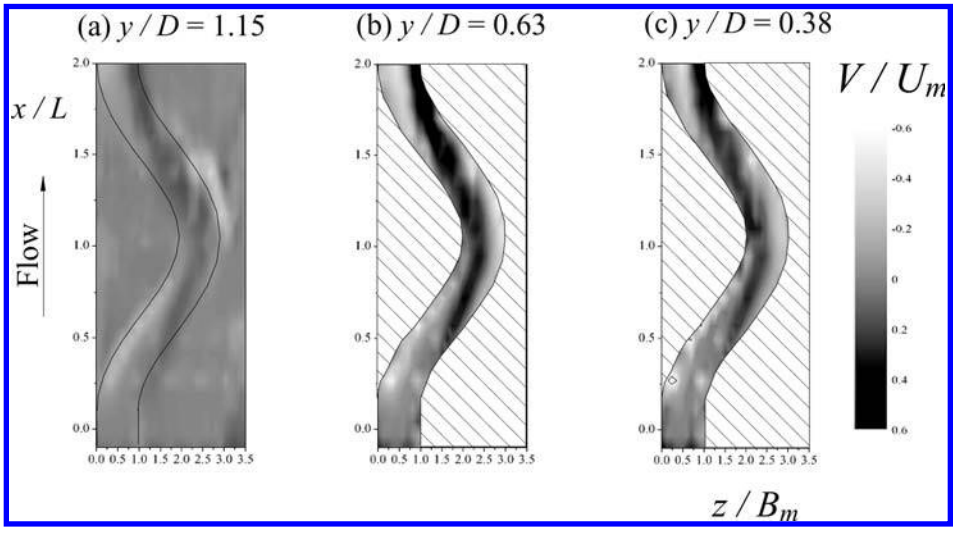

Figure 5. Horizontal distributions of vertical velocity component ($s = 1.22$).

much larger in the inbank layers ($y/D = 0.38$ and 0.63) than in the overbank layer($y/D = 1.15$). In the cross-flow region from $x/L = 0.5$ to 1.0, an upward flow ($V > 0$) appears in the center-line of the main-channel, whereas, a downward flow ($V < 0$) is observed near the left-side floodplain junction. These upward and downward flows correspond to the typical rotational direction of secondary currents as shown in Figure 6. It is therefore said that the present multi-layer PIV system can measure reasonably the existence of secondary currents peculiar to the meandering compound open-channel flows. In the counter cross-flow region from $x/L = 1.5$ to 2.0, there is a strong upward-flow ($V > 0$) zone from the main-channel center-line to the

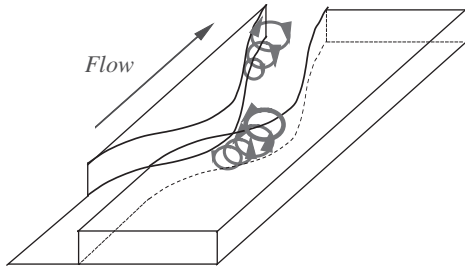

Figure 6. Typical sketch of secondary currents in meandering compound open-channel flow (see Shiono & Muto (1998) and Nezu *et al.* (2005a).

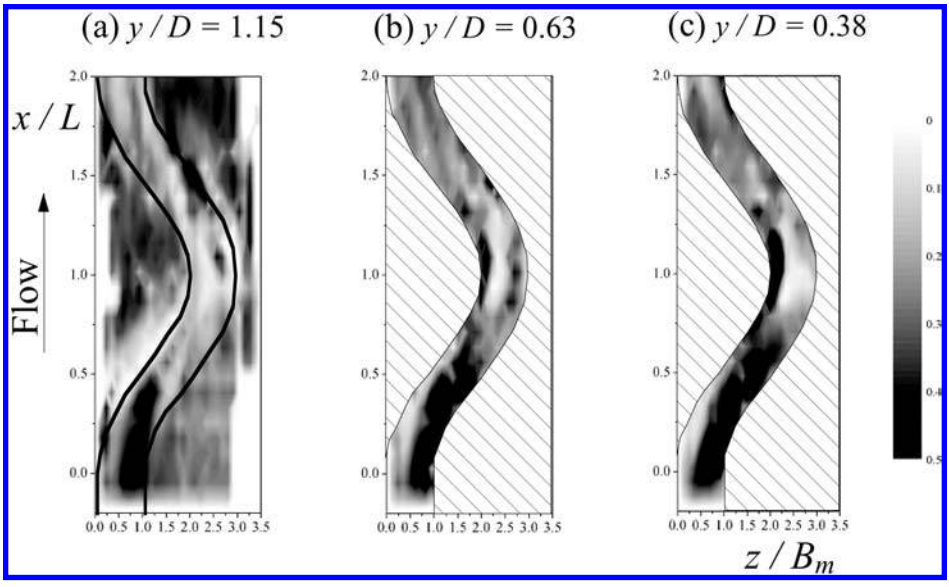

Figure 7. Vortex-existing probability function ($s = 1.22$).

right-side junction, whereas a downward-flow ($V < 0$) zone is observed clearly from the main-channel centerline up to the left-side junction. The downward-flow zone increases in the streamwise direction, and this property is consistent well with the development process of secondary currents in the meandering compound open-channel flows, as pointed out by Shiono & Muto (1998) and Nezu *et al.* (2005a).

3.2 *Vortex-existing probability and time-averaged vorticity*

There are several mathematical methods in order to detect the vortex core in shear flows. One of them is the delta method introduced by Chong & Perry (1990). Fujita & Kumashiro(2005) have recently applied it to backward step flows. The eigenvalues σ of velocity gradient tensor $(\partial \tilde{u}_i/\partial x_j)$ are considered in this method. The eigenvale equation in 2-D flow is given by

$$\sigma^2 - P\sigma + Q = 0 \tag{2}$$

in which,

$$P \equiv \frac{\partial \tilde{u}_i}{\partial x_i} \quad \text{and} \quad Q \equiv \frac{1}{2}\left(\left(\frac{\partial \tilde{u}_i}{\partial x_i}\right)^2 - \left(\frac{\partial \tilde{u}_i}{\partial x_j}\frac{\partial \tilde{u}_j}{\partial x_i}\right)\right) \tag{3}$$

$\tilde{u}_i$ is the instantaneous velocity component, i.e., $\tilde{u}_i \equiv U_i + u_i$. Complex eigenvalues will occur when the discriminant $\Delta \equiv P^2 - 4Q$ is negative, and it corresponds the existence of vortex core.

Figure 7 shows the distribution of the vortex-existing probability Pr defined as follows:

$$Pr \equiv \frac{n_{vor}}{n} \tag{4}$$

n_{vor} is the total count of sampling frame data number in which $\Delta < 0$ and n is the total sampling frame number.

Overbank layer

A stream-like large distribution of the vortex-existing probability Pr appears near the right-side junction in the straight section. This property seems to correspond to the convection of typical horizontal eddies generated by the shear instability between the main-channel and floodplain. The horizontal eddy developed near the right-side junction seems to cross over the meandering main-channel in the cross-flow region. This eddy disappears on the left-side floodplain due to small velocity shear $\partial U/\partial z$. It should be noticed that there is no horizontal eddy in the main-channel from the cross region to the first bend apex ($x/L = 0.5 - 1.0$). In the counter cross-region, a new vortex structure is generated significantly, which may be independent with a horizontal eddy observed in the straight channel region. This renewaly developing vortex is advected downstream near the curving right-side junction.

Inbank layer

In the straight channel region, a large distribution of Pr is seen near the right-side junction as observed in the overbank layer.

Figure 8 shows the distributions of the time-averaged vertical component of vorticity, Ω_y, in the case of $s = 1.22$. Ω_y is defined as

$$\Omega_y \equiv \frac{\partial U}{\partial z} - \frac{\partial W}{\partial x} \tag{5}$$

The signature of vorticity means the rotational direction of the eddy structure. The positive value

Copyright © 2006 Taylor & Francis Group plc, London, UK

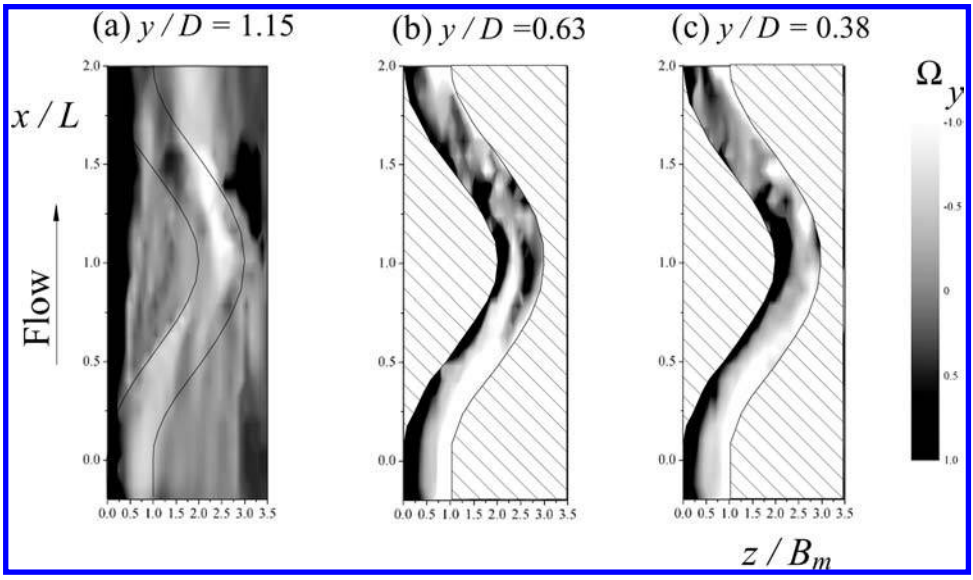

Figure 8. Time-averaged vorticity distribution ($s = 1.22$).

corresponds to the counter clock-wise direction, whereas, the negative value corresponds to the clock-wise direction.

Overbank layer

A large positive zone of $\Omega_y > 0$ appeared along the left-side wall, $z/B_m = 0$. This may not be any eddy structure but the side-wall shear $\partial U/\partial z$ because the vortex-existing probability is very small in this region shown in Figure 7. In the straight section, there is a negative region from the main-channel center-line to the right-side junction. This is the typical horizontal eddy which has a clock-wise rotation. In the counter cross-flow region, there is a negative zone ($\Omega_y < 0$) at $y/D = 1.15$. Therefore, it is found that a renewaly generated vortex has a clock-wise direction in the counter cross-flow region.

Inbank layer

There are strong positive and negative distributions near the curved boundary walls, and thus it is found that the great velocity shear $\partial U/\partial z$ exist even in the inbank layers.

3.3 *Spanwise distribution of velocity*

Figure 9 shows the spanwise profiles of $U(z)$ and $W(z)$ at $y/D = 1.28$ in the upstream region from $x/L = 0.0$ to 1.0, in which the sinuosity s is varied. We consider these distributions in comparison with $s = 1.09$ and 1.22.

Streamwise velocity

In the entrance of meandering area, $x/L = 0.0$, there is a significant difference of U between the

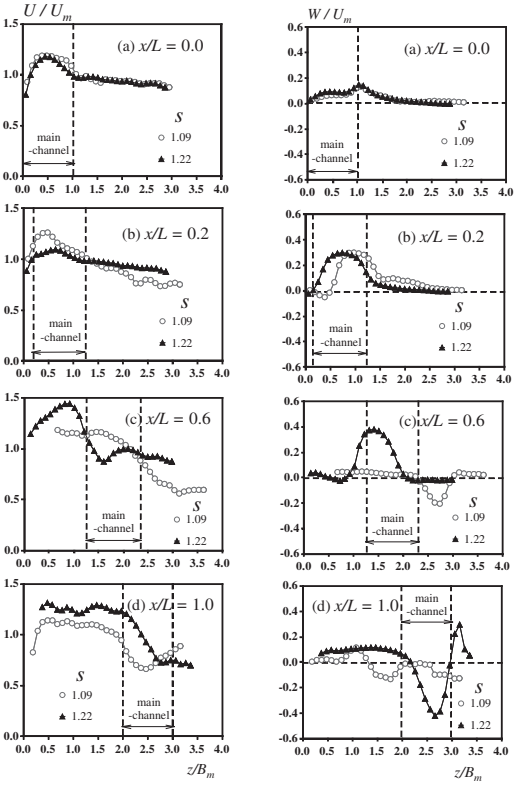

Figure 9. Lateral profiles of the streamwise and spanwise velocities at $y/D = 1.28$ (left hand side: U, right hand side: W).

Copyright © 2006 Taylor & Francis Group plc, London, UK

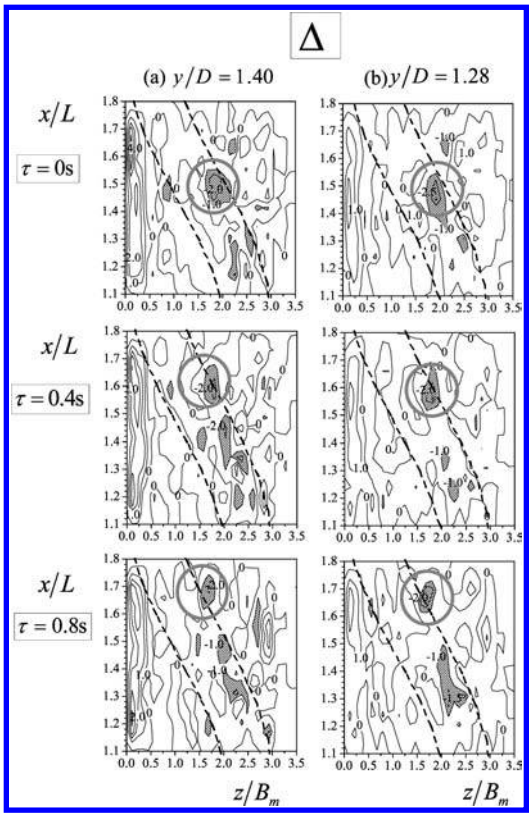

Figure 10. Time-variations of instantaneous delta-value.

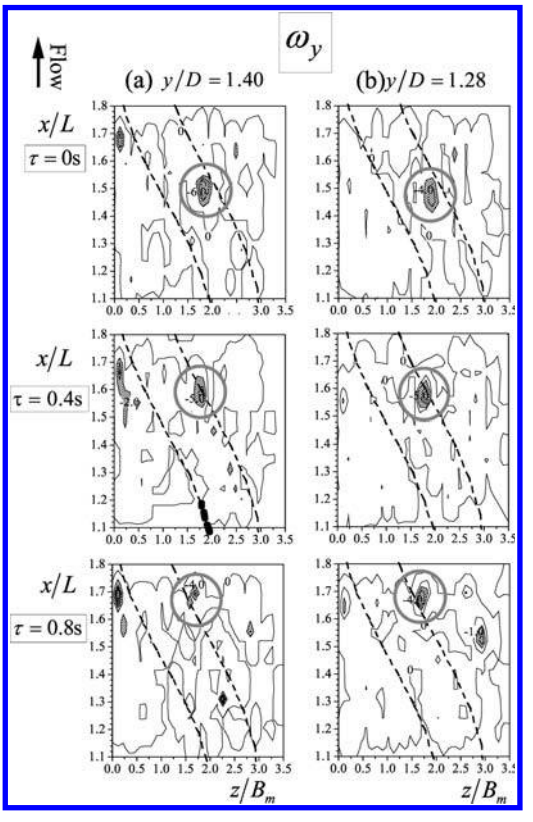

Figure 11. Time-variations of instantaneous vorticity.

main-channel and the right-side floodplain, and the inflectional point appears near the junction in the both cases of $s = 1.09$ and 1.22. At $x/L = 0.2$, the lateral variation becomes smaller, and the main-channel velocity decreases significantly in the case of $s = 1.22$. At $x/L = 0.6$ of the counter cross-flow section, the direction of streamwise flow is changed largely because it flows along the sine generated curve. Therefore a remarkable local decrease appears in the velocity U. Of particular significance is that $U$is accelerated much greatly on the left-side floodplain due to the up-step impinging effect in the case of $s = 1.22$. However, these trends are not seen in the case of $s = 1.09$, and there is one inflectional point as observed in $x/L = 0$. At $x/L = 1.0$, U decreases from the left-side junction to the right-side junction, and one inflectional point appears in the main-channel which correspond to the renewal eddy generation in the counter cross-flow zone.

Spanwise velocity

In the straight section of $x/L = 0$, a small positive zone appears at the right-side junction of $z/B_m = 1.0$. At $x/L = 0.2$, W becomes larger due to the bending effect for both $s = 1.09$ and 1.22. At $x/L = 0.6$, the peak position of W is shifted toward to the left-side junction in the case of $s = 1.22$. In contrast, in the case of $s = 1.09$, W is very small in the main-channel and negative zone is observed on the right-side floodplain. This may be caused by the meandering effect of the downstream region. At $x/L = 1.0$, it is found that there are large negative-value zone in the main-channel in the case of $s = 1.22$.

3.4 *Time-variations of instantaneous eddy structure*

We highlight the visualization area V, in which the coherent horizontal vortex is renewaly generated. Figure 10 shows the instantaneous delta-value Δ at the elevations of $y/D = 1.28$ and 1.40. The time delay of τ was set to be 0.4 sec each. The shadow zone indicates the eddy existing region that is defined as $\Delta < -1.0$. It is observed clearly in both the elevations that the horizontal eddy is convected downstream over the main-channel. The time-dependent position of vorticity core seems to be almost same at $y/D = 1.28$ and 1.40.

Figure 11 shows the distributions of the instantaneous vorticity ω_y, which corresponds to Figure 10.

Copyright © 2006 Taylor & Francis Group plc, London, UK

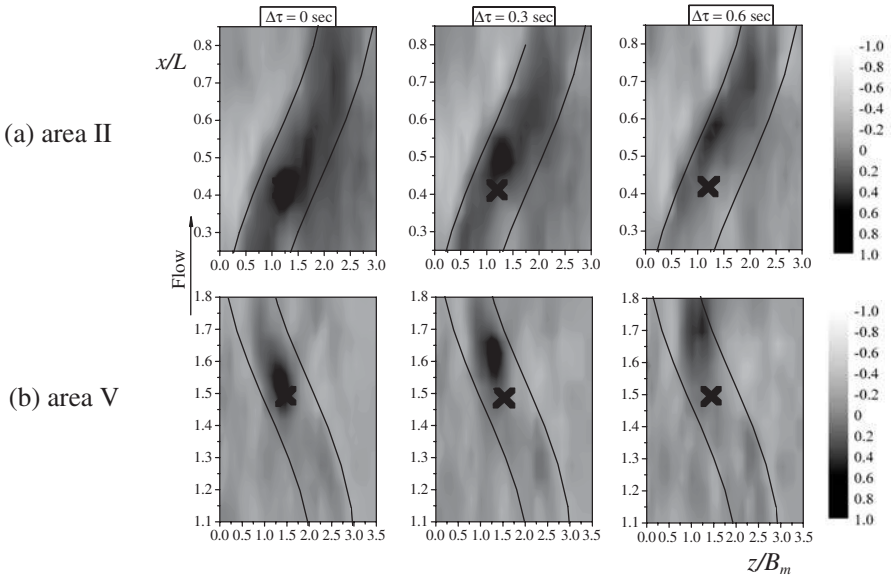

Figure 12. Distribution of space-time correlation function C_{ww} (reference elevation: $y/D = 1.28$, movable elevation: $y/D = 1.40$).

The shadow zone indicates $\omega_y < -2.0$ (1/sec). At the elevations of $y/D = 1.28$ and 1.40, there is a high negative region near $x/L = 1.4$ when $\Delta\tau = 0$. It should be noticed that the time-variation of peak vorticty position corresponds well with the distribution of Δ shown in Figure 10. Therefore, these results suggest strongly that a clock-wise eddy is convected downstream as 3-D tube-like structure in the counter cross-flow region.

3.5 *Space-time correlation analysis*

In order to detect the coherent motion in the meandering compound open-channel flow, the space-time correlation analysis was conducted for the instantaneous spanwise velocity component $\tilde{w}$, because its component is affected significantly by the meandering boundary. A space-time correlation C_{ww} is given by

$$C_{ww} = \frac{\overline{w_0 \times w_{0+\Delta}}}{w_0' \times w_{0+\Delta}'} \tag{6}$$

in which, the subscript 0 denotes a reference point, i.e., (x_0, y_0, z_0, t) and $0 + \Delta$ denotes a movable point $(x_0 + \Delta x, y_0 + \Delta y, z_0 + \Delta z, t + \Delta\tau)$. $w' \equiv \sqrt{\overline{w^2}}$ is the turbulence intensity and the over-bar means the time-averaged operator.

Figures 12(a) and (b) show the horizontal distribution of C_{ww} between the overbank layers of $y/D = 1.28$ and 1.40 as a function of the time delay $\Delta\tau$. "x" means the reference position. Figure (a) and (b) shows the results of the area II and V, respectively. The reference point "x" was chosen to be the center-line of the main-channel curve at $y/D = 1.28$, i.e., $(x_0/L, z_0/B_m) = (0.42, 1.22)$ for the area II and (1.50, 1.37) for the area V.

In the area II, the large peak zone is observed near the reference point at $\Delta\tau = 0$. The peak correlation region moves downstream almost straightly. In the area V, the same trend as the area II is also observed. These results infer that the coherent structure is convected downstream in a vortex-tube manner as indicated in Figures 10 and 11.

Finally, we explain the correlation property between the inbank and overbank layers. Figures 13 (a) and (b) shows the time-dependent distributions of C_{ww} between the overbank of $y/D = 1.05$ and the inbank of 0.93. The horizontal position of reference point was chosen in the same manner as Figure 12. In the area II, the peak correlation is seen near the reference point as well as observed in Figure 12. It should be noted that C_{ww} increases with an increase of $\Delta\tau$. This may be because the spanwise velocity fluctuation of the overbank layer are transported significantly to the inbank layer by the strong downward flow as sketched in Figure 6. In the area V, a weak peak correlation is also recognized near the reference point. This peak correlation moves downstream with a lateral shift toward the left-side junction due to the meandering effects.

4 CONCLUSIONS

In this study, the multi-layer PIV measurements were conducted in meandering compound open-channel

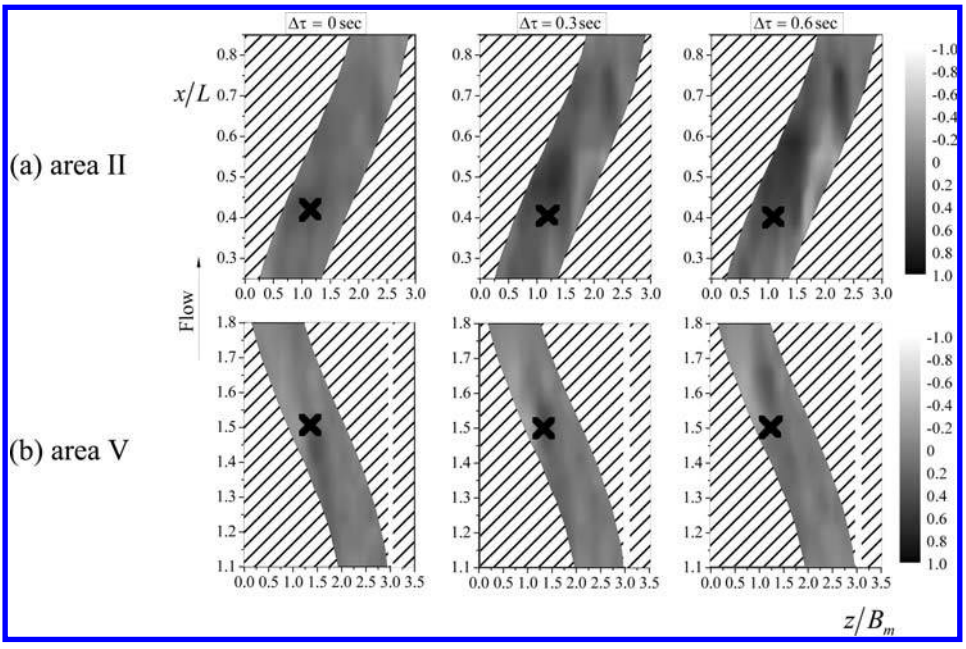

Figure 13. Distribution of space-time correlation function C_{ww} (reference elevation: $y/D = 1.05$, movable elevation: $y/D = 0.93$).

flows in order to reveal the meandering property of coherent eddy structure. The results obtained in the present study are as follows:

1) The typical horizontal eddy, which is developed in the straight-channel zone, crosses over the meandering main-channel and disappears on the floodplain due to the weak velocity shear.
2) A renewal horizontal vortex is generated significantly in the counter cross-flow region.
3) The space-time correlation analysis revealed that there are strong correlations in turbulent fluctuations near the horizontal vortices. These vortices are convected downstream with a 3-D tube-like structure.

Large eddy simulation of turbulent structure in meandering compound open-channel flow

M. Sanjou & I. Nezu
Dept. of Civil Eng., Kyoto University, Kyoto, Japan

ABSTRACT: Horizontal eddies are often observed in compound open-channel flows. The hydrodynamic properties of such coherent voritices were intensively studied by a lot of researchers, because these eddies have significant relations with momentum exchanges between a main-channel and floodplains. However, little attention has been given to the meandering properties of the horizontal eddies developed in a straight open-channel. Therefore, in the present study, a large eddy simulation was conducted in the transition region between the straight and meandering floodplain flows. As the results, coherent eddy structure and correlation properties were investigated numerically in such a complex open-channel flow.

1 INTRODUCTION

Compound open-channel flows are composed of main-channel and floodplains, and we can see them in many actual rivers. In such two-stage flows, the primary velocity distribution has notable inflectional points near the junction between the main-channel and floodplains, and consequently, periodical horizontal vortices are produced due to inflectional shear instability. These eddies promote largely the turbulent transport of various scalars such as suspended sediment in the spanwise direction and furthermore, secondary currents also play a significant role on such a scalar transport associated with coherent eddies. it is, therefore, important in river engineering to reveal these turbulent structure in compound open-channel flows.

Until now, many researchers have studies these interesting topics intensively by using not only measured data but also numerically calculated ones. Recently, various calculation techniques and turbulence models are applied to simulations of compound open-channel flows.

For example, Naot *et al*.(1993) have calculated the compound open-channel flows by using an algebraic stress model (ASM), and they reproduced reasonably the hydrodynamic properties such as the cross-sectional distributions of primary velocity and secondary currents. In particular, their ASM simulations could present the time-averaged motion of the secondary currents which govern significantly turbulence characteristics and momentum transfer between main-channel and floodplains. In order to explain the influences of secondary currents on the mixing solute properties, Lin & Shiono (1995) have developed a 3-D turbulence modeling. Simoes & Wang (1997) have calculated the concentration properties of solutes by using some algebraic eddy viscosity models involved with a buoyancy effect. Nadaoka & Yagi (1998) have developed a depth-averaged 2-dimensional LES model in order to examine the horizontal vortices in compound open-channel flows, and they reproduced the originating, developing and merging processes of these coherent eddies. Sofialidis & Prinos (1999) revealed numerically the effects of floodplain roughness in compound open-channel flows by using an anisotropic $k-\omega$ model.

As mentioned above, although a lot of studies have been conducted about numerical simulations of compound open-channel flows, most of them have focused on rectangular compound straight-channel flows. However, natural river flows have many bending and meandering sections, where typical secondary currents are generated by centrifugal force, i.e., Prandtle's 1-st kind of secondary currents, and quite different from those observed in straight channels, i.e., Prandtle's 2-nd kind of them. Meandering compound open-channel flows observed in rivers in flood have complicated momentum exchanges between the curved lower main-channel flow and the straight overbank flow. Shiono & Muto (1998) have conducted some turbulence measurements in such a meandering compound open-channel flow with a laser Doppler anemometer (LDA), and they revealed the distributions of secondary currents, primary velocity and turbulence in the fully-developed bend region. However, detailed information on the channel-transition effects from the straight to meandering sections is not yet available in meandering compound open-channel

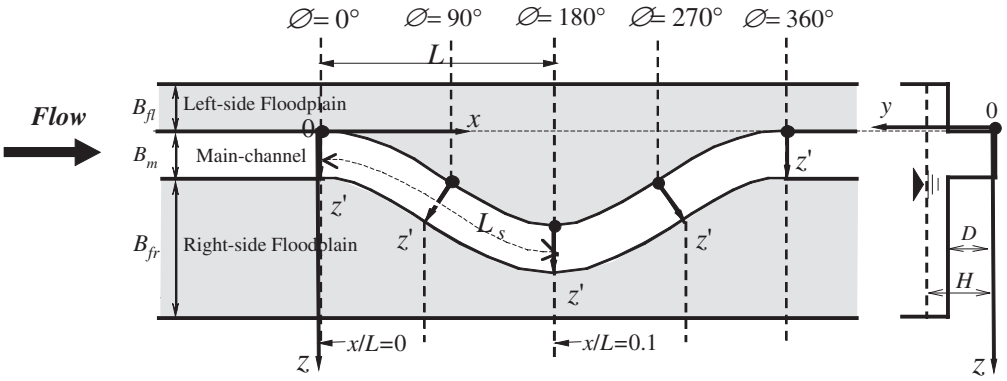

Figure 1. Coordinate system in meandering compound open-channel flow.

flows. In particular, it is very important to investigate the meandering properties of the horizontal eddies generated in the straight channel region, because they are significantly associated with the sediment transport and bed deformation.

Therefore, we highlighted the channel transition effects on the horizontal coherent vortices and tried to reveal them numerically by using a LES. First of all, the examinations of this simulation models were conducted mainly for the primary velocity distributions and secondary currents by comparison with the measured data. Next, the meandering properties of horizontal eddies were examined by using the instantaneous velocity vectors and the space-time correlation analyses.

2 CALCULATION METHOD

2.1 *Basic equations*

The filtered continuity equation and N-S equation are described as follows:
(continuity equation)

$$\frac{\partial\langle\hat{u}_i\rangle}{\partial x_i}=0 \qquad (i=1,2,3) \tag{1}$$

(N-S equation)

$$\frac{\partial\langle\hat{u}_i\rangle}{\partial t}+\langle\hat{u}_j\rangle\frac{\partial\langle\hat{u}_i\rangle}{\partial x_j}=F_i-\frac{\partial\langle\hat{p}\rangle}{\partial x_i}+\frac{\partial}{\partial x_i}(-\tau_{ij}+2\nu\langle\hat{D}_{ij}\rangle) \tag{2}$$

$$F_i=(g\sin\theta,-g\cos\theta,0) \tag{3}$$

$$D_{ij}\equiv\frac{1}{2}\left(\frac{\partial\hat{u}_i}{\partial x_j}+\frac{\partial\hat{u}_j}{\partial x_i}\right) \tag{4}$$

in which, the bracket <> denotes the filtering operation in space and the over hat means the instantaneous components. τ_{ij} is the SGS stress tensor calculated by the standard Smagorinsky model as follows:

$$\tau_{ij}=-2\nu_e\langle D_{ij}\rangle \tag{5}$$

When the local SGS variances are assumed to be isotropic, the SGS eddy viscosity ν_e is given by

$$\nu_e=(C_s\Delta)^2\left(2\langle D_{ij}\rangle\langle D_{ij}\rangle\right)^{1/2} \quad \text{and} \quad \Delta=(\Delta_1\Delta_2\Delta_3)^{1/3} \tag{6}$$

in which C_s is the Smagorinsky constant and $C_s=0.15$ was chosen in this study. $\Delta$is the SGS filter which corresponds with the local grid scale.

The third-order upwind difference scheme was used for convection term and second-order Adams-Bashforth method was adopted for time differentiation.

The computational grids are a boundary-fitted ones and the number of the calculated grids was chosen to be 400, 20 and 80 for the streamwise, vertical and spanwise directions, respectively. The boundary conditions are as follows; the non-slip at the side and bed walls, the free-slip at the water surface and the cyclic boundary condition at the entrance and exit of the calculating region.

2.2 *Calculation case*

The present calculation case was chosen to be the same hydraulic condition as used by Nezu *et al.* (2005) who measured all three components of velocity with electromagnetic velocimetry (EMV). Figure 1 shows the coordinate system in the present study. The streamwise flow shape of the meandering main-channel was defined as a sine generated curve. L is a half wave length of the curved-shaped main-channel (see Fig. 1). L_s is the along-curve length from the meandering entrance to the first bend apex. The EMV measured data used for the comparison with the present LES calculation were the values obtained at five sections.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 1. Calculation case.

D (cm)	B_m (cm)	B_{fl} (cm)	B_{fr} (cm)	H (cm)	H/D	Q (l/s)	U_m (cm/s)	S
5.0	20.0	20.0	60.0	7.0	1.4	7.47	24.9	1.09

These streamwise positions were given as a function of ϕ. Here, ϕ is a phase angle of the sine curve, in which $\phi = 0°$, 90°, 180°, 270° and 360° were considered to compare the LES simulations (Fig. 1). $\phi = 0°$ is the meandering entrance section, i.e., the channel transition from the straight to meandering ones, $\phi = 90°$ is the cross section of the curved lower-flow and the straight overbank-flow. $\phi = 180°$ is the first bend apex, $\phi = 270°$ is the counter cross section and $\phi = 360°$ is the second bend apex. y and z are the vertical and spanwise directions; $y = 0$ is on the main-channel bottom-bed and $z = 0$ at the left-side bank of the floodplain. z' is the spanwise coordinate across the main-channel, and $z' = 0$ is at the junction position between the main-channel and the left-side floodplain. In this study, U, V and W are the time-averaged velocity components in the streamwise (x), vertical (y) and spanwise(z)directions, respectively. u, v and w are the corresponding turbulent fluctuations.

We calculated one example of the hydraulic case of the meandering compound open-channel flow that was measured by Nezu *et al.* (2005). Table 1 shows the hydraulic condition, in which D is the floodplain height, $B_{\rm m}$, $B_{\rm fl}$ and $B_{\rm fr}$ are the main-channel, left-side floodplain and right-side floodplain widths, respectively. H is the main-channel depth, $U_{\rm m}$ is the bulk-mean velocity and $s \equiv L_s/L$ is the sinuosity of the meandering main-channel.

3 RESULTS AND DISCUSSIONS

3.1 *Secondary currents*

Figure 2 indicates the descriptions of the time-averaged velocity vectors (V, W) at the typical five sections, in which the right-hand side is the calculated data by LES and the left-hand side is the measured results by EMV. At the straight section of $\phi = 0°$, the present LES model is able to reproduce the upward flows from the junction edge toward the free-surface. This is a typical secondary flow pattern in straight compound open-channel flows measured with LDA by Tominaga & Nezu (1991), although they are not seen clearly in the EMV data due to its accuracy limitation. At the cross-section of $\phi = 90°$, which is the cross section between both the inbank and overbank flows, a strong eddy structure is observed and it seems to be generated by high-speed overbank flows. This measured data suggests that the inbank secondary flows are convected toward the overbank region on floodplain. The present LES reproduces these flow patterns. This secondary eddy near the right junction of floodplain is developing in the streamwise direction, and consequently, it attains the same length scale as the main-channel width $B_{\rm m}$ at the apex section of $\phi = 180°$, and this direction is contrary to that of secondary currents generated by centrifugal force observed in bend channels with no overbank flows. It is therefore considered that these secondary currents are peculiar to the meandering overbank flows. At the counter cross section of $\phi = 270°$, we can see the secondary current eddy which has a counter rotation to that observed at $\phi = 90°$. It is found that this eddy also develops in the streamwise direction and becomes largest at $\phi = 360°$. It is concluded that the present simulation model can calculate the secondary currents and their rotational directions, developing properties reasonably, although there are some discrepancies.

3.2 *Distributions of streamwise velocity*

Figure 3 shows the contour lines distribution of streamwise velocity U_s along the main-channel curve (Fig. 1) at the five sections that are the same positions as indicated in Figure 2. The values of U_s are normalized by the maximum velocity $U_{\rm max}$ at the straight section. It should be noted in this figure that the distribution of U_s is deformed largely due to the effects of secondary currents mentioned before. In the straight section of $\phi = 0°$, bulge features are observed near the both-side junctions, that are generated by strong upward flows as shown by Tominaga & Nezu (1991).

In the curved region ($0° < \phi \leq 360°$), we can see more remarkable bulges that are peculiar to the meandering compound open-channel flows. They are observed significantly near the right-hand side junction of $\phi = 90°$ and $\phi = 180°$, and near the left-hand side one of $\phi = 270°$ and $\phi = 360°$, respectively. Such bulge features correspond to the directions of secondary flows cross over the main-channel. The variations of U_s observed in the laboratory experiment are surely recognized in the calculated LES data, and thus the accuracy of present model is fairly reasonable. In the following sections, the significant eddy properties in the meandering region are predicted numerically, which have not unfortunately been revealed yet in previous studies.

3.3 *Vector descriptions of horizontal eddies*

Figure 4 shows an example of instantaneous velocity vectors which are indicated in a movable coordinate

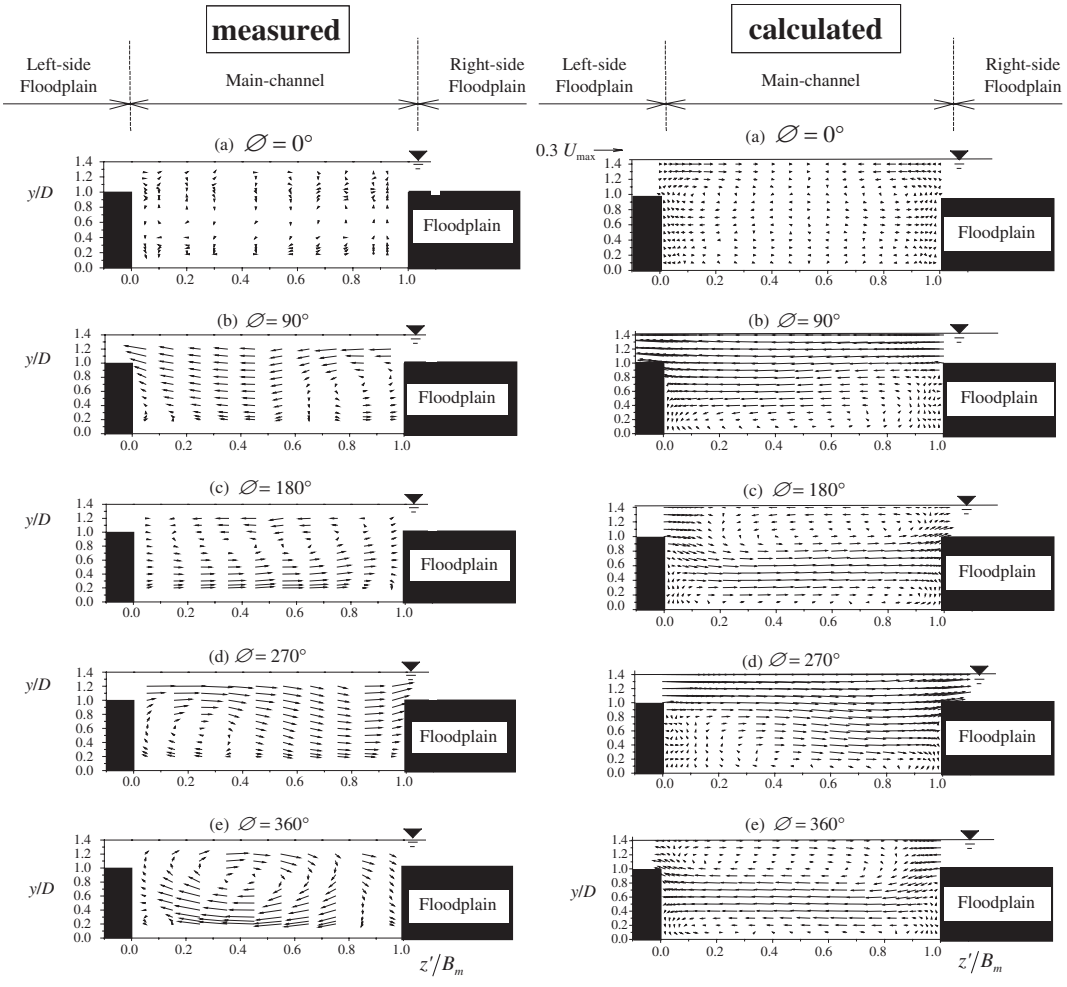

Figure 2. Distribution of the time-averaged secondary currents.

reference with the bulk-mean velocity U_m in the straight flow section. The elevation of flow in Figure 4 was the free-surface one ($y = H$), i.e., the free-surface flow pattern. It is found from these flow vectors that the counter-rotating twin eddy structures appear near the both sides of the main-channel junctions. These are typical large-scale horizontal vortices that have been visualized in compound open-channel flow, e.g., by Sellin (1964), Ikeda & Kuga (1997), Nezu *et al.* (2004), and they are generated periodically by a shear instability of streamwise velocity, as pointed out by Ikeda & Kuga (1997). The present LES reproduces reasonably such a pair of horizontal vortices in the straight compound channel flow.

Figure 5 shows the lateral profile of the spanwise Reynolds stress $-\overline{uw}$ at the meandering entrance of $x/L = 0$, in which the result is normalized by the difference of the maximum to minimum values, i.e., $-\overline{uw}_{\max - \min}$. There are the positive and negative peaks near the right-hand side and left-hand junctions, respectively, and they correspond to a pair of counter-rotating eddies shown in Figure 4. It is found that the momentum exchanges between the main-channel and floodplains are caused significantly by horizontal eddies.

Figure 6 shows the time-variations of these horizontal eddies in the meandering regions, in which instantaneous velocity vectors are indicated at $t = 0.45$s and 0.75s after the results of Figure 4 ($t = 0.0$s). At $t = 0.45$s (, i.e., the just arrival time in the channel-transition section), the vortex pair transported from the upstream side is still observed, in contrast at $t = 0.75$s,

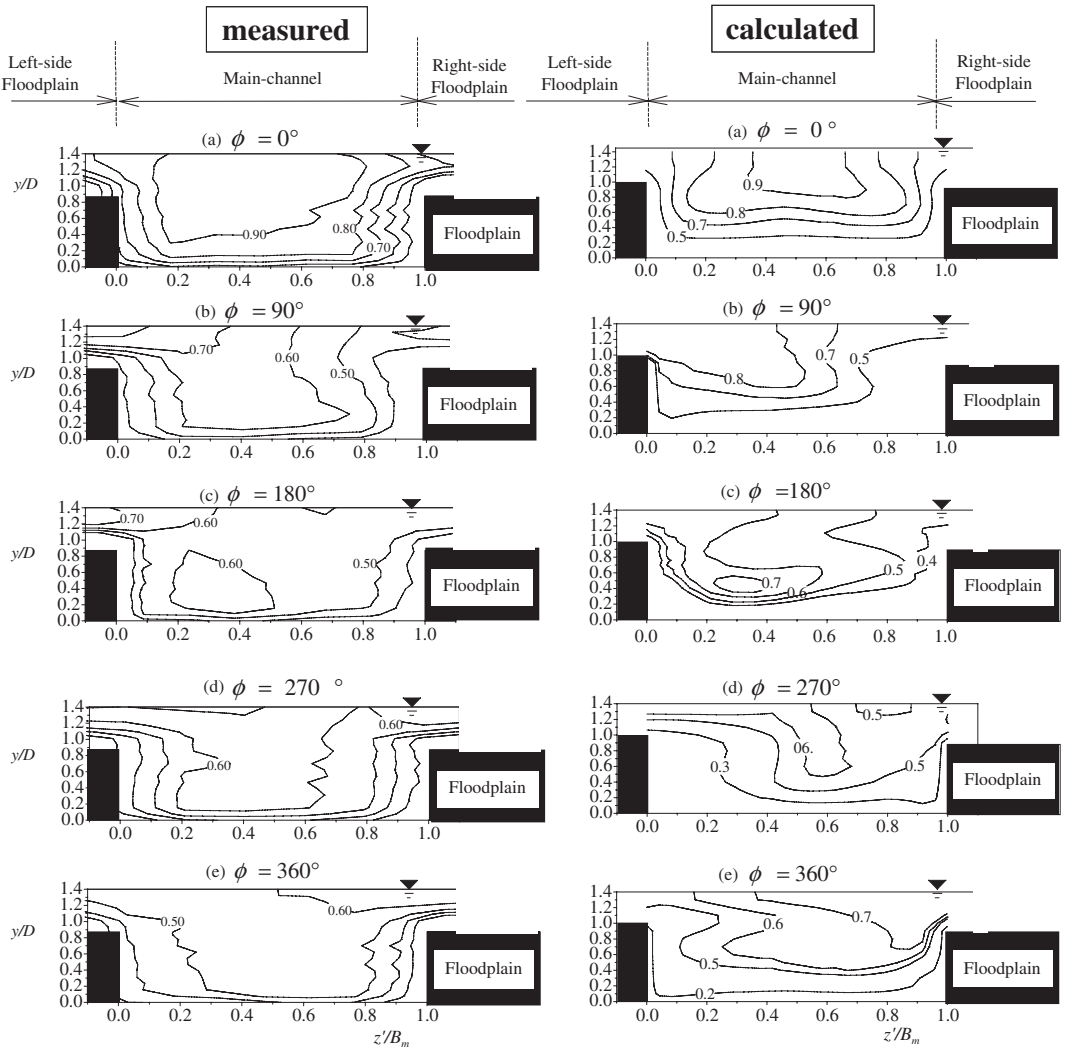

Figure 3. Distributions of the time-averaged streamwise velocity.

the right-side eddy which appeared at $t = 0.45$s in the inner side of main-channel curve, is not visualized clearly. In the following section, this meandering property is examined on the basis of the space-time correlation analyses.

3.4 *Space-time correlation analysis*

In order to visualize the horizontal vortices, it is needed that a movable coordinate is introduced in the instantaneous velocity vector fields. However, such a visualization for eddy detection depends strongly on the subtracted velocity value of the reference, and unfortunately we cannot evaluate the time-variations of vortex form and its core position reasonably. To overcome these difficulties, the unsteady motions of meandering eddies are revealed by using the space-time correlation analysis. Although, the vorticity distribution is often used to detect the eddy structure in the vector field, there may be some numerical errors due to sparse grids. So, we defined the following instantaneous value ϖ, which is the product between streamwise and spanwise velocity components.

$$\varpi \equiv u \times w \tag{7}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

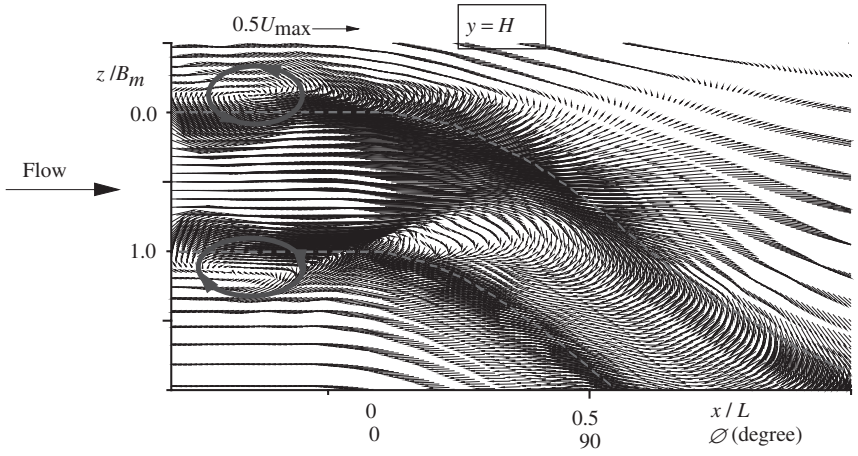

Figure 4. Example of the instantaneous horizontal vortices in the straight channel region.

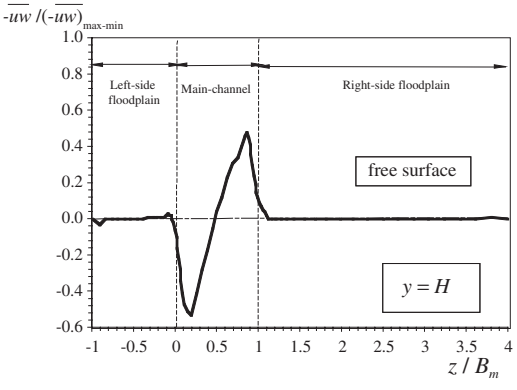

Figure 5. Lateral profile of the spanwise Reynolds stress.

A space-time correlation function $C_{\varpi\varpi}$ is given by

$$C_{\varpi\varpi} \equiv \frac{\overline{(\varpi_o - \overline{\varpi}_o)\times(\varpi_{o+\Delta} - \overline{\varpi}_{o+\Delta})}}{\varpi_o{}'\times\varpi_{o+\Delta}{}'} \tag{8}$$

in which, subscript o denotes a reference point, i.e., (x_o, y_o, z_o, t) and $o+\Delta$ denotes a movable point $(x_o+\Delta x, y_o+\Delta y, z_o+\Delta z, t+\tau)$. $\varpi' \equiv \sqrt{\overline{\varpi\times\varpi}}$ is the standard deviation for normalization and the overbar means the time-averaged operator.

Figure 7 shows the horizontal distributions of $C_{\varpi\varpi}$ as an increases of time-delay τ. Two reference points, that correspond to the twin eddy structure observed in Figure 4, are chosen at the channel-transition section of $x/L = 0$ and $\phi = 0°$. The lateral positions of these reference points are $z'/B_m = 0.15$ and 0.8, respectively, and the elevation is $y/D = 1.1$ above the floodplain height. A maximum correlation region for the left-side eddy moves downstream with an increases of the time-delay,

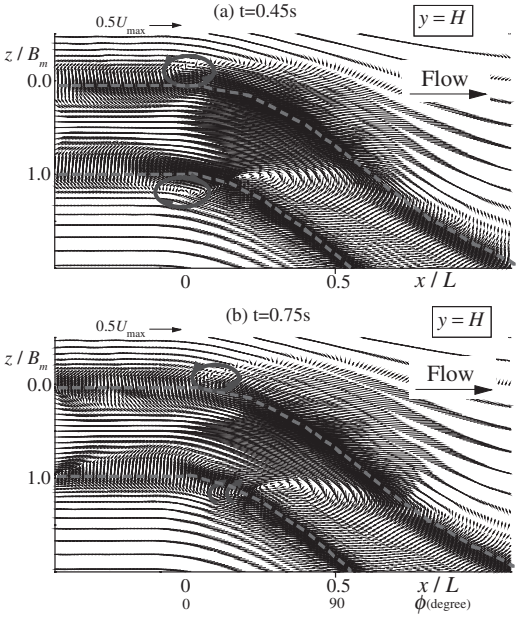

Figure 6. Time-variations of instantaneous velocity vectors.

and it suggests that the left-side eddy is convected almost straightly with streamswise direction. On the other hand, the right-side eddy crosses over the meandering inbank main-channel and moves to the left side floodplain in the apex section of $x/L = 1.0$.

3.5 *Meandering properties of horizontal eddies*

It is suggested from Figure 7 that the right-side eddy which crosses over the main-channel has a more complicated meandering property than the left-side eddy.

Copyright © 2006 Taylor & Francis Group plc, London, UK

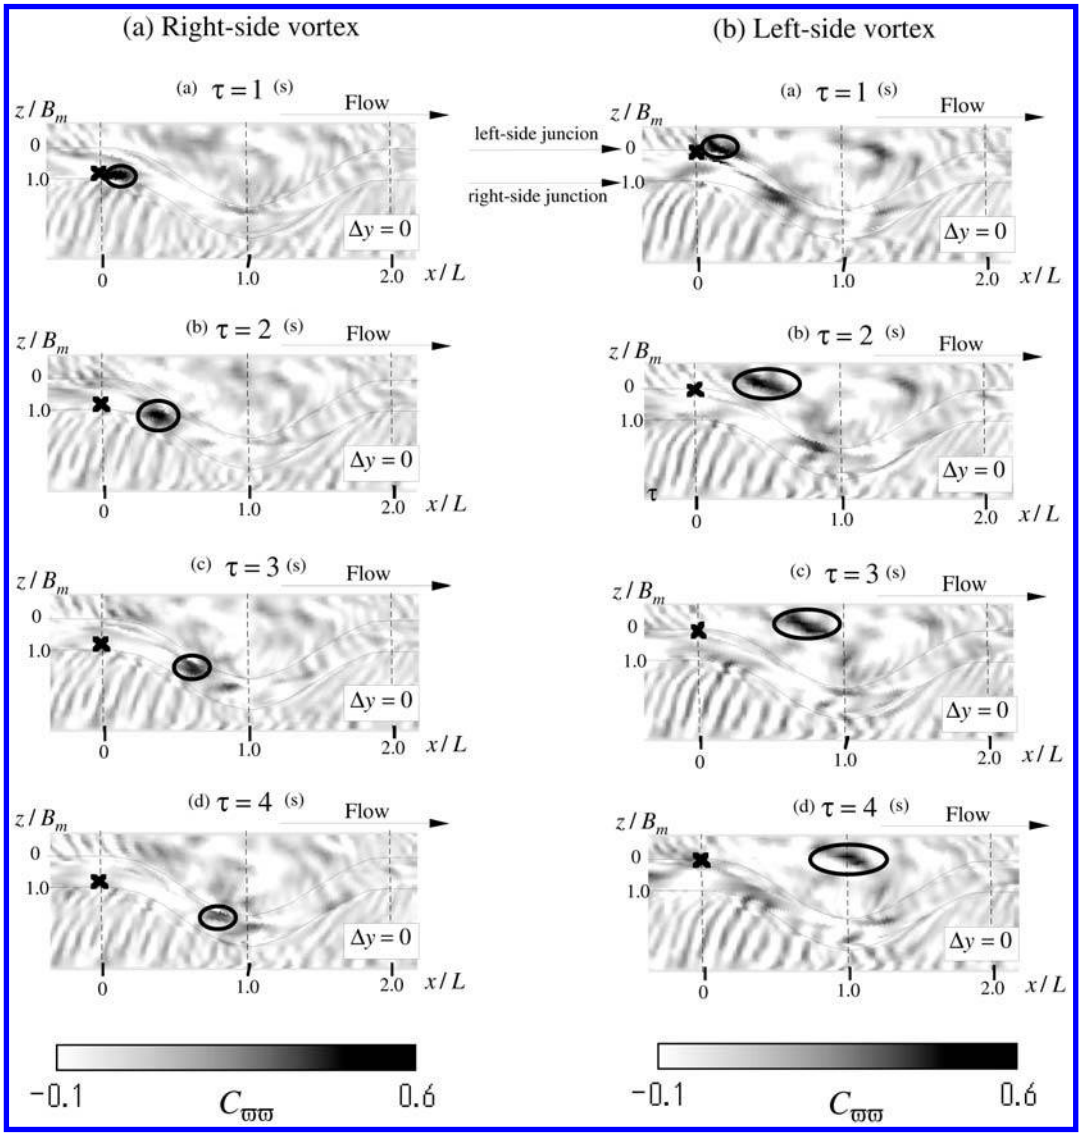

Figure 7. Distributions of space-time correlation function for the right-side and left-side vortices.

The trajectory of the right-side eddy is examined by using the results of correlation analysis. The trajectory is given by connecting the maximum positions of the space-time correlation function $C_{\varpi\varpi}$. Figure 8 shows the trajectories of right-side eddy at several elevations, in which the reference height is fixed at $y/D = 1.1$ and the time-spacing of these plots chosen to be just 1s. This figure indicates clearly that horizontal eddy crosses over the curved main-channel at all elevations. Whereas, we can also see the noticeable property that the horizontal eddy is transported more straightly nearer the free surface, because the curving effects of main-channel become smaller farther from the bottom-bed. This means that the right-side eddy has the complicated tube-like 3-D structure which is inclined with both of the streamwise and spanwise directions. It is comparatively difficult to measure such a 3-D vortex characteristics by experimental methods, e.g. LDA and PIV, and thus the present turbulence simulation is very useful in order to predict and reveal 3-D coherent structure in complex boundary flows.

4 CONCLUSIONS

In the present study, 3-D LES was conducted in compound free surface flow included with the transition section from the straight to meandering channels. The present LES model was examined by comparison with the measured EMV data and the meandering characteristics of horizontal eddies were considered numerically. The main findings are as follows:

1) The calculated results of the secondary currents and velocity distributions were compared with those measured by EMV. The calculated patterns of secondary currents, such as magnitude distribution and rotational directions, are the same trend as observed in the measured data.
2) The present simulation could reproduce a pair of counter-rotating horizontal vortices near the junction between the main-channel and the floodplains. This finding was also recognized from the spanwise distributions of the Reynolds stress in which there are two peaks of positive and negative values.
3) The space-time correlation analysis was conducted by using the present data in order to evaluate the trajectories of the coherent vortex core. It is found from this result that the tube-like vortex, which has a strong correlation vertically, was convected along the meandering line.

ACKNOWLEDGEMENTS

The present study was conducted under the financial support from Hattori Hokokai in Japan, and we thus acknowledge this.

Emergence of large-scale coherent structures in a shallow separating flow

Harmen Talstra, Wim S.J. Uijttewaal & Guus S. Stelling
Environmental Fluid Mechanics Section, Faculty of Civil Engineering and Geosciences, Delft University of Technology, the Netherlands

ABSTRACT: In rivers, the phenomenon of flow separation past obstacles often gives rise to large-scale coherent structures. This study focuses on quasi-2d coherent structures associated with shallow flow separation (vortex shedding). New insights about the physical mechanism governing vortex shedding have been obtained from large-scale Particle Image Velocimetry (PIV) experiments on a Shallow Lateral Expansion (SLE) with a variable inflow width. Analysis of the acquired data stresses the crucial role of the secondary circulation cell, which is often present in shallow separation geometries. A sufficiently developed secondary circulation cell is significantly contributing to vortex shedding. Moreover, the interaction between primary and secondary circulation cells causes a "scale jump" in the horizontal length scale of the shed vortices. An analysis of Reynolds' stresses and the downstream development of conditional averaged eddies does clearly show this jump. Since the scale jump is essentially due to interaction of discrete horizontal eddies, 3D Large Eddy Simulations (LES) are performed in analogy with the measured PIV geometries. The obtained LES data will be used to develop a depth-averaged flow model that will reproduce the discrete horizontal eddy interaction in an accurate way, thus enabling researchers and engineers to predict vortex shedding in river geometries.

1 INTRODUCTION

1.1 *Background and objectives*

The present study focuses on a combination of two classes of turbulent flows. The first class is that of a shallow free-surface flow: geometries with vertical length scales much smaller than the horizontal scales (typical aspect ratio 5% or less), in which most of the large-scale turbulence may be considered as quasi two-dimensional. Both production and dissipation of turbulent kinetic energy are greatly influenced by the presence of bottom friction: see e.g. Uijttewaal & Booij (2000) and Van Prooijen (2004). The second class is that of a separating flow: due to an adverse pressure gradient the main flow separates from a wall, inducing a zone of flow recirculation and possibly the presence of a street of vortices which are shed from the separation point. Both classes come together in many rivers and coastal flow geometries. Shallow separating flows are abundant in nature as well as in man-made environments.

In practice, large-scale coherent structures resulting from a separating shallow flow frequently turn out to cause problems regarding e.g. navigation and bed erosion, the latter combined with settling of sediment in undesirable places. These effects are well-known from rivers normalized by long series of groynes, or harbour entrances becoming less accessible due to large-scale eddies and loss of navigable depth. Since many shallow flows accommodate a variety of functions and interventions in flow systems may have unexpected or unwanted effects, improving the understanding and modelling approach of large-scale coherent structures is of practical relevance. In this study, therefore, an attempt is made to visualize experimentally the emergence and behaviour of individual coherent structures shed from a separation point. This experimental information is being used to validate and inspire further development of numerical models of shallow separation flow geometries.

1.2 *General visualisation of shallow separation*

Figure 1 shows the effect of separation on a shallow channel flow past an obstacle, visualised by the injection of dye. In this case, the separation gives rise to a primary and secondary recirculation cell ("bubble"). In literature, the maximum streamwise recirculation zone length (reattachment length) for this type of lateral expansions is often estimated at approximately 8 times the obstacle size (see Babarutsi, Nassiri & Chu, 1996). At the interface between main flow and recirculation zone, lateral exchange of momentum and dissolved matter takes place due to the presence of a mixing layer and large-scale coherent structures (see e.g. Nassiri & Babarutsi, 1997). The presence of recirculations makes the flow behaviour quite different

Copyright © 2006 Taylor & Francis Group plc, London, UK

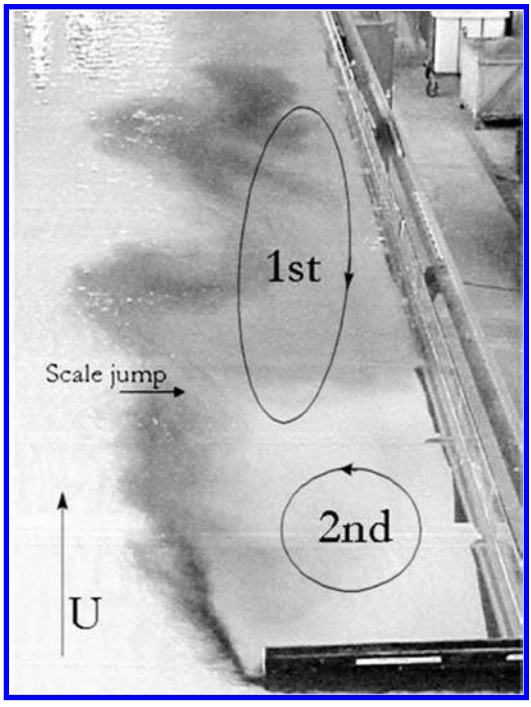

Figure 1. Large-scale structures in a shallow separating flow, visualised by dye. Shown are: direction of the main flow (U), primary bubble (1st), secondary bubble (2nd) and location of the spatial "scale jump" in downstream development of the vortex street.

from that of a plane mixing layer due to a lateral velocity difference only.

In their experimental study on groyne fields, Uijttewaal, Lehman & Van Mazijk (2001) point out a qualitative difference between mixing layer vortices and "vortex shedding". The latter phenomenon is largest in scale and is associated with the presence of a secondary recirculation cell, while the first phenomenon is associated with lateral shear. It is an open question, however, whether there is indeed a difference in physical mechanism for both types of eddies.

From the experiments which are described in this paper, it is visually observed that, indeed, a distinction can be made between the two mechanisms. As soon as a sufficiently well-developed secondary bubble appears, the initial mixing layer changes character and much larger eddies are shed than before. This effect can be associated with the term "vortex shedding". It is observed, however, that the largest eddy scales are emerging not from the separation point, but from a point some distance downstream – approximately at the interface between primary and secondary bubble. At this point, a "scale jump" in vortex sizes is visible. The location of this jump is important, because there is a strong suggestion of positive interaction between the large eddies and the primary bubble ("vortex merging"), while these eddies tend to remain small while passing the secondary bubble slightly upstream. This implies that "vortex shedding" is *not* a distinct mechanism of eddy generation at the separation point, but merely an internal flow feature associated with interaction of existing eddies having the same vorticity sign. This interpretation makes vortex shedding here a typical quasi-2d turbulence phenomenon.

2 DESCRIPTION OF PIV EXPERIMENTS

2.1 *Experimental setup*

In order to study the dynamics of individual large-scale vortices, physical flow experiments have been carried out in a wide and shallow free-surface flume, using the measurement technique of Particle Image Velocimetry (PIV). Because it is desired to study the mere vortex shedding phenomenon with as least geometrical information as possible, the experimental setup has been chosen to be a Shallow Lateral Expansion (SLE). This geometry involves only three length scales: the inflow width, the outflow width and a uniform depth. The SLE is well-known from literature (e.g. Babarutsi, Ganoulis & Chu, 1989), but mostly only with respect to time-averaged quantities rather than individual eddy dynamics. Moreover, it is common practice to take an inflow width equal to 50% of the outflow width, thus effectively reducing the number of length scales to two. In the present study, the inflow width is explicitly chosen to be varied to 3 different values. This yields 3 distinct cases which are object of detailed PIV analysis; the number of qualitative experiments carried out by visual observation, however, is 18 because also depth and discharge have been varied.

The experiments are carried out in a shallow flume with a length of 20.00 m and an outflow width b_2 of 2.00 m. Bottom and wall conditions are hydraulically smooth. In all three PIV experiments, the water depth h is 9.2 cm. The width b_1 of the inflow section is either 0.50, 1.00 or 1.50 m. The three cases are respectively referred to as the 1:4, 2:4 and 3:4 case. The discharge of the first 2 cases being 0.027 m^3/s, the average depth-based Reynolds' number is $Re = 13500$. The discharge of the wide 3:4 case is increased to 0.048 m^3/s ($Re = 24000$) in order to keep the entrance velocity sufficiently high and comparable to the 2:4 case. On the other hand, the 1:4 case discharge is not decreased in order to prevent the recirculation zone from laminarizing. See Figures 2 and 3 for an overview of the experimental geometry and the expected time-averaged flow pattern.

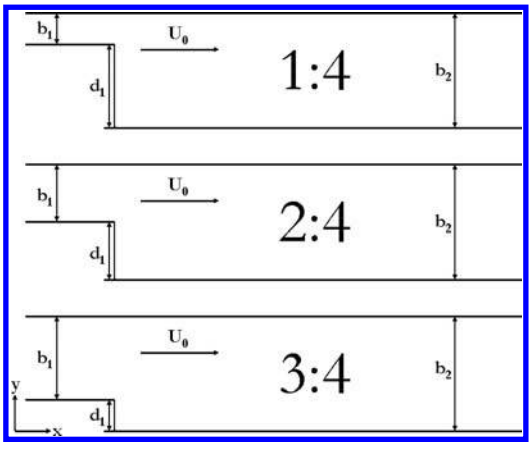

Figure 3. Overview of the 3 PIV geometries (1:4, 2:4 and 3:4).

bottom, are used to visualize the surface velocity field. With a sampling frequency of 10 Hz (2:4 and 3:4 cases) or 15 Hz (1:4 case), instantaneous velocity fields of size $1.50 \times 1.50\,\mathrm{m}^2$ are obtained by a 1 Mpixel digital camera and the PIV algorithm of Davis (version 6.2). Every set of 2 subsequent camera frames is cross-correlated by the algorithm, using an interrogation window overlap of 75%. The results are samples of 2d surface velocity fields on a rectangular co-located grid with a spacing of 2.4 cm in both x- and y-direction. The sample sizes are respectively 7000 frames (2:4 and 3:4 case) and 10500 frames (1:4 case), both accounting for a measurement duration of 700 s.

Because the spatial domain of the camera image is limited to $1.50 \times 1.50\,\mathrm{m}^2$ by resolution requirements, series of samples have to be linearly fit together in order to cover the entire relevant flow area. Therefore, each sample has an overlap of approximately 20% with neighbouring recording areas. The 1:4, 2:4 and 3:4 case data series are consisting of respectively 8, 6 and 4 samples, visualizing the greater part of the vortex shedding areas in downstream direction (Figure 4).

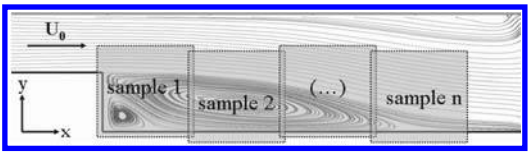

Figure 4. Location of the series $1.50 \times 1.50\,\mathrm{m}^2$ PIV samples.

2.3 *Large eddy visualisation using vector potentials*

A topic requiring special attention is the way in which large-scale eddies within the PIV samples can be detected and visualized. Although a simple look at the velocity vector field often shows these large eddies immediately, it is not always easy to define a straightforward detection algorithm.

Bonnet et al. (1998), Scarano et al. (1999) and Adrian et al. (2000) all give extensive overviews of commonly used identification methods for coherent structures, e.g. based on vorticity, swirling strength or spatial correlations with a "mask eddy". The drawback of the latter method is the spatial inflexibility of the results and their slight dependence on the mask eddy length scale which is chosen *a priori*; the former methods have the disadvantage that, like all gradient-based methods, they tend to enhance the dominance of the small length scales within the velocity signal, rather than the large scales.

In this study, the *vector potential* of a velocity field is used to detect large eddies. The use of vector potentials is quite common within the context of electromagnetism but not within fluid dynamics, in spite of the great mathematical analogy between both scientific fields. Yet, vector potentials are very elegant in use because they allow large vortex scales to be determined directly from instantaneous flow kinematics. They very much resemble the concept of 2d stream functions, but are computed in a different way in order to make a correction for the non-solenoidality of a 2d plane within a 3d velocity field. Vector potentials can be constructed by solving the Poisson equation for each component of the vorticity, using homogeneous Neumann boundary conditions. See the *Appendix* for a full mathematical explanation of construction and relevance of vector potentials.

Each local maximum or minimum of a vector potential function uniquely identifies a large eddy core of positive, resp. negative vorticity sign. The shape of the eddy is given by the surrounding isolines. Within the instantaneous vector potential fields, the permanently present primary and secondary recirculation cells are by far dominant; when the time-averaged pattern is subtracted from instantaneous patterns, however, the result is the visualisation of a straight streamwise line of large vortices being shed from the separation point.

3 RESULTS

3.1 *Visual observations: general flow features*

In order to explore the parameter space of relevant experimental cases, over 30 different flow cases were observed merely visually, using dye and the same black tracer particles as described before. Every flow case was running for about 2 hours and was used to gain insight in the occurring flow features: over-all flow patterns, bubble sizes and large eddy length scales. Water level, discharge and inflow-outflow width ratio were varied in such a way that the flow remained sufficiently turbulent and fully subcritical. In the end, 18 flow cases were concluded to be suitable for mutual comparison.

Table 1 shows the primary and secondary recirculation cell sizes, scaled by the lateral expansion width d_1, for the 2 different discharges (q) and 3 width ratios predefined in Section 2.1. The 18 water depth values are varying for each case because of the practical difficulty to get these exactly equal. The primary bubble size is defined by the reattachment length (L_1) and the secondary bubble size by the x-location of the secondary separation point along the wall (L_2), both taking the expansion's lower left corner as the origin. Both water depth (h) and bubble sizes are made dimensionless by the lateral expansion width.

Table 1. Primary and secondary recirculation cell sizes for 18 different flow cases; visual observations.

* Length scales are made dimensionless by expansion width d_1.

First, the general impression is that the dimensionless reattachment length L_1/d_1 tends to decrease for decreasing dimensionless depth, compared to the maximum deep water limit known from literature. This limit is estimated to lie between 7.0 and 8.0 (the latter number is proposed by Babarutsi, Ganoulis & Chu, 1989). The values found in the 3:4 case seem to confirm this. It is however striking that the values observed in the 1:4 and 2:4 cases exceed this limit, even up to values 9.0 and over, although the reattachment point is usually slightly oscillating. This exceedance may be explained by the hydraulically smooth wall conditions of the present experimental setup, which often are not reached in practice. Also, the relatively large size and the high Reynolds number of this setup may play a role of importance (the experiments of e.g. Babarutsi et al. were carried out on an approximately 3 times smaller scale and with larger values of roughness).

Second, the secondary bubble sizes L_2/d_1 in the 2:4 and 3:4 cases show a pattern opposite to that of the reattachment length: as the relative shallowness increases, the secondary separation point moves further downstream. This can be understood by the primary bubble becoming weaker: as the primary recirculation flow decreases in discharge and energy, it will break away sooner from the solid wall because of the local adverse pressure gradient which previously brought the secondary bubble into being. Hence, with increasing shallowness, the primary bubble is eaten up from two sides, sometimes even to the point that the primary and secondary bubble become comparable in size. The secondary zone of the 1:4 case, on the contrary, is enhanced together with the primary zone. It is observed that, in these cases, the secondary bubble has grown too big to maintain itself within such shallow conditions, and hence breaks up in two or more intermittent structures. In some cases, even a small "tertiary bubble" in the lower left corner is observed.

Third, because of its large relative shallowness (small value of h/d_1), the 1:4 case shows an intermittent bubble opposite to the primary recirculation. The presence of this opposite bubble depends strongly on the passing by of large vortices shed from the separation point. These vortices are able to entrain so much main flow fluid into the mixing layer that the main flow separates from the opposite continuous wall. This feature is however intermittent and is located too close to the outflow boundary to be studied in an accurate way. In the 2:4 and 3:4 cases, it is absent.

Finally, the most important flow feature to be described is the vortex shedding phenomenon. Flow patterns can be described in good detail because of the abundance of tracer particles. Striking is the stability of the near-field mixing layer, in spite of both its small width and the presence of a very strong lateral shear due to the secondary bubble which is almost touching the main flow. The small coherent structures emerging from the separation point seem to be almost immune to their neighbourhood. As soon as the mixing layer approaches the primary bubble, however, the

Copyright © 2006 Taylor & Francis Group plc, London, UK

structures appear to be boosted significantly, both in energy and spatial scale ("scale jump").

This can be explained from the positive interaction between vorticity cores in both mixing layer and primary zone, i.e. the effect of "vortex merging". This effect is well-known from quasi two-dimensional flow theory and can be associated with the suppression of the vortex stretching term in the vorticity equation. The boosted eddies are penetrating to a large extent in both main flow and primary bubble, and are able to exchange a lot of mass and momentum. (This, too, may be an explanation for the remarkably large reattachment lengths that are found in the 1:4 and 2:4 cases.) The zones in between two large shed vortices are observed to be areas of considerable shear. The flow is stretched in streamwise direction here, as well as compressed in spanwise direction. Also, secondary flow in vertical direction is affecting these zones, in contrast with the large vortex cores which appear to be predominantly two-dimensional.

In the 3:4 case the scale jump effect is much weaker, if not absent. In this geometry the secondary bubble zone is relatively deep (largest value of h/d_1). Therefore the bubble remains small and does not touch the main flow. The influence of the primary bubble, hence, is reaching all the way upstream to the separation point, resulting in a smoother and less dramatic mixing layer development. From that point of view, it is not surprising that the reattachment lengths found in the 3:4 case answer better to the expected maximum limit than the 1:4 and 2:4 cases.

In the 1:4 case, the scale jump effect is present but weaker than in the 2:4 case, which contains the most obvious jump. This is explained by a limited influence of the secondary bubble in the 1:4 case, because it tends to break up in separate structures as mentioned above (which is visible in Figure 5a).

Based on the 18 flow cases described above, a representative geometry is selected for detailed PIV analysis. Only the inflow-outflow width ratio remains variable (hence 3 cases). Dimensions and other figures of this geometry have been described in Section 2.1.

3.2 *PIV data analysis: time statistics*

All recorded PIV time series have a sampling period of 700 s, which is equivalent to about 30–70 consecutive large eddies shed from the separation point. In this section, over-all time statistics are shown for the 3 measured flow cases. For each case, neighbouring measurement recording areas were fit together by linear interpolation in the overlapping areas.

Figures 5a to 5i show the contour plots of time-averaged flow quantities: stream function, spanwise turbulent kinetic energy and horizontal Reynolds' stresses of the 1:4, 2:4 and 3:4 cases respectively. The stream functions show that, in the 3:4 case, the

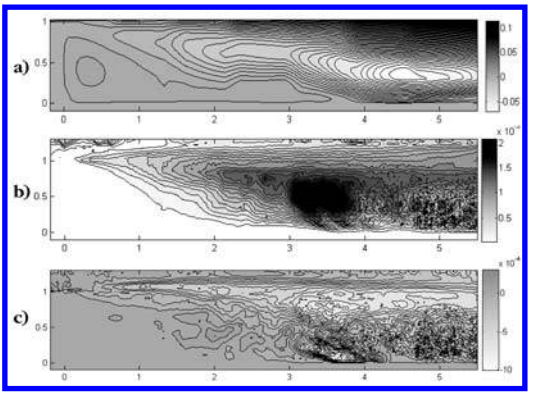

Figure 5a–c. Time-averaged flow quantities of the 1:4 case: a) time-averaged stream function ψ [m^2/s], b) spanwise turbulent kinetic energy $\langle u'^2 \rangle$ [m^2/s^2], c) horizontal Reynolds' stresses $\langle u'v' \rangle$ [m^2/s^2].

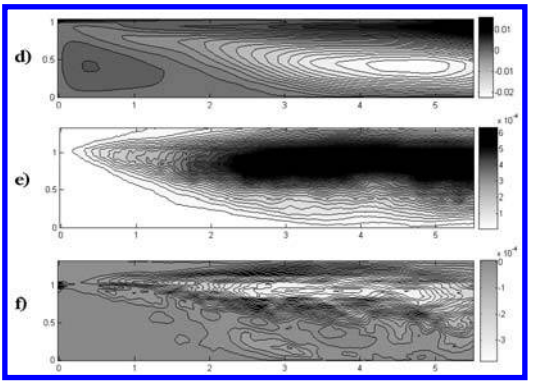

Figure 5d–f. Time-averaged flow quantities of the 2:4 case: d) time-averaged stream function ψ [m^2/s], e) spanwise turbulent kinetic energy $\langle u'^2 \rangle$ [m^2/s^2], f) horizontal Reynolds' stresses $\langle u'v' \rangle$ [m^2/s^2].

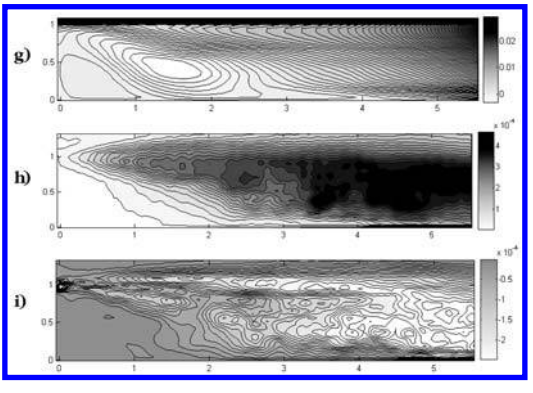

Figure 5g–i. Time-averaged flow quantities of the 3:4 case: g) time-averaged stream function ψ [m^2/s], h) spanwise turbulent kinetic energy $\langle u'^2 \rangle$ [m^2/s^2], i) horizontal Reynolds' stresses $\langle u'v' \rangle$ [m^2/s^2].

Copyright © 2006 Taylor & Francis Group plc, London, UK

secondary bubble is indeed less developed than in the other 2 cases, resulting in a deviant vortex shedding behaviour. Please note the tendency of the 1:4 secondary bubble to break up in two parts.

Reynolds' stress values can be seen as time-averaged indicators for the presence of large-scale coherent structures (velocity correlations). Therefore, it is telling that in the 1:4 and 2:4 cases, the scale jump is visible in the Reynolds' stress contours. In these cases, the negative peak of the Reynolds' stress suddenly widens and deepens from a certain point downstream, while the 3:4 case does not show this behaviour. Furthermore, it is striking that the components of the turbulent kinetic energy show a quite linear development, while the Reynolds' stress contours are more discontinuous. This can be understood by the fact that the velocity variance contains only temporal and local information, whereas the velocity covariance is also pointing towards the spatial structure of the flow field. Apparently, the development of the shed vortices in terms of total energy is pretty continuous, comparable to that of a plane mixing layer; but downstream from the scale jump location, the kinetic energy distribution does shift towards larger length scales. This suggests that the scale jump effect is spatial rather than temporal.

Figure 6 shows the development of the lateral turbulent kinetic energy downstream from the separation point for each of the 3 cases. As expected, no jump is visible here. Examining the downstream development of the associated temporal power density spectra yields the same result. On the other hand, one will expect to find such a jump in the spatial power density spectrum development. Unfortunately, the horizontal dimensions of the PIV camera samples are too limited to allow for reliable spatial spectra.

From the computed Reynolds' stresses a turbulent length scale (Prandtl mixing length) can be defined using a simple mixing length approach. Figure 7 shows the downstream development of this mixing length λ for the three PIV cases. The 2:4 shows the clearest jump. It is however not surprising that this method yields eddy sizes which are almost an order of magnitude too small, because we are using time-averaged statistics of an intermittent phenomenon.

For both reasons mentioned above, spatial vortex scale development can best be examined by conditional averaging of the intermittent shed vortices. Results of this averaging operation are described in the next section.

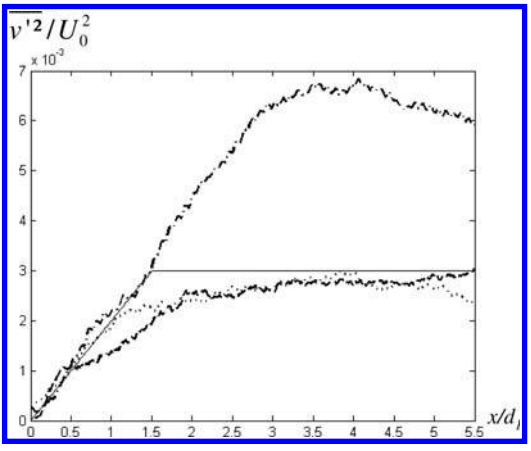

Figure 6. Development of the lateral turbulent kinetic energy downstream from the separation point, normalized by the squared mean inflow velocity. Dashed line: 1:4 case, dash-dot line: 2:4 case, dotted line: 3:4 case, continous: trend line. The downstream distance is scaled by the lateral expansion width. The 2:4 case vortex shedding is containing the largest amount of turbulent kinetic energy relative to the energy of the mean flow. The 1:4 and 3:4 case are quite comparable.

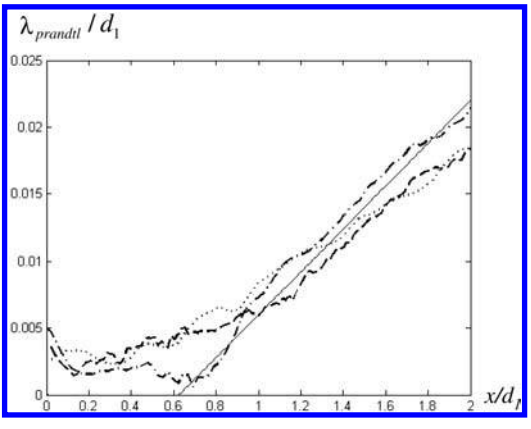

Figure 7. Development of the Prandtl mixing length λ downstream from the separation point, based on measured Reynolds' stresses. Dashed line: 1:4 case, dash-dot line: 2:4 case, dotted line: 3:4 case, continous: trend line downstream of the scale jump location (approximately $x/d_1 = 0.8$). Both the downstream distance and the mixing length are scaled by the lateral expansion width. The 2:4 case shows the most pronounced scale jump behaviour.

3.3 *PIV data analysis: conditional averages*

The location of the conditional averages is the line along which the relevant large eddies are found: the straight streamwise "shadow line" downstream of the separation point. For each point on this line where PIV data are located, the cross section of the flow is checked for the presence of a large eddy. This is done by searching local minima in the vector potential time series *relative* to the mean flow pattern (the latter is needed because otherwise only the primary and

Copyright © 2006 Taylor & Francis Group plc, London, UK

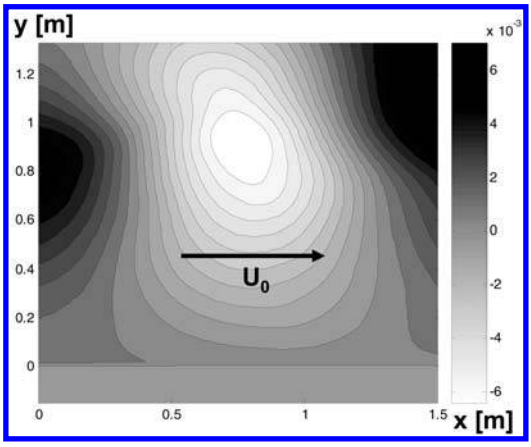

Figure 8. Typical example of a conditionally averaged shed vortex (in the far field of the 2:4 case), visualised by a vector potential field. The computed streamlines agree very well with the associated vector field. The local minimum in the centre of the picture identifies a clockwise large eddy with a diameter of approximately 0.8 m.

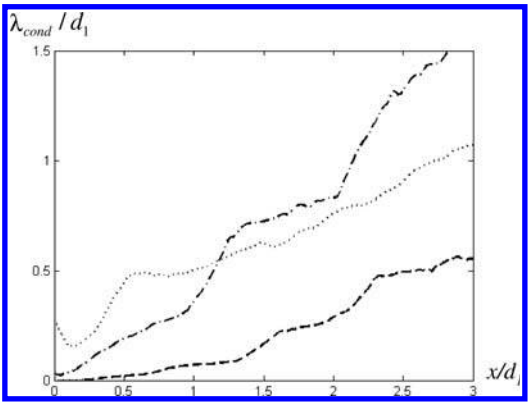

Figure 9. Development of the dominant large eddy scales λ_{cond} downstream from the separation point, based on conditional averaging. Dashed line: 1:4 case, dash-dot line: 2:4 case, dotted line: 3:4 case. The 2:4 case shows the largest eddy scales relative to the lateral expansion width d_1, which is understandable because of the large relative energy of the large-scale turbulence in this case (see also Figure 6).

secondary bubble would be found). After that, statistical operations can be performed on the conditional vortex samples. Figure 8 gives an illustration of the procedure in which the large eddies are detected by means of vector potentials.

In principle, conditional averaging can be done for every point within the measured flow domain. Near the edges of the recording domains, however, the conditional averaged flow fields show biases because of the difficulty to determine a local minimum near a boundary. Therefore, the fitting of neighbouring data recording areas is problematic for conditional averaged quantities. The over-all patterns and trends, however, remain sufficiently clear.

The conditionally averaged spanwise velocity signal (again relative to the mean velocity) is suitable for determining local large eddy length and time scales. Please note that vector potential quantities are used only for performing the conditional averaging process itself and for large eddy detection, but are not suitable as an object of any further data statistics. For determining eddy scales, it is better to return to the velocity signal itself.

The spanwise velocity makes a zero crossing at the location of conditionally averaged eddy cores. An eddy length scale can be defined as the distance between the centroid locations of the vortex velocity profiles left and right of such a zero-crossing; this scale can be computed using first order moments of the signal. A more robust approach, however, is determining the dominant time scales of conditionally averaged vortices and multiplying these by the propagation speed of the large eddy core, thus obtaining an "eddy wave length" (the real eddy size is about 50% of this wave length). The latter approach is much less sensitive to noise and boundary biases, because the obtained PIV data allow for much better temporal than spatial statistics.

Figure 9 shows the computed length scales of the dominant eddies caused by vortex shedding, as a function of x, for each of the 3 PIV cases. Both axes are scaled by the lateral expansion width d_1. Unlike the scales shown in Figure 7, the conditionally averaged eddy sizes do have the correct order of magnitude (of the order of d_1). It is obvious that the 1:4 and 2:4 cases do show a spatial scale jump downstream of the point $x/d_1 = 1.0$, whereas the 3:4 case eddy size development is more linear.

3.4 *Discussion*

In literature, as pointed out in Section 1.2, a distinction can be found between a shallow mixing layer on the one hand and the phenomenon of vortex shedding on the other hand. The latter phenomenon is seen as an extra effect *additional* to a mere mixing layer, typical for shallow separating flows, while a mere mixing layer is considered to be a more general feature of shallow shear flows. With respect to this, e.g. Jirka (2001) treats both types of shallow-flow turbulence separately and speaks of two different mechanisms: respectively the mechanisms of *topographical forcing* (due to flow separation) and *internal transverse shear instabilities* (due to a lateral flow velocity difference). The reason why both mechanisms differ, however, sometimes remains an open question.

The observed phenomenon of the "scale jump" due to a well-developed secondary recirculation cell is a very helpful tool to explain why shallow flow

Copyright © 2006 Taylor & Francis Group plc, London, UK

separation yields large vortices that have a character different from mixing layer vortices. Both vortex types are initially induced by lateral shear, but in a shallow separation geometry, the presence of *permanent* recirculation cell vorticity greatly influences the spatial eddy development. Hence, it can be concluded that in a separation geometry the influence of solid wall friction (inducing recirculations) is never negligible, while a plane mixing layer theoretically does not have walls at al. With that respect, a shallow separation flow is always intrinsically a combination of free turbulence and wall turbulence, whereas a mere mixing layer problem has a free turbulence character to a much larger extent.

The geometry-dependency of shallow separation problems, however, puts also a limit to the amount of conclusions that can be drawn from the current experiments. In practice, many shallow separation geometries do not contain a sufficiently developed secondary bubble (for example due to the presence of downstream obstacles like groynes), so that a less pronounced scale jump effect should be expected there. Also, the local wall and bottom roughness as well as the presence of non-vertical sidewall slopes (which are almost always there in the case of groynes) will play a huge role in most river engineering problems in reality. It is not easy to say how especially the presence of wall slopes will influence the scale jump behaviour. It is not unthinkable that, in the case of groyne fields, scale jump locations will lie so close to a separation point that large eddies seem to be shed directly from the groyne tip.

Therefore, it will be worthwhile to repeat the current experiments replacing the vertical-wall lateral expansions by several real-life groyne geometries, maintaining the level of detail in which the large-scale vortices are detected. However, introducing wall slopes and more associated geometrical parameters will cause the experiments to be less generic in terms of length scales, which will make it more difficult to draw general conclusions from them.

In terms of engineering applications, the current experiments strongly suggest that any attempt to prevent scale jumps from occurring will yield more favourable river flow conditions, thus preventing the well-known navigation and sedimentation problems to a large extent. It is possible to do this by changing shallow separation geometries in an effective way. Especially changing river groyne shapes could be a great asset to river engineers. If groyne shapes can be modified in such a way that they will "shelter off" most of the secondary bubble regions from the main river, this may yield a considerable reduction of the effective lateral shear. A very concise pilot experiment, executed within the same experimental setup as described in this paper, does indeed show that a strong reduction of the vortex shedding intensity is feasible.

4 CONCLUSIONS AND OUTLOOK

Detailed PIV experiments have been performed on a Shallow Lateral Expansion with a variable inflow width. The hypothesis seems to be confirmed that the vortex shedding phenomenon is caused by the presence of a sufficiently developed secondary recirculation cell. A new element of information, however, is that the emergence of large-scale shed vortices is not caused by the flow separation itself, but by interaction of initially induced mixing layer vortices with the primary and secondary recirculation areas. This vortex interaction can be interpreted as a typical feature of shallow (quasi two-dimensional) flows. Also, the location of this large vortex emergence (*scale jump*) does not coincide with the separation point. The decomposition of "mixing layer vortices" and "vortex shedding" opens a perspective of effective manipulation of large eddies in real-world shallow flow situations by changing the geometry with respect to the secondary recirculation cell.

Further analysis of the vortex shedding phenomenon is currently done by performing a series of full 3D Large Eddy Simulations (LES), in full analogy with the three examined PIV geometries. This type of analysis seems to be rewarding because, like PIV data, LES data allow for not only flow statistics but also a very detailed look at the discrete horizontal vortices that are responsible for the observed typical vortex shedding behaviour in shallow flows. Moreover, conditional averaging of large horizontal eddies is an option for LES data analysis too. Although the general flow and turbulence features shown by the already performed LES simulations look quite reasonable, a detailed analysis of the vortex shedding process is not yet available. The obtained LES data will be used to develop and inspire a more concise shallow flow model, possibly fully depth-averaged, yet able to reproduce horizontal eddy interaction in rivers accurately. Meanwhile, examining the vortex shedding process in more various shallow separating flow geometries by detailed physical experiments - thus verifying the proposed scale jump hypothesis – will remain a subject of further research.

APPENDIX: ABOUT VECTOR POTENTIALS

Given a 3d solenoidal velocity vector field:

$$\vec{u} = (u, v, w), \text{ with } \nabla \cdot \vec{u} = 0 \text{ and } \nabla \times \vec{u} = \vec{\omega} \qquad \text{(i)}$$

For such a vector field, a vector potential $\vec{\psi}$ exists such that

$$\vec{u} = \nabla \times \vec{\psi}, \qquad \text{(ii)}$$

for $\nabla \cdot \nabla \times \vec{\psi} = 0$ by definition. Please note that $\vec{\psi}$ is determined apart from an arbitrary gradient field $\nabla\phi$, because $\vec{\psi}' = \vec{\psi} + \nabla\phi$ is also satisfying (ii).

The vorticity $\vec{\omega}$ now can be written as

$$\vec{\omega} = \nabla \times (\nabla \times \vec{\psi}) = \nabla(\nabla \cdot \vec{\psi}) - \nabla^2 \vec{\psi} \qquad \text{(iii)}$$

Because $\vec{\psi}$ has a degree of freedom, it can be chosen such that $\vec{\psi}$ is also solenoidal. In that case, expression (iii) for the vorticity reduces to a Poisson equation:

$$\vec{\omega} = -\nabla^2 \vec{\psi} \qquad \text{(iv)}$$

The wonderful thing about the Laplacian operator in this expression is that it operates on each vector component separately. Therefore, if only one component of the vorticity is known (which is ω_z in this study, for only u and v are known in the horizontal PIV-plane), yet the full z-component of the vector potential can be constructed. On the vector field edges, it is sufficient to use homogeneous Neumann boundary conditions for solving the Poisson equation.

Taking the curl of the constructed ψ_z should yield in turn the original velocity field (u,v). The latter, of course, does only make sense if the vorticity component ω_z is the dominant component within 3d context. This condition is obviously satisfied in case of a shallow quasi-2d flow with large eddies in the horizontal plane. In that case, taking the curl of the vector potential is practically equivalent to:

$$u = \partial\psi_z / \partial y \quad \text{and} \quad v = -\partial\psi_z / \partial x, \qquad \text{(v)}$$

which shows that ψ_z very much resembles a 2d stream function of (u,v), except for the fact that an important correction has been made to circumvent the nonsolenoidality of the (u,v)-plane.

In fact, computing a vector potential is a way to *integrate* the associated velocity field, showing large-scale rotation patterns in the end. On the contrary, computing a vorticity means taking a *derivative* of that velocity field, effectively showing small-scale rotation patterns. This can be understood by considering a velocity signal being a sum of spatial periodical signals (Fourier components). Taking derivatives of the total signal implies multiplying each component i by its wave number k_i, thus enhancing the dominance of the high wave numbers (small scales). Integrating the signal, however, will lead to a division by k_i, hence focussing on the low wave numbers (largest scales). This explains why experimental vorticity data are often very noisy while, on the other hand, vector potential data are quite smooth and hence much easier to handle.

Each local maximum or minimum of a vector potential function identifies a vortex core of positive respectively negative vorticity sign. The function isolines are very well parallel to the original vector field. It may be concluded that vector potentials are a most suitable tool for identifying large eddies.

ABSTRACT: The main objective of this study is to develop efficient and accurate 3D finite element model for hydrodynamic channel flow simulation. To establish governing equation considering turbulent flows, the fundamental 3D Navier-Stokes equation is modified as Reynolds equation. In the governing equation turbulent flow characteristics are expressed using the Smagorinsky scheme in horizontal plan and the Mellor-Yamada scheme for vertical direction. The proposed model adopted the Streamline Upwind/Petrov Galerkin scheme for weighting function in model formulation and moving boundary condition to overcome the limitations of fixed grid. For model validation, the proposed 3D finite element model has been applied for U typed channel flow and compared with the results of existing model to show a good agreement between two models. The simulation results using this model successfully describe 3D flow characteristics for various channel flows with consideration of turbulent flows. Adopting moving boundary conditions in describing water surface variations it is possible to obtain stable and accurate numerical solutions.

1 INTRODUCTION

For hydrodynamic analysis of the channel flow, various numerical schemes have been developed and advanced. Numerous numerical models which solve 2 dimensional shallow water equations are also available for 2-dimensional flow analysis. One of the representative 2-dimensional models is SMS.

In the computation of the channel flow, multi-dimensional numerical analysis is necessary. Especially more accurate numerical analyses are desirable in identifying the flow patterns, pollutant propagations, and sediment transport in the complex channel geometries such as flows in the vicinity of the hydraulic structures, in channel bends, at the points of tributary inflows, and in stratified estuaries. However, to simulate averaged flow characteristics, most of the developed models are depth integrated or laterally averaged. Thus they have limitations in describing the velocity distributions from water surface to channel bed with turbulent flows. To overcome such problems it is necessary to develop 3-dimensional numerical models to differentiate flow characteristics at the water surface and nearby the channel bed. Despite recently advanced computational devices, development of 3-dimensional flow simulation models is very limited.

The main objective of this study is to develop a finite element model which is applicable to simulate 3-dimensional channel flows in complex geometries. The channel flow analysis model proposed in this study is developed by applying the Streamline Upwind/Petrov-Galerkin scheme as a weighting function for the finite element formulation which is combined with the kinematic free-surface conditions. The developed 3-dimensional finite element model employs the Smagorinsky scheme and the Mellor-Yamada scheme to describe the turbulent viscosity in horizontal and vertical direction respectively.

2 REYNOLDS EQUATION

2.1 *Reynolds separation scheme*

In general, analytical solution for the fundamental 3 dimensional Navier-Stokes equations is not available except for particular symmetry conditions. Even such solutions are only limited for laminar flow condition without variations in velocity and pressure fields. For these reasons, it is necessary to introduce Reynolds separation scheme to differentiate the turbulence resulted from fluctuations in the flow regime

Copyright © 2006 Taylor & Francis Group plc, London, UK

due to channel roughness, hydraulic structures, and geometric complexities.

Deriving time average procedure for all variables in Navier-Stokes equations, following Reynolds equations is given as

Momentum equation

$$\rho\left(\frac{\partial \bar{u}}{\partial t}+\bar{u}\frac{\partial \bar{u}}{\partial x}+\bar{v}\frac{\partial \bar{u}}{\partial y}+\bar{w}\frac{\partial \bar{u}}{\partial z}\right)=\Gamma_x-\frac{\partial \bar{P}}{\partial x}+\left(\frac{\partial \bar{\tau}_{xx}}{\partial x}+\frac{\partial \bar{\tau}_{xy}}{\partial y}+\frac{\partial \bar{\tau}_{xz}}{\partial z}\right)$$

$$\rho\left(\frac{\partial \bar{v}}{\partial t}+\bar{u}\frac{\partial \bar{v}}{\partial x}+\bar{v}\frac{\partial \bar{v}}{\partial y}+\bar{w}\frac{\partial \bar{v}}{\partial z}\right)=\Gamma_y-\frac{\partial \bar{P}}{\partial y}+\left(\frac{\partial \bar{\tau}_{yx}}{\partial x}+\frac{\partial \bar{\tau}_{yy}}{\partial y}+\frac{\partial \bar{\tau}_{yz}}{\partial z}\right)$$

$$\rho\left(\frac{\partial \bar{w}}{\partial t}+\bar{u}\frac{\partial \bar{w}}{\partial x}+\bar{v}\frac{\partial \bar{w}}{\partial y}+\bar{w}\frac{\partial \bar{w}}{\partial z}\right)=\Gamma_z-\frac{\partial \bar{P}}{\partial z}+\left(\frac{\partial \bar{\tau}_{zx}}{\partial x}+\frac{\partial \bar{\tau}_{zy}}{\partial y}+\frac{\partial \bar{\tau}_{zz}}{\partial z}\right) \quad (1)$$

Viscosity

$$\bar{\tau}_{xy}=\mu\left(\frac{\partial \bar{u}}{\partial y}+\frac{\partial \bar{v}}{\partial x}\right)-\rho\overline{u'v'} \qquad \bar{\tau}_{xx}=2\mu\frac{\partial \bar{u}}{\partial x}-\rho\overline{u'u'}$$

$$\bar{\tau}_{xz}=\mu\left(\frac{\partial \bar{u}}{\partial z}+\frac{\partial \bar{w}}{\partial x}\right)-\rho\overline{u'w'} \qquad \bar{\tau}_{yy}=2\mu\frac{\partial \bar{v}}{\partial y}-\rho\overline{v'v'}$$

$$\bar{\tau}_{xy}=\mu\left(\frac{\partial \bar{v}}{\partial z}+\frac{\partial \bar{w}}{\partial y}\right)-\rho\overline{v'w'} \qquad \bar{\tau}_{zz}=2\mu\frac{\partial \bar{w}}{\partial z}-\rho\overline{w'w'} \quad (2)$$

where x, y, z are Cartesian coordinates, u, v, w are velocity components in x, y, z direction respectively, ρ is density of fluids, P is pressure, Γ_x, Γ_y, Γ_z is body force per unit mass.

2.2 *Turbulence closure*

Based on the Boussinesq assumption, turbulent stress is given in terms of averaged velocity which can be expressed as Equation 3. In this study eddy viscosity ν_t is computed using the Smagorinsky scheme for 2-dimensional horizontal direction, and the Mellor-Yamada scheme is adopted to compute ν_t along the vertical direction.

$$\tau_{ij}=-\rho\overline{u_i'u_j'}=\rho\nu_t\left(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\right)=\varepsilon_{ij}\left(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\right) \quad (3)$$

(1) Turbulent stress in horizontal direction

Proposed by Smagorinsky, this scheme assumes that the element size and velocity variation to determine the eddy viscosity. The turbulent stress in 2-dimensional horizontal direction is written as follows

$$\nu_t=(C_s\Delta x)^2\sqrt{S_{ij}S_{ij}} \quad (4)$$

where $S_{ij}=\left(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\right)$, Δx is element size, C_s is Smagorinsky constant which ranges between 0.1 and 0.24.

(2) Turbulent stress in vertical direction

In the stratified homogeneous flow, since eddy viscosity of vertical direction varies considerably with flow depth, the proposed model employed the Mellor-Yamada scheme in order to consider such processes.

Determination of the eddy viscosity requires 2 computational steps. In the 1st step, the vertical eddy viscosity is computed assuming stabilized homogeneous flow condition. The vertical eddy viscosity coefficient $E_{xz}=E_{yz}$ at such stable condition is given as follows

$$E_{xz}=E_{yz}=\rho S_m l_m q_t \quad (5)$$

where S_m is a coefficient derived from the experiment conducted by Mellor and Yamada, l_m is the mixing length, and q_t is the variation of turbulent velocity.

3 GOVERNING EQUATIONS FOR 3-DIMENSIONAL FLOW

3.1 *Basic equation*

By assuming that the acceleration term in vertical direction is much less than that in horizontal direction, the complete 3 dimensional equation is composed of 2 momentum equations and integrated continuity equation as follows

$$\rho\left\{\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}+w\frac{\partial u}{\partial z}\right\}+\rho g\left(\frac{\partial h}{\partial x}+\frac{\partial a}{\partial x}\right)-\Gamma_x$$
$$-\frac{\partial}{\partial x}\left(\varepsilon_{xx}\left(\frac{\partial u}{\partial x}\right)\right)-\frac{\partial}{\partial y}\left(\varepsilon_{xy}\left(\frac{\partial u}{\partial y}+\frac{\partial v}{\partial x}\right)\right)-\frac{\partial}{\partial z}\left(\varepsilon_{xz}\left(\frac{\partial u}{\partial z}\right)\right)=0 \quad (6)$$

$$\rho\left\{\frac{\partial v}{\partial t}+u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}+w\frac{\partial v}{\partial z}\right\}+\rho g\left(\frac{\partial h}{\partial y}+\frac{\partial a}{\partial y}\right)-\Gamma_y$$
$$-\frac{\partial}{\partial x}\left(\varepsilon_{yx}\left(\frac{\partial u}{\partial y}+\frac{\partial v}{\partial x}\right)\right)-\frac{\partial}{\partial y}\left(\varepsilon_{yy}\left(\frac{\partial v}{\partial y}\right)\right)-\frac{\partial}{\partial z}\left(\varepsilon_{yz}\left(\frac{\partial v}{\partial z}\right)\right)=0 \quad (7)$$

$$\int_a^{a+h}\left(\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}\right)dz+u_s\frac{\partial(a+h)}{\partial x}+v_s\frac{\partial(a+h)}{\partial y}+\frac{\partial h}{\partial t}-u_b\frac{\partial a}{\partial x}-v_b\frac{\partial a}{\partial y}=0 \quad (8)$$

where h is depth, a is channel bed elevation, u_s, v_s, u_b, v_b are Cartesian velocity components at water surface and channel bed respectively.

The main dependent variables are the horizontal velocity components u, v and flow depth h. Thus, the computation of w is separately conducted.

Copyright © 2006 Taylor & Francis Group plc, London, UK

3.2 *Moving boundary condition*

In the 3-dimensional numerical modeling, it is necessary to consider spatial channel bed changes as well as temporal flow depth variations simultaneously. However, due to the numerical difficulties many finite element models utilize fixed computational mesh adapting sigma modification (King, 1982) or revised sigma modification (King, 1985). Although such methods may have advantages in solution converge, they also have some limitations in describing momentum conservation and water surface velocity. If the numerical difficulties are manageable, employing the moving boundary condition system is considered as ideally best to overcome such problems.

Assuming that (ξ, η, ς, τ') is moving the coordinate system, using chain rule to relate with fixed basic coordinate system in differentiation, and applying $\frac{\partial t}{\partial \xi} = \frac{\partial t}{\partial \eta} = \frac{\partial t}{\partial \varsigma} = 0$, $\tau' = 0$ with respect to time associated with velocity component u gives

$$\frac{\partial u}{\partial t} = \frac{\partial u}{\partial \tau'} - \frac{\partial x}{\partial \tau'}\frac{\partial u}{\partial x} - \frac{\partial y}{\partial \tau'}\frac{\partial u}{\partial y} - \frac{\partial z}{\partial \tau'}\frac{\partial u}{\partial z} \tag{9}$$

Since z component is to compute the free surface variation, Equation 9 is modified as following equation,

$$\frac{\partial}{\partial t} = \frac{\partial}{\partial \tau'} - \frac{\partial z}{\partial \tau'}\frac{\partial}{\partial z} \tag{10}$$

and entire differentiated functions are revised in the same manner.

4 3-DIMENSIONAL FINITE ELEMENT EQUATION

4.1 *Construction of finite element mesh*

Using rectangular cubic isoparameter with a total 20 of nodal points, the velocity fields are assigned to entire 20 nodal points and 8 of them are used to define the flow depth.

In general, applying interpolation function the velocity and flow depth are expressed as discrete form as

$$\tilde{u} = \sum_{i=1}^{n} N_i u_i, \quad \tilde{v} = \sum_{i=1}^{n} N_i v_i, \quad \tilde{w} = \sum_{i=1}^{n} N_i w_i, \quad \tilde{h} = \sum_{i=1}^{n} M_i h_i \tag{11}$$

where N_i is 3rd order interpolation function of 20 nodal points for flow velocity, M_i is 3rd order interpolation function of 8 nodal points for flow depth, $\tilde{u}$, $\tilde{v}$, $\tilde{w}$, $\tilde{h}$ are finite element approximation of u, v, w, h, and u_i, v_i, w_i, h_i are node values of u, v, w, h.

To achieve the benefit of computational efficiency, the model is constructed to have base element, and surface element. The base element is applicable for volume integration, and 3 different types of surface elements allow for boundary integration.

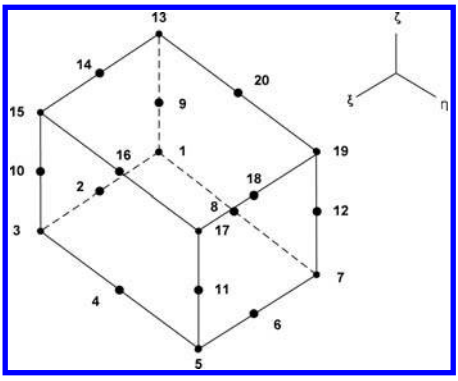

Figure 1. Three dimensional element.

4.2 *Streamline Upwind/Petrov-Galerkin scheme*

Since the Standard Galerkin method yields nonlinear instabilities during numerical simulation of the convection-dominated flow, selective upwind scheme is introduced to remove excessive fluctuation term associated with $2\Delta x$ wave length to overcome such problem. Although upwind scheme is essential for analysis of the convection dominated flow with high Reynolds number, the application is limited because nonlinearity occurs that is related with 2nd order differentiation. To avoid such numerical difficulties this model applies upwind weighting function shown in following equation only for the convection term.

$$W_i = N_i + \frac{\alpha \bar{l}}{2|V|}\left(u\frac{\partial N_i}{\partial x} + v\frac{\partial N_i}{\partial y} + w\frac{\partial N_i}{\partial z}\right) \tag{12}$$

Where W_i is weighting function, $\bar{l}$ is element length in flow direction, $\alpha = \coth \gamma/2 - 2/\gamma$, and $\gamma = Re|V|\bar{l}$ is element Reynolds number.

4.3 *Finite element equation*

Applying integration by parts to viscosity and depth terms, the governing equation can be summarized as following weighted residual form

$$\begin{aligned} f_u = {} & \int W^T \cdot \rho\left(u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} + w\frac{\partial u}{\partial z}\right) + N^T \cdot \rho\left(\frac{\partial u}{\partial t} - \frac{\partial z}{\partial t}\frac{\partial u}{\partial z} - \Omega v\right) \\ & + N_x^T \cdot \left(\varepsilon_{xx}\frac{\partial u}{\partial x} - \rho g h\right) + N_y^T \cdot \varepsilon_{xy}\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right) + N_z^T \cdot \left(\varepsilon_{xy}\frac{\partial u}{\partial z}\right) \\ & + N^T \cdot \left(\rho g\frac{\partial a}{\partial x} - \Gamma_x\right) dV \end{aligned} \tag{13}$$

$$\begin{aligned} f_v = {} & \int W^T \cdot \rho\left(u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y} + w\frac{\partial v}{\partial z}\right) + N^T \cdot \rho\left(\frac{\partial v}{\partial t} - \frac{\partial z}{\partial t}\frac{\partial v}{\partial z} + \Omega u\right) \\ & + N_x^T \cdot \varepsilon_{yx}\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right) + N_y^T \cdot \left(\varepsilon_{yy}\frac{\partial v}{\partial y} - \rho g h\right) + N_z^T \cdot \left(\varepsilon_{yz}\frac{\partial v}{\partial z}\right) \\ & + N^T \cdot \left(\rho g\frac{\partial a}{\partial y} - \Gamma_y\right) dV \end{aligned}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

and for the continuity equation

$$f_c = \int_b M^T \cdot \left[\int_b^{+h} \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right) dz + u_s \frac{\partial (a+h)}{\partial x} + v_s \frac{\partial (a+h)}{\partial y} + \frac{\partial h}{\partial t} - u_b \frac{\partial a}{\partial x} - v_b \frac{\partial a}{\partial y} \right] dA \quad (14)$$
$$= \int M^T \cdot \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right) dV + \int_b \underline{M}^T \cdot \left[u_s \frac{\partial (a+h)}{\partial x} + v_s \frac{\partial (a+h)}{\partial y} + \frac{\partial h}{\partial t} - u_b \frac{\partial a}{\partial x} - v_b \frac{\partial a}{\partial y} \right] dA$$

where W^T is SU/PG weighting function, N^T is the weighting function that is identical to the shape function, and $\underline{M}^T$ is the weighting function for surface element. The wind stress and friction is applied for boundary stress of Γ_x, Γ_y.

5 MODEL APPLICATION

3-dimensional numerical analysis for free surface flow problem is very complicate since it is related with nonlinear characteristics, boundary conditions, physical and numerical instabilities. Through various validation procedures it is necessary to investigate the effect of such factors with computational feasibility, and the proposed model is applied to simulate various types of channel flows to evaluate stability, accuracy, as well as applicability of the model. Model simulation is conducted to identify 3-dimensional flow characteristics for U type channel flows, a confluent channel flow with 90° tributary, and a meandering channel flow with large sinuosity ratio. Then simulation results are compared with existing numerical model RMA-10, also with the experimental results.

5.1 *U-typed channel flow*

Flow field analysis in channel bend is hydraulically important since it yields secondary flow and is 3-dimensional turbulent flow to generate secondary flow. Flow simulation is conducted for the channel with the following configurations: the channel width is 0.3 m, the straight reach of upstream and downstream is 1m respectively, and inner radius of channel bend is 0.15 m. Figure 2 shows 3-layered finite element mesh to have 9,445 node numbers with 3,303 elements. With 0.3 m of flow depth as downstream boundary condition, 0.07 $m^3 s^{-1}$ is assigned for upstream boundary condition.

Along the lines of 1-1(outer side), 2-2(center side), and 3-3(inner side) computed water depth are compared with RMA-10 model, and at (A-A section), (B-B section), and (C-C section) 3 cross sectional velocities and water depth are collected to find velocity and

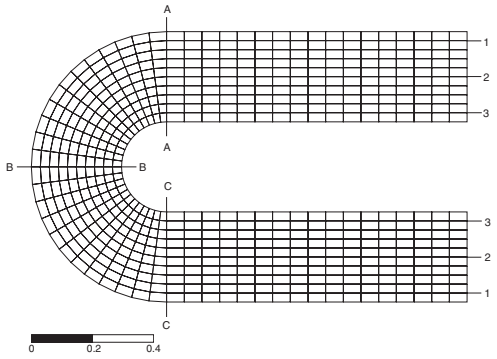

Figure 2. Computational grid for U-type shape channel.

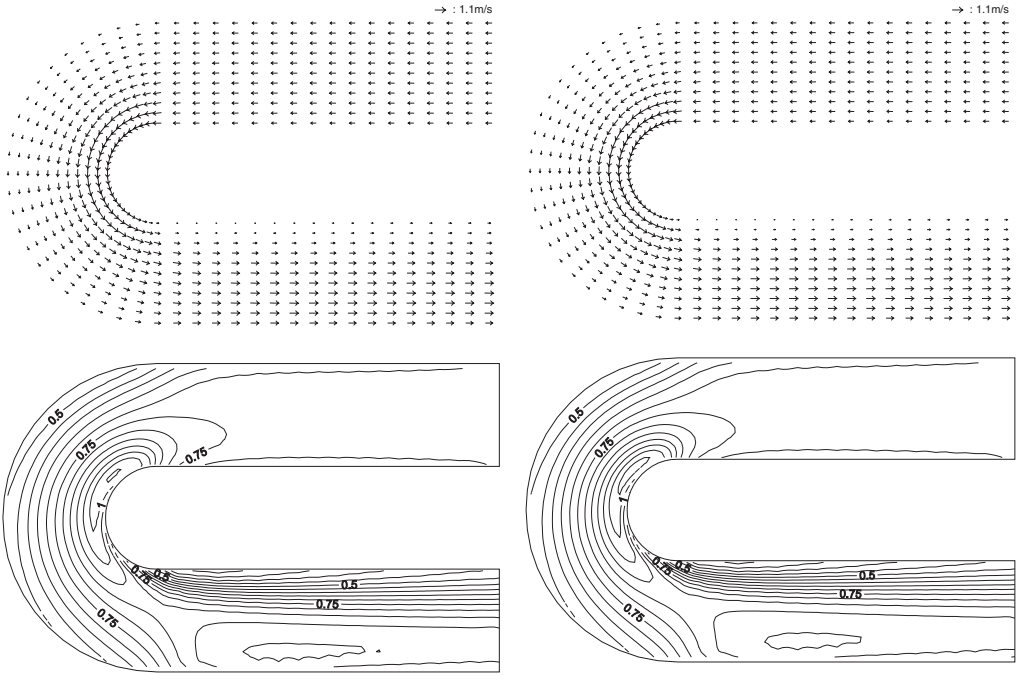
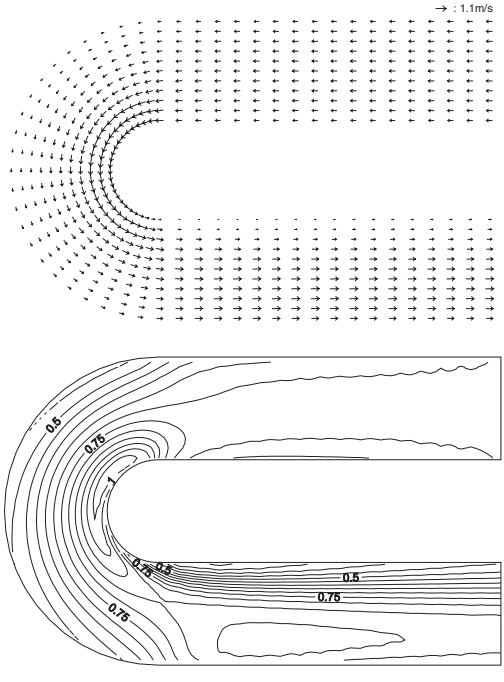
water depth characteristics. During the simulation, it requires 12 times of iteration to obtain the converged solution. Figure 3 & 4 respectively show horizontal velocity distributions in each layer and velocity vectors at each cross section. Figure 3 shows that as the flow approaches channel bend, the inner side horizontal velocity is greater than the outer side and vice versa as it passes channel bend. Shown in Figure 4, the cross sectional velocity vectors move from outer side to inner side at the inlet of channel bend and vice versa at the outlet of channel bend with flow circulation due to opposite flow direction of the surface and the channel bed.



5.2 *Channel with tributary inflow*

The analysis of channel flow with tributary inflow is very important for river mechanics and environmental hydraulics. With simple geometric configuration, since the hydrodynamic of the channel confluence is very complicated, such flow condition is broadly applied for model validation. In this study the proposed model has been applied for the channel given in Figure 5.

The width of both main and tributary channel is given as 0.914 m. With the 9.144 m long tributary, from the confluence the main channel length is 10.973 m toward upstream and 6.401 m in downstream. It is composed of 3 layers to have total 5,859 node number and 2,072 element number. Numerical simulation is conducted for two cases with the definition of following terms: Q_m is flow rate of main channel, Q_b is flow rate of tributary channel, H is downstream water depth, and q^* is a ratio of the flow rate of main channel to total flow rate (Q_m/Q).



Model validation focuses comparison with water depth using the experimental results conducted by Shumat (1998). Figure 6 shows the simulation results applying two different flow conditions. The numeric values are dimensionless water level which is normalized by downstream water level. In both cases

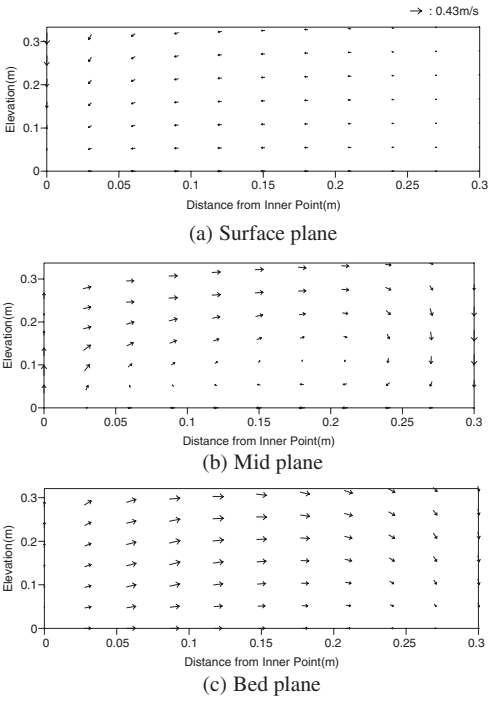

Figure 4. Cross sectional velocity distribution.

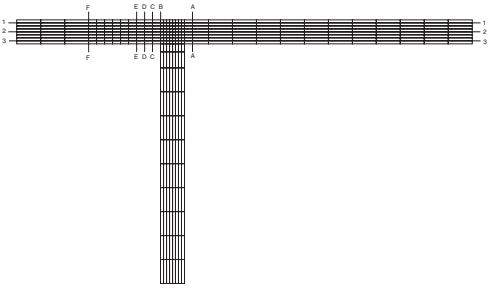

Figure 5. Construction of the finite element mesh.

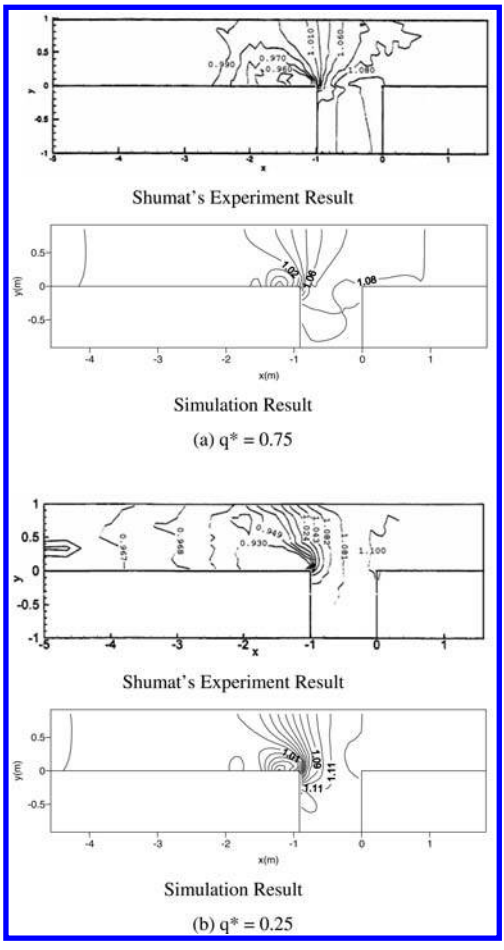
numerical results well describe flow characteristics at channel confluence to show a good agreement with Shumat's experimental results.

Water surface and channel bed velocity distributions are given in Figure 7 to describe flow characteristics due to flow rate changes. Figures 8 and 9 show cross-sectional velocity distributions for two different flow conditions between the reach from A-A section right before tributary inflow to F-F section 3.656 m away after tributary inflow. Tributary inflow alters cross sectional velocity distribution; especially $q^* = 0.25$ with 2nd flow condition, flow circulation is more evident after D-D section since tributary inflow is greater than the main channel flow.



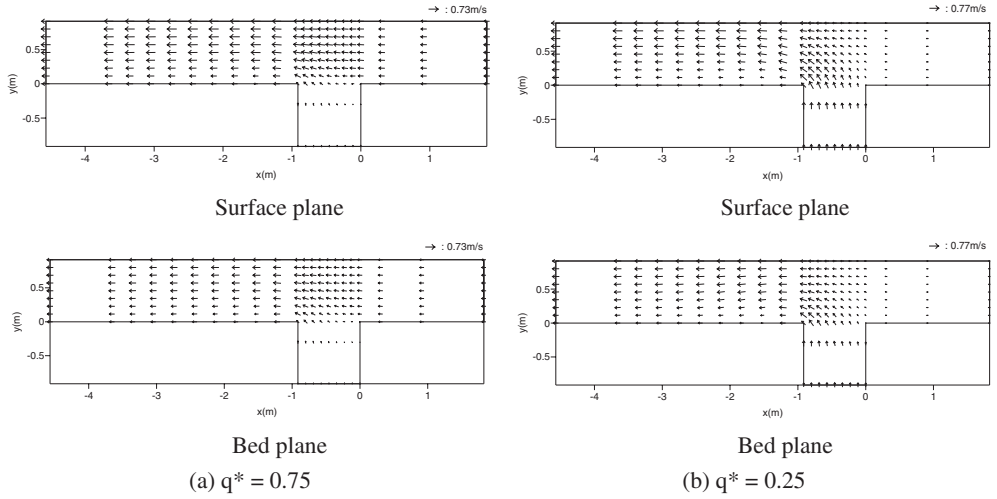


Figure 6. Comparison of water level.

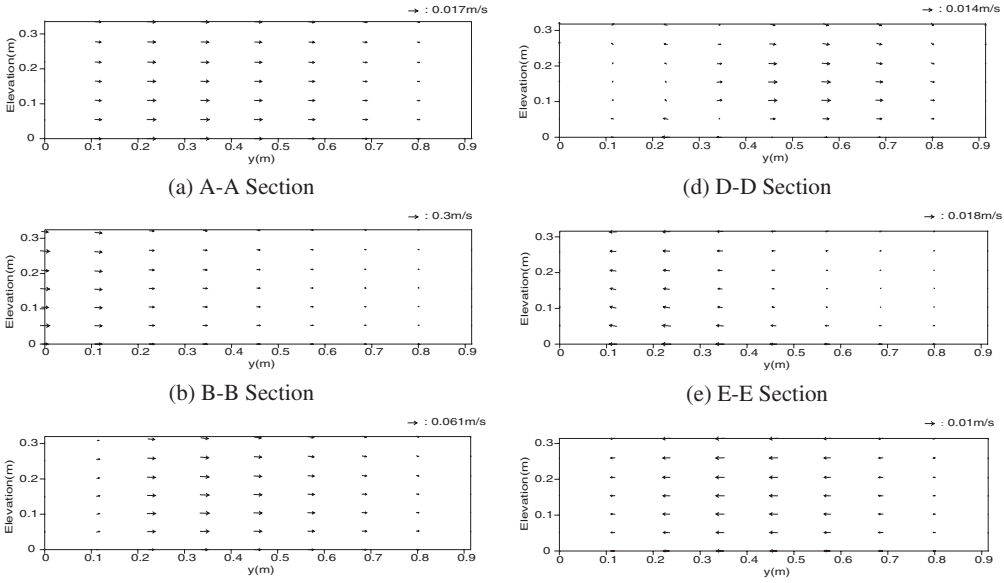
6 CONCLUSIONS

In this study, 3-dimensional finite element model has been developed to simulate hydrodynamics of the channel flow based on the Streamline Upwind/Petrov-Galerkin scheme. Turbulent flow is considered using the Smagorinsky scheme for horizontal plan and Mellor-Yamada scheme in vertical direction. Moving boundary condition is applied for element modification with water surface variations to describe 3-dimensional flow characteristics more accurately. The conclusions of this study can be summarized as follows.



For 3-dimensional channel flow to establish governing equations considering turbulent flow, fundamental 3D Navier-Stokes equation is modified using the Reynolds equation. To describe characteristics of the turbulent flow the Smagorinsky scheme has

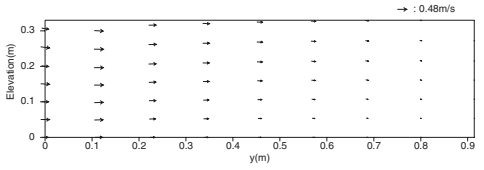
been employed for the horizontal direction, and the Mellor-Yamada scheme for the vertical direction.

3-dimensional finite element model is proposed employing the Streamined Upwind/Petrov Galerkin scheme as weighting function and moving boundary condition to improve the limitations of fixed element.



The proposed 3-dimensional finite element model has been evaluated through the application of U typed channel flow, and 3-dimensional velocity and water depth distributions were compared with the results of existing model. Also for the channel flow with tributary inflow it is compared with Shumat's experimental results to show a good agreement with computational results.

The advantage of the proposed model is to simulate 3-dimensional flow characteristics more accurately for various channel flows with consideration of turbulent flows. By adopting moving boundary conditions in describing water surface variations, it is possible to obtain stable and accurate numerical solutions. Further

Fourth order balanced WENO schemes for shallow water equations

V. Caleffi & A. Valiani
Dipartimento di Ingegneria, Universitá degli Studi di Ferrara – Ferrara (IT)

ABSTRACT: Two WENO schemes, fourth-order accurate in space and time, for the numerical integration of shallow water equations with bottom slope source term, are presented. Spatial accuracy is achieved using WENO reconstructions of the free-surface elevation and of the specific discharge. In the first Central WENO model, based on staggered grids, time accuracy is achieved using a Runge-Kutta (RK) scheme coupled with its Natural Continuous Extension (NCE). In the second Upwind WENO model, time accuracy is obtained using a Strong Stability Preserving Runge-Kutta method, SSPRK(5,4). Original source term treatment, satisfying the *C-property*, i.e. the property of exactly preserving the quiescent flow, is used in both the models. Such a treatment involves the spatial integration of the source term, which is analytically manipulated in order to take advantage from the regularity of the free surface elevation, usually smoother than the bottom elevation. The source term treatment in the Central scheme involves also an original evaluation of the point-values of the flux gradient, coupled with the source term. Several standard one-dimensional test cases are used to verify the high-order accuracy, the C-property, and the good resolution properties of both the models. Both the schemes are reliable for the application to real problems characterized by very irregular bottoms.

1 INTRODUCTION

In recent years, high resolution methods for conservation laws have been extensively applied to shallow water equations to solve problems in fluid mechanics and hydraulic engineering (Toro 1992). More recently, to increase the computational efficiency, the use of coarse grids and high-order accuracy are pursued. In this context, an important contribute are WENO (Weighted Essentially Non Oscillatory) schemes (Liu et al. 1994; Jiang & Shu 1996).

Inside WENO class, two principal approaches can be distinguished. The classical one is the Upwind approach, (Godunov 1959; Shu 1997), in which the eigensystem is extensively used. The main advantage of this method is its strong physical basis, which allows to obtain a good resolution and the maximum reduction of unphysical oscillations near the shocks. The alternative approach is the Centered scheme family, whose origin is the first order Lax-Friedrichs (Lax 1954) staggered method. The eigensystem is ignored by these schemes.

Several works on SWE are recently devoted to the consistent numerical treatment of source term due to bed slope, to allow the application of WENO methods to engineering problems. A recent work by Vuković & Sopta (2002), devoted to the numerical integration of the shallow water equations, applies, in a WENO context, the idea of balancing the momentum flux with the source term. Such a method has been introduced by Bermudez & Vázquez-Cendón (1994) and then improved by Vázquez-Cendón (1999). In Vuković & Sopta (2002), the *C-property* is satisfied, but the complexity of the method is relevant.

High accuracy and well-balancing are also obtained by Črnjarić-Ž ic et al. (2004) using both Finite Volume WENO and Central WENO schemes. In particular, Črnjarić-Ž ic et al. (2004) apply their schemes not only to SWE but also to de Saint-Venant, cross section averaged, open-channel flow equations, where source terms depend on the channel geometry. Good results are also obtained adopting the DFB method, i.e. the Divergence Form for the Bed slope source term, due to Valiani & Begnudelli (2006). In the original paper is shown an enormous increasing in stability for several appropriate test cases, both in one and two dimensions.

The original contribution of the present work regards the proper numerical treatment of bed slope source term for high accuracy, well-balanced, WENO methods. The novel approach is presented in the Central WENO and in the Upwind WENO context and involves three different aspects of the schemes: the WENO reconstructions are formulated according to the Surface Gradient Method (Zhou et al. 2001), i.e. the free-surface elevation is used instead of the flow depth; the numerical approximation of the point-values of the flux derivative and of the source term considered as

Copyright © 2006 Taylor & Francis Group plc, London, UK

a whole is defined to obtain the balancing between the flux gradient and the source term themselves and the preserving of high accuracy; the cell-integral of the source term is defined to obtain high accuracy and well-balancing. The designed scheme assures the fulfillment of the following conditions: the full achievement of fourth-order spatial and time accuracy; the satisfaction of the exact C-property; the prevention of spurious oscillations when complex and irregular bed configuration occurs.

In this paper only simple one-dimensional flow is considered, in order to verify the introduced novelties over simple, well established test cases. However, the strength of the present method consists of a large applicability in a broad range of engineering problems such as river flows, debris flows, mud flows, real world dam break waves, flood waves, etc. See (Valiani et al. 2004) and the references therein. For example it is simple to extend the present concepts to the movable bed case, see also (Valiani et al. 2004) for preliminary examples, and to 2D problems.

2 CENTRAL WENO MODEL

This numerical model is developed starting from the explicit fourth-order Central WENO scheme proposed by Levy et al. (1999), which is suitable for the numerical integration of homogeneous systems of conservation laws. To avoid any ambiguity in the discrete description of the bed profile in staggered schemes – due to the use of two different, coupled grids – the destaggering procedure presented in (Jiang et al. 1998) is applied. In this work the scheme is extended in order to treat the one-dimensional SWE with the geometrical source term, $u_t + f_x = s$. These equation stands for:

$$\frac{\partial}{\partial t}\begin{bmatrix} h \\ vh \end{bmatrix} + \frac{\partial}{\partial x}\begin{bmatrix} vh \\ gh^2/2 + v^2 h \end{bmatrix} = \begin{bmatrix} 0 \\ ghs_0 \end{bmatrix}, \tag{1}$$

where: $u(x,t)$ is the vector of conservative variables; $f(u(x,t))$ is the flux vector; $s(x,u(x,t))$ is the source term relative to the bottom slope. t is the time, x is the space, $h(x,t)$ is the flow depth, $v(x,t)$ is the vertically averaged velocity, g is the gravity, $s_0 = -\mathrm{d}z/\mathrm{d}x$ is the bottom slope and $z(x)$ is the bottom elevation.

An uniformly spaced grid $x_j = j\Delta x$, and a staggered grid $x_{j+1/2} = (j+1/2)\Delta x$ are defined. Each computational step is characterized by a time interval Δt^n, which is selected in order to assure the stability of the numerical scheme (Levy et al. 1999). t^n is the time level of the known variables, while $t^{n+1} = t^n + \Delta t^n$ is the time level of the unknown variables. Denoting: $I_j = [x_{j-1/2}, x_{j+1/2}]$ the j-th cell, centered around the grid point x_j; $\bar{u}_j^n$ the corresponding cell-averaged solution at time t^n; $\bar{s}_j$ the cell-averaged source term, the integration of Equation (1) over $[x_j, x_{j+1}] \times [t^n, t^{n+1}]$ gives:

$$\Delta\bar{u}_{j+1/2} = -\frac{1}{\Delta x}\int_{t^n}^{t^{n+1}} [f_{j+1} - f_j] + \bar{s}_{j+1/2}\,\mathrm{d}t, \tag{2}$$

with $\Delta\bar{u}_{j+1/2} = \bar{u}_{j+1/2}^{n+1} - \bar{u}_{j+1/2}^{n}$ and $f_j = f(u(x_j,t))$. Equation (2) describes the updating in time of the solution from the cell-averages on the original grid to the cell-averages on the shifted grid. In the non-staggered version of central WENO schemes (Jiang et al. 1998) an additional step is added and the updated solution $\bar{u}_{j+1/2}^{n+1}$ is projected back on the original grid, obtaining $\bar{u}_j^{n+1}$. To discretize Equation (2), it is necessary to design (Levy et al. 1999; Xing & Shu 2005): a reconstruction of the variables to evaluate the cell-averaged values on the staggered grid, starting from cell-averaged values over the non-staggered grid and *vice versa*; a well-balanced spatial integration of the source term; a reconstruction of the variables to determine the point-values in the cell-centers; a well-balanced reconstruction to evaluate the point-value flux derivatives coupled with the source term.

2.1 *Time integration*

The grid staggering is particularly useful because time integrals are evaluated in the cell-centers of the non-staggered grid, where the solution can be considered smooth. Such a condition allows to adopt standard numerical techniques for the time integral approximation (Shu 1997; Jiang et al. 1998; Levy et al. 1999). In particular, to achieve the fourth-order integration in time of Equation (2), a Simpson's quadrature rule is selected (Levy et al. 1999):

$$\Delta\bar{u}_{j+\frac{1}{2}} = \frac{\Delta t^n}{\Delta x}\sum_{l=1}^{3} N_l \left[f_j^{n+\beta_l} - f_{j+1}^{n+\beta_l} + \Delta x\, \bar{s}_{j+\frac{1}{2}}^{n+\beta_l} \right] \tag{3}$$

with:

$$\begin{aligned} \bar{s}_{j+1/2}^{n+\beta_l} &= \tfrac{1}{\Delta x}\textstyle\int_{x_j}^{x_{j+1}} s(x, t^n + \beta_l \Delta t^n)\,\mathrm{d}x \\ f_j^{n+\beta_l} &= f(\hat{u}(x_j, t^n + \beta_l \Delta t^n)) \end{aligned} \tag{4}$$

$N = [1/6, 2/3, 1/6]^{\mathrm{T}}$ are the weights and $\beta = [0, 1/2, 1]^{\mathrm{T}}$ are the nodes of the quadrature; $\hat{u}$ is the estimated point-value solution, see (Levy et al. 1999).

The approximation of the point-values at time t^{n+1}, appearing in Equation (3), is performed using a fourth-order Runge-Kutta scheme expressed by:

$$\begin{aligned} \hat{u}^{n+1} &= \hat{u}^n + \Delta t^n \sum_{i=1}^{4} b_i k^{(i)}, \\ \hat{u}^{(i)} &= \hat{u}^n + \Delta t^n \sum_{j=1}^{i} a_{ij} k^{(j)}, \end{aligned} \tag{5}$$

where $b = [1/6, 1/3, 1/3, 1/6]^{\mathrm{T}}$; a is a matrix of zeros with the exception of the elements $a_{2,1} = a_{3,2} = 1/2$

Copyright © 2006 Taylor & Francis Group plc, London, UK

and $a_{4,3}=1$; $k^{(i)}$ are the Runge-Kutta fluxes. For the considered balance law (1), $k^{(i)}$ is a numerical evaluation of $(-f_x+s)$, computed starting from the point-values $\hat{u}^{(i)}$. The Runge-Kutta fluxes computation is performed using an original approach described in Section 2.2.2, which allows the satisfaction of the C-property.

The evaluation of the point-value at time $t^{n+1/2}$, appearing in Equation (3), is obtained using the Natural Continuous Extension procedure (Zennaro 1986; Levy et al. 1999) inside RK method:

$$\hat{u}^{n+1/2}=\hat{u}^n+\Delta t^n\sum_{i=1}^{4}B_i k^{(i)}, \qquad (6)$$

with: $B=[5/24,1/6,1/6,-1/24]^{\mathrm{T}}$.

2.2 *WENO reconstructions*

Following the SGM Method (Zhou et al. 2001) the free-surface level $\eta=h+z$ is chosen as the basis for the WENO reconstruction. This choice provides accurate point-values estimate of the conservative variables at cell-centers and the achievement of the well-balancing between flux gradient and bottom slope source term. The vector of reconstructed variables $\mu=[\eta,hv]^{\mathrm{T}}$ is introduced.

2.2.1 *Cell-averages and point-values*

The updating of the solution from time t^n to time t^{n+1}, see Equation (3), requires the evaluation of the staggered cell-averages, $\bar{u}^n_{j+1/2}$; the time integration procedure, described in Section 2.1, Equation (5), requires the evaluation of the point-values $\hat{u}^n_j$, starting from the cell-averaged values $\bar{u}^n_j$. The procedure to achieve these purposes is summarized in the following three steps (Levy et al. 1999; Qiu & Shu 2002; Shu 1997):

1. The cell-averaged values $\bar{\mu}_j$ are computed using $\bar{\mu}_j=\bar{u}_j+[\bar{z}_j,0]^{\mathrm{T}}$.
2. The proper reconstruction is a piecewise function over the mesh I_j:

$$T(x)=\sum\nolimits_j R_j(x)\,\chi_j, \qquad (7)$$

where χ_j are the characteristic functions of the intervals I_j and $R_j(x)$ are suitable polynomials of degree 2. Once $T(x)$ is given, $\bar{\mu}_{j+1/2}$ is computed using:

$$\bar{\mu}_{j+1/2}=\int_{x_j}^{x_{j+1}}T(x)\mathrm{d}x= \\ =\int_{x_j}^{x_{j+1/2}}R_j(x)\mathrm{d}x+\int_{x_{j+1/2}}^{x_{j+1}}R_{j+1}(x)\mathrm{d}x, \qquad (8)$$

whilst the point-value is $\hat{\mu}_j=T(x_j)=R_j(x_j)$.
3. Cell-averaged values, $\bar{u}^n_{j+1/2}$, and point-values, $\hat{u}^n_j$, are given by $\bar{u}^n_{j+1/2}=\bar{\mu}^n_{j+1/2}-[\bar{z}_{j+1/2},0]^{\mathrm{T}}$ and $\hat{u}^n_j=\hat{\mu}^n_j-[\hat{z}_j,0]^{\mathrm{T}}$, respectively.

To define the reconstruction $T(x)$, the fulfillment of *conservation, accuracy* and *non-oscillation* requirements must be imposed (Caleffi et al. 2006; Levy et al. 1999; Qiu & 2002) and consequently, the following steps may be performed.

Three sets of three cells (*stencils*) $\mathcal{P}_{j+k}=\cup_{l=-1}^{l=+1}I_{j+k+l}$, with $k=-1,0,1$, are selected. The cell I_j belongs to each of them. Three polynomials of degree 2, $P_{j+k}(x)$, with $k=-1,0,1$, are introduced. Each polynomial is associated with a corresponding stencil $\mathcal{P}_{j+k}$. The cell-average of $P_{j+k}(x)$ on each cell of the stencil $\mathcal{P}_{j+k}$ is equal to the cell-average of the conservative variables, i.e.:

$$\frac{1}{\Delta x}\int_{I_{j+k-i}}P_{j+k}(x)\mathrm{d}x=\bar{\mu}_{j+k-i}, \qquad (9)$$

with $k=-1,0,1$ and $i=-1,0,1$. The coefficients of each polynomial $P_{j+k}(x)$ are uniquely determined by Equation (9).

To satisfy the non-oscillatory requirement, the polynomial $R_j(x)$ is written as a convex combination of the three polynomials $P_{j+k}(x)$, using suitable variable *weights*, w_j^k $(k=-1,0,1)$:

$$R_j(x)=\sum_{k=-1}^{1}w_j^k\,P_{j+k}(x). \qquad (10)$$

To compute w_j^k, the *linear weights*, C_k, and the *index of smoothness* function, IS_j^k, are introduced (Qiu & Shu 2002). The linear weights are chosen such that the reconstruction satisfies the accuracy requirement, where the solution is smooth (see Table 1), while the index of smoothness function allows the optimal weighting of polynomials $P_{j+k}(x)$ in Equation (10), where the solution is discontinuous. Several expressions can be used to quantify the index of smoothness inside the stencil (Liu et al. 1994; Jiang & Shu 1996). In this work the L^2*-norm* of the polynomial derivatives, $P^{(l)}_{j+k}(x)$ on the cell I_j, is selected, as suggested in (Jiang & Shu 1996). The final expressions for the weights is:

$$w_j^k=\frac{\alpha_j^k}{\sum_{l=-1}^{l=1}\alpha_j^l}\quad\text{with}\quad\alpha_j^k=\frac{C_k}{\left(\epsilon+IS_j^k\right)^p}, \qquad (11)$$

where ϵ and p are empirically selected constants. The dimensional nature of ϵ and p parameters implies that

universal values of these quantities *do not* exist, and problem-dependent values must be chosen. A detailed analysis has shown that this choice must be devoted to minimize numerical diffusion due to the staggering.

2.2.2 *Reconstruction of Runge-Kutta fluxes*

The fourth-order evaluation of Runge-Kutta fluxes, necessary in Equation (5), is performed by an original approach obtained modifying the reconstruction of flux derivative point-values introduced in classical Central WENO schemes (Levy et al. 1999). This approach, inspired also by the work of Črnjarić-Žic et al. (2004), allows the C-property achievement.

The key element is the introduction of a proper cell function $K_j(x, u(x,t))$ defined by:

$$K_j(x,u(x,t)) = \\ = \begin{bmatrix} (vh)_j - (vh) \\ \left(v^2h + \frac{g(\eta-z)^2}{2}\right)_j - \left(v^2h + \frac{g(\eta-z)^2}{2}\right) \end{bmatrix} + \\ + \begin{bmatrix} 0 \\ 1/2g\left((\eta_j - z)^2 - (\eta_j - z_j)^2\right) \end{bmatrix} \quad (12)$$

and satisfying the two analytical relations:

$$\left.\frac{\partial K_j}{\partial x}\right|_{x=x_j} = k_j = (-f_x + s)_j \quad (13)$$

and, for quiescent flow (i.e. $vh = 0$ and $\eta =$ constant):

$$K_j(x) = 0 \qquad \forall x. \quad (14)$$

Naming $T(x)$ the reconstruction of K_j, defined by an equation formally identical to (7), the Runge-Kutta fluxes on the grid x_j should be approximated by $T'(x_j)$, i.e. $k_j \approx T'(x_j)$. This is a direct consequence of relation (13). The fulfillment of (14) assures the well-balancing between the flux gradient and the source term, as explained in (Caleffi et al. 2006).

The polynomials $R_j(x)$ are defined imposing *accuracy* and *non-oscillation* requirements (see 2.2.1). Let us consider three polynomials $P_{j+k}(x)$ of degree 2, related to the stencils $\mathcal{P}_{j+k}$. Their coefficients are univocally determined by imposing the passage of $P_{j+k}(x)$ through the three point-values of K_j, computed on the cell-centers of the respective stencils:

$$P_{j+k}(x_{j+k+l}) = K_j(x_{j+k+l}, \hat{u}^{(i)}_{j+k+l}), \quad (15)$$

with $k = -1, 0, 1$ and $l = -1, 0, 1$. The polynomial $R_j(x)$ is written as a linear convex combination of the three polynomials $P_{j+k}(x)$, using suitable weights, w_j^k (see Equation (10)). Such weights are computed using Equations (11), with a specific set of linear weights (see Table 1). The computation of the linear weights is performed as in classical Central WENO schemes, see (Qiu & Shu 2002).

2.3 *Source term spatial integration*

The novel technique for the numerical integration in space of the source term, appearing in Equation (4), is described in this Section. This integration must be performed at time t^n, $t^{n+1/2}$ and t^{n+1}.

The first step consists of the analytical manipulation of the second component of bed slope source term integral introducing the function $\xi(x) = gz\mathrm{d}\eta/\mathrm{d}x$, using the relation $h = \eta - z$ and a simple integration by parts:

$$s^{[2]}_{j+1/2} = \frac{1}{2}g\left[z^2_{j+1} - z^2_j\right] - g\left[\eta_{j+1}z_{j+1} - \eta_j z_j\right] + \\ + \int_{x_j}^{x_{j+1}} \xi(x)\mathrm{d}x. \quad (16)$$

The two forms are analytically equivalent but, from the numerical point of view, they may be different. In the classical formulation the integration involves the bed spatial derivatives, while in the latter case the integration involves the free surface spatial derivatives. In the case of irregular bottom, the latter formulation must be preferred, because the spatial derivative of the free surface elevation is more regular than the spatial derivative of the bed elevation, even if the solution is discontinuous (Caleffi et al. 2006).

The discretization of the first two terms of the RHS in Equation (16) does not present difficulties, because they can be exactly computed from the point-values z_j and $\hat{\eta}_j$; only the last term requires an *ad hoc* numerical treatment. This procedure is here summarized.

At each time, t^n, $t^{n+1/2}$ and t^{n+1}, the source term integration needs the reconstruction of free-surface point-value derivatives $\hat{\eta}'_j$, starting from free-surface point-values $\hat{\eta}_j$. A WENO reconstruction similar to that described in Section 2.2.2, in which the function $\eta(x)$ is used instead of $K_j(x, u(x,t))$. The point-values $\hat{\xi}_j = (gz\mathrm{d}\eta/\mathrm{d}x)_j = gz_j\hat{\eta}'_j$ are then computed.

Now, the computation of the integral appearing in Equation (16) is based on a CWENO reconstruction of the function $\xi(x)$. This approach is extensively described in (Caleffi et al. 2006) and is here just sketched.

By introducing $M_{j+1/2}(x)$, suitable polynomials of degree 2, the $\xi(x)$ reconstruction on the staggered grid $I_{j+1/2}$ can be written as:

$$L(x) = \sum_j M_{j+1/2}(x)\chi_{j+1/2}. \quad (17)$$

The cell-averaged values, $\bar{\xi}_{j+1/2}$, on the staggered grid $I_{j+1/2}$ are expressed by:

$$\bar{\xi}_{j+\frac{1}{2}} = \frac{1}{\Delta x}\int_{x_j}^{x_{j+1}} L(x)\,\mathrm{d}x = \frac{1}{\Delta x}\int_{x_j}^{x_{j+1}} M_{j+\frac{1}{2}}(x)\,\mathrm{d}x. \quad (18)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

In this reconstruction, Equation (18) plays the same role of Equation (8) in the staggered cell-averaged variable reconstruction. Notwithstanding this, their structures are quite different. In the case of Equation (18) the staggered cell-average (related to cell $I_{j+1/2}$) involves only one polynomial cell-reconstruction (related to cell $I_{j+1/2}$), whilst in the case of Equation (8) the staggered cell-average involves two polynomial cell-reconstructions (related to cells I_j and I_{j+1}).

The reconstruction $L(x)$ is carried out in order to achieve the fourth-order accuracy and to satisfy the non-oscillation requirement described in 2.2.1, and it is obtained adopting this procedure. On each cell of the staggered grid $I_{j+1/2}$, two stencils of three adjacent cell of the non-staggered grid x_j, are selected, $\mathcal{N}_{j+m}$, with $m=0,1$. Such stencils are centered with respect to the cell boundaries of the cell $I_{j+1/2}$:$\mathcal{N}_{j+m} = \cup_{l=-1}^{l=+1} I_{j+m+l}$. Two polynomials of degree 2, $N_{j+m}(x)$, with $m=0,1$, associated to the stencils $\mathcal{N}_{j+m}$, are defined. Considering the cell-center point-values $\hat{\xi}_{j+m+l}$, with $l=-1,0,1$, related to the stencils $\mathcal{N}_{j+m}$, the coefficients of $N_{j+m}(x)$ are determined solving the system:

$$N_{j+m}(x_{j+m+l}) = \hat{\xi}_{j+m+l} \tag{19}$$

with $m=0,1$ and $l=-1,0,1$. Considering Equation (17) and applying WENO method, $L(x)$ reconstruction on the staggered grid $I_{j+1/2}$ is given by a convex combination of the previously defined polynomials $N_{j+m}(x)$:

$$M_{j+1/2}(x) = \sum_{m=0}^{1} w_j^m N_{j+m}(x), \tag{20}$$

where w_j^m, with $m=0,1$ are two suitable weights, depending on the smoothness of the solution. Linear weights are defined in order to satisfy the proprieties of *convexity* and *symmetry*, described in (Caleffi et al. 2006). From these two conditions an univocal set of coefficients is obtained, whose values are reported in Table 1. Linear weights assure the achievement of the prescribed fourth-order spatial accuracy, too. *Accuracy* condition is *a posteriori* verified (Caleffi et al. 2006). To complete the description of this reconstruction, appropriate weights w_j^m must be defined. Referring to (Section 2.2.1), w_j^m depends on solution regularity over $\mathcal{N}_{j+m}$, whose indicator are the indices of smoothness IS_j^m (Caleffi et al. 2006). Non linear weights are computed using Equation (11). Once $\bar{\xi}_{j+1/2}$ is computed, the second component of the cell-averaged source term can be written as:

$$\begin{aligned} \bar{s}_{j+1/2}^{[2]} &= \frac{g}{2\Delta x}\left(z_{j+1}^2 - z_j^2\right) + \\ &- \frac{g}{\Delta x}\left(\hat{\eta}_{j+1} z_{j+1} - \hat{\eta}_j z_j\right) + \bar{\xi}_{j+1/2}. \end{aligned} \tag{21}$$

The first component of the same cell-averaged source terms is always zero.

3 UPWIND WENO MODEL

The here presented model is developed starting from the Finite Volume WENO scheme, fourth-order accurate in space and time, presented in (Shu 1997), which is extended to allow its application to SWE (1). In particular, the spatial integration of the source term is performed using the same original approach described in Section 2.3. Notwithstanding the great differences between Central and Upwind WENO schemes, the versatility of the proposed method allows its application to both models.

Now, the spatial discretization is based on a single grid, uniformly spaced, defined by $x_j = j\Delta x$, while the time discretization is based on an adaptive time interval Δt^n, which preserves the stability of the numerical scheme (Spiteri & Ruuth 2002). Integrating the Equation (1) over $[x_{j-1/2}, x_{j+1/2}]$ the following semi-discrete expression is achieved:

$$\left.\frac{\mathrm{d}\bar{u}}{\mathrm{d}t}\right|_j = -\left[f_{j+1/2}^* - f_{j-1/2}^*\right] + \bar{s}_j = \mathcal{L}(\bar{u}, x, t) \tag{22}$$

where $f_{j+1/2}^*(\hat{u}_j^R, \hat{u}_{j+1}^L)$ is a numerical flux, computed using the Approximate Riemann Solver HLL due to Toro Toro (1992), which is a function of the right point-value , $\hat{u}_j^R$, related to the cell I_j, and of the left point-value, $\hat{u}_{j+1}^L$, related to the cell I_{j+1}. Equation (22), coupled with an appropriate ODE solver, is used to update the solution from the time level t^n to the time level t^{n+1}, after the definition of a WENO reconstruction for the point-value solution (in correspondence of both the cell boundaries and of the cell-centers) and of a well-balanced spatial integration of the source term.

3.1 *Time integration*

To avoid unphysical oscillations and to guarantee high accuracy and high computational efficiency the SSPRK(5,4) is selected (Spiteri & Ruuth 2002). This method is summarized by the following equations:

$$\begin{aligned} \bar{u}_j^{(0)} &= \bar{u}_j^n \\ \bar{u}_j^{(i)} &= \sum_{k=0}^{i-1}\left(\alpha_{ik}\bar{u}_j^{(k)} + \Delta t \beta_{ik}\mathcal{L}\left(\bar{u}^{(k)}\right)\right) \\ \bar{u}_j^{n+1} &= \bar{u}_j^{(s)} \end{aligned} \tag{23}$$

with $i=1,\ldots,s$ and $s=5$. For the values of the α_{ik} and β_{ik} coefficients and for the details of the method see (Spiteri & Ruuth 2002).

3.2 *WENO reconstructions*

The SGM technique (Zhou et al. 2001) is used also in this model. In this Section the reconstructions of the cell-boundary point-values, $\hat{u}_j^R$ and $\hat{u}_j^L$, necessary for the numerical flux evaluation, and of the cell-center free-surface derivatives, $\hat{\eta}_j'$, necessary for the

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 2. Linear weights – Upwind model.

	C_{-1}	C_0	C_{+1}
$\bar{\mu}_j \Rightarrow \hat{\mu}_j^R$	1/10	6/10	3/10
$\bar{\mu}_j \Rightarrow \hat{\mu}_j^L$	3/10	6/10	1/10

source term spatial integration, are presented. Both the reconstructions start from the cell-averages $\bar{u}_j$.

The reconstruction of $\hat{u}_j^R$ is subdivided in three steps, see also Section 2.2.1:

1. $\bar{\mu}_j$ are computed using $\bar{\mu}_j = \bar{u}_j + [\bar{z}_j, 0]^{\mathrm{T}}$.
2. The polynomials of order 2, $R_j(x)$, are introduced and the pursued, piece-wise parabolic, reconstruction $T(x)$ is again formally defined by Equation (7). Consequently, the point-value of the reconstructed variable on the right boundary of the cell I_j is computed using:

$$\hat{\mu}_j^R = T\left(x_j + \Delta x/2\right) = R_j\left(x_j + \Delta x/2\right). \tag{24}$$

3. $\hat{u}_j^R$ is computed using $\hat{u}_j^R = \hat{\mu}_j^R - [\hat{z}_{j+1/2}, 0]^{\mathrm{T}}$.

Three stencils, $\mathcal{P}_{j+k} = \bigcup_{l=-1}^{l=+1} I_{j+k+l}$ with $k = -1, 0, 1$, are selected. On each stencil a polynomial of order 2, $P_{j+k}(x)$, is defined; its coefficients are univocally determined solving the system (9). The polynomials $R_j(x)$ are convex combination of the polynomials $P_{j+k}(x)$ – see Equation (10) – in which the weights, w_j^k, are computed using Equation (11). The necessary linear weights are summarized in Table 2. The reconstruction of the left cell boundary point-values, $\hat{u}_j^L$, is achieved using the same procedure in which the only difference are the linear weights (see Table 2). Finally, using the same reconstruction with another set of linear weights (Table 2), the estimate of the derivatives of the free-surface elevation in the cell-center is performed considering the first component of $\mu'_j = T'(x_j) = R'_j(x_j)$.

3.3 *Source term spatial integration*

The same technique presented in the Central WENO context (Section 2.3), is here applied to the Upwind WENO scheme. Now the Equation (16) is written focusing the attention on the cell I_j instead of the staggered cell $I_{j+1/2}$:

$$\begin{aligned} s_j^{[2]} &= \frac{1}{2} g \left[z_{j+\frac{1}{2}}^2 - z_{j-\frac{1}{2}}^2 \right] + \\ &- g \left[\eta_{j+\frac{1}{2}} z_{j+\frac{1}{2}} - \eta_{j-\frac{1}{2}} z_{j-\frac{1}{2}} \right] + \int_{x_{j-\frac{1}{2}}}^{x_{j+\frac{1}{2}}} \xi(x) \mathrm{d}x. \end{aligned} \tag{25}$$

The first two RHS terms of Equation (25) can be computed exactly; only the last term requires further elaborations. The first step is the evaluation of the cell-center point-values of the function $\xi(x)$, i.e. $\hat{\xi}_j = (gz\mathrm{d}\eta/\mathrm{d}x)_j = gz_j\hat{\eta}'_j$. Then, a new piece-wise reconstruction is introduced:

$$L(x) = \sum_j M_j(x)\chi_j, \tag{26}$$

where $M_j(x)$ are polynomials of order 2. The averaged value of $\xi(x)$ on the cell I_j may be computed using:

$$\bar{\xi}_j = \frac{1}{\Delta x} \int_{x_{j-\frac{1}{2}}}^{x_{j+\frac{1}{2}}} L(x)\mathrm{d}x = \frac{1}{\Delta x} \int_{x_{j-\frac{1}{2}}}^{x_{j+\frac{1}{2}}} M_j(x)\mathrm{d}x. \tag{27}$$

The polynomial $M_{j+1/2}(x)$, used in the Central scheme and described in Section 2.3, results from the convex combination of *two* polynomials N_{j+m} with $m = 0, 1$. In the reconstruction (26), the polynomial $M_j(x)$ is obtained using a convex combination of *three* polynomials $N_j^m(x)$, with $m = -1, 0, 1$. In both cases the symmetry of the reconstructions is preserved, because the union of the cell stencils involved in the $M_{j+1/2}(x)$ and in the $M_j(x)$ definitions are symmetric with respect to $I_{j+1/2}$ and to I_j, respectively. Moreover, in order to avoid the use of negative weights and the associated computational difficulties (Qiu & Shu 2002), $M_j(x)$ is build using polynomials $N_j^m(x)$ of different order, following the principle defined for the *Compact* WENO reconstructions (Levy et al. 2000). In particular, one central polynomial of order two $\mathcal{N}_j^0 = \bigcup_{l=-1}^{l=+1} I_{j+l}$, and two lateral polynomials of order one, $\mathcal{N}_j^{-1} = \bigcup_{l=-1}^{l=0} I_{j+l}$ and $\mathcal{N}_j^{+1} = \bigcup_{l=0}^{l=+1} I_{j+l}$, are used. On each stencil a corresponding polynomial is defined and the coefficients are given by solving the systems:

$$\begin{aligned} N_j^{-1}(x_{j+l}) &= \hat{\xi}_{j+l} \qquad l = -1, 0 \\ N_j^{0}(x_{j+l}) &= \hat{\xi}_{j+l} \qquad l = -1, 0, 1 \\ N_j^{+1}(x_{j+l}) &= \hat{\xi}_{j+l} \qquad l = 0, 1 \end{aligned} \tag{28}$$

The three polynomials are successively combined through the relation:

$$M_j(x) = \sum_{m=-1}^{m=+1} w_j^m N_j^m(x) \tag{29}$$

The weights w_j^m are given by Equation (11), with the appropriate linear weights summarized in Table 2. Once computed the averaged-values $\bar{\xi}_j$, the cell-averages of the source term on the cell I_j, can be easily computed, see also the Equation (21).

4 APPLICATIONS

4.1 *Unsteady flow over a sinusoidal bump*

The fourth-order space and time accuracy of both the schemes, achieved in smooth regions of the solution, is verified using the test case proposed in (Xing & Shu 2005). Bottom profile is defined by $z(x) = \sin^2(\pi x)$; initial conditions are:

$$\begin{aligned} h(x,0) &= h_0 + e^{\cos(2\pi x)}; \\ vh(x,0) &= \sin(\cos(2\pi x)); \end{aligned} \tag{30}$$

with $h_0 = 5$ m and $x \in [0, 1]$ m. Periodic boundary conditions are assumed. This problem can not be solved analytically and therefore a numerical solution, computed on a very fine mesh of 19683 cells, is adopted as the reference solution. In this test case, $\epsilon = 10^{-6}$ and $p = 2$ are assumed. Figure 1 shows the free surface and the specific discharge after 0.1 s of simulation, computed using the Central WENO model. Results obtained using the Upwind WENO model are very similar and therefore are not reported. It is clear the good agreement between the reference solution and the numerical solution obtained using the coarser grid. In Table 3 the accuracy analysis results, computed considering 81, 243, 729, and 2187 cells are shown. The selected number of cells assures the spatial overlapping of the point-values of the computed solutions with the point-values of the reference solution, simplifying the computation of the norms (Caleffi et al. 2006). For any norm, the fourth-order accuracy is achieved for both the models, confirming that the accuracy of the schemes agrees with the expected one. Similar results are obtained on the specific discharge.

4.2 *C-property test case*

The purpose of this test case, proposed by Xing & Shu (2005), is to verify the achievement of the C-property over non-flat bottom. The bottom profile is described by $z(x) = 5e^{-0.4(x-5)^2}$ m, with $0 \le x \le 10$ m. A constant free surface elevation, $\eta = 10$ m, and a

Copyright © 2006 Taylor & Francis Group plc, London, UK

constant zero discharge are the initial conditions. The quiescent flow must be preserved. A simulation is carried out until $t = 0.5$ s, using a mesh of 200 cells, L^1, L^2 and L^∞ norms of the errors of the water depth are computed (Caleffi et al. 2006). The results, obtained using the double precision floating-point arithmetics in numerical computation, are summarized in Table 4. The differences between the numerical solution and the reference solution, in terms of water depth, are due to round-off errors, see also (Xing & Shu 2005). Similar results are obtained in terms of specific discharge.

4.3 *Steady discontinuous flow over a parabolic bump*

The purpose of this test case is the validation of the source term treatment for the simulation of steady discontinuous flows over a bump (Valiani et al. 2002; Caleffi et al. 2003). This is a classical test problem for transcritical flows. The spatial domain is a 25 m long channel, discretized with 200 cells. The bottom elevation is described by the following function:

$$z(x) = \begin{cases} 0.2 - 0.05(x-10)^2 \text{m} & 8 \le x \le 12 \text{ m} \\ 0 & \text{otherwise,} \end{cases} \quad (31)$$

characterized by a discontinuous first derivative in $x = 8$ m and $x = 12$ m. ϵ and p are set equal to 10^{-6} and 2, respectively. The flow is transcritical and a steady shock is located over the bump. The upstream specific discharge is 0.18 m^2/s and the downstream water surface elevation is set to 0.33 m. The initial free surface elevation is 0.33 m and the initial discharge is everywhere zero.

Table 4. C-property analysis – water depth norms.

	h		
Model	L^1	L^2	L^∞
Central WENO	3.50E–15	1.45E–15	8.88E–16
Upwind WENO	7.51E–11	2.42E–11	9.94E–12

Figures 2 and 3 show the good agreement between the numerical and the analytical solution. The test gives satisfying results in terms of shock resolution and of upstream and downstream water levels reconstruction using both models. The shock position is accurately captured, especially by the Upwind model. Only few numerical point-values of flow discharge do not agree well with the analytical solution, but these points are located at the shock position. Also in this case the Upwind model gives smaller error. The results obtained in this severe test case, in which numerical difficulties due to the discontinuous bottom slope and to the discontinuous nature of the solution coexist, support the reliability of the novel source term technique proposed herein.

4.4 *Pulse over a bump*

This quasi-stationary test case, due to LeVeque (1998), is selected in order to test the capability of the scheme in computing an unsteady flow over a smooth bottom profile. It consists of the simulation of the convection of a pulse, initially 0.1 m long and 10^{-3} m height. The pulse moves in a 1 m long domain initially interested by a quiescent flow characterized by a depth of 1 m. The duration of the simulation is 0.7 s. The bottom profile is described by the following equation:

$$z(x) = \begin{cases} \frac{\left[\cos\left(10\pi\left(x-\frac{1}{2}\right)\right)+1\right]}{4} \text{ m} & \left|x-\frac{1}{2}\right| < 0.1\text{m} \\ 0 & \text{otherwise} \end{cases} \quad (32)$$

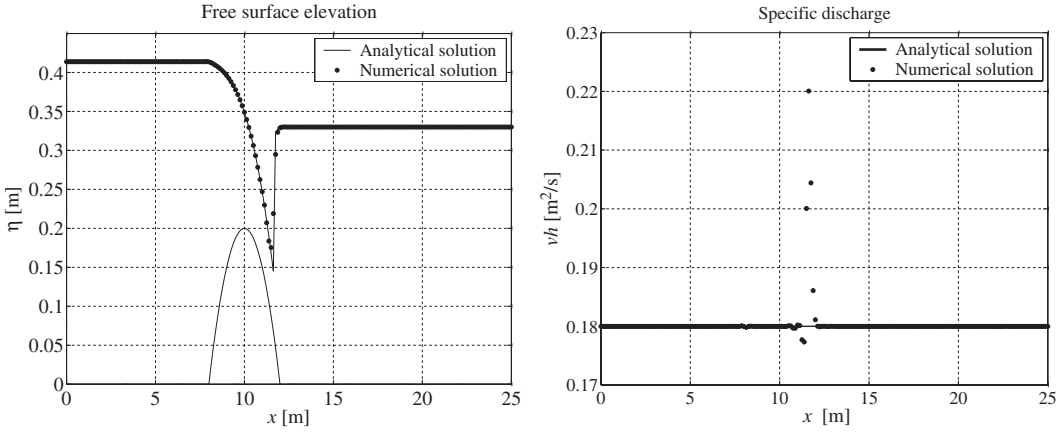

Figure 2. Parabolic bump-transcritical flow test case – Central WENO.

Copyright © 2006 Taylor & Francis Group plc, London, UK

In this case numerical diffusion is minimized using $\epsilon = 10^{-12}$ and $p = 2$, see (Xing & Shu 2005).

The solutions obtained using 100 and 250 cells are compared with the reference solution obtained using 4000 cells. Moreover, the gravity is set to $1\,\mathrm{m/s^2}$ in order to allow a direct comparison with the results obtained by LeVeque (1998). An overall good behavior of the scheme is shown. In particular, it may be noted the absence of perturbations where the bottom elevation is nonzero and this proves the good balancing between source term and flux gradient in unsteady problems. The results obtained using the Upwind model are affected by a greater diffusivity with respect to the results obtained using the Central model. On the other hands, there is not unphysical perturbations over the bump in the results of both models and this is a further proof of the good balancing between flux gradient and source term.

5 CONCLUSIONS

WENO schemes are versatile and efficient tools for the numerical integration of systems of balance laws and can be fruitfully applied to different engineering problems. In particular, applications to the de Saint-Venant open-channel equations and to the movable bed hydraulics show the great potential of these methods. Several aspects of the river mechanics and of the real world hydraulics can be addressed, because the WENO schemes' structure is particularly suitable for the correct modeling of source terms, secondary currents and sediment transport phenomena, which are fundamental keys in the numerical simulation of river evolution. In this work, two original well-balanced schemes, belonging to the family of Central and Upwind WENO schemes respectively, are presented. These schemes are suitable for the integration of the SWE with the

source term due to bottom slope. In particular, attention is focused on a new approach for the source term treatment, which allows the fulfillment of the C-property, preserving the fourth-order accuracy in space and time. This approach can be easily applied to the different WENO schemes. Several test cases are used to verify time and space accuracy, the achievement of the C-property and the shock resolution of both models.

Two-dimensional numerical simulation of flood propagation in presence of buildings

C. Costanzo & F. Macchione
University of Calabria, LAMPIT (Laboratorio di Modellistica Numerica per la Protezione Idraulica del Territorio), Dipartimento di Difesa del Suolo, Rende, Cosenza (Italy)

ABSTRACT: At present, in numerical simulation of flood propagation, a two-dimensional approach is used in the study of inundations affecting areas with complex geometry like the city zones with various kinds of constructions. In this paper different simulations have been carried out in order to investigate the performance of the different numerical techniques of the treatment of the presence of buildings. In order to do that, a test presented in the literature, representing of a flood propagation over a simplified urban area, has been simulated. The upwind finite volume HLLC scheme has been implemented. The obtained results are compared with experimental data in order to evaluate the accuracy of the numerical solutions.

1 INTRODUCTION

Numerical models are useful tools to investigate and predict possible flooding scenarios, which can then be used to formulate suitable flood hazard mitigation measures. In this context, over the last few years, various works on the numerical modelling of inundated urban areas have been performed. In particular, the importance of the interaction between flood flows and the complicated geometries of structures such as road networks, trees, etc., to predict the behaviour of flood flows has been recognized. A two-dimensional approach in numerical simulation of flood propagation is more and more used in the study of inundations affecting areas with a complex geometry like the city zones.

In particular, the research is devoted to integrating the shallow water equations with numerous numerical methods among which currently the one most applied is the Finite Volume method and the shock capturing schemes based on it. However their application to areas with complex topography is not much so common in the literature.

The irregular bathymetry may cause numerical errors, due to incorrect treatment of the source term, present in the equations. Hence, apart from the obvious need for accuracy, it is especially important to integrate the source term in agreement with the flux functions.

Gallati & Braschi (1990) applied a simplified form of the 2D depth-averaged equation to simulate the flood propagation through the city centre of Florence (Italy), Hervouet et al. (2000) modified the shallow water equations introducing a porosity coefficient to represent constriction effects and the volume occupied by obstacles and a specific law of friction for vertical structures. Porosity is also present in Defina et al. (1994) and in Guinot & Soares-Frazão (2006). Haider et al. (2003) used a two dimensional model to simulate the catastrophic flood in the city of Nîmes. Shige-eda & Akiyama (2003) investigated the hydrodynamic force acting on structures. Mignot et al. (2004) tested the ability of a 2D code to model a flood in an urban area.

In the European IMPACT project tests have been devoted to study flow characteristics in urban areas and the capabilities of different numerical models to represent them accurately.

In this paper, simulations have been carried out in order to investigate the performance of the different numerical techniques of the treatment of the presence of buildings such as representing them as solid wall boundaries, as an abrupt bottom variation or as an increase in flow resistance already used by other authors in the IMPACT project (Murillo et al. 2004). In order to do that, a test presented in literature has been simulated. This test represents the flood propagation over a simplified urban area. The upwind finite volume HLLC scheme has been implemented and the influence of the mesh size on numerical results has been investigated. Moreover, in this work, the application of the technique of introducing a porosity coefficient in the shallow water equations has been analyzed, in order to simulate the inundation on a coarse grid with the cell size greater than the dimension of a building, as often happens in real cases. The obtained results are compared with experimental

Copyright © 2006 Taylor & Francis Group plc, London, UK

data in order to evaluate the accuracy of the numerical solutions.

2 GOVERNING EQUATIONS

Two-dimensional shallow water equations in conservative form are:

$$\frac{\partial \mathbf{U}}{\partial t}+\frac{\partial \mathbf{f}}{\partial x}+\frac{\partial \mathbf{g}}{\partial y}=\mathbf{S} \tag{1}$$

where:

$$\mathbf{U}=\begin{pmatrix} h \\ hu \\ hv \end{pmatrix}; \quad \mathbf{f}=\begin{pmatrix} hu \\ hu^2+gh^2/2 \\ huv \end{pmatrix} \tag{2, 3}$$

$$\mathbf{g}=\begin{pmatrix} hv \\ huv \\ hv^2+gh^2/2 \end{pmatrix}; \quad \mathbf{S}=\begin{pmatrix} 0 \\ gh\left(S_{0x}-S_{fx}\right) \\ gh\left(S_{0y}-S_{fy}\right) \end{pmatrix} \tag{4, 5}$$

in which t is time; x, y are the horizontal coordinates; h is the water depth; u, v are the depth-averaged flow velocity in x- and y-directions; g is the gravitational acceleration; S_{0x}, S_{0y} are the bed slopes in x- and y-directions; S_{fx}, S_{fy} are the friction slopes in x- and y-directions, which can be calculated from Strickler's formula.

Equation (1) is discretized with the finite volume method as follows:

$$\mathbf{U}_{i,j}^{n+1}=\mathbf{U}_{i,j}^{n}-\frac{\Delta t}{\Omega_{i,j}}\sum_{r=1}^{4}[\mathbf{f},\mathbf{g}]_r\cdot\mathbf{n}_r\,\Delta L_r+\Delta t\mathbf{S}_{i,j}^{n} \tag{6}$$

where $\mathbf{U}_{i,j}$ is the average value of the flow variables over the control volume $\Omega_{i,j}$ at a given time, $\mathbf{n}$ is the unit normal vector and L is the length of each boundary.

2.1 *Computation of flux and source terms*

In the proposed approach the flux term $[\mathbf{f},\mathbf{g}]_r\,\mathbf{n}_r$ (Eq. 6) is estimated with a Harten - Lax – van Leer Riemann solver (Harten et al. 1983), that, when applied to the two dimensional equations, gives the following expression for the numerical flux across the edge of the computational cell Ω_L on the left and Ω_R on the right:

$$[\mathbf{f},\mathbf{g}]_r\cdot\mathbf{n}_r=\begin{cases}[\mathbf{f},\mathbf{g}]_L\cdot\mathbf{n}_r & if \;\; s_L\geq 0\\ [\mathbf{f},\mathbf{g}]^*\cdot\mathbf{n}_r & if \;\; s_L\leq 0\leq s_R\\ [\mathbf{f},\mathbf{g}]_R\cdot\mathbf{n}_r & if \;\; s_R\leq 0\end{cases} \tag{7}$$

where:

$$[\mathbf{f},\mathbf{g}]^*\cdot\mathbf{n}_r=\frac{s_R([\mathbf{f},\mathbf{g}])_L\cdot\mathbf{n}_r-s_L([\mathbf{f},\mathbf{g}])_R\cdot\mathbf{n}_r+s_Ls_R(\mathbf{U}_R-\mathbf{U}_L)}{s_R-s_L} \tag{8}$$

As Equations (7–8) depend on the value of wave speeds s_L and s_R, it is necessary to introduce approximate expressions of these variables. The wave speed estimators used in this work are obtained by the application of the two-rarefaction Riemann solver theory (Toro 2001):

$$\begin{aligned} s_L&=\min\left([u,v]_L\cdot\mathbf{n}_r-\sqrt{gh_L},u^*-\sqrt{gh^*}\right)\\ s_R&=\max\left([u,v]_R\cdot\mathbf{n}_r+\sqrt{gh_R},u^*+\sqrt{gh^*}\right)\end{aligned} \tag{9}$$

with:

$$\begin{aligned} u^*&=\frac{1}{2}\left([u,v]_L+[u,v]_R\right)\cdot\mathbf{n}_r+\sqrt{gh_L}-\sqrt{gh_R}\\ \sqrt{gh^*}&=\frac{1}{2}\left(\sqrt{gh_L}+\sqrt{gh_R}\right)+\frac{1}{4}\left([u,v]_L-[u,v]_R\right)\cdot\mathbf{n}_r\end{aligned} \tag{10}$$

The third component of the normal flux vector is computed in order to account for the influence of intermediate wave, characterized by a speed s_m calculated as in Fraccarollo & Toro (1995) $s_m=u^*$:

$$\begin{aligned} [f_3,g_3]_r\cdot\mathbf{n}_r&=[f_1,g_1]_r\cdot\mathbf{n}_r\,v_L \quad if \;\; s_m\geq 0\\ [f_3,g_3]_r\cdot\mathbf{n}_r&=[f_1,g_1]_r\cdot\mathbf{n}_r\,v_R \quad if \;\; s_m<0\end{aligned} \tag{11}$$

The source term vector is decomposed into two different parts which are treated separately: the bottom variation $\mathbf{S}_b=[0;\, ghS_{0x};\, ghS_{0y}]$ and the friction term $\mathbf{S}_f=[0;\, -ghS_{fx};\, -ghS_{fy}]$, $\mathbf{S}=\mathbf{S}_b+\mathbf{S}_f$.

The bottom variation $\mathbf{S}_b$ has been discretized in upwind manner in such a way that steady-state conditions are satisfied (Brufau et al. 2002):

$$\tilde{\mathbf{S}}_{br}=\sum_{m=1}^{3}\beta^m\tilde{\mathbf{e}}^m \tag{12}$$

where $\tilde{\mathbf{e}}^m$ are the eigenvectors of the approximate Jacobian matrix and coefficients β^m are calculated as:

$$\begin{aligned} \beta^{1-,3-}&=\pm\frac{1}{2\tilde{c}}\left(1-\frac{|\lambda_1|}{\lambda_1}\right)\left(\mathbf{S}_b^{(2)}n_x+\mathbf{S}_b^{(3)}n_y\right)\\ \beta^{2-}&=\frac{1}{\tilde{c}}\left(1-\frac{|\lambda_2|}{\lambda_2}\right)\left(-\mathbf{S}_b^{(2)}n_y+\mathbf{S}_b^{(3)}n_x\right)\end{aligned} \tag{13}$$

in which $\tilde{c}=[0.5\,g\,(h_r\text{-}h_l)]^{0.5}$ is the wave celerity; λ_1 and λ_2 are the eigenvalues of the Jacobian matrix.

In order to avoid numerical instability due to the presence of the friction term and a thin water depth, a semi-implicit treatment is applied by computing the matrix $\partial\mathbf{S}_f/\partial\mathbf{U}$ and introducing an implicit coefficient θ. After algebraic manipulations, the Equation (6) becomes:

$$\Delta\mathbf{U}_{i,j}=\frac{\left[-\frac{\Delta t}{\Omega_{i,j}}\sum_{r=1}^{4}[\mathbf{f},\mathbf{g}]_r\cdot\mathbf{n}_r\,\Delta L_r+\Delta t\mathbf{S}_{f}{}_{i,j}^{n}\right]}{\left[\mathbf{I}-\Delta t\theta\left(\frac{\partial\mathbf{S}_f}{\partial\mathbf{U}}\right)^n\right]}+\Delta t\mathbf{S}_{b_{i,j}}^{n} \tag{14}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

In this work coefficient θ is set to 0.5.

3 NUMERICAL TEST CASES

To demonstrate the capability of the scheme to simulate the inundation of an urban area with complicated geometries, the benchmark test problems from the European IMPACT project have been simulated. The IMPACT-Investigation of Extreme Flood Processes and Uncertainty project is a study program undertaken by a European research team. In order to compare various numerical methods, the program established a number of test cases and commissioned experimental studies. The project was divided into five technical work packages among which a package labelled "WP3" deals with flood propagation.

In the present work, the comparisons between numerical results and the experimental data of the "Model city flooding experiment" (Alcrudo et al. 2003) have been performed. This test is representative of a flood on a simplified urban area formed by a group of buildings. Various cases are considered by modifying, from one test to the other, the width of the valley, the buildings arrangement (either aligned or staggered) and the numerical techniques in order to simulate the influence of the buildings on flows.

3.1 *Description of physical model*

The experiments were performed using a scale model (1:100) of the Italian Toce river valley at ENEL-CESI (Italy). The model is 7 m long and 3.5–5 m wide depending on the location. In order to analyze the influence of buildings only, some tests were carried out in a modified valley model, narrowed by two masonry walls aligned to the model's main axis with the meandering river bed filled up.

The buildings are formed by cube blocks of 0.15 m sides positioned in either an aligned or a staggered manner. The number of the buildings varied from 20 (Fig.1) to 14 (Fig.2). Water levels were measured by means of 10 gauges fixed in space in all the performed experiments.

The following configurations were performed:

- two different positions of the blocks (aligned and staggered);
- two bathymetric configurations (original Toce river valley and modified narrowed geometry).

3.2 *Numerical conditions*

In the numerical simulations the computational domain was divided in structured quadrangular cells of 0.05×0.05 m except in the analysis of the influence of meshing size.

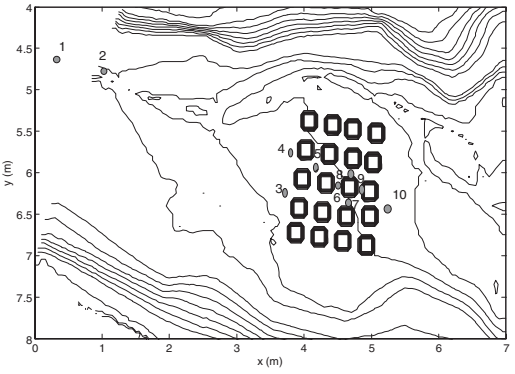

Figure 1. The original model city area with aligned buildings.

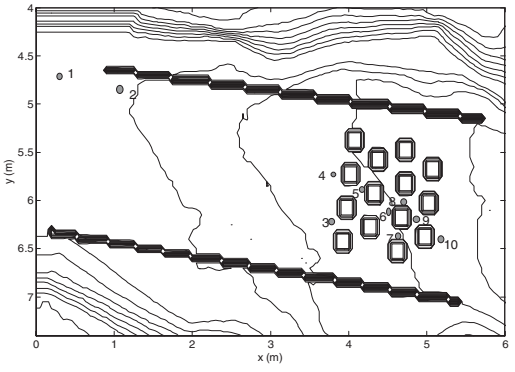

Figure 2. The modified bathymetry with staggered buildings.

In all cases the initial state of the valley was considered dry. The discharge and the water level versus time at probe number 1 were set as upstream conditions. Furthermore, the inflow angle was considered equal to $-23.5°$, as suggested by Alcrudo et al. (2003).

The used hydrograph has a peak of $0.060\ m^3/s$. In the downstream section, critical condition was considered. Strickler's roughness coefficient on the valley is set to $k = 61\ m^{1/3}/s$ and the stability condition is ensured by the Courant-Friedrichs – Lewy condition with a coefficient set to 0.6.

In order to compare the performance of each test, at each gauge j, the norm $L^{(j)}$ was computed as follows:

$$L^{(j)} = \sqrt{\sum_{i=1}^{n_s} \left(h_{si} - h_{n_i}\right)^2 \Big/ \sum_{i=1}^{n_s} h_{s_i}^2} \qquad (15)$$

where: n_s is the number of experimental values; h_{si} is the experimental water depth at gauge j; h_{ni} is the

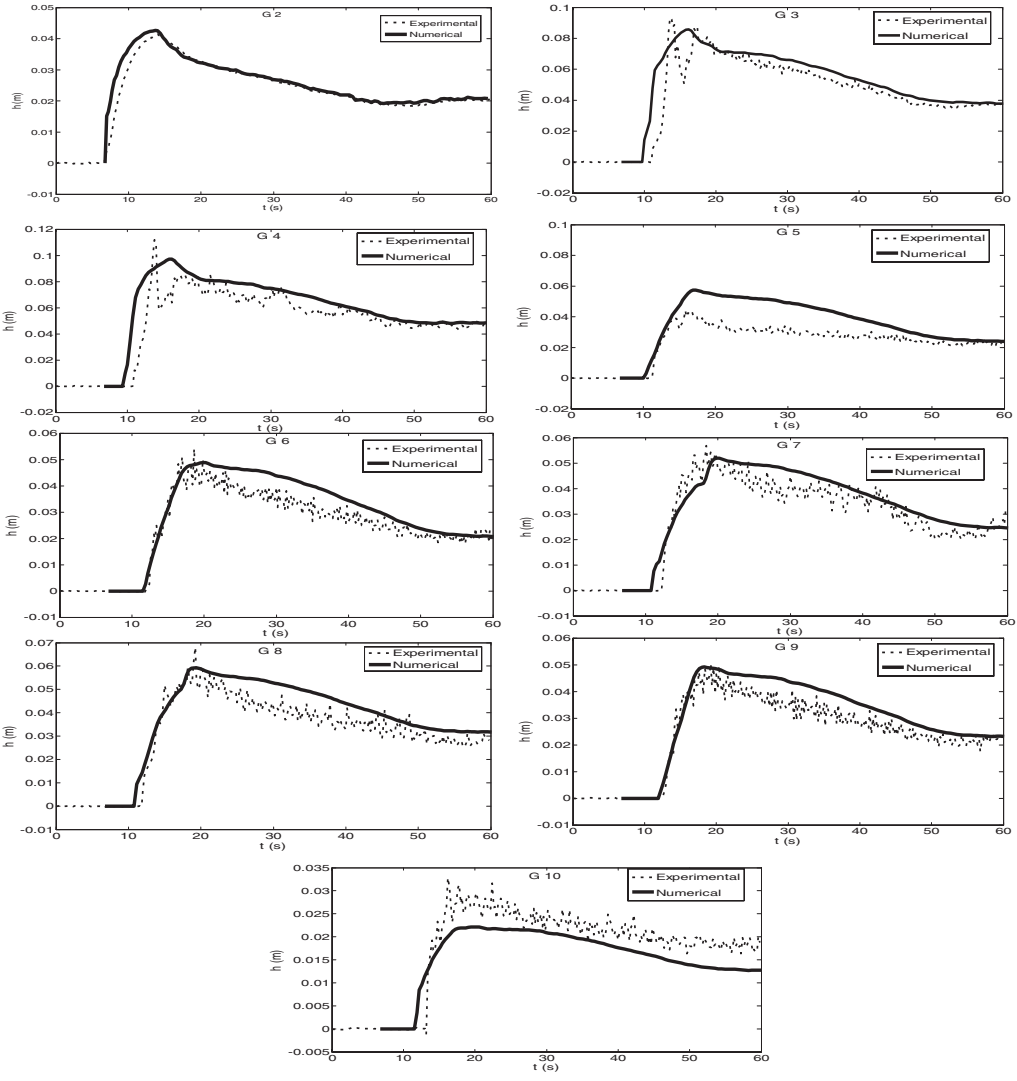

Figure 3. Test 1a: Comparison of the numerical results with the experimental data at various gauges.

computed water depth at gauge j. In particular, the mean value L_m was considered as:

$$L_m = \sum_{j=1}^{P} L^{(j)} / P \tag{16}$$

where P is the number of the gauges.

3.3 *Test 1a and test 1b: Flood propagation on modified bathymetry with aligned and staggered buildings*

These tests simulate the propagation of the inflow hydrograph with a maximum value of 0.060 m^3/s, on the modified bathymetry with the aligned (test 1a) and the staggered (test 1b) position of the buildings. In both cases the effects of the buildings on the flow wave were considered as solid wall conditions on the contours of the same. Figures 3–4 show the comparison between numerical values with observed ones, for the test 1a and the test 1b respectively. The numerical results are in overall good agreement with the experimental data.

At the inlet gauge, number 2, the numerical results are similar to the observed ones which indicates the correctness of the upstream boundary condition. This aspect is also present in the other test cases performed. In both cases, at gauge 10, differences are found due

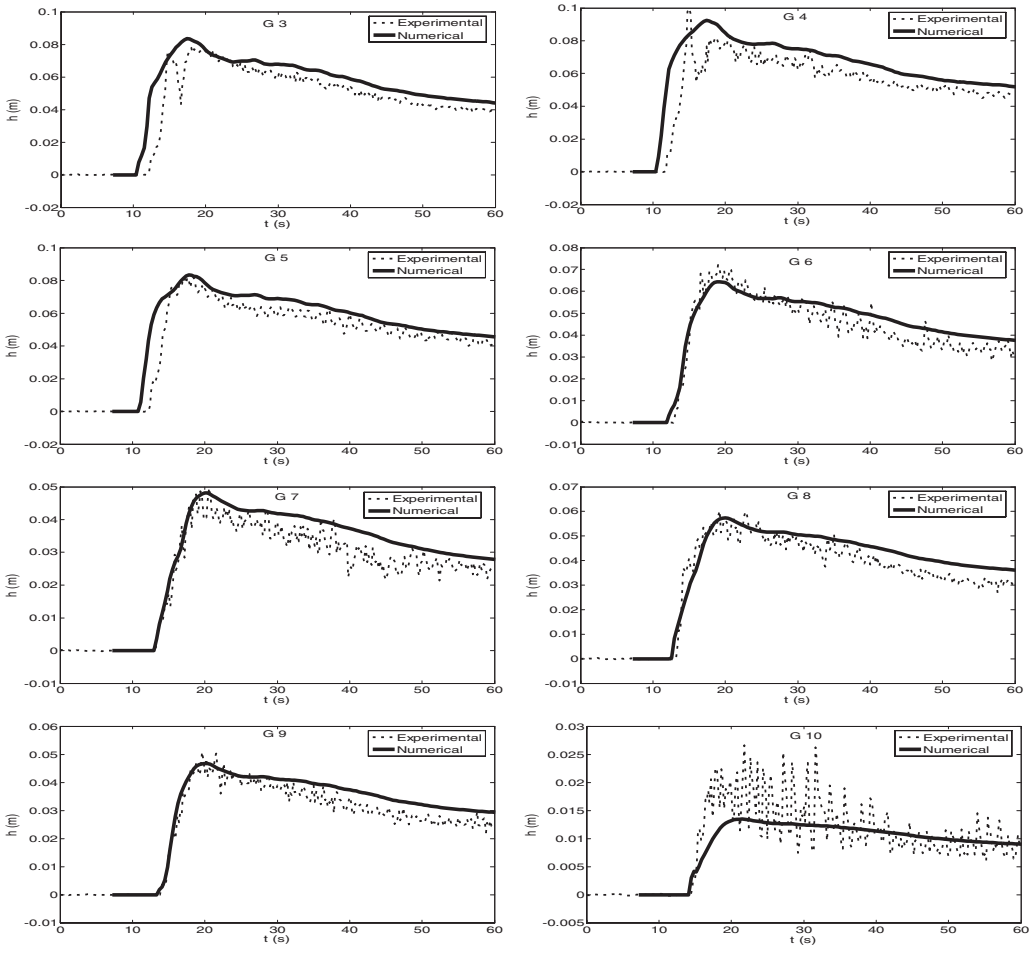

Figure 4. Test 1b: Comparison of the numerical results with the experimental data at various gauges.

to a rapid change of the flow regime at this point and to the downstream conditions, which are considered as critical conditions in all cases. The arrival times are slightly in advance, as are the numerical results obtained by other authors that have carried out the same tests (Murillo et al. 2004). The value of norm L was calculated, at each gauge, to compare numerical solutions with the experimental data in both test cases. As shown in Figures 5–6, L proves to be an acceptable value at all gauges and its mean value is about 0.23 for test case 1a and about 0.18 for test case 1b.

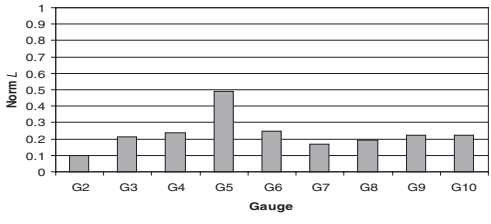

Figure 5. Test 1a: Norm values L at gauges.

3.4 *Test 2a and test 2b: Flood propagation on original bathymetry with aligned and staggered buildings*

The propagation of the hydrograph of the previous test cases was also performed on the original bathymetry of Toce river valley.

The numerical results are compared with the experimental ones in the case where the buildings are aligned (Fig. 7) and in the case where they are staggered (Fig. 8). As can be seen, the numerical results are in good agreement with the observed data.

For test 2a the most significant differences are at gauge 5 as in the previous test case 1a. Figures 9–10

Copyright © 2006 Taylor & Francis Group plc, London, UK

show the values of norm L for test cases 2a and 2b. The mean value of the norm is about 0.20 for both tests.

3.5 *Numerical techniques to simulate the influence of the buildings on the flow wave*

The most important aspects regarding simulations of urban flooding are the correct description of the flow and its interaction with buildings.

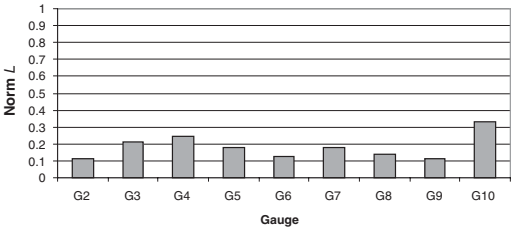

Figure 6. Test 1b: norm values L at gauges.

Different approaches have been implemented to simulate the propagation of the flood on the channelled bathymetry with the staggered position of the buildings. The first approach, used in test 1b, consists in representing the blocks as solid wall boundaries with the normal flow set equal to zero. The second approach is to simulate the influence of the blocks as an abrupt bottom variation.

The final technique is to reproduce the influences of the buildings as an increase in flow resistance assuming Strickler's coefficient equal to 2 $m^{1/3}/s$ on the cells which include the buildings and equal to 61 $m^{1/3}/s$ on the rest. This value of the roughness coefficient in the locations of the buildings is in a range of values commonly used by other authors to simulate flood propagation over an urban area (Alcrudo 2004; Mignot et al. 2004).

In Figure 11 the numerical solutions of the three techniques are compared to the experimental data. The numerical results based on the set of the solid wall conditions appear, as in the previous tests, in agreement

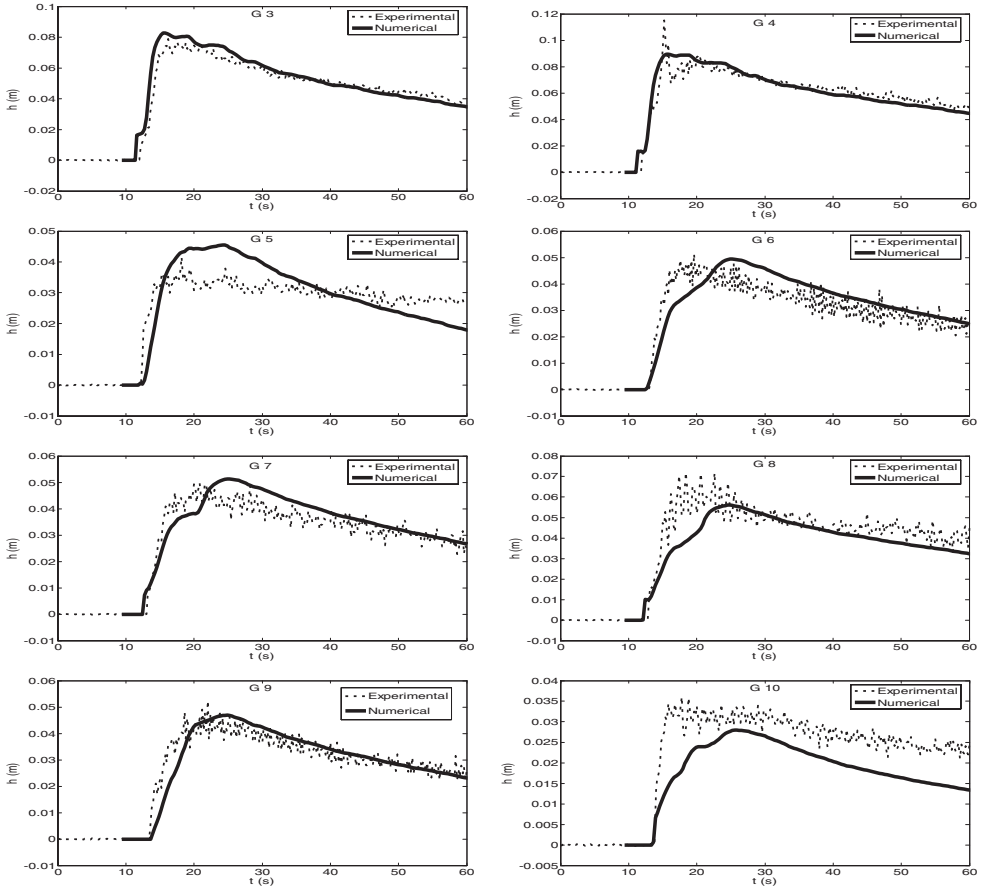

Figure 7. Test 2a: Comparison of the numerical results with the experimental data at various gauges.

Copyright © 2006 Taylor & Francis Group plc, London, UK

with the observed data. The higher differences are in the use of the bottom variation that simulates the recession limb lower than the observations. As observed by other authors, this approach is strictly dependent on the grid size (Alcrudo 2004), so a more refined grid is required. The use of the high friction to simulate the influence of the buildings on the flow wave is the simpler method to implement, although it does not provide a localised description of the flow, but rather an averaged analysis of the event. Moreover, the choice of the proper friction coefficient influences the numerical results, as is possible to note in Figure 12, where, at gauge 6, numerical solutions obtained by using a Strickler's coefficient equal to $2\,m^{1/3}/s$ are compared with those obtained using a Strickler's coefficient set $10\,m^{1/3}/s$.

In all tests, the numerical norm $L$was computed at all gauges (Fig. 13) and the mean values are 0.18 for the use of solid wall boundaries, 0.30 for the use of bottom variation and 0.21 for the use of the high friction coefficient.

3.6 *Influence of mesh size*

The accuracy of the numerical solutions is dependent on the meshing size. Frequently, in real cases it is

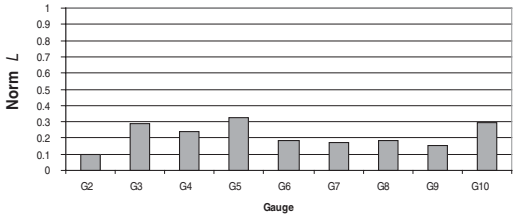

Figure 9. Test 2a: Norm values L at gauges.

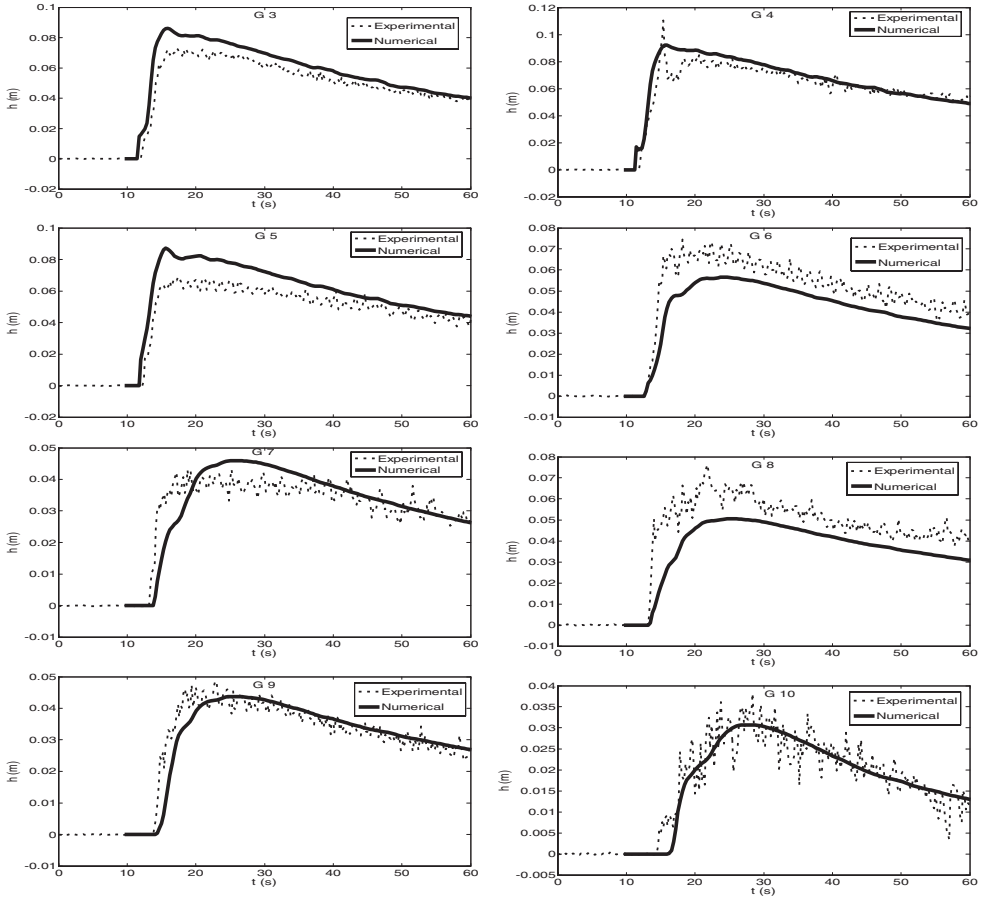

Figure 8. Test 2b: Comparison of the numerical results with the experimental data at various gauges.

Copyright © 2006 Taylor & Francis Group plc, London, UK

not possible to discretize the domain in a mesh fine enough to describe the single building due to the heavy computational requirements and to the relatively low resolution of the original data used.

To analyze the influence of grid size on the computations, the simulation of the flood propagation on the channelled bathymetry with the buildings in a staggered position and mesh size of 0.15 m was performed.

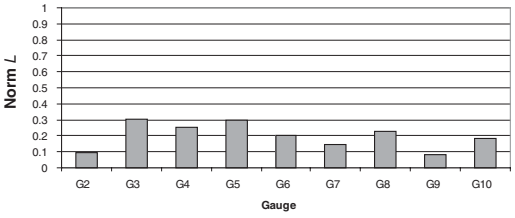

Figure 10. Test 2b: Norm values L at gauges.

Subsequently, a 0.25 m discretized structured mesh size was implemented (Fig.14). In latter case, the mesh size was greater than the single block, so in order to obtain better results, a new technique was used.

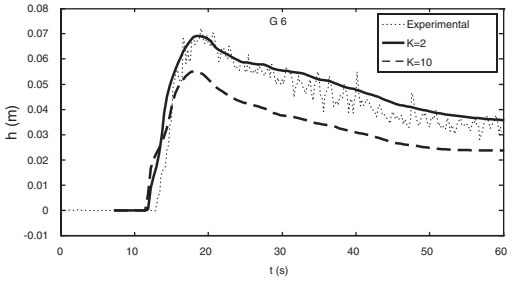

Figure 12. Comparison between numerical solutions using different Strickler's friction coefficients k and experimental data.

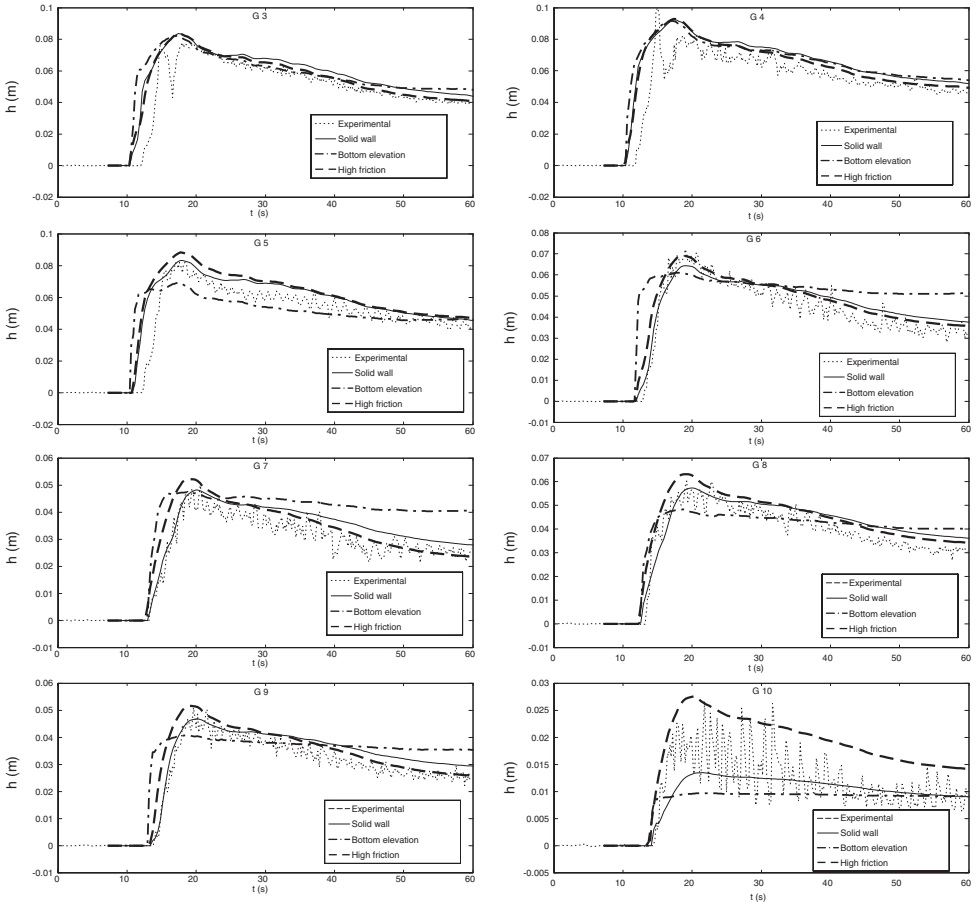

Figure 11. Comparison between numerical solutions of the different techniques to simulate the influence of the buildings on the flow with experimental data.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The shallow water equations were modified by introducing a porosity coefficient φ, that is the ratio between the cell surface area subject to flood and the total cell surface area. Equations 1–6 were modified as follows:

$$\frac{\partial \varphi \mathbf{U}}{\partial t} + \frac{\partial \varphi \mathbf{f}}{\partial x} + \frac{\partial \varphi \mathbf{g}}{\partial y} = \mathbf{S} \tag{17}$$

$$\mathbf{U}_{i,j}^{n+1} = \mathbf{U}_{i,j}^{n} - \frac{\Delta t}{\varphi_{i,j}\Omega_{i,j}} \sum_{r=1}^{4} \varphi [\mathbf{f}, \mathbf{g}]_r \cdot \mathbf{n}_r \Delta L_r + \frac{\Delta t}{\varphi_{i,j}} \mathbf{S}_{i,j}^{n} \tag{18}$$

The source terms are also modified by introducing the difference in pressure, caused by the variation of the porosity, in the term of bottom variation $\mathbf{S}_b$ and a head loss term, caused by a rapid variations in the geometry, in the friction term $\mathbf{S}_f$.

Along the x axis, but in an equivalent way to the y axis, they become (Guinot & Soares-Frazão 2006):

$$S_{bx} = -g\varphi h \frac{\partial z}{\partial x} + g \frac{h^2}{2} \frac{\partial \varphi}{\partial x} \tag{19}$$

$$S_{fx} = -g\varphi h \frac{u\sqrt{u^2+v^2}}{K^2 h^{4/3}} - g\varphi h s_x u \sqrt{u^2+v^2} \tag{20}$$

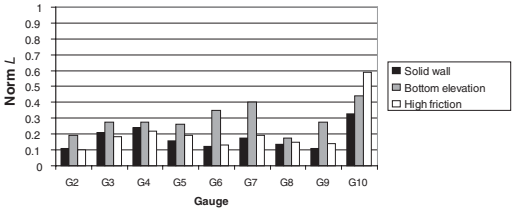

Figure 13. Norm values L with different techniques to simulate the influence of the buildings on the flow at gauges.

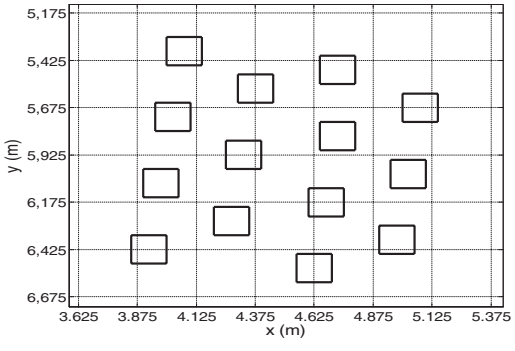

Figure 14. Details of the coarse mesh grid 0.25 m.

where z is the bottom elevation and s_x is a coefficient introduced in order to take into account the head losses of the urban discontinuity calculated by Borda's formula as in Guinot & Soares-Frazão (2006).

In this simulation, the porosity coefficient is set equal to 1 in the whole domain except in the cells that include buildings in which it varies from a value of 0.64 to 0.98 depending on the location of each building (Fig. 14).

The use of a coarse mesh led to less accurate results; the adopted modification to the original equations, on the other hand, provided results similar to those obtained by finer mesh (Fig. 15). The highest differences are found at gauges 5 and 10.

Also in these tests the norm values were computed at all gauges (Fig. 16). The mean value of the norm was about 0.19 for both the cell sizes of 0.15 m and 0.25 m.

4 CONCLUSIONS

In this paper different simulations have been carried out in order to investigate the performance of a number of numerical techniques to assess the presence of buildings in flood simulations. The obtained results prove that the approach based on considering flow interactions with structures such as solid wall boundaries, is the most accurate.

The use of the bottom elevation approach led to less accurate solutions, while the technique to reproduce the influence of buildings as an increase in flow resistance, assuming a high friction coefficient, is closely connected to the choice of the proper coefficient.

The effects of meshing size on numerical results were also analyzed. In order to simulate the propagation on a coarse mesh, the original shallow water equations were modified by introducing a porosity coefficient. In this case, the obtained numerical solutions are similar to those computed on the finer mesh by the solid wall approach.

The results computed by the first order HLLC scheme do not show physical anomalies and they are similar to those obtained with high order schemes used within IMPACT project.

Further studies are in progress in order to simulate real inundation events over urban areas.

A practical approach to estimating the flow capacity of rivers – Application and analysis

C. McGahey & P.G. Samuels
Water Management Department, HR Wallingford Ltd., Howbery Park, Wallingford, Oxon, United Kingdom

D.W. Knight
School of Engineering, University of Birmingham, Edgbaston, Birmingham, United Kingdom

ABSTRACT: In 2001, the Environment Agency of England and Wales commissioned a Targeted Programme of Research (Evans *et al*, 2001) into reducing uncertainty in conveyance estimation, with the intention of bridging the gap between the advances in scientific knowledge over the past three decades and the calculation approaches adopted in United Kingdom industry practice. The key output was the Conveyance Estimation System (CES) software, which incorporates a methodology (Mc Gahey & Samuels, 2003) for estimating conveyance in a range of channel types and flow conditions, including straight, skewed and meandering plan form shape; simple, two-stage and multi-thread channels; and a variety of vegetation and substrate covers (Defra/EA, 2003; Mc Gahey & Samuels, 2004). In this paper, the CES methodology is applied to fourteen river sites from England, Northern Ireland, New Zealand, Ecuador and Argentina, illustrating reasonable model predictions over a broad application range. Discharge and lateral velocity predictions are compared to observed data, with emphasis on practical application, calibration technique and effects of scale. Consideration is given to the relative magnitude of the equation terms with depth, for example, the role of boundary friction, lateral shear and secondary flows, and how these relate to the observed flow structure and the local site characteristics.

1 INTRODUCTION

Rivers and their associated floodplains form the natural system for the transmission of flood flows. Knowledge of river water levels is essential to flood risk management tasks such as flood risk mapping, strategic planning, scheme design, flood warning and emergency evacuation and channel maintenance. In 2001, the Environment Agency of England and Wales commissioned a Targeted Programme of research into reducing uncertainty in conveyance estimation. The key output was the Conveyance Estimation System (CES) software, which provides a practical methodology for estimating flow capacity in rivers, based on the aggregation and extension of previous laboratory derived approaches for application to natural channels. An essential method requirement was the ease of application to rivers of any scale that may be characterised by irregular cross-section shapes, a variety of surface materials, plan form sinuosity and channel braiding.

Previous approaches to calculating flow capacity can broadly be divided into five categories:

1 *Hand calculation methods* commonly termed Single and Divided Channel Methods where the channel cross-sectional is treated as a single unit or divided into more than one flow zone respectively. These include, for example, the methods of Manning (1889), Lotter (1933), Yen & Overton (1973), Ervine & Baird (1982), Lambert & Myers (1998) and Ackers (1991).
2 *Dimensional Analysis* approaches where the dimensionless channel properties such as relative roughness and Froude or Reynolds' Number are evaluated for scale models and assumed similar for the prototype (e.g. Rameshwaran & Willets, 1999).
3 *Additional energy losses due to bends*, for example, the Soil Conservation Service (SCS) and Linearised SCS methods and the work of Chang (1984).
4 *Energy 'loss' methods* which assume that the energy transfers within each flow zone (e.g. main channel or floodplain region) are proportional to the square of the local flow velocity and they are mutually independent and hence the principle of superposition can be applied. Well known methods include those of Ervine & Ellis (1987), James & Wark (1992) and Shiono *et al* (1999).
5 *Reynolds Averaged Navier-Stokes (RANS)* approaches, which are based on the depth-integration

Copyright © 2006 Taylor & Francis Group plc, London, UK

of the RANS equations for flow in the streamwise direction. Significant research contributions include Shiono & Knight (1988), Wark (1993), Abril & Knight (2004), Spooner & Shiono (2003) and Bousmar & Zech (2004).

These previous conveyance approaches have largely focused on experimental channels, which are prismatic, symmetrical and comprise rectangular or trapezoidal cross-section shapes. Although they provide useful quantifiable parameters for estimating discharge such as width ratios, relative depth, relative roughness and main channel side slopes, they are less useful when applied to rivers with irregular, asymmetrical shapes that may be characterised by distributed roughness or channel braiding. The CES methodology utilizes the 'as surveyed' river cross-sections and the observed local roughness features, while incorporating the aforementioned parameter definitions as a guide to understanding and quantifying the energy transfer mechanisms, and hence deriving more universally applicable parameters. This paper demonstrates the broad application range of the CES methodology, through application to fourteen river sites from five countries. An analysis of the relative magnitude of the CES equation terms, i.e. energy transfers due to hydrostatic pressure, boundary friction, lateral shearing and secondary circulations, is undertaken for inbank, main channel overbank and floodplain flow conditions.

2 METHODOLOGY

The methodology is based on the depth-integration of the Reynolds-Averaged Navier-Stokes equations,

$$ghS_o - \frac{\varphi}{8h^2} f q^2 + \frac{\partial}{\partial y}\left[\lambda h \left(\frac{f}{8}\right)^{1/2} q \frac{\partial}{\partial y}\left(\frac{q}{h}\right)\right] = \alpha\Gamma + (1-\alpha) C_{uv} \frac{\partial}{\partial y}[h] \quad (1)$$

where g = gravitational acceleration (ms^{-2}); q = streamwise unit flow rate (m^{2}s); h = local depth normal to the channel bed (m); S_o = reach-averaged longitudinal bed slope; y = lateral distance across the channel cross-section (m); φ = projection of the boundary shear stress onto the plane due to choice of Cartesian coordinate system; and α = function of the reach-averaged sinuosity. Equation 1 has four calibration coefficients: the local friction factor f, the dimensionless eddy viscosity λ, the secondary flow parameter Γ and the coefficient of meandering C_{uv}. The total flow rate, Q (m^{3}s^{-1}), is hence evaluated from,

$$Q = \int_0^b q\, dy \quad (2)$$

where b = the total channel width (m). The fourteen river sites are all located in straight reaches, and thus Equation 1 can be simplified to,

$$ghS_o - \frac{\varphi}{8h^2} f q^2 + \frac{\partial}{\partial y}\left[\lambda h \left(\frac{f}{8}\right)^{1/2} q \frac{\partial}{\partial y}\left(\frac{q}{h}\right)\right] - \Gamma = 0 \quad (3)$$

(1) (2) (3) (4)

where Term 1 is the hydrostatic pressure, Term 2 is the boundary friction, Term 3 is the turbulence due to vertical interfacial shearing and Term 4 represents the secondary circulations due to turbulence in straight channels. The key difference between Equation 3 and the Shiono & Knight (1988) Method (SKM) is the evaluation of f and Γ in natural channels. Here, f is derived from a local unit Manning roughness n_l, which is converted to an equivalent roughness size, k_s, and then the Colebrook-White Law is incorporated to evaluate the lateral distribution of f at each flow depth (Mc Gahey & Samuels, 2004). The dimensionless eddy viscosity is derived from (Abril & Knight, 2004),

$$\lambda = \lambda_{mc}\left(-0.2 + 1.2 D_r^{-1.44}\right) \quad (4)$$

where λ_{mc} = main channel dimensionless eddy viscosity; and D_r = local relative depth given by h/h_{max}. Here, λ_{mc} is taken as 0.24 for rivers after Elder (1959). The secondary flow model Γ, which is based on the work of Abril & Knight (2004), is adapted to incorporate a transitional model Γ_{trans} for asymmetric channels and channels with floodplains at different bed elevations. The main channel inbank, overbank and floodplain formulae are given by (Abril & Knight, 2004),

$$\Gamma_{mci} = 0.05 H \rho g S_o; \quad \Gamma_{mco} = 0.15 H \rho g S_o;$$

$$\Gamma_{fp} = -0.25 H \rho g S_o \quad (5a\text{-}c)$$

where ρ = fluid density (kg m^{-3}). For asymmetric channels or channels with floodplains situated at different bed elevations, the secondary flow model in the main channel transitional region is given by (Mc Gahey, 2006),

$$\Gamma_{mc(trans)} = \frac{(\Gamma_{mco} - \Gamma_{mci})}{(Z_H - Z_L)}(h_l - Z_L) + \Gamma_{mci} \quad (6)$$

where Z_H and Z_L = bed elevation of the higher and lower floodplains respectively (mAD); and h_l = water surface level for the given depth of flow (mAD).

A further difference is that the CES solution technique is based on the continuity of the unit flow rate q rather than the depth-averaged velocity as previously used in the SKM approach. This is due to the strong continuity properties of q with variations in depth, for example, across a vertical face or 'step' in an engineered channel cross-section (Samuels, 1989; Knight *et al*, 2004). The approximation to the solution of Equation 3 is generated by the Finite Element Method (Defra/EA, 2003b).

3 DESCRIPTION OF DATA SETS

The methodology is applied to fourteen data sets from England, Northern Ireland, New Zealand, Ecuador and Argentina. These are summarized in Table 1, including information on bankfull flow rate Q_{bf}, bankfull depth h_{bf}, main channel width b_{mc} and the bed slope S_o. These data sets cover a range of channel types and scales, notably:

1 *Cross-section shape*: the river sections are all irregular in shape and they include simple (*), compound (**) and asymmetrical (***) shapes (Tab. 1) as well as a range of aspect ratios (b/h).
2 *Channel cover*: the bed, bankside and floodplain ground material includes silt, gravel, cobbles and, small and large boulders well as different vegetation types such as grass, heavy weed growth and fallen trees (Tab. 2).
3 *Longitudinal bed slope*: the data includes steep mountain rivers such as the Cuenca and Tomebamba as well as more gentle gradients such as the Severn and the Trent.
4 *Scale*: This includes a range of flow rates and channel sizes, where Q_{bf} ranges from 420 m^3s^{-1} in the Colorado to a mere 7 m^3s^{-1} in the Heathcote and similarly, h_{bf} varies from 1 through to 6 m. The main channel widths vary from 70 m in the Colorado to 6 m in the Blackwater and the floodplain widths vary from 500 m in the Dane to 30 m in the Main.
5 *Channel braiding*: The Torridge and the Blackwater are characterised by high banks or 'levees' with low adjacent floodplains, which provide an effective channel braiding.

4 VELOCITY AND DISCHARGE PREDICTION

Discharge and velocity predictions have been made for the fourteen river sites. The calibration philosophy is based on the bed friction only. The input local unit roughness n_l, from which the friction factor f is derived (Mc Gahey & Samuels, 2004), is varied in order to reduce the overall percentage difference Λ (%) between the predicted Q_{CES} and measured flow rates Q_{data} i.e.

$$\Lambda = \frac{\sum_{i=1}^{n} \left| \frac{Q_{data} - Q_{CES}}{Q_{data}} \right|_i}{n} 100 \qquad (7)$$

where n is the number of data points for comparison. The standard deviation ς is given by,

$$\varsigma = \sqrt{\frac{\sum_{i=1}^{n} \left[\left(\frac{Q_{data} - Q_{CES}}{Q_{data}} \right)_i - \overline{\left(\frac{Q_{data} - Q_{CES}}{Q_{data}} \right)_i} \right]^2}{n}} \qquad (8)$$

For a given channel cross-section, the unit roughness n_l is provided for a 1m depth of flow, and the depth-variation of roughness is introduced through the Colebrook-White Law. Once Λ has been minimised i.e. the overall flow predictions are reasonable for the full depth-range, the lateral distribution of n_l is refined in order to best predict the lateral depth-averaged velocity distributions at each depth of flow. This is based on visual inspection of the predicted and measured velocities. The velocity results are shown for three of the sites, selected to illustrate an example of a simple, compound and asymmetrical braided channel. Figures 1, 2 and 3 show the depth-averaged velocity predictions for the River Colorado, the River Severn and the River Trent at Yoxall and the calibrated n_l values are given in Table 3.

The River Colorado tends to under-predict the high velocities at large flow depths and slightly over-predict the velocities at lower depths. This is most likely a short-coming in the use of the Colebrook-White formulation for establishing the variation of roughness with depth for this wide channel, where bed generated turbulence has a dominant role and the channel banks have less influence. The River Severn data is captured reasonably well, other than the very high velocities in the centre region of the channel. This may indicate that the CES model is over-representing lateral shearing through a large main channel dimensionless eddy viscosity λ_{mc} value of 0.24 in rivers, resulting in an increased retarding effect of the slower floodplain flow on the main channel flow. The River Trent data includes measurements for two depths of flow. The predictions here are considered reasonable given that

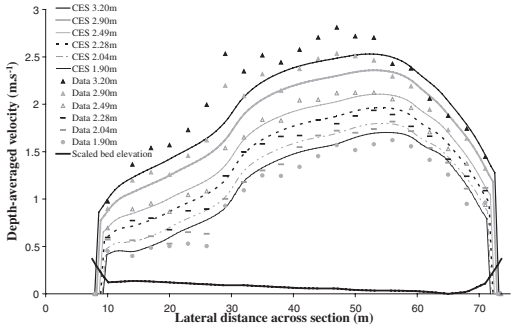

Figure 1. Depth-averaged velocity predictions for different flow depths in the River Colorado, Patagonia.

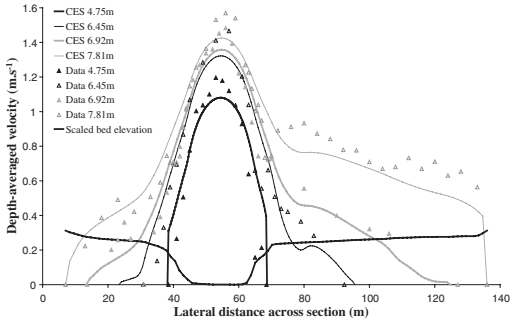

Figure 2. Depth-averaged velocity predictions for different flow depths in the River Severn at Montford Bridge.

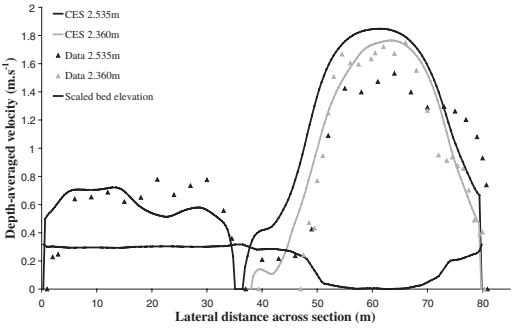

Figure 3. Depth-averaged velocity predictions for two flow depths in the River Trent, Yoxall.

the measurements indicate an overall velocity reduction in the main channel for a larger flow depth. For the braided flow depth, the predicted floodplain velocities are supported by the measurements.

In general, the measured velocities are reasonably well-predicted throughout the depth range for the three rivers.

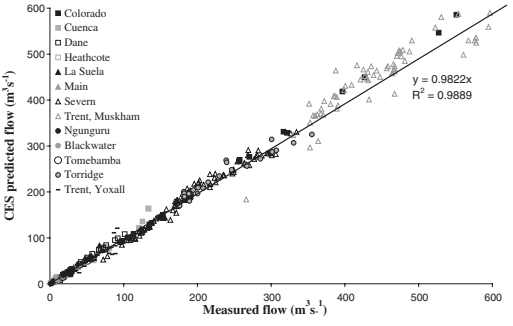

Figure 4. Predicted and measured flow rates for the thirteen river sites.

all the river sites. A perfect match between the model prediction and the data would yield a gradient of 1.0 i.e. $Q_{CES} = Q_{data}$. A least squares regression line gives an R^2 value of 0.9889, indicating a 'good' fit, and a gradient, i.e. Q_{CES}/Q_{data}, of 0.9822. The latter is just less than 1.0, suggesting the CES tends to marginally under-predict the flow rate. Figures 4 and 5 demonstrate the range of scales for which the CES predictions are appropriate, from small rivers such as the Heathcote, with flow rates of $7\,m^3s^{-1}$, through to larger rivers such as the Severn, with flow rates in the range 200 to $300\,m^3s^{-1}$, and finally to much large rivers such as the Trent and the Colorado, with flow rates upwards of $400\,m^3s^{-1}$. The data shows an increasing degree of scatter with increasing flows. This is not surprising since there is more uncertainty associated with river measurements taken at high flows, for example,

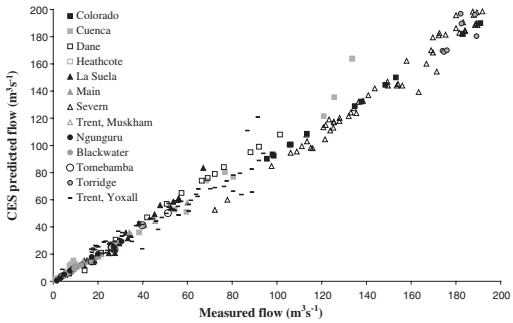

Figure 5. Predicted and measured flow rates for the thirteen river sites (flow rates $<200\,m^3s^{-1}$).

drowned gauge sites, and further to this, the empirically derived model coefficients and models such as Equations 4 and 5 for λ and Γ were largely based on laboratory measurements.

Table 3 provides the overall percentage difference Λ for each data set, giving an average value for the fourteen data sets of 9.9%. This value is inflated by the large contributions of the Trent at Yoxall, the Dane, the Waiwakaiho and the Cuenca. For the Trent, this is not surprising considering the aforementioned trend in the measured velocity data, where greater flow depths have lower velocities. In addition, there is more uncertainty associated with the floodplain measurements, which are beyond the range of the main channel cableway span, and are therefore based on four overbank gauge points. The Dane is characterised by dense seasonal vegetation, and as the high and low flows are typically measured in different seasons, the vegetation characteristics will be different. This seasonal variation is not incorporated in the roughness representation. The Waiwakaiho and the Cuenca are steep mountain rivers with large boulders, and the existing CES methodology does not incorporate a model for boulder roughness. Mc Gahey (2006) demonstrates the improvement in the CES predictions for mountain rivers through application of the Ramette (1992) approach to evaluate the lateral distribution of f with flow depth. Without these four river sites, the average percentage difference is reduced to 6.2%, suggesting a reasonable performance of the CES methodology to at least ten river sites.

Table 3 also includes the standard deviation ς for each site. These values tend to be larger than the overall percentage difference Λ, as the expected or mean value is zero i.e. $Q_{CES} - Q_{data}$, and thus any variation on this mean has a large value relative to zero. The Ngunguru has the largest ς despite the small value of Λ, indicating a high degree of scatter in the data. The Waiwakaiho has a large ς, which is not unexpected considering Λ is a similar order of magnitude. Likewise, the large ς values for the Dane and the Trent

Copyright © 2006 Taylor & Francis Group plc, London, UK

also reflect the large Λ values. For the remaining sites, the standard deviation ς is small and corresponds to the average percentage difference, Λ. This indicates a reasonable model performance in predicting each measured value within each data set, as these measurements are reasonably well-distributed about the CES predicted values.

5 RELATIVE MAGNITUDE OF EQUATION TERMS

Quantifying the relative magnitude of the four principal equation terms in Equation 3 is useful in understanding which flow processes have a dominant role, how these mechanisms change with the depth of flow and what channel properties influence these changes. For example, in wide rectangular channels with no vegetation there may be less lateral mixing than in a heavily vegetated irregular-shaped channel. Essential to this is identifying where the relative contributions are the result of a prescribed model within the CES methodology, for example, a change in the role of the secondary flow term between inbank and overbank flow (Equation 5a-c), compared to external predetermined input parameters such as longitudinal bed slope, channel shape and roughness. The average contributions from the different terms are considered for inbank, main channel overbank and floodplain regions. The river cross-sections and flow depths which are considered are shown in Figures 6 to 16.

Figure 17 provides the relative magnitude of Terms 1 to 4 in Equation 3 for inbank flow conditions in seven rivers.

The averages values are 45% hydrostatic pressure, 43% boundary shear; 9%, vertical interfacial shear and 2% secondary circulations. The large contribution from Term 1 and 2 is not unexpected, as these these constitute the primary balance of forces in the absence of any lateral momentum transfers. Without Terms 3 and 4, Equation 3 would simplify to the well known

Darcy-Weisbach equation. The Term 3 contribution is more variable, indicating different degrees of lateral shear. In wide shallow channels, the side-walls have less influence on the channel centre and the flow is therefore dominated by bed generated turbulence. The velocity gradient is therefore approximately zero in the channel centre, and the Term 3 contribution is small. In narrow deep channels, the side-walls play a larger role, and there is a greater degree of lateral shearing. Figure 18 provides a plot of the percentage lateral shearing versus aspect ratio where the data trend corroborates this reasoning.

The Colorado, the Main, the Waiwakaiho and the Tomebamba all have modest lateral momentum transfers. This is partly due to the large aspect ratios, and partly that the channels have little vegetation and where there is vegetation or boulders there is limited information on the exact location, resulting in the use of average cross-section input unit roughness n_l values. The Heathcote and Ngunguru have a greater degree of lateral shearing which may be explained by the large roughness features which enhance the lateral velocity gradients. The Heathcote has vegetation on the banks and angular cobbles on the channel bed

and the Ngunguru is characterised by gravel and small cobbles.

Secondary circulations have a small role in inbank flow, which is reflected in the low, empirically derived '0.05' coefficient in Equation 5a, and hence through the small contribution of Term 4.

Some of the rivers differ from the more general trend, for example, the River Severn has a low hydrostatic pressure term and a high degree of lateral shear relative to the other sites. The former may result from incorporating a representative reach-averaged longitudinal slope based on measured water levels for at high flow depths, whereas in reality the surface water slope at Montford Bridge varies substantially with depth (Knight, 1989a). The latter may be attributed to the dense channel vegetation.

Figure 19 provides the relative magnitude of Terms 1 to 4 in Equation 3 for main channel overbank flow conditions in five rivers. The averages values are 44% hydrostatic pressure, 35% boundary shear; 14%, vertical interfacial shear and 7% secondary circulations.

The Severn and the Dane have small hydrostatic pressure contributions, which may be related to the high degree of lateral shearing present in the deep narrow main channel regions. As with the inbank case, the Main has substantially less lateral shearing, than for example, the Severn, as there is less vegetation present and the conveyance is therefore largely geometry driven.

The Blackwater has a noticeably small boundary friction contribution. This is most likely related to the cross-section geometry, in that the irregular geometry results in local steep velocity gradients and hence large lateral momentum transfers. This is reflected in the high lateral shear contribution, which off-sets the boundary friction term in balancing the hydrostatic pressure.

The secondary flow contribution for all sites is more than double that of the inbank flow sites, reflecting the larger '0.15' value in Equation 5b.

Figure 20 provides the relative magnitude of Terms 1 to 4 in Equation 3 for the floodplain flow conditions. The averages values are 36% hydrostatic pressure, 49% boundary shear; 5%, vertical interfacial shear and 9% secondary circulations.

The average hydrostatic pressure term is substantially smaller for floodplain flow, which may be attributed to the lower floodplain flow depths and the high boundary friction due to the presence of dense

Copyright © 2006 Taylor & Francis Group plc, London, UK

floodplain vegetation. The most variable contribution is the vertical interfacial shear. This is approximately zero for the Dane, which may be explained by the low floodplain depths. Conversely, the Trent has the highest lateral shear, which results from the steep velocity gradient at the floodplain main channel interface coupled with the relatively short floodplain width i.e. the inundated floodplain extent is not sufficiently wide to achieve a constant lateral velocity gradient.

The average secondary flow contribution is large, reflecting the large value of the prescribed CES model coefficient in Equation 5c.

6 CONCLUSIONS

A practical approach to estimating the flow capacity of rivers has been demonstrated for fourteen rivers sites from five different countries, where the unit roughness n_l was the only calibration parameter. The depth-averaged velocity predictions compared reasonably well to the measured data for a simple, compound and asymmetrical river example over a range of flow depths. The predicted Q_{CES} and measured Q_{data} flows for fourteen river sites showed a least squares regression fit of 0.9889, which is close to an ideal fit of 1.0. The ratio of Q_{CES} to Q_{data} was 0.9882, suggesting that the CES is more likely to slightly under-predict than over-predict the measured flow values. The average percentage difference Λ between the measured and predicted flows for all sites was 9.9%, demonstrating the effectiveness of the model over a range of scales and channel types. This value may be reduced to 6.2% if the mountainous rivers with large boulders are excluded. The CES methodology is therefore a useful approach for application in river engineering practice, as it incorporates models and parameters that can readily be applied to natural channels, over a range of scales, with irregular geometries, roughness features and channel braiding.

An analysis of the relative magnitude of the four terms in Equation 3 was undertaken for inbank, overbank and floodplain flow. As expected, the hydrostatic pressure and the boundary shear terms were large and they constituted the primary force balance. The boundary friction term was ~10% higher in the floodplain region due to low flow depths and greater vegetation roughness. The lateral shearing term was the most variable. For inbank flows, the variations were shown to be closely related to the aspect ratio. For overbank flow, this was dependent on the floodplain flow depths, where for low or very high floodplain depths, the floodplain flow has less retarding influence on the main channel flow. For main channel overbank flow, the degree of lateral shearing is linked to vegetation growth. The secondary flow contributions are generally small relative to the other equation terms, with a larger contribution in compound channels.

This analysis is useful in practice as it enables practitioners to focus their attention on particular river features. For example, river surveys should ideally include detailed descriptions of the exact cross-section location and nature of vegetation features. It further draws attention to the importance of the main channel dimensionless eddy viscosity λ_{mc} value as well as the rule applied in Equation 4, which may not always be appropriate in describing the lateral shearing in two-stage rivers.

7 RECOMMENDATIONS

The CES methodology has been demonstrated for fourteen river sites, all located in straight river reaches. For further testing, it is recommended that a targeted data acquisition programme is implemented, where the data collection focuses on straight and meandering two-stage natural channels, and measurements include discharge, water level, depth-averaged velocities and, where possible, turbulence measurements.

The methodology incorporates the Colebrook-White Law to evaluate the lateral distribution of the friction factor for each depth of flow. For mountain streams with boulders, an alternative formulation, such as the method of Ramette (1992) is proposed.

The importance of the lateral shearing term in two-stage channels is highlighted. Thus, further investigation of the applicability of Equation 4 for the lateral distribution of the dimensionless eddy viscosity λ in two-stage rivers is advocated.

ACKNOWLDEGEMENTS

This paper draws upon the Targeted Programme of research commissioned by the Environment Agency (EA) of England and Wales as project W5A-057 under the joint the Department for Environment, Food and Rural Affairs (Defra)/EA Flood and Coastal Defence R&D Programme. We wish to thank Dr Mervyn Bramley, the Agency Project Manager for his encouragement and support. The views expressed in this paper are, however, personal and the publication does not imply endorsement by either the EA or Defra. The Authors wish to acknowledge Professor Boris Abril and Miss Leticia Tarrab for their contributions to data.

Diffusion wave based modeling of flood inundation based on sub-grid connectivity

D. Yu & S.N. Lane
Department of Geography, University of Durham, Science Laboratories, South Road, Durham

ABSTRACT: We now routinely model flood inundation using reduced complexity models. Traditionally, these have involved both depth-averaging and width-averaging of the mass and momentum equations. Strictly, this assumption is only valid when the flow is shallow and the topographic forcing term is dominant and it still leaves the problem of discretisation and solution, given the strong sensitivity to topographic resolution. In this paper, we present and validate an alternative sub-grid formulation that introduces an explicit representation of finer resolution topographic. This approach uses high-resolution topographic data to develop explicit parameterization of sub-grid-scale topographic variability to represent both the volume of a grid cell that can be occupied by the flow and the effect of that variability upon the timing and direction of the lateral fluxes. This approach is found to give significantly better prediction of fluvial flood inundation in urban areas than traditional calibration of sub-grid-scale effects using Manning's *n*.

1 INTRODUCTION

Fluvial flood modelling in urban areas requires explicit representation of small-scale topographic variation in order to capture the correct patterns of flux near structural elements (e.g. walls, buildings and railroads, etc). However, previous studies (e.g. Horritt & Bates, 2001; Yu and Lane, 2006) demonstrated the severe sensitivity of this type of model to mesh resolution in urban areas and the poor performance of spatially uniform parameterisation using an effective roughness parameter (Manning's *n*). Even using a wetting parameter (following Bradbrook et al., 2004) to reduce the effects of artificial numerical diffusion across the floodplain, strong model sensitivity to mesh resolution was found. Much of this is related to the effects of changing mesh resolution upon topographic information content. Figure 1 shows a hypothetical grid cell set (1a) and an associated coarsened set (1b). The average blockage of the cell in each of 1a and 1b is the same. However, the distribution of sub grid blockages is different. If we consider a cell with water in it, to the left of the coarsened cell (shown in italic) then, in 1a, there should be no inundation. However, averaging as per 1b will lead to inundation when it shouldn't do when water levels to the left of the cells are between 0.15 m and 0.20 m. Thus, with the coarser resolution, and even with the standard wetting treatment used by Bradbrook et al. (2004) and Yu and Lane (2006), water will diffuse more readily across the coarser mesh, leading to a more rapid diffusion of flood inundation extent. It

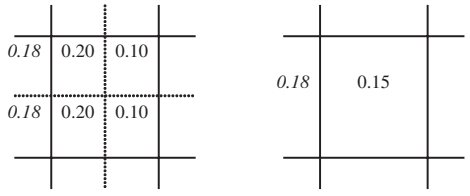

Figure 1. A schematic illustration of the effects of averaging a high resolution topographic dataset (1a) to a lower resolution (1b) in relation to a wave of water moving from the left (elevation shown in italic) and topographic data (non-italic in 1a) subject to averaging (non-italic in 1b). Solid lines are the coarsened mesh cell boundaries. Dotted lines are the sub grid cell boundaries.

may be argued that if the model is only being used to determine inundation extent, the timing is not important. However, Yu and Lane (2006) showed that, for an unconfined floodplain or a large flood on a confined floodplain, the maximum inundation extent was significantly greater for coarser mesh resolutions. This arises because deeper water diffuses too quickly. This may especially be the case in urban areas where the structural complexity of the surface is affected quite significantly by averaging from fine to coarser mesh resolutions. Roughness parameterisation will not deal with this effect fully: even with very high values of the roughness parameter, diffusion will occur across a grid cell in the scenario shown in Figure 1b, even if it is meant not to.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Given the above, this paper seeks to develop a method for sub-grid scale topographic representation with an explicit treatment of the effects of structural elements upon the floodplain upon both blockage and flux. We believe this to be a major contribution to the improved representation of urban flooding noted by Wheater (2002).

2 THEORETICAL DERIVATION OF A SUB-GRID SCALE TOPOGRAPHIC TREATMENT

Bradbrook et al. (2004) and Yu and Lane (2006) review the basis of the model that is modified to provide a sub-grid scale topographic representation in this paper and so it is not covered further. This paper only covers the sub-grid scale topographic representation.

2.1 *Cell blockage effects*

Consider a cell and its sub-grid cells in the configuration shown in Figure 2. The cell is composed of four sub-grid cells with bed elevation e1, e2, e3 and e4 (Figure 2a). These are shown schematically in 1D in Figure 2b. Without a sub-grid scale topographic representation, the elevation of the cell (E) can be calculated simply as the average of the four sub-grid cells. The relationship between water surface elevation and the volume of water that can be stored within the cell without considering the sub-grid topography (i.e. Figure 2a) is a simple linear one, taking the form:

$$V_{ij} = w^2\left(H_{ij} - \frac{1}{N_{ij}}\sum_{k=1}^{N_{ij}} e_k\right) \quad (1)$$

where w is the grid resolution, and H_{ij} is the water surface elevation in cell ij, N_{ij} is the number of sub-grid cells in grid cell ij and e_k is the bed elevation of each sub-grid cell.

However, (1) needs to be modified to represent the actual volume storage effect (Fig. 2b), as (Equation 1) will under-estimate the true volume of storage for $\min(E_{ij}) < H_{ij} < \max(E_{ij})$. Under-estimation of storage volume will lead to over-estimation of water levels, and this partly explains why the effects of mesh coarsening will be amplified in a diffusion type model. In the case of a 2×2 set of cells being averaged to a single cell, the peak under-estimation of volume (or over-estimation of water level) is at $H_{ij} = E_{ij}$ and this diminishes to zero for $H_{ij} = \max(E_{ij})$. This allows us to develop a first approximation of the relationship between water volume (V_{ij}) and water surface elevation (H_{ij}) taking into account sub-grid scale topography:

$$V_{ij} = \frac{w^2}{N_{ij}}\left(N_{ij}^k H_{ij} - \sum_{k=1}^{N_{ij}^k} e_k\right) \quad (2)$$

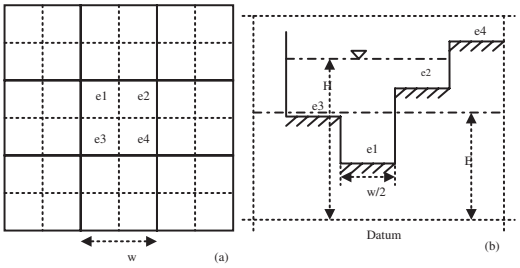

Figure 2. Schematic view of the sub-grid topography. 2a shows the model with its sub-grid cells; e1, e2, e3 and e4 are sub-grid cell bed elevations; w is the resolution of the model grid. 2b shows the four elevations unwrapped onto a 1D plain; H is the sub-grid water surface elevation; B is the bed elevation of the model cell which is equal to the average of its sub-grid cell elevations.

where e_k is the bed elevation of the sub-grid cell k, w is the width of the grid cell which contains N_{ij} sub-grid cells and N_{ij}^k is the number of sub-grid cells within the grid cell that are wet. When the cell is fully wet, $N_{ij}^k = N_{ij}$ and (Equation 2) reduces to (Equation 1).

In a forward differencing scheme, fluxes into and out of cell ij would be determined to give V_{ij}. However, this still leaves two unknowns in (Equation 2), H_{ij} and N_{ij}^k. Thus, N_{ij}^k from the previous time step is taken, used to determine H_{ij}. If H_{ij} exceeds e_{k+1} then N_{ij}^k is increased by one and (Equation 2) is re-evaluated. This continues until H_{ij} no longer exceeds e_{k+1}. A final check is then undertaken to make sure that H_{ij} also exceeds e_k. If not, N_{ij}^k is reduced by one and (Equation 2) is re-evaluated. With the water surface elevation as the dependent variable, the difference between these two scenarios is calculated as:

$$\frac{V_{ij}}{w^2}\left(\frac{N_{ij}}{N_{ij}^k} - 1\right) + \frac{1}{N_{ij}N_{ij}^k}\left(N_{ij}\sum_{k=1}^{N_{ij}^k} e_k - N_{ij}^k\sum_{k=1}^{N_{ij}} e_k\right) \quad (3)$$

(Equation 3) is the general result illustrated above for the case of 2×2 cells: as the water volume increases, the difference in water surface elevation for the two cases decreases, resulting in no difference once all the sub-grid cells are wet, i.e., the number of wet sub-grid cells is equal to the total number of grid cells ($N_{ij} = N_{ij}^k$).

First, when the water surface elevation is less than the average value of the sub grid-scale elevations, but higher than the minimum sub grid-scale elevation, (Equation 2) allows inundation, whereas (Equation 1) does not. Once the water surface is higher than the average sub grid-scale elevation, (Equation 1) will allow inundation. Thus, the peak error with (Equation 1) is when the water surface elevation equals the

Copyright © 2006 Taylor & Francis Group plc, London, UK

average sub grid-scale elevation. The error reduces as the water surface continues to rise until the cell is fully wet when the error is zero. The reverse will occur during the falling limb. Thus, the error due to (Equation 1) is associated with the wetting and drying process in which cells wet up more quickly and dry more slowly than would be the case if (Equation 1) alone were adopted. Second, the sub grid-scale topography has implications for the rate of rise of the water surface within a grid cell. When the cell is wet under (Equation 1), but still partially wet under (Equation 2) (i.e. when the water surface elevation is greater than the average value of the sub grid-scale elevations but less than the maximum value), then the water surface rise within the cell will be more rapid than predicted under (Equation 1).

Third, given that both of these effects determine the rate at which water levels rise, and that diffusion models are based upon the evaluation of water level differences between adjacent cells, the representation in (Equation 2) may affect the way in which water diffuses across the floodplain. With a coarser mesh, when wetting starts, there should already have been flow into (and storage within) the cell. This will have implications for outflow fluxes, with potentially more rapid diffusion of a flood wave than under (Equation 1). However, if the cell is partially wet, then flux cannot occur across all grid cell faces. Thus it is also necessary to look at a sub grid-scale treatment for cell fluxes (see below).

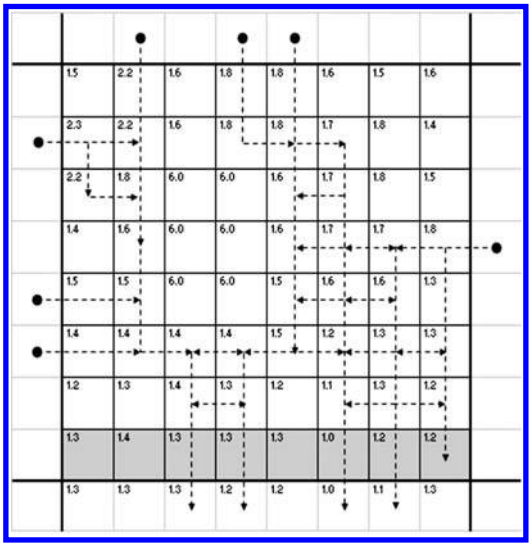

Figure 3. Evaluate the porosity of the bottom side (shaded sub-grid cells) of a model cell with a 1:8 sub-grid ratio through sub-grid connectivity. Numbers in each sub-grid cell are the water surface elevations. Dotted lines with arrows are flow paths and dots are connected flow sources for the sub-grid cells to be evaluated. Five sub-grid cells along this side of the model cell are internally connected to the other three sides and seven sub-grid cells are externally connected in the example. Porosity of this side of the model cell is thus 1/2.

2.2 *Cell flux effects*

We represent cell flux effects using a porosity type treatment which has proved to be a powerful means of representing sub grid scale topographic effects in river flows (e.g. Olsen & Stokseth, 1995; Lane & Hardy, 2002; Lane et al., 2002; Lane et al., 2004) and for representation of wetting and drying processes in depth-averaged hydrodynamic models of floodplain inundation (e.g. Bates, 2000; Bates & Hervouet, 1999). Consider two adjacent grid cells labelled 1 and 2. The first step is to establish a set of rules that determine when flux can occur across the common face of cell 1 and 2, and this has to be done in both directions (i.e. for flux from cell 1 to 2 and from cell 2 to 1). A porosity term is set based upon the percentage of cells that will be able to flux from cell 1 to 2, which varies as a function of water surface elevation. The porosity of each side of the cell is determined by: (i) the internal sub-grid cell connectivity of each sub-grid cell along this side; and (ii) the external sub-grid cell connectivity of each sub-grid cell along this side. Consider the porosity of the bottom side of a model cell with a $1:8$ sub-grid ratio as shown in Figure 3. First, each sub-grid cell along this side is evaluated to check whether it is connected to the other three sides of the model cell (top, left and right sides in Fig. 3). This is based upon the water surface elevation of the sub-grid topography. Dotted lines are the connectivity paths for the sub-grid cells. No rules are defined as to the external connectivity of the sub-grid cells along the connected sides. Second, if a sub-grid cell is connected to the other three sides based on (i), this cell is further evaluated to check whether its water surface elevation exceeds that of its adjacent sub-grid cell. If a sub-grid cell is evaluated to meet (i) and (ii), it is accounted as a connected cell.

If the number of sub grid-scale cells along a common face is l, there will always be $l-1$ values of porosity between zero (no flux across that face) and one (flux across all of the face), and the values of porosity will be multiples of $1/l$. In Figure 3, five sub-grid cells are internally connected to the other three sides and seven externally through the bottom side. Among these, four cells meet both (i) and (ii). Thus, porosity of the bottom side is ½. Flux from this side out to the bottom side is calculated by Manning Equation and further scaled by the porosity of this side explicitly.

One additional correction is introduced. As the flux is a non-linear function of water depth (from the Manning equation), then we need to make sure that the correct water depth is used in the evaluation of flux.

Copyright © 2006 Taylor & Francis Group plc, London, UK

This is done by determining an effective depth for the flux, based upon:

$$d_e = \sqrt[3/5]{\frac{\sum_{i=1}^{n} d_i^{5/3}}{n}} \quad (4)$$

where n is the number of sub-grid cells that are wet along the outflow side of the modelling cell and d_i is the effective depth of the individual sub-grid wetted cells along the outflow wall of the modelling cell. If flux occurs across one sub grid cell face, then the flux evaluated using (4) with the porosity scaling gives the same flux as if a mesh set at the sub grid scale resolution was being adopted. This is not the case when more than one sub grid scale flux occurs because of the non linear form of the depth-flux relationship in the Manning equation. However, provided the topographic variability within fluxing sub grid scale cells is small then the error is small, and the weighting used in (4) further reduces this error.

2.3 *Summary*

In summary, this sub grid cell treatment should represent a simple method for improving the representation of structurally complex topography within two-dimensional diffusion wave modelling. In particular, it should reduce the dependence upon mesh resolution noted by Yu and Lane (2006), especially in dynamic rather than steady state solutions. It differs from the wetting and drying parameter developed by Bradbrook et al. (2004) and used by Yu and Lane (2006) in that the wetting and drying parameter represents an empirical means for dealing with mesh resolution effects whereas the approach used here is explicitly grounded in rules that are locally evaluated in relation to information on the sub grid scale topography in a particular grid cell. In the next section, we evaluate the effects of this development upon sensitivity to mesh resolution within a flood inundation model.

3 MODEL TESTING

This approach described above was assessed using the same flood event as described in (Yu & Lane, 2006). Topographic data processing, validation data and the approach for establishing the connectivity between the river channel and floodplain are described in that paper and are not further covered here. Model time steps and inflow data were also set up in the same way. The model was run using four different spatial resolutions: 4 m, 8 m, 16 m; and 32 m. First, the approach in Section 2 is tested by running the 32 m simulation with different sub-grid ratios (4 m, 8 m and 16 m) using an artificial inflow hydrograph for five hours. Inflow for each bank cells is set constantly at $0.01/m^3s^{-1}$ throughout the simulation. This guarantees the same amount of flux on the floodplain for each simulation. The purpose of these simulations is to investigate the effect of using different orders of sub-grid ratio (32 m: 4 m, 32 m: 8 m and 32 m: 16 m). The inundation extents are compared with the 4 m simulation using the original wetting approach (Bradbrook et al., 2004) at each time step for the whole simulation. Model performance is assessed using a measure of fit (F) for wet cells to compare the model predicted inundation extent with the validation dataset (e.g. Horritt and Bates, 2001; Horritt and Bates, 2002). In terms of a contingency matrix, F is defined by:

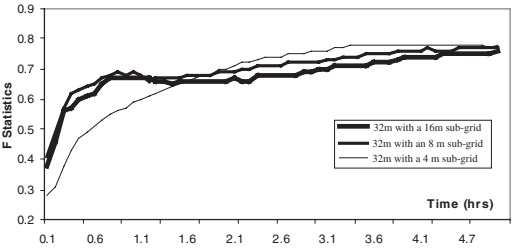

Figure 4. F statistics over time for simulations of different sub-grid coarsens ratios, using 4 m results as reference.

$$F_i = \frac{n_{ii}}{n_{i+} + n_{+i} - n_{ii}} \quad (5)$$

where n_{ii} is the number of cells both observed and predicted as wet, n_{i+} is the number of cells observed as wet, and n_{+i} is the number of cells predicted as wet. The F Statistics for wet cells obtained from simulations of different sub-grid ratios are shown in Figure 4.

The F statistic in Figure 4a suggests that the effect of the higher- order sub-grid treatment is more pronounced during the initial wetting process (first 1.5 hrs). However, the lower-order sub-grid treatment seems to perform better than the higher-order ones later in the simulation. In general, 32 m simulations using 4 m and 8 m sub-grids produce better resemblance to the 4 m results during the initial wetting process, compared with a 16 m DEM as sub-grid. This is an interesting finding as we would expect that a simulation with high-order sub-gird topography ratio will produce better results when compared with the 4 m simulation. However, we don't really know how the original 4 m simulation and 32 m simulation with 4 m sub-grid perform with regard to what happens in the real world. Indeed, for this type of model, others (e.g. Bates & Anderson, 2001) haves suggested that surface velocity might be a more reliable way for model validation. It is clear from these simulations that, there is no immediate benefit of using high orders of sub-grid ratios if the initial wetting process is not going to be examined with real world data.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Given the above, we restricted consideration of sub-grid treatments to a coarsening ratio of 2 : 1 (i.e. we used the sub grid-scale treatment to represent the effects of coarsening: a 4 m mesh to 8 m; an 8 m mesh to 16 m; and a 16 m mesh to 32 m) and apply this approach using the real hydrograph for the flood event. At this point, we used $n = 0.04$ throughout. As with Yu and Lane (2006) the focus of model testing combines both validation and verification. For the purposes of validation, we use the at-a-point in time data at c. 300 hours in the November 2000 flood (see Fig. 2b in Yu & Lane, 2006). Following Yu and Lane (2006), we use a method adopted from remote sensing (Congalton & Green, 1999) to assess model predictions. This sets up model output as a contingency table and calculates the overall accuracy, F (following Bates & Horritt, 2002) Kappa and conditional Kappa from these data (Table 1). As noted by Yu and Lane (2006), reliance upon data from single time periods can give a misleading assessment of model performance, especially where, as in this case, we are interested in reproducing the correct diffusion of inundation through time. Thus, we also undertake verification, and compare the original 8 m, 16 m and 32 m simulations with the 8 m, 16 m and 32 m sub grid model simulations as well as the default 4 m simulation. We also consider the original and sub grid models with different values of n to compare the effectiveness of using n to represent sub grid scale topographic effects with the explicit sub grid treatment. As the focus is the sub grid treatment, we hoped to reduce dependence upon high values of n. Thus, in the first instance, we used $n = 0.04$, 0.06, 0.08 and 0.1; but also undertook simulations with much higher values of n; 1.0 and 10.0; following the findings of Yu and Lane (2006).

4 RESULTS

4.1 *Inundation patterns through time*

Figures 5, 6 and 7 show the first 40 hours of model simulation, with and without the sub grid-scale treatment. It is clear that, in all cases, there is a significant reduction in the rate of inundation diffusion with the sub grid-scale treatment. Figure 5a shows inundation of the confined floodplain by 30.5 hours with the original treatment. With the sub grid treatment, this increases to 40 hours (Fig. 5b), and it is clear that the sub grid treatment has a major impact upon the timing of inundation. The conclusions made regarding the effects of the 8 m sub grid-scale treatment (Fig. 5) are mirrored in the 16 m and 32 m treatments. Flow diffuses much more rapidly in the 16 m (original) case than in the 16 m (sub grid-scale) case (Fig. 6), with almost complete inundation at 30 hours (original case) compared with 36 hours (sub grid-scale). The 32 m (original) case results in extensive inundation within the first

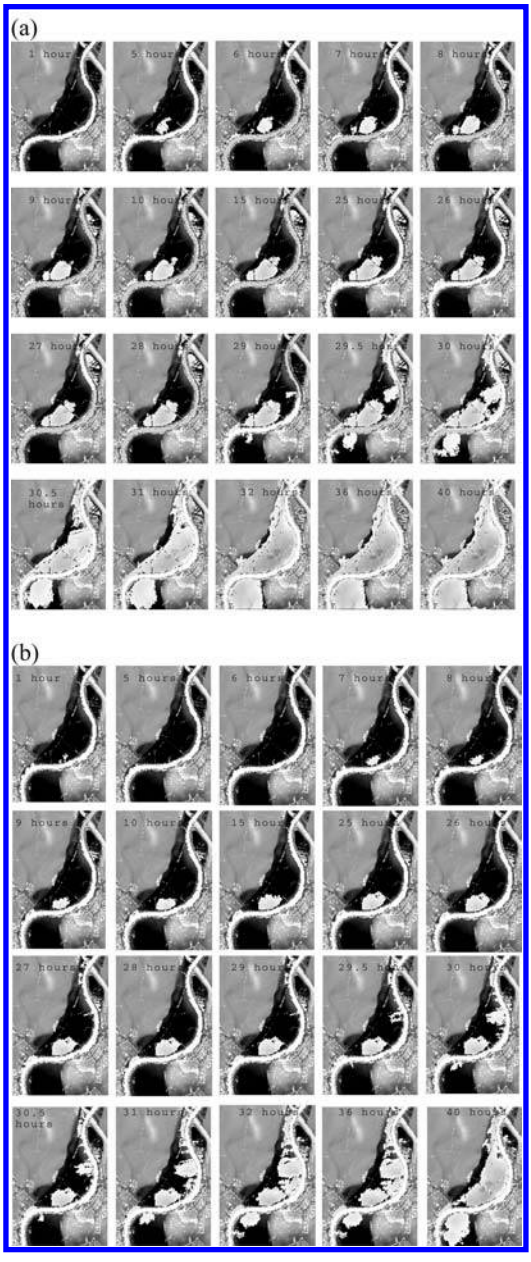

Figure 5. Comparison of the time series inundation extents during the wetting process in the first 40 hours for (a) the original diffusion model; and (b) the sub-grid treatment model; using an 8 m resolution DEM.

10 hours of simulation whereas the 32 m (sub grid-scale) case does not have inundation until c. 31 hours. It seems that, for the first part of the hydrograph, the sub grid-scale treatments delay the inundation process.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Figure 8 shows the effects of the sub grid-scale treatment upon inundated area with $n = 0.04$. This shows that not only do the sub grid-scale treatments reduce the speed of inundation (Figs 5–7) but also the maximum inundation area for all mesh resolutions at all time periods. The original hydrograph had multiple water level peaks. With the 32 m mesh resolution mesh, inundated area responded rapidly to fluctuations in water level, with multiple flood peaks evident in the

inundated area. In the absence of a sub grid-scale treatment, these fluctuations are present in both the 16 m and the 8 m inundated area records. With the sub grid treatments, the inundated area is much less responsive, with response only evident between the third and the fourth water level peak in all sub grid treatments. The sub grid treatments also reduce the total inundation area at all time periods. The differences are quite substantial, especially for the coarsest mesh resolution.

The obvious question that emerges from the above simulations is whether or not the reduced speed of flood wave inundation and the reduced flood inundation extent that is obtained with the sub grid-scale treatment is an improvement over the original diffusion wave formulation. This is addressed with respect to the remotely-sensed validation data and the original 4 m simulation in the next two sections.

4.2 *Model validation*

Table 1 shows the results of the accuracy assessment with the four mesh resolutions simulated and with the three sub grid scale treatments applied to the three coarser mesh resolutions. Table 1 confirms, that as the mesh is coarsened from 8 m to 32 m, all of the accuracy statistics suggest progressively poorer model performance. However, there is an anomaly in that the 4 m resolution only gives the best results for overall accuracy, and performs significantly less well in term of the F statistic. In all cases, Table 1 shows that the sub grid scale treatment improves the level of agreement over the original case. For the 8 m mesh resolution, the improvements in overall accuracy, Kappa and F are small. However, the conditional Kappa improves substantially. The sub grid scale treatment has a progressively greater effect at coarser mesh resolutions with large improvements in F and conditional Kappa at 16 m and in all accuracy statistics at 32 m. Given the discussion in Yu and Lane (2006) of the problems of these types of accuracy measures, reliance on absolute values, from at-a-point in time data, must be treated with caution. What matters here is that, in every case, the sub grid-scale treatment improves the level of agreement as compared with the original diffusion model.

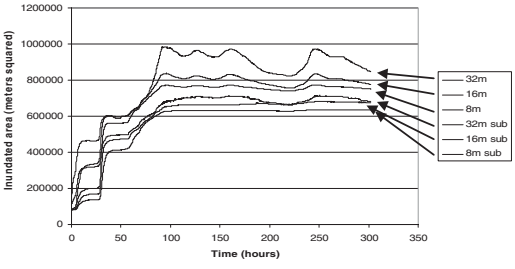

Figure 8. Predictions of inundated area against time for the first 300 hours of model simulation for three mesh resolutions with both default treatments and sub grid-scale treatments.

4.3 *Model verification*

In order to extend the assessment of model performance to a larger number of time steps, accuracy statistics (overall accuracy, Kappa and conditional Kappa) were determined for the first 60 hours by comparing a range of mesh resolutions, with and without sub grid-scale treatments, to the 4 m case (Fig. 9). In all cases, n was held constant at 0.04. The overall accuracy statistic reduces through time (Fig. 9a), reflecting the fact that this statistic is strongly dependent upon the initial number of dry cells used in the comparison and, at the start of a flood event, that both the 4 m and the coarsened mesh and sub grid-scale treatments will both have a larger number of dry cells.

However, Figure 9a shows that use of the sub grid-scale treatment improves agreement with the 4 m case, as judged by overall accuracy. Use of the Kappa

Table 1. Accuracy assessment based upon comparison of model predictions with different mesh resolutions and with and without the sub-grid treatment. The validation data are based upon remotely-sensed imagery obtained at 300 hours during the hydrograph shown in Yu and Lane (2006).

	4 m	8 m	16 m	32 m	8 m sub grid scale treatment	16 m sub grid scale treatment	32 m sub grid scale treatment
Overall accuracy	86.6	87.3	83.4	71.3	88.1	85.6	81.0
Kappa	73.6	75.5	69.6	50.7	76.8	73.5	67.0
F	76.4	78.5	75.0	61.3	80.0	80.4	75.0
Conditional Kappa for wet areas only	66.2	74.0	63.2	40.9	89.5	78.4	65.3

Copyright © 2006 Taylor & Francis Group plc, London, UK

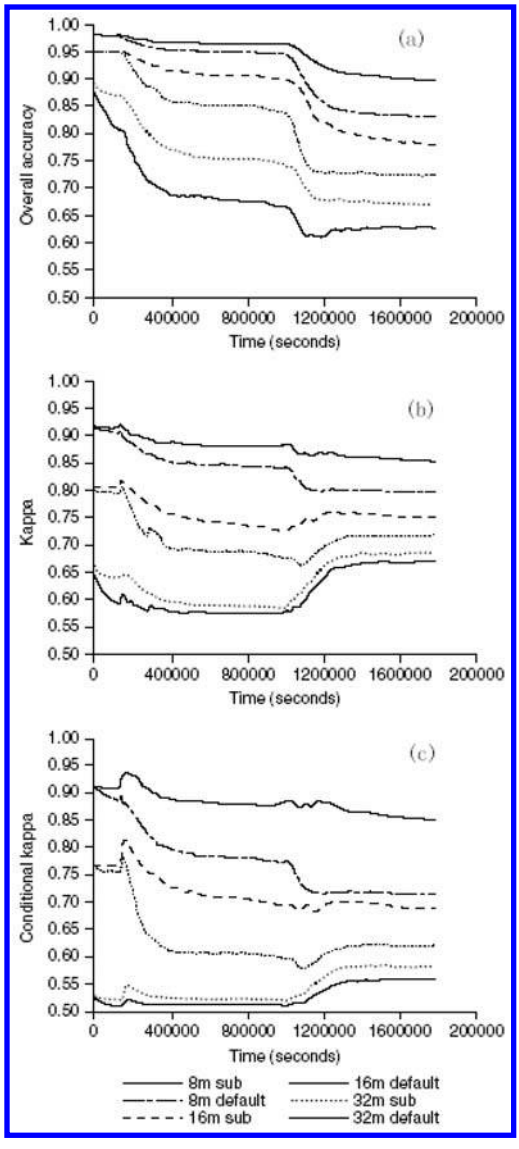

Figure 9. Accuracy statistics (overall accuracy, Kappa and conditional Kappa for wet cells only) determined for model simulations at 32 m, 16 m and 8 m, with and without a sub grid treatment. These are determined as a function of time, taking the 4 m solution without a sub grid treatment as 'true' for verification purposes.

statistic, rather than the overall accuracy, reduces bias in contingency table analyses (Congalton & Green, 1999), although it does not remove completely the dry-bias effect in flood inundation model assessments. Figure 9b confirms that the 32 m and 16 m simulations are more degraded as compared with the 4 m predictions than the 8 m degradation as compared with the 4 m predictions. The sub grid-scale treatments are then most effective in the 8 m case and least effective in the 32 m case. A much more reliable accuracy measure is provided by a conditional Kappa statistic which, in this case, restricts the analysis of the contingency table to only those cells that are predicted as wet. Figure 9c shows the conditional kappa and demonstrates that the sub grid-scale treatment results in a substantial improvement in model accuracy in the 8 m case as compared with the 4 m simulation. It appears that, in all cases, using the sub grid-scale treatment with the 8 m resolution mesh results in a significant improvement in model accuracy, however judged, but that this improvement is reduced at coarser mesh resolutions. This is not surprising as we are only using sub grid-scale topographic data from the 2×2 cells at the next finer resolution (e.g. the 32 m simulations make use of a 16 m DEM). It should be noted that, for the conditional Kappa results (Fig. 9c), accuracy of the 32 m sub grid treatment with respect to the 4 m simulation approaches that of the 16 m no sub grid treatment towards the latter half of the simulation and the 16 m sub grid treatment approaches that of the 8 m no sub grid treatment.

4.4 *Comparison of calibration using Manning's n with sub grid-scale treatment*

The above two sections showed a significant improvement in model predictions through adopting the sub grid-scale treatment in terms of reproducing the time-dependent change in flood inundation. This section compares a more traditional approach to representing sub grid-scale topographic variability based upon calibration using Manning's n by using a sub grid-scale treatment. This is undertaken in terms of both: (1) the inundated area versus time plots; and (2) accuracy statistics, as compared with the 4 m data, reported in the above section. As reported by Yu and Lane (2006), Figure 10a shows that for the 8 m case, there is relatively low sensitivity to Manning's n until $n >> 0.1$. Whereas the sub grid-scale treatment almost exactly recovers the inundation area versus time plot with $n = 0.04$, with $n = 1.0$, the area-time curve almost lies on the 4 m line, but deviates significantly after c. 140000 s. The area-time plot is not recovered as well with the 16 m (Fig. 10b) and 32 m (Fig. 10c) sub grid-scale treatments, although they are still a significant improvement on all values of n without a sub grid-scale treatment. In particular, whilst the area may be correctly estimated with calibration through n alone at certain times during the simulation (e.g. with $n = 10.0$ and a 32 m mesh resolution at c. 120000 s), even with high values of n (> 1.0), the inundated extent exceeds the 4 m inundated extent by the end of the time period.

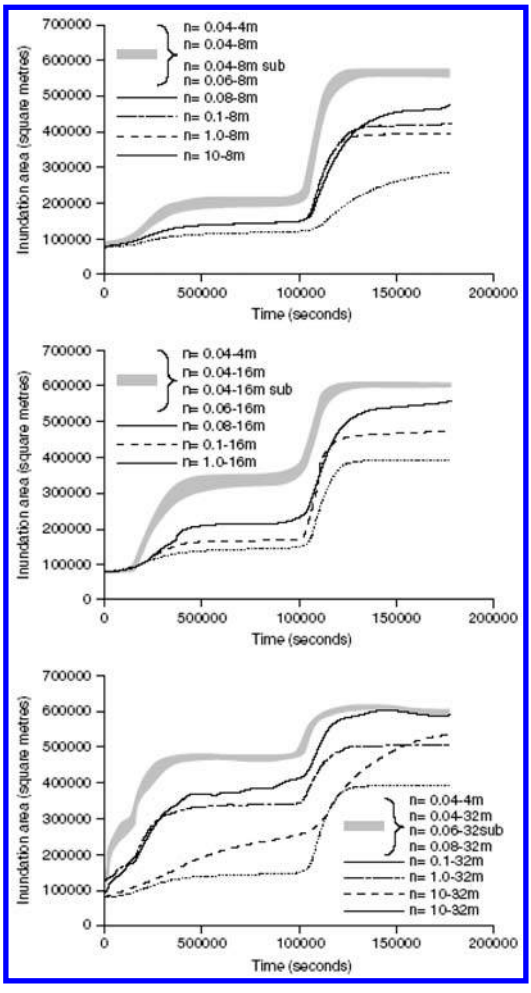

Figure 10. Plots of inundation area versus time for the first 60 hours of simulation, with different mesh resolutions and values of *n*.

5 DISCUSSION

A number of key points emerge from the above results. First, and most importantly, the results show that the sub grid treatment is effective in reducing simulation dependence upon mesh resolution. The sub grid treatment reduced the speed of inundation in the early part of the flood wave (Figs 5–7) and also the maximum inundated area for all mesh resolutions at all time periods (Fig. 8) with a markedly reduced sensitivity of inundated area to water level fluctuations in the main channel. Second, the model used only the immediately finer DEM in parameterising the sub grid treatment (i.e. the 2 × 2 DEM cells in the finer DEM). This was reflected in the comparisons with the 4 m simulations, where degradation to 8 m, with a sub grid treatment, produced the best accuracy statistics through time. It was also reflected in the inundation-time plots, where the 16 m and 32 m sub grid treatments were progressively less effective in reducing inundated area through time back to the 4 m plots. Using a 16 m DEM (i.e. with 8 m sub grid data) and a 32 m DEM (i.e. with 16 m sub grid data) progressively degraded the accuracy statistics derived with respect to the 4 m data. Further research should explore whether using sub grid topographic data with 4 × 4 cells (in this case with 32 m and 16 m meshes) and 8 × 8 (in this case with a 32 m mesh) cells results in accuracy assessment results that approach the 8 m sub grid treatment.

Third, and as expected, the effective value of *n* required to reproduce the 4 m data reduces as mesh resolution is fined. It should be emphasised that this questions the extent to which field estimated values of *n* can be used to parameterise a model such as this. It reinforces the point that *n* is an effective parameter, not only in relation to the sub grid-scale topographic variability but also in relation to decisions being made about how to discretise a model. Any guidance that is provided to assist with roughness specification for floodplain flow should be oriented towards the role of roughness and mesh resolution in the calibration process as well as to how it should relate to the surface of the floodplain under consideration.

However, these simulations (Fig. 10) also showed that *n* alone was not effective in reproducing the inundation-time plot and, although there were some time periods when using very high values of *n* gave a reasonable estimation of inundation for a short period of time, the shape of the area-time plots with high values of *n* with coarser mesh resolutions was often very different to that found with finer mesh resolutions. Introduction of the sub grid treatments was more effective than *n* perturbation in recovering the inundated area-time plot. However, use of the sub grid treatment in turn changed the interaction between model predictions and *n*. In general terms, the model became more sensitive to *n*. This is not surprising as implicit in the sub grid treatment developed here is incorporation of the effects of sub grid scale depth variability, which given the form of the Manning equation will result in greater sensitivity to *n*. The combination of *n* calibration with the sub grid treatment resulted in the best accuracy statistics, aided by a generally increased sensitivity to *n*. This suggests that combining the sub grid treatment with optimisation of *n* may produce optimal model predictions on a coarse mesh but, and more importantly, coarser mesh predictions with the sub grid treatment are more reliable at reproducing the 4 m patterns than those without. This is regardless of whether or not any optimisation using *n* is undertaken.

The obvious question is whether or not all of this matters in terms of applying diffusion wave models to

Copyright © 2006 Taylor & Francis Group plc, London, UK

floodplains that are complex, such as those found in urban areas. The prime effect of changing mesh resolution is to change the timing of flood inundation. The sub grid treatments result in better model validation (Table 1). When taken in combination, this suggests that if the timing of inundation is not right, then it may be difficult to get the inundated area right, whether at the peak flow, or some other point on the hydrograph. This is an important point for any situation where the floodplain is not laterally-confined in relation to the water level associated with the peak inundation extent.

6 CONCLUSION

This paper has described a treatment for representation of the effects of topographic variability at the sub mesh scale. This is based upon explicit representation of sub grid-scale topographic effects through treatment of both sub grid blockage and flux effects. Results suggest that, when using a coarser mesh, this treatment is much more effective than optimization using Manning's n, in terms of both: (1) validation data derived from aerial imagery at a single point on the falling limb of the hydrograph; and (2) recovering the inundated area-time plot obtained with a finer resolution mesh. As the ease with which topographic data are measured and processed is progressively increased, this type of approach should allow diffusion wave models to be applied over very long river reaches whilst still making use of the high resolution of topographic data that can now be acquired.

ABSTRACT: The paper presents an experimental investigation of the flow in a compound channel with symmetrically enlarging floodplains. These results complement previous work on symmetrically narrowing floodplains. Both these data sets enable a better understanding of the mass and momentum transfer occurring in non-prismatic compound channels, without facing the complexity of a fully meandering geometry. The new experiments show that, in this diverging geometry: (1) the flow expends on the floodplains with a significant shift in the downstream direction, with the discharge on the floodplains significantly lower than their conveyance capacity in a prismatic compound channel with the same cross section; (2) the lateral distribution of velocities presents a large gradient from the interface between subsections to the floodplain lateral bank; and (3) in some large discharge cases, the flow behaves like a jet, with the maximum velocity filament oscillating from one main-channel bank side to the other, and recirculation zones developing on the floodplains.

1 INTRODUCTION

Flow modelling in a river flooding overbank is challenging for the engineer. Compound channels present a complex flow behaviour that affects significantly the conveyance prediction. In a prismatic compound channel, the flow velocity is generally larger in the main channel than on the floodplain, thanks to a larger flow depth and a lower flow resistance. A shear layer develops at the interface between both subsections and transfers momentum from main channel to floodplains, reducing accordingly the total channel conveyance. In non-prismatic channels, due to the geometrical changes, a mass transfer appears between subsections that increases the momentum transfer.

Both these effects have to be modelled when attempting to predict stage-discharge curves or water surface profile and flooded areas for a flooding river.

The flow interaction in a prismatic compound channel has been investigated intensively, with large experimental campaigns in the last 20 years. Improved modelling methods resulted from this laboratory work (e.g. Ackers, 1993; Shiono & Knight, 1991; Bousmar & Zech, 1999). Flow in non-prismatic channels was also investigated in laboratory flumes, focusing mainly on meandering compound channels. Similarly, improved modelling methods were proposed (e.g. James & Wark, 1992; Greenhill & Sellin, 1993; Ervine et al., 2000).

Unfortunately, apart from the Exchange Discharge Model (EDM) developed by Bousmar & Zech (1999), and to a certain extend the method by Ervine et al. (2000), the methods dedicated to prismatic channels can not be applied to non-prismatic geometries, and, reciprocally, the methods dedicated to non-prismatic channels are not usable in prismatic channels.

In an attempt to bridge this gap between prismatic and non-prismatic channel modelling, Bousmar et al. (2004a) have designed experiments where the floodplains width reduces symmetrically, highlighting mass-transfer effects, without the influence of meanders. This paper presents the results of a mirror set-up, where both floodplains are symmetrically enlarging.

2 PREVIOUS WORK

Most of the experimental work on non-prismatic compound channels has been devoted to meandering geometries. The main characteristics of such flows

Copyright © 2006 Taylor & Francis Group plc, London, UK

were already highlighted by Toebes & Sooky (1967): (1) a shear layer develops in a horizontal interface between main channel and floodplains, at the bankfull level; (2) large rolling motion, or helical secondary circulation, develops in the main channel in the cross-over region; and (3) the total head loss increases significantly when compared to an equivalent prismatic geometry. These observations were later confirmed and completed by further works (e.g. Sellin et al., 1993; Lambert & Sellin, 1996; Shiono & Muto, 1998).

A simpler geometry was investigated by Elliott & Sellin (1990) and Jasem (1990) with a prismatic main channel skewed to a prismatic floodplain. This situation reproduces adequately the flow in the cross over region of a meandering channel: similar horizontal shear layer and rolling motion are observed.

Experiments focusing more on the mass and momentum transfer mechanisms than on the full complexity of a meandering channel were performed by Bousmar (2002) and Bousmar et al. (2004a): symmetrically narrowing floodplains force flow from the floodplains to the main channel (Fig. 1a–b). Thanks to the symmetry, no centrifugal effect is observed as in meandering geometries. On the other hand, horizontal shearing and helical secondary currents were reproduced. The additional head loss due to the mass transfer was estimated. Its value was in several cases as large as the friction loss. Additional investigations were done using digital imaging to record surface velocities (Bousmar et al., 2004b). The horizontal turbulent structures that develop in prismatic channels were shown to stretch in the converging reach, and their influence on the momentum transfer mechanism decreased rapidly.

Lastly, an asymmetric geometry with a more abrupt convergence was also investigated (Rivière et al., 2002; Proust, 2005; Proust et al., 2006). Larger mass transfer and head loss resulted from the higher convergence angle (22°). The analysis also showed that the head presented distinct evolutions in each subsection. Similar investigations were also initiated for groynes perpendicular to the bank, considered as a limit for the progressive convergence and divergence cases explored in this paper (see e.g. Rivière et al., 2004; Proust, 2005).

3 EXPERIMENTAL SETUP

The experiments were performed in a 10 m long, 1.2 m wide compound channel flume, at the Université catholique de Louvain, Belgium. The bed slope was set up at $S_0 = 0.99 \times 10^{-3}$. The flume bottom was shaped with a symmetrical cross-section made of coated plywood. A main channel, 400 mm wide and 50 mm deep, was flanked by two floodplains 400 mm wide. Movable vertical plywood banks were used to modify

floodplains width, in order to reproduce progressive narrowing (Fig. 1a-b) or enlargement (Fig. 1c–d).

For selected discharges, the downstream tailgate was adjusted to fix the water level to given values at mid-length of the converging/diverging reach. The flow conditions investigated by Bousmar et al. (2004a) and in this paper are summarized in Table 1, where $H^* = (H - h_f)/H$ = relative flow depth; H = total flow depth in main channel; and h_f = bank full depth. As will be discussed below, using such given values of H^* at mid convergence/divergence enables useful comparison of velocity and discharge distributions between

the different geometries and with the reference prismatic case (Fig. 1e).

Water levels were recorded using an automatic point gauge mounted on a trolley. Velocities were measured with a 4 mm diameter Pitot tube, and velocity directions were recorded with a home-made flag-type element. Additional local velocity measurements were obtained with a Nortek NDV acoustic Doppler probe, but results are influenced by the large size of the probe compared to the actual flow depth. The total discharge was measured with an electromagnetic flowmeter. Lastly, some surface velocity measurements were performed using tracers and digital imagery. Details on this method are available in Bousmar et al. (2004b).

4 EXPERIMENTAL RESULTS

4.1 *Flow description*

Figure 2 shows the water surface profile recorded for all Dv6 and Dv4 series. These profiles appear grouped, as the flow depth is fixed at mid-length of the diverging reach ($x = 5$ m for Dv6, $x = 4$ m for Dv4). In all cases, the flow depth increases gradually in the diverging reach, as the section is enlarging and the mean velocity is decreasing. In the upstream prismatic reach (isolated main-channel), the flow depth is generally decreasing (M2 profile) as the depth at the entrance of the non-prismatic reach is lower than the uniform depth for the given discharges. As will be depicted below, the Froude number was in some cases close or even locally larger than 1.

At the junction of prismatic and non-prismatic reaches, surfaces waves (cross-waves) were generated by the non-smooth transition. These waves are particularly visible for the larger discharge ($Q = 20$ l/s), with significant scattering of the water level measurements. Transverse water surface profiles were also recorded, but did not revealed significant transverse surface gradient compared to the cross-waves amplitude.

Depth-averaged velocity U_d distributions are given on Figure 3 for several Dv4 cases. As expected from the water profile analysis, the maximum velocity is decreasing in the downstream direction, as the cross-section area increases. The depth-averaged velocity is almost constant across the main-channel width, and decreases linearly on the floodplain, from the main-channel bank to the floodplain bank. This gradient corresponds to a progressive intrusion of the flow on the floodplain: as depicted by Figure 4 where almost uniform transverse velocity is observed on the floodplains.

For the lower discharge ($Q = 12$ l/s, Fig. 3a–b), a progressive growth of the floodplain velocity is

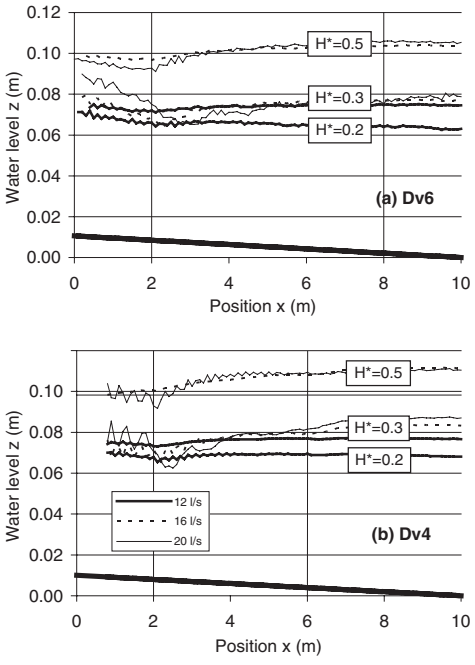

Figure 2. Water surface profiles. (a) Dv6; and (b) Dv4 series.

observed in the downstream prismatic reach, from $x = 6$ m to $x = 8$ m, as a result of this transverse flow. For larger discharges (Fig. 3c–d), this growth is masked by a significant asymmetry of the flow, that will be discussed in the next paragraph.

The uniformity of the depth-averaged velocity observed in the main channel is also observed for the local longitudinal velocity component (Fig. 4a–c). The analysis of the transverse velocity component (Fig. 4d–f) indicates that the helical secondary current cells observed in the main channel of prismatic and converging geometries (flow from bank to axis at water surface and from axis to bank at bottom) do not appear for the diverging case.

Although the transverse velocity components were not measured for all the Dv6 experiments, the distribution of longitudinal velocity for Dv6/03/16 case (Fig. 5) tends to indicate the existence in that case of a secondary current cell with reverse rotating direction when compared to the converging case. Low velocity water seems to move upward from the main channel axis, as shown by the local velocity minimum at the surface.

To conclude this first analysis, based on time and depth-averaged velocities, the velocity distributions of all the diverging series are compared at mid-length of the diverging reach. For this purpose, normalised velocities are obtained by dividing the velocities U_d

by the total discharge Q. Figure 6 shows that the velocity distribution is almost the same in the main channel for a given flow depth $H*$. Differences are observed on the floodplains, partly due to a flow asymmetry, but also, for the larger discharge ($Q = 20$ l/s), to a lower floodplain velocity. Lastly, the main channel velocities are more uniform for Dv4 series than for Dv6: this could indicate lower secondary currents for the shorter diverging reach, where the mass transfer could be too large for such currents to fully develop.

4.2 *Dynamic behaviour of the flow*

Flow asymmetry has been highlighted from the depth-averaged velocity distributions. An improved description of this asymmetry can be obtained from digital imaging. Using automatic tracking of surface tracers, the local surface velocities can be computed from the video sequence (see e.g. Bousmar et al., 2004b). Considering the almost constant velocity profile on a vertical (Fig. 4a–c), the ratio between surface and depth-averaged velocities was computed where the latter were available. This ratio was then interpolated on the whole flow field and the depth-averaged velocity field obtained accordingly from the surface recording.

Figure 7 shows the so-computed velocity field for Dv4 series. The main features observed in the velocity distribution in given cross-section (Fig. 3) are also confirmed when considering the whole velocity field: (a) an almost uniform velocity in the main channel; (b) a linear gradient on the floodplain; and (c) a flow asymmetry for the larger discharges.

The analysis of the whole flow field enables a better description of this asymmetry. The main channel flow tends to behave as a jet in an enlarging channel. Instabilities appear and the maximum velocity filament oscillates from one main channel bank to the other. In almost all the cases, recirculation areas develop intermittently, mainly on the right floodplain ($y > 0.8$ m). Such a recirculation causes a delay to the flow expansion on the floodplain and the growth of time-averaged floodplain velocity.

Although instabilities cause the flow to be asymmetric, it remains more stable than a classical jet flow. Indeed, the maximum velocity is confined by the main channel banks. Moreover, the maximum floodplain velocity is generally on the left floodplain. This permanent asymmetry is expected to be due to slight geometry unevenness. Modifying the tailgate horizontality by 0.5° enabled to force the maximum velocity to the other bank.

For the Dv6 series, such jet behaviour was not observed. The opening angle $2\alpha = 7.6°$ was probably low enough to avoid recirculation development. Tentative tests were also attempted with a Dv2 series (2 m diverging reach, $2\alpha = 22.6°$). In that case the recirculation development and the oscillations of the jet were so high that time-averaged measurement of water level and velocities was too tedious. The Dv4 series was thus preferred as being more stable.

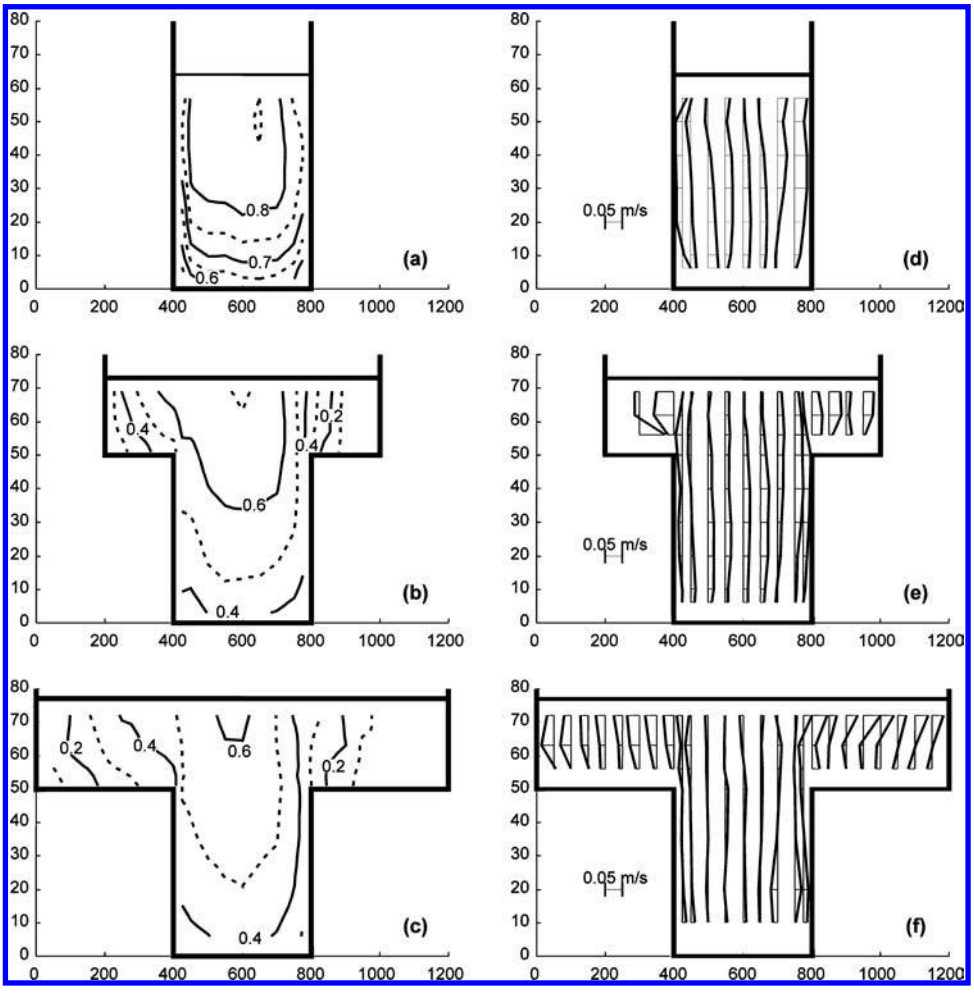

Figure 4. Velocity distribution in a $y-z$ section, Dv4/03/16 case. (a–c) Longitudinal velocity components (m/s); (d–f) transverse velocity components (m/s); (a, d) $x = 2$ m; (b, e) $x = 4$ m; and (c, f) $x = 6$ m.

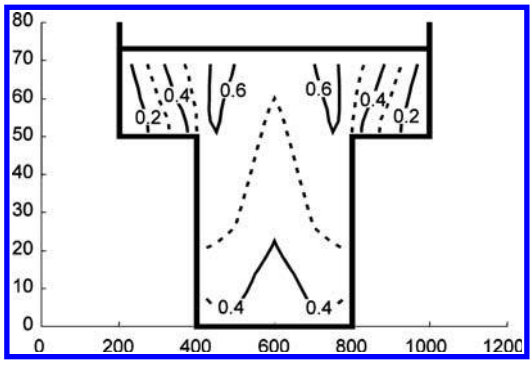

Figure 5. Longitudinal velocity components distribution (m/s) in a $y-z$ section, Dv6/03/16 case, $x = 5$ m.

It is also interesting to point out that the intensity of the oscillation and the asymmetry of the flow increase with the Froude number at the inlet of the diverging reach. This Froude number increases with increasing discharge Q and decreasing flow depth H^*. The larger Froude number is obtained for the Dv4/03/20 case. Figure 8 shows the local Froude number field computed from the depth-averaged velocity obtained by digital imaging. Supercritical Froude number are even observed on the floodplains close to the main-channel banks near the inlet of the diverging reach, where the velocities are the largest and the flow depth the lower. In this area, a small roll, similar to a longitudinal hydraulic jump, was visually observed on the floodplain but was not large enough to be recorded accurately.

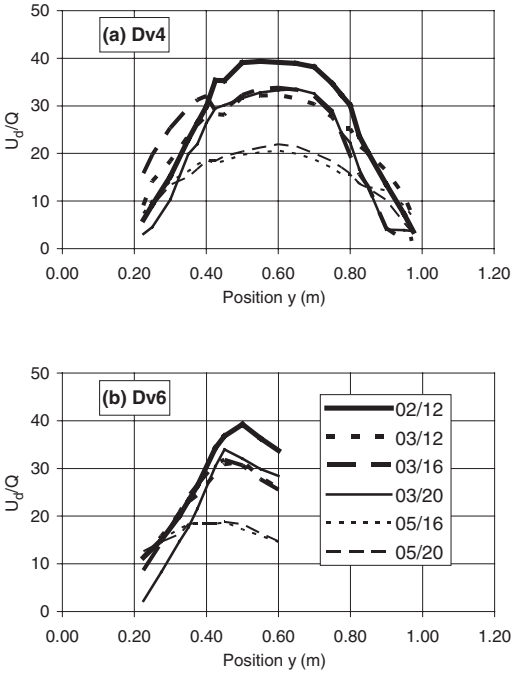

Figure 6. Depth-averaged velocity at mid-length of the diverging reach, normalised by the total discharge. (a) Dv4, $x = 4$ m; and (b) Dv6, $x = 6$ m.

4.3 *Discharge distribution*

The progressive flow expansion out of the main channel is interestingly represented by the discharge distribution between subsections. Figure 9 shows the floodplain discharge expressed as a ratio of the total discharge. This depicts clearly the progressive intrusion of the flow to the floodplain. The discharge distribution is clearly not yet in equilibrium 2 m downstream of the diverging reach ($x = 8$ m), and it can be expected that a much longer prismatic reach would be required to obtain equilibrium (Bousmar et al., 2005).

For $H^* = 0.5$, both cases ($Q = 16$ and 20 l/s) give a similar discharge distribution. For $H^* = 0.3$, the distribution for $Q = 20$ l/s differs from the two other cases, probably due to larger recirculation development. The effects of the recirculation and of the flow asymmetry are clearly depicted by Figure 10: the left and right floodplain discharges present large differences. In some case (Dv4/05/20), almost all the floodplain discharge is conveyed on a unique floodplain, with $Q_{fpl} = 90\%\ Q_{fp}$; where Q_{fpl} = left floodplain discharge.

With the subsection discharge values, it is also possible to compute specific energy $E = z + U_d^2/2g$, or head, for the total cross section and for separate

subsections. Typical energy profiles are given by Figure 11. In all the cases, the total energy decreases in the downstream direction, due to friction and momentum transfer generated head losses. The main channel energy also decreases, but slower. This indicates that a part of the total energy is used for accelerating the floodplain flow: the floodplain energy profiles are indeed growing from upstream to downstream, thanks to the momentum transferred by the flow from main channel to floodplain.

Figure 12 shows that the maximum turbulent shear stress in the xy plane is indeed observed at the interface between subsections, where this momentum transfer takes place.

5 COMPARISON WITH CONVERGING CHANNEL EXPERIMENTS

As depicted in the previous paragraphs, the flow in a symmetrically diverging channel presents significant

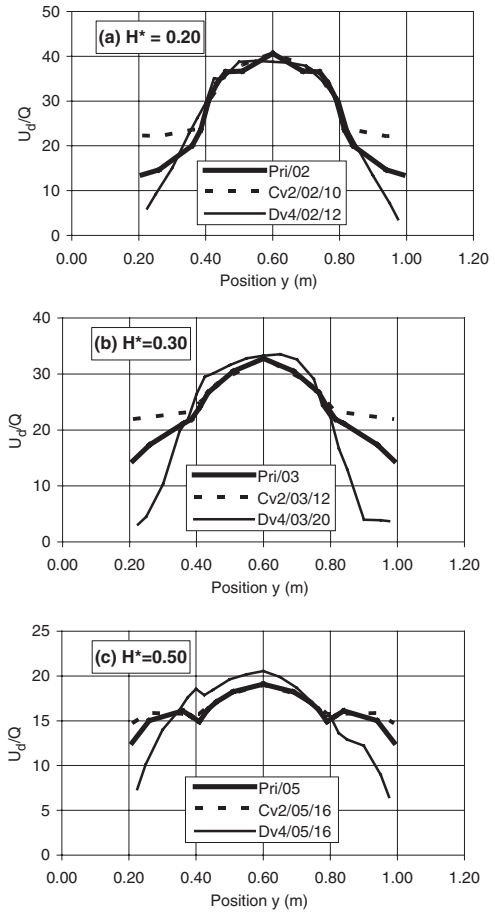

Figure 13. Typical depth-averaged velocity distribution at mid-length of the diverging/converging reach, normalised by the total discharge. (a) $H^* = 0.2$; (b) $H^* = 0.3$; and (c) $H^* = 0.5$.

differences with the flow in a symmetrically converging channel, but also some interesting similarities, mainly in the momentum transfer mechanisms.

Figure 13 shows typical velocity distributions, normalised by the total discharge, for converging and diverging geometries at given flow depth, together with the reference prismatic case (Pri series). The different flow behaviours are clearly depicted:

– In the prismatic case, the flow is dominated by a turbulent momentum transfer. A shear layer develops at the interface between subsections and generates a mild velocity gradient in both main channel and floodplain.
– In the converging case, the flow is dominated by mass transfers between subsections. Due to the floodplain width reduction and to the consecutive flow acceleration, the velocity is almost uniform across the floodplain. The main channel presents a velocity gradient, due to intrusion of slower floodplain flow through the interface (see also Fig. 15).
– In the diverging case, the flow is also dominated by the mass transfer. No inflow influences the main channel velocity distribution, which is almost uniform. On the other hand, a significant velocity gradient is observed on the floodplains. Moreover, as the flow is expanding, instabilities and asymmetry can be observed.

These observations are confirmed and complemented by the corresponding discharge distribution, as depicted on Figure 14. The floodplain discharge in the converging cases is generally slightly larger than for the corresponding prismatic geometry, with discharge distribution in equilibrium, due to a delay in the mass transfer towards the main channel.

On the contrary, the floodplain discharge is lower for the diverging cases. This downstream shift in the discharge distribution is due to the delay in the intrusion of the flow towards the floodplains. When

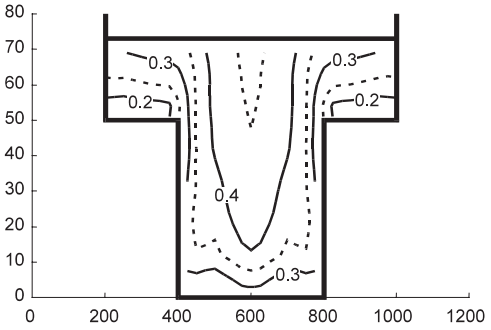

Figure 15. Longitudinal velocity component (m/s) distribution in a $y-z$ section, Cv2/03/12 case, $x = 5$ m.

compared to the converging cases, this delay is here larger, as the flow expansion induces asymmetry and even recirculation development that reduces the floodplain conveyance.

6 CONCLUSIONS

An experimental investigation of the flow in a compound channel with symmetrically enlarging floodplain has revealed the main features of such a flow: the distribution of velocity in the main-channel is almost uniform, while it presents a linear gradient on the floodplains. The floodplain discharge remains significantly lower than the actual conveyance capacity on a long distance. The flow also presents a significant asymmetry: the maximum velocity filament oscillate in the main channel and recirculation zones develop on the floodplains.

The experiments show that momentum is transferred from the main channel to the floodplains with the flow through the interface between these subsections. This transfer causes a decrease in the total head available in the section, and an increase of the local head in the floodplains.

As the momentum transfer between subsections also relies on mass transfer, the diverging geometry flow behaviour presents mirror characteristics with the mirror converging case: (1) the transverse velocity gradient is located on the floodplain and not in the main channel; (2) the discharge on the floodplains is lower and not larger than their conveyance capacity in a prismatic compound channel with the same cross section; and (3) the secondary current cells either disappear or present an inversed rotation direction.

ABSTRACT: Compound channel experiments with a mobile bed in the main-channel show that, under some bed-forms development conditions, the main-channel velocity decreases and can even become lower than the floodplain velocity. This results in a reversal of the momentum transfer between main-channel and floodplains. Most of the compound-channel discharge formulae have been developed for rigid bed data and are not suitable in such conditions. In this paper, the Exchange Discharge Model (EDM) is modified to account also for such a reverse momentum transfer. The improved EDM formula is tested against existing experimental data. The data are therefore re-analysed to express mobile bed roughness as a function of the main-channel discharge and to re-assess floodplain roughness parameter. EDM results match satisfactorily stage-discharge curves and also discharge distribution between subsections. Particularly, the reversal of the velocity gradient is adequately captured.

1 INTRODUCTION

During overbank flow, a strong momentum transfer is observed between main-channel and floodplains, due to the velocity difference and the shear layer between both subsections. This effect can significantly reduce the channel conveyance. When a mobile bed is considered in the main-channel, the flow complexity is further increased: the transport capacity is affected by the momentum transfer, and the bed-forms development affects the flow resistance. It has been observed in laboratory flumes that, under some bed-forms development conditions, the main-channel velocity decreases and can even become lower than the floodplain velocity. This results in a reversal of the momentum transfer.

Other situations exist where such a reversal of the velocity gradient can be observed, e.g. (a) in a main-channel with large vegetation development (algae, bushes, etc.) while the floodplain resistance to flow is lower (meadow); or (b) in the cross-over area of a meandering channel where, due to the large sinuosity of the main-channel, the flow path are no more parallel between subsections.

This reversal of the momentum transfer obviously affects the channel conveyance estimation. Compound-channel discharge formulae were generally developed for prismatic compound channels (e.g. Ackers 1993). They were not tested for such particular flow conditions and will probably perform poorly. In this paper, one of these methods, namely the Exchange Discharge Model (EDM, Bousmar & Zech 1999) is modified to account also for this effect. Since the EDM explicitly models the momentum transfer, this modification will be straightforward, as shown below.

The improved EDM formula is tested against existing experimental data of Atabay (2001). The data is therefore re-analysed to express mobile bed roughness as a function of the main-channel discharge and to re-assess floodplain roughness parameter. Consequently, it is possible to test the EDM against overbank flow data sets without any particular parameter fitting.

2 THEORETICAL DEVELOPMENT

2.1 *Traditional methods*

For an inbank flow, the stage-discharge relationship, or the head loss for a given discharge at a given flow depth, can classically be expressed using the Manning equation:

$$Q = \frac{AR^{2/3}}{n} S_0^{1/2} \quad \text{or} \quad S_f = \left(\frac{Q}{AR^{2/3}/n} \right)^2 = \left(\frac{Q}{K} \right)^2 \qquad (1)$$

where Q = discharge; A = section area; R = hydraulic radius; n = Manning roughness coefficient; S_0 = channel slope; S_f = friction slope; and K = section conveyance. When applied to compound cross-sections, the so-called Single Channel Method (SCM) tends to underestimate the discharge for a given flow depth, due to the sudden decrease of the hydraulic radius at bank level.

Alternatively, to account for the velocity discrepancy between main channel and floodplains, each subsection discharge Q_i can be estimated separately using (1), and the total discharge is obtained by addition

$$Q = \sum_i Q_i = \sum_i \frac{A_i R_i^{2/3}}{n_i} S_0^{1/2} = \sum_i K_i S_0^{1/2} \qquad (2)$$

where subscript i refers to a given subsection. The so-called Divided Channel Method (DCM) improves the flow prediction, but the discharge is now overestimated, as the momentum transfer effect is not accounted for.

To improve further the modelling, several corrections of the DCM were proposed. Ackers (1993) developed empirical formulae to correct the computed discharge. Lambert and Myers (1998) proposed an alternative way to divide the channel in subsections, using a weighting between various discharge computations. Bousmar and Zech (1999) attempted to model explicitly the momentum transfer and developed the EDM. The development of this method is summarised in the next paragraph.

2.2 *EDM governing equations*

Each subsection of a compound channel can be considered as a single channel submitted to a lateral flow per unit length q_l. The conservation of mass may be written

$$\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial x} = q_l = q_{in} - q_{out} \qquad (3)$$

where q_{in} = inflow discharge; and q_{out} = outflow discharge.

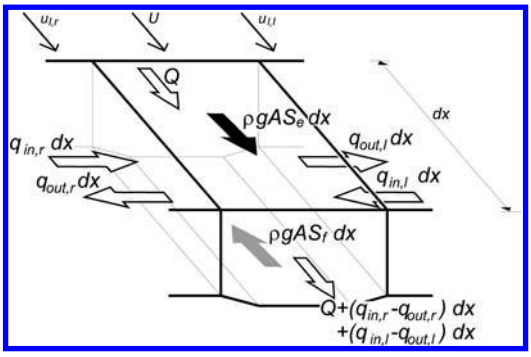

Figure 1. Momentum equilibrium for a compound channel subsection.

The momentum equation for a unit length also accounts for the lateral flow (Fig. 1)

$$\frac{\partial}{\partial t}(\rho AU) = -\frac{\partial}{\partial x}\left(\rho AU^2\right) + \rho q_{in} u_l - \rho q_{out} U + \rho g A\left(S_0 - S_f\right) - \rho g A \frac{\partial H}{\partial x} \qquad (4)$$

where ρ = density of water; g = gravity constant; $U = Q/A$ = mean velocity; H = water depth; and u_l = velocity of the lateral inflow in the direction of the main flow. It is noticeable that inflow and outflow convey different momentum since their initial velocities are not the same.

Assuming steady flow, subtracting the continuity equation (3) multiplied by U from (4), replacing the sum of bed slope and depth gradient by the water level gradient $\partial z/\partial x$, and dividing by gA, the momentum equation reduces to

$$S_e = -\frac{\partial}{\partial x}\left(z + \frac{U^2}{2g}\right) = S_f + \frac{q_{in,r}\left(U - u_{l,r}\right) + q_{in,l}\left(U - u_{l,l}\right)}{gA} = S_f + S_a \qquad (5)$$

where the lateral flow has been divided into right-side r and left-side l inflow; S_e = total head loss per unit length; and S_a = additional loss due to lateral inflow, i.e. momentum transfer effect.

The lateral flows represent turbulent exchange and geometrical transfer (Fig. 2). The turbulent exchange discharge, q^t, is the mass of fluid which oscillates between main channel and floodplain, due to the large vortical structures that develop in the shear layer at the interface, and may be modelled using a mixing length. It is proportional to the velocity difference between

Copyright © 2006 Taylor & Francis Group plc, London, UK

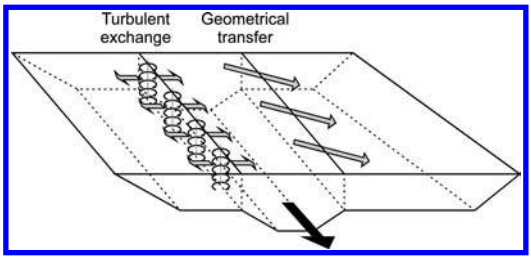

Figure 2. Flow exchange at interfaces between main channel and floodplains.

subsections $|U_c - U_f|$ and to the interface area per unit length $(H - h_f)$, where c and f stands for main channel and floodplain, respectively; and h_f is the bank level:

$$q^t_{cf} = q^t_{fc} = \psi^t \left|U_c - U_f\right| \left(H - h_f\right) \tag{6}$$

where $\psi^t = 0.16 =$ proportionality factor (determined using experimental data). Because turbulent exchange is an oscillating discharge, the lateral inflows q^t_{cf} from main channel to floodplain and the dual inflow q^t_{fc} are equal. Accordingly, the turbulent exchange does not affect the conservation of mass (3) but has a significant effect on the momentum balance (5).

The geometrical transfer, q^g, corresponds to the floodplain conveyance variation due to a non-prismatic geometry or to a gradually varied flow in a prismatic geometry

$$q^g_{fc} = \psi^g \kappa_{fc} \frac{dK_f}{dx} S_{ff}^{1/2}; \; q^g_{cf} = \psi^g \kappa_{cf} \frac{dK_f}{dx} S_{ff}^{1/2} \tag{7}$$

where κ_{fc} and κ_{cf} take the appropriate values, respectively (0, 1) for $dK_f/dx > 0$, i.e. increasing floodplain conveyance, with a transfer from main channel to floodplain; and $(-1, 0)$ for $dK_f/dx < 0$, i.e. decreasing floodplain conveyance, with a reverse transfer. A proportionality factor $\psi^g = 0.50$ has also been included.

Using the momentum equation (5) to correct the friction equation (1), and assuming that the head loss S_e is the same in all subsections, the subsection discharge is given by

$$Q_i = \frac{A_i R_i^{2/3}}{n_i} S_{fi}^{1/2} = K_i S_{fi}^{1/2} = K_i \left(\frac{S_e}{1+\chi_i}\right)^{1/2} \tag{8}$$

where $\chi_i = S_{ai}/S_{fi}$. The total discharge is obtained by addition of subsection discharges.

2.3 *EDM extension*

The practical evaluation of (8) requires the estimation of χ_i values, using (5), (6) and (7). Combining these expressions together, gives

$$\begin{aligned}
\chi_1 &= \frac{1}{gA_1}\left[\psi^t (H-h_1)\left|\frac{R_2^{2/3}}{n_2}\left(\frac{1+\chi_1}{1+\chi_2}\right)^{1/2} - \frac{R_1^{2/3}}{n_1}\right| + \psi^g \kappa_{21}\frac{dK_1}{dx}\right]\cdot\left[\frac{R_1^{2/3}}{n_1} - \frac{R_2^{2/3}}{n_2}\left(\frac{1+\chi_1}{1+\chi_2}\right)^{1/2}\right] \\
\chi_2 &= \frac{1}{gA_2}\left\{\left[\psi^t (H-h_1)\left|\frac{R_2^{2/3}}{n_2}\left(\frac{1+\chi_1}{1+\chi_2}\right)^{1/2} - \frac{R_1^{2/3}}{n_1}\right| + \psi^g \kappa_{12}\frac{dK_1}{dx}\right]\cdot\left[\frac{R_2^{2/3}}{n_2}\left(\frac{1+\chi_1}{1+\chi_2}\right)^{1/2} - \frac{R_1^{2/3}}{n_1}\right]\left(\frac{1+\chi_2}{1+\chi_1}\right)\right. \\
&\quad + \left[\psi^t (H-h_3)\left|\frac{R_2^{2/3}}{n_2}\left(\frac{1+\chi_3}{1+\chi_2}\right)^{1/2} - \frac{R_3^{2/3}}{n_3}\right| + \psi^g \kappa_{32}\frac{dK_3}{dx}\right] \\
&\quad \left.\cdot\left[\frac{R_2^{2/3}}{n_2}\left(\frac{1+\chi_3}{1+\chi_2}\right)^{1/2} - \frac{R_3^{2/3}}{n_3}\right]\left(\frac{1+\chi_2}{1+\chi_3}\right)\right\} \\
\chi_3 &= \frac{1}{gA_3}\left[\psi^t (H-h_3)\left|\frac{R_2^{2/3}}{n_2}\left(\frac{1+\chi_3}{1+\chi_2}\right)^{1/2} - \frac{R_3^{2/3}}{n_3}\right| + \psi^g \kappa_{23}\frac{dK_3}{dx}\right]\cdot\left[\frac{R_3^{2/3}}{n_3} - \frac{R_2^{2/3}}{n_2}\left(\frac{1+\chi_3}{1+\chi_2}\right)^{1/2}\right]
\end{aligned} \tag{9}$$

where subscript 2 stands for the main channel; subscripts 1 and 3 stands for the floodplains; and h_1 and $h_3 =$ main-channel bank level on floodplain 1 and 3 side, respectively.

The system of equations (9) defines the values of the ratios χ_i in an implicit form, and as a function only of water depth, geometry and roughness. An analytical solution of (9) for straight symmetrical uniform flow is given by Bousmar (2002), and Bousmar and Zech (1999) proposed a numerical solution procedure for the general case. When developing these solutions, it was assumed that the main channel velocity was larger than the floodplain velocity. This hypothesis enabled the absolute values in (9) to be replaced by the difference in brackets without any sign change. Solving equation (9) implied the extraction of the roots of quadratic equations. The hypothesis on the velocity gradient enabled one again to select the appropriate root.

In the present work, the solutions of (9) were developed for the case where the floodplain velocity is larger than main channel one. This implies a sign change when replacing the absolute values in (9) by brackets. The tests for selecting the appropriate roots when

Copyright © 2006 Taylor & Francis Group plc, London, UK

developing the solutions also change. For the sake of conciseness, these developments for the general numerical solution procedure are given in an appendix. At least, the same roots can be selected, and only few minor changes are required to obtain a general solution, applicable for both cases. This new solution will now be applied to mobile bed test cases, and the reversal of the momentum transfer direction will be highlighted.

3 EXPERIMENTAL DATA

3.1 *Experimental setup*

The experiments were performed at the University of Birmingham, UK, in a non-tilting 22 m long flume, with a test length of 18 m, moulded into a compound channel, and a bed slope $S_0 = 2.024 \times 10^{-3}$ (Atabay 2001). The flume was 1213 mm wide, and configured into a two-stage channel with a 398 mm wide rectangular main channel and two 407.3 mm wide smooth floodplains at an elevation $h_f = 50$ mm above the main channel bed. Adjustable sidewalls created either an asymmetric compound channel, or an extended rectangular channel isolated from floodplains. Rigid boundaries were constructed from smooth PVC sheets, both for the floodplain and the main channel. For experiments with a mobile-bed, the PVC sheets constituting the bed of the main channel were replaced by sand. The sand was well graded, with a d_{35} & d_{50} sizes of 0.80 mm & 0.88 mm respectively. The flume had three different water supply pipelines, 150 mm, 100 mm and 50 mm in diameter, and discharges were measured by a Dall tube, a Venturi meter and an electro magnetic flow meter respectively.

At the end of the flume a series of three adjustable tailgates were located to produce uniform flow conditions in the 18 m-test length. When uniform flow conditions had been reached, water surface profiles were measured using pointer gauges, also giving the average flow depth and hence mean velocity. In order to obtain local and zonal resistance coefficients the distributions of depth-averaged velocity, U_d, and boundary shear stress were measured for every discharge, using a Novar-Nixon miniature propeller current meter, and a 4.77 mm diameter Preston tube, respectively. It should be noted that measurements were only taken on the rigid bed. Accordingly, no local data are available for the main channel in the loose boundary experiments.

Table 1 summarises the test cases that will be used in this paper. All results are given in Atabay (2001), excepted the LIS series (Ayyoubzadeh, 1997). See also www.flowdata.bham.ac.uk.

3.2 *Results*

The stage-discharge curves for all the test cases are plotted on Figure 3. For a given flow depth, the discharge increases when the floodplain section area contributes to the conveyance: the discharge is higher for the symmetrical channel than for the asymmetrical one; and for the asymmetrical channel than for the isolated main channel. A larger discharge is also obtained for the rigid bed cases than for the mobile bed ones. The bed forms observed in the latter case induce a larger flow resistance.

Table 1. Experimental test cases.

Series	Geometry	Main channel	Discharge (l/s)
RIS	Isolated main channel	Rigid bed	01–30
ROA	Asymmetric overbank	Rigid bed	12–50
ROS	Symmetric overbank	Rigid bed	12–55
LIS	Isolated main channel	Loose bed	01–22
LOA	Asymmetric overbank	Loose bed	11–27
LOS	Symmetric overbank	Loose bed	12–45

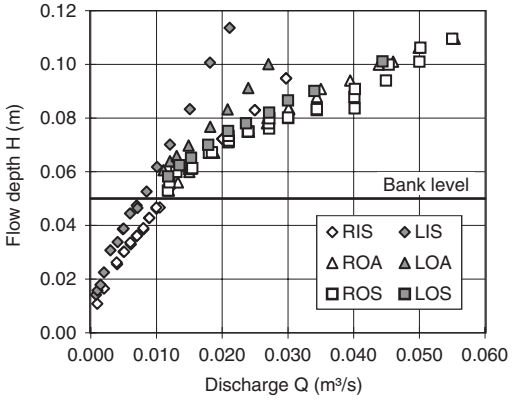

Figure 3. Experimental results: stage-discharge curves.

Figure 4 shows typical depth-averaged velocity distributions for rigid and mobile bed cases. In the rigid bed case, the classical flow behaviour of a compound channel is observed: for the lower discharges, the velocity is significantly larger in the main channel than on the floodplain, generating the shear layer that has been discussed above. When the discharge increases, the floodplain velocity increases faster than the main channel one, as the flow depth also increases, and the velocity gradient decreases.

In the mobile bed case, the flow distribution is obviously affected by the main channel flow resistance. The main channel velocity remains almost unchanged for increasing discharge and flow depth, probably due to bed form development. On the other hand, the floodplain velocity increases rapidly and become even larger than in the main channel. This generates the reversal of the momentum transfer direction discussed previously. A similar behaviour is observed for the bed shear stress distribution.

Copyright © 2006 Taylor & Francis Group plc, London, UK

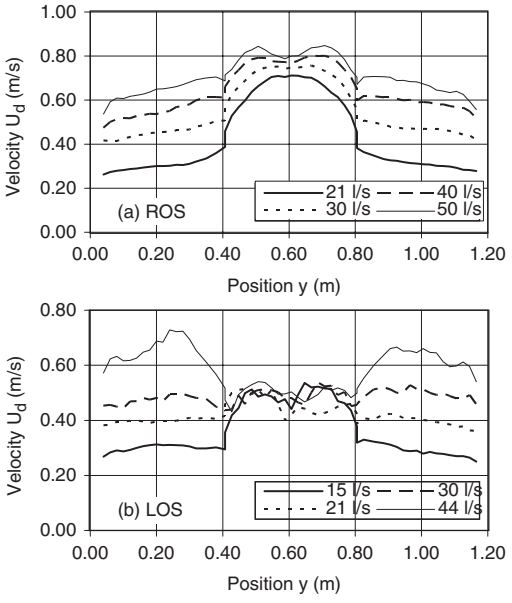

Figure 4. Depth-averaged velocity distribution: (a) ROS series; and (b) LOS series.

The discharge distribution between main channel and floodplain is similarly affected by the main channel flow resistance (Fig. 9). In the rigid bed case, the portion of the total discharge flowing on the floodplain increases with flow depth, but remains always lower than in the main channel. In the mobile bed case, the floodplain discharge becomes larger than the main channel one. A more detailed discussion of all the experimental results can be found in Atabay (2001).

3.3 *Flow resistance*

3.3.1 *Global, zonal and local friction factor*

The resistance, or friction, factor can be defined in different ways for a compound channel: (a) the global resistance factor defined by applying a friction law like (1) to the whole cross-section; (b) the zonal resistance factor defined on a subsection; and (c) the local friction factor obtained by using the local bed shear stress and velocity values. In a single rectangular channel, these three definitions give almost the same friction factor values, depending mainly on the bed material roughness. In a compound channel, significant differences are observed.

The global friction factor encompasses all the head loss occurring in the section, including the effect of the momentum transfer on the channel conveyance. When computed as a Manning roughness coefficient, it presents a sudden drop at bankfull depth to compensate for the reduction in hydraulic radius. The zonal friction factors also encompass momentum transfer

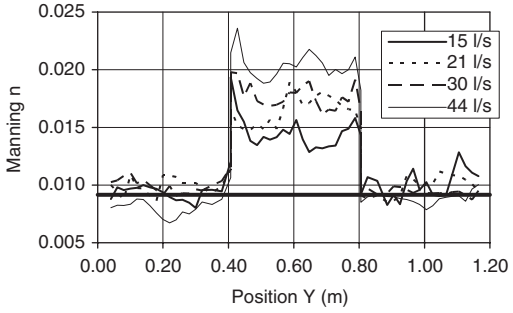

Figure 5. Local Manning roughness coefficient estimated from bed shear stress and velocity measurements. LOS series.

effects. A detailed discussion on the values of these factors obtained from the experimental data can be found in Atabay (2001) and in Atabay and Knight (1999).

In the present analysis, the local friction factor is preferred. As it does not include momentum effects, this factor can be estimated a priori, either from inbank stage-discharge measurements, or from roughness tables. It is then expected that, using the EDM with these a priori determined friction factor, purely predictive modelling could be performed.

3.3.2 *Rigid bed friction factor*

The Manning roughness coefficient n for rigid bed can be estimated from the RIS series (isolated main channel). The best fit between experimental data and a stage-discharge curve computed using (1) is obtained for $n = 0.00916$ s/m$^{1/3}$.

For confirmation, the local roughness value can also be computed from the local bed shear stress τ_b and the local depth-averaged velocity U_d

$$n = \sqrt{\frac{\tau_b H^{1/3}}{\rho g U_d^2}} \tag{10}$$

Typical values of n computed for the LOS series are shown on Figure 5. The values on the rigid floodplains are close to the value computed for inbank flow, while the main channel values are larger, due to the bed forms on the mobile bed.

3.3.3 *Mobile bed friction factor*

The Manning roughness coefficient n_b for the mobile bed can be estimated from the LIS series (isolated main channel), using a wall correction. Figure 6 shows the roughness coefficient as a function of the discharge. The main channel discharge has been selected as abscissa instead of the flow depth, as it is expected that it will be more representative of the transport capacity of the channel and thus of the possible bed forms development for compound channel experiments.

Copyright © 2006 Taylor & Francis Group plc, London, UK

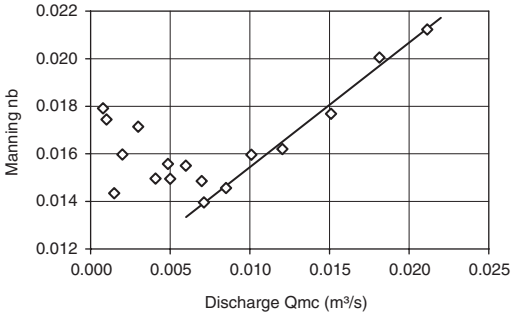

Figure 6. Manning roughness coefficient. LIS series.

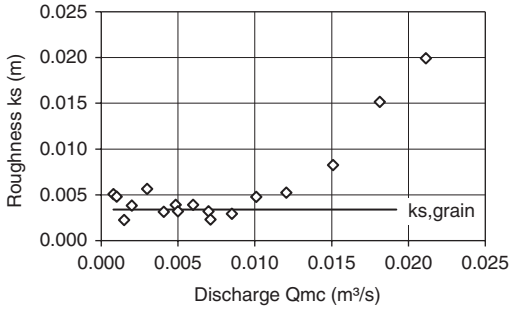

Figure 7. Nikuradse k_s for LIS series.

For a discharge lower than $Q_{mc} = 8$ l/s (i.e. bankfull discharge in compound channel geometries), the Manning n_b value is rather scattered, but tends to decrease. For larger discharge, it varies linearly with the discharge:

$$n_b = 0.0102 + 0.5237\, Q_{mc} \tag{11}$$

Expressing the roughness coefficient as the equivalent roughness of Nikuradse k_s enables a better understanding of its behaviour. The equivalent roughness can be decomposed as

$$k_s = k_{s,grain} + k_{s,form} \tag{12}$$

where $k_{s,grain} = 3\ d_{90}$ = sand roughness; and $k_{s,form}$ = form roughness, due to dune development (Van Rijn, 1982). Figure 7 shows k_s and $k_{s,grain}$ values computed for the LIS series (with $d_{90} = 1.13$ mm). No bed forms were observed for discharges lower than 8 l/s: for these discharges, the roughness is only due to grain roughness, with some experimental scattering for the lower discharge, where flow depths are difficult to record accurately. For larger discharges, bed forms develop and the roughness increases, as already observed in Figure 6 for the Manning n_b. More details on the bed forms development are given by Tang and Knight (2001, 2006).

4 VALIDATION OF EDM

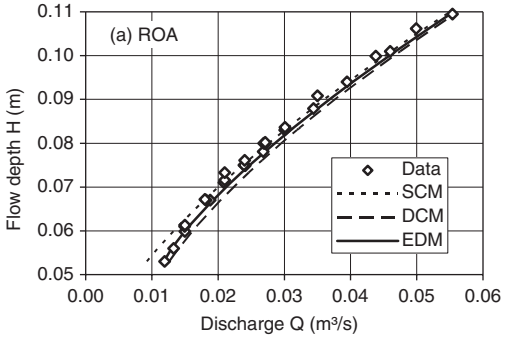
4.1 *Discharge prediction*

Stage-discharge curves and discharge distribution were computed with the EDM using the roughness coefficients estimated in § 3 from inbank measurements, without any further parameter fitting. For the mobile bed cases, the solution is obtained iteratively: after assuming a main-channel bed roughness value n_b, a first computation is done, giving the main channel discharge value Q_{mc}. The roughness n_b is then corrected using (11), and the computation is repeated until it converges (usually in less than 5 iterations).

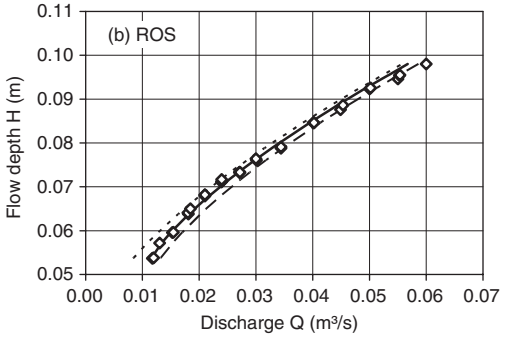
Figures 8 and 9 show the computed stage discharge curves and discharge distributions, respectively, together with SCM and DCM calculations. The stage-discharge predictions are globally better using EDM than SCM and DCM, although the three methods are not so distinct for the mobile bed cases. Indeed, in this case, the larger main-channel roughness influences all three calculations significantly.

Again, the discharge distributions computed with EDM are closer to the experimental data than those computed with DCM or SCM. However, larger discrepancies are observed between EDM and data for floodplain discharge at the lower flow depths for rigid bed cases. This could be partly due to measurement inaccuracy for these discharges, as a 13 mm diameter propeller was used at the level $z = 0.4\,H$, for local H values lower than 20 mm on floodplains. This problem does not appear in the mobile bed cases, where the floodplain velocities were larger.

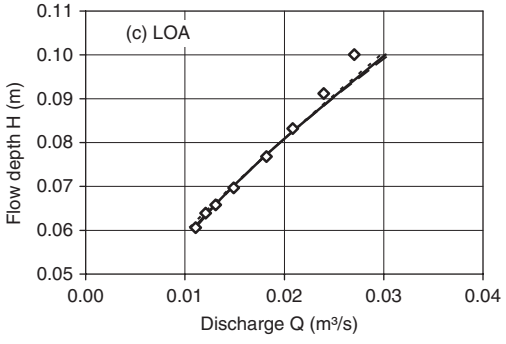
4.2 *Momentum transfer analysis*



The intensity of the actual momentum transfer through the vertical interface between main channel and floodplain can be estimated from experimental data by computing the apparent shear force ASF_v. This apparent shear force is computed as the force required to equilibrate the momentum balance between water slope and bed shear stress (Atabay, 2001):



$$-\rho g A_c \frac{\partial z}{\partial x} = \int_{P_c} \tau_b dP + ASF_v \tag{13}$$



where P_c = main-channel wetted perimeter.

Whereas for rigid-bed experiments, ASF_v was always positive, indicating a momentum transfer from main channel to floodplain, Figure 10 shows that its value become negative for $H > 0.080$ m. This sign change corresponds to the momentum transfer reversal. It occurs when the main channel roughness has increased in such a way that the lateral velocity gradient is reversed, as shown in Figure 4.

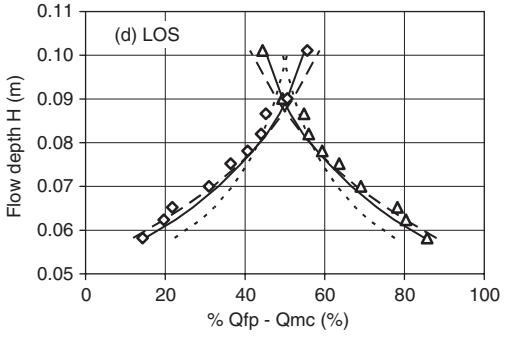

Figure 9. Discharge distribution. Experimental data and computation. (a) ROA; (b) ROS; (c) LOA; and (d) LOS.

Copyright © 2006 Taylor & Francis Group plc, London, UK

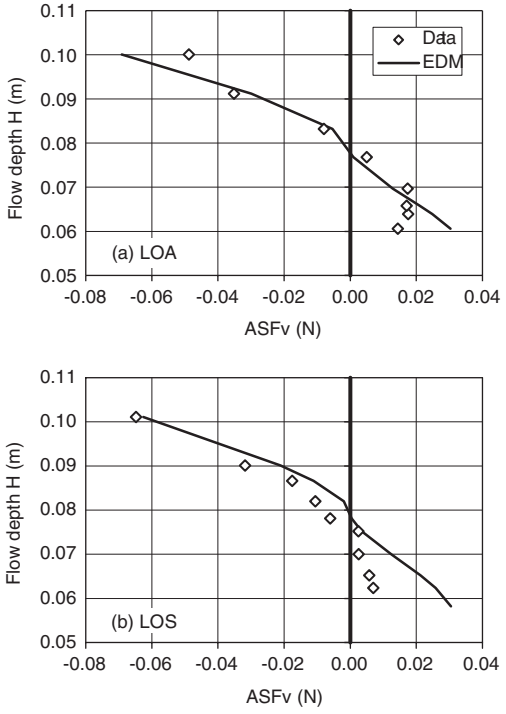

Figure 10. Apparent shear force ASF_v. Experimental data and EDM computation. (a) LOA; and (b) LOS (in this later case, ASF_v is estimated for one interface).

In the EDM, the apparent shear force acting on the interface is modelled explicitly through the additional head loss due to exchange discharges

$$ASF_v = \rho g A_c S_{ac} \tag{14}$$

where S_{ac} expression is given by (5), while its value is computed using the χ_i ratio (see § 2.3).

Figure 10 shows a very good agreement between experimental and EDM-computed values of ASF_v. Not only is the sign reversal modelled, but also the actual values. This result is obtained without any further parameter fitting: the used value of $\psi^t = 0.16$ was calibrated by Bousmar & Zech (1999) for an independent set of data. This last comparison indicates that EDM models adequately the physics of the momentum transfer. It also explains why EDM gets good results for stage-discharge and discharge distribution modelling.

5 CONCLUSIONS

The analysis of compound channel experiments with a mobile bed shows that a reversal of the momentum transfer between main channel and floodplain can be observed. This reversal occurs when large bed forms develop in the main channel and increase its flow resistance. The existing compound channel flow formulae were not tested for such situation.

In this paper, the EDM was modified to account also for such a situation. The mathematical developments show that only minor changes are necessary for such an adaptation, by adding a sign test in the numerical solution.

The EDM was then tested using existing mobile-bed compound-channel experimental data. The data from inbank measurements were re-analysed, in order to determine a priori roughness coefficients. These coefficients were then used for compound channel computations with EDM, without any further parameter fitting.

The EDM gives better results than SCM and DCM, when compared to observed stage-discharge curves and discharge distribution between subsections. It also represents satisfactorily the apparent shear force values, with a sign change at the same flow depth. This confirms that EDM models adequately the actual physics of the momentum transfer between the subsections of a compound channel.

APPENDIX: COMPUTATION OF χ_i RATIOS

To obtain a numerical solution of the system (9), three auxiliary variables are defined:

$$X_i = (1+\chi_i)^{1/2}, \quad i = 1,2,3 \tag{15}$$

For a larger velocity in main channel than on floodplain, the following conditions had to be satisfied (Bousmar & Zech, 1999):

$$\frac{1}{X_1}\frac{R_1^{2/3}}{n_1} \le \frac{1}{X_2}\frac{R_2^{2/3}}{n_2} \text{ and } \frac{1}{X_3}\frac{R_3^{2/3}}{n_3} \le \frac{1}{X_2}\frac{R_2^{2/3}}{n_2}$$
$$0 < X_1 \le 1;\ 1 \le X_2 \text{ and } 0 < X_3 \le 1 \tag{16}$$

where $X_i \le 1$ and ≥ 1 imply velocity increase and decrease respectively, due to momentum transfer, as in (8). When the momentum transfer is reversed, with larger velocity on the floodplain than in the main channel, the conditions (16) become

$$\frac{1}{X_1}\frac{R_1^{2/3}}{n_1} \ge \frac{1}{X_2}\frac{R_2^{2/3}}{n_2} \text{ and } \frac{1}{X_3}\frac{R_3^{2/3}}{n_3} \ge \frac{1}{X_2}\frac{R_2^{2/3}}{n_2}$$
$$1 \le X_1;\ 0 < X_2 \le 1 \text{ and } 1 \le X_3 \tag{17}$$

Equations (9) can be seen as quadratic equations respectively for X_1 and X_3 : extracting the roots and selecting the appropriate ones (fortunately, the same roots X_{1+} and X_{3+} satisfy the conditions given by (16)

Copyright © 2006 Taylor & Francis Group plc, London, UK

or (17), according to the velocity gradient), after simplifications, the following expressions for X_1 and X_3 as functions of X_2 can be obtained:

$$X_1 = \frac{1}{2} X_2 \frac{1}{X_2^2 + \frac{\sigma_1 \psi^t (H - h_1)}{g A_1} \left(\frac{R_2^{2/3}}{n_2} \right)^2} \cdot \left(2 \frac{\sigma_1 \psi^t (H - h_1)}{g A_1} \frac{R_1^{2/3}}{n_1} \frac{R_2^{2/3}}{n_2} - \frac{\psi^g \kappa_{21} dK_1/dx}{g A_1} \frac{R_2^{2/3}}{n_2} + \left\{ \left[4 \frac{\sigma_1 \psi^t (H - h_1)}{g A_1} + \left(\frac{\psi^g \kappa_{21} dK_1/dx}{g A_1} \right)^2 \right] \left(\frac{R_2^{2/3}}{n_2} \right)^2 + 4 X_2^2 \right. \right.$$
$$\left. \left. \cdot \left[1 - \frac{\sigma_1 \psi^t (H - h_1)}{g A_1} \left(\frac{R_1^{2/3}}{n_1} \right)^2 + \frac{\psi^g \kappa_{21} dK_1/dx}{g A_1} \frac{R_1^{2/3}}{n_1} \right] \right\}^{1/2} \right)$$

$$X_3 = \frac{1}{2} X_2 \frac{1}{X_2^2 + \frac{\sigma_3 \psi^t (H - h_3)}{g A_3} \left(\frac{R_2^{2/3}}{n_2} \right)^2} \cdot \left(2 \frac{\sigma_3 \psi^t (H - h_3)}{g A_3} \frac{R_3^{2/3}}{n_3} \frac{R_2^{2/3}}{n_2} - \frac{\psi^g \kappa_{23} dK_3/dx}{g A_3} \frac{R_2^{2/3}}{n_2} + \left\{ \left[4 \frac{\sigma_3 \psi^t (H - h_3)}{g A_3} + \left(\frac{\psi^g \kappa_{23} dK_3/dx}{g A_3} \right)^2 \right] \left(\frac{R_2^{2/3}}{n_2} \right)^2 + 4 X_2^2 \right. \right.$$
$$\left. \left. \cdot \left[1 - \frac{\sigma_3 \psi^t (H - h_3)}{g A_3} \left(\frac{R_3^{2/3}}{n_3} \right)^2 + \frac{\psi^g \kappa_{23} dK_3/dx}{g A_3} \frac{R_3^{2/3}}{n_3} \right] \right\}^{1/2} \right) \quad (18)$$

where $\sigma_i = \text{sign}(R_2^{2/3}/n_2 - R_i^{2/3}/n_i)$. For a velocity larger in the main channel than on the floodplain, $\sigma_i = 1$, and the solution is the same as that developed by Bousmar & Zech (1999).

Using these expressions in equation (9), it is possible to get a single function of X_2 that has to be equal to zero:

$$F(X_2) = 0 = F\left(\frac{X_1}{X_2}, \frac{X_3}{X_2}, X_2 \right) =$$
$$1 - X_2^2 + \frac{1}{g A_2} \left\{ \left[\sigma_1 \psi^t (H - h_1) \left(\frac{R_2^{2/3}}{n_2} \frac{X_1}{X_2} - \frac{R_1^{2/3}}{n_1} \right) + \psi^g \kappa_{12} \frac{dK_1}{dx} \right] \left[\frac{R_2^{2/3}}{n_2} \frac{X_1}{X_2} - \frac{R_1^{2/3}}{n_1} \right] \left(\frac{X_2}{X_1} \right)^2 \right.$$
$$\left. + \left[\sigma_3 \psi^t (H - h_3) \left(\frac{R_2^{2/3}}{n_2} \frac{X_3}{X_2} - \frac{R_3^{2/3}}{n_3} \right) + \psi^g \kappa_{32} \frac{dK_3}{dx} \right] \left[\frac{R_2^{2/3}}{n_2} \frac{X_3}{X_2} - \frac{R_3^{2/3}}{n_3} \right] \left(\frac{X_2}{X_3} \right)^2 \right\} \quad (19)$$

as X_1/X_2 and X_3/X_2 are defined as functions of X_2 by equations (18). The value of X_2 can finally be found using a Newton-Raphson resolution of equation (19), with an initial value of $X_2 = 1$. Getting the value of X_2 as a function of the cross-section geometrical parameters, allows one to obtain the values of the χ_i ratios from the X_i definition (15).

ACKNOWLEDGEMENT

The first author is grateful to FNRS, Belgium, for funding a short stay at Birmingham University in 2004, where this work was initiated.

Performance of several hybrid numerical schemes to determine flooding extent

I. Villanueva & N.G. Wright
School of Civil Engineering, University of Nottingham, United Kingdom

ABSTRACT: Several hybrid approaches that combine 1D modelling for the main river and 2D modelling for the flood plains are discussed and compared. These range from a commercial quasi-2D or storage cell model approach, a 2D raster based approach based in the Manning equation, and a complete 2D shallow water equation solver in explicit and implicit version, based in Riemann solvers with finite volume and alternating direction formulations. The latter includes a multi-processor version which allows studies at small mesh resolutions or large extents.

Two basic scenarios are used for comparison, a typical rural one with a 15 km river length where the terrain data and validation are obtained from remote sensing, and an urban one where only the terrain data is acquired from remote sensing.

Results will show the ease of implementation of the models, their time steps, induced mass error and prediction accuracy and capability. The influence of the grid size resolution is also reported.

Conclusions for predicting flood plain inundation with various models are drawn and future research directions are discussed.

1 INTRODUCTION

Due to global warming long term weather forecasts are predicting more water cycle disruptions, in particular the raising of sea levels, the increase of tropical sea water temperatures which increases the number of intense hurricanes and storms, and an increase in the number of extreme rains generating flash floodings are forecasted. Although the general distribution of these extreme events around the world is still uncertain due to the many climate models and assumptions, average trends are predicted, (Hadley Centre, Meteorological Office).

Flooding prediction studies require a large amount of terrain and hydraulic data to be collected, although modern techniques like remote sensing LIDAR are collecting the majority easier and faster, many other related problems arise, (Wright et al. 2006), for reported manipulations and extractions of Digital Surface Model from Digital Terrain Models and obtaining Manning or friction coefficient maps.

One of the main objectives of this paper is to assess about use of different numerical techniques in order to predict flooding effects depending on the time scale and spatial extent, and according to the characteristics of the provided digital terrain models, working with standard computers or specialized ones.

2 REVIEW OF MODELS

A basic introduction to currently used hydraulic models of floods is given in (Kutija 2002), or classically (Cunge et al. 1980), ranging from steady state ones to hydrodynamic in one- and two-dimensions.

All the studied models covered here are time dependent or allowed for the study of transient states. Steady state models are now not normally used due to the ready availability of one-dimensional complete models which are fast enough in common Pc's for practical applications (Burguete and Garcia-Navarro 2004). Complete 2D models are also increasingly practical (Villanueva and Wright 2006b).

2.1 *Basic equations*

The 1D and 2D shallow water equations or mass and momentum conservation are applied here. A complete definition and description of their properties can be found (Cunge et al. 1980) and (Weiyan 1992), in conservative formulation are:

$$\frac{\partial U}{\partial t} + \nabla \overline{F}\,(U) = H \qquad (1)$$

With U the main variables related to water depth and discharge, F their flows, and H their source terms.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Being a non-linear coupled system of first order PDE's of hyperbolic nature, (Toro 2001).

Different approaches to solve these equations are commented on the following sections.

2.2 *One-dimensional complete single*

These models are used in cases where the valley cross sections have a complete U shape and no flood plains exist or if any, the water surface level is kept the same across the main river and its flood plain. That approach does not deal with different velocity profiles, although some attempts have been made in the past to complete it (Cunge et al. 1980), in the vast majority of the flood modelling within the UK or in relatively flat lands this approach is incomplete, mainly during the filling and drying of the floodplains.

2.3 *One-dimensional complete plus storage cell model*

If the one-dimensional model for the main river is linked to flood plains using spill boundaries between river and flood plain or between flood plains, a quasi-2D model is defined. Flood plains are considered as reservoirs or storage cells, with typical dimensions for width and length of a few hundreds of meters.

As an example of this modelling, a figure of the studied area of Upton upon Severn (15 kms river length) with the commercial scheme Mike11 is covered in Figure 2, showing the 1D H-Q points, link channels and connected storage cells.

The main advantage of this model is its fast delivery of results once it is built, the main disadvantage is its large pre-processing data time and lack of correct propagation times over the floodplains. It continues to be the most used in consultancy.

This model is time consuming to calibrate, as it relies on many geometrical parameters (spill-weirs), but can be efficient if propagation times of flooding are not required and only maximum flooding extents are needed.

In particular the modeller has to be concerned with the storage cells shape and size while working in the post-processing of output data with GIS systems, because it could be possible that the GIS application can extrapolate water depths and flooding extents, resulting in non mass conservative approaches during the mapping display.

2.4 *Cartesian vs unstructured meshes, hybrid modelling*

From the mathematical point of view an unstructured mesh fits better with a terrain model, and leads to a more detailed and accurate solution for the conservation laws, but it is also highly time consuming if the mesh is fine and generally it requires interpolation techniques for the bathymetry or areas under water where no data are available. With the final practical objective of covering large flooding prone areas with millions of cells the authors have selected a structured Cartesian grid. Latest technical advances in shallow water modelling with unstructured meshes have been reported recently (Murillo et al. 2006).

The idea of hybrid 1D-2D modelling through spill line connections, maintains 1D river reach areas with low demand in computing cost and input data with more demanding ones, the 2D, which is in line with the practical availability and compilation of data in a whole catchment, and the idea of recycling and upgrading older 1D-models and quasi-2D with 2D models partially.

Separating the domains through spilling lines is a consistent approach with the shallow water equations, but also a non realistic one because it ignores the momentum exchange, turbulence and non-hydrostatic pressure distribution by the overtopping of embankments, a process which should be covered through a 3D modelling technique.

It can be summarised that it is desirable for a good mathematical performance and consistency to use a 2D unstructured mesh, but realistic topographic data, computational costs for large domains, and an engineering sense still lead to the use of hybrid models and Cartesian grids.

The following sections contain further techniques which take advantage of Cartesian grids and hybrid modelling.

2.5 *One-dimensional complete plus raster based model*

This model being more exigent in computational cost than the previous one, avoids the phase of assigning, drawing and linking the storage cells through weirs. It also gives wrong propagation times along the floodplains, because it does not consider the momentum equation but instead generates a water surface profile parallel to the bed slope which gives more information than the simple storage cells which act like a system of reservoirs.

In the raster based approach the water depth is calculated according to the discharge between cells (assuming the uniform flow Manning equation):

$$Q_{i+1/2} = \frac{H_{flow}^{5/3}}{n}\left(\frac{\partial Z}{\partial x}\right)^{1/2} \tag{2}$$

With $H_{flow} = max(Z_i, Z_{i+1}) - max(Zb_i, Zb_{i+1})$, being Zb the terrain bottom, h the water depth and $Z = Zb + h$. The Manning friction coefficient is n.

This method was proposed by Estrela and Quintas (Estrela and Quintas 1994), and Bates and de Roo (Bates and Roo 2000) used it to develop LISFLOOD-FP which has been used in many studies.

Copyright © 2006 Taylor & Francis Group plc, London, UK

This model does not require the careful drawing and output data checking needed with storage cells, it is easy and robust to implement as a bespoke technique, being always mass conservative as it is not coupled to any momentum equation. However it requires additional calibration techniques for obtaining correct propagation times. In the version calibrated in the work reported here its time step is determined by the finite volume scheme or an alternating direction scheme, in both cases with velocities $(u, v) = 0$.

2.6 *One-dimensional complete plus two-dimensional complete*

2.6.1 *Riemann solvers*

In order to solve the complete system of shallow water equations, approximate Riemann solvers, in particular the Roe one under the Godunov approach, (Toro 2001) and (Guinot 2003), have been considered as a robust and powerful tool for the prediction of shallow water flows in one- and two-dimensional approximations. See for instance (Alcrudo and Garcia-Navarro 1993), (Zhao et al. 1996), (Anastasiou and Chan 1997), (Erduran et al. 2002), (Brufau et al. 2004) and (Burguete and Garcia-Navarro 2004) for river modelling, or (Hubbard and Dodd 2002) for coastal modelling.

Both the two-dimensional complete model and the one-dimensional complete model referred in this paper use a Riemann solver. The one-dimensional complete plus storage cell scheme described in section 2.3 uses the Abbott-Ionescu scheme (DHI 2005), and the raster based one in 2D (section 2.5) uses a single, uncoupled equation under the Godunov approach.

Both the two-dimensional complete model and the one-dimensional complete approximate Roe Riemmann solvers have been calibrated against laboratory tests proposed by the CADAM group (Concerted Action on Dambreak Modelling), (Villanueva and Wright 2005b). A short technical definition follows.

2.6.2 *Explicit formulation*

The most used schemes are the explicit ones due to the ease of implementation. For the augmented 2D system with 3 components (h, u, v), in Cartesian grid, the definition is:

$$U_{i,j}^{n+1} = U_{i,j}^{n} - \frac{\Delta t}{\Delta x}\left[F_{i+1/2,j}^{*} - F_{i-1/2,j}^{*}\right] - \frac{\Delta t}{\Delta y}\left[G_{i,j+1/2}^{*} - G_{i,j-1/2}^{*}\right] + \Delta t H_{i,j}^{n} \quad (3)$$

Reference (Villanueva and Wright 2006a) describes in detail the flows and source terms considered, and the implementation of the Alternating Direction scheme (AD) which allows slighty larger time steps than the FVM implementation.

2.6.3 *Implicit formulation*

An implicit approach has also been tested, using an Alternating Direction technique in X-Y (ADI), it discretizises the system as follows in 1D:

$$\frac{U_i^{n+1} - U_i^n}{\Delta t} + \frac{1}{\Delta x}\left[\theta(F_{i+1/2}^{*n+1} - F_{i-1/2}^{*n+1})\right] + \frac{1}{\Delta x}\left[(1-\theta)(F_{i+1/2}^{*n} - F_{i-1/2}^{*n})\right] = \theta H_i^{n+1} + (1-\theta) H_i^n \quad (4)$$

With θ the implicit parameter of the system. When $\theta = 0$ it is the explicit Euler scheme, if $\theta = 1$ it is the implicit Euler scheme, and if $\theta = 0.5$ it is the trapezoidal method (second order accurate in time). The system is approximated to obtain a tri-diagonal system in every single dimension:

$$AA_i \Delta U_{i-1}^n + BB_i \Delta U_i^n + CC_i \Delta U_{i+1}^n = RHS_i \quad (5)$$

2.6.4 *Multi-processor approach*

The idea of dividing the 2D domain in equal size sub-domains, according to the number of processors is the simplest to implement. This division for a 2D Cartesian grid is easy to generate and robust using MPI libraries, in particular the SENDRECV blocking communications between neighbours. See EPCC MPI introduction course, (MacDonald et al. 2005).

3 DIFFERENT SCENARIOS

3.1 *Rural river flood: Upton upon Severn*

This scenario and the propagation times of the hydrograph peaks represent a flat or slow flooding, which allows the comparison of many of the described techniques.

The 1D model covers 31 cross sections distributed at 500 meters intervals along 15 Kms of river length. The complete LIDAR Digital Terrain Model (DTM) covers a surface of 74 square Kms. For the 18 m grid study this consist of a reduced grid of $213 \times 482 \approx 102\,K$ cells.

The simulation covers approximately 14 days, and the calibration is made with an available ASAR image at approximately t = 700000 seconds (raising limb of second hydrograph peak), see Figure 1.

Results with Mike11, quasi-2D, a commercial one-dimensional complete plus storage cell model which uses the network displayed in Figure 2, took 12 minutes to complete with a 2.66 GHz processor. The predicted

Figure 1. ASAR image (yellow) available for calibration at t = 700000 secs in yellow, the red lines are the embankments which separate main river from the flood plains. The provided image is cut upstream.

Figure 2. Network structure of the Mike11 quasi-2D model, with cross sections, h-q points, link channels and storage cells.

flooding extent is displayed over the ASAR image at Figure 3.

As reported by Villanueva and Wright in (Villanueva and Wright 2005a) and in more detail in this paper, a 18 m resolution 2D grid is a feasible one with a common desktop for this flooding event which covers a couple of weeks time and a dozen of kilometres river length, with results in less than 24 hours computational time using a shock-capturing explicit first order scheme like the complete 1D-2D TRENT-AD.

The tables below compare the performance of all the bespoke and proposed models, where there are 860 2D cells connected to the 31 1D river cross sections.

Table 1. Computational cost indicators (CFL and medium time step) for the set of complete 2D numerical schemes (TRENT) and raster-based approach (LISFLOOD or LF).

Scheme	CFL	Medium Δt(s), dl = 18 m
TRENT-FVM	0.9	1.21
TRENT-AD	0.9	2.43
TRENT-ADI	1.5	4.02
LF-FVM	0.9	1.21
LF-AD	0.9	2.41

A Manning friction value of 0.035 was used for the main river and 0.03 for the flood plains.

In summary the computed water volume over the flood plains is in a similar range for all bespoke

Copyright © 2006 Taylor & Francis Group plc, London, UK

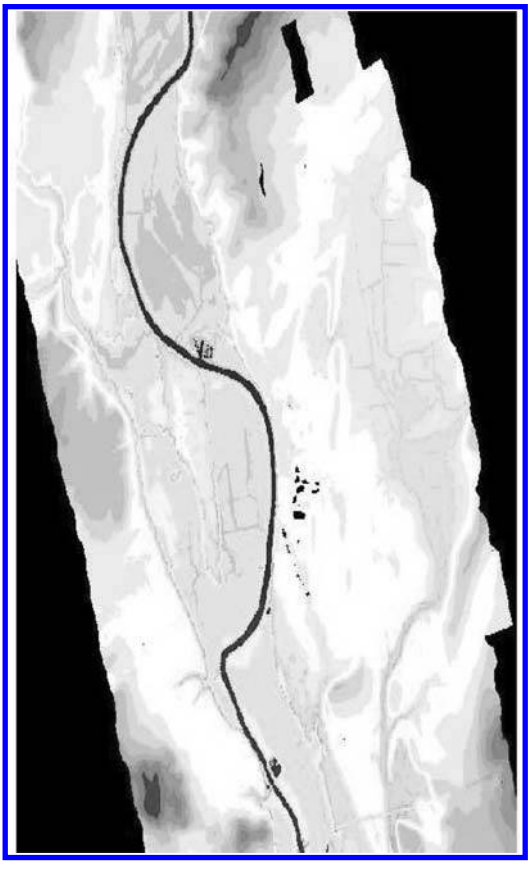

Figure 3. Predicted flooding extent with Mike11 storage-cell model (blue) over ASAR image (yellow).

Table 2. Computational cost for the set of complete 2D numerical schemes (TRENT) and raster-based approach (LISFLOOD or LF). LISFLOOD is around 3 times faster in both versions, FVM and AD. 102 Kcells.

Scheme	Cost, hours : minutes, at 2.8 GHz
TRENT-FVM	38 : 46
TRENT-AD	22 : 25
TRENT-ADI	non-optim
LF-FVM	12 : 33
LF-AD	8 : 24

schemes, (differences less than 10% at 18 m resolution), so for this particular slow flood case, with no need to predict velocities the raster LISFLOOD-AD scheme outputs 2D information in less than 9 hours. It is noticeable that the differences in the maximum flooding extent are less significant than the maximum 10% difference in volume peaks as the surface considered is over 33 squared Kilometers.

Figure 4. Detailed 2D complete FVM flood extent prediction (blue) over ASAR imagery (yellow). Notice that it is only shown the 2D domain result, and the main channel flood is not displayed for the sake of clarity of the hybrid methodology.

Figure 4 shows the flooding extent from TRENT-FVM at the calibration time compared with the ASAR image. All the hybrid models that include a 2D grid produced similar maximum flooding extent and gave better performance than the 1D storage-cell (Figure 3). These methods also have the advantage that the required input data processing is lower. For this particular case the complete 2D models with shock-capturing properties are considered expensive and the raster one feasible with a common desktop.

The implicit scheme (ADI) allowed a time step CFL coefficient of 1.5 for this case, which makes it inefficient, as it sweeps twice in every X and Y direction a value bigger than 2 is needed to make it efficient.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 3. Computational cost indicators for the explicit complete 2D numerical schemes (TRENT) and raster-based approach (LISFLOOD or LF), using a grid computing facility with 36 processors, at a resolution of 3 m simulating first quarter of hydrograph (maximum extent), 3.7 Mcells.

Scheme	Cost, hours, dl = 3 m, at 2.2 GHz
TRENT-FVM	282
LF-FVM	156

With flat bottom test cases it has reached a value of 2.5, keeping its property of shock-capturing.

The 2D complete model in FVM formulation, within a multi-processor version has been used in a 3 m resolution grid, in order to check the computational cost of a highly accurate model. This was also done for the raster-based method in a FVM formulation.

The original 3 m DSM had Nx = 1278 columns, and Ny = 2892 rows, the domain division creates $4 \times 9 =$ 36 subdomains with Nxr = 320, Nyr = 322 each.

The times are shown in the table below for 300000 seconds simulation (maximum hydrograph peak).

Showing that the waiting communication times among processors reduces the rate TRENT/LF to 2:1 against the single processor version which was 3:1, although the results could vary because the numerical code needs to be optimized and another sub-domains sizes can be studied. Predicting the same range of water volume for the flood, the advantage of using a small mesh size of 3 m will be reported in future publications, or the developed systematic could be useful for larger meshes with bigger grid size.

3.1.1 *Grid independence*

As shown in (Villanueva and Wright 2006b), the raster based approach is more sensitive to grid size, whereas the complete 2D is more appropiate as it maintains propagation times and maximum values independently. Figures 5 and 6 display the grid dependence for dl = 9, 18, 27 and 54 m for each model. The complete model has more divergences during the drying processes or decreasing limbs.

Further research is expected to determine the influence of different resolutions in the terrain slopes and surface wetting, although global results in (Villanueva and Wright 2006b) seem to show that the complete 2D model keeps the most important values (times and maximums) at different resolutions.

3.1.2 *Drying process*

Subsequent ASAR images are available for the Upton upon Severn event, but their fitting with numerical predictions require a complete description of the whole drainage system, and the incorporation of infiltration processes. Further the drying process is more sensitive to uncertainties in embankment heights than the wetting, see a more complete description in (Wright et al. 2006).

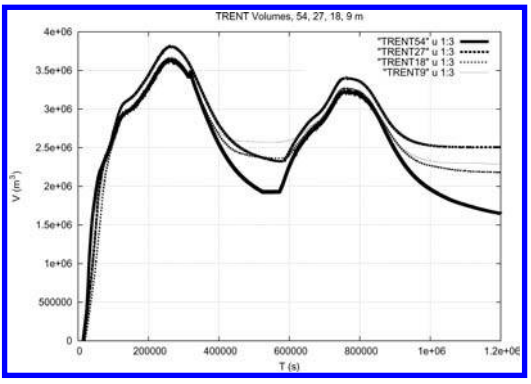

Figure 5. Water volume evolution over one selected floodplain at Upton upon Severn, for TRENT model, dl = 54, 27, 18, 9 m.

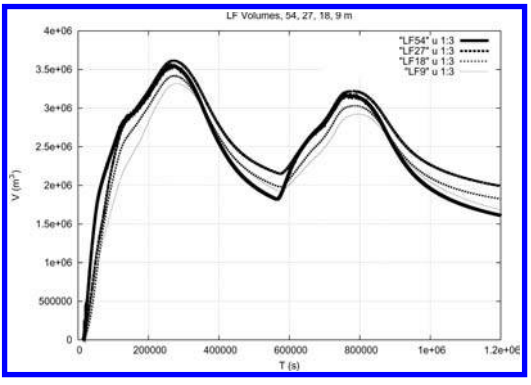

Figure 6. Water volume evolution over one selected floodplain at Upton upon Severn, for LF model, dl = 54, 27, 18, 9 m.

3.2 *Urban tidal flood: London Thames Embankment*

Given the nature of the Upton upon Severn flooding, flat and slow hydrograph in the main river and flooding covering more than 14 days, the use of a raster-based scheme is complete enough for the prediction of flooding extent. For more transient states where propagation times are more important such as the case of an urban flooding, the following study has been included.

A fictitious breach is open in the embankment close to the Thames Barrier in Greenwich, and the induced tidal flow propagates across the floodplain. The experiment is well described in (Tarrant et al. 2006) as scenario C.

An explicit formulation is preferred, due to the nature of the terrain model, which includes streets and

Copyright © 2006 Taylor & Francis Group plc, London, UK

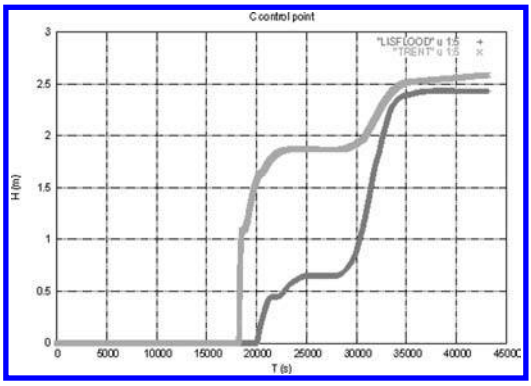

Figure 7. Water depth in C control point at London Thames Barrier, 600 meters away from the breach, red = raster (LISFLOOD) vs green = 2D complete (TRENT).

Figure 8. Maximum flooding extent for both models at London Thames Barrier, red = raster over green = 2D complete.

buildings in an industrial area close to the docks, and because the tidal cycle only covers a few hours.

Figure 7 shows water depth for the raster-based versus 2D complete formulation at a selected point and Figure 8 shows the final flooding extent.

The 2D complete approach propagates the water front faster and higher than the raster one, but in the end they converge, indicating that the LISFLOOD simplification is accurate for long term and final steady states but not for transient ones, at least in urban floods, where there are many reflections between buildings.

To simulate 3 tidal cycles took 70 minutes, with a 2.66 GHz processor for a 10 m resolution grid (184 Kcells) with the 2D complete model and 3 times less with the raster based one.

4 CONCLUSIONS

Practitioners still have reservations about using more complex models than the quasi-2D or storage cells, but their use and efficiency is wide spread in the scientific community. The work presented here tries to show that these models (2D) are feasible with current computers to certain resolutions. They require more technically educated users, but they can save time in the input processing of data, and their output gives much more information. This work also confirms that their coupling with commonly available digital surface models from remote sensing (like LIDAR) is effective.

It is becoming evident that increasing numbers of flood simulations are going to be carried out. The authors support the idea of using flexible programming tools in computer facilities such as multi-processors or grid/cluster computing systems, along with GNU compilers like gcc, mpich and Linux systems. These will provide reliable and high performance tools for fullfilling targets.

Further publications from the research group will cover in detail the London Thames Embankment area with other schemes and other scenarios.

Roughness coefficient for flood plains with macro roughness elements

I. Aydin
Assoc. Prof., Civil Eng. Dept., Middle East Technical University, Ankara, Turkey

Research Engineer, State Hydraulic Works, Technical Research and Quality Control Dept., Hydraulics Lab., Yücetepe, Ankara, Turkey

M. Ustaomer
Graduate Student, Civil Eng. Dept., Middle East Technical University, Ankara, Turkey

ABSTRACT: Manning's roughness coefficient for flood plains with macro roughness elements is experimentally investigated in an 18 m long and 1 m wide laboratory channel. Velocity field was measured in the main and flood plain channels. Total discharge was obtained both from weir measurement and from integration of measured velocity field. Four different surface patterns including smooth and various arrangements of macro roughness elements were considered. Prismatic concrete volumes were placed as macro roughness elements on the flood plains. Wall shear stresses were determined from measured velocity profiles using logarithmic wall functions. Energy slope was determined from the total tractive force obtained by integration of wall shear stresses. Finally, Manning's roughness coefficient was determined from the Manning's formula applied to main channel and the flood plain channels. It is found that the roughness coefficient on the flood plain channels may increase more then two folds when about 2% of the flow volume in the flood plain is occupied by the macro roughness elements.

1 INTRODUCTION

The cross-section of rivers in nature can be thought as compound channels consisting of one deep main channel and one or two flood plains. In dry seasons flood plains may be used for agricultural purposes. In narrow valleys flood plains may extend to settled areas including houses and small sized buildings. Flood plains with large scale obstructions show increased resistance to flow and may cause unexpected increases in the flow depth. Estimation of the discharge capacity or flow depth during seasonal floods over the flood plains with macro sized roughness elements is of crucial importance to prevent life losses.

Throughout the average velocity and discharge capacity analyzes in singly cross-sectioned channels from Manning's or Chezy's equations; it is enough to use the overall hydraulic radius. However, in case of compound channels, as the depth of water increases, the sudden change of cross-section immediately above the main channel will lead to errors due to sudden decrease in hydraulic radius of the channel. Free surface flow calculations in compound channels require special attention on roughness variations over the cross-section to predict the flow resistance accurately.

Compound channels can be analyzed by subsections as flood plains and main channel. The hydraulic radius in flood plains are greater than that of main channels which results significantly higher velocities in the main channel compared to flood plains. Difference between the velocities causes lateral momentum transfer at the interface from fast flowing main channel to the flood plain, which shows itself as apparent shear stress at this interface. The effect of apparent shear stress reduces the discharge capacity of the compound channel significantly. Essentially the methods used to determine the discharge capacity for regular shaped cross-sectional channels may lead either underestimation of discharge capacity which will risk settlement on flood plains, or may lead to overestimation of discharge capacity resulting in over design and waste of resources.

Significant research has been undertaken in hydraulics of compound channels to understand the mechanics of flow and to obtain more accurate methods of discharge estimation. In this study, the flood plain Manning roughness coefficient is determined for the cubic macro roughness elements. Experiments have been performed to measure the flow depths and velocity distributions for different macro roughness

Copyright © 2006 Taylor & Francis Group plc, London, UK

densities on the flood plains. Measured velocity data is used to estimate the boundary resistance by employing the universal wall functions.

2 LITERATURE REVIEW

Considerable research has been carried out in compound channel hydraulics both experimentally and numerically. Large amount of experimental work was devoted to prediction of momentum exchange between the main channel and the flood plains. A variety of roughness types were also studied.

Yen and Overton (1973) tried to determine the lines that divide the cross-section into subsections at which the shear stress is zero. These lines are not included as a part of a wetted perimeter in flow computation when they are used as division lines. Since little information exists as to the location of these interface planes as they are affected by geometry and flow depth, laminar flow cases were solved to gain quantitative insight.

Myers and Elsawy (1975) studied the effect of the interaction mechanism on shear stress distribution in compound channels. The asymmetric shape was chosen to prevent any compensating effect and to simulate rivers having one flood plain. They revealed that the presence of the interaction between channel and flood plain significantly alters the values and the distribution of shear.

Myers (1978) used a Preston tube to measure shear stress distribution around the periphery of a compound channel, consisting of a deep section and one flood plain. Measurements were made with full cross-section flow and with flow confined to main channel. The results were used to quantify the momentum transfer due to interaction between the main channel flow and that its flood plain. Lateral momentum transfer throughout the main channel and flood plain was compared under isolated and interacting conditions.

Rajaratnam and Ahmadi (1979) studied experimentally interaction between the main channel and flood plain flows for a symmetric flood plain for smooth boundaries. Their results demonstrated the transport of the longitudinal momentum from the main channel to the flood plain. They found that the velocity profiles in the flood plain, and in the main channel above the level of the flood plain to be approximately similar if viewed with respect to the undisturbed flood plain velocity. Also empirical correlations have been found for the velocity and length scales. A possible method to estimate the loss in the flow capacity of the compound cross-section due to the interaction was indicated.

Rajaratnam and Ahmadi (1981) presented the results of an experimental study on the interaction between the flow in a wide main channel and the flood plain. This interaction region was shown to resemble a shear layer with some control exercised by the bed shear stress. The length of this interaction region as well as the reduction and increase of bed shear stress in the main channel and flood plain respectively, in dimensionless forms, was correlated with the ratio of the depth of flow to the depth of the main channel.

Wormleaton et al. (1982) performed a series of laboratory tests to measure the boundary shear stress in a compound channel. From these results, they calculated apparent shear stress across three different assumed main channel-flood plain interface plains (vertical, horizontal and diagonal). A statistical relationship for the apparent shear stress on the vertical interface was derived. The accuracy of the different discharge calculation methods was shown to be independent upon the assumptions on the magnitude of the apparent shear stress on the particular interface chosen. An apparent shear stress ratio was proposed which was found to be useful in selecting the best method of discharge calculation.

Knight and Demetriou (1983) performed experiments concerning the discharge characteristics; the boundary shear stress and boundary shear force distributions in a compound section. Equations were presented giving the shear force on the flood plains as a percentage of the total shear force in terms of two dimensionless parameters. Equations were also given for the proportion of the total flow which occurs in the various sub-areas. The division of flow based on linear portion of the areas is shown to be inadequate on account of the interaction between the main channel and flood plain flows.

Knight and Hamed (1984) presented experimental results concerning the boundary shear force distributions in a compound section comprising of one rectangular main channel and two symmetrically disposed flood plains. The flood plains were roughened progressively in six steps so that the influence of differential roughness between the flood plains and the main channel on the lateral momentum transfer process could be studied. Equations were presented giving the shear force on the flood plains as a percentage of the total shear force in terms of four dimensionless parameters. Supplementary equations were also presented giving the apparent shear force on vertical, horizontal and diagonal interfaces within the cross-section. The influence of momentum transfer between sub-areas on the vertical and lateral distribution of longitudinal velocity was also assessed.

Tominaga et al. (1989) investigated the three-dimensional turbulent structure, including turbulence driven secondary currents in an asymmetric compound open-channel. In this study, accurate measurements in fully developed compound open-channel flows were conducted by means of a fiber-optic Laser Doppler anemometer, and then the secondary currents, turbulence intensities and the Reynolds stresses were measured. Moreover, the effects of channel

Copyright © 2006 Taylor & Francis Group plc, London, UK

geometry and bed roughness on turbulent structure were examined.

Wormleaton and Merrett (1990) performed experiments for discharge and boundary-shear stress distribution in symmetric compound channel with flood plain sections of varying widths and roughness. These were used to assess the performance of several standard discharge calculation methods, which assume different locations of the interface between main channel and flood plain sub-areas. It was shown that these methods can produce large errors in total end, more particularly, component discharges. A modified form of the standard discharge calculation method was discussed, which made a more realistic allowance for interaction at the main channel-flood plain interface. It is achieved by the φ-indices method to characterize momentum transfer between adjacent sub-areas, into the calculation. This modified method was shown to be considerably more accurate than the standard methods in the calculation of total and component discharges. A tentative regression equation was presented for calculating φ-indices from easily identifiable cross-sectional characteristics.

Myers and Brennan (1990) demonstrated the effects of momentum transfer from main channel sections. Flow resistance relationships for the compound section, main channel and flood plains were presented in terms of Manning's and Darcy-Weisbach resistance coefficients and compared with that of simple channel sections.

Stephenson and Kolovopoulos (1990) discussed different methods for the apparent shear stresses between a main channel and its flood plains. The methods discussed include the simplistic method of considering the entire hydraulic cross-section as one, dividing the cross-section into independent sections, trying to find an interface with zero shear stress, or allowing for the shear stresses from a momentum balance. Based on evaluation of alternative steady state models, it was concluded that the area method is the most promising for computation of discharge and that the Prinos et al. equation (1985) gives accurate results for apparent shear stresses at the main channel-flood plain interface.

Smart (1992) studied the stage-discharge discontinuity in composite flood channels. From the experiments it was concluded that the increase in Manning's roughness coefficient was related to the ratio of flood plain drag to main channel driving force. The higher the ratio, the effective Manning's resistance coefficient for the main channel increases.

Kayatürk (1997) studied experimentally the interface Manning roughness coefficient in an artificially roughened compound channel to take into account the apparent shear stress occurring at the interface of the main channel and the flood plain. Associated with this roughness coefficient, a method is proposed to estimate the discharge in the compound channels.

Figure 1. Experimental set-up.

Myers and Lyness (1997) examined the ratios of total discharge to the bank-full discharge and main channel discharge to flood plain discharge and concluded that of the compound channel have homogeneous roughness, the ratios depend on geometry only.

Bousmar and Zech (1999) presented a 1-D model of compound channel flows called as the exchange discharge model. The interactions between main channel and flood plain are taken into account as a momentum transfer proportional to the product of the velocity gradient at the interface by the mass discharge exchanged through this interface due to turbulence. The momentum transfer formulated in this model as an additional head loss enabled practical water-profile computations.

Thornton et al. (2001) studied a predictive expression to permit the estimation of the apparent shear stress at the boundary of a main channel and flood plain as a function of the bed shear stress, average velocity, and depth in both main channel and flood plain and the blockage caused by the flood plain.

3 EXPERIMENTAL STUDY

The experimental part of this study was conducted in the Hydraulic Research Laboratory of General Directorate of State Hydraulic Works of Turkey (DSI). Experiments were made in a 18 m long compound channel made of concrete (Fig. 1).

Water is supplied from a constant head tank and discharge is adjusted by the valve on the supply pipe. At the entrance to the compound channel there is a sharp-crested rectangular weir to measure the discharge into the system. Dimensions of the channel cross-section are shown in Fig. 2.

Cubic concrete volumes shown in Fig. 3 are used to represent the macro roughness elements. Different arrangements of roughness elements were considered

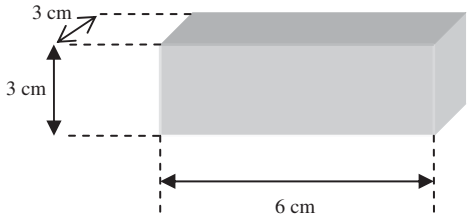

Figure 3. Dimensions of macro-roughness elements.

and each case is named as a roughness pattern. In total, four roughness patterns were used. Pattern-1 is concrete surface with no macro roughness elements. Pattern-2, Pattern-3 and Pattern-4 are as shown in Fig. 4.

AMCA type pitot-tube is used to collect the velocity data in the channel cross-section at about 7.3 m downstream of the entrance section. The velocity distribution is assumed to be symmetrical about the vertical axis (E-F) at centerline of the main channel and velocity data is taken only over the symmetrical half of the channel cross-section. Grid of velocity measuring points for Exp.1 are shown in Fig. 5.

Considering two different discharges with the four different roughness patterns, 8 sets of experiments were conducted. Data describing the experimental cases are given in Table 1. Q_w is the weir discharge, Q_i is the discharge obtained from integration of the measured velocity field over the cross-section, y is water depth, Q_{mc} is the discharge in the main channel, and Q_{fp} is the discharge in one flood plain. The differences between the weir and integral values of the total discharge are less than 5%. Integrated values of discharge will be used in the following analyses. Contourlines of velocity on the symmetrical half of the channel is shown for Exp. 1 in Fig. 6.

4 ANALYSIS

4.1 *Determination of wall shear stresses*

Wall resistance must be determined to express the force balance in the flow direction. Measured velocity

8	Pattern 4	0.200	0.209	0.362	0.090	0.015

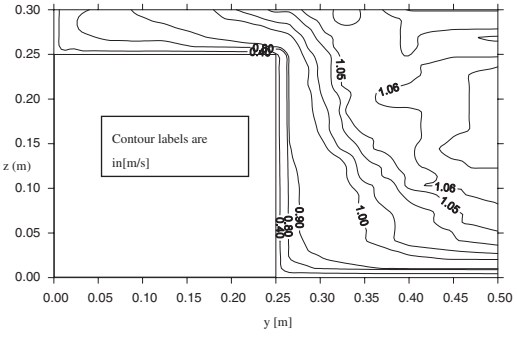

Figure 6. Velocity contour lines for Exp.1.

data is utilized to evaluate the wall shear stresses. It is assumed that the measured velocity all along the wetted perimeter (except the flood plain covered by macro roughness elements) obey the logarithmic wall functions. The law of the wall is written as

$$U^+ = \frac{1}{\kappa}\ln(\eta^+) + D - E \quad (1)$$

$$U^+ = u/U_* \quad (2)$$

$$\eta^+ = \eta U_* / \nu \quad (3)$$

$$U_* = \sqrt{\tau_w/\rho} \quad (4)$$

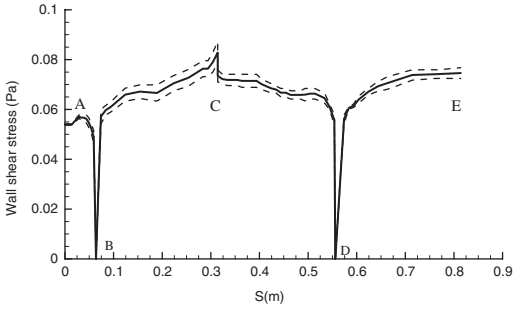

Figure 7. Wall shear stress distributions for Exp. 1.

where U^+ is dimensionless velocity, u is point velocity, η is distance normal to the wall, U_* is the shear velocity, τ_w is the wall shear stress, ρ is fluid density, ν is kinematic viscosity of the fluid, $\kappa = 0.41$, $D = 5.3$, and E is a parameter dependent on surface roughness. After Schlichting (1979),

$$E = \frac{1}{\kappa}\ln(\varepsilon^+) - 3.0 \quad (5)$$

$$\varepsilon^+ = \varepsilon U_* / \nu \quad (6)$$

where ε is the equivalent sand roughness height. Equation 1 is valid in the first 20% of the boundary layer for $\eta^+ > 70$. Only a single point velocity data in the vicinity of the wall is enough to determine the shear velocity from Equation 1 and therefore the wall shear stress provided that the limitations for the existence of the equation are not violated. The wall shear stress along portions of the wetted perimeter without macro roughness elements will be determined by using the wall function method described above. In Exp. 1 and Exp. 5 there are no macro roughness elements in the channel, therefore, the wall function method is applicable for the complete perimeter of the cross-section. Wall shear stress distribution for Exp. 1 is shown in Fig. 7 as function of distance s along the wetted perimeter. Distance s starts from the free surface of the left flood plain (point A in Fig. 2) and ends at the mid point of the channel along the symmetry line (point E). The dashed lines show the wall shear stresses obtained from the first and the second measurement points of velocity next to the wall and the solid line is the average of them which is used in the analysis.

4.2 *Channel slope*

The wall shear stress integrated along the wetted perimeter is equated to the component of gravity force acting in the flow direction.

$$\int_A^E \tau_w \, ds = \frac{\gamma A S_e}{2} \quad (7)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

where γ is specific weight of water, A is flow area and S_e is the energy slope. For uniform flow conditions S_e obtained from Equation 7 must be equal to the channel bottom slope. The channel slopes obtained from data of Exp. 1 and Exp. 5 are 0.00221 and 0.00223 respectively. The average value $S_e = 0.00222$ is used in the computations.

4.3 *Force balance in the flood plain*

The compound channel (Fig. 2) is divided into main and sub-channels through the vertical interface C-G. Momentum conservation can be applied to the main channel and the flood plain separately. However, the friction force acting along the interface C-G must be known. Macro roughness elements are placed along the horizontal line B-C of the flood plain only. Therefore, the wall shear stresses in all experimental cases can be determined by the wall function method except when the line B-C is covered by the macro roughness elements. The equilibrium of forces acting on the left half main channel in the flow direction can be expressed as

$$\frac{\gamma A_m S_e}{2} - \int_C^E \tau_w \, ds - F_{int} = 0 \tag{8}$$

where A_m is the flow area of the main channel, F_{int} is the friction force acting on the interface line C-G between the main channel and the flood plain. A similar expression for the flood plain would be

$$\gamma A_{fp} S_e - \tau_{fp} P_{fp} + F_{int} = 0 \tag{9}$$

where A_{fp} is the effective flow area of the flood plain, τ_{fp} is the average wall shear stress in the flood plain, P_{fp} is the wetted perimeter (from A to C) of the flood plain. The effective flow area of the flood plain is obtained by subtracting the roughness area (normal to flow direction) averaged for unit length of the channel from the cross-sectional area of the flood plain. Friction force at the interface, F_{int}, is in the direction of the flow augmenting the gravity component. Equation (9) can be re-written in terms of effective energy slope, S_{fp}, in the flood plain which is increased due to the friction at the main channel interface.

$$\gamma A_{fp} S_{fp} - \tau_{fp} P_{fp} = 0. \tag{10}$$

Combining Equation 9 and Equation 10 and solving for S_{fp} gives

$$S_{fp} = S_e + \frac{F_{int}}{\gamma A_{fp}} \tag{11}$$

Manning's equation can now be applied to the flood plain to determine the equivalent roughness coefficient for the flood plain.

$$(n_{fp})_{eq} = \frac{A_{fp} R_{fp}^{2/3} S_{fp}^{1/2}}{Q_{fp}} \tag{12}$$

The roughness coefficient for the macro roughness elements, n_{mr}, is determined from

$$n_{mr} = \left[\frac{(n_{fp})_{eq}^2 (y_{fp} + B_{fp}) - y_{fp} n_c^2}{B_{fp}} \right]^{1/2} \tag{13}$$

where n_c is the Manning's roughness coefficient for the concrete side wall of the flood plain.

Table 2. Results of the momentum analysis.

Exp. No	F_{int} (N)	S_{fp} –	n_{mr} –	V_r –
1	0.3672	0.00456	0.0113	1.000
2	0.4495	0.00469	0.0267	0.964
3	0.5608	0.00500	0.0263	0.945
4	0.4588	0.00469	0.0287	0.914
5	0.3548	0.00396	0.0113	1.000
6	0.7541	0.00506	0.0249	0.975
7	0.8166	0.00519	0.0254	0.959
8	0.7209	0.00502	0.0259	0.936

4.4 *Results and discussions*

Data of Exp. 1 and Exp. 5 are used to determine the Manning's roughness for the concrete surface without macro roughness elements. The equivalent sand roughness height is taken as $\varepsilon = 0.0005$ m and the corresponding Manning's value is obtained as $n_c = 0.0117$. This value is obtained directly from Eq. 7 by a single channel treatment.

Data of experiments 2, 3, 4 and 6, 7, 8 are utilized to determine the Manning's roughness for the corresponding macro roughness patterns by the compound-composite channel procedure described through equations 8∼13. The macro roughness is assumed to depend on volume ratio defined as the ratio of volume of flow area in the flood plain averaged for unit length of the channel divided by volume of flood plain without macro roughness elements. The friction force at the interface, the modified energy slope for the flood plain, Manning's roughness for the macro roughness elements and the volume ratio are shown in Table 2.

Roughness values obtained for Exp. 1 and Exp. 5 are very close to the value obtained from single channel solution. Manning's n for flood plain (n_{mr}) is shown as function of volume ratio in Fig.8. Roughness increases more than twice when macro elements are introduced on the flood plain. Dependence of n_{mr} over the volume ratio is very weak or not clear due to less number of data available.

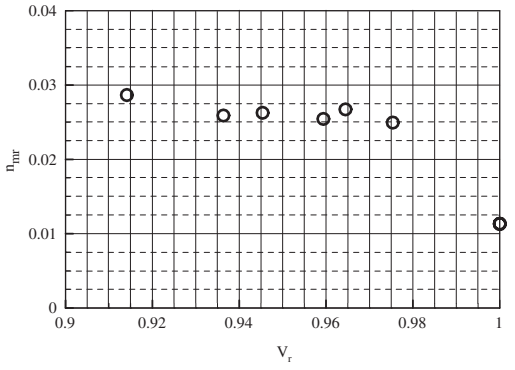

Figure 8. Roughness coefficient for macro roughness elements as function of volume ratio.

5 CONCLUSIONS

Manning's roughness for macro roughness elements on the flood plains of compound channels is investigated through laboratory experiments. The arbitrariness in determination of Manning's roughness for macro roughness elements may be reduced by use of effective flow area for the flood plains in the Manning's equation. More experimental data is necessary to set-up a functional dependence of Manning's n on geometric characteristics of macro roughness elements.

Discretization of the friction term in the shallow water equations

J. Murillo, J. Burguete, P. Brufau & P. Garcia-Navarro
Fluid Mechanics CPS, University of Zaragoza, Spain

ABSTRACT: The numerical simulation of unsteady open channel flows is very commonly performed using the one-dimensional or two-dimensional shallow water models. Friction is one of the relevant forces included in the momentum equation. The friction term participates in the Saint Venant mathematical model as a non-linear sink of momentum. The system is a set of partial differential equations that requires numerical resolution in almost all cases of interest. Therefore, a complete analysis of the role played by friction in an open channel flow model does involve the question of the numerical simulation as well as those of the mathematical modeling. Few previous works have treated in detail the consequences of the discretization of the friction term. The most commonly reported procedure is the pointwise discretization of the term independently of the methodology used for the rest of the system, for simplicity reasons. The numerical stability conditions are revisited in cases of dominant friction terms. Usual numerical stability conditions are based on the prevalence of convective terms and may not be sufficient in cases of high roughness. In many cases, the experience indicates that a spatial grid refinement and a time step size reduction becomes necessary to achieve stable solutions. A new condition, complementary to the basic Courant-Friedrichs-Lewy condition, is used. As the condition leads to a requirement on the spatial grid size it will be shown efficient only in 1D cases. The implicit upwind discretizaton of the friction terms will be shown the best option when dealing with high roughness unsteady problems in two dimensions.

1 INTRODUCTION

The one-dimensional shallow water model involves cross sectional averaging of the original flow equations if not only trivial situations have to be handled. One of the main consequences of such cross sectional average is that the viscous flow boundary condition at solid walls and bottom is transformed into a drag/friction force source term. The form of this friction force term is closely related to the underlying turbulence model. Actually, the presence of the wall roughness term is the only trace of the flow turbulence in the mathematical model.

To model friction, empirical or semi-empirical methods have traditionally been applied. Chezy's model, proposed in the 18th century, was one of the first. Later, in the 19th century, Darcy (Darcy, 1858) and Gauckler-Manning (Gauckler, 1867), (Manning, 1890) proposed analogous models. These three models, despite their very early origin, are still widely used nowadays to compute the effect of roughness in Hydraulics. They are all based in an empirical coefficient dependent on the surface roughness as well as on the flow characteristics, and can be found in tabular form in many references as, for instance, (Chow, 1959).

The friction term participates in the Saint Venant mathematical model as a non-linear sink of momentum. The system is a set of partial differential equations that requires numerical resolution in almost all cases of interest. Therefore, a complete analysis of the role played by friction in an open channel flow model does involve the question of the numerical simulation as well as those of the mathematical modeling. Few previous works have treated in detail the consequences of the discretization of the friction term. The most commonly reported procedure (Huang & Song 1985), (Garcia-Navarro et al., 1999), is the pointwise discretization of the term independently of the methodology used for the rest of the system, for simplicity reasons. A different option is also considered in this work and their ability to produce conservative solutions is compared in a case of steady open channel flow with analytical solution.

Finally, the interaction between a dominant friction term in the equations and stability constraints is investigated. Usual numerical stability conditions are based on the prevalence of convective terms and may not be sufficient in cases of high roughness. In many cases, the experience indicates that a spatial grid refinement and a time step size reduction becomes necessary to achieve stable solutions. Liggett and Cunge (Liggett & Cunge, 1997), proposed a time step limit dictated by the friction coefficient, starting from the analysis of the linearized equations. Even though this criterion may help controlling stability in some cases, it is not a

Copyright © 2006 Taylor & Francis Group plc, London, UK

reliable condition in general cases of flow over rough, irregular beds. A more general condition leading to a requirement on the spatial grid size will be derived and tested in a real case.

2 1D DISCRETIZATION OF THE FRICTION TERM

In a general conservative form, the 1D shallow water equations can be expressed

$$\frac{\partial \mathbf{u}(x,t)}{\partial t} + \frac{d\mathbf{F}(x,\mathbf{u})}{dx} = \mathbf{H}(x,\mathbf{u}) \tag{1}$$

where **U** is the vector of conserved variables, **F** the vector of fluxes and **H** the vector of source terms. The justification of the particular form of (1) can be found in (Burguete & Garcia-Navarro, 2001). Our interest is led by the numerical modelling of one-dimensional shallow water flows of practical application in Hydraulics such as river flows. In that case

$$\mathbf{u} = \begin{pmatrix} A \\ Q \end{pmatrix}, \quad \mathbf{F} = \begin{pmatrix} Q \\ \frac{Q^2}{A} + gI_1 \end{pmatrix}, \quad \mathbf{H} = \begin{pmatrix} 0 \\ g\left[I_2 + A\left(S_0 - S_f\right)\right] \end{pmatrix}$$

where Q is the discharge, A is the wetted cross section, g is the acceleration of gravity and S_0 is the bed slope. The rest of the terms account for pressure forces and for friction forces, with S_f associated to wall friction and represented by the empirical Manning law.

2.1 *Unified discretization*

The conservative form of the system of differential equations (1) can be solved by means of a conservative scheme. The following vector is defined for convenience:

$$\mathbf{G}_{i+(1/2)} = \left(\mathbf{H} - \frac{\delta \mathbf{F}}{\delta x}\right)_{i+(1/2)}$$

$$\mathbf{H}_{i+(1/2)} = \begin{pmatrix} 0 \\ g\left[\frac{\delta I_1}{\delta x} - \overline{A}\left(\frac{\partial z_s}{\partial x} + \overline{S_f}\right)\right] \end{pmatrix}_{i+(1/2)} \tag{2}$$

with z_s the water surface level and using the notation $\delta f_{i+(1/2)} = f_{i+1} - f_i$ and $\overline{f} = (f_{i+1} + f_i)/2$. The unified discretization of the friction term consists of discretizing flux, friction and other source terms in the equation in a similar form. A general conservative scheme with unified discretization can be expressed as (Burguete & Garcia-Navarro, 2001), (Burguete & Garcia-Navarro, 2004);

$$\left(1 - \theta \Delta t \mathbf{K}_i^n\right) \Delta \mathbf{u}_i^n = \Delta t \left(\mathbf{G}_{i-(1/2)}^L + \mathbf{G}_{i+(1/2)}^R\right) \tag{3}$$

where $\mathbf{K} = \partial \mathbf{H}/\partial \mathbf{U}$ is the source term Jacobian, $\theta \in [0,1]$ is a coefficient controlling the implicitness of the source term and $\mathbf{G}^{L,R}$ represents the wave discretization particular to each numerical scheme. See (Burguete et al., 2006) for more details.

2.2 *Pointwise discretization*

Due to the form of the friction source term, it is common to find applications using a pointwise discretization. In this case, the source term is split in two terms, one of them involving only the friction term:

$$\mathbf{H} = \mathbf{R} + \mathbf{S} \tag{4}$$

with

$$\mathbf{R} = \begin{pmatrix} 0 \\ -gAS_f \end{pmatrix}, \quad \mathbf{S} = \begin{pmatrix} 0 \\ g\left(I_2 - AS_0\right) \end{pmatrix} \tag{5}$$

Defining now the vector:

$$\mathbf{G}_{i+(1/2)} = \left(\mathbf{S} - \frac{\delta \mathbf{F}}{\delta x}\right)_{i+(1/2)} \tag{6}$$

A conservative scheme is then applied to all the terms except the friction term that is added as:

$$\left(1 - \theta \Delta t \mathbf{L}_i^n\right) \Delta \mathbf{u}_i^n = \Delta t \left(\mathbf{R}_i^{n+\theta} + \mathbf{G}_{i-(1/2)}^L + \mathbf{G}_{i+(1/2)}^R\right) \tag{7}$$

where $\mathbf{L} = \partial \mathbf{S}/\partial \mathbf{U}$ is the Jacobian of the non-frictional source terms.

Even though this discretization is widespread and recommended in several works (Huang & Song 1985), (Garcia-Navarro et al., 1999) due to its simplicity and the possibility to use a fully implicit discretization of the friction term, it can be shown that it produces the unbalance of the friction term and the rest of the terms in the equation in steady state.

Explicit numerical schemes applied the solve the unsteady Saint-Venant equations are said to be numerically stable if the time step and grid size chosen are linked by the Courant-Friedrichs-Lewy condition:

$$\Delta t \leq \frac{\Delta x}{|u| + c} \tag{8}$$

with $u = Q/A$ the average flow velocity and $c = \sqrt{gA/B}$ the critical celerity, where B is the cross

Copyright © 2006 Taylor & Francis Group plc, London, UK

sectional top width. This is a stability condition based on the advective character of the equations.

The friction source term in the Saint-Venant equations is often one of the dominant terms, especially river flow or surface irrigation applications, and it is essential to establish a stability conditions that takes them into account. Despite a few earlier efforts in this sense, as (Liggett & Cunge, 1997) for instance, we believe that stability conditions of the Saint-Venant equations with important friction terms has not been adequately addressed.

Two particular stability conditions will also be analyzed for the non-linear case. Even though they are not general, they can be useful to throw some light on the conditions that must be fulfilled in order to avoid instabilities due to the friction term.

3 1D STABILITY CONSTRAINTS

One of the traditional forms to analyze the stability of a numerical scheme is to study the amplification of the small perturbations that it produces. Using the Gauckler-Manning model and assuming uniform base flow for simplicity and a sinusoidal form can be chosen for the perturbation, in the particular case of long waves ($k \to 0$) a particular condition can be obtained since the a notable simplification is enabled:

$$\left|1 - \Delta t \frac{2gS_f}{u}\right| \leq 1 \tag{9}$$

where,again, the normal flow condition has been used ($S_0 = S_f$). The following restriction, independent of the grid size is obtained:

$$\Delta t \leq \frac{u}{gS_f} \tag{10}$$

The detailed derivation is in (Burguete et al., 2006). Note that, contrary to the standard Courant-Friedrichs-Lewy condition (8), the present stability condition restricts the time step size independently of the spatial step. Thus, instabilities due to the friction term are most likely in coarse grids. This condition was already considered by Liggett and Cunge (Liggett & Cunge, 1997).

On the other hand, a non-linear stability analysis assuming flat bottom and surface levels leads (see (Burguete et al., 2006)) to the evidence that the stability conditions disappear when using an implicit discretization of the source term. Therefore, the implicit treatment ($\theta = 1$) of the friction term is recommended in case of using a coarse mesh in presence of strong roughness.

Finally, the analysis of the stability constraint in presence of friction and adverse slope provides the result that the grid size appears to be limited by the hydraulic radius and the roughness in order to enforce stability on the numerical solution. All the details can be found in (Burguete et al., 2006). If the Gauckler-Manning friction model is used:

$$\Delta x \leq \frac{2R^{\frac{4}{3}}}{gn^2} \tag{11}$$

where R is the hydraulic radius and n is the Manning roughness coefficient. It is easy to show that always, when the CFL condition holds, this condition is stronger than previous time step restrictions for subcritical flow.

4 2D ANALYSIS

When performing a two-dimensional modelling of the flow, it has been previously stated (Brufau et al. 2004) that a pointwise explicit discretization of the friction term produces numerical oscillations when roughness is high. Furthermore, at the wetting/drying fronts, characterized by small values of water depth, this term dominates over any other influence. To avoid friction-driven oscillations, the following conditions must be ensured:

$$\begin{aligned}
&(hu)_i^{n+1} \geq 0, \quad \text{if } (hu)_i^n > 0 \\
&(hu)_i^{n+1} \leq 0, \quad \text{if } (hu)_i^n < 0 \\
&(hv)_i^{n+1} \geq 0, \quad \text{if } (hv)_i^n > 0 \\
&(hv)_i^{n+1} \leq 0, \quad \text{if } (hv)_i^n < 0
\end{aligned} \tag{12}$$

It is easy to show that a pointwise implicit discretization of the friction terms leads to:

$$\begin{aligned}
(hu)_i^{n+1} &= \frac{(hu)_i^*}{1 + g\Delta t\,(S_{fx}/u)_i^*} \\
(hv)_i^{n+1} &= \frac{(hv)_i^*}{1 + g\Delta t\,(S_{fy}/v)_i^*}
\end{aligned}$$

where the superscript $*$ stands for the frictionless updated values and that inconditionally holds 12. On the other hand, it is straightforward to see (Murillo, 2006) that a pointwise explicit discretization of the friction terms leads to a conditional stability where:

$$\Delta t \leq \min\left(\frac{1}{g\,(S_f/|\mathbf{u}|)_i^*}\right)$$

involving the modulus of (S_{fx}, S_{fy}). Finally, it is not difficult to see that an explicit upwind discretization

Copyright © 2006 Taylor & Francis Group plc, London, UK

of the friction terms is compatible with 12 provided that

$$\Delta t \leq \min\left(\left(\frac{gn^2\,|\tilde{\mathbf{u}}_\mathbf{k}|\,d_n l_k}{\min(A_i,A_j)\tilde{h}_k^{4/3}}\right)^{-1}\right)_{k=1,Nedge}$$

where i and j are the labels of the cells separated by every edge k and the $\tilde{h}, \tilde{u}$ variables are evaluated at the average state between them, l_k is the length of edge k and d_n is the distance between cell centers measured normal to the edge.

5 1D EXAMPLES

MacDonald (MacDonald et al., 1997) proposed a series of theoretical steady open channel flow test cases with analytical solution. In all of them sloping bed and friction term are considered. The steady Saint-Venant equations

$$Q = \text{const.}$$
$$\frac{\partial}{\partial x}\left(\frac{Q^2}{A} + gI_1\right) = g\left[I_2 + A(S_0 - S_f)\right] \qquad (13)$$

Given a constant discharge and an analytical water depth function, the steady solutions can be found from the momentum equation:

$$S_0 = S_f + \frac{1}{gA}\left[-gI_2 + \frac{\partial}{\partial x}\left(\frac{Q^2}{A} + gI_1\right)\right] \qquad (14)$$

where S_f is modelled via the Gauckler-Manning friction law. Then, the channel bed form can be obtained.

One of these test cases has been chosen to show the influence of the discretization of the friction term on the quality of the solution. A subcritical flow in a channel of rectangular cross section 10 m wide and 150 m long is assumed. The steady discharge is 20 m^3/s and the bed material is characterized by a friction Manning coefficient 0.03 $sm^{-\frac{1}{3}}$. The water depth is defined by the function:

$$h = 0.8 + 0.25\exp\left[-\frac{135}{4}\left(\frac{x-75}{150}\right)^2\right] \qquad (15)$$

The water depth and surface water level longitudinal profiles are displayed in Figure 1 and Figure 2 for this test case.

Figure 3 and Figure 4 show the numerical results obtained using the first order upwind scheme and both the unified and pointwise methods for the friction term. It can be seen that only the unified method is able to provide a right balance and a perfect conservation in the steady discharge.

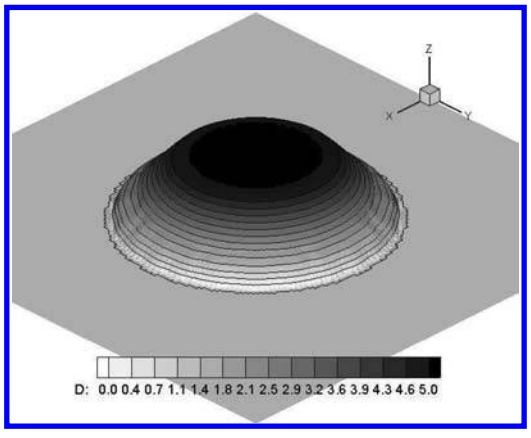

Figure 5. Water level at t = 20s in the 2D radial dam break test case. Implicit pointwise discretization of the friction terms.

6 2D EXAMPLE

A radial dam break flow is used as two-dimensional example. In a flat 4000 m × 4000 m closed domain, the following initial conditions are assumed:

$$r = \sqrt{x^2 + y^2} \leq 800m \quad h = 5m, u = 0, v = 0$$

$$r = \sqrt{x^2 + y^2} > 800m \quad h = 0.01m, u = 0, v = 0$$

The Manning roughness coefficient is $n = 0.03$. 51200 triangular cells have been used to generate Figures 5 and 6. They show the shape of the water level after 20 seconds and correspond to computations where, respectively, a pointwise implicit discretization and an upwind explicit discretization of the friction terms

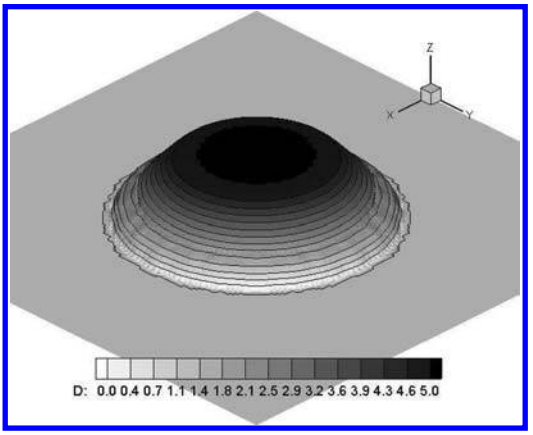

Figure 6. Water level at t = 20 s in the 2D radial dam break test case. Explicit upwind discretization of the friction terms.

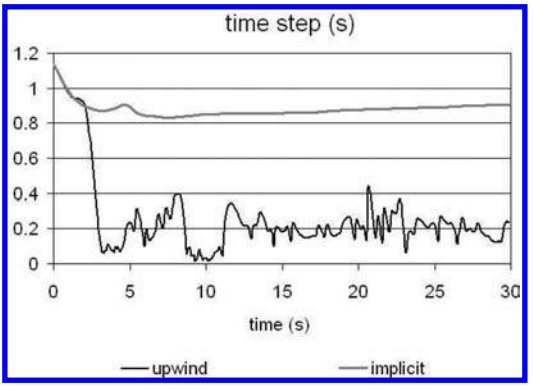

Figure 7. Time evolution of the time step size in the 2D radial dam break test case comparing pointwise implicit and upwind explicit discretization of the friction terms.

have been used. The results are almost identical and both stable. However, the computational cost of such stability is different as Figure 7 shows, where the variations in time of the time step size compatible with stability has been plotted for each method.

7 1D RIVER FLOW APPLICATION

Neila River flows through a mountain region of central Spain. It is highly irregular in shape and steep (with average slope around 20% in some reaches). The base flow is very low (around $1\,m^3/s$) and the stony but vegetated river bed is associated to a high friction factor $n = 0.05\,sm^{-\frac{1}{3}}$. A reach of 18 Km has been characterized by means of 48 cross sections.

The physical conditions of steep slope, low base discharge and high roughness make this river a challenging test case for the numerical schemes to be able

to produce a stable solution. The water depth in the base flow steady profile can be as low as 4 *cm* in some parts producing, from the stability condition (11) the following requirement:

$$\Delta x \leq 1.1m \tag{16}$$

Figures 8–19 display the results obtained using the first order upwind scheme to convergence to the base flow steady state with dry bed initial conditions. The scheme has been provided with a semi-implicit unified discretization of the friction term. Several spatial grid and time step sizes have been evaluated to estimate their influence in the numerical results. In all cases, the following water depth threshold value, derived from (11) was imposed

$$h_i^n \leq \left(\frac{gn^2\Delta x}{2}\right)^{\frac{3}{4}} \Rightarrow Q_i^n = 0 \tag{17}$$

This condition is necessary to stabilize the solution since it avoids irrealistic growing tendencies in the

discrete friction terms. It stops water at depth values less than the limit imposed leading, for coarse grids, to some kind of pulses in the flow during the transient calculation that spoil the quality of the solution.

It was found that $\Delta x = 1\,m$, following (16), is the only grid size ensuring smooth, continuous and steady discharge results. As the grid size is increased above the friction stability limit, and despite the semi-implicit discretization of the friction term, the numerical solutions become eventually unstable. The traditional remedy of trying to reduce the instabilities by decreasing the time step size does not work since, using in $\Delta x = 2\,m$ the time step given by CFL = 0.25 or CFL = 0.02 in the grid $\Delta x = 10\,m$, did not improve the stability of the solution due to the inadequacy of the space discretization.

8 CONCLUSIONS

The unified discretization of the friction term allows for a perfect balance between source terms and flux derivatives at the discrete level, enabling a better quality solution than the pointwise discretization of the friction term at steady state.

The stability constraints linked to important values of the friction terms have been analyzed both in 1D and 2D. The main options considered are to apply a pointwise implicit, a pointwise explicit and an upwind explicit discretization. A new roughness-related numerical stability condition has been derived for the case of upwind explicit discretizations. It restricts the size of the spatial grid as a function of the water depth and the bed roughness. It has been tested in simulations of a real river flow case showing that, for low discharges in very rough river beds, it becomes necessary to restrict the spatial grid size under the prescribed limit to be able to reach stable numerical solutions. For 2D calculations, it is excessively restrictive and the preferable option is to apply an implicit pointwise discretization.

ABSTRACT: The Paraná de las Palmas River is one of the lower branches of the Paraná River system and part of the most important waterway in Argentina, transporting 80% of the Argentinean agricultural export products. The complex and unpredictable flow patterns, especially in the river bends, lead to a limitation of the maximum vessel Length-Over-All (LOA) of 230 m, which has a significant influence on economic aspects of navigation in this region. Because most of the navigation problems occur in the river bends, extensive 3-D ADCP (Acoustic-Doppler-Current-Profiler) velocity measurements have been carried out to analyze the flow pattern in different locations where the navigational problems are most severe. Unsteady 1-D simulations have been performed using HEC-RAS to describe the behavior of the river and to get appropriate boundary conditions which were used then to conduct 3-D RANS (Reynolds-Averaged-Navier-Stokes) simulations using a CFD numerical code in a 3 km river stretch with strong curvature. In the result section the 3-D simulations are compared with the field measurements.

1 INTRODUCTION

Knowledge of the complex flow pattern in the river bends of the Paraná de las Palmas river is important to analyze the shipping conditions in these river stretches and has been an important objective during recent years.

The reason for the pronounced non-homogeneous flow field derives from the characteristics of this river stretch. Compared with European navigable rivers the cross-sectional shape of the Paraná de Las Palmas River is much more compact, with width to depth ratios between 8 to 44. This is an indicator for the existence of strong three-dimensional secondary motions including upwelling effects and spiral motions, especially in the bends. Another particularity of the river is the significant tide influence on water surface elevation and discharge over the complete river stretch of 132 km.

A natural bend in the Paraná de las Palmas river leading to the most difficult flow field is the San Antonio bend of approximately 3 km length (Figure 1).

Different studies were made to predict the flow pattern on this bend. A physical model was developed in the year 1991 (Loschacoff, C. and Hopwood A.J.) and different field studies were done during last years. Drifters were used in October 2003. Three ADCP campaigns were carried out during 2003 and 2004.

This paper presents new contribution to this topic using numerical simulations. 3-D RANS (Reynolds-Averaged-Navier-Stokes) simulations with the standard k-ε model through San Antonio bend using a numerical code called SSIIM, Simulation on Sediment movements In water Intakes with Multiblock option (Olsen N.R.B. 2005).

The aim of this paper is to demonstrate the potential of this numerical model as a research tool for large rivers like the Paraná de las Palmas river with respect to different aspects, such as navigation, environmental quality and the relationship between fluvial behavior and tidal influence.

Neither sediment transport processes nor wind influence are discussed on this paper. Sediment transport processes will be studied in the future using SSIIM but results are not ready for publication yet.

2 THE RIVER

The Paraná de las Palmas river is located at the eastern part of the province of Buenos Aires and is a branch of

Copyright © 2006 Taylor & Francis Group plc, London, UK

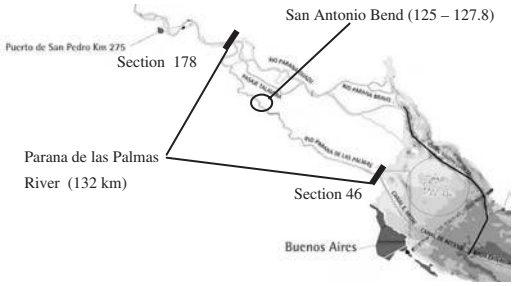

Figure 1. Scheme of the Paraná de las Palmas river and its zone.

the Paraná Inferior River (PIR) discharging its water in the Rio de la Plata estuary (RdeP). It has a length of 132 km and is part of the most important waterway in Argentina, between the section 46 (RdeP) and section 178 (PIR), corresponding to river kilometres.

In Figure 1, the complete river and the zone of study are presented.

The main characteristics of this river can be summarized as: an average discharge of 4200 m^3/s, a typical width of 400 m, a water depth varying from 10 m to 46 m, and a slope of approximately 0.001%. The mean horizontal flow velocity is about 1 m/s.

The study site, San Antonio bend, is a 3 km highly sinuous section of the river situated between section 125 and section 127.8.

2.1 *San Antonio bend*

The plan configuration of San Antonio bend consists of two consecutive bends curving in opposite direction connected by a short 300 m straight reach. A geomorphologic analysis about the variation in the river bed during the last five years was done based on recent topographic surveys.

Changes in bed levels were not significant and therefore, a fixed geometry bed has been used to study the velocity pattern without sediment transport calculations. Erosion processes in the left margin of the river was observed only in two cross-sections by this analysis. This process of erosion is due to the recirculations in the flow field, but was not sufficiently important to be included in this first part of the study. In Figure 2, one cross-section of the bed geometry during the last five years is shown.

The grain size distribution along the bend can be inferred using two studies at different points near the San Antonio bend, one located 7.8 km upstream and the other 8.0 km downstream. Both samples were taken from the upper sediment layer. In Figure 3, the measured grain size distributions at these two points are shown. A bed sediment sample obtained from the hopper of a Trailing Suction Hopper Dredge

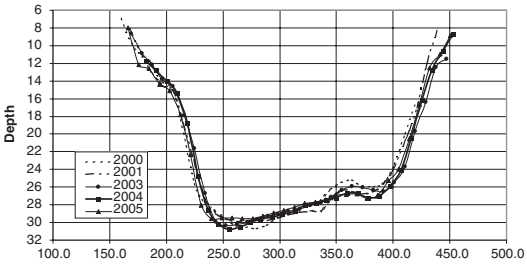

Figure 2. Cross-section surveys of the last five years showing the stability of the bed geometry.

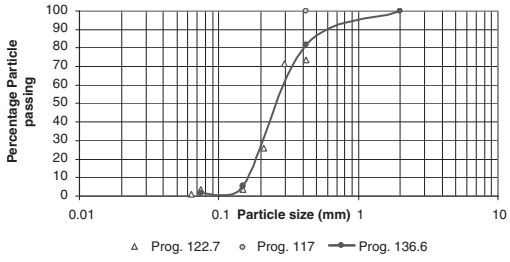

Figure 3. Particle grain size distribution of bed material near San Antonio bend.

three kilometre upstream of San Antonio bend is also included in the plot.

These three curves plotted in Figure 3 show that the material can be classified as small sand with a $d_{50} = 0.26$ mm and $d_{90} = 0.48$ mm.

Extensive 3-D ADCP (Acoustic-Doppler-Current-Profiler) velocity measurements using 2 second time intervals between vertical instantaneous samplings while the equipment is crossing the river, have been carried out to analyze the flow pattern in cross-sections every 100 m.

These measurements were done using the minimum possible time not to have great changes in the flow pattern due to changes in levels and discharges by the tide influence. A plan view of the San Antonio bend with the cross-sections where ADCP surveys have been done is shown in Figure 4. This campaign represents 8 hours of measurements including all the tidal changes.

3 NUMERICAL SIMULATION

In the following the adopted numerical methods are given followed by a description of the model setup including geometry, grid and a roughness development.

3.1 *Methods*

The SSIIM (Olsen, 2005) program solves the Navier-Stokes equations with the k-ε turbulence model on a

Copyright © 2006 Taylor & Francis Group plc, London, UK

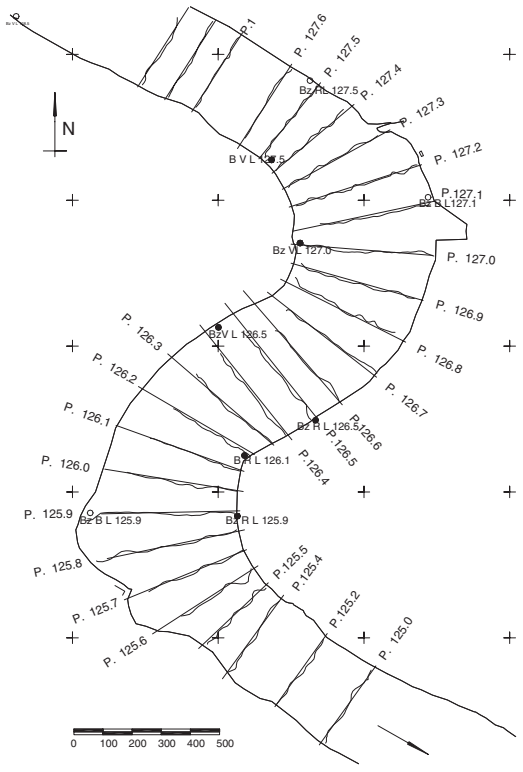

Figure 4. Plan view of the bend, location of the cross-sections measured with ADCP and current direction.

three-dimensional non-orthogonal grid. A control volume method is used for the discretization, together with the power-law scheme (POW) or the second order upwind scheme (SOU). The SIMPLE method (Patankar, 1980) is used for the pressure coupling.

The program uses the Reynolds-Averaged-Navier-Stokes equations for a non-compressible and constant density flow as follow:

$$\frac{\partial U_i}{\partial t} + U_j \frac{\partial U_j}{\partial x_j} = \frac{1}{\rho}\frac{\partial}{\partial x_j}\left(-P\delta_{ij} - \rho\overline{u_i u_j}\right) \quad (1)$$

where U is the velocity, t is time, P is the pressure, δ is the Kronecker delta which is 1 if $i = j$ and 0 if $i \neq j$.

The Navier-Stokes equations for turbulent flow are solved to obtain the water velocity using an implicit solver. The k-ε model is used for calculating the turbulent shear stress. The gravity term is not included in the standard algorithms. The criteria employed to establish the convergence of the iterative algorithm was the reduction of all normalized residuals to at least 10^{-3}. The computation of the water surface was obtained using a free surface algorithm based on the pressure or using a rigid lid approach.

Table 1. Aspect ratios for the final grid.

Cell numbers				Aspect ratios			
Total	i	j	k	$D_{i/j}$	$D_{j/k}$ bank*	$D_{i/k}$ bank*	$D_{i/k}$ max. depth
184500	225	41	20	1.25	135.7	169.6	5.5

*"Bank" implies that depths are small, leading to large distortion ratios.

The results shown in this paper are based on the use of the SOU scheme in the discretization of the convective terms.

3.2 *Model setup*

The geometry of the San Antonio river bed was specified using cross-sectional field surveys of 10-3-2005. In these surveys, cross-sectional profiles were obtained every 200 m in longitudinal direction and a spatial resolution of 9 m in lateral direction from section 125.0 to section 127.8.

The geometry was transferred using a linear interpolation to the numerical grid.

3.2.1 *Numerical grid*

SSIIM uses a non-orthogonal, non-staggered grid to represent the geometry of the river bed. The final grid had 184500 cells, divided in 225 cells in a streamwise direction, 41 cells in a lateral direction and 20 cells in a vertical direction.

The grid cells are approximately 10 m in the lateral direction and 12.5 m in the streamwise direction. This resolution is more than sufficient taking into consideration that the main flow pattern is the goal of this work, and most of the available measurement data have a streamwise resolution of 100 or 200 m only.

For vertical resolution the cells were distributed at every 5% of depth, giving a cell every 2.3 m in vertical in the deepest zones and every 0.07 m near the bank.

The first cell near the bottom was defined to cover 30% of depth all around the first 20 m from the banks and 10% of the depth in vertical profiles cases inside these limits. This change in the size of the first cell elevation was defined to maintain a reasonable ratio between the length of the first cell and the roughness height.

Expansion ratios (in all cases near 1) and aspect ratios were also taken into account to define the grid. The maximum aspect ratios for the final grid are presented in Table 1.

In order to optimize the grid with respect to accuracy and computing time, six different grids were compared. The final grid was selected from which the coarser grid was needed to obtain approximately the same results when the number of cells was doubled.

Copyright © 2006 Taylor & Francis Group plc, London, UK

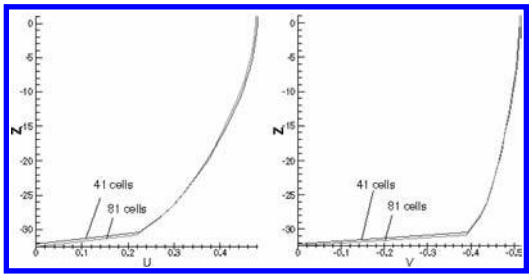

Figure 5. East (U) and North (V) horizontal components of the velocities in (m/s) using different grids.

To define the vertical and lateral resolution, a comparison of results was used. In the streamwise direction the aspect ratio was taken into account.

In Figure 5, comparison of the vertical profiles of the horizontal velocity components of different grids using 41 cells (final grid) and 81 cells (364500 cells) in the lateral direction are shown.

Figure 5 shows that increased resolution leads to negligible changes. In the same way, a resolution in vertical direction of 20 cells was enough to obtain similar results.

Once resolutions in vertical and lateral direction were optimized, the longitudinal resolution was adopted to have an aspect ratio of 1.3. A surface plan view of the final grid is shown in Figure 6.

3.2.2 *Bottom roughness*

One difficulty of numerical modeling of natural river bends is that the distribution of the roughness height along the bed is not usually known. The particle size distribution at the river bed, shown in Figure 3, results in a Manning roughness coefficient value of 0.011. This is unrealistically small and it means that bed forms have a dominating influence on the roughness.

The spatial resolution of the grid is much larger than grain size and the available survey data in cross-sections every 200 m do not have sufficient accuracy to represent bed forms. Therefore, bed form resistance has to be included into the bed roughness. This leads to much greater values of Manning coefficients than if the coefficients were based on the sediment particle size.

Due to this problem, a detailed study of the bed roughness was carried out from three different approaches.

First, the roughness along the bends has to be in the same order of magnitude or smaller than the roughness coefficient obtained for the 1-D numerical model, since the value used in the 3-D numerical model reflects all morphological heterogeneities inside the geometry.

As explained above, the roughness has to include the effect of bed forms. For that purpose, the effective roughness was approximated using Van Rijn's method

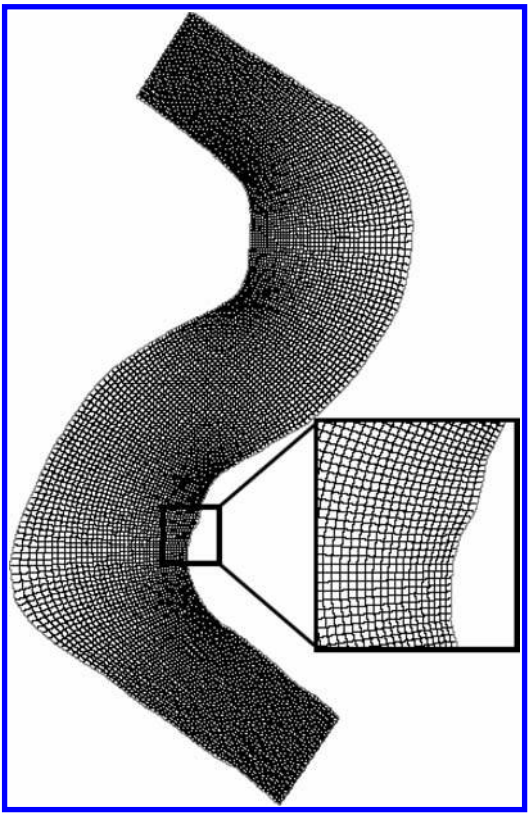

Figure 6. Plan view of the final grid.

(Van Rijn 1984) where the hydraulic roughness of a movable bed surface is caused by grain roughness ($k_{s,grain}$) and by form roughness ($k_{s,form}$) and is linked to the following parameters: particle diameter, D_{50}, flow depth, d, transport stage parameter, T, and bed form steepness, Δ/λ. With T defined as:

$$T = \frac{(u_*')^2 - (u_{*cr})^2}{(u_{*cr})^2} \quad (2)$$

where $u_*' = (g^{0.5}/C')\overline{u}$ is the bed shear velocity and u_{*cr}' is the critical bed shear velocity according to Shields.

The particle size distribution shown in Figure 3 and three representative cross-sections of San Antonio bend with the maximum ($d = 43.2$ m), minimum ($d = 13.3$ m) and average ($d = 23.3$ m) hydraulic depths were used for this analysis.

Dunes were obtained as a result of those three representative cross-sections. The bed form height, Δ, was calculated using Van Rijn formula (1984).

$$\frac{\Delta}{d} = 0.11\left(\frac{D_{50}}{d}\right)^{0.3}\left(1 - e^{-0.5T}\right)(25 - T) \quad (3)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 2. Different roughness obtained by three different approaches.

Approach	Hydraulic property		Roughness	
	Hydr. radius (m)	Depth (m)	Height (m)	Manning n ($s/m^{1/3}$)
HEC-RAS			–	0.038
Van Rijn	13.3	13.3	0.267	0.031
prediction	26.8	23.3	0.226	0.030
	60.2	43.2	0.041	0.026
SSIIM			0.448	0.034
prediction			0.236	0.030
			0.024	0.021

And the bed form steepness was calculated from:

$$\frac{\Delta}{\lambda} = 0.015\left(\frac{D_{50}}{d}\right)^{0.3}\left(1-e^{-0.5T}\right)(25-T) \quad (4)$$

Finally the hydraulic roughness was computed as:

$$k_s = 3D_{90} + 1.1\Delta\left(1-e^{-25\frac{\Delta}{\lambda}}\right) \quad (5)$$

Table 2 shows Manning coefficients obtained for these three representative sections with their depths, d, and hydraulic radius, R_h.

In a third step, the particle size distribution of the river bed was used as input information to the SSIIM morphological module, such that the roughness height was obtained for all of the cells at the bottom as a numerical solution. SSIIM uses the Van Rijn (1984) procedure to obtain the roughness height and the following equation to convert Manning n, into a roughness height of the bed, k_s:

$$\frac{1}{n} = \frac{26}{k_s^{1/6}} \quad (6)$$

The law of the wall for rough boundaries is used as given by Schlichting and Gersten (1979).

$$\frac{U}{u_*} = \frac{1}{\kappa}\mathrm{Ln}\left(\frac{30y}{k_s}\right) \quad (7)$$

where k_s is the roughness height.

In Figure 7, the variation of roughness heights in the complete river reach obtained using SSIIM is shown. Manning's coefficients are in the range between 0.034 and 0.021.

Results obtained by the three different approaches are summarized in Table 2.

In Table 2 it may be observed that the Manning's coefficients obtained are in a range from 0.038 to 0.021.

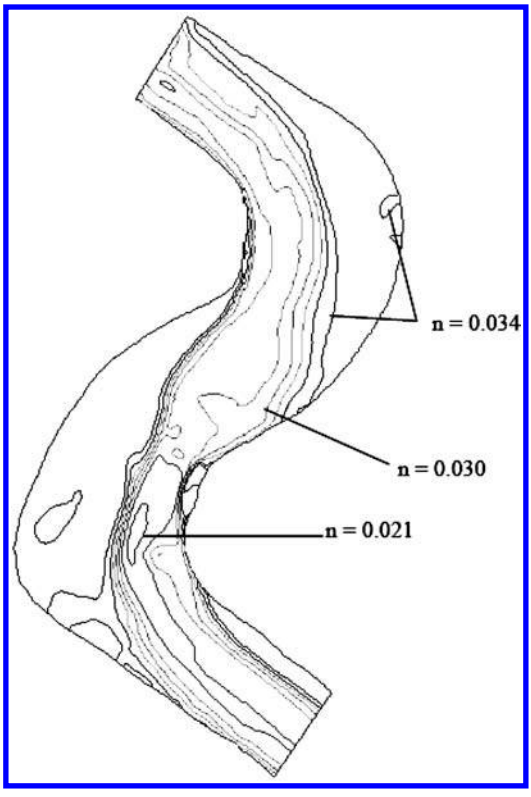

Figure 7. Variation of roughness height all around the bed. Contours show corresponding Manning coefficient values.

The higher limit was obtained in a 1-D approach where all morphological heterogeneities are taken into account inside the parameter.

In a 2-D approach using Van Rijn's formula and three representative cross-sections with constant hydraulic depths and hydraulic radius, Manning n values ranged from 0.031 to 0.026.

For a 3-D calculation, results present a perfect match with the 2-D prediction, but in this case, the range of Manning n values is higher with a variation between 0.034 to 0.021. These changes in limits may be explained since 3-D calculation take into account all different depths present in the geometry of the reach. The lower limit for the Manning n coefficient, $n = 0.021$, corresponds to the deepest zones and the higher limit, $n = 0.034$, to zones of smaller depths than those used in the Van Rijn prediction.

As explained above, all of the Manning n coefficients obtained maintain a logical concordance among approximations and show that roughness heights for San Antonio bend can be estimated using Manning coefficients in a range from 0.034 to 0.025. The three methods provide some confidence in the roughness calibration procedure.

Copyright © 2006 Taylor & Francis Group plc, London, UK

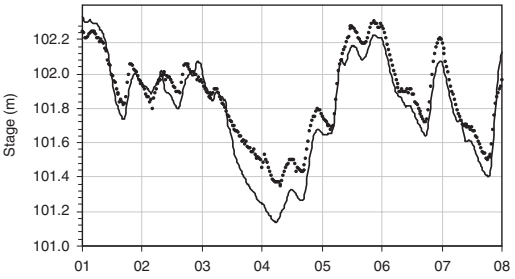

Figure 8. Measured (dotted line) and calculated levels (continuous line) for an unsteady run of 7 days (February-2004).

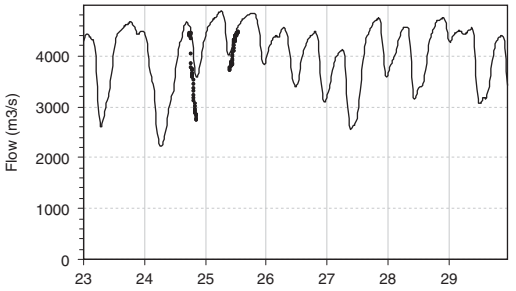

Figure 9. Measured (dotted points) and calculated discharge (continuous line) in a one week period (November-2003).

Different runs using constant Manning values of 0.034, 0.029 and 0.025 were performed. They showed that the influence of the roughness in the case under study is small compared to the expected uncertainties and do not influence the final conclusions.

Therefore, further refinement of the bed roughness does not appear to have any significant effect on the numerical results.

3.2.3 *Boundary conditions*

The definition of appropriate upstream and downstream boundary conditions in the case of a tidal influenced river, is a crucial task.

To understand the behavior of the Paraná de las Palmas river between section 89.0 and section 141.6, an unsteady 1-D numerical model using HEC-RAS 3.1.3 was performed for two different time windows each consisting of seven days.

In Figure 8, the water levels obtained with HEC-RAS compared with measured water levels from a tide gauge during one week of February 2004 are shown.

From Figure 8 it may be seen the tides influence in a section 60 km upstream of the RdeP estuary with mean water level changes of approximately 110 cm in four days and 20–30 cm daily due to this influence.

The maximum error between the predicted levels with HEC-RAS and the measured values is about 0.28 m and the average error is about 0.10 m. These errors are acceptable if they are compared with the geometry of the section where the tide gauge is located: 400 m width, 42 m depth.

The error represents 0.37% of the maximum depth in section 105.8. and did not produce changes in the general behavior of the Paraná de las Palmas River.

In Figure 9, an unsteady behavior of the flow obtained from the numerical model (continuous line) during one week in November 2003 in one cross-section of San Antonio bend is presented. This figure shows the strong variation in discharge with time. Values between 2200 m^3/s and 5000 m^3/s were predicted by the model. These values are compared with discharges in the same time period obtained by integrating the measured ADCP velocities. As may be seen, discharge variations are well represented by the numerical results.

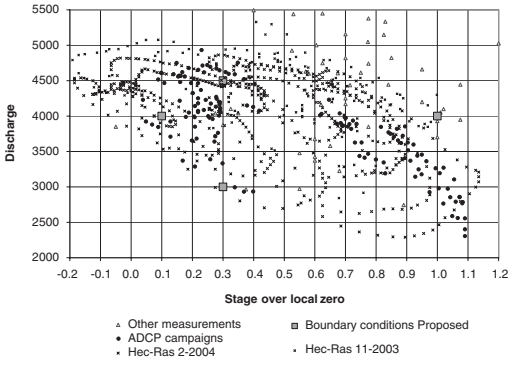

Figure 10. Possibilities for different boundary conditions.

In order to find appropriate discharge and water level boundary conditions for the steady 3-D simulations, historical measurements, ADCP measurements and results of the 1-D numerical model were used as plotted in Figure 10.

Figure 10 shows that is impossible to obtain a rating curve for the Paraná de las Palmas river, due to the influence of the semi-diurnal tide in the RdeP estuary.

Therefore, four different combinations (indicated by the larger squares in Figure 10) were selected with the objective of studying the influence of discharge changes and of level changes on the flow pattern. That means a quasi-steady simulation. Influence of the tidal wave and its celerity are not taken into account.

4 RESULTS AND DISCUSSION

Four different numerical runs were carried out using four different upstream discharge boundary conditions and downstream stage boundary conditions to obtain a quasi-steady simulation.

Results from the numerical model and measured velocities are presented below in the form of vector

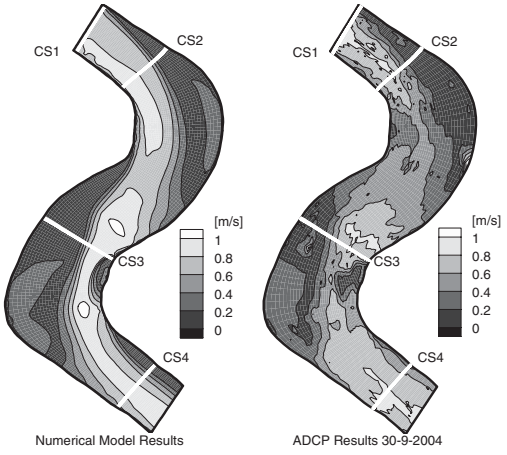

Figure 11. Plan view of the streamwise horizontal velocities near the surface; left: numerical model; right: ADCP measurements on 30-9-2004.

plots and contour plots of the streamwise horizontal velocity distribution, for a plan view and at different cross-sections. Also, a transverse velocity field is shown at some cross-sections.

Results shown in this paper correspond with the use of a Second Order Upwind (SOU) scheme in the discretization of the convective terms using an implicit solver, and with the use of a uniform roughness Manning $n = 0.025$.

The numerical simulation was done with fixed values of Q and H. It has to be noted that the measured velocities represent values obtained during a time period of 8 hours and are influenced by tidal changes.

4.1 *Results of the reference case*

With the four cases defined as boundary conditions, a reference case of study was defined with a Discharge 4000 m^3/s – Relative height (h_r) 1.0 m. This height is related to a local zero in San Antonio bend.

A plan view contour plot of the streamwise horizontal velocity components near the water surface is presented in Figure 11. For easier comparison the ADCP results have been interpolated to the numerical grid.

Figure 11 shows that the highest flow velocities are located at the inner banks of the bends in a range of 0.6 m/s to 1.0 m/s. On the outer banks of the bends, recirculation zones covering the complete water depth are present, which are more clearly visible in the vector plots in Figure 16.

In Figures 12 to 15 the streamwise horizontal calculated velocities are compared with the ADCP results in four different cross-sections corresponding to the indicated cross-sections in Figure 11. The cross-sections (CS) were chosen to represent time windows where the

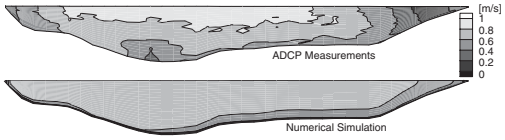

Figure 12. Comparison between measurements on 30-9-2004 with $Q = 3722\ m^3/s$, $h_r = 1$ m (upper picture) and calculated (lower picture) streamwise velocities at cross-section (CS 1) close to the inflow boundary.

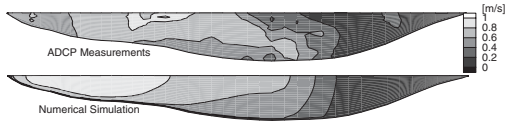

Figure 13. Comparison between measurements on 30-9-2004 with $Q = 3456\ m^3/s$, $h_r = 1.07$ m (upper picture) and calculated (lower picture) streamwise velocities at CS 2.

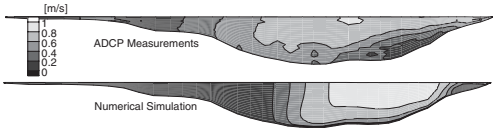

Figure 14. Comparison between measurements on 30-9-2004 with $Q = 3820\ m^3/s$, $h_r = 0.98$ m (upper picture) and calculated (lower picture) streamwise velocities at CS 3.

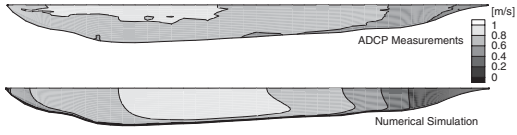

Figure 15. Comparison between measurements on 30-9-2004 with $Q = 3901\ m^3/s$, $h_r = 0.80$ m (upper picture) and calculated (lower picture) streamwise velocities at CS 4.

ADCP measurements are governed by approximately the same boundary conditions than those used for the numerical simulation.

Figures 12 and 13 show that the numerical model is not able to predict the flow field accurately close to the inflow boundary, but 400 m downstream of the inflow boundary, the simulated flow field represents the measured flow field with reasonable accuracy.

A plan view of the vector field near the water surface is given in Figure 16, where only one every four vectors is plotted in streamwise direction and one every two vector is plotted in lateral direction. The measured flow velocities are interpolated to the numerical grid.

The same cross-sections 1 to 4 used to show the streamwise horizontal velocity are now used to show the transverse velocity fields in Figures 17 to 20.

Figures 17 and 18 show the development of the secondary currents with increasing distance from the inflow boundary.

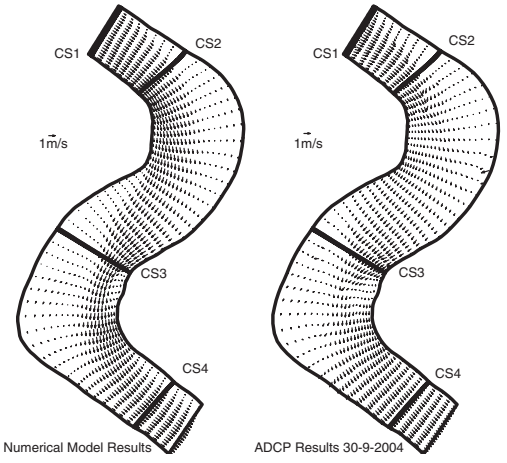

Figure 16. Comparison of the calculated (left picture) and measured (right picture) velocity vector fields.

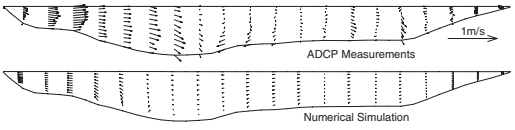

Figure 17. Comparison between measurements on 30-9-2004 with $Q = 3722\,m^3/s$, $h_r = 1\,m$ (upper picture) and calculated (lower picture) secondary current velocities at CS 1 close to the inflow boundary.

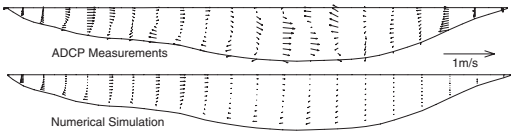

Figure 18. Comparison between measurements on 30-9-2004 with $Q = 3456\,m^3/s$, $h_r = 1.07\,m$ (upper picture) and calculated (lower picture) secondary current velocities at CS 2.

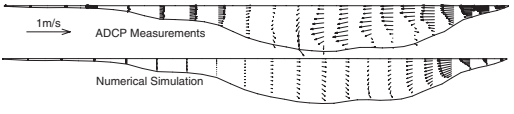

Figure 19. Comparison between measurements on 30-9-2004 with $Q = 3820\,m^3/s$, $h_r = 0.98\,m$ (upper picture) and calculated (lower picture) secondary current flow velocities in CS 3.

Both comparisons, cross-sectional view and plan view indicate that the main flow field including the recirculation zones are well represented by the numerical simulation.

Slight variations can be observed in the areas given by the numerical results for the higher streamwise

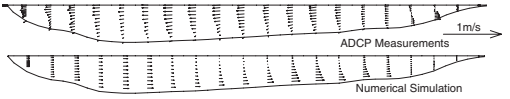

Figure 20. Comparison between measurements on 30-9-2004 with $Q = 3901\,m^3/s$, $h_r = 0.80\,m$ (upper picture) and calculated (lower picture) secondary current flow velocities in CS 4.

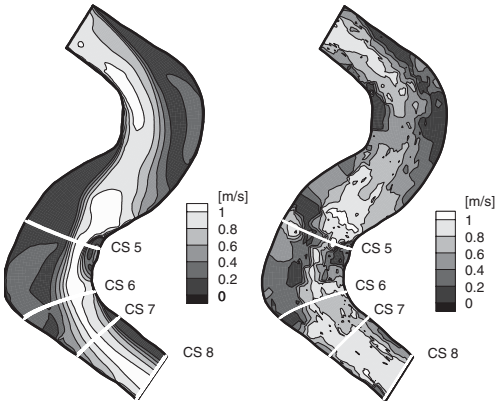

Figure 21. Plan view of the streamwise horizontal velocities near surface; left: numerical model; right: ADCP measurements on 4-2-2004.

horizontal velocities compared with measurements, in all cases the numerical results present larger areas for these velocities.

More discrepancies can be seen in the case of secondary currents, but the scale of these velocities are too small to take these discrepancies into consideration here.

4.2 *Influence of tidal changes*

Additional simulations have been performed with different boundary conditions in order to analyze the influence of the tidal changes on the main flow field.

4.2.1 *Discharge 4500 m³/s – relative height 0.3 m*

In Figure 21 a simulation where the discharge has been increased to $4500\,m^3/s$ and the water surface level at the outflow boundary has been reduced to 0.3 m is compared with measurements of another ADCP campaign made during February 2004.

Compared to the calculated reference case in Figure 11 no strong changes in the mean flow field can be observed.

The larger flow rate leads to higher flow velocities, but the recirculation zones and the secondary currents are only slightly affected.

In Figures 22 to 25 the streamwise flow pattern results is compared with measurements at different cross-sections. Again, cross-sections were chosen to

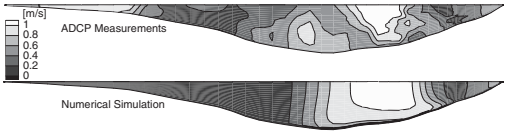

Figure 22. Comparison between measurements on 4-2-2004 with $Q = 4652\,\mathrm{m^3/s}$, $h_r = 0.22\,\mathrm{m}$ (upper picture) and calculated (lower picture) streamwise velocities at CS 5.

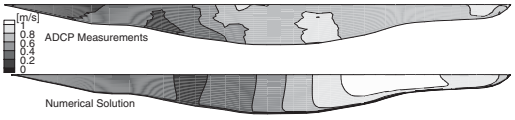

Figure 23. Comparison between measurements on 4-2-2004 with $Q = 4559\,\mathrm{m^3/s}$, $h_r = 0.18\,\mathrm{m}$ (upper picture) and calculated (lower picture) streamwise velocities at CS 6.

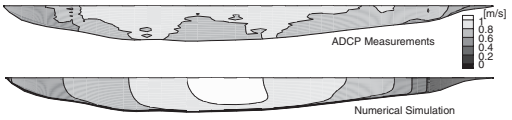

Figure 24. Comparison between measurements on 4-2-2004 with $Q = 4479\,\mathrm{m^3/s}$, $h_r = 0.16\,\mathrm{m}$ (upper picture) and calculated (lower picture) streamwise velocities at CS 7.

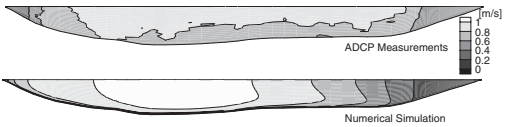

Figure 25. Comparison between measurements on 4-2-2004 with $Q = 4557\,\mathrm{m^3/s}$, $h_r = 0.15\,\mathrm{m}$ (upper picture) and calculated (lower picture) streamwise velocities at CS 8.

represent time windows where the ADCP measurements were governed by boundary conditions close to those used for the numerical simulation.

The comparison between measured and calculated velocities in Figures 21 to 25 shows good agreement with respect to the mean flow pattern.

However, in all cases, regions of high flow velocities are predicted by the numerical simulation that are less pronounced in the measurements, leading to the conclusion that the influence of the increase in discharge is less important than predicted by the model. That means that the importance of the high discharge influence is not so big in reality as is predicted by the numerical resolution.

4.2.2 *Discharge 4000 m^3/s – relative height 0.1 m*

In Figures 26 and 27 a simulation where the discharge has been maintained in $4000\,\mathrm{m^3/s}$ and the water surface level at the outflow boundary has been reduced to $h_r = 0.1\,\mathrm{m}$ is compared with results of the reference

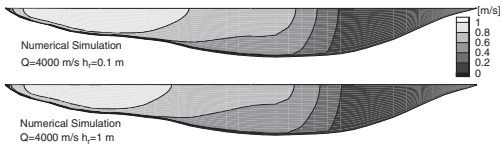

Figure 26. Results using different boundary levels conditions for Relative Height 0.1 m (upper picture) and the reference case (lower picture) at CS 1.

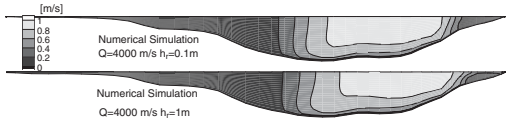

Figure 27. Results using different boundary levels conditions for Relative Height 0.1 m (upper picture) and the reference case (lower picture) at CS 3.

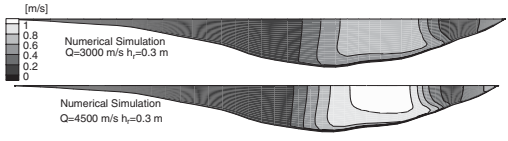

Figure 28. Results using different boundary Discharge conditions for $Q = 3000\,\mathrm{m^3/s}$ (upper picture) and $Q = 4500\,\mathrm{m^3/s}$ (lower picture) at CS 5.

case. As is shown in these Figures, the influence of the levels on the mean flow pattern is not as important for the main flow velocity field as the discharge.

4.2.3 *Discharge 3000 m^3/s – relative height 0.3 m*

In Figure 28 a simulation where the discharge has been changed from 4500 to $3000\,\mathrm{m^3/s}$ and the water surface level at the outflow boundary has been maintained as $h_r = 0.3\,\mathrm{m}$ is compared. It can be seen that the influence of the discharge on the mean flow pattern is important for the calculated main flow velocity field, as was already shown in Figures 22 to 25.

4.3 *Influence of changing bottom roughness*

In order to analyze the influence of locally changing roughness height on the mean flow field, an additional simulation has been performed using local roughness heights calculated by SSIIM. According to Table 2 the Manning n values vary in a range of 0.021 to 0.034. A comparison with the velocity field results using constant roughness shows that this differentiation is of minor importance. The main flow patterns are only slightly affected by the changing roughness bed.

In Figure 29, a plan view of streamwise velocity at surface for both cases is presented.

The same cross-sections 1 and 3 used before are now used to compare results using different roughness height values all across the bend and results using a constant Manning n value of 0.025.

Copyright © 2006 Taylor & Francis Group plc, London, UK

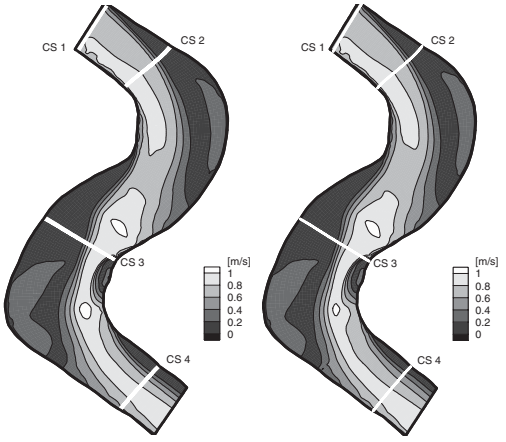

Figure 29. Plan view of the streamwise horizontal velocities at surface. With constant roughness height (left picture) and with variable roughness height (right picture).

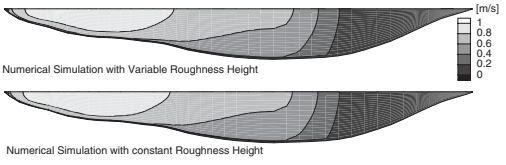

Figure 30. Streamwise horizontal velocity results using variable roughness height (upper picture) and constant roughness height (lower picture) for CS 1.

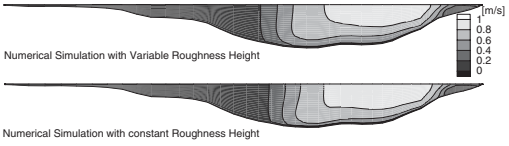

Figure 31. Streamwise horizontal velocity results using variable roughness height (upper picture) and constant roughness height (lower picture) for CS 3.

Results show that in this range of Manning *n* values, there is no significant sensitivity to calibration and a constant value of Manning *n* can be used all around the bed to obtain the mean flow velocity field.

5 CONCLUSIONS AND RECOMMENDATIONS

It could be shown that 3-RANS simulations using SSIIM are a suitable approach for analyzing the complex mean flow pattern in the river bends of the Paraná de las Palmas river, and their effects on navigation. The main characteristics of the flow field that control the shipping conditions in a 3 km river stretch in the so called San Antonio bend could be represented with sufficient accuracy. It seems to be possible to transfer the numerical model, implemented with SSIIM, to different sections of the Paraná de Las Palmas River to determine the behavior of the mean flow at different discharge and water level conditions.

The use of a quasi-steady simulation using different upstream boundary condition discharge and levels at downstream boundary conditions is an adequate approach to represent the regime variations.

The comparison of the results between the four simulations with different boundary conditions show that the influence of the water levels on the mean flow pattern is less important than the influence of the changing discharge, but changes in discharge lead to an overestimation of the flow changes compared to the measured changes.

In the present case, a distance of 400 m from the upstream boundary to the first bend is long enough to reproduce fully developed 3-D recirculating motions in the bend. The approach length is 10 times the depth of the cross-section CS 2 where the first bend starts. In the present case where the water depths are larger, the results are independent of the use of free surface computations or a rigid lid approach that reduces the computational time.

The implementation of a numerical model using SSIIM and its calibration has a relatively low cost and reduced computational effort. The overall effort appeared to be lower than for a physical model, Large-Eddy-Simulations or field measurements for determining the mean flow patterns.

The use of unsteady calculations in the present case is of lesser importance, but can be employed in the future to look at more advanced problems, such as sediment transport. In order to get better comparison between steady computations and unsteady flow measurements (tidal changes), the measured flow fields in the future should be conditioned with respect to the tidal cycle. Furthermore, a comparison between the use of first and second order schemes especially in the recirculation zones would be useful.

ACKNOWLEDGEMENTS

This work is the result of an exchange visitor program between the Institute of Hydrodynamics (IfH), University of Karlsruhe, and the Post Graduate School in Port Engineering, Faculty of Engineering, University of Buenos Aires, during which the first author stayed in IfH.

The authors would like to thank Thorsten Stößer, Dominic von Terzi and John Fenton for their help during the investigation.

Selection of interface plane in the assessment of discharge in two stage meandering and straight compound channels

Kanhu Charan Patra & K.K. Khatua
National Institute of Technology, Rourkela, Orissa, India

ABSTRACT: An investigation concerning the distribution of shear stress in the main channel and floodplain of meandering and straight compound channels are presented. Discharge in meandering compound channels is strongly dependant on the interaction between flow in the main channel and that in the floodplain. The usual practice in one dimensional analysis is to separate a compound section into subsections using 'divided channel method' through the assumed interface planes running from the main channel–floodplain junctions. Discharge for each subsections are calculated using Manning's equation and added up to get the total discharge of the compound section. If the assumed interface is wrong the resultant discharge becomes erroneous. The apparent shear force at the assumed interface plane gives an insight into the magnitude of flow interaction between the main channel and the adjacent floodplains basing on which the merits of the selection of the interface plains for discharge estimation are decided. Alternative uses of the traditional vertical interface plane for separation of compound channels are proposed. A set of smooth and rough sections is studied with aspect ratio varying between 2 and 5. The discharge results are compared with the results of variable-inclined interface method.

1 INTRODUCTION

Almost all natural rivers meander. In fact straight river reaches of lengths exceeding ten times its width are rather rare. Meandering is a degree of adjustment of water and sediment laden river with its size, shape, and slope such that a flatter channel can exists in a steeper valley. During floods, part of the discharge of a river is carried by the main channel and the rest is carried by the floodplains located to its sides. Once a river stage overtops its banks, the cross sectional geometry of flow undergoes a steep change. The channel section becomes compound and the flow structure for such section is characterized by large shear layers generated by the difference of velocity between the main channel and the floodplain flow. Due to different hydraulic conditions prevailing in the river and floodplain, mean velocity in the main channel and in the floodplain are different. Just above the bank-full stage, the flow in the main channel exerts a pulling or accelerating force on the flow over floodplains, which naturally generates a dragging or retarding force on the flow through the main channel. This leads to the transfer of momentum between the channel section and the floodplain. At the junction region between the main channel and that of the floodplain, Sellin (1964) and Knight and Demetriou (1983) indicated the presence of artificial banks made of vortices, which acted as a medium for transfer of momentum. At low depths over floodplain, transfer of momentum takes place from the main channel flow to the floodplain leading to the decrease in the main channel velocity and discharge, while its floodplain components are increased. As the depth of flow in the floodplain increases beyond a limiting depth, transfer of momentum does not takes place between the main channel and the floodplain. And at still higher depths over floodplains the process of momentum transfer reverses, the floodplain supplies momentum to the main channel. Due to the continuous stream wise variation of radius of curvature, the velocity and flow parameters are considerably more complex in a meandering channel than in a straight channel. The flow geometry in a meandering channel is in the state of either development or decay or both.

In the laboratory the mechanism of momentum transfer between the deep river section and shallow floodplain was first investigated and demonstrated by Zheleznvakov (1965) and Sellin (1964). While calculating discharge in compound channels, a method based on 'divided sections' is usually employed. Imaginary interface planes running from the junction between the main channel and floodplain are used to separate the main channel from the floodplain of the compound section. Momentum transfer between these subsections does not take place, when the shear stress at this fluid boundary is found to be zero. Yen and

Copyright © 2006 Taylor & Francis Group plc, London, UK

Overton (1973) used isovel plots to locate interface planes of zero shear. The data showed that the angle of inclination to the horizontal of the interface plane increased with depth over floodplain.

Following the previous work of Wormleaton et al. (1982), Knight and Demetriou (1983), Knight and Hamed (1984), and Myers (1987) on straight compound channels, with one to four types of geometries and smooth to six types of boundary roughness, the present study is aimed at understanding the general nature of the interaction between the main channel and the floodplain flows in meandering compound sections and propose suitable methods to calculate discharge in such channels.

Wright and Carstens (1970) observed that the calculation of discharge using the 'divided channel method' for compound sections compared well with the observed values although segment discharges varied up to $\pm 10\%$. They included the interface length in the wetted perimeter of the main channel subdivision only, as they considered that the slower flowing floodplain flow exerted a drag on the faster flowing main channel flow. Discharge assessment for compound sections between straight reaches also have been presented by Knight and Demetriou (1983), Knight and Hamed (1984), Wormleaton et al. (1982, 1985), Ackers (1993) covering smooth and rough boundaries.

There are limited reports covering investigation of a meandering channel with floodplains. Toebes and Sooky (1967) carried out laboratory experiments on two composite channel sections and showed that a nearly horizontal fluid boundary located at the junction between the main channel and floodplain would be more realistic than a vertical fluid boundary along the banks of the meandering channel in dividing the compound channel for discharge calculation. Using the data of the Flood Channel Facility at HR Wallingford, Greenhill and Sellin (1993) reported a method of estimation of discharge of meandering compound channels using Manning's equation and by extending the conventional divided channel method. The method assumed a fully developed shear layer at the interface between the main channel and the floodplain flows. For low over bank flow or for a very wide main channel, the method was found to give inaccurate results. Patra (1999), and Patra and Kar (2000) proposed a variable interface plane of separation of compound channel for a better estimate of discharge in meandering and straight compound river sections. The percentages of total flow carried by the main channel and floodplain of a compound section in terms of four dimensionless channel parameters were suitably modeled. The effect of flow interaction between the floodplain and main channel for various depths of flow over floodplain was adequately taken care.

Review of the literature show that investigators propose alternatives interface planes to calculate the total discharge carried by a compound channel section. Either including or excluding the interface length in the wetted perimeter does not make sufficient allowance for discharge calculation for all depths of flow over floodplain. It results either overestimate or underestimate of the discharge results. The work presented in this paper is based on a series of six channel sections with depth ratio between floodplain to main channel flow up to 0.404. In one series of experiment all the surfaces of main channel and floodplains are roughened uniformly.

2 EXPERIMENTAL SETUP

Experimental data from six series of channels are presented in this paper. Summary of experiments conducted are given in Table 1. The ratio α between overall width B and main channel width b are varied from 2.13 to 5.25 for the six sets (series A to I) of observations, of which the series I is symmetrical, the series A (Fig. 1a) is made with two unequal floodplains attached to both sides of the main channel, and the rest are asymmetrical channels with floodplain attached to one side only. The channel sections are made from Perspex sheets for which the roughness of floodplain and main channel are identical. All surfaces of the channels of series F and G are roughened with rubber beads of diameter 4 mm at 12-mm center to center. All observations are made at the section of maximum curvatures (bend apex) of the meandering channels. Plan forms of the types of meandering experimental channels with floodplains are shown in Fig. 1 .Though all the surfaces of the channel series D, F and G are roughened with rubber beads of diameter of 4 mm @ 12 mm center to center, no significant change is observed between the two types of channel in respect of flow characteristics and bed shear stresses.

Boundary shear stress is measured using locally fabricated Preston micro pitot tube in conjunction with a water manometer. Details of the experimental setup and procedure concerning the flow and velocity observations in meandering channels with floodplains are reported earlier (Patra 1999, Patra and Kar 2000). Experiments are conducted utilizing the facilities available at the Water Resources and Hydraulic Engineering Laboratory of the Civil Engineering Department of the IIT Kharagpur, India.

3 THEORETICAL CONSIDERATIONS

The vertical, horizontal, and diagonal plains of separation of compound channel are represented by the interface lengths aa_1, aa, and aa_2 respectively where as the interface plane aa_3 is a variable and is located by measuring the angle θ that it makes with the vertical

plane aa_1 (Fig. 2). Various boundary elements of the compound channels are labeled from 1–4 in Fig. 2. Label (1) denotes the vertical wall(s) of floodplain with length $[2(H-h)]$ and label (2) denotes floodplain bed(s) with length $(B-b)$. Label (3) denotes the two main channel walls and the bed of the main channel is represented by label (4).

3.1 *Shear force on the assumed interface planes*

The measured shear stresses were integrated over the respective lengths of each of the boundary elements (labeled 1–4 in Fig. 2), to obtain the boundary shear force per unit length for the elements. The sum of the boundary shear forces for all beds and walls of the compound channel was used as a divisor to calculate the shear force percentages carried by the boundary elements. The shear force percentage carried by the flood plains is represented as $\%S_{fp}$, and for the main channel it can be taken as $\%S_{mc}$.

The shear force percentages carried by the floodplain with depth ratio β for all the compound channels of varying geometries ($\alpha = 2.13$ to 5.25) are given in col. (3) of Table 2. The total shear force carried by the floodplain beds and walls are very important because the apparent shear force acting on the assumed boundaries originating from the junction between floodplain

and main channel can be determined once this quantity is known. Following the previous work of Knight and Demetriou (1983), Patra and Kar (2000) proposed a general equation for the percentage of shear force carried by the floodplains of meandering compound channels as

$$\%S_{fp} = 48(\alpha - 0.8)^{0.289}(2\beta)^{m}[1 + \alpha \mathrm{Re}^{-1325\beta\delta}]\{1 + 1.02\sqrt{\beta}\log\gamma\} \quad (1a)$$

where the exponent m can be calculated from the relation

$$m = \frac{1}{0.75\, e^{0.38(\alpha - R)}} \quad (1b)$$

in which R = ratio of the amplitude ε of the meandering channel to the top width B of the compound section the values of which are given in col. (11) of Table 1, δ = aspect ratio of the main channel b/h, and γ = the ratio of Manning's roughness n of the floodplain to that for the main channel. For a straight channel the value of R is zero. A zero value of R reduces equations (1a) and (1b) to the form of Knight and Hamed (1984) and for channels with equal surface roughness in the floodplain and main channel ($\gamma = 1$), equation (1) further reduces to the form proposed by Knight and Demetriou (1983). Using (1) the calculated percentage of total shear force carried by the floodplains is given in Table 2 (column 4). Patra and Kar (2000) have reported the adequacy of equation (1).

Once the shear force carried by the floodplain is known, the apparent shear force acting on the imaginary interface of the compound section can be calculated. These apparent shear forces may then be used to get an idea of the momentum transfer between the different subsections of the compound channel. For any regular prismatic channel under uniform flow conditions the sum of boundary shear forces acting on the main channel wall and bed together with an 'apparent shear force' acting on the interface plane between main channel and floodplain must be equal to the resolved weight force along the main channel.

$$\rho g A_{mc} S = \int_{mc} \tau dp + ASF_{ip} \quad (2)$$

in which g = gravitational acceleration, ρ = density of flowing fluid, S = slope of the energy line, A_{mc} = area of the main channel defined by the interface plane, $\int_{mc} \tau dp$ = shear force on the surfaces of the main channel consisting of two vertical walls and bed, and ASF_{ip} = apparent shear force of the imaginary interface plane. Because the boundary shear stress carried by the compound section (ρgAS) is equal to 100%, where A is the total cross section of the compound channel, the percentage shear force carried by the main channel surfaces can be calculated as

$$\% S_{mc} = 100 \frac{\int_{mc} \tau dp}{\rho gAS} = 100 \frac{\rho g A_{mc} S}{\rho gAS} - 100 \frac{ASF_{ip}}{\rho gAS} \quad (3)$$

But since $\%S_{mc} = 100 - \%S_{fp}$; and $100(ASF_{ip}/\rho gAS)$ = percentage of shear force on the assumed interface, substituting the values, the apparent shear force on the interface plane can be calculated as

$$\% ASF_{ip} = 100 \frac{A_{mc}}{A} - \{100 - \% S_{fp}\} \quad (4)$$

in which $\%ASF_{ip}$ = percentage of shear force in the interface plane. Having computed $\%S_{fp}$ through (1), it is easy to evaluate (4) for the assumed interface plane. For example, for vertical interface between the boundary of the floodplain and main channel shown by the

Copyright © 2006 Taylor & Francis Group plc, London, UK

lines aa_1 in Fig. 2, the value of A_{mc} is the area marked by a_1abbaa_1, which when substituted in (4), yields $\%ASF_{ip}$. Similarly for horizontal or diagonal interfaces, A_{mc} can be estimated from the areas marked as aabb or a_2abbaa_2, respectively, in Fig. 2. These apparent shear forces can be expressed as percentages of the total channel shear force using the following relations:

$$\%\,ASF_V = \frac{50}{[(\alpha-1)\beta+1]} - \frac{1}{2}\{100 - \%\,Sfp\} \quad (5a)$$

$$\%\,ASF_D = \frac{25(2-\beta)}{[(\alpha-1)\beta+1]} - \frac{1}{2}\{100 - \%\,Sfp\} \quad (5b)$$

$$\%\,ASF_H = \frac{100\,(1-\beta)}{[(\alpha-1)\beta+1]} - \{100 - \%\,Sfp\} \quad (5c)$$

in which $\%S_{fp}$ can be calculated from (1). Percentages of apparent shear force for the assumed vertical, horizontal, and horizontal interface planes from series A to I are given in Table 2 (columns 5 to 10). The table compares the measured shear force percentages carried by the floodplains in each case along with the computed values using equations (1) and (5).

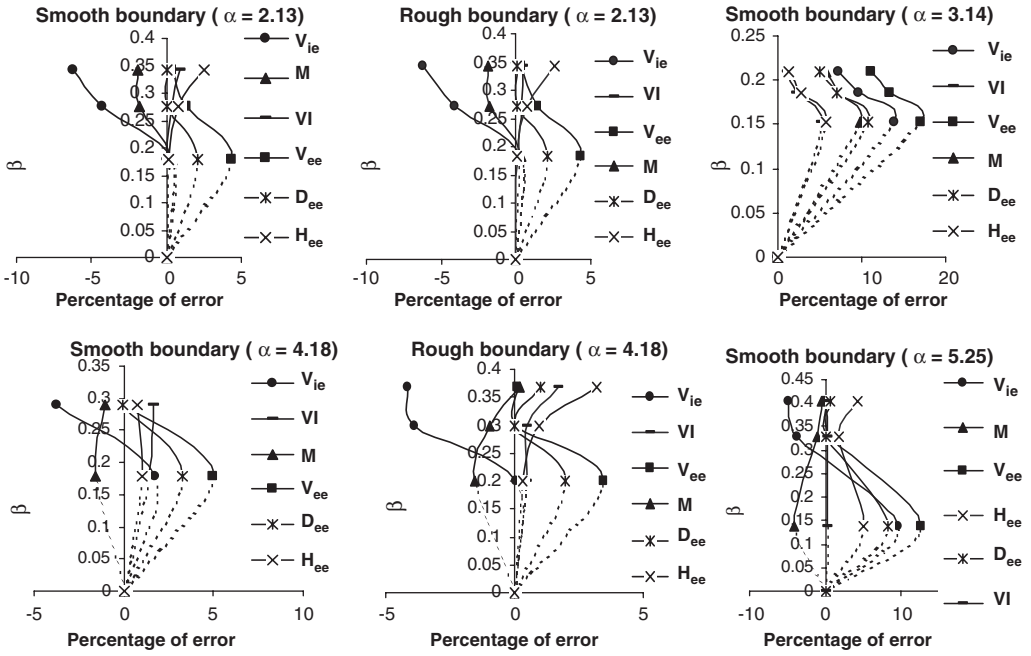
For the assumed vertical interface plane the shear force is always positive for the ranges of α and β tested. A positive value indicates transfer of momentum from the main channel to the floodplain at the assumed plane indicating the floodplain flow retarding the main channel flow. This apparent shear stress is higher than the bed-shear stress at low floodplain depths and reduces gradually as β increases. For example, for channel series A.1 the apparent shear stress is 4.2% per unit length of the interface plane while the bed shear stress of the main channel per unit length of wetted perimeter is 1.2% of the total shear stress. This follows a similar trend for all channels for the runs C.1, D.1, E.1, F.1, and I.1. For the diagonal and horizontal interface planes it can be observed that the apparent shear force is positive at low depths and changes sign as depth increases indicating that at higher depths over floodplain there is transfer of momentum from the floodplain to the main channel. A smaller value of apparent shear stress renders the interface plane more suitable, but a large negative value of apparent shear stress at higher depths makes the interface plane unsuitable for separating the channel into hydraulically homogeneous zones for calculating discharge of compound channels by the divided channel method. However, none of the above methods explain a boundary for which there is no transfer of momentum for all depths.

3.2 *A variable-inclined interface plane*

Patra and Kar (2000) proposed a method of selecting the interface plane for meandering channel for which the apparent shear stress is found to be nearly zero. This variable plane of separation can be located by an angle θ it makes with the vertical line aa_1 (Fig. 2), and in radians it is expressed as

$$\theta = (\alpha - R\beta)(1-\beta)^{\beta}(5.25\beta)^{0.075}\,e^{-\beta(\alpha-R)} \quad (6)$$

The angle is dependent on the depth of flow over the floodplain, the flowing out width of the floodplain, and the amplitude of the meandering channel. The adequacy of this interface plane for separating the main channel from floodplain for calculating discharge by divided channel method are explained by Patra (1999), and Patra and Kar (2000). Once the angle θ is known (from 6) the area of the main channel A_{mc} representing the area a_3abbaa_3 in Fig. 2 can easily be estimated. For regular and prismatic channels under uniform flow conditions, the apparent shear force percentage of this plane can be obtained from the equation given as



$$\%ASF_{VI} = \frac{100\,A_{mc}}{bH[(\alpha-1)\beta+1]} - \{100 - \%Sfp\} \quad (7)$$

where $\%ASF_{VI}$ = apparent shear force on the variable-inclined interface as percentage of total, b = width of main channel, and H = depth of flow over the main channel. Using (6) and (7) Patra and Kar (2000) had shown that (col. 11–12 of Table 2) the calculated shear force percentage at the variable interface are almost zero for all the channels shown in Table 1. Considering all 17 runs, the standard error between the measured and the estimated apparent shear force using the variable plane of interface is found to be 3%.

4 DISCHARGE RESULTS

Easily located vertical, horizontal or diagonal interface planes running from the main channel floodplain junctions are mostly used to separate a compound channel section into subsections. Discharges for each subsection are calculated using Manning's equation and added to get the total discharge of the compound section. To identify an accurate, simple, but practicable way of calculating discharge for meandering compound channels the cross section of the compound channel is divided into subsections by the preceding four easily identifiable interface planes running from the floodplain-main channel junction. In all the cases, the interface length is not included in the wetted perimeter. Discharge results for the channel sections using the above four interface planes are given in Table 2 (col.13–16). The percentage of error between the observed and calculated discharge results of Table 2 for the four interface planes are shown in Fig. 3. It can be seen in the figure that the error percentage is comparatively less for the variable-inclined interface plane. The error percentage increases gradually to a maximum for the vertical interface through

Figure 3. Error percentages between calculated and observed discharges for various interface planes.

horizontal and diagonal planes. Excluding the interface length in the wetted perimeter overestimates the discharge capacity of the channel even at higher depths of flow for the ranges of β tested. This is quite in agreement with the results given by Wormleaton and Hadjipanos (1982).

A look into the apparent shear force at the vertical interface (col. 5, Table 2) shows that there is always transfer of momentum across this interface and therefore what adjustments are to be made to take care of the momentum transfer or shear force acting at this plane has been the subject of present research. In this paper alternative uses of the vertical interface planes are tested to give an insight to the flow processes and to propose the best discharge results.

5 ALTERNATIVE VERTICAL INTERFACE METHODS

5.1 *Interface plane included to the main channel perimeter*

The effect of momentum transfer at low depths of flow over floodplain ($\beta < 0.4$) is to decrease the velocity and discharges of main channel while its floodplain components are increased. It is argued that the interface length $(H - h)$ should be included to the main channel perimeter only to take care of the momentum transfer so that the overestimation of the discharge is checked. Therefore in this method the interface length $(H - h)$ is added to the main channel boundary only. Resulting discharge errors for the compound channels are shown as curves V_{ie} in Fig. 3.

5.2 *Modified vertical interface method*

The vertical interface plain is neither shear free nor the apparent shear at this surface is equal to boundary shear of main channel surface or of the floodplain surface. Myer (1975), Wormelaton et al. (1982), and Knight and Demetriou (1983) have shown that apparent shear in the vertical, horizontal or diagonal interface is many times greater than the boundary shear stress in main channel or floodplain at low floodplain depths. Therefore either excluding or including the interface length to the main channel/floodplain boundary does not fully take care of the interaction effect. It has been shown convincingly that failure to allow for the existence of such mechanism results in erroneous compound channel analysis.

Wormelaton et al. (1982) have shown that the total dragging force on the main channel due to floodplain

Copyright © 2006 Taylor & Francis Group plc, London, UK

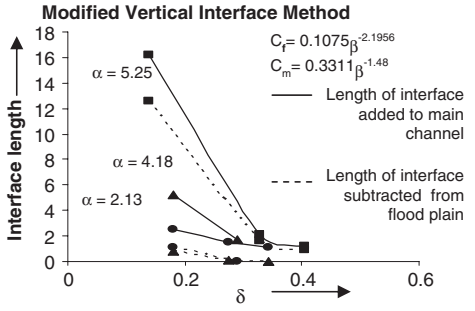
at the interfaces must be equal to the accelerating force on floodplain due to the main channel. Therefore the wetted perimeter of the main channel needs to be increased suitably to take care of the net dragging force on the main channel. Similarly the wetted perimeter of the floodplain needs to be reduced by subtracting a suitable length of interface to account for the accelerating force on the floodplain due to the pulling of the main channel water. Net force at the assumed vertical interface should balance each other. Let X_{mc} be the interface length for inclusion in the main channel wetted perimeter and X_{fp} the length of interface length to be subtracted from the wetted perimeter of floodplain. By assuming the channel to be regular, prismatic, and flow under uniform conditions the sum of the boundary shear forces acting on the main channel plus the shear force on the assumed interface must be equal to the weight component of water of the main channel and is written as

$$(P_{mc}\tau_{mc} + X_{mc}\tau_{mc}) = \rho g A_{mc} S \tag{8a}$$

Similarly for the floodplain, equation (8a) is expressed as

$$(P_{fp}\tau_{fp} + X_{fp}\tau_{fp}) = \rho g A_{fp} S \tag{8b}$$

where P_{mc} = the wetted perimeter of the main channel, P_{fp} = the wetted perimeter of the floodplain, A = the area of cross section of the compound channel section = $A_{mc} + A_{fp}$, A_{mc} and A_{fp} = the area of cross sections of main channel and floodplain subsections respectively, τ_{mc} and τ_{fp} = the mean boundary shear stress in main channel and floodplain per unit length, and S = the longitudinal slope of the channel. Again for a compound section, the total boundary shear must be equal to the weight component of flowing fluid along longitudinal direction and is written as



$$\left(P_{mc}\,\tau_{mc} + P_{fp}\tau_{fp}\right) = \rho g A S \tag{9}$$

Since $\rho g A_{mc} S + \rho g A_{fp} S = \rho g A S$, the sum of weight components represented by (8a and 8b) must be equal to the weight component represented by (9) from which we get

$$X_{mc}\,\tau_{mc} = -X_{fp}\,\tau_{fp} \tag{10}$$

Equation (10) shows that the shear force on the main channel arising out of the assumed vertical interface must be equal and opposite to that considered for the floodplain by the divided channel approach. At the assumed vertical interface plane the term $X_{mc}\tau_{mc} = -X_{fp}\tau_{fp}$ is taken as the apparent shear force ASF_{ip}. Now from equation (8a) a general expression for X_{mc} for any interface is written as

$$X_{mc} = \frac{\rho g A_{mc} S - \tau_{mc} P_{mc}}{\tau_{mc}} \tag{11}$$

C_m= Interface length added to main channel = eq 16/(H-h);
C_f= Interface length subtracted from floodplain = eq 17/ (H-h)

Figure 4. Variation of interface length with β.

And for the vertical interface equation (11) is simplified to

$$X_{mcV} = \frac{100\ P_{mc}}{(100 - \%\,S_{fp})\{1 + (\alpha - 1)\beta\}} - P_{mc} \tag{12}$$

Following the above steps, the equivalent decrease in length of floodplain wetted perimeter for any interface can be written similar to (11) as

$$X_{fp} = P_{fp}\left[\frac{100}{\%\,S_{fp}}\left(\frac{A_{mc}}{A} - 1\right) - 1\right] \tag{13}$$

And for vertical interface, equation (13) is written as

$$X_{fpV} = P_{fp} - \frac{100\,(\alpha - 1)\beta}{(\%\,S_{fp})\{1 + (\alpha - 1)\beta\}} P_{fp} \tag{14}$$

where the percentage of shear force ($\%S_{fp}$) carried by the floodplains can be calculated from equation (1).

Knowing $\%S_{fp}$ and channel geometries parameters the interface lengths X_{mcV} and X_{fpV} are calculated. Next the discharge for main channel and floodplain are calculated using Manning's equation given as

$$Q = \frac{\sqrt{S_f}}{n} A_{mc}^{5/3}\left(P_{mc} + X_{mc}\right)^{-2/3} + A_{fp}^{5/3}(P_{fp} - X_{fp})^{-2/3} \tag{15}$$

The lengths in terms of $(H - h)$ times X_{mcV} and X_{fpV} are plotted against β in Fig. 4. The percentage of error between observed and calculated discharges for all the channels are shown as curves M in Fig. 3.

5.3 *Validation of the methods for straight channel*

The methods are tested with experimental data of Knight and Demetriou (1983) for the three types of straight compound channels ($\alpha = 2$, 3, and 4). The three channels give similar results as in the case of meandering sections. The results of Knight and Demetriou (1983) are presented in Fig. 5. Curves H_{ee} and D_{ee} are plotted in the same figure for comparison.

Copyright © 2006 Taylor & Francis Group plc, London, UK

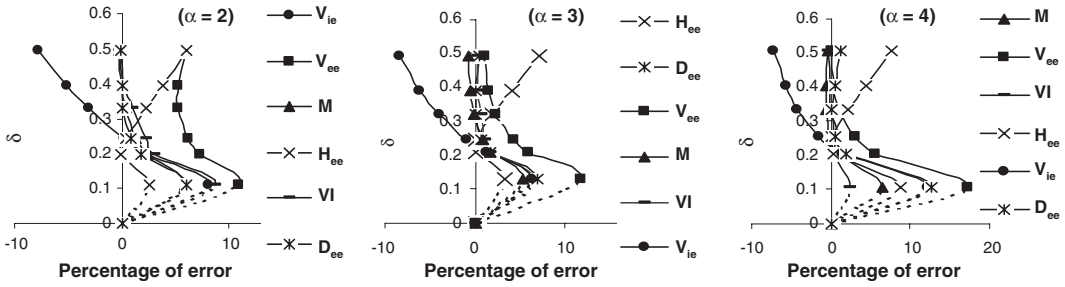


Figure 5. Error percentages between calculated and observed discharges for various interface planes for the channel of Knight and Demetriou (1983).

6 RESULTS AND DISCUSSIONS

Errors in the percentage of discharge between observed and computed values of the compound channel sections are found to be the maximum (up to 17%) for β values between 0.13 and 0.2 when the interface plane is not included in the wetted perimeter of both main channel and floodplains. The error percentage curves then decreases to a minimum when $\beta \approx 0.4$. This shows that momentum transfer is maximum at $\beta = 0.15 - 0.2$ and the transfer of momentum across the vertical boundary is complete at around $\beta = 0.4$.

When an interface length equal to the depth of floodplain is included in the main channel only of the compound section, the error in discharge between observed and computed values are found to be less than the method excluding it (up to 14%). However, at higher depths of flow over floodplain ($\beta > 0.2$), large negative values of discharge errors are obtained (up to -8%) indicating that when the momentum transfer between main channel with that of floodplain is nearly complete at these depths, the method gives inaccurate results.

Modified vertical interface method gives good results of discharge estimates for the compound channels having low α values and for β up to 0.2. But for channels with narrow flood plains carrying flow at higher depths or for wider channels ($\alpha = 5.25$) carrying lower depths of flow, the method gives higher percentages of errors in discharges (up to -5%). From the plots between β and the length of interface added to main channel and subtracted from floodplain the lengths of interfaces are modeled as interface length added to main channel is given as

$$C_m \times (H\text{-}h) \text{ where } C_m = 0.3311\beta^{-1.48} \quad (16)$$

Interface length subtracted from floodplain is given as

$$C_f \times (H\text{-}h) \text{ where } C_f = 0.1075\beta^{-2.19563} \quad (17)$$

The Variable Inclined Interface plane method proposed by Patra and Kar (2000) is based on the theoretical background of locating interface plane of zero shear. The method gives good results but is not as straight forward as the above vertical interface planes.

7 CONCLUSIONS

The following conclusions can be made from the above discussions:

1. Either by including or excluding the length of interface equal to the depth of floodplain to the wetted perimeter of the main channel or to the floodplain does not make sufficient allowance for discharge calculation for all depths of flow over floodplain. These methods either overestimate or underestimate the discharge results.
2. By balancing the magnitudes of shear force at the vertical interface (named as Modified Vertical Interface Method) gives better discharge results (maximum error up to $+9\%$ and -4% respectively at $\beta = 0.15$. This is an improved method of discharge estimation for compound sections. However the method lacks in giving good results for the main channel and the floodplains subsection discharges.
3. The Variable Inclined Interface plane method proposed by Patra and Kar (2000) is based on the theoretical background of locating interface plane of zero shear. The method gives good discharge results but involves more steps in identifying the interface plane and the subsequent discharge estimation.

NOTATIONS

The following symbols are used in this paper:

A = total cross-sectional area of compound channel;
B = top width of compound channel;
b = width of main channel;
C_m = Interface length added to main channel using equation $16/(H - h)$;

Copyright © 2006 Taylor & Francis Group plc, London, UK

C_f = Interface length subtracted from floodplain using equation $17/(H-h)$;
g = gravitational acceleration;
H = depth of flow in main channel;
h = height of main channel up to floodplain bed;
m = exponent used in Eq. (1a);
n = Manning's roughness factor;
R = ratio of amplitude of compound channel to top width B;
S_f = energy slope line;
s_r = sinuosity of meander channel = (ls/lc);
α = width ratio = B/b;
β = relative depth = $(H-h)/H$;
γ = ratio of floodplain roughness to main channel roughness;
δ = ratio between main channel width to its depth (b/h);
ε = amplitude of meander channel;
ρ = density of flowing liquid;
τ = boundary shear stress;
$\int_{mc} \tau\, dp$ = shear force on surfaces of main channel;
$\%ASF$ = percentage of total channel shear force carried by assumed interface planes;
$\%ASFH$ = ASF on horizontal interface (aa) as percentage of total shear force;
$\%ASFip$ = ASF on an interface plane as percentage of total shear force;
$\%ASFV$ = ASF on vertical interface (aa_1) as percentage of total shear force;
$\%ASFVi$ = ASF on variable-inclined interface (aa_3) as percentage of total shear force;
ASF_{IP} = apparent shear at the interface;
P_{mc} = the wetted perimeter of the main channel,
P_{fp} = the wetted perimeter of the floodplain,
A = the area of cross section of the compound channel section and
A_{mc} = are the area of main channel
A_{fp} = flood plain subsections respectively,
τ_{mc} = the mean boundary shear stress in main channel per unit length longitudinally
τ_{fp} = mean boundary shear stress in flood plain per unit length longitudinally
S = the longitudinal slope of the channel.
τ_{av} = is the average shear stress in the assumed vertical interface whose interface length is $l_v = H - h$
$\%S_{fp}$ = the percentage of shear force carried by the floodplains
$\%S_{mc}$ = the percentage of shear force carried by the floodplains
Q = Calculated discharge.
X_{mc} = Length of interface added to main channel subsection
X_{fp} = Length of interface subtracted from flood plain subsection
X_{mcv} = Length of vertical interface added to main channel subsection
X_{fpv} = Length of vertical interface subtracted from flood plain subsection.

Mathematical modelling and analysis of river flows in transitional waters

M. Santos
ESTIG – Polytechnic Institute of Beja, Portugal

J. Hipólito
IST – Technical University of Lisbon, Portugal

ABSTRACT: River flows in transitional regions, between inland surface waters and coastal waters, suffer the effects of downstream boundary tides that may enhance several river events or phenomena like floods and erosions among others. The purpose of this paper is to present the study carried out to analyse the influence of tides in the river subcritical flows. So, based on the complete 1-D Saint-Venant equations and using the implicit Preissmann finite-difference method, a mathematical model was developed to simulate one-dimensional unsteady flows in rivers, with irregular and variable cross-sections. The model was applied to the Sado river, more precisely, to a reach of this Portuguese river, right upstream Alcácer do Sal city, in which the fluvial flows are influenced by the tide and during flood events has caused important damage, either human or material. Discharge rating functions on the last section of the river reach were analysed and are described. The correlations between some of the rating functions and the results of the model are quite good. The contributions to the friction slope value of each one of its dynamic components in the last downstream spatial step are also presented.

1 INTRODUCTION

The influence of tides in the flow of tidal rivers may be very important in several river events or phenomena that might occur like floods and erosions located near fluvial structures. However, this type of flow has not been a much explored subject in the existent related bibliography, especially in what concerns the analysis of the discharge in river sections influenced by the tide effects.

Thus, this paper presents the study carried out to analyse the impact of tides in the flow of tidal rivers. The mathematical formulation of the problem was done using the complete 1-D Saint-Venant equations and for its solution the implicit Preissmann finite-difference method was used. In this way a computational model was developed to simulate one-dimensional unsteady flows in rivers, with irregular and variable cross-sections, and with the downstream boundary affected by the tide effects.

In this analysis the important aspect of the interaction between the flood plain and the in bank flow, recently referred by some authors (for example Shiono and Knight 1991, Ackers 1993, Tominaga et al. 1995, Lyness et al. 1997, Bousmar and Zech 1999), as well as the consideration of flow velocity coefficients were left apart.

The tributaries discharges, as well as the salinity effects on flow dynamics, were also left apart.

An application of the referred computational model was carried out to the Sado River, more precisely, to a reach of this Portuguese river, right upstream Alcácer do Sal city, in which the fluvial flows experiment the tide influence and during flood events has caused important damage, either human or material, in the neighbourhood, particularly in that town.

The purpose of this application was to achieve several flow computational simulations in the considered river reach relatively to some flood events, with the intention of studying the fluvial flow influenced by the tide in what concerns its characteristics in terms of discharge, water depth, flow velocity and Froude number. Another intention was the analysis of the relationship between the water depth and the discharge in the last section of the river reach in study.

To illustrate some of the results obtained during the study phase of the work it is only presented in this paper the flow simulation for a flood event, in which the maximum value of the discharge is 2820 m^3/s.

2 MATHEMATICAL MODELLING

The mathematical modelling of the problem in study is based on the complete Saint-Venant equations, which are usually used to represent the unsteady open channel flows that occur in rivers.

Copyright © 2006 Taylor & Francis Group plc, London, UK

In this manner, the one-dimensional unsteady flows in rivers, with arbitrary shape cross-sections which may vary along their length, assuming also that the water density is constant and the flow velocity coefficients are the unit, may be described by the variables water depth, h, and discharge, Q, at any given river cross-section. These dependent variables define the water motion along the river course and in time, i.e. as a function of two independent variables: the space, x and the time, t.

So, the mathematical formulation of the problem leads to the following two partial differential equations, namely the continuity equation and the dynamic equation, both expressed under their matrix form, as it can be seen for example in Chaudhry (1993), Cunge et al. (1980) and Santos (2004):

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F(U)}}{\partial x} = \mathbf{S(U)} \tag{1}$$

where

$$\mathbf{U} = \begin{bmatrix} A \\ VA \end{bmatrix} \tag{2}$$

$$\mathbf{F(U)} = \begin{bmatrix} VA \\ V^2 A + gA\bar{h} \end{bmatrix} \tag{3}$$

$$\mathbf{S(U)} = \begin{bmatrix} 0 \\ gA(S_0 - J) + gI_2 \end{bmatrix} \tag{4}$$

where $A\bar{h} = I_1$ and $\bar{h}$ is the depth of the flow area centre of gravity.

The symbols that appear in those equations have the following significance:

$A = A(x,t)$ – wetted cross-sectional area,

$Q = VA$ – water discharge through the cross-section, where $V = V(x,t)$ is the uniform cross-sectional velocity,

t – time (independent variable),

x – distance in the flow direction (independent variable),

g – acceleration due to gravity,

I_1, I_2 – cross-sectional moment integrals, which are calculated with the following expressions:

$$I_1 = \int_0^{h(x)} [h(x) - \eta]\sigma(x,\eta)\,d\eta \tag{5}$$

$$I_2 = \int_0^{h(x)} [h - \eta]\left[\frac{\partial \sigma}{\partial x}\right]_{h=h_0} d\eta \tag{6}$$

h – water depth in the considered river cross-section,

$\sigma(x,\eta)$ – width of the cross-section where the water depth is η,

S_0 – bed slope in the x-direction,

J – energy line slope in the x-direction (friction slope); according to the Manning-Strickler formula the friction slope is given by the expression below:

$$J = \left(\frac{Q}{KAR^{2/3}}\right)^2 = \left(\frac{nQ}{AR^{2/3}}\right)^2 \tag{7}$$

where

R – hydraulic radius,

$n = 1/K$ – Manning coefficient.

To solve the problem two computer programs were developed, namely: one for the computation of the fundamental geometric and hydraulic characteristics of the river cross-sections (Geohid_Sectransv model) and the other interrelated with the previous for the computation of the flow variables using the implicit Preissmann finite-difference method (Esquema_Implícito model).

Thus the computation of the flow through the Esquema_Implícito model is based on the numerical discretization of the Preissmann scheme, according to the following expression, as it can be seen for example in Chaudhry (1993) and Santos (2004):

$$\begin{aligned} &\mathbf{U}_i^{j+1} + \mathbf{U}_{i+1}^{j+1} + 2\frac{\Delta t}{\Delta x}\left[\theta\left(\mathbf{F}_{i+1}^{j+1} - \mathbf{F}_i^{j+1}\right) + (1-\theta)\left(\mathbf{F}_{i+1}^{j} - \mathbf{F}_i^{j}\right)\right] + \\ &+ \Delta t\left[\theta\left(\mathbf{S}_i^{j+1} + \mathbf{S}_{i+1}^{j+1}\right) + (1-\theta)\left(\mathbf{S}_{i+1}^{j} + \mathbf{S}_i^{j}\right)\right] = \mathbf{U}_i^{j} + \mathbf{U}_{i+1}^{j} \end{aligned} \tag{8}$$

where

i – cross section index,

j – time instant index,

θ – weighting coefficient in the finite difference approximations of functions and their space derivatives $(0,5 < \theta \leq 1)$,

Δx – spatial step,

Δt – temporal step.

It is important to remark another aspect of this study which consisted in the analysis for the last downstream spatial step of the contributions to the friction slope value of each one of its dynamic components.

Thus, according to Santos (2004), based on the Manning-Strickler resistance law, the continuity equation and the dynamic equation expressed in terms of the water depth and the flow velocity variables, the friction slope may be given by the expression presented below:

$$J = S_0 - \left(1 - \frac{V^2}{c^2}\right)\frac{\partial h}{\partial x} + \frac{V}{c^2}\frac{\partial h}{\partial t} + \frac{V^2}{gA}\left.\frac{\partial A}{\partial x}\right|_{h=cte} - \frac{1}{g}\frac{\partial V}{\partial t} \tag{9}$$

One of the flow computational model explorations that is also important to refer was carried out with the intent of its application to the analysis of the discharge rating function on the last section of the river reach in

Copyright © 2006 Taylor & Francis Group plc, London, UK

study. So the results obtained with the computational model were confronted and criticized face to those which were estimated using the kinematic, diffusive and dynamic wave theories with constant parameters which are described below.

In the study of the discharge rating function, taking into account the above referred contributions to the friction slope, further simplifications were considered:

– the contribution of the component

$$\left.\frac{\partial A}{\partial x}\right|_{h=cte} \tag{10}$$

was disregarded, which is equivalent to consider the final river reach approximately prismatic;

– the contribution of the component

$$\frac{\partial V}{\partial t} \tag{11}$$

was disregarded, thus allowing an explicit formulation for the discharge,

$$Q = Q\left(h, \frac{\partial h}{\partial x}, \frac{\partial h}{\partial t}\right) \tag{12}$$

In this way, considering:

$$\xi = 1 - \frac{V^2}{c^2} \tag{13}$$

$$\eta = \frac{V}{c^2} \tag{14}$$

where c is the wave celerity, the expressions that were tried to estimate the discharge, according to the wave theories and where ah^b stands for the conveyance of the channel in the last section, are the following:

$$\hat{Q} = sgn\left(S_0 - \xi\frac{\partial h}{\partial x} + \eta\frac{\partial h}{\partial t}\right) \times a h^b \sqrt{\left|S_0 - \xi\frac{\partial h}{\partial x} + \eta\frac{\partial h}{\partial t}\right|} \tag{15}$$

for the dynamic wave theory, named dynamic wave (2nd. analysis),

$$\hat{Q} = sgn\left(S_0 - \frac{\partial h}{\partial x} + \eta\frac{\partial h}{\partial t}\right) \times a h^b \sqrt{\left|S_0 - \frac{\partial h}{\partial x} + \eta\frac{\partial h}{\partial t}\right|} \tag{16}$$

where $\xi = 1$, for the dynamic wave theory, named dynamic wave (1st. analysis),

$$\hat{Q} = sgn\left(S_0 - \frac{\partial h}{\partial x}\right) \times a h^b \sqrt{\left|S_0 - \frac{\partial h}{\partial x}\right|} \tag{17}$$

where $\xi = 1$ and $\eta = 0$, for the diffusive wave theory,

$$\hat{Q} = sgn(S_0) \times a h^b \sqrt{|S_0|} \tag{18}$$

where $\xi = 0$ and $\eta = 0$, for the kinematic wave theory.

In these mathematical formulations *a, b,* ξ and η are considered constant parameters to be estimated by the least squares approximation, using the Preissmann weighting scheme to approach the derivatives.

3 APPLICATION TO A REAL CASE STUDY

The Esquema_Implícito model with $\Delta t = 1800$ s and $\theta = 0{,}6$ was applied to a reach of approximately 24 km of the Sado River right upstream of Alcácer do Sal city, in which thirteen cross-sections spaced at a distance of about 2 km were considered (Figure 1).

The main reasons because this real case study was chosen are that the fluvial flow in the referred river reach experiments the tide influence and during some flood events has caused important damage, either human or material.

Although during the study phase of the work several flows were simulated in the considered river reach, in this paper only the flow simulation for a flood event, in which the maximum value of the discharge is 2820 m^3/s, is presented to illustrate some of the results obtained.

Figure 2 shows the hydrograph considered in this simulation for the upstream boundary (section P1).

To characterize the downstream boundary condition the flow water depth induced by the tide was considered (section P13 in Figure 3).

It should be remarked that for all the simulations that were realized the flow regime was subcritical all over the length of the river reach in study.

Figures 2 to 4 show the results obtained through the computational model application to the referred flood event in what concerns the characteristics of

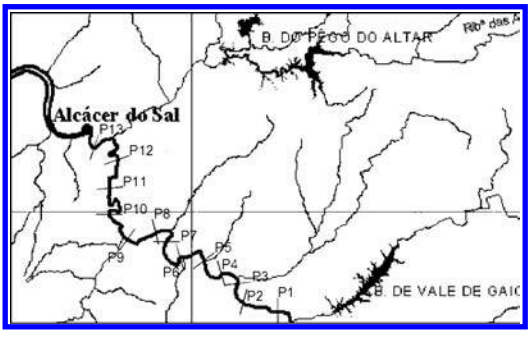

Figure 1. Location of the thirteen cross-sections considered in the river reach in study (adapted from "Plano da Bacia Hidrográfica do Rio Sado" 2002).

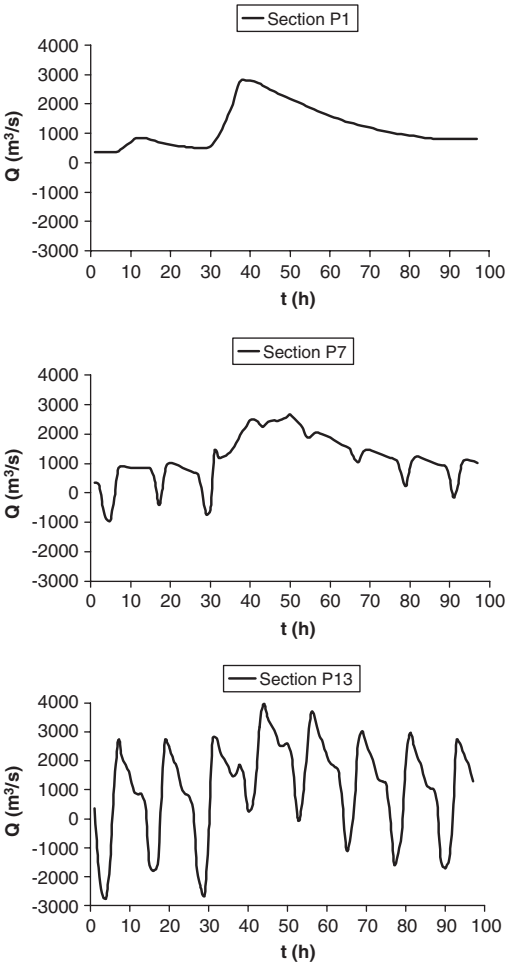

Figure 2. Variation in time of the discharge at the sections P1, P7 and P13 of the river reach in study (estimated flood event).

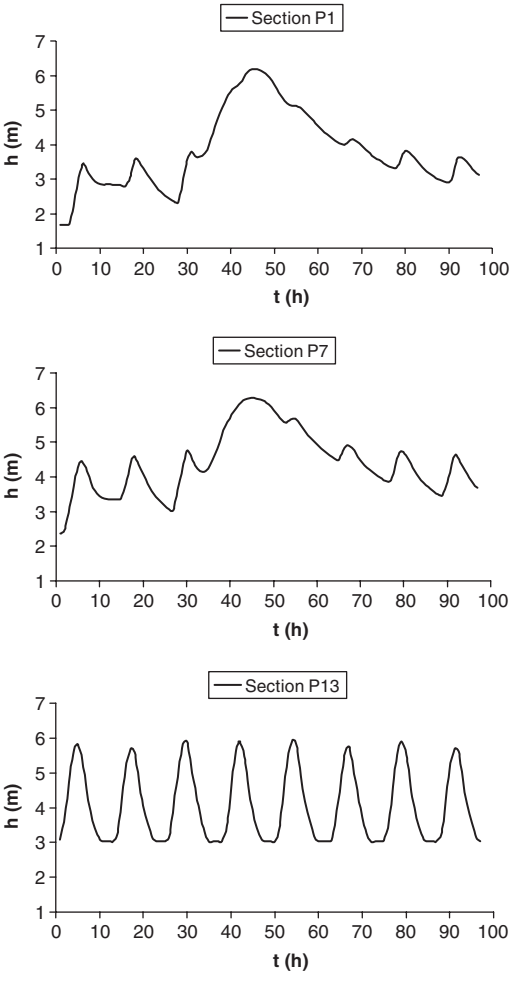

Figure 3. Variation in time of the water depth at the sections P1, P7 and P13 of the river reach in study (estimated flood event).

the fluvial flow influenced by the tide expressed in terms of the variations in time of the discharge, the water depth and the flow velocity in the sections P1, P7 and P13 of the considered river reach. These figures show that there is an inversion of the flow due the tide influence in the fluvial flow and that there is an attenuation of this influence from downstream (section P13) to upstream (section P1), which is more evident upstream the section P7 because this is the narrowest cross-section considered in the river reach in study.

From the analysis of the Figures 5 and 6, where the temporal evolution of discharge and water depth (Figure 5) and the temporal evolution of flow velocity and water depth (Figure 6) in the last section of the considered river reach are shown, it is possible to conclude that the maximum values of the discharge, the water depth and the flow velocity do not occur simultaneously. This fact can lead to increased velocity values which may enhance the "normal" expected erosion near fluvial structures that might exist in the considered river reach.

Those figures also show that the maximum discharge is about one and an half times larger than the maximum discharge that enters upstream of the river reach in study, although the average velocities in absolute value are less than 1 m/s, they can correspond in some places to very large maximum flow velocity values, that, as it was already said, may put in danger the security of some fluvial structures that might exist in the referred river reach.

Copyright © 2006 Taylor & Francis Group plc, London, UK

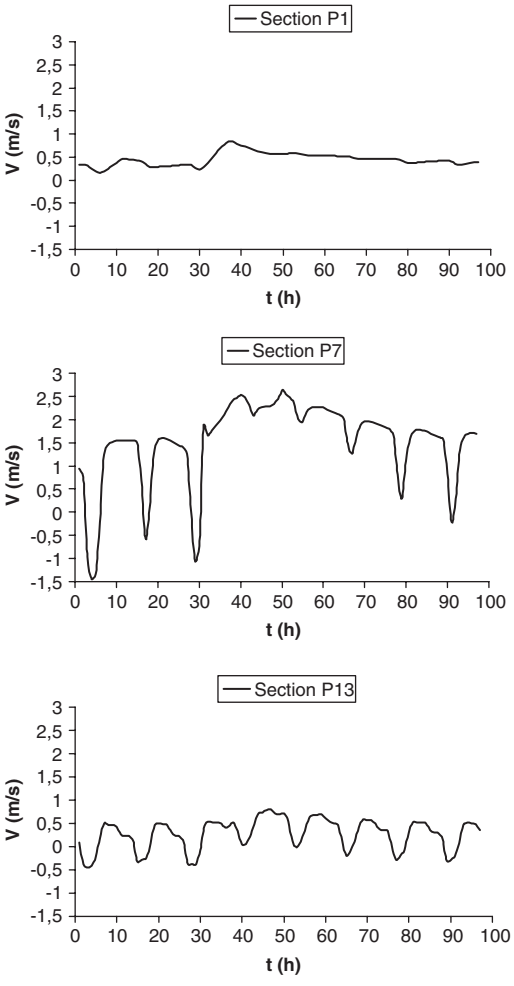

Figure 4. Variation in time of the flow velocity at the sections P1, P7 and P13 of the river reach in study (estimated flood event).

Although the hysteresis is a well known phenomenon when connected to floods in non tidal rivers, when related to tide induced phenomena the cyclical behaviour occurs in an inverse order. That is the maximum water depth occurs in the first place, followed by the maximum discharge and after those by the maximum flow velocity.

Figures 7 to 9 with different ordinate scales show the results obtained in the analysis for the last downstream spatial step of the contribution to the friction slope value of each one of its dynamic components normalized through their division by S_0. The analysis of those figures lead to the conclusion that in the referred last spatial step, with the exception of S_0/S_0, the normalized dynamic component of the friction slope that contributes the most for the variation of its value is

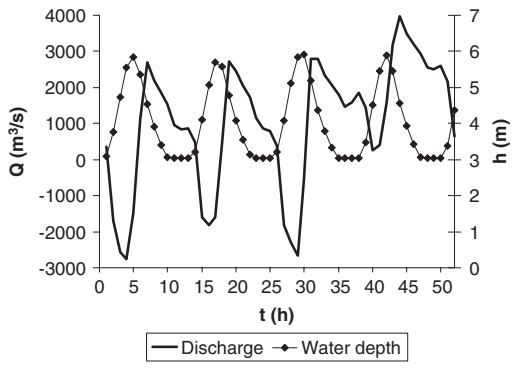

Figure 5. Discharge and water depth hydrographs in the last section of the river reach in study (estimated flood event).

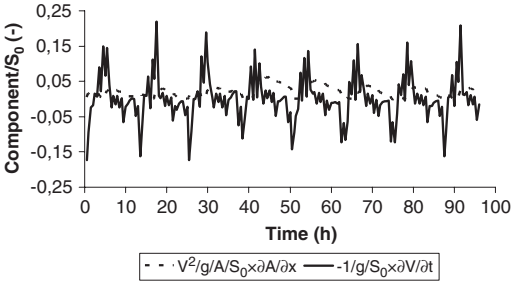

Figure 8. Contribution of the friction slope dynamic components $V^2/g/A/S_0 \times \partial A/\partial x$ and $-1/g/S_0 \times \partial V/\partial t$ to its value in the last downstream spatial step (estimated flood event).

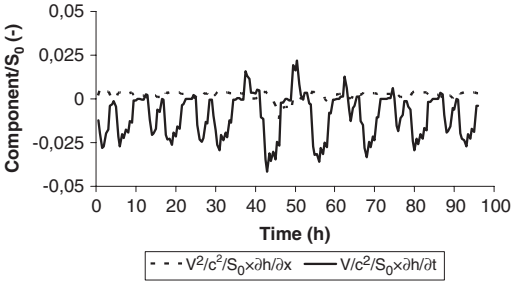

Figure 9. Contribution of the friction slope dynamic components $V^2/c^2/S_0 \times \partial h/\partial x$ and $V/c^2/S_0 \times \partial h/\partial t$ to its value in the last downstream spatial step (estimated flood event).

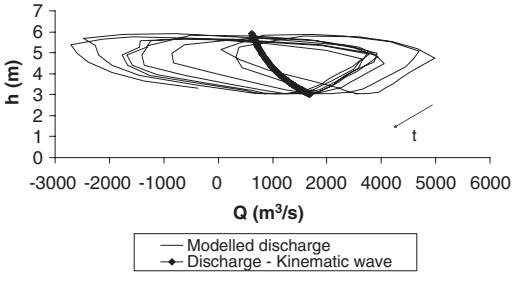

Figure 10. Discharge rating function in the last section of the river reach in study obtained with the flow computational model and the mathematical formulation of the kinematic wave (estimated flood event).

effectuated using the flow computational model and the four presented mathematical formulations based on the kinematic, diffusive and dynamic wave theories. The analysis of the cited figures shows that the kinematic wave theory as expected is not at all appropriate to study the flow in tidal rivers, particularly to study the discharge rating function on a river cross-section influenced by the tide effects. Contrarily, the other wave theories are very adequate for the above referred studies.

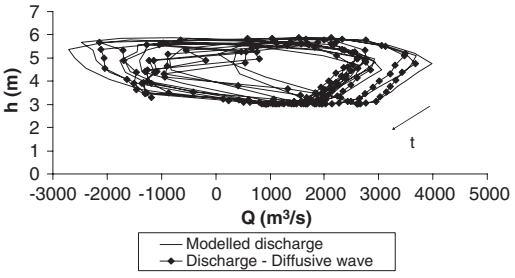

Figure 11. Discharge rating function in the last section of the river reach in study obtained with the flow computational model and the mathematical formulation of the diffusive wave (estimated flood event).

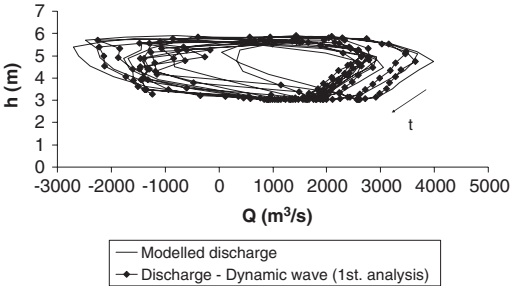

Figure 12. Discharge rating function in the last section of the river reach in study obtained with the flow computational model and the mathematical formulation of the dynamic wave: 1st. analysis (estimated flood event).

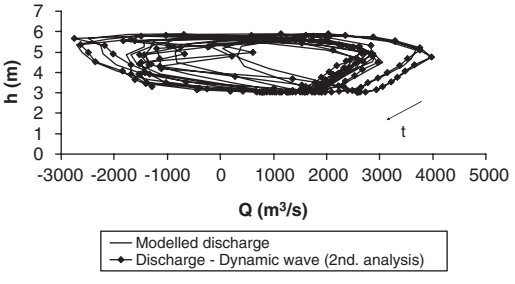

Figure 13. Discharge rating function in the last section of the river reach in study obtained with the flow computational model and the mathematical formulation of the dynamic wave: 2nd. analysis (estimated flood event).

Effectively the correlations between the discharge rating functions modeled and estimated through the diffusive and the dynamic wave theories are quite good. Another result that should be noted from this study is that in tidal rivers the relation between the water depth and the discharge presents great and complex hysteresis and it can be verified that there is more dispersion of the discharges for higher water depths.

Copyright © 2006 Taylor & Francis Group plc, London, UK

4 CONCLUSION

From the analysis of the results obtained in this study it is possible to verify that the tide may represent an important disturbance factor relatively to possible flood wave propagations in tidal rivers.

For the considered flood event, it was shown that there is inversion of the river flow due the tide influence in the fluvial flow and that there is an attenuation of this influence from downstream to upstream of the river reach in study.

In what concerns the last cross-section of the referred river reach in study it is important to note that the maximum discharge may be more than one and an half time larger than the maximum discharge that enters upstream of that river reach and occurs for water depths which are not maximum, which can consequently correspond to very large maximum flow velocity values. In this way, these phenomena can lead to a large increase of the erosions near some fluvial structures that might exist in the considered river reach and can therefore put in danger their security.

One of the aspects of the realized study that is important to refer is the analysis for the last downstream spatial step of the contribution to the friction slope value of each one of its different dynamic components. Thus in the referred last downstream spatial step the dynamic component which contains the partial spatial derivative of the water depth is the one that more contributes for the variation of the friction slope value.

Another part of this study that should be remarked is the flow mathematical model exploration that was done with the intent of its application to the discharge rating function analysis on the last section of the considered river reach. Effectively the correlations between the discharge rating functions obtained with the flow computational model and those which were estimated through the realized adjustment studies based on the diffusive and dynamic wave theories were quite good. Contrarily the kinematic wave theory is not at all appropriate to study the flow in tidal rivers, particularly to study the discharge rating function on a river cross-section influenced by the tide effects.

It is also important to note that in tidal rivers the relation between the water depth and the discharge presents great and complex hysteresis and it can be verified that there is more dispersion of the discharges for higher water depths.

Modelling the distribution of boundary shear stress in open channel flows

M. Omran
Arup, Solihull, UK

D.W. Knight
The University of Birmingham, Department of Civil Engineering, Birmingham, UK

ABSTRACT: Determining the boundary shear stress in open channel flows is not a straightforward procedure due to the poor simulation of the secondary flow currents. The Shiono and Knight Method (SKM) overcomes this problem by linking the secondary current term to the position and rotational direction of the secondary current cells. This novel approach makes the SKM a simple two-dimensional tool capable of predicting the depth-averaged velocity and the boundary shear stress distributions accurately for both inbank and overbank flows.

1 INTRODUCTION

The boundary shear stress distribution in open channel flow is important when dealing with sediment transport, dispersion, river habitat, bank protection and other practical river engineering problems. Modelling the boundary shear stress in straight prismatic channels is not an easy task due to the pattern of longitudinal secondary flow cells that occur in the flow. These cells are highly dependent on the nature of the anisotropic turbulence and they are controlled by both the shape of the cross-section and the heterogeneity of the roughness distribution around the wetted perimeter. See Knight et al (1982 & 1994) for further details and the various data sets that are available for different geometries and flow conditions (e.g. at www.flowdata.bham.ac.uk).

The complexity in determining the boundary shear stress distribution can be revealed when adopting a depth-averaged approach for modelling flow in straight channels. Even when the distribution of the depth-averaged velocity is modelled with acceptable accuracy, the corresponding computed boundary shear stress might not necessarily match the experimental data. This paper investigates different philosophies for modelling the secondary flow cells based on the Shiono and Knight Method (SKM). The obtained results are compared to a variety of experimental data for validation.

2 SUMMARY OF THE SHIONO AND KNIGHT METHOD

The Shiono and Knight Method (SKM) is based on a depth-averaged form of the streamwise Reynolds Averaged Navier-Stokes (RANS) equations, expressed for steady uniform flow in a prismatic channel by the following equations:

$$\rho g H S_0 - \frac{1}{8}\rho f U_d^2\left(1+\frac{1}{s^2}\right)^{1/2} + \frac{\partial}{\partial y}\left[\rho\lambda H^2\left(\frac{f}{8}\right)^{1/2} U_d \frac{\partial U_d}{\partial y}\right] = \frac{\partial}{\partial y}\left[H(\rho(UV)_d\right] \quad (1)$$

$$U_d = \frac{1}{H}\int_0^H U dz \; ; \; \tau_b = \left(\frac{f}{8}\right)\rho U_d^2 \; ; \; \bar{\tau}_{yx} = \rho\bar{\varepsilon}_{yx}\frac{\partial U_d}{\partial y} \; ; \; \bar{\varepsilon}_{yx} = \lambda U_* H \; ; \; \frac{\partial H(\rho UV)_d}{\partial y} = \Gamma \quad (2)$$

$$\tau_b\left(1+\frac{1}{s^2}\right)^{1/2} = \rho g H S_o + \frac{\partial}{\partial y}\left\{H\bar{\tau}_{yx}\right\} - \Gamma \quad (3)$$

where (3) is a simplified form of (1) in terms of stress, and ρ = fluid density, g = gravitational acceleration, H = depth, S_o = channel bed slope, f = Darcy-Weisbach friction factor, U_d = depth-averaged streamwise velocity, s = channel side slope (1:s, vertical: horizontal), λ = dimensionless eddy viscosity, U = streamwise velocity, V = transverse velocity, y = lateral co-ordinate, z = co-ordinate normal to bed, τ_b = local boundary shear stress, $\bar{\tau}_{yx}$ = depth-averaged Reynolds stress, $\bar{\varepsilon}_{yx}$ = depth-averaged eddy viscosity, U_* = shear velocity and Γ = transverse gradient of secondary flow term. The depth-averaged parameters of velocity, Reynolds stress and secondary flow are governed by the coefficients f, λ and Γ, concerned with bed friction, lateral shear and secondary

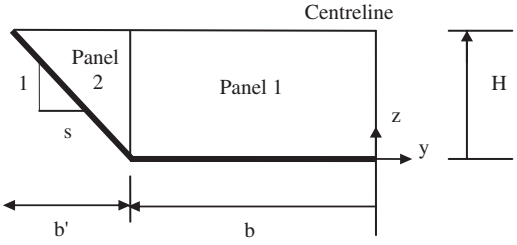

Figure 1. Typical cross-section of trapezoidal channel, with side slopes 1:s.

flow/vorticity respectively. Further details of the SKM, and its application, can be found in Shiono & Knight (1991), Knight & Shiono (1996) and Knight *et al.* (2004).

3 ILLUSTRATION OF A PROBLEM IN THE DISTRIBUTION OF BOUNDARY SHEAR STRESS

Yuen (1989) performed experimental studies measuring the depth-averaged velocity, U_d, and boundary shear stress, τ_b, simple trapezoidal channels with homogeneous roughness. These data are used to illustrate the difficulty associated with modelling the lateral distribution of boundary shear stress. Experimental 16 of Yuen (1989) corresponds to a simple trapezoidal channel with $s = 1$ and $b = 0.075$ m. The SKM was used to model this channel by dividing the cross-section into two domains, one for the side slope region and another for the flat bed, as shown in Figure 1.

Throughout the modelling in this paper, the friction factors used were obtained by applying Darcy-Weisbach equation, $f = 8\tau_b/\rho U_d^2$, to the experimental data. Constant 'standard' values for λ were imposed in all the panels, $\lambda = 0.07$, to make the calibration simple, and only the Γ values were adjusted to match the experimental depth-averaged velocity data. Some guidance on the selection of parameter values is given in Knight & Chlebek (2006) for inbank flows in rectangular channels and in Abril & Knight (2004) for overbank flows in compound channels.

When no experimental data are available, the user has to specify a roughness value in the form of Manning's n for example, from which the friction factor can be computed using $f = 8n^2\, gR^{-1/3}$. Some guidance or empirical equations are required for the Γ term since it is difficult to calibrate it due to the lack of measured data despite knowing its sign from Figure 6.

Figure 2 shows that despite the fact that the analytical U_d distribution was modelled accurately, when compared with the experimental data, the corresponding τ_b distribution was poor, notably in the corner

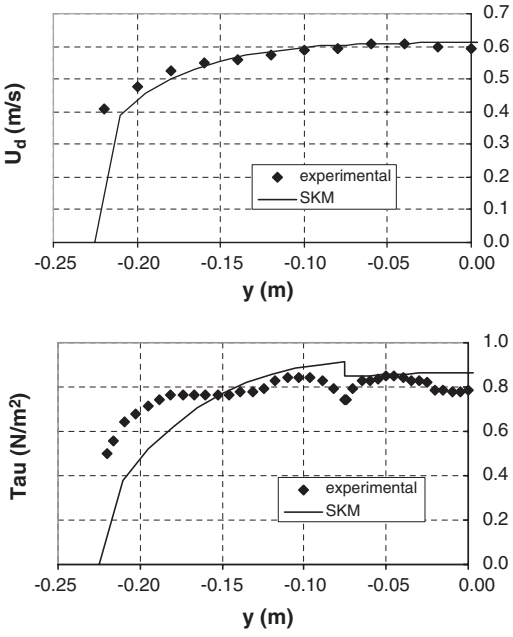

Figure 2. Analytical U_d and τ_b distributions for a simple trapezoidal channel [experiment 16, Yuen, (1989)].

region, at the channel centreline and at the edge of the channel. This distribution was obtained with parameter values of $f_1 = 0.0185$, $f_2 = 0.020$, $\lambda_1 = \lambda_2 = 0.07$, $\Gamma_1 = 0.5$ & $\Gamma_1 = -0.2$.

According to Knight *et al.* (2006), the inadequacy in the τ_b distribution is directly related to the fact that the model as it stands does not incorporate the secondary current cells and their effects.

4 PROPOSED PHILOSOPHY FOR MODELLING SECONDARY CURRENT CELLS IN SIMPLE TRAPEZOIDAL CHANNELS

Tominaga *et al.* (1989) performed experimental studies to determine the pattern of secondary current cells in simple trapezoidal channels. They observed three majors cells, as illustrated in Figure 3. The rotations and approximate positions of these cells were also observed by Knight & Patel (1985a&b) Melling & Whitelaw (1976), Rhodes (1991), Rhodes & Knight (1994), and Yuen (1989).

Figure 4 shows two typical distributions for the longitudinal and transverse velocities. In the former, U, is always positive, with larger values near the free surface than the bed, while in the latter, V, is only a small fraction of U and alters sign depending on the rotational direction of the secondary cell. Hence, at the location corresponding to the centreline position of

Copyright © 2006 Taylor & Francis Group plc, London, UK

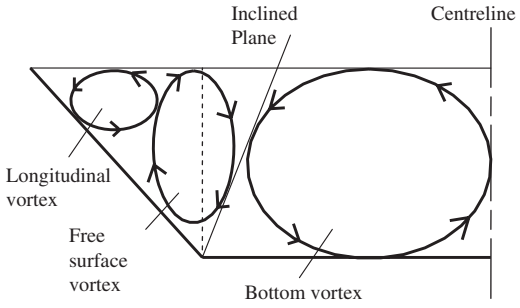

Figure 3. Secondary flow cells in half a trapezoidal channel (after Tominaga *et al*., 1989).

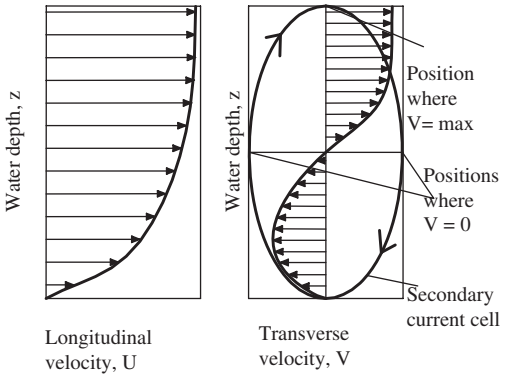

Figure 4. Vertical distribution of the longitudinal and transverse velocities.

a secondary cell, the depth-averaged value of the term UV, $(UV)_d$, can be either positive or negative. As a consequence, as illustrated in Figure 5, $(UV)_d$ at the centreline position of the secondary current cell has a maximum positive value for clockwise rotating cells and a maximum negative value if the cell is rotating in a counter-clockwise direction. It should be noted that at the edge of the secondary current cell, $V = 0$, as previously illustrated in Figure 4, hence at this position, $(UV)_d = 0$. It therefore follows that $(UV)_d$ varies from zero at the edge of the secondary cell to a maximum positive or negative value at the centreline of the cell (depending on the rotational direction) before reaching zero again at the other edge. Knight *et al.* (2006) assumed that the variation of $(UV)_d$ is linear for simplicity.

The philosophy of the SKM is based on using a constant Γ value for each panel, and therefore each time the sign of Γ changes an additional panel is required. As a consequence, Figure 5 shows that half a simple trapezoidal channel should be divided into at least four panels to account for the secondary current cells; two

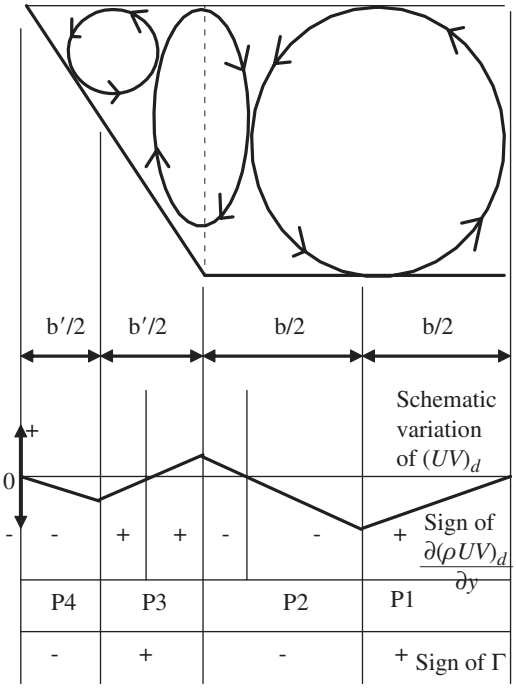

Figure 5. Four panel approach and signs of secondary current term.

of them over the flat bed region and the other two over the side slope domain.

Experiment 16 from Yuen (1989) was then re-modelled by dividing the channel into four panels, following the pattern of Figure 5. Figure 6 shows that the analytical boundary shear stress distribution (marked 'constant f') is better near the channel centreline and near the walls, but that discontinuities in τ_b obviously still remain. These discontinuities are an inevitable consequence of adopting a depth-averaged approach, since changing f between panels is to introduce abrupt changes in τ_b. To overcome this problem, Knight *et al*. (2006) proposed varying f linearly by adopting a common f value at panel interfaces, and then varying f linearly within each panel to match these values. This resulted in a smoother τ_b distribution, as can be seen in Figure 6.

Although the distribution of τ_b in Figure 6 matches the experimental data quite well, the dip in the corner region (at $y = -0.76$ m) is not simulated at all. This arises because of the steep lateral gradients in flow parameters in this region, which then have to be modelled by the insertion of an additional pair of panels, as shown by Knight et al. (2006). However, apart from this minor defect, it is apparent that the SKM with 4 panels is sufficiently sensitive enough to be able to predict the lateral distribution of boundary shear stresses with reasonable accuracy.

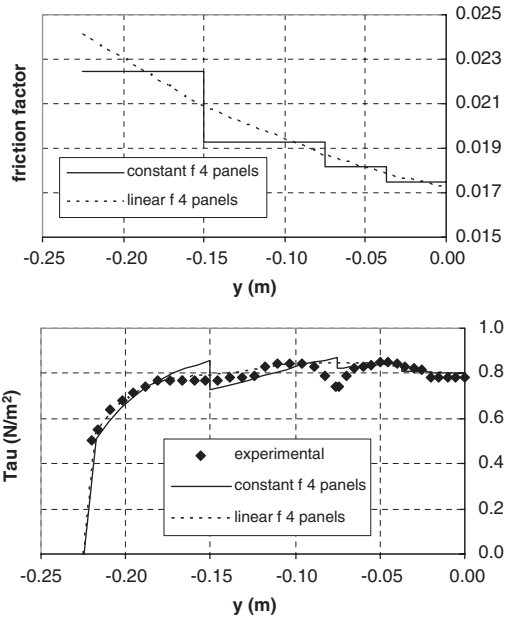

Figure 6. (a) Constant and linear friction factor variation with 4 panels, and (b) corresponding boundary shear stress distributions (experiment 16, Yuen, 1989).

5 EFFECT OF THE SECONDARY CURRENT TERM Γ ON THE DISTRIBUTION OF BOUNDARY SHEAR STRESS

Figure 7 shows that panels 2 and 3 might be composed of two regions each, on account of two different flow cells having some effect in each panel. In panel 2, both regions have a negative sign for Γ, while the two regions in panel 3 have a positive sign for Γ. Previously it was assumed that the same value of Γ could be used in both regions of panel 2 resulting in a single panel with constant negative Γ value. The same assumption was made for panel 3 resulting in one panel with a constant positive Γ value. This section investigates the effect on the analytical solution if these assumptions were not made. In fact, Figure 7 shows that two extra panels, P2a and P3a need to be created by splitting panels 2 and 3 respectively. As a result, panels P2 and P2a will both have negative values of Γ with different magnitudes and panels P3 and P3a will have positive Γ with different values. This will result in six different panels, three in each domain of the simple trapezoidal channel. The same equation of f is used to represent the variation of the friction factor in panels P2 & P2a, this also applies to panels 3 and 3a.

Experiment 08 from Yuen (1989) was used to compare the results of these two philosophies. Experiment 08 corresponds to a simple trapezoidal channel with $H = 0.08$ m, $b = 0.075$ m and $s = 1$. Figure 8 (a)

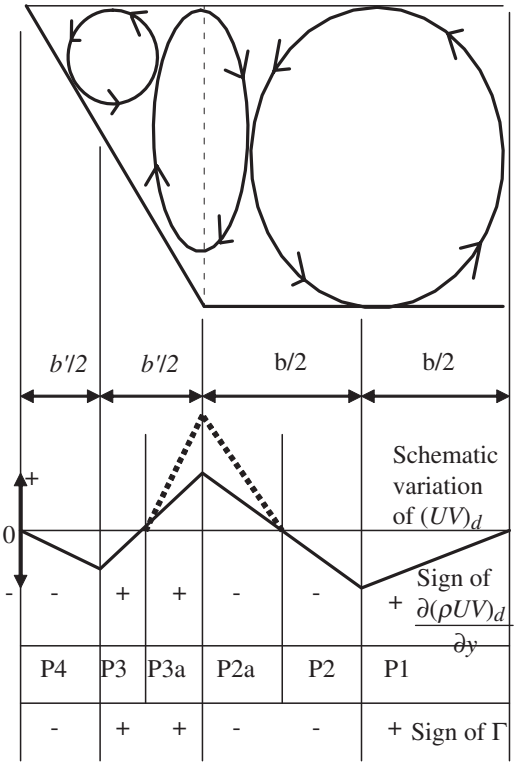

Figure 7. Six panel approach and signs of secondary current term.

shows the analytical results for U_d obtained from both approaches. A small difference of only 0.3% exists between the two. This was expected since U_d is generally well predicted by different approaches and is the reason why the main focus is on predicting the τ_b distribution. Figure 8 (b) shows the shear stress distributions obtained by the two approaches. The differences in the results computed by the two philosophies are again small, and the mean stress differs by less than 1%.

6 EFFECT OF ASSUMING PAIRED VALUES FOR THE SECONDARY CURRENT CELLS

The possibility of allocating a single Γ value for each secondary current cell is now investigated, based on dividing the channel into six panels, as already indicated by Figure 7. In this way, the user will only need to input three values for Γ since $\Gamma_1 = -\Gamma_2$, $\Gamma_{2a} = -\Gamma_{3a}$ and $\Gamma_3 = -\Gamma_4$.

Experiment 03 from Tominaga *et al.* (1989) was used to compare the results of this approach and of the one adopted in section 4. It corresponds to a simple trapezoidal channel with $H = 0.0905$ m, $b = 0.1$ m and s = 1.035. To check the effects on assuming paired

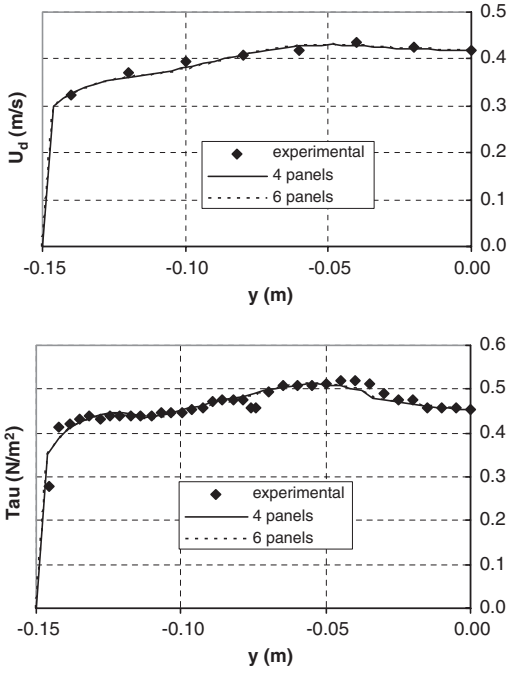

Figure 8. Lateral distributions of U_d & τ_b, based on 4 or 6 panels.

values for the secondary current term Γ, the same experiment was simulated using 6 panels and the same variation of f was used. The Γ term for the bottom vortex was given a value of 0.38, the one for the free surface vortex was 0.30 and the one for the longitudinal vortex was 0.15.

Figure 9 (a) shows the U_d distribution obtained by adopting the paired value approach, as well as the results using just 4 panels. It can be seen that there is not much difference between both approaches when it comes to the U_d distributions, and the difference in the total discharge was only 0.4%. In both approaches, the modelled results match the experimental data well.

7 APPLICATION OF THE MODELLING PHILOSOPHY TO SIMPLE TRAPEZOIDAL CHANNELS

In order to test the analytical model further, trapezoidal channel data from various sources were selected, in which the $2b/H$ values varied from 1.0 to 30. For cases with $2b/H \leq 2.2$, the half width of the channel was divided into four panels and not six, in order to illustrate that in most circumstances, four panels were quite adequate for modelling the τ_b distributions effectively using the SKM.

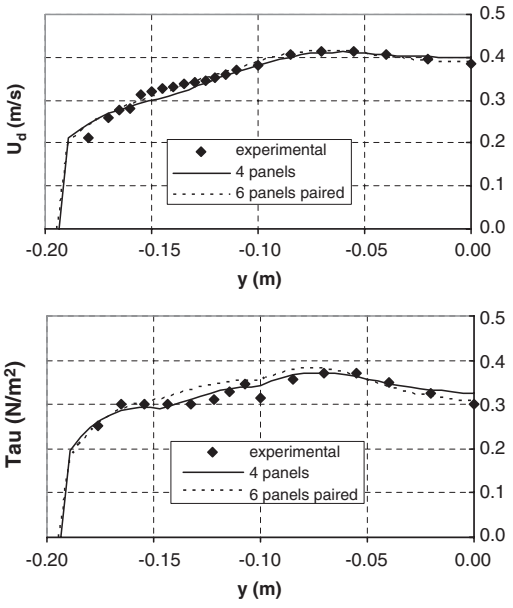

Figure 9. Effect of assuming paired values for the secondary current cells.

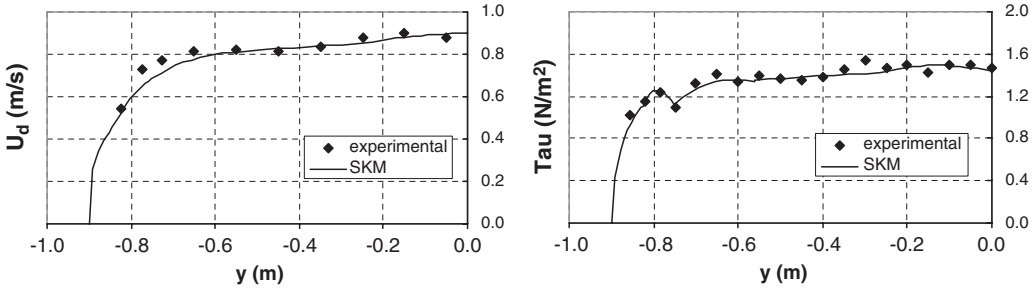
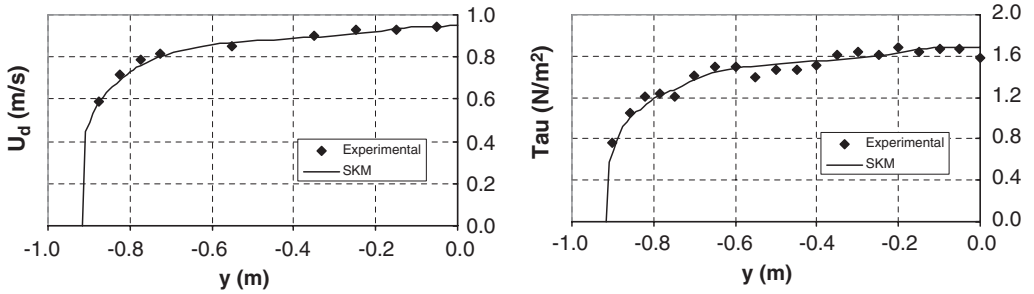


For cases with $2b/H \geq 4.0$, five panels were used to represent the half width of the channel. The friction factor was varied linearly between the panels based on the values adopted at panel interfaces. The λ term was again assumed to be constant at $\lambda = 0.07$ for all panels, while the Γ term was calibrated following the sign convention of Figure 5 so that the analytical U_d results matched the experimental results. Figure 10 shows that accurate distributions of U_d & τ_b were obtained.

8 MODELLING PHILOSOPHY FOR STRAIGHT OVERBANK CHANNELS



Shiono & Knight (1990 & 1991) computed the secondary current flow contribution based on experimental data obtained from the Flood Channel Facility (FCF). This computation was limited to series that corresponded to compound channels with main channel side slopes of $s = 0$, 1 & 2.

In series 02, with $s = 1$, the half width of the main channel was 0.75 m and of the floodplain 3.15 m, both measured from the channel centreline. The bankfull level was set at 0.15 m. Figure 11 shows the variation of $-(\rho UV)_d$ across the channel for different relative depths. It shows that in the main channel $-(\rho UV)_d$ decreases almost linearly up to the interface between the main channel and the floodplain. On the floodplain, $-(\rho UV)_d$ was found to increase approximately linearly. Hence, this figure suggests that Γ, the lateral

gradient of $(\rho UV)_d$, is positive in the main channel and negative on the floodplain.

FCF experimental depth-averaged velocity and boundary shear stress data are available, from which the friction factors can be back-calculated using the Darcy-Weisbach equation. Abril & Knight (2005) showed that the SKM is not very sensitive to the variation of λ across the channel for wide channels and proposed that a constant value of $\lambda_{mc} = 0.07$ be used in the main channel flat bed region, together with equation (4) to compute λ elsewhere across the channel. The Γ term was calibrated, assuming it is positive in

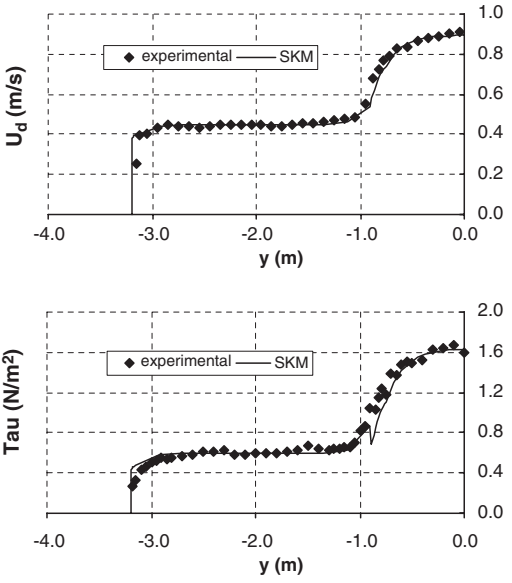

Figure 12. FCF 0205, $f_1 = f_2 = 0.0163$, $f_3 = f_4 = 0.0238$ $\Gamma_1 = \Gamma_2 = 0.35$, $\Gamma_3 = \Gamma_4 = -0.11$.

the main channel and negative on the floodplain, so that the analytical U_d matched the experimental data.

$$\lambda = \lambda_{mc}\left(-0.2 + 1.2Dr^{-1.44}\right) \quad (4)$$

Figure 12 shows that the analytical results match the experimental data for both the U_d and the τ_b distributions. It should be noted that the f and Γ values for the side slope regions in the main channel and floodplain were assumed to be identical to the ones of the corresponding flat bed domain. This comes from the fact that the side slope regions are small compared to the flat bed domains; hence such an assumption facilitates the work of the modeller without affecting the outcomes greatly.

9 CONCLUSIONS

- Secondary flow effects are accounted for in the SKM by specifying the number, position and strength of the cells for a particular flow, and then ascribing an appropriate value for Γ. The values of Γ have been shown to alternate in sign laterally, dependent on the sense of direction of the secondary flows, commensurate with the derivative of the term $H\rho(UV)_d$ with respect to y.
- The number of secondary current cells is found to depend on the channel aspect ratio, $2b/H$.
- For $2b/H \leq 2.2$, the number of secondary current cells in a simple trapezoidal channel was found to be equal to three, with two located over the side slope region and one over the flat bed region.
- For $2b/H \geq 4.0$, the number of secondary current cells in a simple trapezoidal channel was found to be equal to four, with two located over the side slope region and two over the flat bed region.
- Good results for both U_d and τ_b distributions have been obtained for different sets of data, when the proposed method is used with a linear variation of the friction factor across the section.
- The assumption that the maxima, minima and zero values of $(\rho UV)_d$ are aligned is valid and has a little impact on the analytical approach. As a result, the modeller can input four values of Γ, in the four panel case, instead of six values and obtain very much the same accuracy.
- Using paired values of Γ for adjacent panels reduces the accuracy but this simpler calibration philosophy is clearly sufficient to obtain a reasonable first estimate of the τ_b distribution.
- The SKM is able to predict accurately the depth-averaged velocity and the boundary shear stress distribution for overbank channels with a positive and negative value of Γ for the main channel and floodplain respectively.

ABSTRACT: This paper focuses on numerical modelling of non-uniform flows in prismatic and non-prismatic compound channels. A new 1D computation methodology is presented which is called "Independent Subsections Method" (ISM). While conventional 1D models solve the momentum or energy equation on the overall cross-section area, the ISM treats the flow dynamics in the main channel and the floodplains separately. It solves an ordinary differential equations system which calculates the water level and mean velocity in the floodplains and the main channel, simultaneously. This method accounts explicitly for lateral mass exchanges, interfacial shear stress and associated momentum transfer between subsections. ISM simulations of water level and subsection velocities are in agreement with experimental data for four different geometries: straight compound channel; slightly narrowing floodplains; abrupt floodplain contraction; and skewed floodplain boundaries.

1 INTRODUCTION

Flooding rivers usually present flow-width variations that give rise to non-uniform flows in non-prismatic compound geometries. These flows are characterized by turbulent exchanges due to the velocity difference between the flows in the main channel and floodplains, and by mass transfer and associated momentum exchange between subsections. Turbulence and mass transfer induce noteworthy additional head loss that reduces the overall channel conveyance and affects the discharge distribution across the channel.

Non-uniform flows in non-prismatic compound channels were physically described in the case of meandering two stage channels (e.g. Sellin et al. 1993) or skewed floodplains boundaries (e.g. Elliott & Sellin 1990, Sellin 1993). For these flow configurations, the total channel width is constant and accordingly, the subsections flow-depths are nearly invariable in the longitudinal direction. Other experiments focused on non-uniform flows with channel width variations: over bank flows in symmetrically narrowing floodplains (Bousmar 2002, Bousmar et al. 2004); flows in compound channel with abrupt floodplain contraction (Proust 2005, Proust et al. 2006) or with symmetrically enlarging floodplains (Proust 2005, Bousmar et al. 2006).

Various one-dimensional methods were developed to cope with the modelling problems of such gradually varied flows. Every 1D model incorporates a specific approach for the modelling of the momentum exchange at the interface between the main channel and the floodplains. The classical Divided Channel Method (DCM) used in HEC-RAS (USACE) ignores the momentum transfer through subsections boundaries (Brunner 2001). The Debord Formula used in the program Talweg-Fluvia (Cemagref) gives an empirical correction of the DCM that merely models the turbulent transfer (Nicollet & Uan 1979), in a same way as in the flow formulae proposed by Ackers (1993). The Exchange Discharge Model (EDM), developed by Bousmar and Zech (1999) and implemented in the program Axeriv (Université Catholique de Louvain), accounts for both mass and turbulent exchanges.

However, using these three 1D programs for non-uniform flows with width variations leads to moderate errors on the floodplain water depth values (maximum relative error of 25%) but significant errors, up to 100%, on the discharge distributions (Proust 2005, Proust et al. 2006). Accordingly, when simultaneous prediction of both water levels and mean velocity in the flood plain is needed, e.g. for the evaluation of vulnerability in urbanized flood plains or sediment transport in natural floodplains and for the science of habitat hydraulics, these 1D approaches seem to be less relevant.

The computation of backwater surface profile using a 1D energy equation (e.g. in HEC-RAS & Axeriv)

Copyright © 2006 Taylor & Francis Group plc, London, UK

or a 1D momentum equation (in Talweg-fluvia) on the overall cross-section area is less appropriate when significant mass and momentum transfers are observed.

Another 1D approach consists in separating the flow dynamics in the main channel and floodplains. It was first proposed by Yen (1985) for flows in straight compound channels: the author proposed a "quasi-one-dimensional" backwater computation method. This method releases several constraining 1D-assumptions and boundary conditions which are imposed by the conventional 1D models. To the authors knowledge, it was unfortunately not compared to experimental data.

This paper presents the extension of this method to non-prismatic compound channels and its validation against laboratory experiments. A new differential equations system with a specific treatment of the interfacial exchanges is proposed. The results of this method are then compared to experimental data in four different flow configurations: non-uniform flows in straight compound channels (Bousmar et al. 2005), flows with abrupt floodplain contraction (Proust et al. 2006), with slightly narrowing floodplains (Bousmar et al. 2004), and with skewed floodplain boundaries (Sellin 1993).

2 THE INDEPENDENT SUBSECTIONS METHOD

2.1 *Flow equations*

The flow dynamics in the main channel and the floodplains can be separated by writing a 1D momentum equation in each subsection. These equations are linked together by lateral mass discharges and momentum exchange terms acting at the interface between two adjacent subsections. An additional equation ensures the mass conservation on the overall cross-section area.

The compound channel considered here consists of rectangular main channel and floodplains whose width can vary. Subscripts "mc", "lfp", and "rfp" are used for mean values of hydraulic parameters in the main channel, the left flood plain and the right flood plain, respectively. Moreover, water level Z across the compound channel is supposed constant, as $Z_{mc} = Z_{rfp} = Z_{lfp}$.

For such a compound channel, the 1D momentum equations can be simplified for the three subsections (Proust 2005) as:

$$\left(1-\frac{U_{lfp}^{\ 2}}{gh_{lfp}}\right)\frac{dh_{lfp}}{dx} = S_o - Sf_{lfp} + \frac{U_{lfp}^{\ 2}}{gB_{lfp}}\frac{dB_{lfp}}{dx} + \ldots + \frac{\tau_{lfp}.h_{lfp}}{\rho g A_{lfp}} + \frac{q_{lfm}\left(2U_{lfp} - U_{int.lfp}\right)}{gA_{lfp}} \quad (1)$$

$$\left(1-\frac{U_{rfp}^{\ 2}}{gh_{rfp}}\right)\frac{dh_{rfp}}{dx} = S_o - Sf_{rfp} + \frac{U_{rfp}^{\ 2}}{gB_{rfp}}\frac{dB_{rfp}}{dx} + \ldots + \frac{\tau_{rfp}.h_{rfp}}{\rho g A_{rfp}} + \frac{q_{rfm}\left(2U_{rfp} - U_{int.rfp}\right)}{gA_{rfp}} \quad (2)$$

$$\left(1-\frac{U_{mc}^{\ 2}}{gh_{mc}}\right)\frac{dh_{mc}}{dx} = S_o - Sf_{mc} + \frac{U_{mc}^{\ 2}}{gB_{mc}}\frac{dB_{mc}}{dx} + \ldots + \frac{\tau_{lfp}.h_{lfp}}{\rho g A_{mc}} + \frac{\tau_{rfp}.h_{rfp}}{\rho g A_{mc}} \ldots - \frac{q_{lfm}\left(2U_{mc} - U_{int.lfp}\right)}{gA_{mc}} - \frac{q_{rfm}\left(2U_{mc} - U_{int.rfp}\right)}{gA_{mc}} \quad (3)$$

where x = longitudinal direction; h = subsection flow depth; U = subsection mean velocity; U_{int} = longitudinal velocity at the interface; B = subsection width; A = subsection area; S_o = bed slope; S_f = subsection friction slope; τ = shear stress at the interface in the x direction.

Besides, q_{rfm} (resp. q_{lfm}) is the lateral mass discharge per unit longitudinal length between the right floodplain (resp. the left floodplain) and the main channel, being positive from a floodplain to the main channel.

The friction slope S_f is calculated with classical Manning's formula applied to a subsection.

The continuity equations in both floodplains are:

$$\frac{dQ_{lfp}}{dx} = -q_{lfm} \qquad \frac{dQ_{rfp}}{dx} = -q_{rfm} \quad (4)$$

and the mass conservation on the overall cross-section area writes:

$$\frac{dQ_{mc}}{dx} = q_{lfm} + q_{rfm} \quad (5)$$

where the sum of the subsection discharges, Q_{mc}, Q_{frm} and Q_{flm} is the total discharge Q.

The Independent Subsections Method consists thus in solving the set of equations (1), (2), (3) and (5), with closure equations defining the interface shear stress τ and velocity U_{int}.

2.2 *Momentum transfer modeling*

2.2.1 *Turbulent transfers*

Yen (1985) proposed to relate the interfacial side shear stress τ to the velocity gradient in the lateral direction y across the channel, assuming a constant eddy viscosity ν_t. But Wilson et al. (2002) showed that this assumption leads to overestimate turbulent diffusion and therefore to reduce the velocity difference between flows in the main channel and the floodplains.

Table 1. Calibration of turbulent exchange coefficient Ψ^t for uniform flows (h_r is the relative water depth).

UCL flume		LMFA flume	
h_r [−]	Ψ^t [−]	h_r [−]	Ψ^t [−]
0.09	0.0173	0.2	0.0164
0.18	0.0200	0.3	0.0165
0.27	0.0167		
0.41	0.0159		

Other Authors preferred to evaluate the interfacial shear on the subsection boundary by using a mixing length model in the horizontal plane. This model was validated by Ervine & Baird (1982) from experimental data collected by Myers (1978), Rajaratnam & Ahmadi (1981), Ghosh & Jena (1971) and Sellin (1964), by Lambert & Sellin (1996) and by Bousmar (2002). Finally, the mixing length model included in the Exchange Discharge Model was retained (Bousmar & Zech 1999). The side shear stress τ on the two interfaces are modelled by:

$$\left|\tau_{lfp}\right| = \rho \Psi^t \left(U_{mc} - U_{lfp}\right)^2 \quad (6)$$

$$\left|\tau_{rfp}\right| = \rho \Psi^t \left(U_{mc} - U_{rfp}\right)^2 \quad (7)$$

where Ψ^t = a constant coefficient of turbulent exchange.

The Ψ^t value was calibrated using six uniform flows data set, varying relative water depth $h_r = h_{fp}/h_{mc}$. The uniform flows experiments were conducted in two different compound channel flumes (see §3), at the Laboratoire de Mécanique des Fluides et d'Acoustique, Lyon, France (LMFA) and at the Université catholique de Louvain, Belgium (UCL). Results of calibration are reported on Table 1.

Coefficient Ψ^t values are in the range 0.016 to 0.020. They are quite stable in both compound channel flumes. In the sequel, ISM simulations were done with $\Psi^t = 0.020$.

2.2.2 *Mass transfers*

In Equation (1), (2) and (3), $U_{int.lfp}$ is the x-component velocity of lateral mass discharge q_{lfm} (left interface) and $U_{int.rfp}$ is related to q_{rfm} (right interface). Consequently, the momentum transfer due to mass exchange strongly depends on the interfacial velocities values.

Determination of these velocities relies on experimental observations. For flows in compound channels with floodplain(s)-width decrease, the longitudinal velocity of water entering the main channel is very close to the floodplain mean velocity, as observed for symmetrical narrowing floodplains (Bousmar et al. 2004) and abrupt floodplain contraction (Proust et al. 2006). In that case, interfacial velocities can be modelled by:

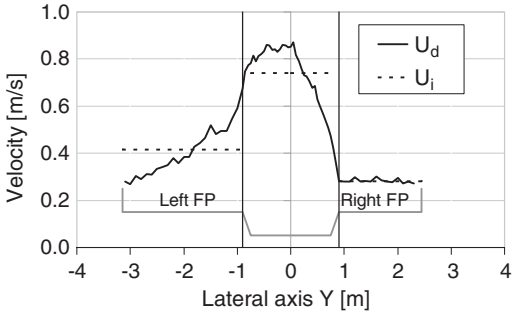

Figure 1. Typical transverse profile of depth-averaged velocity U_d and subsection velocity U_i for skewed floodplain boundaries (skew angle = 9.2°, $h_r = 0.15$).

$$\begin{aligned} U_{int.lfp} &= U_{lfp} \\ U_{int\,rfp} &= U_{rfp} \end{aligned} \quad (8)$$

Conversely, for flows in compound channels with floodplain(s)-width increase, the longitudinal velocity of water leaving the main channel is very close to the main channel mean velocity (Proust 2005, Bousmar et al. 2006). It comes:

$$\begin{aligned} U_{\text{int.}lfp} &= U_{mc} \\ U_{\text{int}\,rfp} &= U_{mc} \end{aligned} \quad (9)$$

For flows in the Flood Channel Facility (FCF) at HR Wallingford, UK, with skewed floodplains boundaries (see Figure 3 and Sellin 1993), both phenomena are observed simultaneously, since the left floodplain is enlarging and the right one is narrowing. Figure 1 shows a typical transverse profile of depth-averaged velocity for a skew angle of 9.2° and a relative water depth h_r of 0.15. In that case, the interfacial velocities are adequately modelled by:

$$\begin{aligned} U_{int.lfp} &= U_{mc} \\ U_{int\,rfp} &= U_{rfp} \end{aligned} \quad (10)$$

Accordingly, the interfacial velocities in ISM are modelled depending on the mass transfer direction for each interface.

2.3 *Differential equations system*

Equations (5), (1), (2) and (3) can be written as an ordinary differential equation system (11), where coefficients a_1, a_2, a_3, a_4, b_1, b_2,c_1, c_4, d_1, d_2 and d_4 are

Copyright © 2006 Taylor & Francis Group plc, London, UK

non-linear functions of velocities U_{lfp}, U_{rfp}, U_{mc}, water depth h_{fpl}, geometrical parameters and subsection manning roughness (Proust 2005).

$$\begin{cases} a_1 \dfrac{dh_{lfp}}{dx} + a_2 \dfrac{dU_{lfp}}{dx} + a_3 \dfrac{dU_{mc}}{dx} + a_4 \dfrac{dU_{rfp}}{dx} = e_1 \\ b_1 \dfrac{dh_{lfp}}{dx} + b_2 \dfrac{dU_{lfp}}{dx} = e_2 \\ c_1 \dfrac{dh_{lfp}}{dx} + c_4 \dfrac{dU_{rfp}}{dx} = e_3 \\ d_1 \dfrac{dh_{lfp}}{dx} + d_2 \dfrac{dU_{lfp}}{dx} + d_4 \dfrac{dU_{rfp}}{dx} = e_4 \end{cases} \quad (11)$$

The differential equations system (11) can also be expressed in matrix form:

$$\begin{bmatrix} a_1 & a_2 & a_3 & a_4 \\ b_1 & b_2 & 0 & 0 \\ c_1 & 0 & 0 & c_4 \\ d_1 & d_2 & 0 & d_4 \end{bmatrix} \cdot \begin{bmatrix} \dfrac{dy(1)}{dx} \\ \dfrac{dy(2)}{dx} \\ \dfrac{dy(3)}{dx} \\ \dfrac{dy(4)}{dx} \end{bmatrix} = \begin{bmatrix} e_1 \\ e_2 \\ e_3 \\ e_4 \end{bmatrix} \quad (12)$$

where $y(1) = h_{lfp}$; $y(2) = U_{lfp}$; $y(3) = U_{mc}$; and $y(4) = U_{rfp}$. It should be noticed that $h_{lfp} = h_{rfp} = h_{mc} - h_b$, with $h_b =$ the bank full flow depth in the main channel.

Equation (12) is equivalent to:

$$\frac{dY}{dx} = F(Y) \qquad \text{with} \qquad Y = \begin{pmatrix} y(1) \\ y(2) \\ y(3) \\ y(4) \end{pmatrix} \quad (13)$$

The Independent Subsections Method consists thus in solving both flow depth and subsection velocities simultaneously. The MATLAB solving procedure ODE45 for ordinary differential equations was used: it is based on a Runge-Kutta explicit scheme of 4th or 5th order.

For subcritical flows, the ISM is solved iteratively: the upstream experimental discharge distribution and a tentative upstream water level are given. The downstream water level results from the computation. The upstream level is then adjusted until the suitable downstream level is obtained.

3 EXPERIMENTAL DATA

The ISM was tested in seven different flow geometries. Hydraulic and geometrical parameters of flow configurations are reported in Table 2, where variations of floodplains-widths B_{lfp} and B_{rfp} and relative water depth h_r between upstream and downstream boundaries are exposed. For non-prismatic reaches, the angle between floodplains walls and main channel axis (longitudinal direction x) is noted α.

Experiments on non-uniform flows in straight compound channels were performed in the laboratory flumes of LMFA and UCL. Non-uniform flows result from a non-equilibrated upstream discharge distribution at the inlet of the flume. The floodplain discharge is too large and a mass transfer towards the main channel occurs along the flume (Bousmar et al. 2005).

Experiments in compound channel with narrowing floodplains were conducted in the UCL flume (Bousmar et al. 2004). Two different geometries were explored: a linear decrease of floodplains-width on 6 meters long ($\alpha = 3.8°$) or 2 meters long ($\alpha = 11.3°$).

Flows in compound channel with abrupt floodplain contraction were obtained in the laboratory of Compagnie Nationale du Rhône (CNR, Figure 2). An obstacle was set on the floodplain, presenting a strong convergence of length 3.5 m and of projected width 1.43 m perpendicularly to the main flow direction (mean angle $\alpha = 22°$). The flow was studied on a 4.5 m length (Proust et al. 2006).

The last data set is the skewed channel geometry studied in the FCF. A prismatic main channel is skewed to prismatic floodplain, with an angle $\alpha = 5.1°$ or 9.2°), while the overall channel width remains constant (Figure 3).

Mass transfers are observed on the one hand, from the right floodplain to the main channel, and on the other hand, from the main channel to the left floodplain (Elliott & Sellin 1990, Sellin 1993). The velocity distribution both in the main channel and over the two floodplains are thus distorted by the cross-flow (Figure 1).

4 ISM SIMULATIONS

In the investigated geometries, three types of ISM simulations were carried out: (1) ignoring the momentum transfer; (2) taking merely into account a modelling of turbulent exchanges; (3) accounting for the total momentum transfer (mass & turbulence). Modifications of dynamical equations for cases (1) and (2) are detailled in Proust (2005).

Afterwards, simulations (1) are labelled "bed friction" on figures, as the bed friction is the only dissipation source; labels "Turb. Transfer" and "Turb. & Mass transfers" are used for simulations (2) and (3), respectively.

measured floodplain discharge are given on Figure 4; where Q_{fp} = sum of Q_{lfp} and Q_{rfp}.

When the total momentum transfer is considered, ISM reproduces satisfactorily the discharge distribution evolution. Conversely, ignoring both mass and turbulent exchanges in the momentum transfer leads to a 20 % underestimation of the floodplain discharge at the downstream end of the studied reach.

Comparison between "Turb. & Mass transfers" and "Turb. transfer" curves, also indicates that turbulence has a predominant role in the momentum transfer. Similar results were obtained for the other straight channel cases (Proust 2005). A correct modelling of the turbulent transfer is necessary to obtain the proper discharge distribution when the flow tends to uniformity (in the downstream part of the reach).

When the relative flow depth increases, the weight of the momentum transfer terms in the ISM reduces: for $h_r = 0.27$, ignoring the momentum transfer just induces a 9% underestimation of Q_{fp}.

Variations of the computed and experimental flow depths are not represented here, as they are less than 1.5 *mm* between upstream to downstream boundaries.

Eventually, it was observed that equations of mass conservation (Equations 4 and 5) and bed friction terms control the ISM system close to the upstream

boundary ($x < 2$ m), while bed friction and turbulent transfer govern the flow in the downstream part of the flume.

4.2 *Symmetrical narrowing floodplains*

For flows in compound channels with narrowing floodplains, ISM simulations of $\{h_{lfp};\ U_{lfp};\ U_{rfp};\ U_{mc}\}$ accurately match the experimental data for the ten flow configurations where the relative flow depth h_r varies in the range [0.50; 0.22]. For these flows depths, accounting for the momentum transfer has practically no influence on the ISM results.

For lower h_r [0.22; 0.12], the momentum transfer influences more significantly the results, as shown on Figure 5 for the case: $\alpha = 11.3°$, $Q = 10\,l/s$. Considering the whole momentum transfer, the floodplain discharge Q_{fp} is computed with a maximum relative error of -13% (resp. 0%) at station $x = 4\,m$ (resp. $x = 5m$). Conversely, the floodplain discharge rate is underestimated of 44% (resp. 38%) at these two stations, when neglecting both mass and turbulence in the momentum transfer. Figure 5 also shows that mass exchanges have far more influence than turbulence in the momentum transfer, contrarily to non-uniforms flows in compound channels.

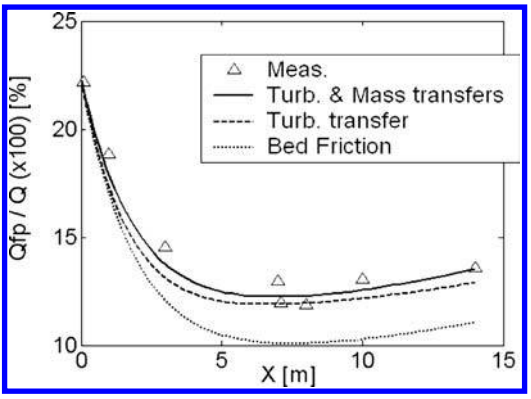

Figure 4. Longitudinal profile of discharge rate in both floodplains Q_{fp} (as percentage of the total discharge Q) – UCL flume, $Q = 10$ l/s, $h_r = 0.18$.

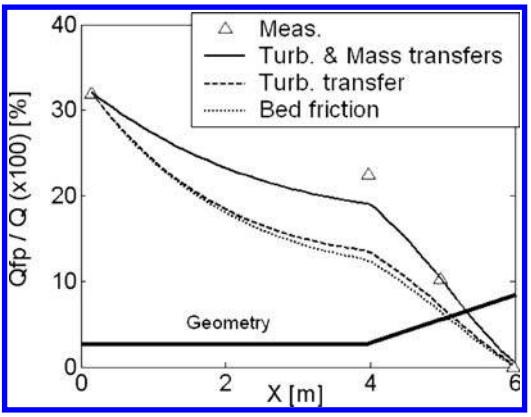

Figure 5. Longitudinal profile of discharge rate in both floodplains Q_{fp} (percentage of the total discharge Q) – Narrowing floodplains, $\alpha = 11.3°$, $Q = 10\,l/s$, $h_r \in [0.22; 0.12]$.

Finally, errors on the floodplains flow depth in the converging reach are less than 4% for the ISM with the whole momentum transfer, and grow up to 23% when considering only bed friction (Figure 6).

ISM simulations clearly demonstrate that momentum transfer due to mass exchanges has to be taken into account for the low over bank flows, when attempting to model flow depth and discharge distribution in such a geometry.

4.3 *Abrupt floodplain contraction*

In this particular geometry, the mass transfers become severe and the flow is clearly three-dimensional (Proust et al. 2006). However, ISM still predicts correctly both water surface and floodplain velocity profiles (see Figures 7 and 8, for $Q = 150\,l/s$). The

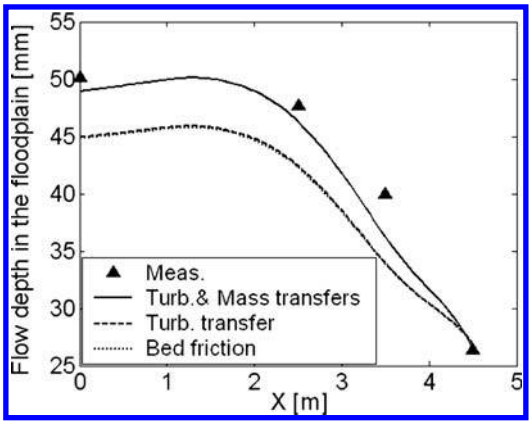

Figure 7. Longitudinal water surface profiles – ISM calculation against experimental data. CNR flume, $Q = 150\,l/s$, $h_r \in [0.23; 0.14]$.

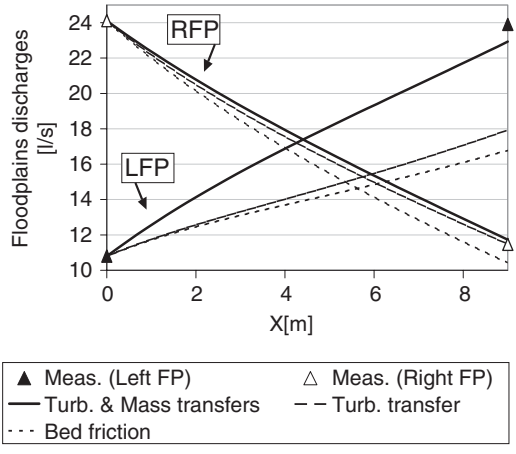

Figure 9. Discharge profiles in both floodplains (Left floodplain & right floodplain) – ISM calculation against experimental data in the Flood Channel Facility, $Q = 254\,l/s$, $h_r = 0.146, \alpha = 9.2°$.

flow depth h_{fp} and velocity U_{fp} are computed with a maximum relative error of -8% and -10%, respectively.

Accounting for the turbulence transfer does not influence the computations, when compared to results with only the bed friction, while considering the momentum transfer due to mass exchange significantly reduces prediction errors, notably on the flow depth. Such an observation confirms the above conclusions for the narrowing floodplains cases.

4.4 *Skewed floodplains boundaries*

ISM computes each floodplain discharge with a maximum error of -7% for the seven flow configurations investigated (see Tab. 2). It also reproduces the observed flow depth profile, with no variation between the upstream and downstream boundaries (variations of computed flow depth are less than 1 *mm*).

For flows with relative water depths $h_r = 0.4$ and 0.5, using ISM with or without the momentum transfer does not modify the simulations.

From $h_r = 0.25$ to 0.15, influence of momentum transfer appears only in the enlarging floodplain, i.e. the left floodplain (Figure 9). In this latter, ISM simulations only considering the bed friction induces a -30% underestimation of discharge Q_{lfp}.

Moreover, this influence seems to be mainly related to mass transfer: this last result is consistent with experimental momentum balances obtained by Elliott and Sellin (1990). They showed that influence of

Copyright © 2006 Taylor & Francis Group plc, London, UK

turbulent transfer rapidly decreases when momentum related to mass transfer between subsections increases.

The asymmetry of the momentum effect of mass transfers between the narrowing right floodplain and the enlarging left one was explored in Proust (2005). Comparison of flows in symmetrical narrowing floodplains (see §4.2) and flows in symmetrical enlarging floodplains (Bousmar et al. 2006) shows that the relative weight of momentum due to mass exchanges is three times larger in the enlarging reaches, for a same angle α. For skewed geometries, this asymetry could be expected from the observation of the gradients of depth-averaged velocities U_d over the two floodplains (Figure 1): nil on the converging floodplain and marked on the enlarging one.

5 1D SIMULATIONS ON THE OVERALL CROSS-SECTION

Three 1D programs were tested in the compound channel with abrupt floodplain contraction (Proust et al. 2006): HEC-RAS (USACE), Talweg-Fluvia (Cemagref) and Axeriv (UCL). All these programs predict water profiles and discharge distribution between subsections.

HEC-RAS solves the Bernoulli equation on the overall cross-section area. It neglects the momentum transfer by using the DCM. However, it accounts for contraction losses by an empirical equation (Brunner 2001). It should be noticed that contraction losses were built to adjust the water surface profile. They do not depend on subsection discharges and hence, do not deal with discharge distribution.

Talweg-Fluvia solves the 1D-momentum equation on the whole cross-section. It accounts for the turbulent exchange through the Debord formula which modifies the conveyance on the whole cross-section by empirical coefficients (Nicollet & Uan 1979). The momentum transfer due to mass exchanges is not considered. The bed friction slope and the discharge distribution in a specific reach are thus the same as the ones obtained for a uniform flow having the same hydraulic radius and averaged velocity.

Axeriv solves the Bernoulli equation on the whole cross-section. The bed friction slope is computed by Manning's formula using the DCM approach. It models the momentum transfer with the Exchange Discharge Model. The EDM accounts for both mass and turbulent exchanges in the momentum transfer. It calculates additional head losses due to the momentum effect in the subsections and the total cross-section (Bousmar & Zech 1999).

Last but not least, the three codes assume the equality of subsection head loss gradients.

Figure 10 shows the measured and computed water surface profiles. The downstream boundary condition

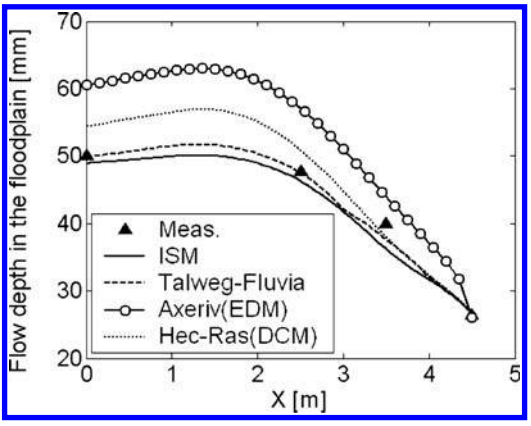

Figure 10. Longitudinal flow depth profile (in the floodplain) – calculation against experimental data: CNR flume, abrupt floodplain contraction, Q = 150 l/s.

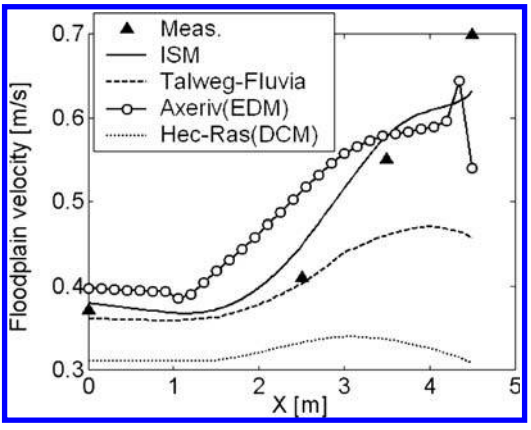

Figure 11. Floodplain velocity profiles – calculation against experimental data: CNR flume, abrupt floodplain contraction, Q = 150 l/s.

used for the computations is the experimental water level, averaged across the total channel width. Computed and measured floodplain velocities are given on Figure 11.

These results show that a 1D-equation defined on the total cross-section can not simultaneously predist both flow depth and mean velocity in the floodplain satisfactorily. The floodplain flow depths are computed with maximum relative errors of +9%, −5.2%, +20% for HEC-RAS, Talweg-Fluvia and Axeriv, respectively, while errors on the floodplain velocity are respectively −57%, −36%, −25%.

Several causes for the poor quality of these results can be identified:

– Incorrect (or missing) estimation of momentum transfer due to mass exchange.

Copyright © 2006 Taylor & Francis Group plc, London, UK

– Incorrect estimation of the lateral mass discharge.
– Assumption of a downstream discharge distribution equal to the distribution in an equivalent uniform flow, which induces erroneous momentum transfer estimations in the EDM.
– Assumption of equal head loss gradients in all subsections.
– Impossibility for HEC-RAS to obtain the actual discharge distributions by calibrating the contraction loss coefficient.

The computed errors on h_{fp} and U_{fp} in the ISM simulations were −8% and −10%, respectively. The comparison of these results with the classical 1D methods clearly demonstrates that: (1) lateral mass discharge and momentum transfer have to be explicitly modelled by separating the flow equations in the subsections; (2) mass transfers have to be modelled by starting the computation from the upstream boundary where the observed discharge distribution is imposed.

ISM also enables to reproduce different head loss gradients in the main channel and the floodplain as physically observed (Proust et al. 2006).

6 CONCLUSIONS

The Independent Subsection Method was developed for modelling non-uniform flows in prismatic or non-prismatic compound channels. The flow dynamics in the main channel and the floodplains are separated by writing a 1D momentum equation in each subsection. An additional equation ensures the mass conservation on the overall cross-section. The ISM solves thus a differential equations system that calculates both flow depth and subsection velocities simultaneously.

The ISM explicitly models lateral mass discharges and momentum transfer between the subsections due to both mass and turbulent exchanges. The closure equations defining the interface shear stress and interfacial velocity are based on a mixing length model in the horizontal plane and experimental observations, respectively.

ISM simulations are compared to experimental data in four flow configurations: non-uniform flows in straight compound channels, flows with abrupt floodplain contraction, with slightly narrowing floodplains, and with skewed floodplain boundaries. The ISM reproduces correctly both water surface and discharge distribution profiles whatever the strength of mass transfers. Results show that turbulent exchanges are predominant in the momentum transfer for non-uniform flows in prismatic geometry. Conversely, the momentum transfer is mainly controlled by mass exchanges in non-prismatic channels.

The ISM is also compared to three conventional 1D methods for the abrupt floodplain contraction case. The prediction of the flow depth and mean velocity in the floodplain is far more accurate with ISM than with the classical 1D methods. These results clearly show that: (1) the computation of backwater surface profile on the total cross-section is no more relevant when mass transfers are significant; (2) lateral mass discharge and momentum transfer have to be explicitly modelled by separating the flow equations in the subsections.

A coupled 1D to 2D model for flood plain simulation

Varvara Roubtsova, Georges Tchamen, Joseph Abdo & Rene Kahawita
Ecole Polytechnique de Montreal, Montreal, Canada

ABSTRACT: The computation of flood wave propagation is generally computed on the basis of either one-dimensional or two-dimensional models. The exclusive use of a one-dimensional model to simulate the phenomenon can lead to significant errors in mapping the flood plain contours whereas a fully two-dimensional model requires significant computer resources. The approach taken in this project is to use a one-dimensional model in areas where the river is confined laterally by its banks and couple it seamlessly to a simplified two-dimensional model in areas where the topography delineates a flood plain. The advection-diffusion equation is also implemented in the two-dimensional formulation so that the spread of a pollutant plume resulting from the flooding of a toxic source may be simulated. One advantage of the simplified two-dimensional scheme is that regions of wetting and drying are handled without any difficulty. The scheme has been tested on two cases with good results.

1 INTRODUCTION

The computation of flood wave propagation in a river containing flood plains is generally computed on the basis of either one-dimensional or two-dimensional models. The exclusive use of a one-dimensional model to simulate the phenomenon can lead to significant errors in the computation of flood wave propagation times, maximum water levels and discharge since an essentially two-dimensional system is being modeled as a one-dimensional system. To avoid these errors, some 1D models use 'off bank channel storage' terms to avoid participation of the flood plain in the main flow momentum equations. The other choice, which is formally 'correct', is of course to use a fully two-dimensional model; unfortunately this solution frequently requires significant computer resources especially if a flood of long duration and large-scale extent is being studied. Furthermore, a situation confronted quite frequently is a river that is confined to its banks for most of its trajectory but then opens onto a shallow flood plain in certain regions. Consequently, the approach taken in this project is to use a one-dimensional model in laterally confined areas of the river, and couple it seamlessly to a simplified two-dimensional model in areas where the topography delineates a flood plain. Recently, some similar approaches have been proposed [Paquier & Sigris (1997)], some commercial numerical models use a similar technique. The strategy used in the SOBEK model from Delft Hydraulics [Verwey (2001), Dhondia & Stelling (2002)] for example, is to use a one dimensional channel and completely integrate its mesh into the two dimensional mesh of the flood plain. These two meshes are coupled through the continuity equations which are discretized and solved using an implicit finite difference technique. The TUFLOW model strategy is similar to the one presented here in that the two dimensional mesh only covers the area of the flood plain, and not the one dimensional channel. However, the 2D mesh used in TUFLOW is of the finite difference type.

In the present paper, the complete St. Venant formulation is used in the one-dimensional component of the model, numerical solutions being obtained with a Riemann solver using a TVD (Total Variation Diminishing) algorithm. The two-dimensional component is based on a reduced set of the St. Venant equations, which requires that the Froude numbers on the flood plain are small. In fact the approximation made is that invoked for the diffusion analogy for flood wave propagation.

2 THEORETICAL DEVELOPMENT

2.1 *The 1-D approach*

The one-dimensional component is based on the TVD based KIMBULA model developed at Hydro-Quebec. For completeness a brief development of the model will be presented here.

The 1-D approach to the unsteady flow of water is governed by the St-Venant equations with additional

Copyright © 2006 Taylor & Francis Group plc, London, UK

inflows or outflows. Written in conservation law form they are:

$$\frac{\partial \mathbf{U}}{\partial t}+\frac{\partial \mathbf{F}(\mathbf{U})}{\partial x}=\mathbf{G},$$

$$\mathbf{U}=\begin{bmatrix}A\\Q\end{bmatrix},\quad \mathbf{F}(\mathbf{U})=\begin{bmatrix}Q\\\frac{Q^2}{A}+gI_1\end{bmatrix}$$

$$G=\begin{bmatrix}q\\gI_2+gA(S_0-S_f)\end{bmatrix}$$

where

$$S_f=\frac{Q^2n^2}{A^2R^{\frac{4}{3}}}$$

$$R=\frac{A}{P}$$

$$I_1=\int_0^h(h-\eta)b\,d\eta$$

$$I_2=\int_0^h(h-\eta)\frac{\partial b}{\partial x}\,d\eta$$

A is the area of the wetted cross- section;
Q is the discharge;
g is the gravitational acceleration;
S_0 is the local bed slope;
S_f is the local friction slope;
P is the wetted perimeter;
n is the Manning's roughness coefficient;
I_1 is the hydrostatic pressure force term;
I_2 is the pressure force term due to longitudinal width variation;
h is the water depth;
η is the integration variable indicating distance from the bed;
$b(x, \eta)$ is the river width at height η from the bed;
q is the unit bank flow discharge (positive or negative).

2.2 *The 2-D approach*

The development of the two dimensional component uses the reduced form of the full Saint-Venant Equation. (The diffusion equation approximation).

$$\frac{\partial H}{\partial t}+\frac{\partial}{\partial x}\left(k\cdot\frac{\partial H}{\partial x}\right)+\frac{\partial}{\partial y}\left(k\cdot\frac{\partial H}{\partial y}\right)=0 \qquad (1)$$

Here H is the water surface elevation and k the 'diffusion coefficient' is defined in equation (7). Equation (1) is valid when the magnitude of the inertial terms in the momentum equations is negligible. In this case, the momentum equations reduce to:

$$\frac{\partial H}{\partial x}=-S_{fx} \qquad (2)$$

$$\frac{\partial H}{\partial y}=-S_{fy} \qquad (3)$$

with

$$S_{fx}=\frac{N^2\cdot\sqrt{u^2+v^2}}{h^{4/3}}\cdot u \qquad (4a)$$

$$S_{fy}=\frac{N^2\cdot\sqrt{u^2+v^2}}{h^{4/3}}\cdot v \qquad (4b)$$

It is possible to verify the following identity:

$$\left(\frac{\partial H}{\partial x}\right)^2+\left(\frac{\partial H}{\partial y}\right)^2=\frac{N^4}{h^{8/3}}\cdot\left(u^2+v^2\right)^2 \qquad (5)$$

and the relations:

$$uh=-\left(\frac{h^{\frac{7}{3}}}{N^2\cdot\sqrt{u^2+v^2}}\right)\cdot\frac{\partial H}{\partial x}=k\cdot\frac{\partial H}{\partial x} \qquad (6a)$$

$$vh=-\left(\frac{h^{\frac{7}{3}}}{N^2\cdot\sqrt{u^2+v^2}}\right)\cdot\frac{\partial H}{\partial y}=k\cdot\frac{\partial H}{\partial y} \qquad (6b)$$

where

$$k=-\frac{h^{\frac{7}{3}}}{N^2\cdot\sqrt{u^2+v^2}}=-\frac{h^{\frac{5}{3}}}{N\cdot\varphi(\nabla H)} \qquad (7)$$

If $\varphi(\nabla H)$ is defined with the help of identity (5):

$$\varphi(\nabla H)=\left[\left(\frac{\partial H}{\partial x}\right)^2+\left(\frac{\partial H}{\partial y}\right)^2\right]^{\frac{1}{4}} \qquad (8)$$

Consequently, it appears that (1) is simply the continuity equation

$$\frac{\partial H}{\partial t}+\frac{\partial uh}{\partial x}+\frac{\partial vh}{\partial y}=0 \qquad (9)$$

combined with (6a) and (6b).

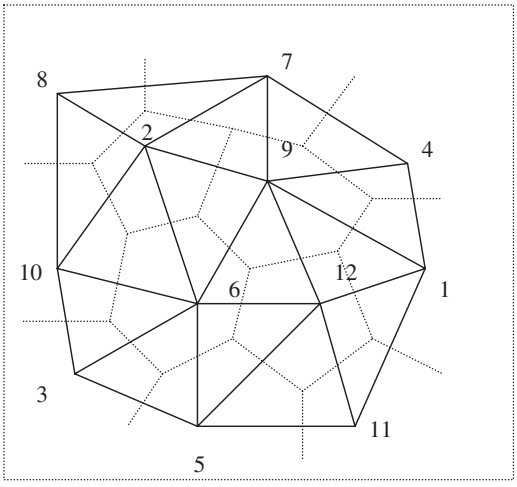

Figure 1. The 2-D area.

Referring to Figure (1), which depicts adjacent computational cells in two space dimensions, the velocity at the interface between a cell and its surrounding neighbors may be computed from the Manning relation. The water surface elevation and depth are defined at the center of the cell while the velocities are defined at the interface between two cells. The cells are fixed and may be dry or wet. Clearly, a horizontal water surface will generate zero velocities and thus result in a zero exchange of volume between cells as expected. Using a simple time-stepping scheme, at each time step Δt, the volume of water exchanged between the cells is computed and their water surface elevations adjusted in consequence using volume conservation. For purposes of computation, each cell is treated as a control volume having constant depth and constant water surface elevation. In order to treat the possibility of a pollutant source (example: a warehouse storing toxic chemicals) being flooded and releasing a pollutant plume, an implementation of the two-dimensional advection-diffusion equation has also been incorporated in the formulation and has been illustrated by an example.

3 1 TO 2D IMPLEMENTATION

Coupling between the 1D and 2D models is achieved by means of mass transfer between the two models. The momentum transfer is driven by difference in water surface elevations.

Before this can be accomplished, it is necessary to develop the mesh over the computational domain:

- A series of one dimensional geometrical cross sections that cover the main channel is established;

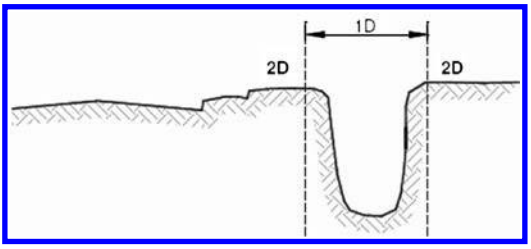

Figure 2. 1D/2D linkage at the cross section level.

- For each 1D cross section, the threshold level above which water flow into the flood plain is established (see figure 2);
- A 2D triangular mesh is generated to cover the flood plain.

An equation of the type (6a & 6b) is used to compute the mass transfer between the channel and the flood plain at the boundaries between the two domains.

4 TESTS

Validation Test for the Two-dimensional Component:

A test computation was performed in a rectangular channel of width 100 m, length 100 m with a constant slope of 0.0005. The Manning's coefficient was set to 0.033. Downstream water surface elevation was 3 m and the upstream discharge 100 m^3/s. Initially the computational domain is dry. The analytical solution is [*Goutal & Rissoan 2000*]:

$$\frac{\partial h}{\partial x} = \frac{S_0 - \dfrac{q^2}{\left(\dfrac{1}{n}\right)^2 h^{10/3}}}{1 - \dfrac{q^2}{gh^3}} \qquad (10)$$

where

S_0 is the slope,

n is the Manning's coefficient,

q is the unit lateral discharge as defined previously,

Equation (10) was integrated numerically using the Runge-Kutta formula.

Comparison with the numerical solution is shown in Figure (3)

In order to demonstrate an application of the model to a real world case, the simulation of a flood in the Eastmain river valley in Quebec, Canada was undertaken. The upstream boundary condition imposed on the 1D component was the inflow hydrograph shown in Figure (4). A constant water surface elevation of 1.5 m was imposed at the downstream border. Initial conditions were simply a constant discharge for the 1D component while the 2D computational area was dry.

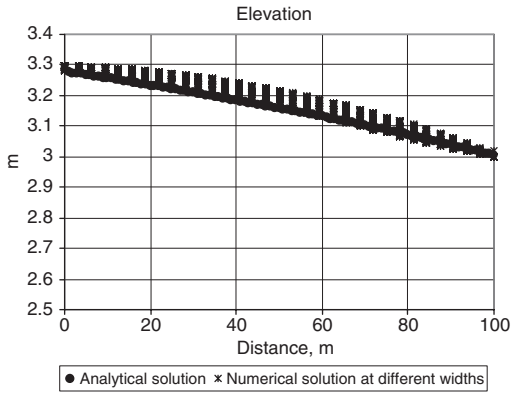

Figure 3. Longitudinal variation of water surface elevation.

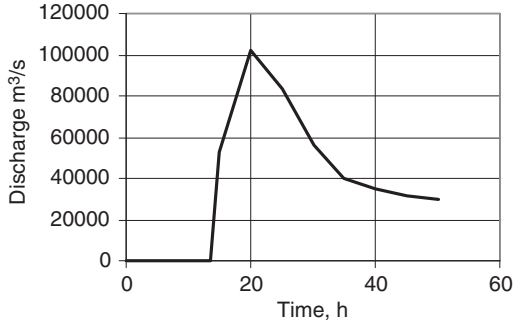

Figure 4. The upstream hydrograph.

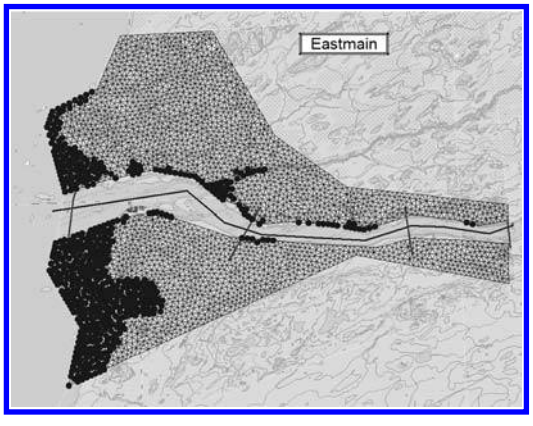

Figure 5. The inundation limits.

Figure (5) indicates the extent of flooding (dark areas) and closely follows the topographic input.

The model was used on a further test case, a region in Quebec where the EDF (Eléctricité de France) TELEMAC two-dimensional model had been used.

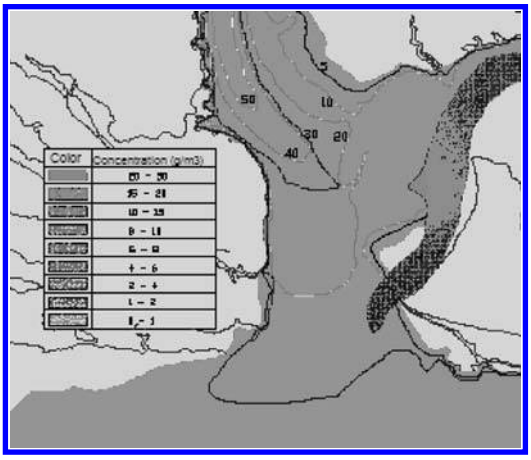

Figure 6. Flood contour lines at 1.5 h.

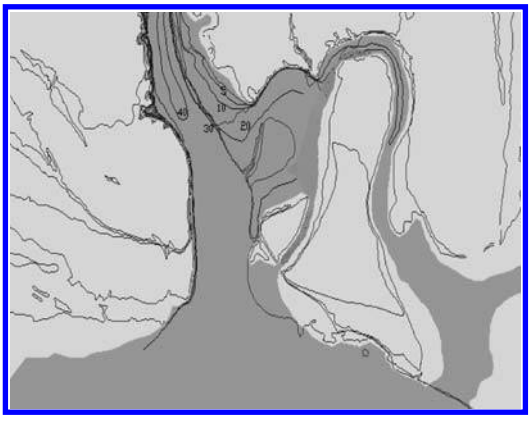

Figure 7. Flood contour lines at 4 h.

The TELEMAC model uses a finite element formulation on a triangular mesh and integrates the full St. Venant shallow water wave equations with no approximations being made. In this case study, the limits of flooding in a large urban area due to a dambreak far upstream was investigated. The present model was implemented a small distance upstream of the urban area where the inertial effects may have been attenuated since the site of the dam failure was over a hundred kilometers upstream. Boundary conditions for the one-dimensional component were obtained from the results of the TELEMAC model. (However, it must be re-iterated that the model is not intended to simulate the surge wave propagation following a dambreak) To assess the pollutant dispersion component of the model a fictitious source of pollution was introduced. Figures (6) to (8) indicate the extent and limit of flooding at 1.5, 4 and 5.5 hours after the arrival of the flood wave

Copyright © 2006 Taylor & Francis Group plc, London, UK

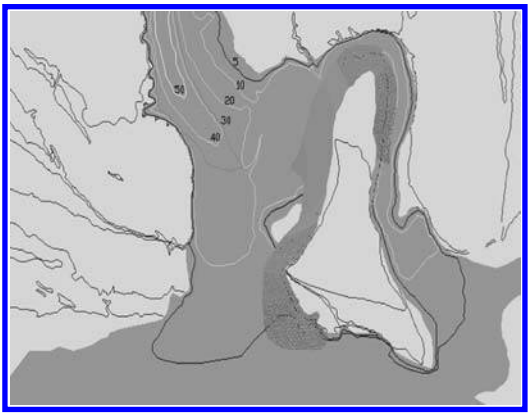

Figure 8. Flood contour lines at 5.5 h.

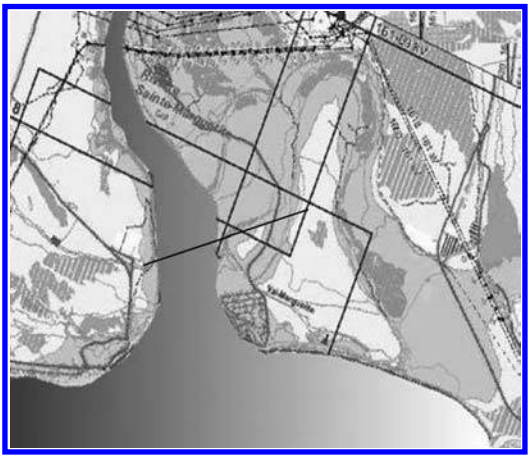

Figure 9. Flood contour lines at 5.5 h Results with TELEMAC model.

(grey areas). The dispersion and spreading of the pollutant plume especially in figure 6 (dark areas) is also clearly seen. Figure 8 when compared to Figure (9) (TELEMAC Results) show excellent agreement on the areas flooded. Computational time for the present model was extremely low.

5 CONCLUDING REMARKS

The model is quite robust and provides good results. It is expected that attempts to model higher velocity flows will result in degradation in quality of the results For flows with low local Froude Numbers good results may be expected.

1D complex modelling with lateral exchanges coupling two reaches

N. Goutal, C. Cheviet & G. Duvivier
Electricité de France R&D, Chatou, France

ABSTRACT: This paper presents a 1D complex modelling with lateral exchanges coupling two reaches. This study has been performed in the general context of re-assessment of the design values for all French nuclear power plants in case of extreme flood (probability less than 10^{-3}). The main features of the 1D hydrodynamic system Mascaret developed by EDF R&D and used for this study are presented. Then the developments performed to take into account the linking by the lateral exchanges are explained. In the last part of this paper, we present the main results of this study.

1 INTRODUCTION

On the 27th of December, 1999, a severe storm occurred in France and generated a lot of damages (buildings, forests…). It passed very close to a Nuclear Power Plant (NPP) located along the estuary of La Gironde (South West of France). The extreme storm surge and waves due to the storm led to a partial flooding of the NPP, without any impact on safety.

This event was extreme enough to lead EDF (Electricité de France, French utility) to review the methodology of protection against floods and re-assess the design values for all the French NPP (19 in all). 1D and 2D numerical hydraulic models have thus been built.

We will deal here with the complex hydraulic study done for a French plant situated near a regulated river, combining 1D and 2D simulations. We will focus mainly on the 1D part of the study, which necessitated specific developments.

1D hydrodynamic simulations were performed with the software Mascaret developed by EDF R&D – LNHE (National Laboratory of Hydraulics and Environment). After a general description of the software and its main features, we will present a general description of the study and the frame of the study. The fourth chapter will focus on the developments performed to deal properly for this study, on the presentation of the results and leads to the conclusion and the prospects.

2 SOFTWARE MASCARET

The Mascaret system is a one dimensional hydraulic simulation tool solving the shallow water equations, developed by EDF R&D. Three modules are available: a module for steady subcritical flows, a module for unsteady subcritical flows and a module for unsteady sub- and supercritical flows. In this paper, we focus on the features of the third module.

2.1 *Resolution of the shallow water equations*

The shallow water equations can be written as follows:

$$\begin{aligned} &\frac{\partial A}{\partial t}+\frac{\partial Q}{\partial x}=Q_a; \\ &\frac{\partial Q}{\partial t}+\frac{\partial}{\partial x}\left(\beta\frac{Q^2}{A}\right)+gA\frac{\partial y}{\partial x}+S_f=0 \end{aligned} \qquad (1)$$

where $A(y,t)$ = cross-sectional area (m^2); Q_a = lateral discharge; g = gravitational acceleration (m/s^2); $y(x,t)$ = water surface elevation (m); $Q(x,t)$ = discharge (m^3/s); x = longitudinal axis (m); t = time (s); $S_{f=}$ friction slope, expressing the resistance opposed by the river bed to the flow (m^3/s^2); and β = adimensional coefficient expressing the variation of the velocity in the section. This coefficient is taken into account in case of compound channel, i.e. when floodplains are treated as effective flow areas containing water that is actively being conveyed. We have:

$$\beta=\frac{A}{Q^2}\int u^2 dA \qquad (2)$$

Shallow water equations are solved using an explicit finite volume scheme: the Roe scheme. Details on the numerical scheme and the numerical treatment of source terms can be found in (Goutal & Maurel, 2002). We can notice that the time discretisation of the

Copyright © 2006 Taylor & Francis Group plc, London, UK

flux terms and of the source terms are explicit. So, the time step has to respect the following condition called Courant-Friedrich-Levy (CFL) condition.

$$\max\left(\frac{|u+c|\Delta t}{\Delta x}\right) < 1 \quad (3)$$

where u = water velocity (m/s); c = wave celerity (m/s); Δt = time step (s) and Δx = space step (m).

2.2 *Main features*

The module used offers a large range of modelling possibilities like:

- propagation of dam break waves over a dry bed
- modelling of branched or looped networks
- 2D modelling of the confluence
- modelling of compound channel and progressive integration of the floodplains in the active flow area when embankments are overtopped
- modelling of singularities in the geometry when the stage/discharge relationship is unknown
- modelling of storage basins to take into account ineffective flow areas.

Some of these features will be useful for our study. They are detailed just below.

2.3 *2D modelling of confluences*

The confluence between reaches is modelled by a 2D automatically built grid (see Figure 1), made of 4n cells (where n is the number of reaches joining together) leaning on the last cross section of each reach. In the 2D grid, the shallow water equations are solved using the same explicit volume scheme as for the 1D solution.

More details about this modelling and the coupling between 2D and 1D grids are available in the reference manual (Goutal & Maurel, 1996a) (Goutal & Maurel, 1996b).

2.4 *Weirs in the geometry*

With the software Mascaret, it is possible to model a weir directly in the geometry, i.e. to describe the geometry of the weir by the evolution of the bed level. This feature is very useful when the stage/discharge relationship is unknown. However, to obtain good results it is necessary to have a very fine grid around the weir.

2.5 *Storage basins*

Ineffective flow areas can be treated as interconnected storage basins, for each of which the relation between storage volume and water surface elevation is known or assumed. The flow calculation between the basins is based on continuity of volume for each basin and

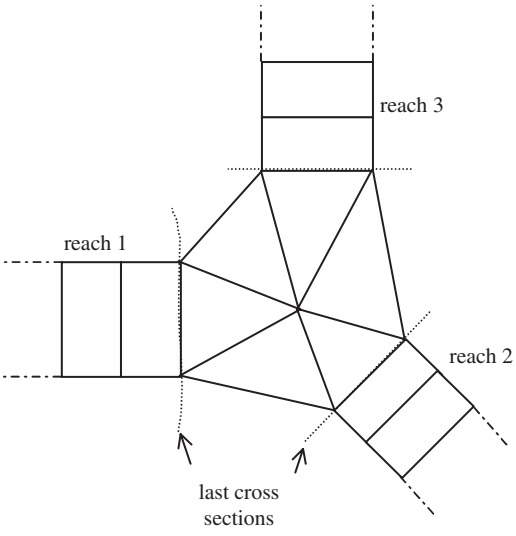

Figure 1. 2D modelling of a confluence.

non-inertial flow laws between basins. Continuity of volume V_j in a floodplain basin j is expressed as:

$$\frac{\partial V_j}{\partial t} = \sum_{i=1}^{n} Q_{ij} \quad (4)$$

where $V_j = V_j(y_j, t)$ volume of water in basin j (m^3); $Q_{ij}(t)$ = discharge from basin i to basin j or from river's cross section i to basin j (m^3/s); n = number of connections leading to basin j; t = time (s).

Discharge Q_{ij} is function of water levels in two adjacent basins or in the river and the basin j. These functions represent basic hydraulic features such as: weirs, sills, siphons, short channels.

For more details about this modelling see the reference manual (Rissoan, 2002).

The following features have been used : complex network with a 2D modelling of the confluence, interaction with lateral storage basins through specific hydraulic links, compound beds.

3 STUDY PRESENTATION

3.1 *Presentation*

The study that we will present here has been undertaken in order to assess the flooding risk for a French nuclear power plant situated near a regulated river.

From East to West, we can note (see conceptual scheme on Figure 2):

- The main river, flowing from South to North, bypassed by a channel. A dam is located at the upstream end, just after the beginning of the regulated channel,

Copyright © 2006 Taylor & Francis Group plc, London, UK

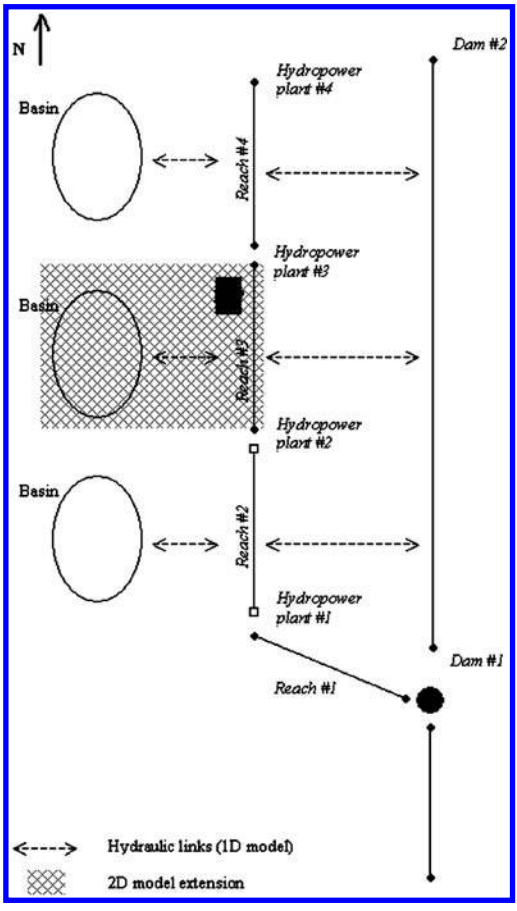

Figure 2. Conceptual scheme.

– A part of floodplain, which is in fact an island,
– The regulated channel, with four hydropower plants delimiting four reaches. At the downstream end, the flow coming from the channel comes back to the river,
– A plain (West end of the model), where the NPP is located (close to the 3rd hydropower plant).

A cross-sectional graph (Figure 3) shows the main topographical features of the study.

In case of flood, the flow is evacuated through the main river because the discharge in the regulated channel is limited. If the flood is not extreme, there is no overflowing of the main river and consequently no links between the regulated reaches and the main river. In this case, the 1D software Mascaret is used with its "standard" release. The model has been calibrated with such a flow.

In case of extreme flood (probability $< 10^{-3}$), the river and the channel are connected through lateral exchanges due to the main river overflowing (it has never been observed in reality). Lateral hydraulic exchanges between the two branches, above the floodplain, are taken into account through specific links (see the next paragraph), whereas the western flood plain is roughly modeled with 3 storage basins linked to the regulated reach. In a second step, in order to obtain the water elevation near the NPP, a 2D code (TELEMAC (Hervouet, 2003)) has been used to model the plain (water potentially flowing towards the NPP). The flow input in the 2D model comes from the flow rate overtopping the dykes on the left bank of the channel (flow rates are recovered from the 1D model using schematic basins in place of the western plain).

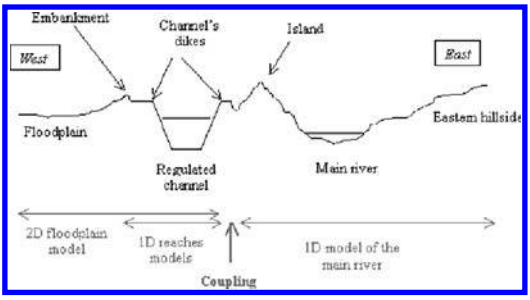

Figure 3. Topographical cross-section.

4 DEVELOPMENTS FOR THIS STUDY AND RESULTS

In order to enable the coupling of the main river with the 3 regulated reaches involved (#2 to #4, see conceptual scheme on Figure 2), new developments have been performed which allow the water transfer between the 3 regulated reaches and the main river. The lateral water transfers are taken into account in the continuity equations written for each reach and for the main river.

4.1 *Water transfer between the main river and the 3 reaches*

As explained previously, the main river is separated from the 3 reaches by an island which is like a "natural" dike with a varying crest elevation. In case of flood, this dike is not submerged. But in case of extreme flood, this dike can be overtopped and consequently, there is a lateral transfer flow between the main river and the 3 reaches (see the hydraulic exchanges schematically drawn on Figure 4).

The water can flow from the main river to the 3 reaches and the discharge in the reaches 2, 3 and 4 influences the water level downstream the reach 4. With such an extreme discharge, a water transfer becomes possible between the regulated reaches and the main river (such extreme conditions have never been observed in reality since the channels' building).

Copyright © 2006 Taylor & Francis Group plc, London, UK

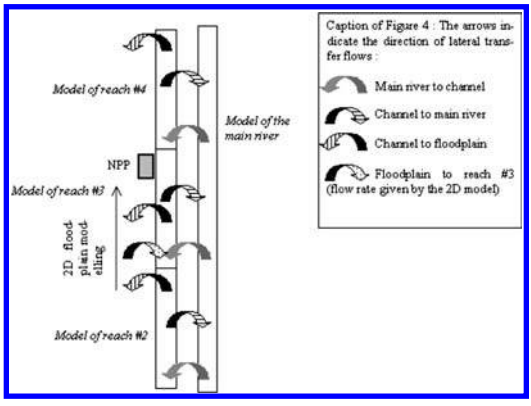

Figure 4. Hydraulic exchanges inside the 1D model.

So, there is a feedback on the main river water level. The different reaches and the main river are coupled through these water transfers.

The other kind of flow transfer is observed from the reaches 2, 3 and 4 to the flood plain situated on the West of the regulated reaches (Fig. 4). This case is easier to deal with because the water level in the flood plain has no influence on the hydraulic state in the 3 reaches.

Now, we are going to write the 1D shallow water equations for the different reaches and the main river and the coupling terms which model the water transfer. These terms will be taken into account only in the continuity equations. The influence on the momentum equations is neglected.

4.2 *Shallow water equations in the main river*

$$\begin{aligned} &\frac{\partial A_{mr}}{\partial t}+\frac{\partial Q_{mr}}{\partial x}=Q_{output}(A_{mr},x)+Q_{input}(A_{reach},x) \\ &\frac{\partial Q_{mr}}{\partial t}+\frac{\partial}{\partial x}\left(\beta\frac{Q_{mr}^{\ 2}}{A_{mr}}\right)+gA_{mr}\frac{\partial y_{mr}}{\partial x}+S_f=0 \end{aligned} \quad (5)$$

where A_{mr} = hydraulic section of the main river (m^2); Q_{mr} = total discharge in the main river (m^3/s); Q_{output} = output lateral discharge due to the overflow (m^3/s) (note that it depends on the water level in the main river); and Q_{input} = lateral discharge due to the flow transfer from the reach 2, 3 and 4 to the main river (m^3/s) (note that it depends on the water level in the regulated reaches).

4.3 *Shallow water equations in the different reaches*

$$\begin{aligned} &\frac{\partial A_{ri}}{\partial t}+\frac{\partial Q_{ri}}{\partial x}=Q_{input}(A_{mr},x)+Q_{output}(A_{ri},x) \\ &\frac{\partial Q_{ri}}{\partial t}+\frac{\partial}{\partial x}\left(\beta\frac{Q_{ri}^{\ 2}}{A_{ri}}\right)+gA_{ri}\frac{\partial y}{\partial x}+S_f=0 \end{aligned} \quad (6)$$

where A_{ri} = hydraulic section of the reach i (m^2); Q_{ri} = total discharge in the reach i (m^3/s); Q_{input} = input lateral discharge due to the overflow (m^3/s) (note that it depends on the water level in the main river); and Q_{output} = lateral discharge due the flow transfer from the reaches 2, 3 and 4 to the main river (m^3/s).

The coupling between the shallow water equations written in the different reaches and in the main river is performed through the source terms (lateral discharge) and this coupling is a strong one due to the feedback of the output-input discharge of the reaches on the hydraulic state of the main river and vice-versa.

This coupling through the source terms has been implemented in the finite volume scheme used to solve the 1D shallow water equations with source terms in the continuity equation.

4.4 *Discretised shallow-water equations in the main river and in the regulated reaches*

Thanks to a finite volume formulation with explicit time discretisation, the shallow water equations can be written as follows (see § 4.5 and 4.6).

We assume that:

- the domain computation is discretised with N finite cells C_i
- the time interval [0,T] is discretised in n sub intervals $[t_n,t_{n+1}]$.

(a) Discretised shallow-water equations in the main river:

For each cell C_i, $i = 1,N$

$$\frac{W_{mr,i}^{n+1}}{\Delta t}=\frac{W_{mr,i}^{n}}{\Delta t}+F_{mr,i+1/2}^{n}-F_{mr,i-1/2}^{n}+TS_i^n+TS_{mr}(W_{mr},W_j)$$

where $(W_{mr})=(A_{mr},Q_{mr})$; F = numerical flux at the interface between two cells; TS = source terms; and TS_{mr} = source terms due to the coupling between the main river and the regulated reaches.

(b) Discretised shallow-water equations in the different reaches

For each cell C_i, $i = 1,N$ and each reach j:

$$\frac{W_{j,i}^{n+1}}{\Delta t}=\frac{W_{j,i}^{n}}{\Delta t}+F_{j,i+1/2}^{n}-F_{j,i-1/2}^{n}+TS_i^n+TS_j(W_{mr},W_j)$$

where $(W_j)=(A_j,Q_j)$; F = flux at the interface between two cells; TS = source terms; TS_j = source terms due to the coupling between the main river and the regulated reaches.

For more details on the finite volume scheme and the discretisation of the source terms, the reader can report to the reference (Goutal & Maurel, 1996a). In this case, we will focus only on the numerical coupling

Copyright © 2006 Taylor & Francis Group plc, London, UK

of the two hydraulic systems by the source terms in the continuity equation.

To deal with this coupling, we have different possibilities:

– to use an implicit discretisation of the source terms. So in this case, we have to solve the global system: the global state is composed with the hydraulic states in the main river and in the different reaches. It will be necessary to re-write an important part of the software.
– to use an explicit time discretisation of the source terms as it is done for the "classical" source terms and the flux terms in the Mascaret software. Consequently, the two hydraulic systems are no more numerically coupled. But, the main drawback of this method is linked to the choice of the time step which must not be too large in order to obtain the stability of the numerical scheme

We retained the second solution for the main following reasons: the explicit time discretisation is in good agreement with the original finite volume numerical scheme of the software Mascaret; so the coupling source terms are discretised in the same way as the classical source terms in the continuity equation. As we have to respect the CFL condition due to the explicit discretisation of the flux terms and of the source terms, the coupling through the source terms is not a supplementary constraint on the time step for this study where the source terms due to the lateral exchanges are not too stiff.

In the case of implicit scheme for the shallow-water equations, the time step will be larger and we will have to iterate in order to obtain the convergence of the uncoupled system.

4.5 *Results*

These specific developments allowed us to simulate the extreme hydraulic behaviour corresponding to the design conditions.

An example of the results is shown on Figure 5: the maximum surface level along reach #3 corresponds to the sloping line, whereas the right bank elevation is bold-plotted (geometrical shape) and the maximum island elevation is the thin line rapidly varying. We can see on this figure some zones where the maximum surface level exceeds the island elevation : lateral transfers from the main river to the regulated reach occur in these places (the main ones are located by horizontal segments).

Another kind of result that can be given is the hydrograph of overflows, from the main river to reach #3 for example on Figure 6. This hydrograph represents the water quantities passing in transit through the coupling terms specifically written for this study.

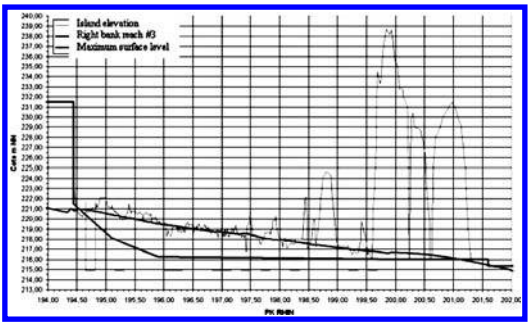

Figure 5. Maximum surface level for an extreme flood along the reach #3.

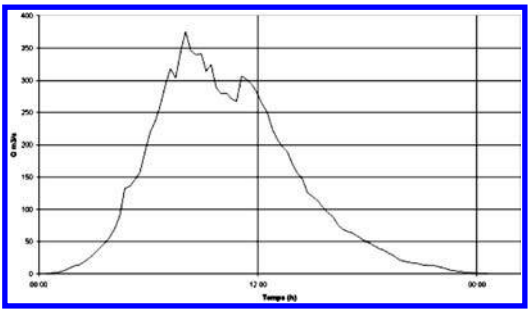

Figure 6. Hydrograph of overflow from the main river to reach #3.

4.6 *2D model implementation*

A two-dimensional model, based on TELEMAC-2D hydro-informatic software (Hervouet, 2003), has been built in order to represent the flow path in the western floodplain, towards the power plant.

The extension of this model can be seen on Figure 2 and on Figure 3 (on the left of the cross section).

The 1D and 2D models were not numerically coupled, but simply connected by giving the 1D results as a boundary condition for the 2D model.

Thus, the flow input in the 2D model comes from the flow rate overtopping the dykes on the left bank of the channel (flow rates are recovered from the 1D model using schematic basins in place of the western plain).

5 CONCLUSION AND PROSPECTIVES

The developments implemented in the 1D Mascaret hydro-informatic software and presented in this article enabled us to simulate complex extreme flows with lateral exchanges between a regulated channel and the main river.

Copyright © 2006 Taylor & Francis Group plc, London, UK

This complex case study raises the need of linking different models (1D-1D as well as 1D-2D) and consequently the necessity for a more general frame for models' interoperability.

The next step will be the development of the 1D model as a linkable model in order to improve the possibility of data exchange between different 1D-1D models and 1D-2D models and to make easier the coupling between different models.

A marching in space and time solver for the complete 2D shallow water equations: Application to real test cases

C. Aricò, C. Nasello & T. Tucciarelli
Dipartimento di Ingegneria Idraulica ed Applicazioni Ambientali, Università di Palermo, Palermo, Italy

ABSTRACT: A novel methodology for the solution of the 2D shallow water equations is proposed and applied to both synthetic and experimental tests. The algorithm is based on a fractional step decomposition of the original system in a convective and in a diffusive component. In the case of existing scalar potential of the velocity field, the convective component is solved using a Marching in Space and Time (MAST) procedure, that solves a sequence of small systems of ODEs, one for each computational cell, according to the decreasing value of the scalar potential. If inertial terms are not neglected in the momentum equations and the exact potential does not exist, it is shown that a second MAST procedure has to be applied, to solve again the ODEs according to the increasing value of a new function, called approximated potential. For this last case, results of numerical tests are compared with: 1) results of a classical ideal dam-break case proposed in literature and 2) lab data of a dam-break experiment carried out by Fraccarollo and Toro (1995).

1 INTRODUCTION

Saint Venant (SV) equations (or shallow water equations) are usually applied and numerically solved for the simulation of unsteady shallow water flows (Saint Venant, 1871). Both explicit and implicit numerical methods can be used for the solution. Even though implicit schemes are stable for CFL numbers greater than 1, they lead to the solution of large non linear algebraic systems, and the computational effort grows very quickly along with the number of elements. Implicit Preissman schemes show also other limitations, especially for simulations of transcritical flows (Meselhe et al., 1997).

For these reasons, during the last years, Authors have proposed explicit schemes. Several Finite Volume Godunov methods have been proposed for the 'non viscous' form of the SV equations, where source term in the momentum equation is zero (Alcrudo and Garcìa-Navarro, 1993; Mingham and Causon, 1998).

A fractional time step procedure (Toro, 1997) can be applied for the solution of the shallow water equations when source terms cannot be neglected. The corresponding non homogeneous form of the governing equations is solved in two sequential steps. During the first step, the homogeneous problem (without the source term) is solved. In the second step a set of ordinary differential equations including source terms are solved sequentially, one after the other. A similar approach is simple, but often produces bad solutions, especially in stationary cases (LeVeque, 1998).

In the last decade many Authors have developed Godunov-type schemes for the solution of balance laws, including source terms. The main focus of these schemes is the balance between the numerical flux and the source term, when the same numerical discretization is applied. Bermudez and Vazquez-Cendon (1994), using a "Q" scheme with 1st spatial approximation order and upwind discretization of both flux and source terms, introduced the notion of exact conservative property in order to preserve quiescent state. Hubbard and Garcìa-Navarro (2000) extended this approach the a 2nd order MUSCL scheme with flux limiter. Upwinding the source term is computationally expensive, because source term has to be projected on a basis of eigenvectors. LeVeque (1998) introduced a Riemann problem inside the cell for balancing the source term and the flux gradient; the method preserves steady and quasi-steady flow conditions. Vukovic and Sopta (2002) and Zic et al. (2004) developed one of the first version of higher order schemes (ENO and WENO), where numerical flux terms balance the source terms.

The main limitation of these numerical methods proposed for balance laws is that they have been developed for specific forms of the source terms and miss generality.

Copyright © 2006 Taylor & Francis Group plc, London, UK

In the present paper a new numerical scheme is proposed for the solution of the SV equations. The governing equation system is initially split in a convective component and in a diffusive component.

The convective system is solved applying a MArching in Space and Time (MAST) procedure, where the convective fluxes are solved using an Eulerian approach and the computational cells are required to be ordered and solved according to a decreasing scalar potential value. MAST procedure has been recently applied for the solution of the pure convective transport problem (Bascià and Tucciarelli, 2004; Aricò and Tucciarelli, 2006), the 1D and 2D shallow water problem with irrotational flow field (Tucciarelli and Termini, 2000; Noto and Tucciarelli, 2001) and the 1D shallow water problem with a mono-oriented flow (Tucciarelli, 2003).

The correction step computes the diffusive corrective fluxes by means of the solution of a linear system, that has the order of the cell number, but is sparse, symmetric and well conditioned.

The potential is defined as a scalar whose gradient is opposite to the flux direction. Because the flow field computed solving the SV equations has not a scalar potential, an approximated potential has to be used, along with a second correction step that is aimed to compute the rotational fluxes. This approximated potential is defined according to the flow direction inside each element at the beginning of the time step.

2 THE SV EQUATIONS

2D SV equations can be written as:

$$\frac{\partial h}{\partial t}+\frac{\partial p}{\partial x}+\frac{\partial q}{\partial y}=0 \tag{1}$$

$$\frac{\partial q}{\partial t}+\frac{\partial}{\partial x}\left(\frac{p^2}{h}\right)+\frac{\partial}{\partial y}\left(\frac{pq}{h}\right)+ +gh\frac{\partial h}{\partial x}+gh\left(\frac{\partial z}{\partial x}+\frac{n^2 p\sqrt{p^2+q^2}}{h^{10/3}}\right)=0 \tag{2}$$

$$\frac{\partial q}{\partial t}+\frac{\partial}{\partial y}\left(\frac{q^2}{h}\right)+\frac{\partial}{\partial x}\left(\frac{pq}{h}\right)+ +gh\frac{\partial h}{\partial y}+gh\left(\frac{\partial z}{\partial y}+\frac{n^2 q\sqrt{p^2+q^2}}{h^{10/3}}\right)=0 \tag{3}$$

where x and y are the spatial coordinates, t is the time, g is the gravitational acceleration, p and q are the x and y components of the flow per unit width in x and y directions, h is the water depth, z is the ground level and n is the Manning friction coefficient.

The unknowns in the system (1)–(3) are the water depth h and the two flow rates components p and q.

3 INTEGRAL FORM OF THE SV EQUATIONS

Integration in space of eqs. (1), (2) and (3), as well as application of the Green's theorem provides:

$$\frac{\partial h}{\partial t}\sigma_e+\sum_{j=1,3}F_{e,j}=0 \tag{4}$$

$$\frac{\partial p}{\partial t}\sigma_e+\sum_{j=1,3}M^x_{e,j}+R^x_e=0 \tag{5}$$

$$\frac{\partial q}{\partial t}\sigma_e+\sum_{j=1,3}M^y_{e,j}+R^y_e=0 \tag{6}$$

where σ_e is the element area and the source terms R^x_e, R^y_e are defined as:

$$R^x_e=\sigma_e gh\left(\frac{\delta H_e}{\delta x}+\frac{n^2 p_e\sqrt{p_e^2+q_e^2}}{h_e^{10/3}}\right) \tag{7}$$

$$R^y_e=\sigma_e gh\left(\frac{\delta H_e}{\delta y}+\frac{n^2 q_e\sqrt{p_e^2+q_e^2}}{h_e^{10/3}}\right) \tag{8}$$

where H_e is the element water level. Volume fluxes $F_{e,j}$ and moment fluxes $M^x_{e,j}, M^y_{e,j}$ are given respectively by:

$$\begin{aligned}&F_{e,j}=p_e\left(y^e_{jp}-y^e_j\right)-q_e\left(x^e_{jp}-x^e_j\right),\\ &M^x_{e,j}=F_{e,j}\frac{p_e}{h_e},\quad M^y_{e,j}=F_{e,j}\frac{q_e}{h_e}.\end{aligned} \tag{9}$$

where subindex jp indicates the node following node j in couterclockwise direction and $(x^e_{jp}-x^e_j)$ and $(y^e_{jp}-y^e_j)$ represent the projections in $x(y)$ direction of the element side connecting nodes j and jp.

4 FRACTIONAL STEP DECOMPOSITION

Assume that a scalar value ϕ^k_e, called approximated potential, is assigned at the beginning of each time step to each element of the domain. After integration in time, prediction step of system (4)–(9) is defined as:

$$\frac{h^{k+1/3}-h^k}{\Delta t}\sigma_e+\frac{1}{\Delta t}\sum_{j=1,3}\int_{\Delta t}F^p_{e,j}dt=0 \tag{10}$$

$$\frac{p^{k+1/3}-p^k}{\Delta t}\sigma_e+\frac{1}{\Delta t}\left(\sum_{j=1,3}\int_{\Delta t}M^{px}_{e,j}dt+\int_{\Delta t}R^{px}_e dt\right)=0 \tag{11}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

$$\frac{q^{k+1/3}-q^{k}}{\Delta t}\sigma_e+\frac{1}{\Delta t}\left(\sum_{j=1,3}\int_{\Delta t}M_{e,j}^{py}dt+\int_{\Delta t}R_e^{py}dt\right)=0 \tag{12}$$

where:

$$\begin{aligned}R_e^{px}&=\sigma_e gh\left(\frac{\delta H_e^k}{\delta x}+\frac{n^2 p_e\sqrt{p_e^2+q_e^2}}{h_e^{10/3}}\right)\\ R_e^{py}&=\sigma_e gh\left(\frac{\delta H_e^k}{\delta y}+\frac{n^2 q_e\sqrt{p_e^2+q_e^2}}{h_e^{10/3}}\right)\end{aligned} \tag{13}$$

and

$$\begin{aligned}&F_{e,j}^{p}=max\left(0,p_e\left(y_{jp}^e-y_j^e\right)-q_e\left(x_{jp}^e-x_j^e\right)\right),\\ &M_{e,j}^{px}=F_{e,j}^{p}\frac{p_e}{h_e},\quad M_{e,j}^{py}=F_{e,j}^{p}\frac{q_e}{h_e}\end{aligned} \tag{14}$$

if $\phi_e^k\geq\phi_{ep}^k$ and ep is the index of the element sharing the jth side of element e,

$$\begin{aligned}&F_{e,j}^{p}=min\left(0,p_{ep}\left(y_{jp}^e-y_j^e\right)-q_{ep}\left(x_{jp}^e-x_j^e\right)\right),\\ &M_{e,j}^{px}=F_{e,j}^{p}\frac{p_{ep}}{h_{ep}},\quad M_{e,j}^{py}=F_{e,j}^{p}\frac{q_{ep}}{h_{ep}}\end{aligned} \tag{15}$$

otherwise.

Correction prediction system is defined as:

$$\frac{h^{k+2/3}-h^{k+1/3}}{\Delta t}\sigma_e+\frac{1}{\Delta t}\sum_{j=1,3}\int_{\Delta t}F_{e,j}^{c}dt=0 \tag{16}$$

$$\frac{p^{k+2/3}-p^{k+1/3}}{\Delta t}\sigma_e+\frac{1}{\Delta t}\left(\sum_{j=1,3}\int_{\Delta t}M_{e,j}^{cx}dt\right)=0 \tag{17}$$

$$\frac{q^{k+2/3}-q^{k+1/3}}{\Delta t}\sigma_e+\frac{1}{\Delta t}\left(\sum_{j=1,3}\int_{\Delta t}M_{e,j}^{cy}dt\right)=0 \tag{18}$$

$$\begin{aligned}&F_{e,j}^{c}=\min\left(0,p_{ep}\left(y_{jp}^e-y_j^e\right)-q_{ep}\left(x_{jp}^e-x_j^e\right)\right),\\ &M_{e,j}^{cx}=F_{e,j}^{c}\frac{p_{ep}}{h_{ep}},\quad M_{e,j}^{py}=F_{e,j}^{c}\frac{q_{ep}}{h_{ep}}\\ &\text{if }\ \phi_e^k\geq\phi_{ep}^k,\end{aligned} \tag{19}$$

$$\begin{aligned}&F_{e,j}^{c}=\max\left(0,p_e\left(y_{jp}^e-y_j^e\right)-q_e\left(x_{jp}^e-x_j^e\right)\right),\\ &M_{e,j}^{cx}=F_{e,j}^{c}\frac{p_e}{h_e},\quad M_{e,j}^{cy}=F_{e,j}^{c}\frac{q_e}{h_e}\end{aligned} \tag{20}$$

otherwise.

Diffusive correction system is defined as:

$$\frac{h^{k+1}-h^{k+2/3}}{\Delta t}\sigma_e+\frac{1}{\Delta t}\sum_{j=1,3}\int_{\Delta t}F_{e,j}^{d}dt=\frac{1}{\Delta t}\sum_{j=1,3}\int_{\Delta t}F_{e,j}dt \tag{21}$$

$$\frac{p^{k+1}-p^{k+2/3}}{\Delta t}\sigma_e+\frac{1}{\Delta t}\int_{\Delta t}R_e^{dx}dt=\frac{1}{\Delta t}\int_{\Delta t}R_e^{px}dt \tag{22}$$

$$\frac{q^{k+1}-q^{k+2/3}}{\Delta t}\sigma_e+\frac{1}{\Delta t}\int_{\Delta t}R_e^{dy}dt=\frac{1}{\Delta t}\int_{\Delta t}R_e^{py}dt \tag{23}$$

where index d states that $F_{e,j}^{d}$, R_e^{dx}, R_e^{dy} are computed as $F_{e,j}$, R_e^{x}, R_e^{y} defined in eqs. (7), (8) and (9), but using the water heads and the flow rates of the final correction steps. Initial condition of the convective correction system are the final values of the prediction system and initial values of the diffusive correction system are the final values of the convective correction system. Spatial piezometric gradient $\partial H^k/\partial x$ is assumed constant (in time) in all the systems. Observe that summing all the terms of eqs. (10)–(23), eqs. (4)–(9) are found again. After simple manipulations, eigenvalue analysis provides that characteristic polynomial in both the prediction and the convection correction systems have only one root $\lambda_x=u_x$ and $\lambda_y=u_y$; this implies that both the systems represent simple convection and the characteristic surface, with vertex in a generic x, y, t point, degenerates into a line.

Characteristic polynomial of the diffusive correction system has real and opposite in sign eigenvalues $\lambda_x=\lambda_y=\pm\sqrt{gh}$. This implies that convective fluxes are missing and upwinding techniques are not required to solve the problem with standard finite volume techniques.

5 THE APPROXIMATED SCALAR POTENTIAL

Fractional step methodology provides accurate results only if the solution of the prediction step is close to the corrected one; otherwise, the computation of the spatial gradients at different time levels can strongly affect the solution. In our case, to minimize the variable change in the convective correction step, it is important to choose an approximated potential with a gradient flux opposite in sign, as much as possible, to the water flux along the element sides. If an exact potential exists and this condition is always attained, convective correction system vanishes and the following condition holds:

$$h_e^{k+2/3}=h_e^{k+1/3}\quad p_e^{k+2/3}=p_e^{k+1/3}\quad q_e^{k+2/3}=q_e^{k+1/3} \tag{24}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

In order to find a good approximated potential, define flux Fl_j^e trough the jth side of element e according to the following rule:

$$Fr_j^e = p_e\left(y_{jp}^e - y_j^e\right) - q_e\left(x_{jp}^e - x_j^e\right) \tag{25}$$

$$Fl_j^e = Fr_j^e \quad \text{if} \quad \left|Fr_j^e\right| \geq \left|Fr_{jm}^{em}\right| \tag{26}$$

$$Fl_j^e = -Fr_{jm}^{em} \quad \text{if} \quad \left|Fr_{jm}^{em}\right| > \left|Fr_j^e\right| \tag{27}$$

where em is the index of the element sharing with element e the side following the jth node in counterclockwise direction and jm is the index of the node of element em preceding the same side in the same direction. ϕ_e and ϕ_{em} indicate the potential values in cells e and em at the beginning of the time step.

An approximated potential can be found as the solution of the following Linear Programming (LP) problem:

$$\text{Min } CT = \sum_{e=1,N}\sum_{j=1,3}\left|Fl_j^e\right|\lambda_j^e \tag{28}$$

$$\text{s. t.} \begin{cases} \left(\phi_e - \phi_{em}\right)Sign\left(Fl_j^e\right) - 1 + \lambda_j^e \geq 0 \\ \lambda_j^e \geq 0 \end{cases} \tag{29}$$

where $Sign(Fl_j^e) = 1$ if $Fl_j^e \geq 0$ and $Sign(Fl_j^e) = -1$ if $Fl_j^e < 0$.

A fast solution can be obtained starting each search, at each time level, with the same basis of the previous optimal solution and initializing the auxiliary variables with:

$$\lambda_j^e = \max\left(0, 1 - \left(\phi_e - \phi_{em}\right)Sign\left(Fl_j^e\right)\right) \tag{30}$$

Even if the flow rates are consistent with the potential gradient at the beginning of the time step, they can change sign along the time step integration. For this reason, the solution of a new convective correction system is required also in the 1D cases, where an easy solution of problem (28)–(29) with zero optimal objective function can always be found.

5.1 *Solution of the prediction and the convective correction systems*

In both the prediction and the convective correction systems (10)–(15) and (16)–(20) unresolved integrals appear. Because both systems represents non linear convection, it is possible to change the integral equations in ordinary differential equations and find efficiently a fast solution using a variable step Runge-Kutta method with adaptive stepsize control (Press et al., 1988). For prediction, as example, the corresponding ODEs system is:

$$\frac{dh_e}{dt}\sigma_e + \sum_{j=1,3} F_{e,j}^p(t) = 0 \tag{31}$$

$$\frac{dp_e(t)}{dt}\sigma_e + \sum_{j=1,3}\left(M_{e,j}^{px}(t) + R_e^{px}(t)\right) = 0 \tag{32}$$

$$\frac{dq_e(t)}{dt}\sigma_e + \sum_{j=1,3}\left(M_{e,j}^{py}(t) + R_e^{py}(t)\right) = 0 \tag{33}$$

Terms $F_{e,j}^p$, $M_{e,j}^{px}$, $M_{e,j}^{py}$ can represent fluxes either leaving or entering the element.

Assuming a first order approximation of all the variables, we assume that the leaving fluxes are function of the element variables, and the entering ones are function of the variables in the neighbour element, as shown in eqs. (14), (15). This allows to solve sequentially the ODEs systems after ordering the elements according to a decreasing value of the approximated potential. In this case, in fact, the entering fluxes will be either given by the mean value leaving from neighbour elements with higher potential, or by the assigned boundary value, where:

$$F_{e,j}^p = BF_{e,j}, \quad M_{e,j}^{px} = BM_{e,j}^x, \quad M_{e,j}^{py} = BM_{e,j}^y \tag{34}$$

if j is the local index of a boundary side with entering flux ($BF_{e,j} \leq 0$). For the solution of the convective correction step the opposite order has to be followed, starting from the elements with lower and ending to the elements with higher potential. In this case boundary fluxes are assumed to be zero.

After the single system of element e is solved along the time step, the mean leaving fluxes have to be estimated. The mean volume flux through each side can be estimated by partitioning the total mean leaving flux, obtained from the mass balance in the element and equal to:

$$\frac{1}{\Delta t}\sum_{out}\int F_{e,out}^p dt = \frac{1}{\Delta t}\sum_{in}\int F_{e,in}^p dt - \frac{h_e^{k+1/3} - h_e^k}{\Delta t}\sigma^e \tag{35}$$

where subindex *in* and *out* indicate the incoming and leaving fluxes. Partition can be done adopting for the mean values the same ratio computed for the final ones. Due to non linearity of the source terms, the same methodology cannot be applied for the estimation of the mean values of the leaving momentum fluxes.

After integration, the mean $M_{e,j}^{px}, M_{e,j}^{py}$ values are given by:

$$\begin{aligned} &\frac{1}{\Delta t}\sum_{out}\int M_{e,out}^{ex} dt = \frac{1}{\Delta t}\sum_{in}\int M_{e,in}^{ex} dt + \\ &-\frac{p_e^{k+1/3} - p_e^k}{\Delta t}\sigma^e - \frac{1}{\Delta t}\int R_e^{px} dt \\ &\frac{1}{\Delta t}\sum_{out}\int M_{e,out}^{ey} dt = \frac{1}{\Delta t}\sum_{in}\int M_{e,in}^{ey} dt + \\ &-\frac{q_e^{k+1/3} - q_e^k}{\Delta t}\sigma^e - \frac{1}{\Delta t}\int R_e^{qy} dt \end{aligned} \tag{36}$$

where the mean values of the source terms have to be numerically estimated. Because the ODEs integration

Copyright © 2006 Taylor & Francis Group plc, London, UK

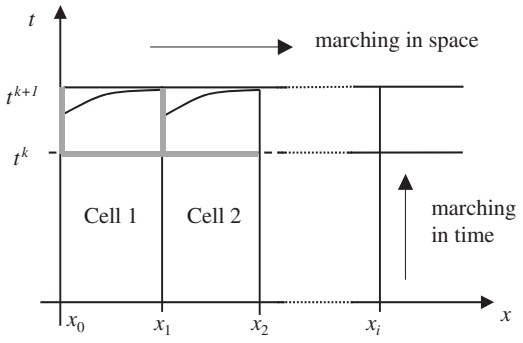

Figure 1. The core of the MAST procedure.

adopts a variable integration step, it is more convenient to assume for the source terms a third order polynomial interpolation, where the initial and final values are known along with the corresponding time derivatives. This computation is not due in the convective correction step, where the source terms are missing. Application of the mass balance can be easily proved to guarantee the local and global mass conservation. Observe that it is possible to solve sequentially the ODEs systems, without any restriction on the size of the time step, because the characteristic line of the convective problem is oriented according to the velocity direction. This is equivalent, after solution of cell 1 from time t^k to time t^{k+1}, to "translate" the boundary condition (thick segment in figure 1) at the interface between cell 1 and 2, to get the initial value of the characteristic curve carrying on the solution of cell 2 and so on through all the computational domain. Because of this, the method can be classified, other than "*marching in time*", also "*marching in space*".

5.2 *Computation of the gradients for the convective systems*

In each element *e*, water depth gradients are computed according to the bottom elevation gradient and to the element location with respect to the boundary. One of the following cases can be selected:

1. At least one side is part of the boundary and its volume flux is positive (leaving flux), or two sides are impervious. In the first case there is no need to compute the water depth gradient and in the second case this one is assumed opposite to the bottom elevation gradient.
2. There are not boundary sides. In this case convective gradient computation is split in two steps. In the first step second order gradient approximation is computed (see for example Mohamadian et al., 2005). If the node *jx* with maximum *y*-coordinate follows node *jn* with minimum *y*-coordinate in counterclockwise direction, it is:

$$\frac{\partial h}{\partial x} \approx \frac{(y_{jx} - y_{jn})h_{jn}}{2\sigma_e} + \frac{(y_{jx} - y_{jm})h_{jx} + (y_{jm} - y_{jn})h_{jm}}{2\sigma_e} \quad (37)$$

where h_n, h_x and h_m are the water depth at the elements next in counterclockwise direction to the nodes *jn*, *jx* and *jm*. In the other case, it is:

$$\frac{\partial h}{\partial x} \approx \frac{(y_{jx} - y_{jm})h_{jm} - (y_{jm} - y_{jn})h_{jn}}{2\sigma_e} + \frac{(y_{jx} - y_{jn})h_{jx}}{2\sigma_e} \quad (38)$$

Second order gradient component in the *y* direction can be computed in a similar way.

Once gradient direction is computed, its norm is estimated according to its first order downstream value, in order to avoid spurious oscillations. If ξ and η are respectively the coordinate along the gradient and its orthogonal left-handed directions, derivative along ξ is given by:

$$\frac{\partial h}{\partial \xi} = \frac{(\eta_{jx} - \eta_{jn})(h_{jn} - h_e)}{\sigma_e} \quad (39)$$

$$\frac{\partial h}{\partial \xi} = \frac{(y_{jx} - y_{jm})h_{jm} + (y_{jm} - y_{jn})h_{jn}}{\sigma_e} + \frac{(y_{jx} - y_{jn})h_e}{\sigma_e} \quad (40)$$

according to the maximum and minimum node coordinate in the η direction. Once the components along the ξ-η coordinate system are computed, they are mapped again in the original *x*-*y* system.

3. One side *j* is an impervious boundary. In this case, the boundary side is chosen as the water level gradient direction, oriented toward the triangle with larger water depth and the derivative along the side direction is given by:

$$\frac{\partial h}{\partial \xi} = \frac{A_e(h_e - h_f)}{\sigma_e} \quad (41)$$

where A_e is the height of element *e* with respect to its impervious side and h_f is the water depth of the triangle, close to element *e* and with smaller water level.

4. One side *j* is a boundary side with entering flux and the other two sides are internal. In this case the gradient direction is computed using a second order approximation along the direction of the boundary side and a first order approximation

Copyright © 2006 Taylor & Francis Group plc, London, UK

along the orthogonal one. Once again, after gradient direction is computed, its norm is estimated according to a first order scheme, applied to the derivative computed along the chosen direction.

5.3 *Boundary conditions for the prediction system*

Boundary terms of eqs. (31)–(33) at time level $k + 1/3$ depend on the flux sign and on the Froude number F_r of the velocity component orthogonal to the boundary side inside the element.

One of the following cases can be selected:

1. Flux through the boundary side is entering the domain. In this case the following equalities hold:

$$BF_{e,j} = bp_{e,j}\left(y^e_{jp} - y^e_j\right) - bq_{e,j}\left(x^e_{jp} - x^e_j\right),$$
$$BM^x_{e,j} = BF_{e,j}\frac{bp_{ej}}{h^k_e}, \quad M^{py}_{e,j} = BF_{e,j}\frac{bq_{ej}}{h^k_e} \qquad (42)$$
$$\text{if } F_r \le 1$$

$$BF_{e,j} = bp_{e,j}\left(y^e_{jp} - y^e_j\right) - bq_{e,j}\left(x^e_{jp} - x^e_j\right),$$
$$BM^x_{e,j} = BF_{e,j}\frac{bp_{e,j}}{bh_{e,j}}, M^y_{e,j} = BF_{e,j}\frac{bq_{e,j}}{bh_{e,j}} \qquad (43)$$

   if $F_r > 1$,

   where $bh_{e,j}$, $bp_{e,j}$ and $bq_{e,j}$ are the assigned boundary water depths and flow rate per unit width components;

2. Flux through the boundary side is leaving the domain. In this case water depth gradient is not known and prediction (or correction) system is replaced, for element e and in both the prediction and the convective correction system, with the hypothesis of neglecting the flow rate and momentum local changes in the same elements. This is equivalent to say that the leaving volume and momentum fluxes are equal to the entering ones. From the previous hypothesis, we obtain:

$$h^{k+1/3}_e = h^k_e, \quad p^{k+1/3}_e = \frac{MT^x_e}{FT_e}h^k_e, \quad q^{k+1/3}_e = \frac{MT^y_e}{FT_e}h^k_e \qquad (44)$$

$$FT_e = -\sum_{j=1,3} min\left(0, F^{k+1/3}_{em,jm}\right),$$
$$MT^x_e = -\sum_{j=1,3} min\left(0, F^{k+1/3}_{em,jm}\right)\frac{p^{k+1/3}_{em}}{h^{k+1/3}_{em}}$$
$$MT^y_e = -\sum_{j=1,3} min\left(0, F^{k+1/3}_{em,jm}\right)\frac{q^{k+1/3}_{em}}{h^{k+1/3}_{em}} \qquad (45)$$

   with the same meanings specified for eqs. (25)–(27).

5.4 *Solution of the diffusive system*

Diffusive system (21)–(23) is simplified by changing the integral mean values with the fully implicit time discretization and linearizing the source terms. This provides a diffusive effect, that goes to zero along with the size of the source terms and the diffusive fluxes. This size is proportional to the time step, as can be observed in eqs. (22) and (23). According to these hypothesis, the same momentum equations can be written in the form:

$$p^{k+1}\left(\frac{1}{\Delta t} + \frac{g\,n^2\left(\sqrt{p^2+q^2}\right)^{k+2/3}}{\left(h^{7/3}\right)^{k+2/3}}\right) + gh^{k+2/3}\frac{\partial h}{\partial x} =$$
$$gh^{k+2/3}\frac{\partial h^k}{\partial x} + \left(\frac{gn^2 p\sqrt{p^2+q^2}}{h^{7/3}}\right)^{k+2/3} + \frac{p^{k+2/3}}{\Delta t} \qquad (46)$$

$$q^{k+1}\left(\frac{1}{\Delta t} + \frac{g\,n^2\left(\sqrt{p^2+q^2}\right)^{k+2/3}}{\left(h^{7/3}\right)^{k+2/3}}\right) + gh^{k+2/3}\frac{\partial h}{\partial y} =$$
$$gh^{k+2/3}\frac{\partial h^k}{\partial y} + \left(\frac{gn^2 q\sqrt{p^2+q^2}}{h^{7/3}}\right)^{k+2/3} + \frac{q^{k+2/3}}{\Delta t} \qquad (47)$$

that is:

$$p^{k+1}_e = -elem_e\frac{\partial h^{k+1}_e}{\delta x} + cost^x_e + p^{k+2/3}_e,$$
$$q^{k+1}_e = -elem_e\frac{\partial h^{k+1}_e}{\delta y} + cost^y_e + q^{k+2/3}_e$$
$$elem_e = \frac{g\left(h^{10/3}_e\right)^{k+2/3}\Delta t}{\left(h^{7/3}_e\right)^{k+2/3} + \Delta t\,g\,n^2\left(\sqrt{p^2_e+q^2_e}\right)^{k+2/3}} \qquad (48)$$
$$cost^x_e = elem_e\frac{\partial h^k_e}{\partial x} \quad cost^y_e = elem_e\frac{\partial h^k_e}{\partial y}$$

where variables with index $k + 2/3$ are known from the solution of the convective correction system. Substituting eqs. (48) in eq. (21), the following equation is obtained:

$$\frac{h^{k+1}_e - h^{k+2/3}_e}{\Delta t}\sigma_e + \sum_{j=1,3}\delta^e_{j,jp}F^{k+1}_{e,j} = 0 \qquad (49)$$

where diffusive fluxes are discretized as:

$$F^{k+1}_{e,j} = -elem_e\frac{h^{k+1}_{ep} - h^{k+1}_e}{\sigma_e}L^2_{e,j} + \quad \text{if } F^k_{e,j} \ge 0 \qquad (50)$$
$$cost^x_e\left(y^e_{jp} - y^e_j\right) + cost^y_e\left(x^e_{jp} - x^e_j\right)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

$$F_{e,j}^{k+1} = -elem_{ep}\frac{h_{ep}^{k+1} - h_e^{k+1}}{\sigma_{ep}} L_{e,j}^2 + \cos t_{ep}^x \left(y_{jp}^e - y_j^e\right) + \cos t_{ep}^y \left(x_{jp}^e - x_j^e\right), \quad \text{if } F_{e,j}^k < 0 \quad (51)$$

$L_{e,j}$ is the length of the jth side of element e, $\delta_{j,jp}^e = 1$ if the jth and jpth nodes of element e are shared by the elements e and ep (internal nodes), $\delta_{j,jp}^e = 0$ if not (boundary nodes). After computation of the new water depths h_e^{k+1}, the flow rates per unit width can be computed with Eqs. (48) estimating the convective gradients $(\partial h_e^{k+1}/\partial x, \partial h_e^{k+1}/\partial y)$ as already explained in section 5.2.

5.5 *Boundary conditions of the diffusive system*

At the beginning of each time steps, elements with one boundary side j and positive (leaving) flux are selected. The Froude number $fr_{c,j}$ of the flux per unit length is computed as:

$$fr_{c,j} = \frac{p_e\left(y_{jp} - y_j\right) - q_e\left(x_{jp} - x_j\right)}{L_{e,j}\, h^{3/2}\sqrt{g}} \quad (52)$$

If $fr_{c,j} > 1$, zero diffusive flux is assigned, that is $F_{e,j}^{k+1} = 0$. If $fr_{c,j} \le 1$ two possibilities exist. If the assigned boundary water depth is smaller than the critical depth corresponding to the specific flow rate, that is:

$$bh_{e,j} \le \left(\frac{p_e^2 + q_e^2}{g}\right)^{1/3} \quad (53)$$

a total flux corresponding to the critical depth is assigned to the element boundary side, that is:

$$F_{e,j}^{k+1} = \sqrt{g}\left(h_e^{k+2/3}\right)^{3/2} L_{e,j} - F_{e,j}^{k+2/3} \quad (54)$$

If inequality $fr_{c,j} \le 1$ does not hold, boundary water depth is assigned to element e, along with the corresponding Dirichlet condition and diffusive flux is computed a posteriori by means of eq. (49).

6 TEST CASES

6.1 *Test 1. Rectangular partial dam-break*

It is assumed that in the centre of a 200 m × 200 m square area a partial dam-break takes place instantaneously. The breach is 75 m long and extremes are 30 m from the left bank and 95 m from the right bank (see figure 2). Initial water depth is 10 and 5 m respectively upstream and downstream the breach. Zero slope and friction factors are assumed.

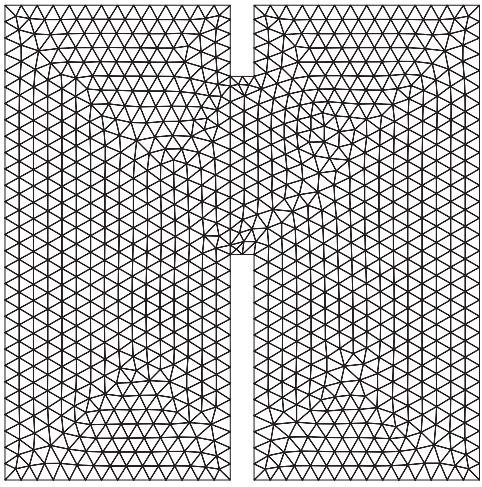

Figure 2. Computational mesh for test 1.

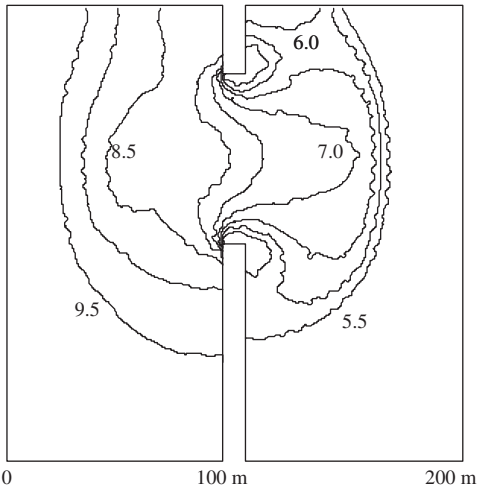

Figure 3. Contour depths; $\Delta t = 0.1$ s.

Immediately after the breach opening, water is released, forming a positive wave that propagates downstream and a negative wave that spreads upstream.

An unstructured triangular mesh with 1962 elements has been used for numerical simulations (see figure 2); the mean value of element area is approximately 25 m^2. Elevation contours are shown in figure 3 at the simulation time $T = 7.2$ s; a time step Δt equal to 0.1 s has been used, with a corresponding 0.57 maximum value of the CFL number. Figure 4 shows the elevation contours at the same simulation time T, but obtained with a Δt equal to 0.6 s; the corresponding maximum value of the CFL number is 3.08. These

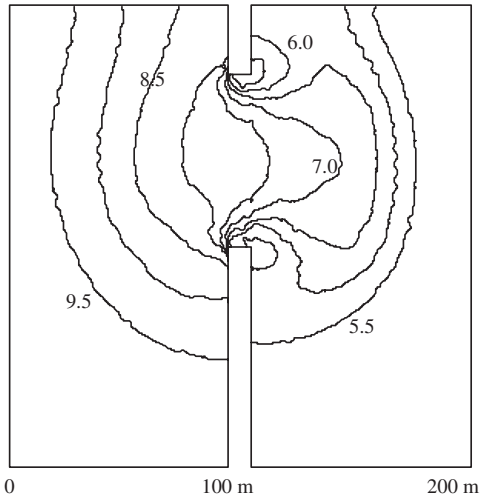

Figure 4. Contour depths; $\Delta t = 0.6$ s.

results show the stability of the proposed method with regard to the time step size. Using a Pentium 4 processor, for $\Delta t = 0.6$ s CPU time for the two convection systems is approximately 0.21 s, while CPU time for the diffusive system is 0.0156 s.

The general shape of the surface and the waves fronts computed for both Δt values appear in good agreement with numerical results given by other explicit numerical methods previously proposed (Glaister, 1993; Fennema and Chaudry, 1990; Mingham and Causon, 1998; Hubbard, 1999; Wang et al., 2003). In these models, either regular quadrilateral mesh with an equivalent element area, or unstructured triangular mesh have been used and the maximum size of the time step is limited by the Courant-Friedrichs-Levy condition.

6.2 *Test 2. 2D dam-break experiment by Fraccarollo and Toro (1995)*

The experimental flume, shown in figure 5, is a flat dry area, 2 m wide and 3 m long. After the first meter, a vertical wall forms a reservoir, filled up to 0.6 m (see Fraccarollo and Toro, 1995). Both the walls and the bottom are covered with the same material, corresponding to a Manning coefficient of 0.0095 s/m$^{1/3}$. The width of the movable gate, symmetrically centred, is 0.40 m. The flood-plain boundaries are all open.

Numerical results have been compared with the measured and the computed ones by Fraccarollo and Toro (1995) and with the results computed by Gottardi and Venutelli (2004).

Fraccarollo and Toro (1995) applied a WAF (Weighted Averaged Flux) scheme (Toro, 1989), a 2nd order conservative, shock capturing Godunov-type

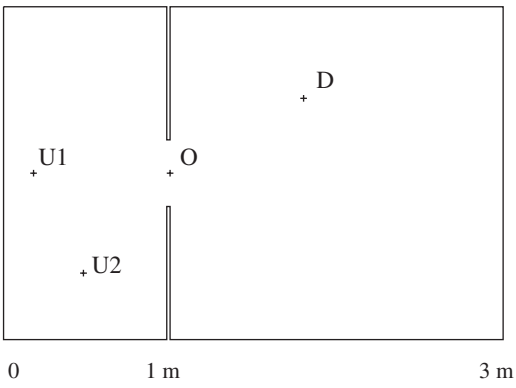

Figure 5. Experimental flume of Fraccarollo and Toro (1995).

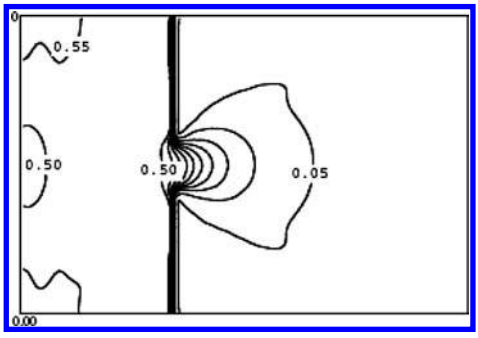

Figure 6a. Water depths by Gottardi and Venutelli (2004).

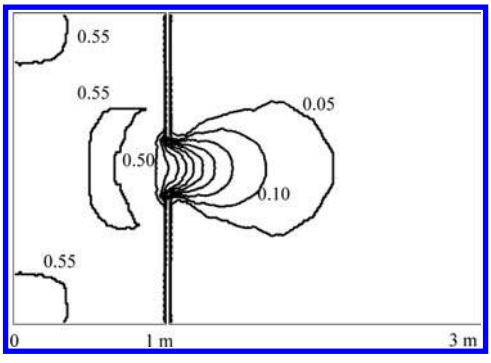

Figure 6b. Water depths computed by the MAST scheme.

scheme. The Authors discretized the domain by means of a regular mesh of 150×50 points along x and y directions respectively, with a corresponding element area 8.E-04 sm.

Gottardi and Venutelli applied an explicit 2nd order central scheme, initially proposed by Kurganov and Tadmor (2000); integration in time has been

Copyright © 2006 Taylor & Francis Group plc, London, UK

performed by means of a 3rd order TVD-Runge-Kutta scheme. They discretized the domain using a regular quadrilateral mesh with side Δx equal to 0.02 m.

For numerical simulations with the MAST scheme a regular mesh with equilateral triangles has been used; total elements number is 8606 with area 8.E-04 sm.

In figures 6a and 6b the contour plot of the water depths are shown for the proposed model and the one by Gottardi and Venutelli at the simulation time $T = 0.5$ s. Maximum value of the CFL number in the reference scheme is 0.5; in the proposed scheme a time step 0.01 s has bees assumed, with a corresponding maximum value of CFL number approximately equal to 3. Numerical results are similar, in spite of the different approximation orders, mesh and time step size.

CPU time for computation of the two convective systems is about 1.4 s and for diffusive system is 0.0625 s.

In figures 7a–7d numerical results are compared for a simulation time $T = 10$ s with data measured at some points and reported in figure 5: "O" ($x = 1$ m, $y = 1$ m), "U1"($x = 0.18$ m, $y = 1$ m), "U2" ($x = 0.48$ m , $y = 0.4$ m) and "D"($x = 1.802$ m, $y = 1.45$ m). Numerical results are in good agreement with the experimental ones. Observe the difference between measured and numerical results for small times at point "O". After the sudden opening of the gate a strong rarefaction wave moving in upstream direction is originated. As in the 1D case, water depth at the gate location (point "O" in the specific case) drops to a local minimum value (about 4/9 of the initial depth) after the opening of the gate. This is analogous to the 1D solution by Ritter (1992) in a horizontal and frictionless channel. After the minimum is reached, a rising stage follows, due to the contribute of the lateral propagation and 2D effects.

Inside the reservoir, Fraccarollo and Toro (1995) measured also the static pressure values at the bottom. In fact, according to the hydrostatic hypothesis, these data represent an indirect measure of the water depths. Pressure measures are reported in meters of water column. For measurement points "U1" and "U2" pressures and water levels values are very close each other and only water levels are reported in figures 7b and 7c; at point "O", as expected, the are some discrepancies between measured and hydrostatic pressures, because of some 3D effects. Observe that at point "O" numerical results are in better agreement with the pressure measures.

In figure 8, numerical results computed by the proposed schemes are compared with numerical results by Fraccarollo and Toro (1995) for the measure point "O". Model results are in good agreement, even if the proposed schemes shows some diffusive effect missing in the results of Fraccarollo and Toro (1995), because of the higher approximation order of the reference scheme with respect to proposed one.

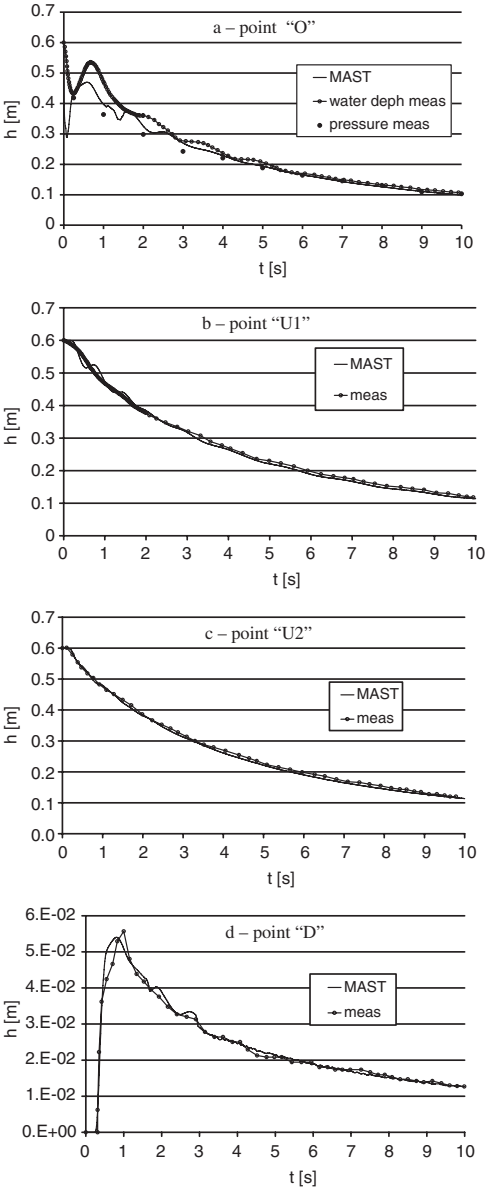

Figure 7. Comparison between experimental data and numerical results computed by the MAST scheme.

The delay between measured and computed data for point "O" is likely due to the small time required for the real opening of the gate (about 0.1 s).

7 CONCLUSIONS

A novel procedure has been proposed for the numerical solution of the 2D shallow water equations.

Copyright © 2006 Taylor & Francis Group plc, London, UK

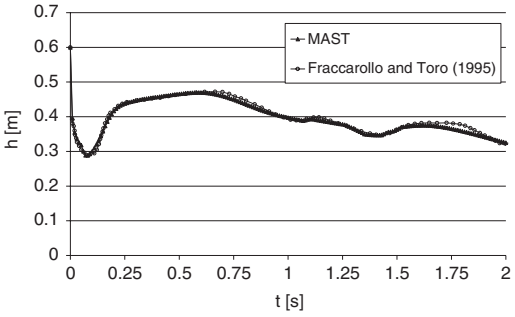

Figure 8. Comparison between numerical results at measure point "O".

In the MAST algorithm, the solution is found in each time step solving three different sub-problems. The main advantage of the algorithm is that the first and the second non linear sub-problem can be solved locally element after element, without any stability restriction on the size of the time step. The computational time of the third problem has been always the smaller one in all the performed simulations. The larger CPU is actually dedicated to the computation of the approximated potential. The use of a bad approximated potential leads to a poor solution, because the spatial gradients are computed at different time levels in each sub-problem and the good performance of the fractional step approach is based on the quality of the prediction step. A promising research is actually in progress in order to find a good compromise between the quality of the approximated potential and the required computational burden.

An application of BGK numerical method to tidal flow

Deng Jiaquan
Pearl River Hydraulic Research Institute, Ministry of Water Resources, Guangzhou, China

ABSTRACT: Based on the Bhatnagar-Gross-Krook (BGK) Boltzmann theory for molecule motions, numerical method for open channel flows is formulated and a second-order two-dimensional numerical model for unsteady flows is established. This new method has many advantages comparing to traditional methods which based on Saint-Venant equations and it satisfies the entropy condition and thus prevents unphysical oscillations in computations. The high accuracy and efficiency of this method have been proved. This paper demonstrates the main procedures of the formulation of the method and its application to tidal flows in the Macao water area. The computational results show a good agreement between the computed and measured field data.

1 INTRODUCTION

It has been show that numerical method based on the Bhatnagar-Gross-Krook (BGK) Boltzmann theory for molecule motions has many advantages comparing to traditional methods which based on Saint-Venant equations (Xu, 1995, 1996, Deng, 2000). This method satisfies the entropy condition and thus prevents unphysical oscillations in computations. Its high accuracy and efficiency of this method have been proved. However, molecule motion computations are different from natural river flow computations where irregular river bed slopes exist. For considering this, Xu (2002) proposed a harmonious scheme based on the molecule theory by including the effect in the fluxes terms. This paper uses Xu's method to consider the effect of the bed slope in the proposed two-dimensional BGK model. To improve the accuracy of the proposed numerical model, the water level, instead of the water depth, is used in this study to reconstruct initial data. Based on finite volume method and BGK Boltzmann equation, this paper demonstrates the main procedures of the formulation of the two-dimensional irregular grid BGK numerical model and its application to tidal flows in the Macao water area which has a tidal confluence and complicated boundary.

2 TWO-DIMENSIONAL BGK SCHEME ON IRREGULAR GRIDS

2.1 *BGK Boltzmann equation and basic relationships*

Two-dimensional BGK Boltzmann equation can be written as follows (Deng, 2000)

$$\frac{\partial f}{\partial t}+c_x\frac{\partial f}{\partial x}+c_y\frac{\partial f}{\partial y}+\frac{F_x}{m}\frac{\partial f}{\partial c_x}+\frac{F_y}{m}\frac{\partial f}{\partial c_y}=\frac{q-f}{\tau} \quad (1)$$

where f is molecule speed distribution function, is time, c_x and c_y are molecule speeds in x and y direction; F_x and F_y are external force acting on the molecule in x and y direction; is the molecule mass, q is molecule speed distribution function at equilibrium state, τ is the collision time between molecules.

For two-dimensional water flows, there are following basic relationships between the equilibrium molecule speed distribution function q and water depth h and velocities u and v in x and y direction(Deng, 2000):

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}qdc_xdc_y=h,\quad \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}c_xqdc_xdc_y=hu,$$
$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}c_yqdc_xdc_y=hv \quad (2)$$

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}c_xc_yqdc_xdc_y=huv,$$
$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}c_x^2qdc_xdc_y=hu^2+\frac{gh^2}{2} \quad (3)$$

According to the conservation laws for the mass and the momentum, the collision function on the right-hand side of equation (1) obeys following conditions(Deng, 2000)

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{q-f}{\tau}dc_xdc_y=0,\quad \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}c_x\frac{q-f}{\tau}dc_xdc_y=0,$$
$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}c_y\frac{q-f}{\tau}dc_xdc_y=0 \quad (4)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

2.2 *BGK-based model for water flows*

Multiplying equation (1) with $(1, c_x, c_y)^T$ and integrating it by using relationships (2) to (4), we can obtain the following two-dimensional water flow BGK-based model:

$$\frac{\partial U}{\partial t}+\frac{\partial F}{\partial x}+\frac{\partial G}{\partial y}=S \tag{5}$$

where $U=(h, uh, vh)^T$,

$$F=\left(\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}c_x f dc_x dc_y,\ \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}c_x^2 f dc_x dc_y,\ \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}c_x c_y f dc_x dc_y\right)^T$$

$$G=\left(\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}c_y f dc_x dc_y,\ \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}c_x c_y f dc_x dc_y,\ \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}c_y^2 f dc_x dc_y\right)^T,$$

$$S=\left(0, gh(S_{0x}-S_{fx}), gh(S_{0y}-S_{fy})\right)^T.$$

F and G are momentum fluxes in x and y directions respectively. S is source term (external forces).

2.3 *BGK model on irregular grids*

Based on the finite volume method, the increments of the conservative variables in the control volume in time Δt should be equal to the product of Δt and the sum of the fluxes on volume surfaces and the source term, i.e.,

$$A(U_i^{n+1}-U_i^n)=\Delta t\left[-\int_{\partial\Omega}(Fn_x+Gn_y)ds+AS\right] \tag{6}$$

where A is the control volume area n_x and n_y are direction derivatives in x and y directions respectively. The fluxes can be written as

$$\begin{aligned}Fn_x+Gn_y&=F\frac{\Delta y}{\Delta s}-G\frac{\Delta x}{\Delta s}\\&=F\cos\theta+G\sin\theta=T^{-1}F(T(\theta)U)\end{aligned} \tag{7}$$

where θ is the angle between volume surface and y coordinate.

$$\text{coordinate. } T(\theta)=\begin{bmatrix}1&0&0\\0&\cos\theta&-\sin\theta\\0&\sin\theta&\cos\theta\end{bmatrix},$$

$T^{-1}=T^T$, $U_N=TU=(h, hu_\xi, hv_\eta)^T$, $\xi-\eta$ is local coordinate.

Thus, the finite volume equation can be written as

$$A_i\left(U_i^{n+1}-U_i^n\right)=\Delta t\left[-\sum_{j=1}^{m}\left(T_j^{-1}F_{N_j}s_{i_j}\right)+S_iA_i\right] \tag{8}$$

2.4 *Fluxes computation*

Molecule motion computations are different from natural river flow computations where irregular river bed slopes exist. For considering this, Xu (2002) proposed a harmonious scheme based on the molecule theory by including the effect in the fluxes terms. This paper uses Xu's method to consider the effect of the bed slope.

When computing natural river flows, the effect of the river bed slope on the equilibrium molecule distribution function should be considered. For two-dimensional case (Xu, 2002, Deng, 2000),

$$\left(\frac{1}{\sqrt{\pi gh}}e^{-\frac{[(c_x-S_{0x}(t-t^n))-u]^2}{gh}}\right)\left(\frac{1}{\sqrt{\pi gh}}e^{-\frac{[(c_y-S_{0y}(t-t^n))-v]^2}{gh}}\right)h$$

Using Taylor expansion (ignoring higher order of $t-t^n$), we have

$$\begin{aligned}q(x, y, c_x, c_y, t)=&\left[\left(\frac{1}{\sqrt{\pi gh}}e^{\frac{-(c_x-u)^2}{gh}}\right)\left(\frac{1}{\sqrt{\pi gh}}e^{\frac{(c_y-v)^2}{gh}}\right)h\right]\\&\times\left[1+\frac{2}{gh}\left(\alpha S_{0x}(c_x-u)(t-t^n)+\beta S_{0y}(c_y-v)(t-t^n)\right)\right]\end{aligned} \tag{9}$$

where α and β are coefficients for considering the effect of ignoring higher order of $t-t^n$.

Thus, the molecule distribution function in the control volume can be expressed as (Xu, 2002)

$$\begin{aligned}f(x_{i+\frac{1}{2}}, y_j, t)=&\kappa_1\Big\{H(c_x)q^n_{i+\frac{1}{2}^-,j}+[1-H(c_x)]q^n_{i+\frac{1}{2}^+,j}\\&-t\Big\{H(c_x)\left[\left(c_x\frac{\partial q}{\partial x}-\frac{2}{gh}\alpha S_{0x}(c_x-u)(t-t^n)\right)\right.\\&\left.+\left(c_y\frac{\partial q}{\partial y}-\frac{2}{gh}\beta S_{0y}(c_y-v)(t-t^n)\right)\right]^n_{i+\frac{1}{2}^-,j}\\&+[1-H(c_x)]\left[\left(c_x\frac{\partial q}{\partial x}-\frac{2}{gh}\alpha S_{0x}(c_x-u)(t-t^n)\right)\right.\\&\left.+\left(c_y\frac{\partial q}{\partial y}-\frac{2}{gh}\beta S_{0y}(c_y-v)(t-t^n)\right)\right]^n_{i+\frac{1}{2}^+,j}\Big\}+\kappa_2\bar{q}^n_{i+\frac{1}{2},j}\\&+\kappa_3\left(\frac{\partial\bar{q}}{\partial t}\right)^n_{i+\frac{1}{2},j}+\kappa_4\left[\left(c_y\frac{\partial\bar{q}}{\partial y}-\frac{2}{gh}\beta S_{0y}(c_y-v)(t-t^n)\right)\right]^n_{i+\frac{1}{2},j}\\&+[1-H(c_x)]\left(c_x\frac{\partial\bar{q}}{\partial x}-\frac{2}{gh}\alpha S_{0x}(c_x-u)(t-t^n)\right)^n_{i+\frac{1}{2}^+,j}\\&+H(c_x)\left(c_x\frac{\partial\bar{q}}{\partial x}-\frac{2}{gh}\alpha S_{0x}(c_x-u)(t-t^n)\right)^n_{i+\frac{1}{2}^-,j}\Big]\end{aligned} \tag{10}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

where H is Heaviside function and

$$\kappa_1 = e^{-\frac{t}{\tau}}, \quad \kappa_2 = 1 - e^{-\frac{t}{\tau}}, \quad \kappa_3 = \tau\left(\frac{t}{\tau} - 1 + e^{-\frac{t}{\tau}}\right),$$
$$\kappa_4 = \tau\left(-1 + e^{-\frac{t}{\tau}}\right) + te^{-\frac{t}{\tau}}.$$

From integrations of (8), and by considering

$$erfc(0) = 1, \exp(0) = 1, \quad \frac{\partial(b+h)}{\partial x} = 0, \quad \frac{\partial(b+h)}{\partial y} = 0,$$

we can obtain

$$\alpha_1, \beta_1 = \frac{3}{4}, \quad \alpha_2, \beta_2 = 1 \text{ and } \alpha_3, \beta_3 = \frac{5}{4}.$$

Thus, by substituting (10) into (5) we can obtain the solutions for considered variables.

3 DATA RECONSTRUCTION

Since the variation of the water level is relatively small, it is used to reconstruct the initial data, instead of the water depth.

$$\begin{cases} \begin{pmatrix} \eta \\ hu \\ hv \end{pmatrix}^n = \begin{pmatrix} \eta \\ hu \\ hv \end{pmatrix}^n_{i,j} + \underbrace{\frac{\partial}{\partial x}\begin{pmatrix} \eta \\ hu \\ hv \end{pmatrix}^n_{i,j}}_{x-slope}(x - x_i) + \underbrace{\frac{\partial}{\partial y}\begin{pmatrix} \eta \\ hu \\ hv \end{pmatrix}^n_{i,j}}_{y-slope}(y - y_i) \\ h = \eta - B \end{cases} \quad (11)$$

4 APPLICATION OF BGK NUMERICAL METHOD TO TIDAL FLOWS

4.1 *Computed water area and hydrological data*

The proposed numerical method is applied to the tidal flow in the Macao water area which is quite complicated due to the confluence and irregular boundaries. The computed scope includes the Hongwan waterway (west to Maliuzhou stage), the Qianshan waterway (north to the Wanzhai stage), the Shizimen waterway (south to the Hongqi stage) and the Macao Bay (east to the Waigang stage) (see Fig. 1).

Hydrological data used in the computation was measured on March 28, 1997. Computational boundaries are: water levels are given at Mangzhou and Hongqi stages; discharges are given at Wanzhai and Waigang stages. The computed results are compared with measured data at two stages Maliuzhou and Shizimen which are located in the computed water area.

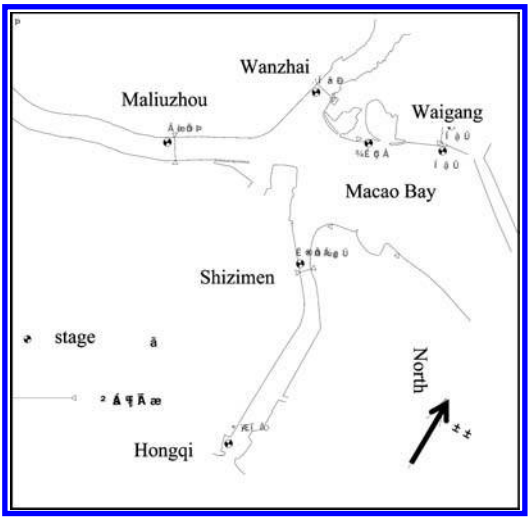

Figure 1. Computed Macao water area.

Table 1. Computed and measured tidal levels unit: m.

Stage	Tidal level	Measured	Computed	Error
Maliuzhou	Highest	0.52	0.57	0.05
	Lowest	−0.78	−0.77	0.01
	Average	−0.06	−0.04	0.02
	Tidal range	1.30	1.34	0.04
Shizimen	Highest	0.49	0.52	0.03
	Lowest	−0.82	−0.84	0.02
	Average	−0.11	−0.13	0.02
	Tidal range	1.31	1.36	0.05

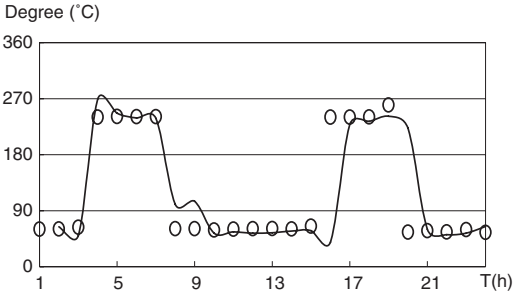

Figure 7. Computed and measured (solid line) flow directions at Maliuzhou.

Figures 8 and 9 show the computed tidal flow fields in the confluence area which agree with measured tidal flow fields well.

5 CONCLUSIONS

Based on finite volume method and BGK Boltzmann equation, this paper proposed a new numerical model for computing two-dimensional practical river or tidal flows with irregular bed slopes. This new method

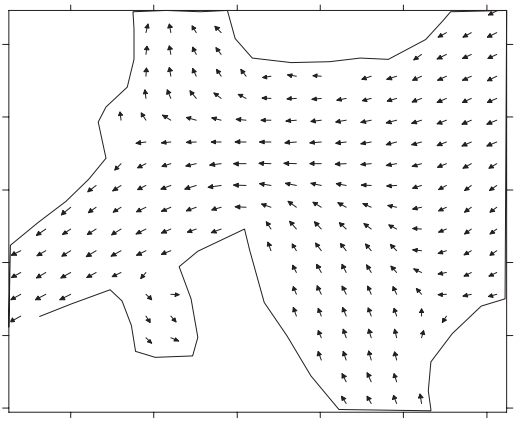

Figure 8. Computed flow field in confluence area (flood tide).

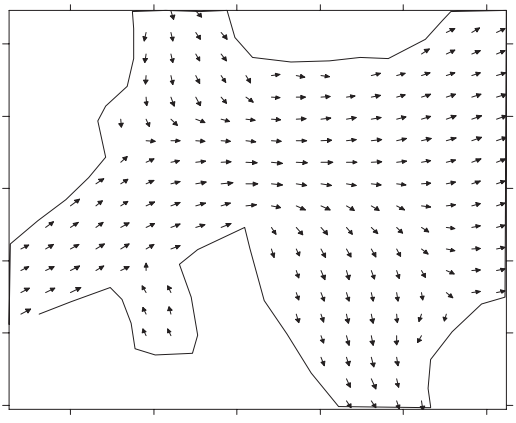

Figure 9. Computed flow field in confluence area (ebb tide).

employs two-dimensional irregular net grids and considers the effect of the bed slope on the molecule distribution function. It suits for any kind of river or estuaries boundary. The application of the new method to model the tidal flow in the Macao water area show this two-dimensional irregular grid BGK numerical model can well simulate the flows with complicated boundaries.

ABSTRACT: This paper presents the development and validation of a robust numerical scheme of Riemann solver category applied to one-dimensional free surface flow simulation modelled by the Saint-Venant equation set. The scheme presented here is based on a discharge equation in non-conservation form coupled with a matrix transformation that converts the discharge evolution into a velocity evolution that proves to be more robust. The resulting scheme has all the positive attributes of Riemann solvers such as stability through transcritical flow regimes, ability to resolve hydraulic jumps, stability and accuracy with respect to dry bed calculations and robustness in front of rapidly varying flows such as dam-breaks. Most importantly, the present scheme is able to treat large variations in river geometry allowing the use of space steps of the order of hundreds or thousands of meters. The resulting model that uses explicit time steps is so fast on current machines that the incorporation of complicated implicit algorithms is unnecessary.

1 INTRODUCTION

The last fifteen years or so have seen a rapid rise in the use of Riemann solvers as the numerical method of choice, to treat problems in fluvial hydraulics. This is due to their robust properties in being able to handle transcritical flows with shocks, theoretically the sole restriction being compliance with the well-known Courant-Friedrichs-Levy criterion for the time step.

On a practical basis however, all these numerical algorithms exhibit stability problems when applied to natural rivers that may have highly variable geometries in the longitudinal direction. This necessitates the utilization of a very fine mesh, resulting in a significant increase in computational times. It will be shown in this paper that the so called 'conservation' form of the equation set, favoured by most authors because of its suitability for evaluation of the surface flux expressions in the basic equations, is the cause for the deterioration in robustness. Using the strictly conservation form of the governing equations in one dimension results in the appearance of a series of terms dependant on geometric properties of the watercourse. The order of magnitude of their variation may be many times higher than the order of magnitude of the terms that are essentially functions of the flow variables. The alternate non-conservation form of the equations corresponding to an equation for fluid velocity in place of fluid discharge is known to exhibit difficulties in predicting hydraulic jumps.

The scheme presented here uses a linearization around local wetted area or volume to apply a Roe's Riemann solver technique to the original discharge form of the Saint-Venant equations. An additional step that transforms problem variable from discharge to velocity brings more stability, with respect to large space step, to the overall scheme.

Three test cases where analytical solutions are available have been used for validation purposes and to assess model performance. The real case simulation of the filling of a headrace tunnel, some reaches of which have a sixty-degree slope is presented. Two other real cases applied to Canadian rivers are shown, one is the case of a dam break during the passage of the probable maximum flood over a river basin located in northern Canada, and the second is the propagation of a dam break wave in a river in North-Eastern Canada.

2 GOVERNING EQUATIONS

2.1 *Basic one-dimensional Saint-Venant system*

The one dimensional Saint-Venant Equation set constitutes the mathematical basis of the following analysis. This mathematical model is valid for all free surface

Copyright © 2006 Taylor & Francis Group plc, London, UK

flow for which the assumptions of moderate bed slope and negligible vertical acceleration are valid. It is described by the following pair of equations for one space dimension (Cunge et al, 1980):

$$\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial x} = 0 \tag{1.a}$$

$$\frac{\partial Q}{\partial t} + \frac{\partial (VQ)}{\partial x} + gA\frac{\partial H}{\partial x} + gAS_f = 0 \tag{1.b}$$

Equation (1.a) is derived on the basis of mass conservation principle, and (1.b) is based on the principle of momentum conservation.

To complete the description if the system (1) above, it is necessary to define its different variables:

t = designates the time.
x = designates the coordinate position measured along the river bed axis.
A = A(x,t) is the wetted area.
Q = Q(x,t) is the discharge .
V = V(x,t) is the mean velocity; V = Q/A.
H = H(x,t) designates the water surface elevation with respect to reference.
S_f = is the friction term. In practice, the well known Manning Equation is used to express this term.

$$S_f = \frac{N^2|V|}{R^{4/3}} \bullet V$$

R = A/P is the hydraulic radius, with P being the wetted perimeter. N = is the Manning friction coefficient.

The system (1) cannot be written under strict conservation form, i.e.

$$\frac{\partial U}{\partial t} + \frac{\partial F(U)}{\partial x} = 0 \tag{2}$$

Riemann solvers are usually developed on the basis of such conservation forms. This is the reason why most implementations of Riemann solver for Saint-Venant model have used a slightly modified version of (1) which is written under the following quasi conservation with a source term:

$$\frac{\partial U}{\partial t} + \frac{\partial F(U)}{\partial x} = G \tag{3}$$

Where

$$U = \begin{bmatrix} A \\ Q \end{bmatrix}, \qquad F(U) = \begin{bmatrix} Q \\ \left(\frac{Q^2}{A}\right) + g \cdot I_1 \end{bmatrix}, \tag{4a}$$

$$G(U) = \begin{bmatrix} 0 \\ g \cdot A \cdot (S_0 - S_f) + I_2 \end{bmatrix} \tag{4b}$$

The relation which permits the original equation set (1) to be written under the form (4) is the following one:

$$g \cdot A \cdot \frac{\partial H}{\partial x} = \frac{\partial I_1}{\partial x} - I_2 - g \cdot A \cdot S_0 \tag{5}$$

With

$$I_1 = g \int_{Z_f}^{H} A(x,\xi)\, d\xi \tag{6}$$

$$I_2 = g \int_{Z_f}^{H} \frac{\partial A(x,\xi)}{\partial x}\, d\xi \tag{7}$$

And

$$S_0 = -\frac{\partial Z_f}{\partial x} \tag{8}$$

2.2 *Hydraulic head conservation system*

The following system can be derived from the original system (1):

$$\frac{\partial A}{\partial t} + \frac{\partial (V \cdot A)}{\partial x} = 0 \tag{9a}$$

$$\frac{\partial V}{\partial t} + \frac{\partial \left(\frac{V^2}{2}\right)}{\partial x} + g\frac{\partial H}{\partial x} = -g \cdot S_f \tag{9b}$$

This system (9) can be written under matrix form for frictionless flows:

$$\frac{\partial W}{\partial t} + \frac{\partial E(W)}{\partial x} = H \tag{10}$$

With

$$W = \begin{bmatrix} A \\ V \end{bmatrix}, \qquad E(W) = \begin{bmatrix} V \cdot A \\ \left(\frac{V^2}{2}\right) + g \cdot H \end{bmatrix} \tag{11a}$$

$$H(W) = \begin{bmatrix} 0 \\ -g \cdot S_f \end{bmatrix} \tag{11b}$$

For frictionless flows ($S_f = 0$), the system (9) respects the conservation form.

Note that when the flow variables A, Q and V are differentiable, it possible to write the following identity

$$\partial U = \begin{bmatrix} \partial A \\ \partial Q \end{bmatrix} = \begin{bmatrix} \partial A \\ V \cdot \partial A + A \cdot \partial V \end{bmatrix}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

That is

$$\partial U = \begin{bmatrix} 1 & 0 \\ V & A \end{bmatrix} \begin{bmatrix} \partial A \\ \partial V \end{bmatrix} = K \bullet \partial W$$

This relation can also be verify between the equation presented above:

$$(1) = K \bullet (9)$$

The inverse of this relation is a corner stone of the proposed scheme (see equation 16).

In fact, systems (1) and (9) are equivalent for regular flows, i.e. flows without discontinuities. For flow with discontinuities like hydraulic jumps, the solutions of the two systems are not identical (see Hervouet 2003, or Tchamen 2006). In this case, it is recommended that the solution of the system (1) be retained.

There have been a number of propositions to applied Riemann solvers to the original Saint-Venant equation set. The first propositions (Alcrudo & Garcia-Navarro 1992, Glaister 1988) did not apply to general river geometry case, but rather to frictionless prismatic channel. Later, it has been realized that for general river with arbitrary geometry, a coherent integration of geometric and friction source terms is vital for the overall stability and accuracy of the numerical scheme. Number of works (Bermudez 1995, Goutal and Maurel 2002) has focused on the technique design to integrate those source terms in a way that is coherent with the Riemann solver applied to the homogeneous part of the equation set.

Although these proposals seem to have effectively addressed the challenge of source term integration and work rather well for simple cases that possess analytical solutions, or even for flows in rivers with mild geometric variation, there is a degradation in robustness when applied to rivers with very irregular geometries.

3 A RIEMANN SOLVER FOR THE NON CONSERVATION EQUATION SET (1)

The Riemann solver proposed in the present paper is an implementation of the Roe scheme (Roe 1981, Tchamen 2006) applied to the original set of equation (1).

Figure 1 shows a schematisation of the partition of the physical domain (a river valley) by means of a finite number of geometrical cross sections (S_i, i = 1 to N). A cell associated to the dependent variable $W_i = [A_i, V_i]^T$ is delimited by the two consecutive cross sections S_i and S_{i+1}.

The proposed new scheme is a six step procedure.

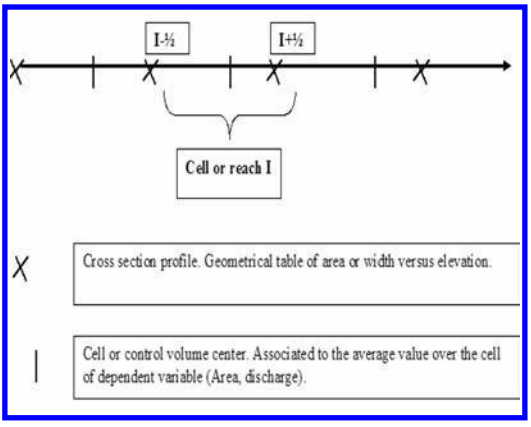

Figure 1. Schematization of domain discretization.

3.1 *Variable transformation*

This is the simplest step. It corresponds of the transformation of the variable W in the scheme into the corresponding variable U for the Riemann problem.

$$U = \begin{bmatrix} A \\ Q \end{bmatrix} = \begin{bmatrix} A \\ V \cdot A \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & A \end{bmatrix} \bullet \begin{bmatrix} A \\ V \end{bmatrix} = N \bullet W$$

Here, N is the transformation matrix:

$$N = \begin{bmatrix} 1 & 0 \\ 0 & A \end{bmatrix}$$

3.2 *Riemann flux for U variable*

This is one of the most important steps of the present scheme. It corresponds to the now classical Roe's formula (Roe 1981), to evaluate the Riemann flux through the interface between two neighbouring cells, applied to the original equation set (1).

$$F_{I+1/2} = F_{I+1/2}(U_I, U_{I+1}) = \frac{1}{2}\left[F(U_I) + F(U_{I+1}) - |J_{I+1/2}| \bullet \Delta U\right] \quad (12)$$

It is necessary here to underline two main points in the application of this formula.

a) **Local linearization for flux formulation.** Original equation set (1) is not in conservation form. The proposal here is to write it in the following form

$$\frac{\partial U}{\partial t} + \frac{\partial F^P(U)}{\partial x} = G$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

$$\text{With } F^P(U)=\begin{bmatrix} Q \\ (V\cdot A)+A_P\cdot(g\cdot H)\end{bmatrix}$$
$$\text{And } G(U)=\begin{bmatrix} 0 \\ A\cdot g\cdot S_f\end{bmatrix} \quad (13)$$

This means that the linearization is performed around the point P which represents the cell over which the equation set is integrated.

b) **Choice of variable.** In the above formula, the variable to $U=[A,Q]^T$ represents the cell average of the area and discharge respectively, as it is generally understood, but for the jump $\Delta U=\begin{bmatrix} A_{I+1}-A_I \\ Q_{I+1}-Q_I\end{bmatrix}$ in the numerical viscosity $|J_{I+1/2}|\bullet\Delta U$, it is proposed that the classical jump be replaced by a modified one:

$$\Delta U^{CS}=\begin{bmatrix} A_{I+1}^{CS}-A_I^{CS} \\ Q_{I+1}-Q_I\end{bmatrix}$$

Where :

A_I^{CS}, A_{I+1}^{CS} are cross section areas corresponding respectively to water surface elevations H_I and H_{I+1}. This choice is made so that for an initially still horizontal water surface, $H_I=H_{I+1}$, the jump ΔU^{CS} is null and so is the Riemann flux at the interface.

With the above modification, in place of the standard Roe flux (12), the following modified formula is used:

$$F_{I+1/2}^P=F_{I+1/2}^P(U_I,U_{I+1})=\frac{1}{2}\left[F^P(U_I)+F^P(U_{I+1})-|J_{I+1/2}|\bullet\Delta U^{CS}\right] \quad (14)$$

In (14), the point P may represent I or I+1 depending whether the integration is performed over the first or the second of these cells. Clearly, from (13), there is no symmetry:

$$F_{I+1/2}^I\neq F_{I+1/2}^{I+1}$$

3.3 *Temporal variation: U variable*

This step corresponds to the discrete representation of Equation set (1) without friction integrated over a cell I:

$$\Delta_t U^{n+1}=\left(U_I^{n+1}-U_I^n\right)$$
$$\Delta_t U^{n+1}=\frac{\Delta t}{\Delta X^I}\cdot\left[F_{I+1/2}^I-F_{I-1/2}^I\right] \quad (15)$$

3.4 *Evolution of W variable*

Evolution of W variable is realized on the basis of equation (15) together with the following transformation relation:

$$\partial W=\begin{bmatrix}\partial A \\ \partial V\end{bmatrix}$$
$$\partial W=\begin{bmatrix} 1 & 0 \\ -V/A & 1/A\end{bmatrix}\bullet\begin{bmatrix}\partial A \\ \partial Q\end{bmatrix}=T\bullet\partial U \quad (16)$$

Using (15) and (16), it is easy to derive the following relation for the evolution of W:

$$W_I^{n+1}=W_I^n-\frac{\Delta t}{\Delta X^I}\cdot\begin{bmatrix} 1 & 0 \\ \dfrac{-V_I^n}{A_I^n} & \dfrac{1}{A_I^n}\end{bmatrix}\bullet\left[F_{I+1/2}^I-F_{I-1/2}^I\right] \quad (17)$$

3.5 *Friction term*

The friction term is integrated in a separate fractional step method with an implicit algorithm which is known to preserve the stability of the overall procedure (Tchamen and Kahawita, 1998).

The equation to integrate is:

$$\frac{\partial W}{\partial t}=H(W)=\begin{bmatrix} 0 \\ -g\cdot S_f\end{bmatrix}$$
$$\frac{\partial W}{\partial t}=-\begin{bmatrix} 0 & 0 \\ 0 & C_f\end{bmatrix}\bullet W=-K\bullet W \quad (18)$$

Where

$$S_f=\frac{N^2}{R^{4/3}}|V|\cdot V,\qquad C_f=g\cdot\frac{N^2}{R^{4/3}}|V|$$
$$K=\begin{bmatrix} 0 & 0 \\ 0 & C_f\end{bmatrix} \quad (19)$$

Implicit integration of (18) results in

$$W_I^{n+1}=\begin{bmatrix} 1 & 0 \\ 0 & \left(1+\Delta t\cdot C_f^n\right)\end{bmatrix}^{-1}\bullet W_I^n$$
$$=\begin{bmatrix} 1 & 0 \\ 0 & \dfrac{1}{\left(1+\Delta t\cdot C_f^n\right)}\end{bmatrix}\bullet W_I^n \quad (20)$$

3.6 *Update of the cell mean water elevation*

This is a geometric operation which is done for every cell by using the updated cell average area A_I^{n+1} and the

Copyright © 2006 Taylor & Francis Group plc, London, UK

boundary cross section profiles. In fact the algorithm in charge of this step should determine the water level corresponding to the volume $VOL_I^{n+1} = A_I^{n+1} \cdot \Delta X_I$, with the geometry of the cell specified by the mean of the two boundary cross section profiles.

The cell mean water surface level is used in step 2 (Riemann flux).

4 THEORETICAL TEST CASES

The results of three theoretical tests which were proposed within the framework of the European CADAM [Concerted Action on Dam break Modeling] Project by Goutal & Maurel (1997) as validation cases for numerical models designed to simulate dam break flows.

4.1 *Initially quiescent pool of water within a pond of irregular bathymetry*

The purpose of this test is to verify correct treatment of the gravity term, which means that an initially horizontal water surface should remain unchanged in the absence of any inflow or outflow.

Figure 2a and 2b indicate that the chosen bathymetry and channel width is quite irregular. Figure 2c presents the water level after 1000 seconds of simulated time while Figure 2d shows the velocities at the same time. Clearly, no spurious velocity has been generated by the proposed scheme and water surface remains horizontal.

4.2 *Transcritical flow over a hump*

The second test takes place in a frictionless straight channel of rectangular cross section presenting a parabolic hump in the bed elevation. The geometry of this channel may be described by:

- for $X \leq 8$ and $X \geq 12$, $Z_f = 0$
- for $8 \leq X \leq 12$, $Z_f = 0.2 - 0.05(X-8)^2$

A steady state flow is established over this channel, with subcritical regime upstream which goes supercritical over the bump before returning to subcritical regime after going through an hydraulic jump, by imposing a constant specific discharge of $q = 0.18\ m^2/s$ at the entrance, and a constant depth of $H = 0.33$ m at the outlet.

Figure 3a and 3b show respectively the simulated water level and velocity profile against the analytical solution. It appears that the profile simulated on the basis of the system of head conservation (plus sign line), could not detect the hydraulic jump.

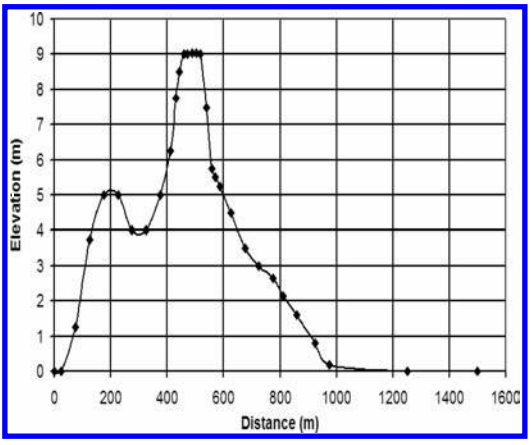

Figure 2a. Theoretical test 1. Bottoms profile.

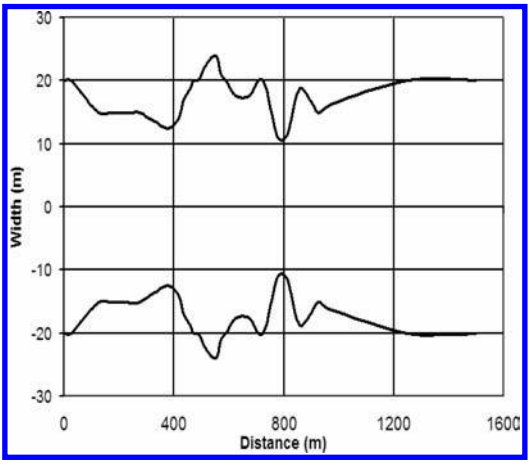

Figure 2b. Theoretical test 1. Profile of channel width.

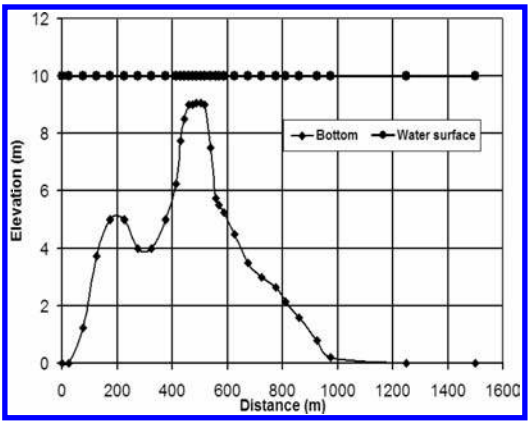

Figure 2c. Theoretical test 1. Water surface profile after 1000 seconds.

Copyright © 2006 Taylor & Francis Group plc, London, UK

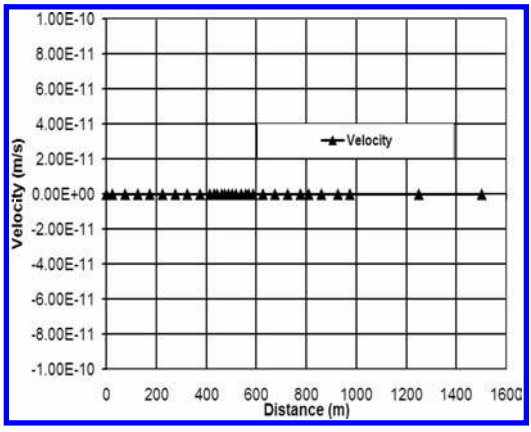

Figure 2d. Theoretical test 1. Velocity profile after 1000 seconds.

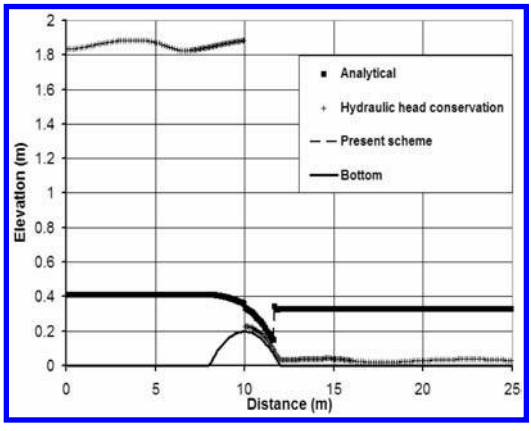

Figure 3a. Theoretical test 2. Water surface profile.

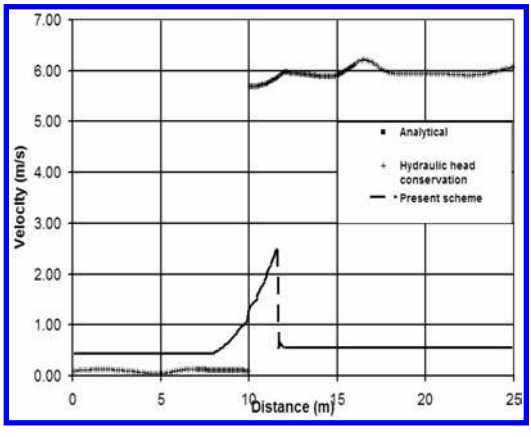

Figure 3b. Theoretical test 2. Velocity profile.

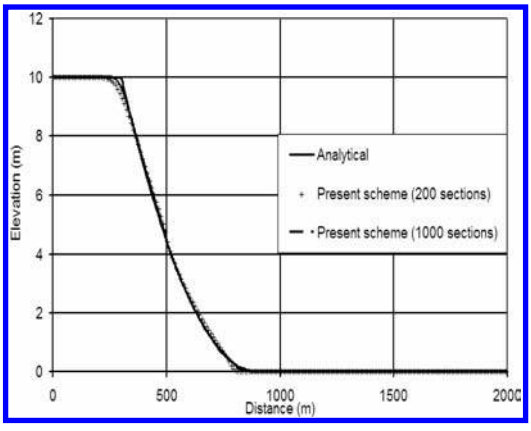

Figure 4a. Theoretical test 3. Water surface profile 20 seconds after dam break.

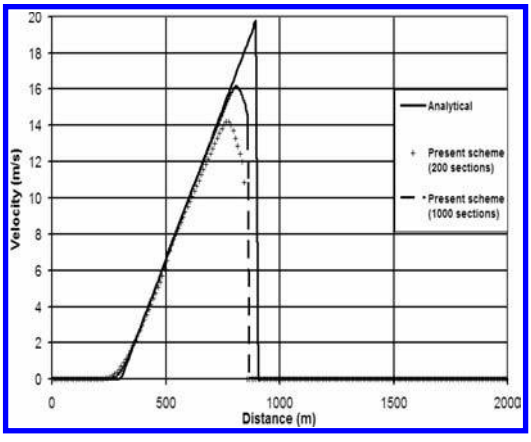

Figure 4b. Theoretical test 3. Velocity profile 20 seconds after dam break.

4.3 *Dam break over a frictionless channel with downstream dry bed*

This test corresponds to the theoretical dam break cases in a prismatic rectangular channel on a horizontal bed. The dam is located at approximately mid reach of the channel and separates a reservoir upstream, having a depth of 10.0 m, from a dry bed downstream.

Figure 4a and b compare respectively the longitudinal water surface profiles and velocities between the numerical and analytical solutions. The resolution of the advancing surge front improves with a finer mesh.

5 APPLICATION TO REAL CASES

5.1 *Filling a headrace tunnel*

For this particular case, the challenge for the numerical scheme is the presence of a mid section inclined

Copyright © 2006 Taylor & Francis Group plc, London, UK

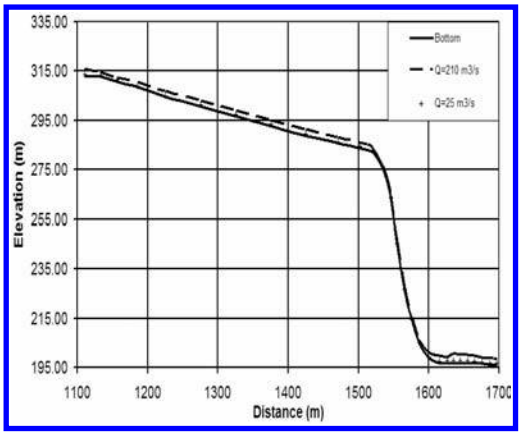

Figure 5a. Practical test 1. Bottom and water surface profiles.

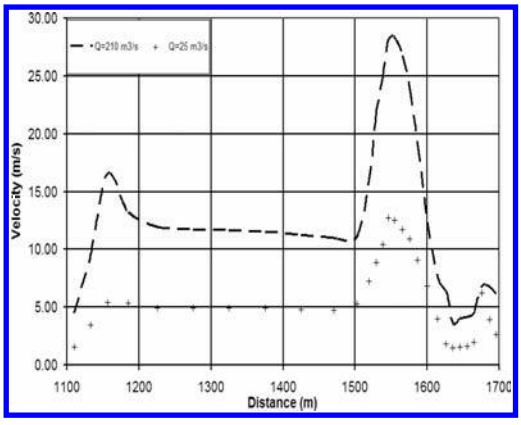

Figure 5b. Practical test1. Longitudinal profile of velocity.

tunnel which presents a sixty degree angle with the horizontal plane. The longitudinal bottom profile is shown in Figure 5a. The tunnel is approximately 1700 meters long, 17 meters wide and 17 meters in height. The tunnel is bounded upstream by a water intake. The opening of the intake vane controls the discharge into the tunnel. The tunnel is bounded downstream by a turbine group.

Two discharge scenarios in the tunnel have been simulated in order to select safe operation with regard to coarse debris entrainment.

Figure 5a and 5b show respectively longitudinal profiles of water surface and mean velocity for discharge values of 25 m^3/s and 210 m^3/s. It is seen that for the 210 m^3/s discharge, velocity values are greater than 6 m/s beyond 1600 m which corresponds to the base of the inclined reach and the entrance to the penstocks. Numerical tests have indicated that the present scheme is capable of treating velocities > 25 m/s in the tunnel.

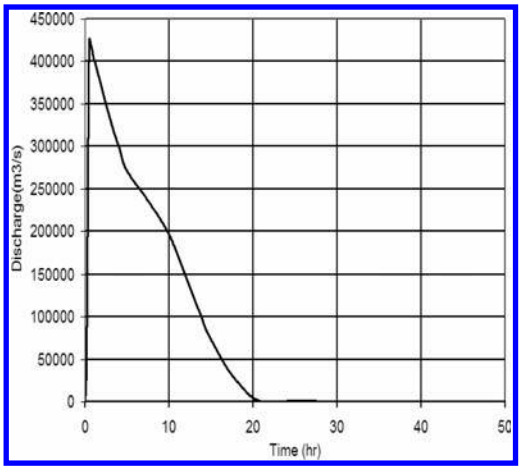

Figure 6a. Practical test 2. Hydrograph of SM3 dam breaking.

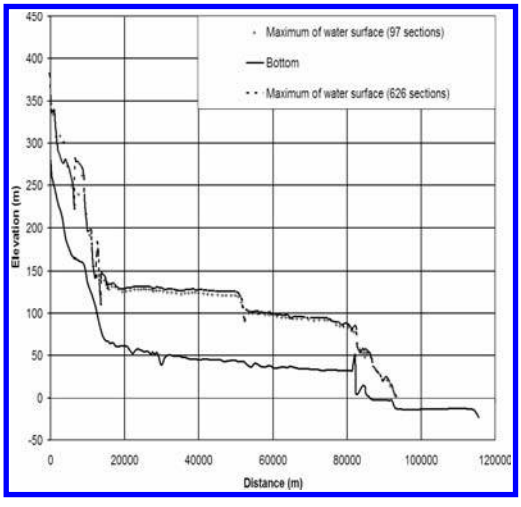

Figure 6b. Practical test 2. SM3 dam breaking. Longitudinal profile of maximum height.

5.2 *Sunny day dam failure in a river in Eastern Canada river*

The examples indicated here correspond to an actual river dam combination located in northeast Quebec, Canada. The failure scenario is completely fictitious, although judged realistic from an engineering risk analysis point of view.

The dam which is more than 100 meters in height would generate a formidable hydrograph, with a peak discharge exceeding 400 000 m^3/s as shown in Figure 6a. Figure 6b shows the longitudinal profile of maximum height over the downstream valley of the

Copyright © 2006 Taylor & Francis Group plc, London, UK

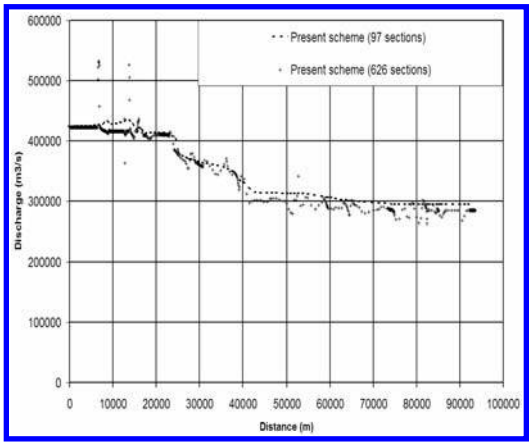

Figure 6c. Practical test 2. SM3 dam breaking. Longitudinal profile of maximum discharge.

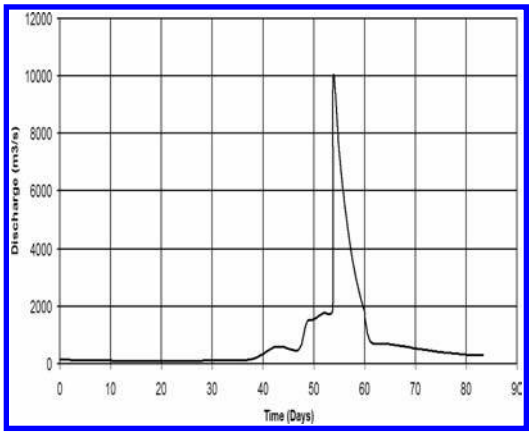

Figure 7a. Practical test 3. Hydrograph of Bourque dam breaking during probable maximal flood.

river with an irregular bottom. Figure 6c presents he longitudinal profile of maximum discharge.

Clearly, the present scheme is capable of handling extreme hydraulic flows in a numerically stable manner. Computational space steps ~ 1 km, were used although it is obvious that for accuracy purposes, it may be necessary to use a finer grid locally.

5.3 *Dam break during passage of probable maximum flood*

This represents a typical scenario that is studied to evaluate dam resistance against extreme flood events in the context of dam safety analyses. The principal challenge is to simulate the propagation of a flood in a natural river valley over a long time period of say two to three months while expending a reasonable amount of computational time. The key for the model is the

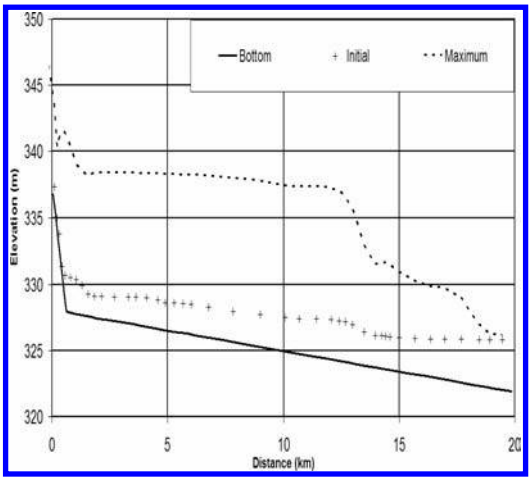

Figure 7b. Practical test 3. Bourque dam breaking. Longitudinal profile of maximum height.

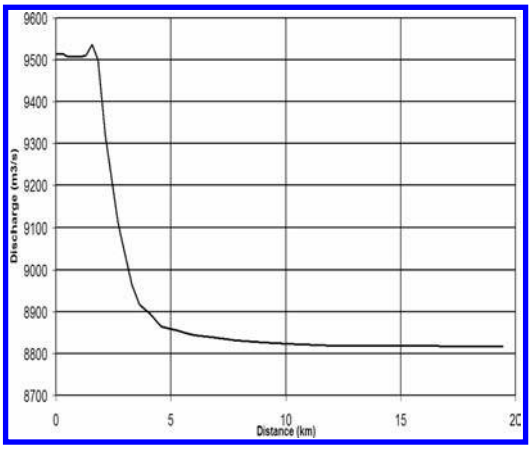

Figure 7c. Practical test 3. Bourque dam breaking. Longitudinal profile of maximum discharge.

speed of its numerical algorithm and the robustness necessary to handle space steps of several hundreds of meters.

In this example as well, a real river situated in northern Quebec Canada forms the basis of the study. The Probable Maximum Flood (PMF) has been synthesised from the standpoint of the site hydrology. Figure 7a indicates the outflow hydrograph expected if dam failure occurred during the flood peak.

Figure 9b shows the envelope of maximum water surface elevations expected along the 20 km downstream valley. Figure 7c shows the longitudinal profile of maximum discharge. The calculation for this scenario was performed with a 2 GHZ Pentium 4 in under 5 minutes.

Copyright © 2006 Taylor & Francis Group plc, London, UK

6 CONCLUSIONS

A new numerical scheme belonging to the class of Riemann solvers has been proposed for one dimensional Saint-Venant Equations. The novelty of this scheme resides on a local linearization, of the gravity term, which avoid to have to deal with various source terms which depends on river geometry and may be complicated to evaluate numerically. This scheme also innovates in adding an stabilizing step which transforms dependent variable from discharge to velocity.

Validation of the scheme has been carried by simulating theoretical test cases proposed in CADAM workshop. The scheme has also been applied to simulate dam break and extreme flood flows on natural river valleys. The scheme proved to accurately approximate analytical solution when they exist, but more importantly, for real case on natural river valleys, it shows great robustness which permits the use of space step of several hundred of meter. For practical cases, the scheme is so fast that it can be used for real time simulation.

1-Dimensional numerical analysis of tsunami in river

H. Yasuda
Civil Engineering Research Institute for Cold Region, Sapporo, Japan

ABSTRACT: The aim of the paper is to develop a 1-dimensional numerical model of tsunami in river and to apply it to Tokachi-oki earthquake tsunami on September 2003 in Hokkaido, Japan. The computational results of arrival time and water level at each wave gauge agree well with the observed data a high accuracy of less than 10%. Although the actual status of results of field survey is still unknown before the computation, the observed results were explained by the numerical analysis.

1 INTRODUCTION

Tsunamis cause tremendous damage to coastal areas, but they also have the potential to run up rivers and cause damage on a similar scale several kilometers upstream from the mouth. For example, after the 2003 Tokachi-oki Earthquake, a tsunami ran up multiple rivers on the Pacific coast of Hokkaido, Japan, making us strongly recognize that phenomena and realize its potential destructiveness. Although tsunami runup in rivers has been identified as a danger, it has drawn relatively little academic attention, partly because there are few records of the phenomenon.

At the front of a tsunami wave that enters a river, it is possible for the vertical acceleration to exceed the gravitational acceleration and for there to be a deviation from the hydrostatic pressure. When this phenomenon occurs, the wave characteristics totally change. The structural stability that is maintained as long as there is hydrostatic pressure is disrupted and the wave transforms into a new state of structural stability. This phenomenon has a clear bifurcation point between the two states. When a tsunami intrudes into a river channel and exceeds this bifurcation point, a wave number dispersion phenomenon called soliton dispersion, which is accompanied by a water level increase that is not seen under the condition of hydrostatic pressure, occurs at the wave front and an undular bore forms. In the tsunamis from the 1986 Nihonkai-chubu Earthquake(Tsuji, Y. et al. 1991) and 2003 Tokachi-oki Earthquake(Yasuda, H. et al. 2004) and in the 2004 Indian Ocean Tsunami(Tanaka, H. et al. 2006), soliton dispersions are known to have occurred when the tsunamis intruded into rivers. So far, neither the basic characteristics of tsunami waves in rivers, including the scale of water level increase with soliton dispersion at the wave front, nor specific behaviors of tsunami runup have been fully clarified.

Studies on tsunamis in river channels have been conducted by Iwasaki et al. (1977), Goto et al. (1981), Tsuji et al. (1991) and others. All these were based on shallow-water theory, except the studies by Tsuji et al., which employed the KdV-Burgers equation. This is why there has not been sufficient discussion on the undulant nature of wave fronts in undular bore phenomena. Nonetheless, it is of great significance, especially from the viewpoint of fluvial hydraulics, to discuss soliton dispersion at the wave front and the possibility and scale of water level increases even in cases that do not necessarily involve soliton dispersion but occur under non-hydrostatic pressure conditions.

Partial differential equations describing motions of tsunami runup in rivers completely agree, within a limited range, with the shallow-water equation applied to analyses of unsteady flow in rivers. Here, "limited range" means the range where hydrostatic pressure is acting. This means that if one is to perform an analysis of wave number dispersion phenomena based on long-wave equations, a non-linear dispersive wave theory (the Boussinesq equation(1872)) should be applied, because wave number dispersion phenomena do not appear when hydrostatic pressure is acting. Yasuda et al. (2003) pointed out that the non-linear dispersive wave equation is essential for analyses of undular bores running upstream and forming steep wave fronts, as shallow-water equations underestimate the maximum height of undular bores. Yasuda et al. (2005) subsequently conducted a numerical simulation on tsunami runup in river channels using the non-linear dispersive wave equation as the governing equation, and they identified some basic characteristics, such as maximum intrusion distance, maximum water level and its locations of occurrence.

This paper gives a one-dimensional analysis method to describe tsunami runup in rivers and discusses its applicability through a simulation of tsunami intrusion

from the 2003 Tokachi-oki Earthquake into rivers on the Pacific coast.

2 MATHEMATICAL MODELS

2.1 *Governing equations*

In this study, similarly to the analysis by Yasuda et al. (2005), when Ursell number, U_r, is of the order of one, an integral of the Peregrine equation (Peregrine, D.H. 1967) is derived:

$$\frac{\partial q}{\partial t}+\frac{\partial}{\partial x}\left[\frac{q^2}{D}\right]+gD\frac{\partial \eta}{\partial x}=\frac{h^2}{3}\frac{\partial^3 q}{\partial t x^2}-\frac{C_f}{D^2}|q|q \qquad (1)$$

where q is the flow flux, t is the time coordinate, D is the water depth, x is the coordinate for the flow direction, g is the gravitational acceleration, η is the water level, h is the initial water depth, C_f is the bed resistance coefficient. This integral is applied as an equation of non-linear dispersive wave theory, where:

$$\frac{\partial \eta}{\partial t}+\frac{\partial q}{\partial x}=0 \qquad (2)$$

is the corresponding continuity equation. Furthermore, in consideration of application to generalized cross-sections of river channel, the integral of the Peregrine equation is expanded as:

$$\frac{\partial Q}{\partial t}+\frac{\partial}{\partial x}\left[\frac{Q^2}{A}\right]+gA\frac{\partial \eta}{\partial x}=\frac{R^2}{3}\frac{\partial^3 Q}{\partial t x^2}-\frac{C_f}{AD}|Q|Q \qquad (3)$$

where Q is the discharge of the river, A is the cross-sectional area of the flow and R is the hydraulic radius. The continuity equation is rewritten as:

$$\frac{\partial \eta}{\partial t}+\frac{1}{B}\frac{\partial Q}{\partial x}=0 \qquad (4)$$

where B is the width of water surface. The shallow-water equations that express flow flux in a generalized cross section are Eqs. (1) and (3), with the first term in the right-hand side omitted for each equation.

For the influence of bed shear force on tsunami, it was decided to apply an expression with a bed resistance coefficient determined by the relationship between water depth and bed material diameter, as shown in the second terms in the right-hand side of Eqs. (1) and (3). C_f is written as:

$$C_f=\frac{1}{\phi^2} \qquad (5)$$

where ϕ is the flow velocity coefficient determined according to small-scale bed morphology. This C_f and the frequently used Manning's roughness coefficient, n, have a relationship of $n^2=C_f h^{1/3}/g$ via a Manning's uniform-flow equation.

2.2 *Method of numerical analysis*

In non-linear dispersive wave equations like the Peregrine equation, time derivative terms are included not only in local terms but also in dispersion terms; therefore, it is necessary to use an implicit scheme to obtain appropriate solutions. Moreover, for equations with physical dispersive, application of a difference scheme that has a numerical dispersion term (i.e., a dominant truncation error term) will also be reflected in the results. In selecting a difference scheme, it is necessary to consider the truncation error characteristics. When considering computational efficiency and expansion to two-dimensional computation and other phenomena, a two-step mixed finite-difference method (Goto, C. 2003) that combines the staggered Leap-Frog method and the Thomas algorithm to allow for efficient implicit computation would be appropriate. In this study, it was decided to apply the two-step mixed finite-difference method that we used in a previous study(2005).

When applying the two-step mixed finite difference method to Eq. (3), the linear long-wave equation is explicitly solved by the Leap-Frog method in the first step as:

$$\frac{1}{\Delta t}\left[Q^*_{i+1/2}-Q^j_{i+1/2}\right]+\frac{gD}{\Delta x}\left[\eta^{j+1/2}_{i+1}-\eta^{j+1/2}_{i}\right]=0 \qquad (6)$$

In the second step, the convection term and the dispersion term are discretized and solved to fit tridiagonal matrices as:

$$\begin{aligned}&\frac{1}{\Delta t}\left[Q^{j+1}_{i+1/2}-Q^*_{i+1/2}\right]\\&+\frac{1}{4\Delta x}\left[\left\{\left(\frac{Q}{A}\right)^j_{i+3/2}Q^{j+1}_{i+3/2}-\left(\frac{Q}{A}\right)^j_{i-1/2}Q^{j+1}_{i-1/2}\right\}\right.\\&\left.+\left\{\left(\frac{Q}{A}\right)^j_{i+3/2}Q^{j}_{i+3/2}-\left(\frac{Q}{A}\right)^j_{i-1/2}Q^{j}_{i-1/2}\right\}\right]\\&=\frac{1}{3}\left(R^j_{i+1/2}\right)^2\frac{1}{\Delta t\Delta x^2}\\&\left[\left(Q^{j+1}_{i+3/2}-2Q^{j+1}_{i+1/2}+Q^{j+1}_{i-1/2}\right)\right.\\&\left.-\left(Q^{j}_{i+3/2}-2Q^{j}_{i+1/2}+Q^{j}_{i-1/2}\right)\right]\end{aligned} \qquad (7)$$

where Q^* is the intermediate value of $Q^{j+1}_{i+1/2}$ given by linear theory, and i and j are discretization steps for space and time, respectively.

Copyright © 2006 Taylor & Francis Group plc, London, UK

In a previous study, the author conducted a numerical simulation in which a smooth function was used to express the incident tsunami at the mouth of a river with a uniform bed slope. In that simulation, the convection term was discretized by the second-order central difference (Eq.7)). In this two-step mixed finite-difference method, there are two main truncation error terms. One is the third-order derivative term that appears in the process of the Leap-Frog difference and in discretization of the convection terms in the second step; this term causes numerical dispersion. The other is the fourth-order derivative term that appears in the process of discretization of the dispersion term; this term causes numerical viscosity. In such computation, computational instability will be of less concern if appropriate intervals for division of space and time are given.

This study takes a different approach, focusing on computation for a river with the generalized cross section, where changes in forms, such as the form of incident wave of tsunami and those of longitudinal and transverse river sections, cause unwanted high-frequency components. The scheme shown in Eq. (7), having a small numerical viscosity, if used in the computation of this study eventually results in having crucial instability because once high-frequency components are generated they do not readily attenuate but instead remain in the computational domain.

As one can see from the fact that theoretical solutions to a diffusive partial differential equation for $u(x,t)$ with a $2n$-th derivative term are given by

$$u = \exp[-k^{2n}\epsilon t]\exp[\mathbf{i}kt] \tag{8}$$

the higher order of the even-order derivative terms, the more effective is that term in suppressing higher-frequency components. Here, ϵ is the diffusion coefficient, k is the wave number and $\mathbf{i}$ is the imaginary unit. To implement stable computation while maintaining physical dispersion, a difference scheme that includes a truncation error term of higher even-order and focuses on suppressing high-frequency components should be adopted. One effective scheme that meets these conditions is the third-order upwind difference that has a fourth derivative term as the main truncation error term. In this case, in consideration of forming the tridiagonal matrix, the convection term can be discretized as:

$$\begin{aligned}\frac{1}{6\Delta x}\Bigg[&\psi_1\left\{\left(\frac{Q}{A}\right)^j_{i+5/2}Q^j_{i+5/2}\right\}\\ &+\psi_2\left\{\left(\frac{Q}{A}\right)^j_{i+3/2}Q^{j+1}_{i+3/2}+\left(\frac{Q}{A}\right)^j_{i+3/2}Q^j_{i+3/2}\right\}\\ &+\psi_3\left\{\left(\frac{Q}{A}\right)^j_{i+1/2}Q^{j+1}_{i+1/2}+\left(\frac{Q}{A}\right)^j_{i+1/2}Q^j_{i+1/2}\right\}\\ &+\psi_4\left\{\left(\frac{Q}{A}\right)^j_{i-1/2}Q^{j+1}_{i-1/2}+\left(\frac{Q}{A}\right)^j_{i-1/2}Q^j_{i-1/2}\right\}\\ &+\psi_5\left\{\left(\frac{Q}{A}\right)^j_{i-3/2}Q^j_{i-3/2}\right\}\Bigg]\end{aligned} \tag{9}$$

where $\psi_1 \sim \psi_5$ are upwind-coefficients determined depending on whether $Q^j_{i+1/2}$ is positive or negative.

Here, to compare the characteristics of Eqs. (7) and (9), numerical simulation was conducted (Figure 1). The incident condition for the simulation is that only 1/4 period of sine wave is incident at the beginning, followed by a constant water level. As one can tell from the figure, the equations agree very well except for a very small difference in phase at the end of the dispersed wave train.

Regarding computation of the shallow-water equation, the Leap-Frog method was applied to terms other than the convection term, and the first-order upwind difference scheme was applied to the convection term. In computation of the convection term in this equation, it is of course possible to enhance the accuracy by introducing the implicit scheme, such as was introduced for computation of the non-linear dispersive wave equation, or by applying difference schemes of higher-order accuracy. However, application of higher-accuracy schemes to such computation would present the possibility of water level overestimation resulting from the numerical Gibbs oscillation at the wave front, which is caused by the numerical dispersion of the Leap-Frog scheme and becomes more evident when the forward tilting of the tsunami wave is promoted. To avoid this, a first-order upwind difference scheme was applied, as it is expected to show appropriate

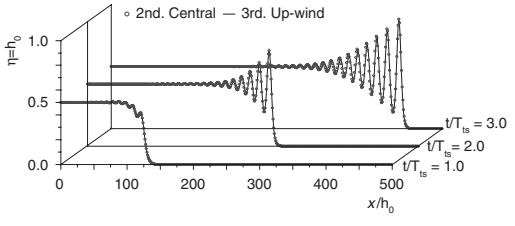

Figure 1. Comparison between second-order central difference and third-order upwind difference scheme in numerical analysis of Soliton dispersion phenomenon. (The third-order upwind difference scheme has a very slight delay in the phase of the wave train, relative to the second-order centered difference scheme, but the two agree very well in terms of wave front.)

numerical viscosity in numerical analyses of the same phenomena.

3 SIMULATIONS

3.1 *Tsunami runup in rivers on the Pacific Coast of Hokkaido from the 2003 Tokachi-oki Earthquake*

The tsunami generated by the Tokachi-oki Earthquake of September 2003 was confirmed to have intruded into the Tokachi, Kushiro, Saru and Mu rivers on the Pacific coast of Hokkaido (Figure 2). An undular bore from tsunami runup was videotaped in the Tokachi River by Japan's Self Defense Forces. The average channel bed slopes of these four rivers are about 1/5,000, 1/7,500, 1/750 and 1/1,000, respectively.

Water level fluctuations indicating tsunami intrusion were clearly observed. On the Tokachi River, the fluctuations were observed approximately 9.5 km in stream centerline distance from the mouth; in the Kushiro River, they were observed approximately 8 km from the mouth, where the channel suddenly narrows. On the Mu and the Saru Rivers, which have steeper channel bed slopes than the two rivers mentioned above, water level fluctuations believed to be caused by the tsunami were observed at the gauging stations nearest to the respective river mouths.

In this study, tsunami runup was simulated for the Tokachi River (Figure 3), based on the analysis method described in the previous sections. Figure 4 shows time waveforms of water level at 10-minute intervals up to four hours after the earthquake. These records were obtained at the Ohtsu, Tabikorai and Dousuiro (the flood way to connect branch to Tokachi River) gauging stations, where significant water level fluctuations

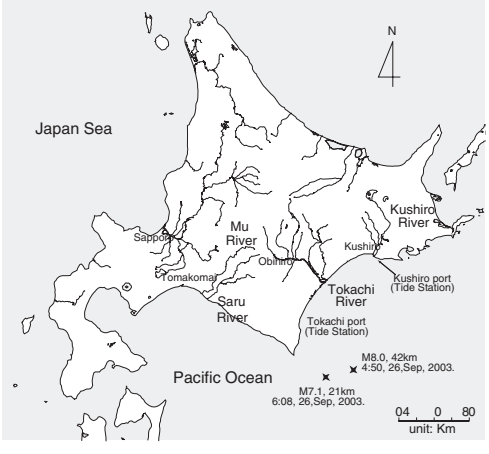

Figure 2. Map of Hokkaido Island and rivers affected by tsunami.

indicated the passage of tsunamis. Within four hours after the occurrence of earthquake, six tsunami waves with a period of 30–40 minutes arrived at the mouth of the Tokachi River. These waves ran up about 7 km from Ohtsu to Tabikorai in about 20 minutes. The time varied depending on the wave height at arrival at the mouth.

The water level gauges at the Ohtsu, Tabikorai and Dousuiro gauging stations have a measuring precision that allows them to detect water level fluctuations of around 2 cm, which is the magnitude of wind waves. They obtain water level measurements every second and output 15-sec averages at 10-minute intervals. It should be noted that although these observed values are highly reliable in terms of each output, they may not be able to fully express continuous waveforms (e.g., wave gradients) due to the observation intervals. This point should be borne in mind when using these observation values.

3.2 *River channel morphology*

The section for analysis was 20 km in stream centerline distance of the Tokachi River from the mouth. However, due to bends and other factors there are sections

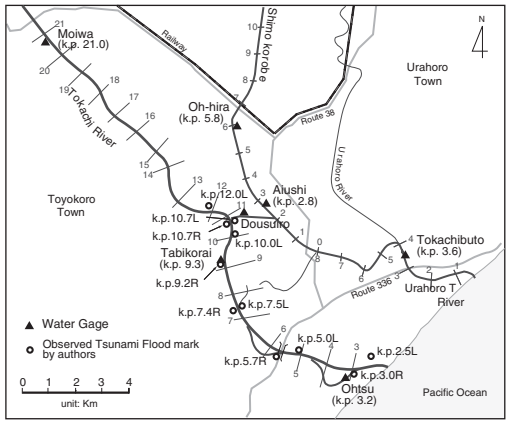

Figure 3. Location map of Tokachi River.

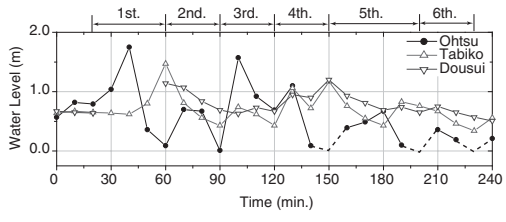

Figure 4. Water level records at 10-minute intervals for the four hours after the occurrence of earthquake. (*interpolated value, since the records did not have values for 0 m and below)

Copyright © 2006 Taylor & Francis Group plc, London, UK

where there is a large difference between the distance indicated by kilometer post (KP) and the stream centerline distance. Therefore, all longitudinal distances in this paper are expressed as stream centerline distances. Figure 5 shows an overview of longitudinal profile for this section of the Tokachi River: The average channel bed gradient is about 1/5,000 and the bed material diameter for this section is approximately 1 to 6 mm. The locations of Ohtsu, Tabikorai and Dousuiro gauging stations are shown in the upper frame of Figure 5. As for the transverse distances, the distance between the embankments of the subject section is about 1,000 m and the low-flow channel width is about 300 m.

It should be noted that hydraulic radius, R, is assigned as a coefficient of the dispersion term in the first term of the right-hand side of Eq.(3). In an non-uniform flow computation with a flow rate increasing by 500 m^3/s, R and average water depth showed close agreement at any flow rate. Therefore, it is considered reasonable to apply R to the computation of this term.

3.3 *Initial conditions*

3.3.1 *Estimation of bed morphology*

Generally, small-scale bed morphology is estimated based on a relationship between the dimensionless tractive force, τ^*, and the flow velocity coefficient, ϕ. As a result of applying this relationship, the section was roughly classified as having a flat bed with little changes from sediment movement. Here, the flow velocity coefficient is

$$\phi = 6 + 2.5 \ln\left(\frac{D}{2.5 d_s}\right) \tag{10}$$

as indicated by Engelund & Hansen (1967), where d_s is the average grain diameter of bed material.

3.3.2 *Estimation of initial flow rate*

Initial flow rate was estimated by an non-uniform flow computation in which the input flow rate increase was set at 20 m^3/s so that water levels at the time of earthquake occurrence could be most appropriately simulated for the Tabikorai, Dousuiro and Moiwa gauging stations. Calculated values and measured values at each observation point have the closest agreement at the flow rate of 220 m^3/s. In this non-uniform flow computation, the water level at the Ohtsu gauging station at the occurrence of earthquake was given as the water level at the downstream end of the section for analysis.

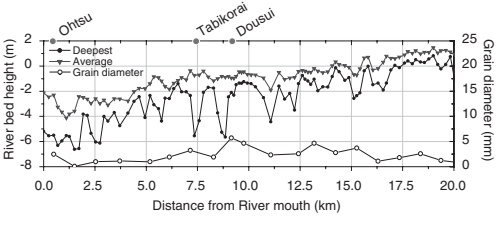

Figure 5. Longitudinal morphology and longitudinal distribution of average grain diameter in the Tokachi River.

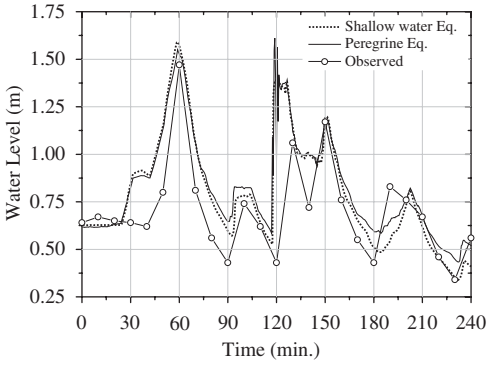
3.4 *Boundary conditions*

Boundary conditions for the upstream end were decided as follows: Precipitation records for multiple points along the Tokachi River revealed that although there was some precipitation in the catchment during the 24 hours before and the 24 hours after the earthquake, the rainfall was a small amount of about 30 mm; therefore, its influence on river flow rate was assumed to be negligible. Based on this, the flow rate at the upstream end was set in steady state at 220 m^3/s, which is the value obtained in the estimation above.

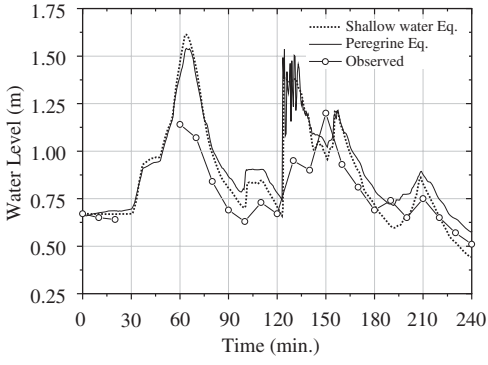
Next, for the boundary conditions at the downstream end, the water level observed at the Ohtsu gauging station at 10-minute intervals (the solid black line in Figure 4) was used after interpolation according to Δt. The reasons for using the Ohtsu values are the following: First, the Ohtsu gauging station is about 0.7 km from the mouth. Second, the non-uniform flow computation revealed that the water surface gradient of the section near the mouth that includes the Ohtsu gauging station was very small. The water level data routinely measured at Ohtsu Fishing Harbor at the mouth of Tokachi River did not include the values at the time of tsunami intrusion; therefore, we needed to interpolate the values missing from the Ohtsu gauging station values.

3.5 *Computational conditions*



Simulations were performed for a period of four hours from the occurrence of earthquake, during which tsunami intrusion was clearly detected. A spatial discrete interval, Δx, was set at 2 m to avoid aliasing errors and to attain satisfactory description of dispersed wave trains. Meanwhile, time discrete intervals, Δt, were set at 0.02 sec and 0.0002 sec, respectively, for the shallow-water equation and non-linear dispersive wave equation.

4 APPROPRIATENESS OF SIMULATIONS, AND DISCUSSION



4.1 *Comparison of water level: observed and simulated*

To confirm the appropriateness of the simulations, observed values were compared with the results of numerical computation based on the shallow-water equation and non-linear dispersive wave equation. As

Copyright © 2006 Taylor & Francis Group plc, London, UK

(a) Tabikorai gauging station (stream centerline distance: 7.5 km, KP9.3)

(b) Dousuiro gauging station (stream centerline distance: 9.0 km, KP10.8)

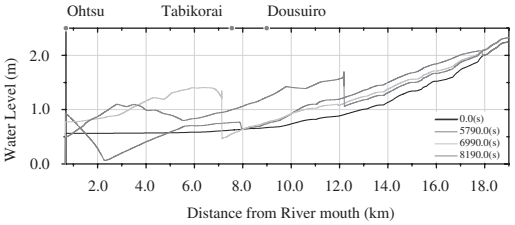
Figure 6. Water level: observed (at 10-minute intervals) and simulated. (Observed values and calculated values of the same time points were compared. Average difference within the simulated period shows a tendency of overestimation of slightly less than 10% for the shallow-water equation and about 15% for the non-linear dispersive wave equation.)

seen in Figures 6 (a) and (b), it can be said that simulations based on either of the governing equations successfully reproduced the arrival time of tsunami at each observation point. Water levels were reproduced with relatively high accuracy, although there was a tendency for calculated values to slightly exceed observed ones. It was also revealed by the computation based on the non-linear dispersive wave equation that only the third wave formed a clear undular bore.

In the first and third waves, differences were seen in some cases between the recorded and calculated water levels. The differences were attributed to the following.

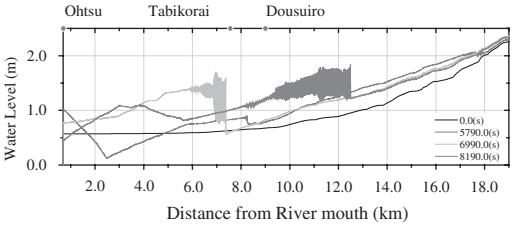
In the third wave, the difference between the recorded and calculated water levels was the greatest 130 minutes after the earthquake at both the Tabikorai and Dousuiro gauging stations. Because the shallow-water equation cannot describe the soliton dispersion phenomena (the apparent soliton dispersion at the wave front is actually caused by truncation error), reasons for such a difference can be hypothetically explained by considering the calculation results of the non-linear dispersive wave equation: Calculation results shown in Figure 6 indicate that both points saw the passage of the third tsunami wave, which was the only wave with a clear soliton dispersion at the wave front. Considering that the third wave passed through the observation points in the form of undular bore, it is assumed that the water level gauges captured the values at the troughs of the undular bore. This is why a great difference eventually appears between the calculation results and the water level records.

In the calculated water level values for the first wave, the highest and lowest points of the wave are overestimated by about 0.20 m. However, the causes of that overestimation have not been identified.



4.2 *Spatial waveforms*

As mentioned in the section above, based on simulations performed in this study the third wave is assumed to have generated a significant soliton dispersion. Figure 7 show computed spatial waveforms of this third wave for every 30 minutes. Figure 7(a) is based on the shallow-water equation, Figure 7(b) on the non-linear dispersive wave equation with the convection term discretized by a second-order central difference, and Figure 7(c) on the non-linear dispersive wave equation with the convection term discretized by a third-order upwind difference.



In Figure 7(a), waveforms at $t = 6990$ and 8190 sec seem to represent slightly soliton dispersion at the wave front. However, these are thought to be high-frequency components (the so-called numerical Gibbs oscillation), caused by numerical dispersion from the Leap-Frog method, which did not attenuate due to numerical viscosity associated with the first-order upwind difference.

In contrast to the waveforms in Figure 7(a), the waveforms at $t = 6990$ and 8190 sec in Figure 7 (b) and (c) show wave number dispersion, where the amplitude decreases with increasing distance from the wave front. The length of the section from the wave front to the end of the train gradually increases as the tsunami wave runs upstream. The authors lacked data on the length of the section with this soliton dispersion, and knowledge on the breaking limits for soliton dispersion, so it was not possible to determine whether Figure 7 (b) or (c) is more physically appropriate. Nonetheless, the results in Figure 7 (c) are thought to appropriately reflect the effects of physical dispersion terms alone, because Figure 1 show that second-order central and third-order upwind difference scheme are

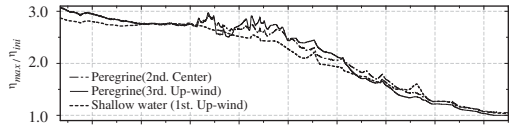
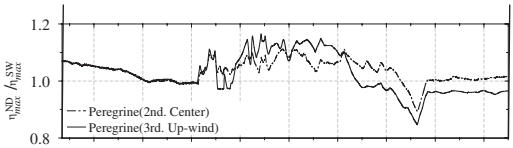
(a) Shallow-water equation

(b) Non-linear dispersive wave equation (central difference, second-order accuracy)



(c) Non-linear dispersive wave equation (upwind difference, third-order accuracy)

Figure 7. Spatial waveforms of the third wave (every 30 minutes).



little difference in the numerical simulation on soliton dispersion under ideal conditions, and moreover, intervention of numerical dispersion terms derived from Staggered Leap-Frog scheme can be better controlled by fourth-order numerical viscosity derived from third-order upwind difference.

4.3 *Maximum rate of water level increase and length of river section where wave number dispersion occurs*

A study was made on maximum rates of water level fluctuation associated with tsunami intrusion into rivers and on rates of water level increase at each point caused solely by wave number dispersion phenomena. The results are shown in Figure 8. In Figure 8(a), η_{ini} is the initial water level, η_{max} is the maximum water level; in Figure 8 (b), η_{max}^{ND} is the maximum water level obtained from the calculated values of the non-linear

(a) Maximum rate of water level increase

(b) Rate of water level increase associated with wave number dispersion phenomena

Figure 8. Maximum rate of water level increase and the section where wave number dispersion phenomena occurred.

dispersive wave equation and η_{max}^{SW} is that obtained from the shallow-water equation.

First, according to Figure 8 (a), the attenuation rate of tsunami wave height was not very great up to about 6 km from the mouth, but beyond this point the attenuation rate seems to be greater. This figure shows the results from the shallow-water equation and the nonlinear dispersive wave equation, and by looking at the latter, one can tell that a significant wave number dispersion phenomenon was generated after the tsunami wave arrived at the point about 6 km upstream of the mouth. Furthermore, although the amplitude of the wave train with high wave number caused by the wave number dispersion phenomenon was gradually attenuated, it was maintained 15 km and further upstream from the mouth.

As one can see from Figure 8(b), water level increases associated with wave number dispersion phenomena occur in a section over several kilometers. The rate of water level increase is at least 10% under either difference scheme and around 15% under a third-order upwind difference where interference of the numerical dispersion term is small.

4.4 *Discussions on actual phenomena based on simulation results*

4.4.1 *Flood channel inundation*

Yasuda et al. (2004) conducted a trace survey and an analysis of water level records for the runup of this tsunami in this river. Based on the survey and analysis they discussed the possibility of the tsunami reaching the flood channel. Figure 9 shows the relationship between the maximum water level envelope and the elevation of the flood channels. According to this figure, it is highly likely that flood channel

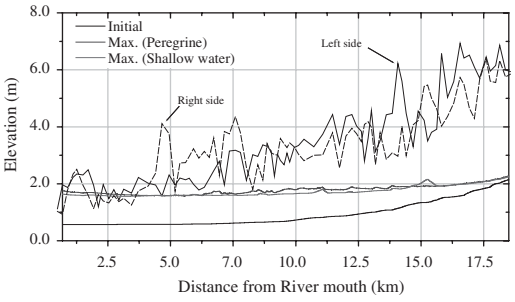

Figure 9. Relationship between maximum water level and flood channel height.

Figure 10. Videotaped undular bore in Tokachi river at 3.2 km upstream from the mouth on 6:30, 26th Sep., 2003 by Japan's Self Defense Force.

inundation took place on the right bank side and on a part of the left bank up to at least 3.7 km (KP 6.0) from the mouth. These results agree well with results obtained in the trace survey, although according to the figure there is no flood channel inundation on the right bank near 3.2 km (KP 5.7) whereas vegetation knocked down in the upstream direction was confirmed in the trace survey and there is no inundation on the left bank at 5.6 km (KP 7.5) where inundation traces were also confirmed.

4.4.2 *Using video footage to verify computation results*

An undular bore formed by tsunami runup was videotaped in the Tokachi River by Japan's Self Defense Forces about 100 minutes after the occurrence of the earthquake, at the point around 3.2 km (KP5.7) upstream of the mouth (Figure 10). As one can tell from Figure 6 and other data, this is the third wave. The numerical analysis shows that a rapid forward inclination of the wave front of the third wave takes place to form an undular bore near a point 5.0 km from the mouth about 108 minutes after the earthquake. The

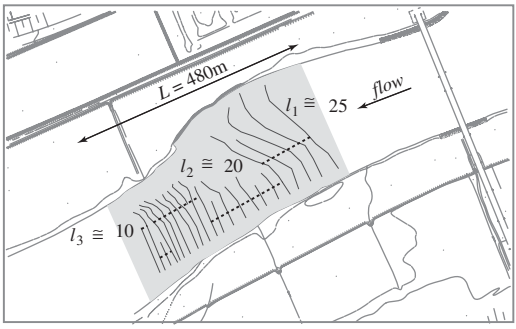

Figure 11. Wavelengths of soliton wave trains videotaped on the Tokachi River.

discrepancy can be interpreted as follows: When passing Ohtsu, the third wave has slightly greater steepness than the measured steepness, but this is not reflected in the observed value due to the 10-minute observation intervals. Since the wave steepness obtained from water level records at Ohtsu and used as the boundary conditions is less than the observed steepness, undular bore formation appears further upstream in calculations than in the observations.

Wavelengths of the videotaped soliton wave train were measured (Figure 11). The video frame that most clearly captured the tsunami was selected, and from there, wave crests of the tsunami wave were mapped on a plane (the solid lines on water surface in Figure 11) and distances between the crest lines were measured on the dotted lines in Figure 11. Distances between the wave crests of the wave group located most upstream, l_1, were about 25 m with some variations, those for l_2 were about 20 m and those for l_3 were about 10 m. As mentioned earlier, the calculated appearance positions of the soliton wave trains were farther upstream than the position observed in the video. In a comparison of distances between the wave crests, however, the values measured as shown in the figure and the calculated values showed close agreement. Nonetheless, there is room for further examination on the validity of the individual soliton waves in the wave train obtained by the non-linear dispersive wave equation.

5 CONCLUSIONS

One-dimensional analysis for tsunami runup in rivers was presented, and its appropriateness was confirmed by using it to reproduce actual phenomena. The results show that although this is a simple analysis method, calculated values and measured values agree well in terms of arrival time, maximum water level and other values. Questions remain regarding certain details, but the study clarifies that water level increases associated with wave number dispersion phenomena occur

Copyright © 2006 Taylor & Francis Group plc, London, UK

over a long section and on a considerable scale. In numerical analyses of these phenomena, the non-linear dispersive wave equation should be applied as the governing equation, and numerical computation should be performed based on careful consideration of calculation efficiency and characteristics of truncation errors. Continuous discussions are needed on the influence of sharp bends and meso-scale bed morphology on the phenomena and on cases of large finite amplitudes.

ACKNOWLEDGEMENTS

The author would like to thank the Hokkaido Development Agency of the Ministry of Land, Infrastructure and Transport and its Obihiro Development and Construction Department for supporting this study and providing valuable reference materials, including water level records and river channel morphology data.

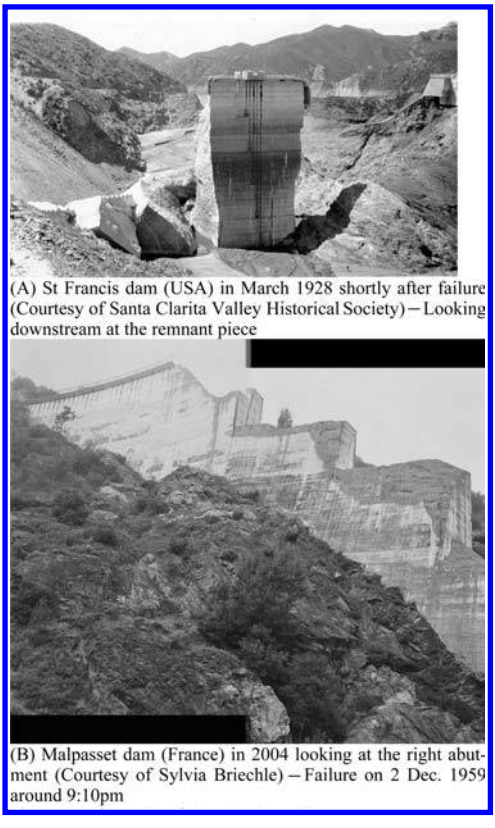
Analytical solutions of laminar and turbulent dam break wave



H. Chanson
Civil Engineering, The University of Queensland, Brisbane, Australia

ABSTRACT: Modern predictions of dam break wave rely often on numerical predictions validated with limited data sets. Basic theoretical studies were rare during the past decades. Herein simple solutions of the dam break wave are developed using the Saint-Venant equations for an instantaneous dam break with a semi-infinite reservoir in a wide rectangular channel initially dry. New analytical equations are obtained for both turbulent flow and laminar flow motion on horizontal and sloping inverts with non-constant friction factor. The results are validated by successful comparisons between theoretical results and several experimental data sets. The theoretical developments yield simple explicit analytical expressions of the dam break wave with flow resistance. The results compare well with experimental data and more advanced theoretical solutions. The developments are simple, yielding nice pedagogical applications of the method of characteristics for horizontal and sloping channels. These analytical solutions may be used to validate numerical solutions, while the simplicity of the equations allows some extension to more complex fluid flows (e.g. non-Newtonian fluids).

1 INTRODUCTION

Dam break waves have been responsible for numerous losses of life (e.g. Fig. 1). Figure 1 illustrates two tragic accidents. Related situations include flash flood runoff in ephemeral streams, debris flow surges and tsunami runup on dry coastal plains. In all cases, the surge front is a sudden discontinuity characterised by extremely rapid variations of flow depth and velocity. Dam failures motivated basic studies on dam break wave, including the milestone contribution by Ritter (1892) following the South Fork (Johnstown) dam disaster (USA, 1889). Physical modelling of dam break wave is relatively limited despite a few basic experiments (Table 1). In retrospect, the experiments of Schoklitsch (1917) were well ahead of their time, and demonstrated that Armin von Schoklitsch (1888–1968) had a solid understanding of both physical modelling and dam break processes.

For the last 40 years, there have been substantial efforts in dam break research, in particular with the European programs CADAM and IMPACT, and some American programs. These efforts were associated with the development of numerous numerical models and a few physical model studies. But, at a few exceptions, there has been no new theoretical developments since the basic works of Dressler (1952) and Whitham (1955) for horizontal channel and Hunt (1982,1984) for sloping channel. There have been also contradictory arguments on flow fundamentals. For example, some measurements highlighted a boundary layer region in the surging wave leading edge

*D: initial reservoir height; L: channel length; W: channel width.

(e.g. Mano 1984, Davies 1988, Fujima and Shuto 1990, Chanson 2005c) while others obtained quasi-ideal vertical velocity distributions (Estrade 1967, Wang 2002, Jensen et al. 2003). Most studies were restricted to Newtonian fluids, but a few (e.g. Piau 1996, Chanson et al. 2006), while air entrainment at the shock leading edge was nearly always ignored (Chanson 2004a).

This study describes simple analytical solutions for instantaneous dam break wave based upon the method of characteristics. The solutions are developed for initially-dry horizontal and sloping channels with either laminar or turbulent motion assuming non-constant friction coefficient. Results are compared with several data sets obtained in large-size facilities. It is the aim of this work to provide simple explicit solutions of dam break wave problems that are easily understood by students, young researchers and professionals.

2 DAM BREAK WAVE ON A HORIZONTAL CHANNEL

2.1 *Presentation*

A dam break wave is the flow resulting from a sudden release of a mass of fluid in a channel. For one-dimensional applications, the continuity and momentum equations yield the Saint-Venant equations:

$$\frac{\partial d}{\partial t} + \frac{A}{B}\frac{\partial V}{\partial x} + V\frac{\partial d}{\partial x} + \frac{V}{B} * \left(\frac{\partial A}{\partial x}\right)_{d=constant} = 0 \quad (1)$$

$$\frac{\partial V}{\partial t} + V\frac{\partial V}{\partial x} + g\frac{\partial d}{\partial x} + g\,(S_f - S_o) = 0 \quad (2)$$

where d is the water depth, V is the flow velocity, t is the time, x is the horizontal co-ordinate with $x = 0$ at the dam, S_o is the bed slope ($S_o = \sin\theta$), θ is the angle between invert and horizontal with $\theta > 0$ for downward slopes, and S_f is the friction slope (Liggett 1994, Viollet et al. 2002, Chanson 2004b).

The Saint-Venant equations cannot be solved analytically usually because of non-linear terms that include the friction slope:

$$S_f = \frac{f}{2}\frac{V^2}{g\,D_H} \quad (3)$$

where D_H is the hydraulic diameter and f is the Darcy-Weisbach friction factor that is a non linear function of Reynolds number and relative roughness.

For a prismatic rectangular channel, Equations (1) and (2) yield:

$$\frac{\partial d}{\partial t} + \frac{\partial (d\,V)}{\partial x} = 0 \quad (4)$$

$$\frac{\partial V}{\partial t} + V\frac{\partial V}{\partial x} + g\frac{\partial d}{\partial x} + \frac{f}{2}\frac{V^2}{D_H} = g\,S_o \quad (5)$$

2.1.1 *Ideal fluid flow solution*

For a frictionless dam break in a wide horizontal channel, the analytical solution of Equations (4) and (5) yields Ritter solution (Ritter 1892):

$$U = 2\sqrt{g\,D} \quad (6)$$

$$\frac{x}{t\sqrt{g\,D}} = 2 - 3\sqrt{\frac{d}{D}} \quad (7)$$

where U is the wave front celerity (Fig. 2). Equation (7) was first derived by Barré de Saint Venant (1871).

Equations (6) and (7) give the wave front celerity and instantaneous free-surface profile at any instant $t > 0$. The flow velocity everywhere may be derived from the method of characteristics.

2.1.2 *Real fluid flow solution*

Let us consider an instantaneous dam break in a rectangular, prismatic channel with bed friction and for a semi-infinite reservoir. The turbulent dam break flow

Copyright © 2006 Taylor & Francis Group plc, London, UK

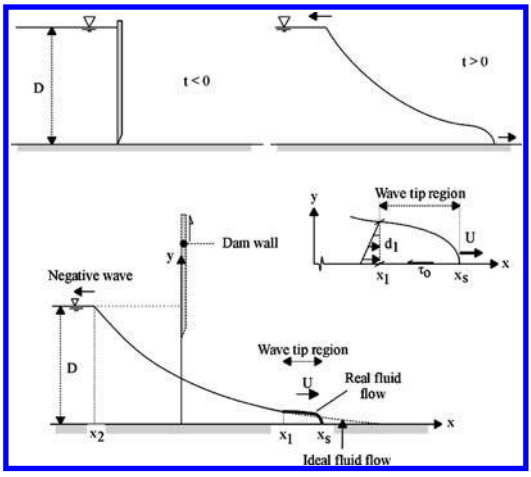

Figure 2. Sketch of dam break wave in a horizontal channel.

is analysed as an ideal-fluid flow region behind a flow resistance-dominated tip zone (Fig. 2). Whitham (1955) introduced this conceptual approach that was used later by other researchers (e.g. Piau 1996, Debiane 2000), but these mathematical developments differ from the present simple solution.

In the wave tip region ($x_1 \leq x \leq x_s$, Fig. 2), the flow velocity does not vary rapidly in the wave tip zone (Dressler 1954, Estrade 1967, Liem and Kongeter 1999). If the flow resistance is dominant, and the acceleration and inertial terms are small, the dynamic wave equation (Eq. (5)) may be reduced into a diffusive wave equation. Assuming that the flow velocity in the tip region is about the wave front celerity U, Equation (5) yields:

$$\frac{\partial d}{\partial x} + \frac{f}{8}\frac{U^2}{g\,d} = 0 \qquad \text{Wave tip region} \qquad (8)$$

In the ideal fluid flow region behind the friction-dominated tip region, Equations (4) and (5) are used with $f = 0$.

Chanson (2005a,b) solved analytically Equations (4), (5) and (8) assuming a constant Darcy friction factor in the wave tip region. In the following paragraphs, the method will be extended to non-constant friction factor.

The solutions involve the conservation of mass. That is, the mass of fluid in motion ($x_2 \leq x \leq x_s$) must equal the initial mass of fluid at rest ($x_2 \leq x \leq 0$):

$$\int_{x_2}^{x_s} d\,dx = -x_2\,D \qquad \text{at any time t} \qquad (9)$$

In Equation (9), right handside term, the negative sign indicates that the negative wave propagates upstream (Fig. 2) and that $x_2 < 0$.

2.2 *Solution for turbulent flow motion ($S_o = 0$)*

For turbulent motion, the flow resistance may be approximated by the Altsul formula first proposed in 1952:

$$f = 0.1\left(1.46\frac{k_s}{D_H} + \frac{100}{Re}\right)^{1/4} \qquad (10a)$$

where k_s is the equivalent sand roughness height, Re is the Reynolds number ($Re = \rho V D_H/\mu$), and ρ and μ are the fluid density and dynamic viscosity respectively. Equation (10) is a simplified expression that satisfies the Moody diagram and which may be used to initialise the calculations with the Colebrook-White formula (Idelchik 1969, Chanson 2004b).

Assuming that Equation (10) holds in unsteady flows, and for a wide channel (i.e. $D_H \approx 4\,d$), it may be rewritten as:

$$f = \frac{1}{\left(\frac{d}{D}\right)^{1/4}} G^{1/4} \qquad (10b)$$

where the dimensionless term G equals:

$$G = 3.65\text{ E-}5\,\frac{k_s}{D} + \frac{2.5\text{ E-}3}{Re_D\,\frac{U}{\sqrt{g\,D}}} \qquad (11)$$

and $Re_D = \rho\sqrt{g\,D^3}/\mu$ is a dimensionless Reynolds number defined in terms of the initial reservoir height D and fluid properties.

The integration of Equation (9) gives the shape of the wave front:

$$\frac{d}{D} = \left(\frac{9}{32}G^{1/4}\left(\frac{U}{\sqrt{g\,D}}\right)^2\frac{x_s - x}{D}\right)^{4/9} \qquad \text{Wave tip region} \qquad (12)$$

for turbulent dam break wave.

Combining Equations (4), (5), (8), (9) and (12), the flow properties at the transition between the wave tip and ideal-fluid regions are:

$$\frac{d_1}{D} = \left(\frac{9}{32}G^{1/4}\left(\frac{U}{\sqrt{g\,D}}\right)^2\frac{x_s - x_1}{D}\right)^{4/9} \qquad (13)$$

$$\frac{x_1}{t\sqrt{g\,D}} = \left(\frac{3}{2}\frac{U}{\sqrt{g\,D}} - 1\right) \qquad (14)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

The conservation of mass (Eq. (9)) yields an explicit relationship between the wave celerity U and time t:

$$\frac{\frac{32}{13}\left(1 - \frac{1}{2}\frac{U}{\sqrt{g\,D}}\right)^{7/2}}{G^{1/4}\left(\frac{U}{\sqrt{g\,D}}\right)^{2}} = \sqrt{\frac{g}{D}}\,t \qquad (15)$$

as well as the location of the wave leading edge:

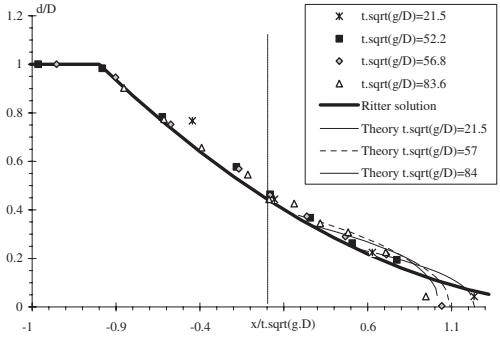
$$\frac{x_s}{D} = \left(\frac{3}{2}\frac{U}{\sqrt{g\,D}} - 1\right)\sqrt{\frac{g}{D}}\,t + \frac{32}{9}\frac{1}{G^{1/4}\left(\frac{U}{\sqrt{g\,D}}\right)^{2}}\left(1 - \frac{1}{2}\frac{U}{\sqrt{g\,D}}\right)^{9/2} \qquad (16)$$

The instantaneous free-surface profile is then:

$$\frac{d}{D} = 1 \qquad x \le x_2 \qquad (17a)$$

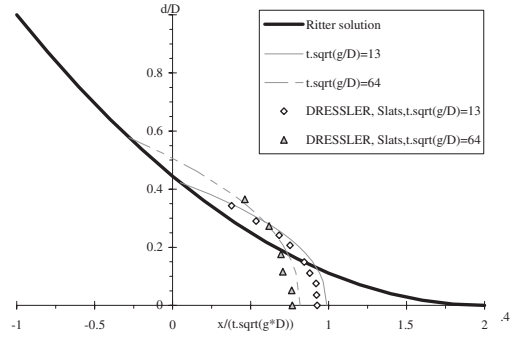
$$\frac{d}{D} = \frac{1}{9}\left(2 - \frac{x}{t\sqrt{g\,D}}\right)^{2} \qquad x_2 \le x \le x_1 \qquad (17b)$$

$$\frac{d}{D} = \left(\frac{9}{32}G^{1/4}\left(\frac{U}{\sqrt{g\,D}}\right)^{2}\frac{x_s - x}{D}\right)^{4/9} \qquad x_1 \le x \le x_s \qquad (17c)$$



$$\frac{d}{D} = 0 \qquad x_s \le x \qquad (17d)$$

where G is defined in Equation (11).



Equation (15) gives the wave front celerity at any instant t (t > 0), Equations (16) and (17) provide the entire free-surface profile, and the flow velocity may be deduced everywhere.

The analytical solution was compared systematically with several experimental studies (Table 1). Figure 3 shows some examples illustrating the good agreement between theory and experiments. Figure 3 shows instantaneous free-surface profiles for different types of invert and different times from dam break. The comparative analysis suggested that the results were sensitive to the choice of the equivalent sand roughness height k_s and that its selection must be based upon a match with instantaneous free-surface profiles. Alternate comparisons with wave front celerity or location data are approximate and often unsuitable.

Present results were also compared successfully with the analytical solutions of Dressler (1952), Whitham (1954) and Chanson (2005b). The differences were small and much smaller than experimental uncertainties.

(A) Experiments of Cavaillé (1965) with smooth invert

(B) Experiments of Dressler (1954) with slats - Calculations assuming $k_s/D = 0.2$

Figure 3. Instantaneous free-surface profiles: comparison between the present theory and experiments (turbulent flow motion).

2.3 *Solution for laminar flow motion ($S_o = 0$)*

In very viscous fluids, the flow motion is laminar and the resistance must be estimated accordingly. Some researchers argued that the flow resistance in unsteady flows may differ from classical steady flow estimates and they suggested that the friction factor may be estimated as: $f = \alpha\,64/Re$ where α is a correction coefficient and $\alpha = 1$ for steady flows (e.g. Aguirre-Pe et al. 1995, Debiane 2000). For a wide channel (i.e. $D_H \approx 4\,d$), the Darcy friction factor in the wave tip region becomes:

$$f = \frac{16\,\alpha}{Re_D\,\frac{U}{\sqrt{g\,D}}\,\frac{d}{D}} \qquad (18)$$

The integration of Equation (8) yields the shape of wave tip region for a laminar flow motion:

$$\frac{d}{D} = \sqrt[3]{6\,\alpha\,\frac{\mu\,U}{\rho\,g\,D^2}\,\frac{x_s - x}{D}} \qquad (19)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

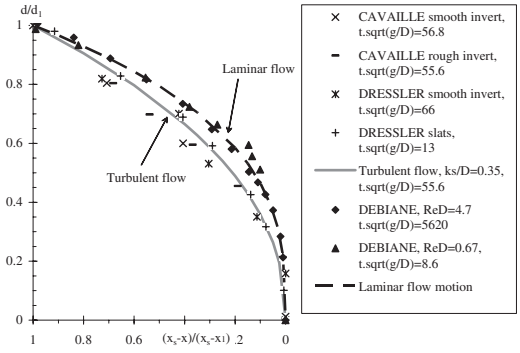


Figure 4. Dimensionless free-surface profiles in the wave tip region – Comparison between Equations (12) and (19), and experimental data (Laminar flow: Debiane 2000, Turbulent flow: Dressler 1954, Cavaillé 1965).

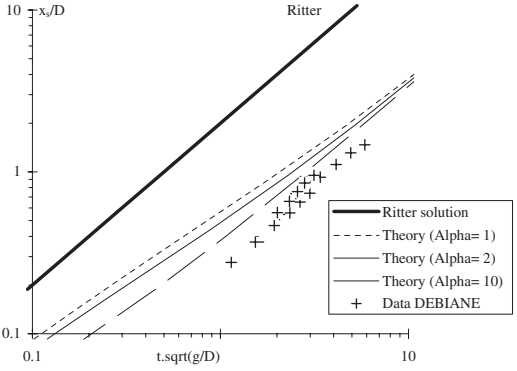

Figure 5. Dimensionless wave front location in laminar dam break flow motion – Comparison between Equations (21), ideal fluid flow solution and experiments (Debiane 2000).

Equation (19) is compared with experimental data and with Equation (12) in Figure 4. Equation (19) was found to be in qualitative agreement with experimental data by Tinney and Bassett (1961), Aguirre-Pe et al. (1995) and Debiane (2000), and the analytical solution of Hunt (1994).

Figure 4 presents the dimensionless water depth d/d_1 as function of the dimensionless distance $(x_s - x)/(x_s - x_1)$ where the subscripts s and 1 refer respectively to the wave leading edge and to the transition between ideal fluid and wave tip regions. Note the good agreement between Equations (12) and (19) and their corresponding experimental data. The results suggest further that the wave front is comparatively steeper in a laminar dam break wave than in turbulent flow motion.

For a rectangular horizontal channel, the integration of the continuity equation within the boundary conditions gives a simple expression of the wave front celerity:

$$\frac{1}{8\,\alpha}\,Re_D\,\frac{\left(1 - \frac{1}{2}\frac{U}{\sqrt{g\,D}}\right)^5}{\frac{U}{\sqrt{g\,D}}} = \sqrt{\frac{g}{D}}\,t \qquad (20)$$

while the location of the wave leading edge is:

$$\frac{x_s}{D} = \left(\frac{3}{2}\frac{U}{\sqrt{g\,D}} - 1\right)\sqrt{\frac{g}{D}}\,t + \frac{1}{6\,\alpha}\,\frac{Re_D}{\frac{U}{\sqrt{g\,D}}}\left(1 - \frac{1}{2}\frac{U}{\sqrt{g\,D}}\right)^6 \qquad (21)$$

The instantaneous free-surface profile is:

$$\frac{d}{D} = 1 \qquad x \le x_2 \qquad (22a)$$

$$\frac{d}{D} = \frac{1}{9}\left(2 - \frac{x}{t\sqrt{g\,D}}\right)^2 \qquad x_2 \le x \le x_1 \qquad (22b)$$

$$\frac{d}{D} = \sqrt[3]{6\,\alpha\,\frac{\mu\,U}{\rho\,g\,D^2}\,\frac{x_s - x}{D}} \qquad x_1 \le x \le x_s \qquad (22c)$$

$$\frac{d}{D} = 0 \qquad x_s \le x \qquad (22d)$$

The characteristic locations x_1 and x_2 are given by:

$$\frac{x_1}{\sqrt{g\,D}\,t} = \left(\frac{3}{2}\frac{U}{\sqrt{g\,D}} - 1\right) \qquad (23)$$

$$\frac{x_2}{t\sqrt{g\,D}} = -1 \qquad (24)$$

A comparison with experimental results is restricted by a lack of detailed measurements. Debiane (2000) presented a rare set of experimental data performed in a 3 m long 0.3 m wide channel using glucose-syrup solutions of dynamic viscosities between 12 to 170 Pa.s. Figures 4 and 5 show some comparison between theory and experiments during the early stages of the dam break. Figure 5 presents a comparison in terms of dimensionless wave front location in horizontal channel. Experimental data are compared with Equation (21) for three values of α and with an ideal dam break (Ritter solution).

Experiments with very viscous solutions showed a trend similar to theoretical calculations (Present study, Piau and Debiane 2005) (Fig. 4). But the data gave consistently a slower wave front propagation as observed in Figure 5. Debiane experienced some experimental difficulties (Debiane 2000, pp. 161–163). The gate opening was relatively slow and could not be considered to be an instantaneous dam break. Some fluid

Copyright © 2006 Taylor & Francis Group plc, London, UK

remained attached to the gate while other portions were projected away. Sidewall effects were also observed for the most viscous solutions ($\mu = 170$ Pa.s) including some fluid crystallisation next to the walls at the shock front. Debiane's comments underlined the difficulties associated with physical modelling, but his advice is nonetheless useful for future experiments.

3 DAM BREAK WAVE ON A SLOPING CHANNEL

3.1 *Presentation*

The above development were obtained for a horizontal channel ($S_o = 0$). They may be extended to situations with some initial flow motion and to sloping invert. The former development was discussed by Chanson (2005a) and the latter case is discussed below.

For an ideal fluid flow, the friction slope is zero and Ritter solution may be extended using a method of superposition (Peregrine and Williams 2001, Chanson 2005a). For a mild, constant slope, the solution of the Saint Venant equations is:

$$\frac{d}{D} = \frac{1}{9}\left(2 + \frac{1}{2}\sqrt{\frac{g}{D}}\,S_o\,t - \frac{x}{t\sqrt{g\,D}}\right)^2 \qquad -1 \leq \frac{x}{t\sqrt{g\,D}} \leq 2 + \frac{1}{2}\,S_o\sqrt{\frac{g}{D}}\,t \tag{25}$$

$$\frac{V}{\sqrt{g\,D}} = \frac{2}{3}\left(1 + S_o\sqrt{\frac{g}{D}}t + \frac{x}{t\sqrt{g\,D}}\right) \qquad -1 \leq \frac{x}{t\sqrt{g\,D}} \leq 2 + \frac{1}{2}\,S_o\sqrt{\frac{g}{D}}\,t \tag{26}$$

where the bed slope S_o is positive for a downwards lope. The celerity of the wave leading edge is:

$$\frac{U}{\sqrt{g\,D}} = 2 + S_o\sqrt{\frac{g}{D}}\,t \tag{27}$$

For a channel inclined upwards (e.g. beach face), the wave front stops ($U = 0$) at: $t = -2\sqrt{D/g}S_o$.

3.2 *Solution for turbulent flow motion*

Considering a turbulent flow down a constant slope, the momentum equation in the wave tip region becomes:

$$\frac{\partial d}{\partial x} + \frac{f}{8}\frac{U^2}{g\,d} = S_o \qquad \text{Wave tip region} \tag{28}$$

where the Darcy friction factor f satisfies Equation (10). The complete integration yields a complicated

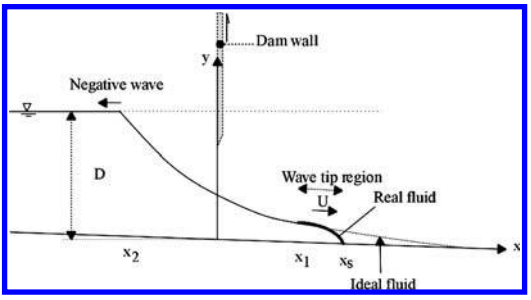

Figure 6. Definition sketch of dam break wave in a sloping channel.

result that is presented in the Appendix. A Taylor series expansion of the solution gives the earlier result:

$$\frac{d}{D} = \left(\frac{9}{32}\,G^{1/4}\left(\frac{U}{\sqrt{g\,D}}\right)^2\frac{x_s - x}{D}\right)^{4/9} \qquad \text{Wave tip region} \tag{12}$$

where the dimensionless term G is:

$$G = 3.65\text{ E-}5\,\frac{k_s}{D} + \frac{2.5\text{ E-}3}{Re_D\,\frac{U}{\sqrt{g\,D}}} \tag{11}$$

and $Re_D = \rho\sqrt{g\,D^3}/\mu$. Equation (12) implies that both acceleration, inertial and gravity terms are small in the wave tip region. The assumption is valid on mild slope and more generally for $S_f \gg S_o$. Equation (12) was successfully compared with field observations in the Casino I powerplant tunnel by Montuori(1965).

Using Equation (12), the integration of the conservation of mass (Eq. (9)) yields an explicit relationship between the wave front celerity U and the time since dam break t:

$$\frac{32}{13}\frac{\left(1 + \frac{1}{2}\sqrt{\frac{g}{D}}\,S_o\,t - \frac{1}{2}\frac{U}{\sqrt{g\,D}}\right)^{7/2}}{G^{1/4}\left(\frac{U}{\sqrt{g\,D}}\right)^2} = t\sqrt{\frac{g}{D}} \tag{29}$$

while the location of the wave front is:

$$\frac{x_s}{D} = \left(\frac{3}{2}\frac{U}{\sqrt{g\,D}} - \sqrt{\frac{g}{D}}\,S_o\,t - 1\right)\sqrt{\frac{g}{D}}\,t + \frac{32}{9}\frac{\left(1 + \frac{1}{2}\sqrt{\frac{g}{D}}\,S_o - \frac{1}{2}\frac{U}{\sqrt{g\,D}}\right)^{9/2}}{G^{1/4}\left(\frac{U}{\sqrt{g\,D}}\right)^2} \tag{30}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

The instantaneous free-surface profile at any instant $t > 0$ is:

$$\frac{d}{D} = 1 \qquad x \le x_2 \quad (31a)$$

$$\frac{d}{D} = \frac{1}{9}\left(2 - \frac{x}{t\sqrt{g\,D}}\right)^2 \qquad x_2 \le x \le x_1 \quad (31b)$$

$$\frac{d}{D} = \left(\frac{9}{32} G^{1/4} \left(\frac{U}{\sqrt{g\,D}}\right)^2 \frac{x_s - x}{D}\right)^{4/9} \qquad x_1 \le x \le x_s \quad (31c)$$

$$\frac{d}{D} = 0 \qquad x_s \le x \quad (31d)$$

while the characteristic location x_1 satisfies:

$$\frac{x_1}{D} = \left(\frac{3}{2}\frac{U}{\sqrt{g\,D}} - \sqrt{\frac{g}{D}} S_o\, t - 1\right)\sqrt{\frac{g}{D}}\, t \quad (32)$$

Equations (29), (30), (31) and (32) define the entire free-surface at a given instant. Note that, in Equation (29), the time t appears in both right and left handside terms. Equation (29) is hence non-linear.

3.3 *Solution for laminar flow motion*

The same reasoning may apply to a laminar flow motion. The exact solution in terms of wave front celerity is:

$$\frac{1}{8\,\alpha}\frac{\rho\sqrt{g\,D^3}}{\mu}\frac{\left(1 + \frac{1}{2}\sqrt{\frac{g}{D}} S_o\, t - \frac{1}{2}\frac{U}{\sqrt{g\,D}}\right)^5}{\frac{U}{\sqrt{g\,D}}} = \sqrt{\frac{g}{D}}\, t \quad (33)$$

The wave front location is given by:

$$\frac{x_s}{D} = \left(\frac{3}{2}\frac{U}{\sqrt{g\,D}} - \sqrt{\frac{g}{D}} S_o\, t - 1\right)\sqrt{\frac{g}{D}}\, t + \frac{\frac{4}{f}}{\frac{U^2}{g\,D}}\left(1 + \frac{1}{2}\sqrt{\frac{g}{D}} S_o\, t - \frac{1}{2}\frac{U}{\sqrt{g\,D}}\right)^4 \quad (34)$$

The instantaneous free-surface equations are:

$$\frac{d}{D} = 1 \qquad x \le x_2 \quad (35a)$$

$$\frac{d}{D} = \frac{1}{9}\left(2 + \frac{1}{2}\sqrt{\frac{g}{D}} S_o\, t - \frac{x}{\sqrt{g\,D}\,t}\right)^2 \qquad x_2 \le x \le x_1 \quad (35b)$$

$$\frac{d}{D} = \sqrt[3]{6\,\alpha \frac{\mu\, U}{\rho\, g\, D^2}\frac{x_s - x}{D}} \qquad x_1 \le x \le x_s \quad (35c)$$

$$\frac{d}{D} = 0 \qquad x_s \le x \quad (35d)$$

The location of the transition between ideal fluid and wave tip regions is:

$$\frac{x_1}{D} = \frac{3}{2}\frac{U}{\sqrt{g\,D}} - S_o\sqrt{\frac{g}{D}}\, t - 1 \quad (36)$$

Note also that the expression of the wave front celerity (Eq. (33)) is a non-linear equation.

3.4 *Remarks*

The writer was alerted that Takahashi (1991) and Toro (2001) presented some related developments for dam break wave down a sloping chute.

4 DISCUSSION

The present theoretical solutions are based upon a few key assumptions. These include (a) $V(x,t) = U(t)$ in the wave tip region and (b) some discontinuity in terms of $\partial d/\partial x$, $\partial V/\partial x$ and bed shear stress at the transition between wave tip and ideal fluid flow regions (i.e. $x = x_1$). Turbulent flow data tended to support the first approximation (a). For example, the data of Estrade (1967), Lauber (1997) and Liem and Kongeter (1999). The experimental results showed little longitudinal variations in velocity in the wave tip region. Further the comparisons between present diffusive wave solutions and experimental results were successful for a fairly wide range of experimental data obtained independently (Fig. 4). Such comparisons constitute a solid validation. Whitham (1955) and Dressler (1952) produced two very different analytical solutions with and without a discontinuity at the transition between ideal flow region and wave tip region (e.g. Fig. 7) Figure 7 illustrates differences in longitudinal bed shear stress distributions between the different theoretical models. Yet all theories gave close results in terms of wave front celerity and instantaneous free-surface profiles and good agreement with experimental data. All these suggest little effects of some discontinuity at $x = x_1$, although the physics of a constant Darcy friction factor is questionable!

Copyright © 2006 Taylor & Francis Group plc, London, UK

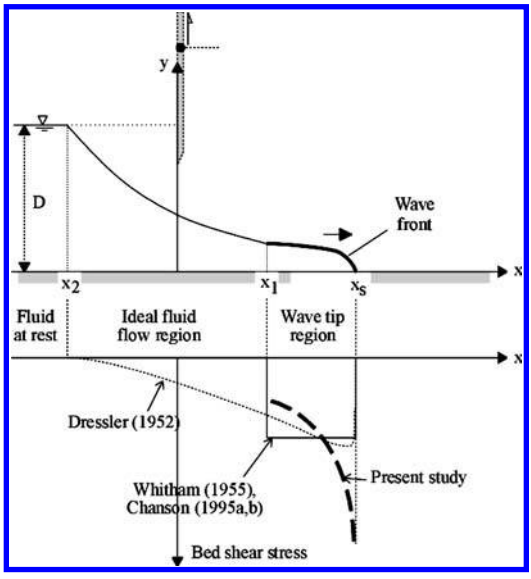

Figure 7. Sketch of longitudinal bed shear stress in turbulent dam break wave for the theoretical models of Dressler (1952), Whitham (1955), Chanson (2005a,b) and present study.

Ultimately, a practical question is: which is the best theoretical model for turbulent dam break wave? Dressler's (1952) method is robust, but the treatment of the wave leading edge is approximate: "*To handle the tip region accurately, some type of boundary-layer technique would be necessary* […] *but no results are yet available.* […] *In the absence of more satisfactory boundary layer results, we will apply* […] *approximate considerations to obtain some data about the wavefront*" (Dressler 1952, pp. 223–224). Whitham's (1955) method is also a robust technique, but the results are asymptotic solutions. Both the model of Chanson (2005a,b) with constant friction factor and present results provide complete explicit solutions of the entire flow field. The velocity field and water depths are explicitly calculated everywhere. Note that the methods of Dressler, Whitham and Chanson (2005a,b) assume a constant friction factor, and the results are sensitive to the selection of the flow resistance coefficient value. In contrast, the present method requires only the selection of an equivalent roughness height. In practice, the selection of a suitable analytical model is linked with its main application. For example, for pedagogical purposes, the writer believes that Chanson's (2005a,b) model based upon a constant friction coefficient in the wave tip region is nicely suited to introductory courses and young professionals because of the explicit and linear nature of the results.

The new developments shown herein present substantial advantages over previous works. The theoretical results yield simple explicit analytical expressions for real-fluid flows that compares well with experimental data and more advanced theoretical solutions. They cover a wide range of applications that include linear and turbulent flows, horizontal and sloping channels. The proposed solutions are simple pedagogical applications, linking together the ideal fluid flow equations yielding Ritter solution, with a diffusive wave equation for the wave tip region. These explicit results may be used to validate numerical solutions of the method of characteristics applied to dam break wave problem. The development may be also extended to a wider range of practical applications including non-Newtonian fluids (e.g. Chanson and Coussot 2005).

5 SUMMARY AND CONCLUSION

New analytical solutions of dam break wave with bed friction are developed for turbulent and laminar flow motion with non constant friction factors. For each development, the dam break wave flow is analysed as a wave tip region where flow resistance is dominant, followed by an ideal-fluid flow region where inertial effects and gravity effects are dominant. In horizontal channels, turbulent flow solutions were validated by successful comparisons between several experimental data sets obtained in large-size facilities and theoretical results in terms of instantaneous free-surface profiles, wave front location and wave front celerity. The former comparison with instantaneous free-surface data is regarded as the most accurate technique to estimate the flow resistance and relative roughness, hence the best validation technique. A new analytical solution of dam break wave with laminar flow motion is also presented. The shape of the wave front compared well with experimental observations. The results were further extended to sloping channels.

These simple theoretical developments yield explicit, non-linear expressions that compare well with experimental data. The simplicity of the equations will allow some extension of the method to more complex geometries, flow situations and broader applications, including non-Newtonian fluids, sheet flow and beach swash.

It must be acknowledged that the present approach is limited to semi-infinite reservoir, rectangular channel and quasi-instantaneous dam break. Further experimental data with very viscous fluids and non-Newtonian fluid flows are also needed.

6 APPENDIX

Let us consider an instantaneous dam break wave in an initially dry inclined channel. In the

Copyright © 2006 Taylor & Francis Group plc, London, UK

friction-dominated tip region, the dynamic wave equation becomes:

$$\frac{\partial d}{\partial x} + \frac{f}{8}\frac{U^2}{g\,d} = S_o \qquad \text{Wave tip region} \qquad \text{(A-1)}$$

where the Darcy friction factor satisfies the Altsul formula:

$$f = \frac{1}{\left(\frac{d}{D}\right)^{1/4}} G^{1/4} \qquad \text{(A-2)}$$

and the dimensionless term G is:

$$G = 3.65\ \text{E-5}\,\frac{k_s}{D} + \frac{2.5\ \text{E-3}}{Re_D\,\frac{U}{\sqrt{g\,D}}} \qquad \text{(A-3)}$$

Equation (A-1) may be rewritten in dimensionless form as:

$$\frac{\partial d'}{\partial x'} + \frac{X}{d'^{5/4}} = S_o \qquad \text{(A-4)}$$

where $d' = d/D$, $x' = x/D$ and

$$X = \frac{0.1}{8}\left(\frac{1.46}{4}\frac{k_s}{D} + \frac{100}{4}\frac{\nu}{U\,D}\right)^{1/4} \frac{U^2}{g\,D}$$

with $\nu = \mu/\rho$ is the kinematic viscosity.

The boundary conditions are $d' = 0$ at the leading edge ($x' = x'_s$). For a non-zero slope, the exact solution of Equation (A-4) is:

$$S_o\,(x_s' - x') = 0.020034\left(\frac{X}{S_o}\right)^{4/5} - d' - \frac{4}{5}\left(\frac{X}{S_o}\right)^{4/5} \text{Ln}\left(\left(\frac{X}{S_o}\right)^{1/5} - d'^{1/4}\right) - \frac{2\sqrt{2\,(5+\sqrt{5})}}{5}\left(\frac{X}{S_o}\right)^{4/5} \text{ArcTan}\left(\frac{(-1+\sqrt{5})\left(\frac{X}{S_o}\right)^{1/5} + 4\,d'^{1/4}}{\sqrt{2\,(5+\sqrt{5})}\left(\frac{X}{S_o}\right)^{1/5}}\right) - \frac{2\sqrt{10-2\sqrt{5}}}{5}\left(\frac{X}{S_o}\right)^{4/5} \text{ArcTan}\left(\frac{(1+\sqrt{5})\left(\frac{X}{S_o}\right)^{1/5} + 4\,d'^{1/4}}{\sqrt{10-2\sqrt{5}}\left(\frac{X}{S_o}\right)^{1/5}}\right) - \left(\frac{1}{\sqrt{5}} - \frac{1}{5}\right)\left(\frac{X}{S_o}\right)^{4/5} \text{Ln}\left(\left(\frac{X}{S_o}\right)^{2/5} - \frac{-1+\sqrt{5}}{2}\left(\frac{X}{S_o}\right)^{1/5} d'^{1/4} + \sqrt{d'}\right) + \left(\frac{1}{\sqrt{5}} + \frac{1}{5}\right)\left(\frac{X}{S_o}\right)^{4/5} \text{Ln}\left(\left(\frac{X}{S_o}\right)^{2/5} + \frac{1+\sqrt{5}}{2}\left(\frac{X}{S_o}\right)^{1/5} d'^{1/4} + \sqrt{d'}\right) \qquad x_1 \le x \le x_s \qquad \text{(A-5)}$$

Efficient implicit upwind schemes for river flow simulation with or without shocks

J. Burguete, P. Garcia-Navarro, P. Brufau & J. Murillo
Fluid Mechanics, CPS, University of Zaragoza, Spain

ABSTRACT: In this work, first order upwind implicit schemes are considered. The traditional tridiagonal scheme is rewritten as a sum of two bidiagonal schemes in order to produce a simpler method better suited for unsteady transcritical flows. On the other hand, the origin of the instabilities associated to the use of upwind implicit methods for shock propagations is identified and a new stability condition for non-linear problems is proposed. This modification produces a robust, simple and accurate upwind semi-explicit scheme suitable for discontinuous flows with high *CFL* numbers.

The performance of the proposed technique will be shown in the solution of an ideal dam-break test case and in a realistic flood routing problem, where stable and accurate solutions will be presented using *CFL* values up to 100.

1 INTRODUCTION

Implicit schemes are well known for the property of allowing numerical stability in the resolution of partial differential equations in presence of time steps not restricted by the Courant-Friedrichs-Lewy condition. Therefore, they have traditionally been the most attractive methods in CFD for steady or gradually unsteady flows. Computational Hydraulics has been a field of frequent search for accurate and robust implicit schemes. Some research has been recently oriented to the development of new implicit techniques able to deal with transcritical flows in order to overcome deficiencies found in previous implicit methods. The results from the mentioned schemes are however characterized by a limitation in the allowable time step size in cases of unsteady and discontinuous flow. It is usually found that *CFL* values bigger than 3 lead to instabilities in the resolution of moving front waves. This is due to a poor treatment of the linearization of the implicit flux terms, which are often locally evaluated. In this work, first order upwind implicit schemes are considered. The traditional tridiagonal scheme is rewritten as a sum of two bidiagonal schemes in order to produce a simpler method better suited for unsteady transcritical flows. On the other hand, a new stability condition for non-linear problems is used that produces a robust, simple and accurate upwind semi-explicit scheme suitable for discontinuous flows with high *CFL* numbers. The performance of the proposed technique will be shown in the solution of unsteady realistic flood routing and dam-break problems, where stable and accurate solutions will be presented using high *CFL* values.

2 MATHEMATICAL MODEL

We are interested in solving as efficiently as possible 1D hyperbolic systems with source terms. In a general conservative form

$$\frac{\partial \mathbf{u}(x,t)}{\partial t} + \frac{d\mathbf{F}(x,\mathbf{u})}{dx} = \mathbf{H}(x,\mathbf{u}) \tag{1}$$

where $\mathbf{u}$ is the vector of conserved variables, $\mathbf{F}$ the vector of fluxes and $\mathbf{H}$ the vector of source terms. Our interest is led by the numerical modelling of one-dimensional shallow water flows of practical application in Hydraulics such as river flows. In that case

$$\mathbf{u} = \begin{pmatrix} A \\ Q \end{pmatrix}, \quad \mathbf{F} = \begin{pmatrix} Q \\ \frac{Q^2}{A} + gI_1 \end{pmatrix}, \quad \mathbf{H} = \begin{pmatrix} 0 \\ g\left[I_2 + A\left(S_0 - S_f\right)\right] \end{pmatrix}$$

where Q is the discharge, A is the wetted cross section, g is the acceleration of gravity and S_0 is the bed slope. The rest of the terms account for pressure forces and for friction forces, with S_f associated to wall friction and represented by the empirical Manning law (Cunge et al., 1980).

Copyright © 2006 Taylor & Francis Group plc, London, UK

From the equations in conservative form (1), it is possible to pass to an associated non-conservative form

$$\frac{\partial \mathbf{u}(x,t)}{\partial t} + \mathbf{J}(x,\mathbf{u}) \frac{\partial \mathbf{u}(x,t)}{\partial x} = \mathbf{H}'(x,\mathbf{u}) \tag{2}$$

where $\mathbf{J} = \frac{\partial \mathbf{F}}{\partial \mathbf{u}}$ is the Jacobian matrix of the original system and $\mathbf{H}' = \mathbf{H} - \frac{\partial \mathbf{F}}{\partial x}$. In shallow water equations

$$\mathbf{H}' = \begin{pmatrix} 0 \\ gA\left(S_0 - S_f - \frac{dh}{dx} + \frac{1}{B}\frac{dA}{dx}\right) \end{pmatrix}$$

$$\mathbf{J} = \begin{pmatrix} 0 & 1 \\ c^2 - u^2 & 2u \end{pmatrix}$$

with h the depth, $u = Q/A$ the fluid velocity, $c = \sqrt{gA/B}$ the velocity of the infinitesimal surface waves and B the top width.

It is now convenient to develop the characteristic form of the equations given the importance it has for the correct formulation of upwind schemes and boundary conditions. This form is obtained from a diagonalization of the Jacobian in (2). Calling $\mathbf{P}$ and $\mathbf{P}^{-1}$ the matrices that make $\mathbf{J}$ diagonal, and Λ the resulting diagonal matrix

$$\mathbf{J} = \mathbf{P}\Lambda\mathbf{P}^{-1}, \quad \Lambda = \mathbf{P}^{-1}\mathbf{J}\mathbf{P}$$

The matrix Λ is formed by the eigenvalues of $\mathbf{J}$, and $\mathbf{P}$ is constructed with its eigenvectors. Let $\mathbf{w}$ be the set of variables (characteristic variables) that verify

$$d\mathbf{u} = \mathbf{P}d\mathbf{w}, \quad d\mathbf{w} = \mathbf{P}^{-1}d\mathbf{u}$$

Then,

$$\frac{\partial \mathbf{w}(x,t)}{\partial t} + \Lambda(x,\mathbf{w}) \frac{\partial \mathbf{w}(x,t)}{\partial x} = \mathbf{P}^{-1}(x,\mathbf{w})\,\mathbf{H}'(x,\mathbf{w}) \tag{3}$$

In the one-dimensional shallow water model, the above matrices are

$$\mathbf{P} = \begin{pmatrix} 1 & 1 \\ u+c & u-c \end{pmatrix}, \quad \Lambda = \begin{pmatrix} u+c & 0 \\ 0 & u-c \end{pmatrix}$$

3 NUMERICAL SCHEMES

The most common definition of a conservative scheme follows the structure (Toro, 1997, p. 171)

$$\Delta\mathbf{u}_i^n = \Delta t \left[\mathbf{H}_i^* - \frac{1}{\delta x}\left(\mathbf{F}_{i+\frac{1}{2}}^* - \mathbf{F}_{i-\frac{1}{2}}^*\right)\right] \tag{4}$$

where $\mathbf{H}^*$ is the numerical source at cell i and $\mathbf{F}_{i+\frac{1}{2}}^*$ is the numerical flux at cell interface $i+\frac{1}{2}$. They represent a suitable approximation of the true source and flux terms in the equation. Δ will be used for time increment $\Delta f_i^n = f_i^{n+1} - f_i^n$, and δ represents spatial increment $\delta f_{i+\frac{1}{2}} = f_{i+1}^n - f_i^n$. Schemes so defined will be conservative since they cancel the contributions of the flux at the grid interfaces, being the global variation of the conserved variables due only to the source terms and to the fluxes at the boundaries.

A numerical flux $\mathbf{F}_i^T$ can also be defined at the grid nodes (Burguete & García-Navarro, 2001). The difference in this flux between two nodes can be decomposed into parts affecting the two nodes. Schemes so built follow

$$\delta\mathbf{F}_{i+\frac{1}{2}}^T = \mathbf{F}_{i+1}^T - \mathbf{F}_i^T = \delta\mathbf{F}_{i+\frac{1}{2}}^R + \delta\mathbf{F}_{i+\frac{1}{2}}^L$$

$$\Delta\mathbf{u}_i^n = \Delta t \left[\mathbf{H}_i^* - \frac{1}{\delta x}\left(\delta\mathbf{F}_{i+\frac{1}{2}}^R + \delta\mathbf{F}_{i-\frac{1}{2}}^L\right)\right] \tag{5}$$

This also leads to conservative schemes since this form can be shown to be equivalent to (4) (Burguete & García-Navarro, 2001).

In addition, and following evidences from previous works (Glaister, 1988), (Bermúdez & Vázquez-Cendón, 1994), (García-Navarro & Vázquez-Cendón, 2000), (Burguete & García-Navarro, 2001), we consider a non-pointwise contribution of the source terms

$$\mathbf{H}_{i+\frac{1}{2}}^T = \mathbf{H}_{i+\frac{1}{2}}^R + \mathbf{H}_{i+\frac{1}{2}}^L$$

so that the following formulation for the conservative scheme is proposed

$$\Delta\mathbf{u}_i^n = \Delta t \left[\left(\mathbf{H} - \frac{\delta\mathbf{F}}{\delta x}\right)_{i-\frac{1}{2}}^L + \left(\mathbf{H} - \frac{\delta\mathbf{F}}{\delta x}\right)_{i+\frac{1}{2}}^R\right] \tag{6}$$

Conservative schemes can also be derived from the non-conservative form of the equations (2) (Burguete & García-Navarro, 2001). The advantage is that the latter form tends to be simpler to deal with than the conservative form. We need to establish the conditions under which schemes derived in this way are equivalent to the conservative scheme (6) derived from the conservative equations. First of all, the following equality must hold at the discrete level

$$\mathbf{G}_{i+\frac{1}{2}} \equiv \left(\mathbf{H} - \frac{\delta\mathbf{F}}{\delta x}\right)_{i+\frac{1}{2}} = \left(\mathbf{H}' - \mathbf{J}\frac{\delta\mathbf{u}}{\delta x}\right)_{i+\frac{1}{2}} \tag{7}$$

Note that this equality requires a non-pointwise treatment of source terms and is an extension of the

Copyright © 2006 Taylor & Francis Group plc, London, UK

Roe's average (Roe, 1981). In shallow water this average is (García-Navarro & Vázquez-Cendón, 2000)

$$\tilde{u}_{i+\frac{1}{2}} = \frac{Q_{i+1}/\sqrt{A_{i+1}} + Q_i/\sqrt{A_i}}{\sqrt{A_{i+1}} + \sqrt{A_i}}, \quad \tilde{c}_{i+\frac{1}{2}} = \sqrt{g\frac{A_{i+\frac{1}{2}}}{B_{i+\frac{1}{2}}}}$$

From (7) it follows that two equivalent forms of building conservative schemes with non-pointwise source terms are possible (Burguete & García-Navarro, 2001). Defining $\mathbf{G}$ as

$$\mathbf{G}_{i+\frac{1}{2}} \equiv \left(\mathbf{H} - \frac{\delta \mathbf{F}}{\delta x}\right)_{i+\frac{1}{2}} \tag{8}$$

the form (6) is achieved, whereas defining this term like

$$\mathbf{G}_{i+\frac{1}{2}} \equiv \left(\mathbf{H}' - \mathbf{J}\frac{\delta \mathbf{u}}{\delta x}\right)_{i+\frac{1}{2}} \tag{9}$$

with the restriction (7), the non-conservative form of the conservative scheme is derived. In any case

$$\Delta \mathbf{u}_i^n = \Delta t \left(\mathbf{G}_{i-\frac{1}{2}}^L + \mathbf{G}_{i+\frac{1}{2}}^R\right) \tag{10}$$

where the decomposition in left and right parts is to be defined according to every particular numerical scheme.

Conservative schemes based in the characteristic form of the equations are the basis for the wave decomposition of upwind schemes. From (3) it is possible to rewrite

$$\frac{\partial \mathbf{w}}{\partial t} = \mathbf{P}^{-1}\left(\mathbf{H}' - \mathbf{J}\frac{\partial \mathbf{u}}{\partial x}\right) = \mathbf{P}^{-1}\mathbf{G}$$

Then, a discrete wave decomposition into left and right moving contributions can be done (Burguete & García-Navarro, 2001)

$$\left(\mathbf{P}^{-1}\mathbf{G}\right)_{i+\frac{1}{2}} = \left(\Omega^L \mathbf{P}^{-1}\mathbf{G}\right)_{i+\frac{1}{2}} + \left(\Omega^R \mathbf{P}^{-1}\mathbf{G}\right)_{i+\frac{1}{2}}$$

being Ω^L and Ω^R diagonal matrices to be defined in every particular numerical scheme. In order to ensure the conservative character of the scheme, they have to obey

$$\left(\Omega^L + \Omega^R\right)_{i+\frac{1}{2}} = \mathbf{I} \tag{11}$$

Multiplication by $\mathbf{P}$ gives the final form for the discretization in terms of the conserved quantities

$$\Delta \mathbf{u}_i^n = \Delta t\left[\left(\mathbf{P}\Omega^L \mathbf{P}^{-1}\mathbf{G}\right)_{i-\frac{1}{2}} + \left(\mathbf{P}\Omega^R \mathbf{P}^{-1}\mathbf{G}\right)_{i+\frac{1}{2}}\right] \tag{12}$$

Note that this discretization requires again a non-pointwise formulation of the source terms, being equally possible (8) or (9) for $\mathbf{G}$. Both options can be inserted into the general form of the conservative schemes (10) by definition of:

$$\mathbf{G}^{L,R} = \mathbf{P}\Omega^{L,R}\mathbf{P}^{-1}\mathbf{G} \tag{13}$$

3.1 *Tridiagonal upwind scheme*

Upwind schemes are based on the idea of approximating the spatial derivatives by non-centered differences biased in the sense of propagation of information in the physical problem. In order to construct a first order scheme, suitable for left and right moving propagation velocities, the following wave decomposition can be made:

$$\mathbf{F}_i^T = \mathbf{F}_i^{n+\theta}, \quad \delta \mathbf{F}_{i+\frac{1}{2}}^L = \left(\delta \mathbf{F}^+\right)_{i+\frac{1}{2}}^{n+\theta}$$

$$\delta \mathbf{F}_{i+\frac{1}{2}}^R = \left(\delta \mathbf{F}^-\right)_{i+\frac{1}{2}}^{n+\theta}$$

leading to:

$$\Delta \mathbf{u}_i^n = \Delta t\left[\left(\mathbf{G}^+\right)_{i-\frac{1}{2}}^{n+\theta} - \left(\mathbf{G}^-\right)_{i+\frac{1}{2}}^{n+\theta}\right] \tag{14}$$

where $\mathbf{G}^-$, $\delta \mathbf{F}^-$ and $\mathbf{J}^-$ are associated to negative velocities, and $\mathbf{G}^+$, $\partial \mathbf{F}^+$ and $\mathbf{J}^+$ to positive velocities and the notation $f^{n+\theta} = \theta f^{n+1} + (1-\theta) f^n$ is used. From (12), the following wave decomposition is assumed for this scheme in order to select the appropriate influence region in every case.

$$\Omega^L = \Omega^+ = \frac{1}{2}\left[\mathbf{I} + \Lambda^{-1}|\Lambda|\right],$$

$$\Omega^R = \Omega^- = \frac{1}{2}\left[\mathbf{I} - \Lambda^{-1}|\Lambda|\right]$$

$$\mathbf{J}^{\pm} = \mathbf{P}\Omega^{\pm}\mathbf{P}^{-1}\mathbf{J}, \quad \delta \mathbf{F}^{\pm} = \mathbf{P}\Omega^{\pm}\mathbf{P}^{-1}\delta \mathbf{F},$$

$$\mathbf{G}^{\pm} = \mathbf{P}\Omega^{\pm}\mathbf{P}^{-1}\mathbf{G} \tag{15}$$

A linear analysis of the homogeneous equations shows that the stability condition is

$$(1-2\theta)CFL \leq 1 \tag{16}$$

with $CFL = \max|a^k|\Delta t/\delta x$ the Courant-Friedrichs-Lewy (CFL) number and a^k the eigenvalues of the Jacobian, being unconditionally stable if $\theta \geq \frac{1}{2}$. This linear analysis also shows that the scheme is Total variation Diminishing (TVD) if (Burguete & García-Navarro, 2005)

$$CFL \leq \frac{1}{1-\theta} \tag{17}$$

being this condition more restrictive. The scheme is unconditionally TVD if $\theta = 1$.

With non-linear equations this scheme requires to involve $\mathbf{F}^{n+1}$ and $\mathbf{H}^{n+1}$, which represents a difficulty.

Copyright © 2006 Taylor & Francis Group plc, London, UK

In order to avoid this problem, a linearization can be made (Burguete & García-Navarro, 2005).

Using the wave decomposition (15), the conservative scheme in characteristic form (12) can be expressed

$$\theta\frac{\Delta t}{\delta x}\left(\mathbf{J}^{-}\Delta\mathbf{u}\right)^{n}_{i+1}+\left[1-\theta\Delta t\left(\mathbf{K}-\frac{\mathbf{J}^{+}}{\delta x}+\frac{\mathbf{J}^{-}}{\delta x}\right)\right]^{n}_{i}\Delta\mathbf{u}^{n}_{i}$$
$$-\theta\frac{\Delta t}{\delta x}\left(\mathbf{J}^{+}\Delta\mathbf{u}\right)^{n}_{i-1}=$$
$$\Delta t\left[\left(\mathbf{G}^{+}\right)^{n}_{i-\frac{1}{2}}-\left(\mathbf{G}^{-}\right)^{n}_{i+\frac{1}{2}}\right] \qquad (18)$$

with $\mathbf{J}^{\pm}=\mathbf{P}\Omega^{\pm}\mathbf{P}^{-1}\mathbf{J}$. It is worth noting that it is simpler to make the upwind treatment of the source terms in the explicit operator keeping a pointwise discretization for $\mathbf{K}$ in the linearized implicit operator.

The numerical scheme, as described in (14) or in the linearized version (18), is unable to deal with transonic problems of the type subcritical to supercritical flow, requiring in these cases the introduction of an artificial viscosity (Harten & Hyman, 1983). Therefore, the quantities $\mathbf{G}^{\pm}$ will be redefined to cope with the mentioned transitions as

$$\left(\mathbf{G}^{\pm}\right)^{n}_{i+\frac{1}{2}}=\left(\mathbf{P}\Omega^{\pm}\mathbf{P}^{-1}\mathbf{G}\pm\nu\frac{\delta\mathbf{u}}{\delta x}\right)^{n}_{i+\frac{1}{2}} \qquad (19)$$

This linearized implicit scheme was developed (Yee, 1987) in the context of Gas Dynamics and succesfully used for steady problems. The performance for steady problems is highly sensitive to the *CFL* used during the transient phase. When shocks are present in the solution of a non-linear equation and a high time step is used, the propagation velocities (eigenvalues in the system case) can change strongly between the two time levels. The implicit linearized methods are not unconditionally stable in these cases because the linearization involves the evaluation of the Jacobian at time level *n*. In the references the test cases presented confirm this behaviour.

3.2 *Bidiagonal scheme*

The scheme built as in (18) leads, in general, to a linear block tridiagonal system of equations. In order to work with a simpler block bidiagonal system and to avoid spurious errors in the transcritical points, the original scheme (18) can be altered. The following modification by splitting the increments due to positive and negative propagations was proposed (Burguete & García-Navarro, 2005)

$$\mathbf{F}^{T}_{i}=\mathbf{F}^{n}_{i}+\theta\left(\mathbf{J}^{+}\Delta\mathbf{u}^{+}+\mathbf{J}^{-}\Delta\mathbf{u}^{-}\right)^{n}_{i}$$
$$\delta\mathbf{F}^{L}_{i+\frac{1}{2}}=\left(\delta\mathbf{F}^{+}\right)^{n}_{i+\frac{1}{2}}+\theta\delta\left(\mathbf{J}^{+}\Delta\mathbf{u}^{+}\right)^{n}_{i+\frac{1}{2}}$$
$$\delta\mathbf{F}^{R}_{i+\frac{1}{2}}=\left(\delta\mathbf{F}^{-}\right)^{n}_{i+\frac{1}{2}}+\theta\delta\left(\mathbf{J}^{-}\Delta\mathbf{u}^{-}\right)^{n}_{i+\frac{1}{2}}$$

and the original scheme is transformed in a two-step block bidiagonal system:

$$\left[1-\theta\frac{\Delta t}{\delta x}\left(\mathbf{J}^{-}\right)\right]^{n}_{i}\left(\Delta\mathbf{u}^{-}\right)^{n}_{i}+\theta\frac{\Delta t}{\delta x}\left(\mathbf{J}^{-}\Delta\mathbf{u}^{-}\right)^{n}_{i+1}=$$
$$=\Delta t\left(\mathbf{G}^{-}\right)^{n}_{i+\frac{1}{2}}$$
$$\left[1+\theta\frac{\Delta t}{\delta x}\left(\mathbf{J}^{+}\right)\right]^{n}_{i}\left(\Delta\mathbf{u}^{+}\right)^{n}_{i}-\theta\frac{\Delta t}{\delta x}\left(\mathbf{J}^{+}\Delta\mathbf{u}^{+}\right)^{n}_{i-1}=$$
$$=\Delta t\left(\mathbf{G}^{+}\right)^{n}_{i-\frac{1}{2}}$$
$$\left(1-\theta\Delta t\mathbf{K}^{n}_{i}\right)\Delta\mathbf{u}^{n}_{i}=\left(\Delta\mathbf{u}^{+}+\Delta\mathbf{u}^{-}\right)^{n}_{i} \qquad (20)$$

When dealing with scalar equations with no source terms, this discretization is always identical to the classical tridiagonal scheme except for transcritical points. Hence, the stability (16) and TVD (17) conditions, deduced for linear cases, are equally valid for this scheme.

Despite the improvement achieved by the splitting phylosophy in transcritical flow points, this scheme is still not able to cope with high *CFL* numbers in presence of moving shocks.

3.3 *Semi-explicit NDA first order upwind scheme*

In a different approach the scheme (20) can be improved by means of a locally defined spatial weighting parameter. A wave decomposition like (Burguete & García-Navarro, 2005)

$$\mathbf{F}^{T}_{i}=\mathbf{F}^{n}_{i}+\frac{\delta x}{\Delta t}\left(\xi^{+}\Delta\mathbf{u}^{+}-\xi^{-}\Delta\mathbf{u}^{-}\right)^{n}_{i}$$
$$\delta\mathbf{F}^{L}_{i+\frac{1}{2}}=\left(\delta\mathbf{F}^{+}\right)^{n}_{i+\frac{1}{2}}+\frac{\delta x}{\Delta t}\delta\left(\xi^{+}\Delta\mathbf{u}^{+}\right)^{n}_{i+\frac{1}{2}}$$
$$\delta\mathbf{F}^{R}_{i+\frac{1}{2}}=\left(\delta\mathbf{F}^{-}\right)^{n}_{i+\frac{1}{2}}-\frac{\delta x}{\Delta t}\delta\left(\xi^{-}\Delta\mathbf{u}^{-}\right)^{n}_{i+\frac{1}{2}}$$

Produces the following numerical scheme

$$\left(1+\xi^{-}\right)^{n}_{i}\left(\Delta\mathbf{u}^{-}\right)^{n}_{i}-\left(\xi^{-}\right)^{n}_{i+1}\left(\Delta\mathbf{u}^{-}\right)^{n}_{i+1}=$$
$$=\Delta t\left(\mathbf{G}^{-}\right)^{n}_{i+\frac{1}{2}}$$
$$\left(1+\xi^{+}\right)^{n}_{i}\left(\Delta\mathbf{u}^{+}\right)^{n}_{i}-\left(\xi^{+}\right)^{n}_{i-1}\left(\Delta\mathbf{u}^{+}\right)^{n}_{i-1}=$$
$$=\Delta t\left(\mathbf{G}^{+}\right)^{n}_{i-\frac{1}{2}}$$
$$\left(1-\theta\Delta t\mathbf{K}^{n}_{i}\right)\Delta\mathbf{u}^{n}_{i}=\left(\Delta\mathbf{u}^{+}+\Delta\mathbf{u}^{-}\right)^{n}_{i} \qquad (21)$$

It is worth noting that this definition of the parameters ξ modifies the wave decomposition of the implicit

Copyright © 2006 Taylor & Francis Group plc, London, UK

operator in a manner very similar to the introduction of the artificial viscosity applied in the explicit operator to correct the sub-super transitions. This suggests that the physical meaning of these parameters is analogous and that the ξ's represent an implicit artificial viscosity.

From a non-linear analysis based on a scalar equation, (Burguete & García-Navarro, 2005), the set of parameters ξ will be calculated as

$$\xi_i^{\pm} = \max\left[\pm\frac{\Delta t}{\delta x}a_{i\mp\frac{1}{2}}^{\pm} - 1, \xi_{i\mp1}^{\pm} - 1, 0\right] \tag{22}$$

In those cases of transition from subcritical to supercritical flow, an artificial viscosity needs also to be included and (19) must be applied. It can be easily verified through a detailed non linear analysis (Burguete & García-Navarro, 2005), that the artificial viscosity also modifies the set of parameters ξ as

$$\xi_i^{\pm} = \max\left[\pm\frac{\Delta t}{\delta x}a_i^{\pm} - 1, \xi_{i\mp1}^{\pm} - 1, 0\right] \tag{23}$$

3.4 *Boundary conditions*

A correct numerical model for unsteady flow problems must be based not only on a numerical scheme with good properties but also on an adequate procedure to discretize the boundary conditions. The theory of characteristics provides clear indications about the number of necessary external boundary conditions to define a well posed problem. When a characteristic curve defined in the $x-t$ plane enters the computational domain, the influence region associated to it is exterior to the domain and therefore one external boundary condition is required. This kind of boundary conditions is also called physical boundary conditions. On the other hand, when the characteristic curve leaves the domain, the influence region belongs to the computational domain and the information linked to that characteristic curve depends exclusively on the interior points. This kind of boundary conditions are also called numerical boundary conditions.

All the methods proposed in the past to discretize the numerical boundary conditions generate error in the global mass conservation. In this work, a method based on the integral form of the mass conservation equation extended to the full domain (global mass conservation) is also considered. The technique can be adapted to any conservative numerical scheme used for the interior points leading to a machine accuracy global mass conservation in all steady or unsteady situations.

4 EXAMPLES

4.1 *Ideal dam-break wave*

The unsteady flow induced by an ideal dam-break is the most widely used test case for numerical schemes

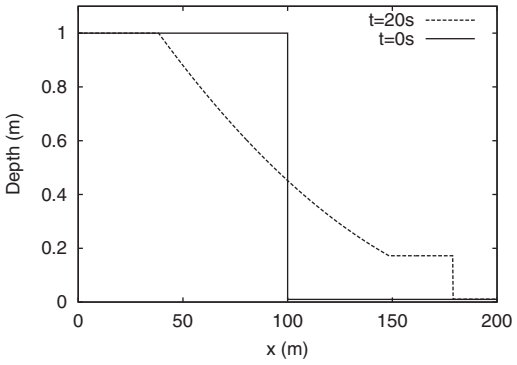

Figure 1. Initial conditions for the water surface ($t = 0$) and exact water surface solution at $t = 20$s for the ideal dam-break problem.

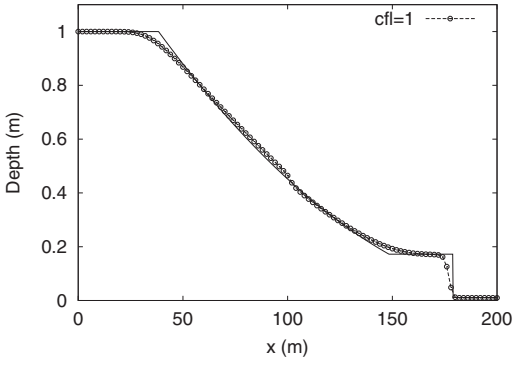

Figure 2. Water depth profiles for the dam-break test case. NDA semi-explicit. $CFL = 1$.

of the kind considered here. The initial conditions defining this nonlinear problem, as well as the exact solution are plotted in Figure 1. Implicit methods are particularly affected by the discontinuous character of the initial conditions and are usually reported to fail for most applications using *CFL* values above 3 or 4. In the example presented here an initial depth ratio of 100 was used. The numerical solutions are displayed for comparison on Figures 2, 3 and 4 together with the exact solution (Stoker, 1957). They show the solution obtained with the NDA semi-explicit method using $CFL = 1$, $CFL = 10$ and $CFL = 100$ respectively. In the case of $CFL = 100$ the numerical solution is obtained in only one time step and shows a strong dependence on the discontinuous initial conditions. The stability limit for the bidiagonal implicit scheme in this case is shown in Figure 5 after one time step of calculation (approximately corresponding to $CFL = 6$). The oscillation shown makes a second time step impossible. It is worth to note that the solution is even more accurate at low *CFL* values in this example

than using the bidiagonal implicit. The stability of the NDA scheme with $CFL = 100$ contrasts again with the strange shape of the solution at the first time steps. In order to follow how the solution of this example evolves in time, Figures 6 and 7 show the water depth at times $t = 60\,s$ and $t = 150\,s$ in a longer domain. The

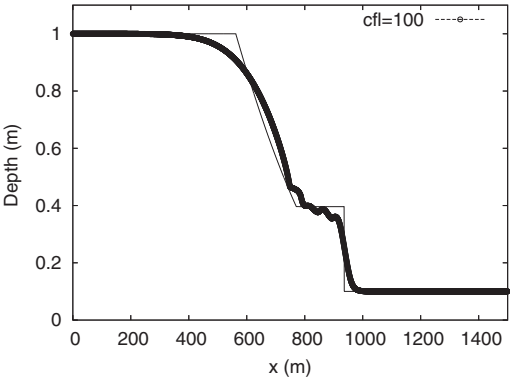

Figure 6. Analytical and numerical solution of the dam-break case using the NDA semi-explicit scheme with $CFL = 100$ in a longer domain at $t = 60\,s$.

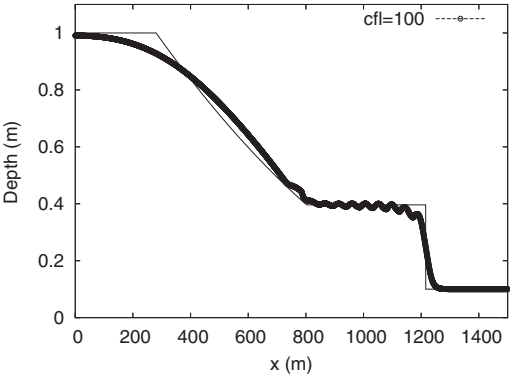

Figure 7. Analytical and numerical solution of the dam-break case using the NDA semi-explicit scheme with $CFL = 100$ in a longer domain at $t = 150\,s$.

main shape of the wave is well reproduced despite small oscillations.

4.2 *Flood wave in a river*

The river reach used for the simulation belongs to the lower part of the Ebro river and therefore has very mild average slope and low water velocities. The river cross section is highly variable in shape along the axis of the river and presents an irregular tendency in the bottom level variation leading to adverse and important slopes in some parts.

The total length of the simulated reach is around $11400\,m$. Geometric data were available at 49 cross sections. The Manning coefficient was assumed uniform and equal to $0.03\,sm^{-1/3}$.

A first run supplied the initial condition for the flooding simulation. This first run started from dry bed and introduced an upstream constant discharge of $Q = 200\,m^3/s$ until convergence.

Copyright © 2006 Taylor & Francis Group plc, London, UK

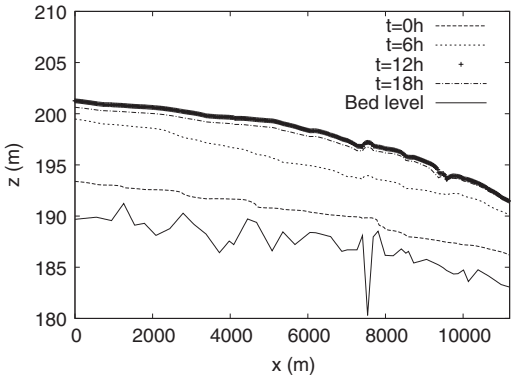

Figure 8. Water surface at base flow ($t = 0$), and at times $t = 6\,h$, $12\,h$ *(peak inflow) and* $18\,h$ using the NDA semi-explicit scheme with CFL = 1.

Unsteady shallow water flow over dry beds is at present one of the topics of research in computational hydraulics. Our approach consists of a calculation of the front position as it advances over a computational mesh covering all the physical domain and in which there are both wet and dry cells at the same time. The set of equations we are solving are written in terms of wetted cross section size and average velocity. The information concerning the original velocity profile is therefore reduced to a friction source term which takes into account the wall tangential stress and other viscous effects. The option chosen in this work is based on the empirical correlation proposed by Strickler in 1923 for the Manning coefficient in rivers,

$$n = 0.041 d_{50}^{1/6}$$

Given an estimation for the global or local Manning coefficient, the above relation supplies the order of magnitude of the mean diameter of the bed material d_{50}. In our model, this value is used as the minimum water depth required at the front position to allow front advance. For water depths below that value, water is forced to stop and accumulate.

Using the converged steady state as initial condition, the flood was represented by means of an upstream hydrograph, used as upstream boundary condition. The shape of this hydrograph was simplified making it triangular and only the peak discharge, $Q = 5300\,m^3/s$, corresponded to the estimated maximum discharge for the flood event of return period equal to 500 years. The downstream boundary condition was set to critical flow in all cases.

From the numerical point of view, 400 nodal values were used and different values for the *CFL* number. Figures 8, 9, 10 and 11 show the results obtained with the NDA semi-explicit scheme with $CFL = 1$ and $CFL = 100$, leading to CPU times of around $90\,s$, $2\,s$ respectively for the 36 hours simulated event on a

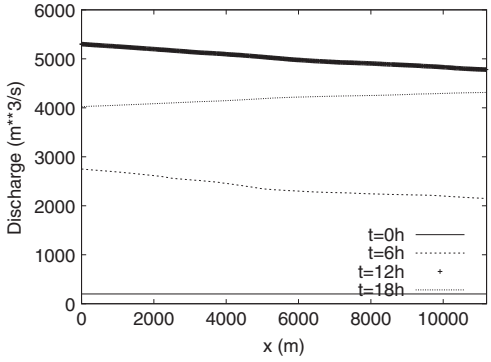

Figure 9. Discharge profile at base flow ($t = 0$), and at times $t = 6\,h$, $12\,h$ (peak inflow) and $t = 18\,h$ using the NDA semi-explicit scheme with CFL = 1.

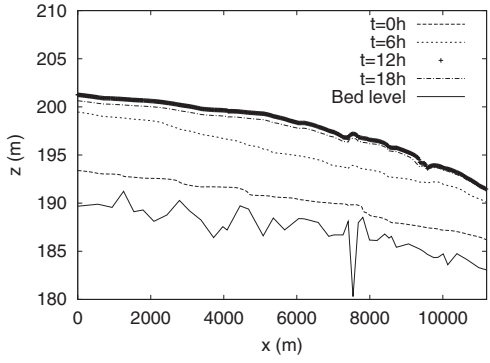

Figure 10. Water surface at base flow ($t = 0$), and at times $t = 6\,h$, $12\,h$ (peak inflow) and $t = 18\,h$ using the NDA semi-explicit scheme with CFL = 100.

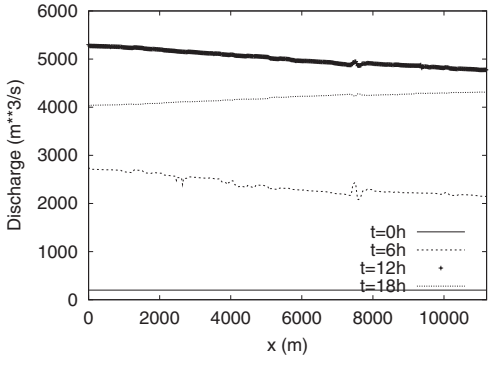

Figure 11. Discharge profile at base flow ($t = 0$), and at times $t = 6\,h$, $12\,h$ (peak inflow) and $t = 18\,h$ using the NDA semi-explicit scheme with CFL = 100.

1 GHz Pentium III PC. For the sake of comparison in this real test case, the same simulation was performed with the bidiagonal implicit upwind schemes. The results are presented in Figures 12 and 13 with

Copyright © 2006 Taylor & Francis Group plc, London, UK

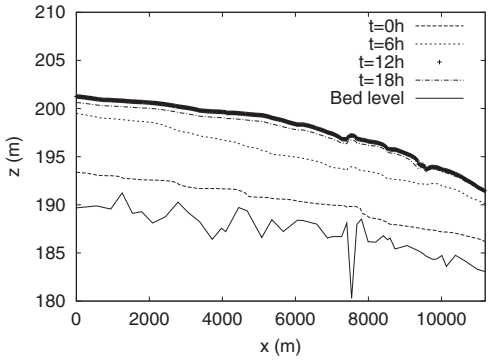

Figure 12. Water surface at base flow ($t = 0$), and at times $t = 6\,h$, $12\,h$ (peak inflow) and $t = 18\,h$ using the bidiagonal implicit scheme with CFL = 5.

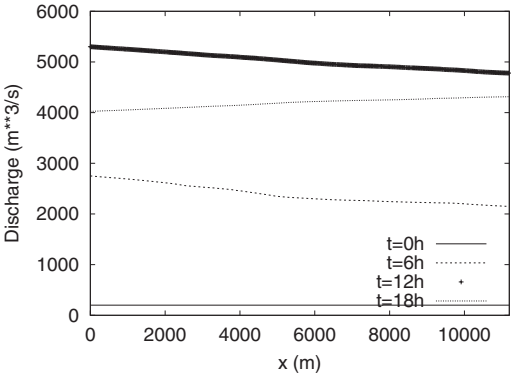

Figure 13. Discharge profile at base flow ($t = 0$), and at times $t = 6\,h$, $12\,h$ (peak inflow) and $t = 18\,h$ using the bidiagonal implicit scheme with CFL = 5.

$CFL = 5$ (CPU time $= 10\,s$) for the bidiagonal implicit. Higher values of the *CFL* number were not possible for stable solutions using this scheme.

The water depth and discharge profiles plotted and displayed correspond to the hypothesis of vertical walls at the left and right points of every supplied cross section, that is, no lateral water loses are assumed. A control over the global volume conservation of the numerical results gives accuracy to machine precision in all cases. The results are remarkably similar and almost independent of the CFL (time step) used in this transient flow problem.

5 CONCLUSIONS

Conservative implicit methods belonging to the family of linearized upwind schemes have been presented. They are in general suitable for the numerical treatment of a variety of hydraulic problems. Among them, the basic linearized scheme is restricted to low *CFL* values for the simulation of unsteady transcritical flow with shocks. Two modifications of this scheme have been derived introducing the idea of splitting the scheme in a superposition of negative and positive wave influences: a bidiagonal implicit and a semi-explicit scheme.

The performance of the implicit schemes has been tested in a dam-break problem arising from the shallow water equations and in a transient river flow example.

Both the bidiagonal implicit and the semi-explicit schemes are able to handle unsteady problems involving transcritical shocks. However, only the NDA semi-explicit can handle these problems with no stability restriction on the *CFL*.

Numerical and experimental modelling of the generation and propagation of waves caused by landslides into reservoirs and their effects on dams

Rita Fernandes de Carvalho & José Simão Antunes do Carmo
University of Coimbra, Portugal

ABSTRACT: Slope failures may occur on the margins of reservoirs, and they give rise to water level variations in the reservoir. In this work, the generation of water waves in dam reservoirs by landslides and their effect on dams was investigated by means of laboratory measurements and two mathematical models. The experimental work was done in a channel of dimensions 12 m × 1 m × 1 m, on which a variable slope bank and a dam 10 m away were built. The waves were generated by the falling of calcareous blocks and the time history of the surface elevation was measured at several points. The waves overtopping and breaking on the dam were also measured using a video camera to obtain the time history of the surface elevation above the crest. The hydrodynamic force on the dam was measured using four pressure transducers. The experimental work was complemented by numerical simulations using two mathematical models, one based on Boussinesq-type equations and another on the 2D Reynolds-averaged Navier-Stokes equations coupled with a Volume-Of-Fluid (VOF) method for treating arbitrary free surfaces. There was a fair agreement between the numerical solutions and the experimental results. It was concluded that the approach described in the present study, using both physical and numerical modeling, is promising for future studies on dam safety.

1 INTRODUCTION

Dam safety is a significant issue in dam engineering and the study of causes and consequences of dam failure is now mandatory for authorities responsible for the operation of many existing dams. Dam failure may be caused by natural accidents or human action. Singh (1996) summarises the main causes of dam failure as follows:

i) 30% floods exceeding spillway capacity;
ii) 37% foundation problems (seepage, piping, excess pore pressures, fault movement, settlement);
iii) 10% (slides (earth, rock, glacier, avalanches), and
iv) 23% improper design and construction, inferior quality of material, acts of war, lack of operation and maintenance.

The high costs associated with the building of a dam, as well as the material and human losses which would result from a break imply that careful studies of natural accidents and their consequences should be made, both at the project and regular operations stages.

Reservoirs in mountainous terrain are vulnerable to landslides activated by earthquakes. Reservoir slope stability studies are needed if it is feared that landslides into the reservoir may either reduce its volume available for storage or produce a tidal wave that may overtop the dam and cause flooding downstream. Overtop of the dam could cause the instability of the downstream slope due to the erosion and the unloading suction effect of the water. A breach at the dam crest may be initiated, which could also cause the failure of the dam. The integrated study of the phenomena related with natural accidents must be considered in the project phase of a dam, especially when the construction site is placed in a high risk seismic activity zone, or when a geological study of the banks indicates the existence of a potential landslide area. These slides may occur at a considerable distance from the reservoir and travel to it as a flow or avalanche, via a tributary valley.

Dynamic loading from earthquakes increases the shear stresses in a slope and may initiate slope failures. Heavy rains also act like a process accelerator.

In 1963, at the Vajont reservoir, the whole of the disturbed mountain-side slid downhill with such momentum that it crossed the river gorge (99 m wide) and rode 135 m up the other side of the valley. More than 25×10^7 m^3 had moved, at a speed of about 24 ms^{-1}. This sliding lasted for 20 seconds, produced a seismic shock that was recorded throughout Europe, and sent a huge wave over the dam which, however, survived. The wave levelled five villages in the valley below and killed more than 2500 people. After

Copyright © 2006 Taylor & Francis Group plc, London, UK

the Vajont disaster, the International Commission On Large Dams – ICOLD advised to the risk of slope failure on the margins of dam reservoirs, and these concerns were included in the regulations for the safety of dams. Measures such as carrying out geological, seismic and geo-technical studies of the region as well as studies of structural safety in normal and break scenarios, are included in existing Portuguese legislation ("Regulations for Dam Security", appendix to Portuguese Legislation DL (Dec Lei) No 11/90). Such precautions are also a motivation for the implementation of a study programme involving all problems under consideration.

In order to identify and characterize the main causes and consequences, to the valley downstream, after a dam overtopping or even its failure, a characterization of the waves generated is essential.

The characteristics of the wave packets generated by landslides are dependent of the following factors:

i) the sliding mass volume;
ii) the sliding mass velocity at the moment of impact, that will be dependent on the out of balance forces/moments, which will be influenced by the dynamic properties of soil, by the soil brittleness and by topographic effects;
iii) the size, or volume, and the reservoir depth.

Experimental studies of impulse waves generated by landslides composed by granular rockslide were presented in Fritz *et al*. (2004). According to these studies, four wave types were determined: weakly, nonlinear oscillatory, nonlinear transition and solitary wave. Fritz *et al*. (2004) proposed several empirical formulas to predict the wave characteristics, based on three fundamental dimensionless parameters: slide Froude number, $F = v_s/\sqrt{gh_0}$, where v_s is the slide velocity, h_0 is the initial reservoir water level and g the acceleration due to gravity; dimensionless slide volume, $V = V_s/(bh_0^2)$ where V_s, is the slide volume and b is the slide width and dimensionless slide thickness, $S = s/h_0$, where s is the slide thickness.

In this work, the wave generations by a block sliding over inclined planes as well as the overtopping and hydrodynamic force on a dam placed downstream were studied using laboratory experiments and two different numerical models. The experimental work was performed in a channel with dimensions $12\,\text{m} \times 1\,\text{m} \times 1\,\text{m}$, where the time history of the surface elevation was measured at several points as well as the hydrodynamic pressures on the dam. These measurements were complemented with the evaluation of sliding and overtopping over the dam using a video camera. The laboratory experiments were complemented with numerical simulations obtained using two numerical models, one based on the Boussinesq equations and another on the 2D Reynolds-averaged Navier-Stokes equations with a VOF approach fortreating arbitrary free surfaces. The Boussinesq model is less computationally intensive and can treat larger domains, whereas the VOF model can treat more complicated phenomena, such as wave overturning and breaking.

The rest of this paper is organised as follows. In the following section, the characterization of the physical processes resulting from landslides and parameters for the laboratory setup are described. In section 3, the numerical models and the installation are described. Section 4 contains a summary of the numerical and experimental results obtained. In section 5, the main conclusions are presented.

2 CHARACTERIZATION OF THE PROCESSES AND MODELLING FACILITIES

2.1 *Characterization of landslides on banks*

The risk evaluation of a slope failure into a reservoir should at first be evaluated using geological information complemented with remote sensing techniques. Concerning the geological information, the lithology, the geomorphology, the geological structure and the stress on the existing or potential shear zones are extremely important in the threshold of failure movements on slopes. Only a detailed field survey can provide the evaluation of the local geological characteristics prone to slope instability in the margins of reservoirs. The geological information must be analysed together with the water level fluctuations in the reservoir and correlated with other external factors promoting slope instability, like rain, water or earthquakes.

On areas prone to slope failure, the size of the sliding mass and the potential for fast slope movements should be investigated. The rate of displacement is a function of the pos failure brittleness and of soil dynamic properties.

Concerning brittle soil slide induced, whatever causes the initial failure of the slide ceases to be in equilibrium and moves to a new flatter position. Failures of slopes on high plasticity clays, showing positive rate effects, have a contained failure, the strength increases with velocity and the slide decelerates. The rate of displacement is low and the movement may last over a long period of time, instead of seconds as it will have been predicted if the dynamic properties of the soil were not considered (Lemos, 1991; Lemos & Coelho, 1991, and Lemos *et al.*, 1994). It is of interest to note that the reduction of static shear resistance with displacement is a function of the velocity and not a displacement due to of the interference of the rate of displacement in the clay particle alignment. When the slide comes into rest it will be in equilibrium with its slow residual strength operating.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Slide in a granular soil with a neutral rate effect, initiated by any external force, the drop from peak to constant volume shear strength is accompanied by volume expansion. The brittleness increases with the initial density and structural bonding. When the gravity and friction forces are no longer in balance, the sliding mass accelerates and may reach a considerable velocity, as it happens in the more plastic clays, due to the increase in the viscous component of the shear resistance.

Failures of slopes on low plasticity clays show negative rate effects, with high losses of shear resistance beyond a critical fast displacement rate; if the critical displacement rate is not exceeded, the behaviour is similar to the one described above, for the positive rate effect. However, if the critical displacement rate is exceeded, the slide accelerates and a fast movement can result as the slide develops momentum, which carries it beyond the equilibrium point. As pointed out, above the drastic reduction to the fast residual strength needs free water access to the shear zone.

2.2 *Physical modelling*

It is impossible to take into account all aspects involved on the process of landslides. For practical reasons, the landslide was reproduced in the laboratory installation by calcareous mass falling sliding over a bank placed on a channel 1 m wide. The bank was made using acrylic glass, with dimensions 10 mm × 2.51 m × 0.992 m, supported by a metallic structure which allows the slope variation between 30° and 45°. At the bank, 0.95 m and 1.05 m away from the bottom, a gate was placed for sustain calcareous material. The gate was also made by acrylic glass with dimensions 10 mm × 0.98 mm × 0.51 m and moving in two U gutters, connected in a guide pulley system to a counter balance. The falling of the counter balance provokes the ascension of the gate, and so the falling of the material. Figure 1 shows a view of the bank and the mechanism that permits the falling of the material over the bank.

Falling masses were simulated by several calcareous blocks, with dimensions 7 cm × 8 cm × 10 cm, with density $\rho_s = 2.3755$, porosity $\eta_{por} \approx 0.40$, and friction angle determined experimentally. Some blocks were cut for adjusting the gate. Two positions of the gate were considered for avoiding two different high falls, and two different sets of blocks were considered. Figure 2 illustrates the two sets of material composed by:

i) volume 1 → a volume of 0.0814 m^3 corresponding to a mass of 193.29 Kg and a friction slope $\phi \approx 23.83°$;
ii) volume 2 → a volume of 0.168 m^3 corresponding to a mass of 400.85 Kg and a friction slope $\phi \approx 26.02°$.

61.5	30.7	0.0814	84.16
51.5	30.7	0.1687	85.08
51.5	39.5	0.0814	76.60
61.5	39.5	0.0814	86.60
51.5	39.5	0.1687	89.97

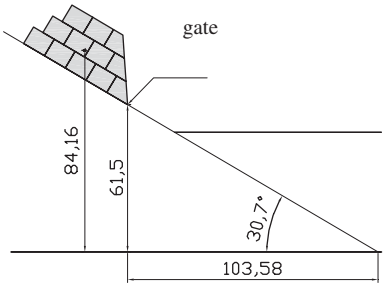

Figure 3. Mass centre at: position gate n° 1 and bank angle n°1.

For both volumes, mass centers were calculated for the two positions at the bank (61.5 cm and 71.5 cm), and for two different angles (30.7° and 39.5°). Table 1 illustrates the different parameters tested, and Figure 3 illustrates the mass center position for position 1 of the gate and for angle 1 of the bank.

3 GENERATION, PROPAGATION AND IMPACT OF WAVES CAUSED BY LANDSLIDES

3.1 *Numerical approach*

The results of two distinct numerical models, based on different mathematical formulations, were compared with physical data obtained at five probes installed into the reservoir.

The first model is based on the Reynolds-averaged Navier-Stokes equations governing the motion of the mean 2D incompressible flows in the $x-z$ plane, in which the free surface is described using a refined Volume-Of-Fluid (VOF) method. The internal obstacles are described by means of the Fractional Area-Volume Obstacle Representation (FAVOR) algorithm.

The mass and momentum conservation equations (Navier-Stokes equations) are:

$$\nabla.(\theta\,\vec{u}) = 0 \tag{1}$$

$$\frac{\partial \vec{u}}{\partial t} + \frac{1}{\theta}\nabla.(\theta\,\vec{u}\otimes\vec{u}) = -\frac{1}{\rho}\nabla p + \\ + \frac{1}{\theta}\nabla.\left[\theta(\nu+\nu_T)\left\{\nabla\vec{u} + (\nabla\vec{u})^T\right\}\right] + \vec{g} \tag{2}$$

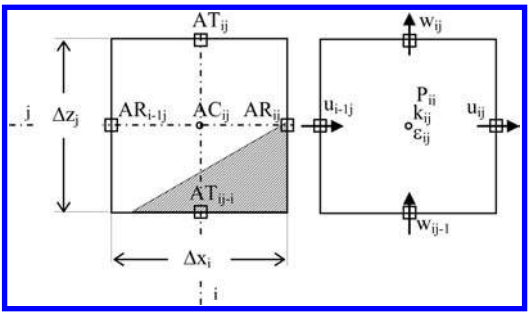

Figure 4. Definition of geometric and dependent variables in a typical mesh cell.

where $\vec{u} = (u(x,z,t),\ w(x,z,t))$ is the mean velocity vector, $p = p(x,z,t)$ is the mean pressure, ν is the coefficient of kinematic viscosity, ν_T is the eddy viscosity, $\vec{g} = (g_x, g_z)$ is the body force term and $\theta = \theta(x,z)$ is the porosity function whose value is "0" for a point inside an obstacle and "1" for a point that can be occupied by the fluid. If $\theta = \theta(x,z) = 1$ for all points of the domain, equations (1) and (2) reduce to the usual Navier-Stokes equations.

Since the position of the free surface is not known a-priori its configuration has to be determined as part of the solution. The fluid configuration can be described in terms of the VOF-function $F = F(x,z,t)$ whose value is 1 for a point occupied by the fluid and zero elsewhere. The equation governing the time evolution of F is:

$$\frac{\partial F}{\partial t} + \frac{1}{\theta}\nabla.(\theta\,\vec{u}) = 0 \tag{3}$$

which states the lagrangian invariance of F in an Eulerian representation.

The governing equations were discretized using a finite difference staggered grid system of rectangular cells (control volume) with variables width Δx_i and height Δz_j. The porosity function θ is defined at the horizontal and vertical faces of each control volume using the mesh-wide arrays AT and AR and at the centre of the control volume using another array AC. This forms the basis of the FAVOR method that allows the treatment of curved boundaries in cartesian meshes without stair-step instabilities. The arrangement of the geometric and dependent variables in a typical mesh cell is illustrated in Figure 4.

The main computational cycle by which the dependent variables are updated from u^n, w^n, p^n, F^n, at time level $n\,\Delta t$ to $u^{n+1}, w^{n+1}, p^{n+1}, F^{n+1}$, at time $(n+1)\,\Delta t$ consists of the following steps:

Step 1: A provisional velocity field $\vec{u}^* = (u^*, w^*)$ is computed using the discretized momentum equation with the advanced-time pressure p^{n+1} replaced by p^n. This provisional velocity field is not div-free since

Copyright © 2006 Taylor & Francis Group plc, London, UK

p^{n+1} is not yet known (it is important to treat the advection term accurately – in the computer code, this term was approximated using the SMART scheme to obtain the interpolated values at the four cell faces E, W, N and S (see Darwish and Moukalled, 1996);
Step 2: The advanced-time velocity $\vec{u}^{n+1} = (u^{n+1}, w^{n+1})$ and pressure p^{n+1} are computed using a pressure-velocity iterative scheme based in a cell by cell pressure-velocity relaxation scheme so that $\vec{u}^{n+1}$ is discretely div-free;
Step 3: The advanced-time fluid configuration F^{n+1} is computed at all cells of the domain using a special discretization of eq. (3) for maintaining the sharpness of the interface and conserving total fluid volume (Hirt & Nichols, 1981 and Rider & Kothe, 1998).

The details of the can be found in Carvalho (2002).

To describe a properly posed problem, initial and boundary conditions for eqs. (2)–(5) must be specified. The inflow boundary is very important to reproduce the physical wave.

The second model solves an extension of the modified Boussinesq equations, which are considered a suitable mathematical model for obtaining the characteristics of a wave caused by a landslide and its propagation within the reservoir. These equations may be derived from the fundamental equations of the Fluid Mechanics relating to a three-dimensional and quasi-irrotational flow of a viscous fluid. The set of equations thus obtained can be solved numerically using, for example, a finite element method for spatial discretization of the partial differential equations (Antunes do Carmo *et al*., 1993; Antunes do Carmo, 1995; Antunes do Carmo & Seabra Santos, 1996). Similarly, an equation can be developed to calculate the pressure field exerted on the upstream face of the dam during the approach and possible overtopping of the wave (Antunes do Carmo, 1996). The complete set of 1D equations is written:

$$\frac{\partial h}{\partial t} + \frac{\partial (h\bar{u})}{\partial x} = 0$$
$$\frac{\partial \bar{u}}{\partial t} + \bar{u}\frac{\partial \bar{u}}{\partial x} + g\frac{\partial (h+\xi)}{\partial x} - \frac{(H-\xi)^2}{3}\frac{\partial^3 \bar{u}}{\partial x^2 \partial t} + $$
$$+ (H-\xi)\frac{\partial^2 \bar{u}}{\partial x \partial t}\frac{\partial \xi}{\partial x} + \frac{H-\xi}{2}\frac{\partial \bar{u}}{\partial t}\frac{\partial^2 \xi}{\partial x^2} - \nu\frac{\partial^2 \bar{u}}{\partial x^2} - \frac{\tau(\xi)}{h} = 0 \quad (4)$$

as well as the following equation to obtain the dynamic pressure on the upstream face:

$$\frac{1}{\rho}p(z) = g(\eta - z) + (\eta - z)\frac{\partial \xi}{\partial x}\frac{\partial \bar{u}}{\partial t} + (\eta - z)\frac{\partial^2 \bar{u}}{\partial x \partial t}\left(\frac{\eta - z}{2} + H - \xi\right)$$

where h is the total water depth, H the initial water level, $\bar{u}$ the horizontal mean velocity and ξ the bed elevation; $\tau(\xi)$ represents bottom shear stress and $\eta = h - H + \xi$.

Grouping terms containing $\bar{u}$-derivatives in time in this equations system, we can re-write an equivalent form of system (4) in the form (5). It is easy to show that after substituting the third equation in the second one of system (5), we again find the final equation system (4).

$$\frac{\partial h}{\partial t} + h\frac{\partial \bar{u}}{\partial x} + \bar{u}\frac{\partial h}{\partial x} = 0$$
$$\frac{\partial \bar{r}}{\partial t} = -\bar{u}\frac{\partial \bar{u}}{\partial x} - g\frac{\partial (h+\xi)}{\partial x} + \nu\frac{\partial^2 \bar{u}}{\partial x^2} - \frac{\tau(\xi)}{h}$$
$$\bar{u} - \frac{(H-\xi)^2}{3}\frac{\partial^2 \bar{u}}{\partial x^2} - (H-\xi)\frac{\partial (H-\xi)}{\partial x}\frac{\partial \bar{u}}{\partial x} - $$
$$- \frac{H-\xi}{2}\frac{\partial^2 (H-\xi)}{\partial x^2}\bar{u} = \bar{r} \quad (5)$$

Schematically, the last set of equations can be written as (6) and a finite element method was utilized to obtain the solution of this equation system.

$$-\frac{\bar{u}_i^n}{4\Delta x}h_{i-1}^{n+1} + \left[\frac{1}{\Delta t} + \frac{1}{2}\left(\frac{\partial \bar{u}}{\partial x}\right)_i^n\right]h_i^{n+1} + \frac{\bar{u}_i^n}{4\Delta x}h_{i+1}^{n+1}$$
$$= \left[\frac{1}{\Delta t} - \frac{1}{2}\left(\frac{\partial \bar{u}}{\partial x}\right)_i^n\right]h_i^n - \bar{u}_i^n\frac{1}{2}\left(\frac{\partial h}{\partial x}\right)_i^n$$
$$h_i^{n+\theta} = (1-\theta)h_i^n + \theta\, h_i^{n+1}$$
$$\bar{r}_i^{n+1} = \bar{r}_i^n - \left[\bar{u}_i^n\left(\frac{\partial \bar{u}}{\partial x}\right)_i^n + g\left(\frac{\partial h}{\partial x} + \frac{\partial \xi}{\partial x}\right)_i^{n+\theta} - \nu\left(\frac{\partial^2 \bar{u}}{\partial x^2}\right)_i^n + \left(\frac{\tau}{h}\right)_i^n\right]\Delta t$$
$$\left[-\frac{(H-\xi)^2}{3\Delta x^2} + \frac{(H-\xi)}{2\Delta x}\frac{\partial (H-\xi)}{\partial x}\right]_i \bar{u}_{i-1}^{n+1} +$$
$$+\left[1 + \frac{2(H-\xi)^2}{3\Delta x^2} - \frac{H-\xi}{2}\frac{\partial^2 (H-\xi)}{\partial x^2}\right]_i \bar{u}_i^{n+1} +$$
$$+\left[-\frac{(H-\xi)^2}{3\Delta x^2} - \frac{(H-\xi)}{2\Delta x}\frac{\partial (H-\xi)}{\partial x}\right]_i \bar{u}_{i+1}^{n+1} = \bar{r}_i^{n+1}$$
$$\bar{u}_i^{n+\theta} = (1-\theta)\bar{u}_i^n + \theta\, \bar{u}_i^{n+1} \quad (6)$$

The numerical procedure used to compute the solution of equation system (4) (values of the variables h and u at time $t + \Delta t$) is based on the following numerical scheme, itself based on the last equation system (5), for the variables h, r and $\bar{u}$ (Antunes do Carmo *et al.*, 1993; Antunes do Carmo & Seabra Santos, 1996):

Step 1; The first equation allows us to predict the values of variable h ($h_p^{t+\Delta t}$) utilizing a semi-implicit scheme, considering the known values of h and u at time t in the whole domain.
Step 2; The second equation allows the explicit prediction of the values of variable r ($r_p^{t+\Delta t}$), considering the values of $h^{t+\theta\,\Delta t} = (1-\theta)h^t + \theta\, h_p^{t+\Delta t}$, u and r^t, known for the whole domain.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Step 3; The third equation allows us to obtain the values of variable u at time $t + \Delta t$ ($u^{t+\Delta t}$) utilizing a semi-implicit scheme, considering the predicted values of r ($r_p^{t+\Delta t}$) in the whole domain.
Step 4; The first equation allows us to compute the depth h at time $t + \Delta t$ ($h^{t+\Delta t}$), taking into account the values of variables h^t and $u^{t+\theta\,\Delta t} = (1-\theta)u^t + \theta\, u^{t+\Delta t}$ known for the whole domain.
Step 5; The second equation allows us to compute the values of variable r at time $t + \Delta t$ ($r^{t+\Delta t}$), taking into account the values of variables r^t, $h^{t+\theta\,\Delta t} = (1-\theta)h^t + \theta\, h^{t+\Delta t}$ and $u^{t+\theta\,\Delta t} = (1-\theta)u^t + \theta\, u^{t+\Delta t}$ known for the whole domain.

3.2 *Experimental data*

Data on the characteristics of waves formed when large masses of soil and/or rock fall into the reservoir were collected in the laboratory installation consisting by a channel where the bank, a reservoir and a dam were placed. The dimensions were settled considering non-dimensional characteristics equivalent to prototype disturbances. The reservoir water level varied between 0.30 m and 0.55 m.

The movement and the impact velocity of the mass into the water are essential to characterize the wave generation and the inflow condition for the numerical simulations (Carvalho & Carmo, 2006). The movement was filmed using a video-camera. The images were subsequently analyzed to obtain an estimate of the submerged mass and volume as a function of time, that is $M = f(t)$. This knowledge was required to solve equation (7), which describes the movement of the sliding block:

$$M\frac{dv_s}{dt} = Mg\sin\alpha - M_w g\frac{\rho_s}{\rho_w}\sin\alpha - Mg\cos\alpha\tan\phi - \frac{1}{2}C_x\rho_w A V^2 \qquad (7)$$

where M is the mass of the sliding block, M_w is the submerged mass, v_s is the slide mass velocity, α is the bank slope, ϕ is the friction slope, ρ_s is the density of slide mass, ρ_w is the water density, C_x is the drag coefficient for the slide, A is the slide mass section, t is the time and g is the acceleration due to gravity. For solving eq. (7), a 4th Runge-Kutta method was used.

An equipment based on a three laser pointed on the channel was also tested, but due to the channel glass characteristics, the measures were not trustable.

Between the bank and the dam, five probes (HR Wallingford wave probe monitors 0.6 m) were positioned at 2, 4, 6 and 8 m away from the bank for measuring the water level. A probe more closed to the mass slide impact was desirable, but the probe could not be secure.

Figure 5. Physical model, including the sliding slope, the water mass (reservoir) and one of the five gauges.

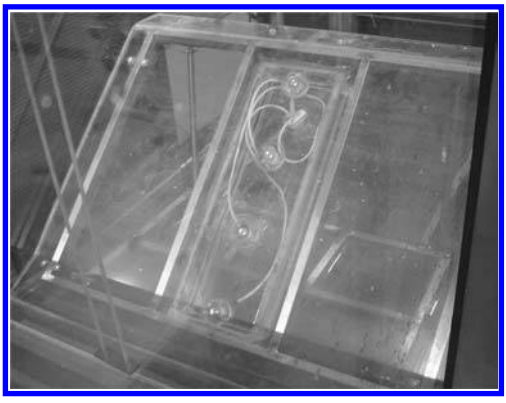

Figure 6. Dam with the four pressure gauges installed.

The wave impact and reflection on the upper face of the dam were also obtained in the laboratory experiments. This was done by measuring both the wave height and the pressure exerted on the wall. Figure 5 shows the physical model, including the sliding slope, the water mass (reservoir) and the first gauge, placed 2 m after the bank, and Figure 6 shows the dam with the four pressure transducers installed.

4 RESULTS

4.1 *Experimental essays*

The laboratory study of the wave characteristics and the hydrodynamic effects caused by landslides was based on a test matrix that included 18 different conditions. The relevant parameters governing the wave generation consist of: mass of the sliding block, the still water level in the reservoir, the slide velocity, the slide mass, the slope and the initial position of the sliding block. The four parameters were varied as follows:

i) slide slope, $\alpha = 30.7°$ and $39.5°$;
ii) reservoir water level, $h_0 = 0.50$ m and 0.55 m;

iii) slide volume $V = 0.0814\,\text{m}^3$ and $0.1687\,\text{m}^3$;
iv) centroid slide mass position.

Table 2 shows the different parameter values chosen for the 18 experiments.

For the 18 experiments, the position of the sliding block was calculated using eq.(7) and the images processed form the video recordings. The time history of the water level and pressure on the upper face of the dam were also measured simultaneously using software that permits real time visualization on the computer.

4.2 *Wave generation – wave type*

Based on wave type classification proposed by Noda (1970) and used by Fritz *et al.* (2004), the fundamental parameters were calculated. Table 3 shows the predicted wave types for the 18 essays.

The slide Froude number was determined by the following expression deduced taking into account the energy balance between the positions before and after the slide:

$$v_s = \sqrt{2g\Delta z \sin(\alpha - \phi)} \tag{8}$$

where v_s is the slide velocity when the centroid arrives to the water surface, Δz is the height between the position of the centroid before and after the slide fall, g is the acceleration due to gravity, α is de slide slope and ϕ is the friction slope. The velocity was compared with the calculated values obtained through eq. (7) and in the majority of the essays, it was observed an acceptable proximity of the maximum slide velocity, except for the lower slide slopes and smaller centroid heights. Figure 7 shows the variation of the slide mass velocity during the fall calculated by eq. (7).

Figure 7 illustrates the importance of the chosen parameters. The initial water level position, for small bank angles, is not so important (slide mass velocity variation during the fall is similar in E01-E03 and E04-E06). For the higher angle, the maximum velocity difference become visible (E08 and E11). For the slide mass volume, similar results could be observed (E01 and E03). However, the slide mass volume variation could not be analyzed dissociated from the centroid initial position. This parameter is very important both in the initial and maximum slide mass velocity (see E01 and E02, E07 and E08, E10 and E11 or E16 and E17). The slide slope is also very influent in the maximum slide mass velocity (see E01 and E07). In particular, when the initial water level is low, this parameter causes large slide initial velocity (see E16 and E17). Concerning the velocity variation, the following ascending variation could be observed: parabolic (E01–E12), linear (E13–E17) and sinusoidal (E18). Sudden descending variations were verified due to the reservoir water level, which is not large enough to decelerate the slide mass.

4.3 *Wave characteristics and propagation*

The knowledge of the wave amplitude and celerity is very important for the risk prediction and hazard prevention, i.e. for efficient activation of emergency

Copyright © 2006 Taylor & Francis Group plc, London, UK

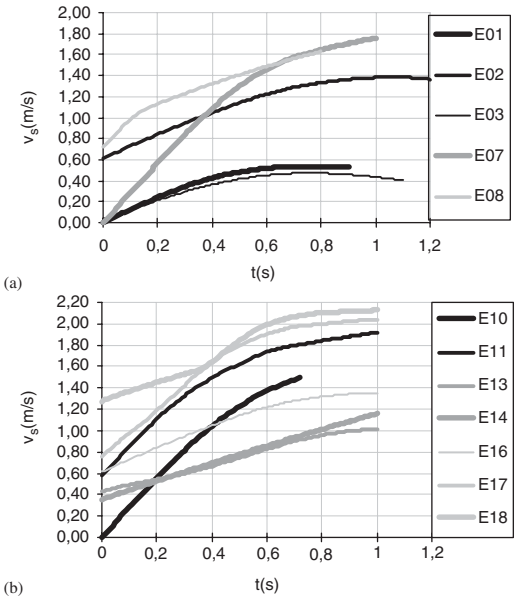

Figure 7. Variations of the slide mass velocity during the fall: (a) essays E01, E02, E03, E07 and E08; (b) E10, E11, E13, E14, E16, E17 and E18.

plans. In most of the tests, the maximum wave amplitude was attained by the first wave. However, in gauge number 4, placed 8 m far from the bank, the amplitude of the second wave exceeded that of the leading wave in tests E10 and E11.

The maximum positive wave amplitude was observed in E03 and E13, the minimum was observed in E04. These results show the strong dependence of the phenomena on the mass (volume) of the sliding mass and the initial water level. In terms of the dimensionless parameter a_c/h_0, the maximum wave amplitude was observed in E17 (0.46) due to the greater velocity which is in turn due to the higher bank slope and minor water level. This result agrees with the formula proposed by Fritz *et al*. (2004):

$$\frac{a_C}{h_0} = 0.25\left(\frac{v_s}{\sqrt{gh_0}}\right)^{1.4}\left(\frac{s}{h_0}\right)^{0.8} \quad (9)$$

The maximum negative wave amplitude was observed for E10 and E11 and the minimum for E16, where the wave shows solitary characteristics.

The minimum wave length L is observed in E05, which corresponds to the greater wave steepness a_c/L. E08 presents the maximum wave length and the minimum wave declivity (0.02). The value of L/h_0 is maximum in E18 and minimum in E05. It was obtained: $4.55 < L/h_0 < 12.28$ and $0.02 < a_c/L < 0.05$. All values are less than 0.06, the limit of breaking. However, it can't be negligible that the first wave amplitude values were obtained at the first gauge placed 2 m after the bank.

For non linear waves, celerity is strongly dependent on the relative amplitude, a_c/h_0, wave length, L, and initial water level, h_0. Propagation velocity decreases with the amplitude and wave length. According to Boussinesq theory, the following expression for the solitary wave velocity is valid: $c_{c1}/\sqrt{gh_0} = 1 + a_{c1}/(2h_0)$, where 1 refers to the first wave. According to Fritz et al (2004), velocities 30% greater than those calculated by eq. (10) were observed. In the present study values in the range $0.9 < c_{c1}/\sqrt{gh_0} < 1.2$ for the first wave and $0.6 < c_{c1}/\sqrt{gh_0} < 1.0$ for the second one were obtained. All values of a_c/h_0 are greater than 0.03, all values of a_c/L are greater than 0.006 and the Ursell number is always greater than 1, which confirms the waves nonlinearity characteristics. Figure 8 shows a comparison between numerical results and laboratory data of the reservoir water level variations in essay E14 at 2, 4, 6 and 8 m from the slide mass falling point.

Figure 8 shows a good agreement between both models. However, after the second wave the numerical solutions show a lag in time relative to the experimental results. The results for other simulations were similar. It can be concluded that the numerical models:

i) underestimate the negative amplitude of the first wave in E10 and E11;
ii) overestimate positive and negative amplitudes in E16 and E18;
iii) in general,the VOF model produced better agreement with the laboratory measurements;
iv) the numerical solutions are very sensitive to the inflow condition: small variations in the velocity function could produce remarkable amplitude differences.

4.4 *Wave impact on dam*

Hydrodynamic pressures on the upper dam face were measured by pressure transducers. Figure 9 illustrates pressure data measured at the four transducers placed on the face of the dam and the time history of the water level at gauge 5, placed 10 m far from the slide mass falling point (just close to the beginning of the upper dam face, where the pressure transducers were installed).

An instability was observed when the wave is reflected upstream at the upper face of the dam. It also could be noted that the negative wave amplitude is greater on the pressure transducer placed close to the free surface. These could not be perceptible by the gauge measures and should be studied in more detail.

Other experimental and numerical results are under development.

5 CONCLUSIONS

Data on the wave characteristics formed when large masses of soil or rock fall into a reservoir were presented. The wave propagation and its impact on a dam were examined by means of laboratory measurements and numerical models with different approaches.

Numerical results showed a fair agreement with experimental data. It could be concluded that numerical simulations are strongly dependent on the definition of the inflow boundary condition, which in turn depends on the velocity variation of the sliding mass.

More experiments are needed to improve and detail the measurements that lead to the slide mass velocity function during the fall, to allow a better numerical solution.

However, this work permitted to conclude that:

- different velocity diagrams (inflow boundary condition): nearly linear, sinusoidal and parabolic were produced;
- different types of waves are formed depending on the relevant parameters governing the wave generation: mass of the sliding block, still water level in the reservoir, sliding velocity, slide mass, bank slope and initial position of the sliding block;
- numerical results can predict fair accurately the wave formed by landslide, mainly the amplitude and length of the first wave;
- hydrodynamic pressure appeared on the upstream face of the dam.

In general, more essays results are essential to support correlation and develop formulas able to predict the wave amplitude and velocity propagation. It could also be pointed that the amplitude of the first wave should be measured closer to the slide mass impact.

High-order finite volume modelling of one-dimensional flows

L. Cozzolino & D. Pianese
Department of Hydraulic and Environmental Engineering, Federico II University, Naples, Italy

ABSTRACT: In this paper, a numerical model is presented, aiming at the accurate solution of the one-dimensional Shallow-water Equations with bed slope source terms. The numerical model, which is fully third-order precise in time and space, is based on the Spectral Volume Method, and makes use of the HLL approximate Riemann solver to evaluate the fluxes at the interfaces between the cells. The source terms are treated, in the context of the HLL solver, in an upwinded fashion. A number of numerical experiments are reported, showing the promising capabilities of the model to solve real-world problems with complicate topographies.

1 INTRODUCTION

The numerical solution of the one-dimensional flow equations is useful to model a variety of physical phenomena such as tidal flows at river estuaries, flood propagation through natural and artificial channel networks, bore wave propagation, etc. Since these equations are non linear, they admit the formation of discontinuities in the flow field even in case of smooth initial conditions: such discontinuities are also encountered in the case of propagation of the flood on an initially dry bed.

Moreover, the momentum equation is characterized by the presence of a geometrical source term, due to gravity, which balances the advective fluxes when a steady-state condition is attained. The numerical solution of the Shallow-water Equations with source terms has to take into account this fact, in order to avoid spurious oscillations of the numerical solution and instability of the algorithm, even in the case of water-at-rest solutions. The numerical schemes which preserve the steady state conditions, and that balance the fluxes with the source terms, independently of the grid mesh, are called *well-balanced* (Greenberg & Leroux, 1996). A number of well-balanced schemes for the solution of Shallow-water Equations, which are at most second-order accurate, can be found in literature (see for example Gosse, 2000, Jin, 2001).

Of course, the preservation of any possible steady-state condition is quite a restrictive requirement, and attention has been focused on numerical schemes which satisfy the water-at-rest condition: these schemes have demonstrated to improve the numerical solution for more general cases. The schemes that satisfy the water-at-rest condition exactly or within a fixed order of accuracy are said to satisfy the *C-property* (Bermúdez & Vázquez, 1994, Bermúdez et al., 1998). In this context, a number of different approaches have been considered (see Xing & Shu, 2005, for a brief review): among others, the upwinding of source terms has proven to be very effective (Bermúdez & Vázquez, 1994, Hubbard & García Navarro, 2000).

Modelling long-term flow transients in shallow-water bodies is a challenging task: the current numerical models, which are usually second-order accurate in time and space, have demonstrated their ability to correctly manage special situations as fast transients following dam-break phenomena, but they show excessive numerical dissipation when applied to the case of long transients. In the context of the Finite Volume Method, a number of high-order schemes for the solution of the one- and two-dimensional Shallow-water Equations with source terms have been presented. Kurganov and Levy (2002) have considered a central-upwind scheme with a third-order approximation of the fluxes and a second-order approximation of the source terms: the scheme behaved better than a fully second-order scheme, of course. Črnjarić-Žic et al. (2004) have proposed a Finite Volume WENO scheme with upwind treatment of source terms: their approach allows for the use of non-uniform grids, but the proposed treatment of the central part of geometrical source terms degrades the theoretical accuracy of the scheme (as confirmed by their convergence experiments). The same authors propose a Central WENO scheme, on staggered grids: it respects the theoretical accuracy, but is not suitable for non-uniform grids. Noelle et al. (2005) extended the original source-terms treatment by Audusse et al. (2004) to the third-order theoretical accuracy, and they used a fifth-order WENO approximation for the fluxes. Their convergence experiments seem to show that their scheme is

Copyright © 2006 Taylor & Francis Group plc, London, UK

fifth order accurate. Ortega (2005) proposed a third-order ENO scheme for the fluxes and a second-order integration rule for the source terms: the convergence experiments in steady-flow conditions confirmed that the accuracy order of the scheme was less than three.

Continuing the work started in Cozzolino & Pianese (2005), in this paper a new Finite Volume numerical model is described, aiming at the solution of the one-dimensional Shallow-water Equations with bed-slope source terms, with the third-order of accuracy. Following Alouges et al. (1999), source terms are treated in an upwind fashion, just like the advective fluxes. The concept of Spectral (Finite) Volume (Wang, 2002) is used for the space discretization of the equations, and the fluxes are calculated by means of the HLL approximate Riemann solver. Runge-Kutta's algorithm is applied to solve the set of ODE's obtained after the space discretization.

2 THE NUMERICAL METHOD ADOPTED

2.1 *Shallow-water equations and the finite volume method*

The 1D Shallow-water Equations are a system of hyperbolic partial differential equations which can be written, in vector form, as

$$\frac{\partial \vec{U}}{\partial t} + \frac{\partial \vec{F}(\vec{U})}{\partial x} = \vec{S}(x, \vec{U}) \tag{1}$$

The symbols in Equation 1 have the following meanings:

$$\vec{U} = \begin{pmatrix} h & hU \end{pmatrix}^T \tag{2}$$

is the vector of the conserved quantities h (water height) and hU (discharge per unitary width), where U is the velocity;

$$\vec{F} = \begin{pmatrix} hU & hU^2 + \frac{1}{2}gh^2 \end{pmatrix}^T \tag{3}$$

is the vector of the fluxes, and

$$\vec{S} = \begin{pmatrix} 0 & -gh\frac{dz_b}{dx} \end{pmatrix}^T \tag{4}$$

is the vector of the source terms, where z_b represents the bed elevation.

If the computational domain is subdivided into N finite volumes, Equation 1 can be spatially integrated in each of these elements, obtaining

$$\frac{d\vec{U}_i}{dt} = \vec{L}_i(\vec{U}), \quad i = 1...N \tag{5}$$

where

$$\vec{L}_i(\vec{U}) = -\frac{1}{\Delta x_i}\left[\vec{F}^*_{i+\frac{1}{2}} - \vec{F}^*_{i-\frac{1}{2}}\right] + \frac{1}{\Delta x_i}\int_{x_{i-\frac{1}{2}}}^{x_{i+\frac{1}{2}}} \vec{S}\,dx \tag{6}$$

and

$$\vec{U}_i = \frac{1}{\Delta x_i}\int_{x_{i-\frac{1}{2}}}^{x_{i+\frac{1}{2}}} \vec{U}\,dx \tag{7}$$

is the vector of the cell-averaged values of the quantities conserved in the finite volume i, whose left and right boundaries have abscissas $x_{i-1/2}$ and $x_{i+1/2}$ respectively, and lengths $\Delta x_i = x_{i+1/2} - x_{i-1/2}$. The numerical source terms are evaluated from the cell-averaged values z_{bi} of the bed elevation z_b in each of the finite volumes.

If the quantities on the right-hand side of Equation 5 (numerical fluxes and numerical source term) depend on the averaged values $\vec{U}_i$ of the conserved quantities, then the Equation 5 represents a system of ordinary differential equations which can be properly integrated in time (method of lines).

2.2 *HLL Riemann solver*

Since the Shallow-water Equations are a system of non linear hyperbolic equations, discontinuities in the flow field can also develop in the case of continuous initial conditions, and numerical fluxes F^* between two cells must account for this.

Here, the approximate Riemann solver HLL is adopted (Toro, 1999):

$$\vec{F}^* = \alpha\vec{F}_L - \beta\vec{F}_R + \gamma(\vec{U}_R - \vec{U}_L) \tag{8}$$

where $\vec{F}_L$ and $\vec{F}_R$ are the physical fluxes, while $\vec{U}_L$ and $\vec{U}_R$ are the conserved quantities, on the left and right sides of each interface, respectively. In Equation 8 the following positions have been made:

$$\alpha = \frac{s_R}{s_R - s_L}; \quad \beta = \frac{s_L}{s_R - s_L}; \quad \gamma = \frac{s_R s_L}{s_R - s_L} \tag{9}$$

and the wave speeds s_L and s_R can be evaluated as in Fraccarollo & Toro (1995).

The conserved quantities at each interface can be calculated, from the averaged values of the quantities conserved in each finite volume, by means of proper polynomial reconstruction. In the present case, the variables h, hU and $\varsigma = z_b + h$ (water surface elevation) have been chosen for the reconstruction (Audusse et al., 2004), implying that the bottom elevation reconstruction changes at each time step, according to the water surface elevation and water depth reconstruction.

Copyright © 2006 Taylor & Francis Group plc, London, UK

After that the reconstruction of the conserved quantities has been accomplished, the physical fluxes and the wave speeds can be evaluated on both sides of each interface.

2.3 *Upwinding of source terms*

Bermúdez & Vázquez (1994) have shown that the upwinding of source terms in the Shallow-water Equations can enforce the respect of the *C-property*: in their original method, the source terms are integrated on a mesh that is staggered with respect to the original finite volume mesh, and then they are projected onto the eigen-vectors of Roe's Jacobian, in the context of Roe's approximate Riemann solver. Following this approach, the numerical source term can be regarded as the sum of two cell-interface contributions. Delis (2003) applied a first-order method, in the context of HLL-E approximate Riemann solver, again by projecting the integral of the source terms onto the eigen-vectors of Roe's Jacobian: this approach doubles the number of wave speeds to be calculated.

Hubbard & García-Navarro (2000) extended the scheme by Bermúdez & Vázquez (1994) to the second-order precision in time and space. They remarked that, in the context of slope-limited schemes, a central source-term has to be introduced to the interfaces source term contributions in order to enforce the equilibrium with the advective fluxes. Ortega (2005) explicitly added the primitive of the source terms to the fluxes, and this sum was reconstructed by means of a third-order ENO-Roe reconstruction. However, the formal order of precision of the algorithm was degraded because of the quadrature rule used to compute the source term integrals. Črnjarić-Žic et al. (2004) proposed a Finite Volume scheme with WENO reconstruction of the conserved variables: the proposed treatment of the central part of geometrical source terms degraded the theoretical accuracy of the scheme.

Here, the original idea by Alouges et al. (1999) is applied. The geometrical source terms can be rewritten in divergence form

$$\vec{S} = \frac{\partial}{\partial x}\int_{x_a}^{x} \vec{S} dx = -\frac{\partial \vec{B}}{\partial x} \tag{10}$$

and then added to the divergence of fluxes. Equation 1 can be rewritten as

$$\frac{\partial \vec{U}}{\partial t} + \frac{\partial \vec{H}}{\partial x} = 0 \tag{11}$$

where

$$\vec{H} = \vec{F} + \vec{B} = \vec{F} - \int_{x_0}^{x} \vec{S} dx \tag{12}$$

and the following numerical flux can be defined:

$$\vec{H}^{*} = \alpha \vec{H}_L - \beta \vec{H}_R + \gamma\left(\vec{U}_R - \vec{U}_L\right) \tag{13}$$

Since at each interface one has, by construction,

$$\alpha - \beta = 1 \tag{14}$$

we can write

$$\begin{aligned} &\left[\alpha \vec{H}_L\right]_{i+\frac{1}{2}} - \left[\beta \vec{H}_R\right]_{i+\frac{1}{2}} - \left[\alpha \vec{H}_L\right]_{i-\frac{1}{2}} + \left[\beta \vec{H}_R\right]_{i-\frac{1}{2}} = \\ &= \left[\alpha\left(\vec{H}_R - \vec{H}_L\right)\right]_{i-\frac{1}{2}} - \left[\beta\left(\vec{H}_R - \vec{H}_L\right)\right]_{i+\frac{1}{2}} + \\ &+ \left(\vec{H}_L\right)_{i+\frac{1}{2}} - \left(\vec{H}_R\right)_{i-\frac{1}{2}} \end{aligned} \tag{15}$$

Finally, the following equation holds:

$$\begin{aligned} &\vec{H}^{*}_{i+\frac{1}{2}} - \vec{H}^{*}_{i-\frac{1}{2}} = \left[\gamma\left(\vec{U}_R - \vec{U}_L\right)\right]_{i+\frac{1}{2}} + \\ &- \left[\gamma\left(\vec{U}_R - \vec{U}_L\right)\right]_{i-\frac{1}{2}} + \left[\alpha\left(\vec{H}_R - \vec{H}_L\right)\right]_{i-\frac{1}{2}} + \\ &- \left[\beta\left(\vec{H}_R - \vec{H}_L\right)\right]_{i+\frac{1}{2}} + \left(\vec{H}_L\right)_{i+\frac{1}{2}} - \left(\vec{H}_R\right)_{i-\frac{1}{2}} \end{aligned} \tag{16}$$

which is the HLL version of the slope-limited Roe scheme proposed by Hubbard & García-Navarro (2000). Recalling that

$$-gh\frac{\partial z_b}{\partial x} = \frac{1}{2} g \frac{\partial h^2}{\partial x} - gh\frac{\partial \varsigma}{\partial x} \tag{17}$$

one has:

$$\begin{aligned} &\Delta x_i \frac{d(hU)_i}{dt} = -\left[\gamma(hU_R - hU_L)\right]_{i+\frac{1}{2}} + \\ &+ \left[\gamma(hU_R - hU_L)\right]_{i-\frac{1}{2}} - \left(\alpha h U_L^2\right)_{i+\frac{1}{2}} + \left(\beta h U_R^2\right)_{i+\frac{1}{2}} + \\ &+ \left(\alpha h U_L^2\right)_{i-\frac{1}{2}} - \left(\beta h U_R^2\right)_{i-\frac{1}{2}} - \alpha_{i-\frac{1}{2}} \int_{x^{-}_{i-\frac{1}{2}}}^{x^{*}_{i-\frac{1}{2}}} gh\frac{\partial \varsigma}{\partial x} dx + \\ &+ \beta_{i+\frac{1}{2}} \int_{x^{-}_{i+\frac{1}{2}}}^{x^{*}_{i+\frac{1}{2}}} gh\frac{\partial \varsigma}{\partial x} dx - \int_{x^{*}_{i-\frac{1}{2}}}^{x^{-}_{i+\frac{1}{2}}} gh\frac{\partial \varsigma}{\partial x} dx \end{aligned} \tag{18}$$

If the bed is continuous (not necessarily smooth), the following condition holds

$$z_{bi+\frac{1}{2}} = \left(\varsigma_R - h_R\right)_{i+\frac{1}{2}} = \left(\varsigma_L - h_L\right)_{i+\frac{1}{2}} \tag{19}$$

and it is easy to show that

$$\int_{x^{-}_{i+\frac{1}{2}}}^{x^{*}_{i+\frac{1}{2}}} gh\frac{\partial \zeta}{\partial x} dx = g\left[\frac{h_L + h_R}{2}\left(\varsigma_R - \varsigma_L\right)\right]_{i+\frac{1}{2}} \tag{20}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

The last integral, on the right-hand side of Equation 18, can be evaluated by means of a proper quadrature formula. Here, the approach by Noelle et al. (2006) is used:

$$\int_{x_{i-\frac{1}{2}}^{+}}^{x_{i+\frac{1}{2}}^{-}} gh\frac{\partial \zeta}{\partial x}dx = \frac{2g}{3}(h_1+h_2)(\zeta_2-\zeta_1)+ \\ +\frac{2g}{3}(h_2+h_3)(\zeta_3-\zeta_2)-\frac{g}{6}(h_1+h_3)(\zeta_3-\zeta_1) \tag{21}$$

where the following positions have been made:

$$\begin{cases} h_1=(h_R)_{i-\frac{1}{2}}; \quad h_2=(h_C)_i; \quad h_3=(h_L)_{i+\frac{1}{2}} \\ \zeta_1=(\zeta_R)_{i-\frac{1}{2}}; \quad \zeta_2=(\zeta_C)_i; \quad \zeta_3=(\zeta_L)_{i+\frac{1}{2}} \end{cases} \tag{22}$$

and the quantities with the subscript C are evaluated at the centres of the finite volumes. It can be demonstrated that Equation 21 is a fourth-order approximation of the integral over a finite volume of the central part of the source terms (Press et al., 1992): of course, it is only a third-order approximation of the cell-averaged value of the source term in the finite volume.

In spite of its form, which resembles a discretization of the non-conservative equation

$$\frac{\partial hU}{\partial t}+\frac{\partial\left(hU^2\right)}{\partial x}=-gh\frac{\partial \zeta}{\partial x} \tag{23}$$

the Equation 18 is a conservative discretization of the second component of the Equation 1. In fact, in the case where bed-slope source terms are absent, one has

$$-gh\frac{\partial \zeta}{\partial x}=-gh\frac{\partial h}{\partial x} \tag{24}$$

and some algebra demonstrates that

$$-\alpha_{i-\frac{1}{2}}\int_{x_{i-\frac{1}{2}}^{-}}^{x_{i-\frac{1}{2}}^{+}} gh\frac{\partial \zeta}{\partial x}dx+\beta_{i+\frac{1}{2}}\int_{x_{i+\frac{1}{2}}^{-}}^{x_{i+\frac{1}{2}}^{+}} gh\frac{\partial \zeta}{\partial x}dx+ \\ -\int_{x_{i+\frac{1}{2}}^{+}}^{x_{i+\frac{1}{2}}^{-}} gh\frac{\partial \zeta}{\partial x}dx=-\left(\alpha g\frac{h_L^2}{2}\right)_{i+\frac{1}{2}}+\left(\beta g\frac{h_R^2}{2}\right)_{i+\frac{1}{2}}+ \\ +\left(\alpha g\frac{h_L^2}{2}\right)_{i-\frac{1}{2}}-\left(\beta g\frac{h_R^2}{2}\right)_{i-\frac{1}{2}} \tag{25}$$

2.4 *Spectral (Finite) Volume Method*

In order to reach high-order accuracy in space, proper reconstruction of the conserved variables has to be accomplished in each control volume, starting from the cell-averaged values: here, the relatively recent *Spectral (Finite) Volume Method* (Wang, 2002) has been adopted. This method, which was originally developed in the context of gas-dynamics, was applied to the solution of the Shallow-water Equations by Choi et al. (2004) too. However, in their application, they neglected the bed-slope source terms.

The computational domain has been subdivided into *NS* non–overlapping domains named *Spectral Volumes*, whose lengths are

$$\Delta x_i=x_{i+1/2}-x_{i-1/2}; \quad i=1,2...,NS \tag{26}$$

To reach the k-th order of accuracy, each of the Spectral Volumes has been again subdivided into k Finite Volumes, whose lengths are

$$\Delta x_{i,j}=x_{i,j+1/2}-x_{i,j-1/2}; \quad i=1,2...,NS; j=1,2...k \tag{27}$$

If $u_{i,j}$ is the cell-averaged value of the conserved variable in the finite volume $C_{i,j}$, there exists only one polynomial reconstruction $p_i(x)$ of degree $(k-1)$ in the spectral volume S_i that ensures

$$\int_{x_{i,j-\frac{1}{2}}}^{x_{i,j+\frac{1}{2}}} p_i(x)dx=u_{i,j}\Delta x_{i,j} \tag{28}$$

for each control volume $C_{i,j}$. Given the reconstruction $p_i(x)$, it is easy to show that the reconstructed values of the variable u at the interfaces of the finite volumes are a linear combination of the cell-averaged values $u_{i,j}$: the coefficients of this linear combination depend only on the computational mesh, thus they can be precalculated and stored in memory. The finite volumes in each spectral volume are not equally spaced, in order to reduce the spurious oscillations at the boundaries of each spectral volume (Wang & Liu, 2004). Here, the Gauss-Lobatto points

$$\frac{x_{i,j+1/2}-x_i}{\Delta x_i}=-\frac{1}{2}\cos\left(\frac{j\pi}{k}\right); \quad j=0,1,...,k \tag{29}$$

have been used to collocate the interfaces between the control volumes, where x_i is the mid point of the spectral volume S_i.

We observe that the compactness and linearity of the reconstruction scheme leads to an efficient treatment of boundary conditions, and savings in CPU requirements. Moreover, the method is suitable for non-uniform grids, and its extension to quadrilateral

Copyright © 2006 Taylor & Francis Group plc, London, UK

and triangular non-structured meshes is possible. The Spectral (Finite) Volume Method permits to attain very high-order precision in space: Choi et al. (2004) presented schemes up to the eighth order for the solution of the Shallow-water Equations without source terms. Here, third-order precision in space is attained by making use of $k = 3$ control volumes for each spectral volume.

Once that the reconstructed variables are known on both sides of the cell interfaces, limitation of data is accomplished where needed. Aiming at this, the TVBM limiter by Cockburn & Shu (1989) is used, in order to avoid accuracy degeneration near extrema, which is consequent to the use of a total variation diminishing limiter. The TVBM limiter depends on a constant M to be tuned, namely an upper bound to the absolute value of the second-order derivative of the solution at local extrema: for a system of equations, a different value of the constant M can be used for each of the variables.

To determine the interface value of the flow depth, the following algorithm has been applied (Audusse et al., 2004), after the polynomial reconstruction and limitation of ς and h: first, the bed elevation value

$$z_b^* = \max\left(\varsigma_{L,i,j+1/2} - h_{L,i,j+1/2}; \varsigma_{R,i,j+1/2} - h_{R,i,j+1/2}\right) \quad (30)$$

is determined at each interface; then the water depths

$$\begin{cases} h_{R,i,j+1/2} = \max\left(\varsigma_{R,i,j+1/2} - z_b^*, 0\right) \\ h_{L,i,j+1/2} = \max\left(\varsigma_{L,i,j+1/2} - z_b^*, 0\right) \end{cases} \quad (31)$$

are chosen for the computations.

After the reconstruction and limitation of the conserved variables at the boundaries of each control volume, the value at the centre can be calculated by means of the following third-order approximation

$$u_{C\,i,j} = \frac{-u_{R\,i,j-1/2} + 6u_{i,j} - u_{L\,i,j+1/2}}{4} \quad (32)$$

2.5 *Time evolution*

To solve Equation 5, for each of the control volumes, the third-order optimal Runge-Kutta scheme is used, namely (Gottlieb & Shu, 1998):

$$\begin{cases} \vec{U}_{i,j}^{(1)} = \vec{U}_{i,j}^{n} + \Delta t \vec{L}_{i,j}\left(\vec{U}^{n}\right) \\ \vec{U}_{i,j}^{(2)} = \dfrac{3\vec{U}_{i,j}^{n}}{4} + \dfrac{\vec{U}_{i,j}^{(1)}}{4} + \dfrac{\Delta t}{4}\vec{L}_{i,j}\left(\vec{U}^{(1)}\right) \\ \vec{U}_{i,j}^{n+1} = \dfrac{\vec{U}_{i,j}^{n}}{3} + \dfrac{2\vec{U}_{i,j}^{(2)}}{3} + \dfrac{2\Delta t}{3}\vec{L}_{i,j}\left(\vec{U}^{(2)}\right) \end{cases} \quad (33)$$

where $\vec{U}^n$ is the vector of the conserved variables at the time level t^n, and $\Delta t = t^{n+1} - t^n$ is the time step. Finally, the spatially averaged value of the conserved variables in the spectral volume S_i can be calculated at each time step by means of

$$\vec{U}_i = \frac{\sum_{j=1}^{k} \Delta x_{i,j} \vec{U}_{i,j}}{\Delta x_i} \quad (34)$$

2.6 *C-property*

It is easy to demonstrate that the proposed scheme satisfies the *C-property* exactly. In fact, in the case of water-at-rest, Equation 18 reduces to

$$\begin{aligned} \Delta x_i \frac{d(hU)_i}{dt} = &-\alpha_{i-\frac{1}{2}} \int_{x_{i-\frac{1}{2}}^{-}}^{x_{i-\frac{1}{2}}^{+}} gh\frac{\partial \varsigma}{\partial x} dx + \\ &+ \beta_{i+\frac{1}{2}} \int_{x_{i+\frac{1}{2}}^{-}}^{x_{i+\frac{1}{2}}^{+}} gh\frac{\partial \varsigma}{\partial x} dx - \int_{x_{i-\frac{1}{2}}^{+}}^{x_{i+\frac{1}{2}}^{-}} gh\frac{\partial \varsigma}{\partial x} dx \end{aligned} \quad (35)$$

Starting from the rest conditions, the water surface elevation is uniform in the computational domain and equal to ς_o: the polynomial reconstruction ensures that the values of ς reconstructed at the centre and at the interfaces of each control volume are equal to ς_o. This implies that the source terms at the right-hand side of Equation 35, as calculated by means of Equations 20 and 21, are null, and the fluid does not accelerate. Significantly, the scheme chosen for the integration in time does not alter this equilibrium, which is satisfied at each of the inner steps of the Runge-Kutta algorithm (Equation 33).

3 NUMERICAL EXPERIMENTS

3.1 *Introduction*

In this section, a number of numerical experiments are presented, in order to verify the accuracy properties of the numerical scheme proposed, as well as its capability to preserve water-at-rest states, by using classical tests very often reported in the literature.

3.2 *Verification of the C-property*

The first test aims to verify if the numerical scheme proposed satisfies the *C-Property*. A channel, $L = 1500$ m long, with rectangular cross-section of unitary width, has a complicate bottom topography

Copyright © 2006 Taylor & Francis Group plc, London, UK

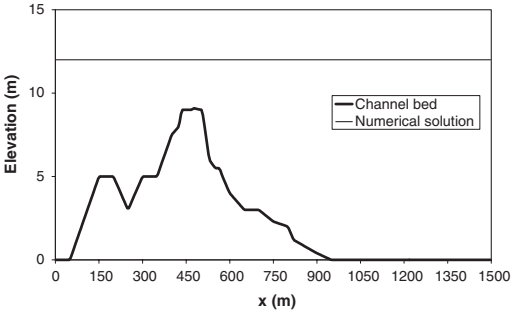

Figure 1. Quiescent flow test-case: water surface elevation, t = 1000 s.

(Figure 1), inspired to that of the test-case proposed by Goutal & Maurel (1997).

The quiescent initial conditions are $\varsigma_o = 12$ m, and $(hU)_o = 0$ m^2/s. The upstream and downstream boundaries of the channel are open and the physical boundary condition $(hU)_u = 0$ m^2/s is imposed upstream, while $\varsigma_d = 12$ m is imposed downstream. In spite of the complicate bottom topography, the analytical solution is of quiescent water, which is maintained indefinitely.

The results shown in Figure 1 ($t = 1000$ s) have been calculated, in double precision, on a uniform grid of 300 spectral volumes ($\Delta x = 5$ m), with time step $\Delta t = 0.02$ s. The limiting parameters used in the test are $M_h = 50$, $M_\varsigma = 50$, $M_{hU} = 0$.

Significantly, the error for the water surface elevation is of the order of the machine epsilon, and it has not been reported here. The L_∞ error norm (maximum absolute error) for the specific discharge hU is $3.67 \cdot 10^{-13}$ m^2/s, while the L_1 error norm (which is proportional to the average absolute error, if the grid is uniform) is $1.15 \cdot 10^{-13}$ m^2/s. Since after 50000 time steps the errors are very small, and not far from the level of round-off, it remains confirmed that, if the exact *C-Property* is satisfied, the water-at-rest solutions can be respected with good precision, and numerical stability is ensured.

3.3 *Convergence test*

In order to verify the accuracy of the numerical model, a convergence test has been accomplished, considering a subcritical flow over a bump. A horizontal channel is considered, $L = 25$ m long and 1 m wide, where a parabolic bump of height $H = 0.2$ m is present. The topography of the channel is defined as follows (see Figure 2):

$$z_b(x) = \begin{cases} 0; & x \le 8 \\ 0.2 - 0.05(x-10)^2; & 8 < x < 12 \\ 0; & x \ge 12 \end{cases} \qquad (36)$$

Table 1. hU errors and numerical orders of accuracy.

Number of spectral volumes	L_1 error		L_∞ error	
	error	order	error	order
25	$3.5 \cdot 10^{-5}$		$2.8 \cdot 10^{-4}$	
50	$4.6 \cdot 10^{-6}$	2.92	$4.1 \cdot 10^{-5}$	2.76
100	$6.1 \cdot 10^{-7}$	2.91	$5.3 \cdot 10^{-6}$	2.95
200	$7.6 \cdot 10^{-8}$	3.01	$7.0 \cdot 10^{-7}$	2.94
400	$9.6 \cdot 10^{-9}$	3.01	$8.9 \cdot 10^{-8}$	2.98
800	$1.2 \cdot 10^{-9}$	2.94	$1.3 \cdot 10^{-8}$	2.79

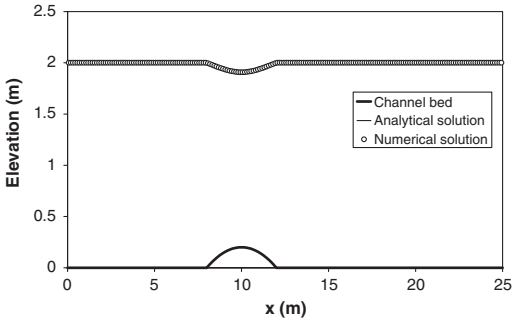

Figure 2. Subcritical flow over a bump: water surface elevation, t = 300 s.

A steady-state condition is considered where the specific discharge flowing through the channel is $hU = 4.42$ m^2/s, and a downstream boundary condition $\varsigma = 2$ m is imposed. In this case, the flow is subcritical, and an analytical solution exists, which can be found by means of the Bernoulli Theorem.

The test has been repeated for different grids, considering a number of spectral volumes ranging from 25 to 800, and keeping the Courant number constant, with time steps ranging from 0.05 s to 0.0015625 s. The limiter parameters were $M_h = 50$, $M_\varsigma = 50$, $M_{hU} = 0$ in all the convergence tests. The L_1 and L_∞ error norms are shown in Table 1, with the order of accuracy, for the specific discharge hU. It can be clearly seen that the third order of accuracy is attained by the numerical scheme.

In Figure 2 are compared the exact and calculated water surfaces elevations for the case of 200 spectral volumes ($\Delta x = 0.125$ m, $\Delta t = 0.00625$ s) at $t = 300$ s: it is apparent that the numerical solution is in close agreement with the analytical one.

In Figure 3 the specific discharge error is plotted for the 200 spectral volumes test, showing the good conservation properties of the scheme proposed.

3.4 *Transcritical flow without shock*

In this test the bed-topography of the channel is the same as in the preceding case. A steady-state condition

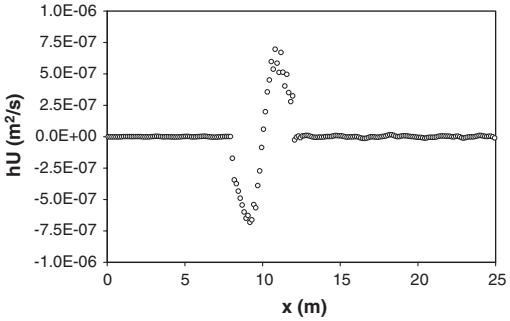

Figure 3. Subcritical flow over a bump: specific discharge error, t = 300 s.

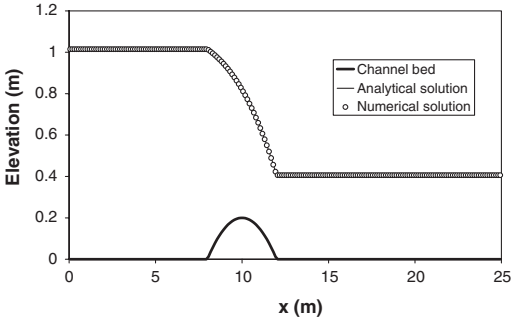

Figure 4. Transcritical flow over a bump: water surface elevation, t = 300 s.

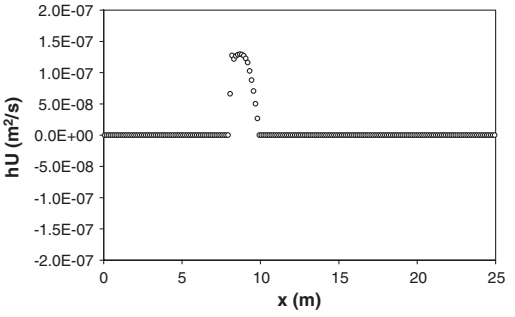

Figure 5. Transcritical flow over a bump: specific discharge error, t = 300 s.

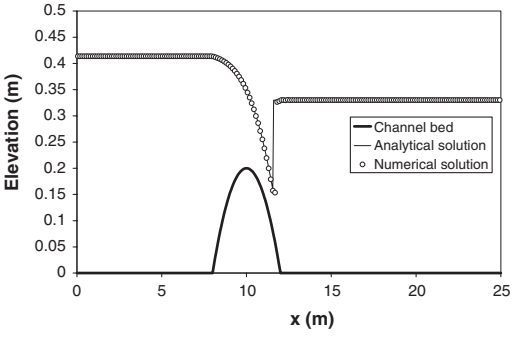

Figure 6. Transcritical flow over a bump with shock: water surface elevation, t = 300 s.

is considered where the specific discharge flowing through the channel is $hU = 1.53\,\mathrm{m}^2/\mathrm{s}$, and a downstream boundary condition $\varsigma = 0.66\,\mathrm{m}$ is imposed, which influences the flow until the condition downstream is supercritical. An analytical solution exists, which can be found by means of the Bernoulli Theorem, corresponding to a transition of the flow from subcritical to supercritical conditions, passing over the bump. For this test, a grid of 200 spectral volumes has been considered ($\Delta x = 0.125\,\mathrm{m}$), with time step $\Delta t = 0.005$ s. Again, the limiting parameters $M_h = 50$, $M_\varsigma = 50$, $M_{hU} = 0$ were used. The analytical water surface elevation and the numerical solution at time $t = 300$ s are compared in Figure 4, showing very good agreement.

The error at time $t = 300$ s, with reference to the specific discharge, is plotted in Figure 5, confirming good conservation properties of the scheme.

3.5 *Transcritical flow with shock*

The same bed topography and computational grid as in the preceding case has been used. A steady-state condition is considered where the specific discharge flowing through the channel is $hU = 0.18\,\mathrm{m}^2/\mathrm{s}$, and a downstream boundary condition $\varsigma = 0.33\,\mathrm{m}$ is imposed. An analytical solution exists, which can be determined by coupling the Bernoulli Theorem with the Rankine-Hugoniot condition, corresponding to a transition from subcritical to supercritical flow, passing over the bump, and again from supercritical to subcritical flow downstream of the bump: the second transition implies the formation of a stationary shock. The time step used for the test is $\Delta t = 0.001$ s, while the limiting parameters used are $M_h = 20$, $M_\varsigma = 20$, $M_{hU} = 0$.

The analytical water surface elevation and the numerical solution, at time $t = 300$ s, are compared in Figure 6, again showing good agreement.

The presence of the stationary shock is a challenging feature of the flow to be modelled, and conservation errors are expected to appear in the numerical solution. The specific discharge at time $t = 300$ s is plotted in Figure 7, showing that the major conservation errors influence a little number of cells. The results shown compare favourably with those available in literature (Delis, 2003, Xing & Shu, 2005).

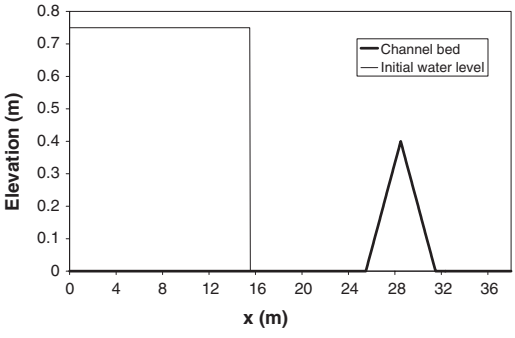

Figure 8. Dam-break over a triangular bump: initial condition.

3.6 *Dam-break experiment*

In this test, the results of the numerical model are compared with the experimental data of the laboratory dam-break performed by Hiver at the Recherches Hydrauliques Lab. Chatelet, together with the Universitè Libre de Bruxelles (Alcrudo & Soares Frazão, 2000).

The experimental set-up consisted of a 38 m long channel, of rectangular cross section, with 0.75 m constant width, where a gate divided a 15.5 m long reservoir from the dry bottom portion of the channel. A symmetric triangle-shaped bump, 6 m long and 0.40 m high, was located 10 m downstream of the gate. The end of the channel consisted of a free outlet. The Strickler roughness coefficients 80 $m^{1/3}/s$ and 90 $m^{1/3}/s$ were evaluated for the bed and for the vertical walls, respectively. The initial conditions consisted of 0.75 m of water in the reservoir (see Figure 8): the sudden removal of the gate permitted to reproduce the instantaneous failure of a dam. Seven gauges (G2, G4, G8, G11, G12, G13, G20) were collocated at different distances from the gate (see Table 2), in order to measure the water depth variations during the transient consequent to the dam failure.

Table 2. Gauge positions.

Gauge	abscissa (m)
G2	17.5
G4	19.5
G8	23.5
G10	25.5
G11	26.5
G13	28.5
G20	35.5

In order to perform this numerical test, the friction losses source term S_f was added to the bed-slope source term in Equation 4, obtaining the following source term vector:

$$\vec{S} = \begin{bmatrix} 0 & gh\left(-\frac{dz_b}{dx} - S_f\right) \end{bmatrix}^T \tag{37}$$

The Gauckler-Strickler formula was used for the evaluation of the punctual friction slope, with Strickler coefficient equal to 80 $m^{1/3}/s$. Again, the bed slope source term was evaluated by means of the upwind approach, while a pointwise approach was used for the friction slope: in order to attain third-order precision, the Simpson rule was used to approximate the integral

$$g\int_{x_{i,j-\frac{1}{2}}}^{x_{i,j+\frac{1}{2}}} hS_f\,dx = \frac{g\Delta x_{i,j}}{6}\left[\left(hS_f\right)_1 + \left(4hS_f\right)_2 + \left(hS_f\right)_3\right]_{i,j} \tag{38}$$

where the addends at the right hand side of Equation 38 were evaluated at the boundaries (hS_{f1} and hS_{f3}) and at the centre (hS_{f2}) of each control volume.

A tolerance ε was defined to handle possible instabilities at the wetting front, due to the evaluation of the friction terms where the water depth is very small: in particular, the slope friction was not evaluated in the cells with water depth smaller than ε, where the cell velocity was set to zero. No other special treatment was adopted in order to deal with the wetting/drying fronts. The computational domain was subdivided in 760 spectral volumes (each 0.05 m long), and the following parameters were used for the calculations: $\Delta t = 0.005$ s, $M_h = 0$, $M_\varsigma = 0$, $M_{hU} = 0$, $\varepsilon = 0.001$ m.

In Figure 9 a comparison is made between the experimental data at the gauge G4 and the numerical results. It can be seen that the numerical model fairly predicts the wave arrival time, as well as the maximum water level at the gauge. The successive waves reflected by the bump are reproduced less accurately with respect to the arrival time.

The results related to the gauge G10 are shown in Figure 10. Again, the numerical model fairly predicts the first and second wave arrival time, as well as the wave receding stage, with a slight over-prediction

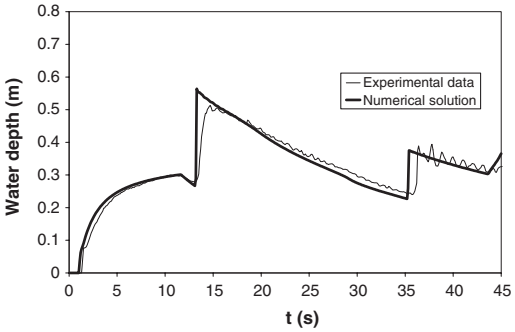

Figure 9. Dam-break over a triangular bump: gauge G4.

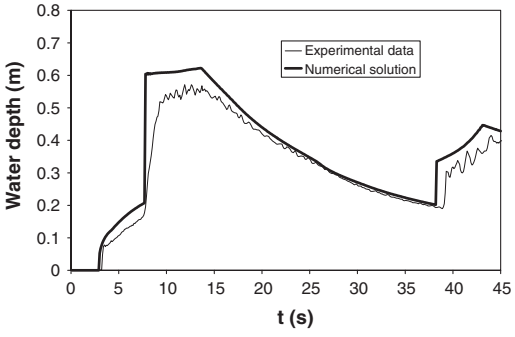

Figure 10. Dam-break over a triangular bump: gauge G10.

of the maximum water level at the gauge. The third wave time arrival is under-predicted. The results can be compared with those presented by Zhou et al. (2004), where a HLL Riemann solver is used, coupled with the Surface Gradient Method for the treatment of source terms: the comparison shows a better behaviour of the model presented here.

Interestingly, the main discrepancies between the numerical solution that has been proposed here and the experimental data are shared with other numerical models available in literature (Brufau et al., 2002, Črnjarić-Žic et al., 2004): this fact addressesthe importance of real water effects (turbulence, three-dimensional effects) which can not be well reproduced by the one-dimensional Shallow-water Equations mathematical model.

The inspection of the plot related to the Gauge G13 (Figure 11), located on the top of the bump, where the three-dimensional effects are expected to have a major influence on the flow behaviour, seems to confirm the last observations.

4 CONCLUSIONS

A Spectral Volume model aiming at the accurate solution of the Shallow-water Equations with bed-slope

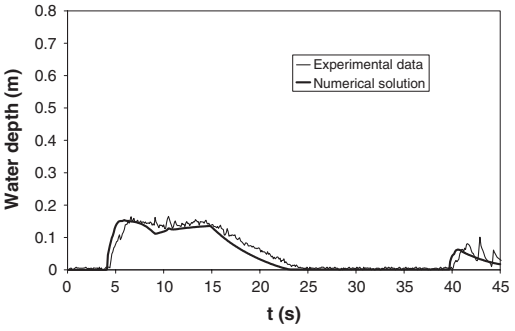

Figure 11. Dam-break over a triangular bump: gauge G13.

source terms has been presented. The special treatment of the source terms, which can be decomposed in interface (upwind) contributes, and a central contribute, ensures the full order of accuracy of the method. A number of tests have been presented, in order to verify the capability of the model to manage complicate topographies, both in steady and in transient conditions, as well as its capability to enforce the respect of the *C-Property*. The third-order accuracy of the model was confirmed by the convergence test carried out: in the case that a higher order of approximation is required, different quadrature formulas for the source terms can be used, which make use of the variables reconstructed at proper quadrature points by means of the methods considered above.

The use of the Spectral Volume Method, which allows to attain very high orders of precision, can be extended from one- to two-dimensional problems, in the context of triangular and quadrilateral unstructured grids, which are preferable when dealing with natural geometries; moreover, the extension of the method presented here to the solution of the Open-channel flow Equations can be considered, introducing not only the bed-slope source term, but also the source terms arising from slight cross-section variations along the channel: these topics will be the object of future communications.

Nonparallel spatial stability of shallow water flow down an inclined plane of arbitrary slope

P. Bohorquez & R. Fernandez-Feria
E.T.S.Ingenieros Industriales, Universidad de Málaga (Spain)

ABSTRACT: Roll waves are known to occur in the frictional flow of a thin layer of water down an inclined solid surface. For a layer of constant depth, the formation of these waves on a solid plane with small slope angle have been explained as a hydrodynamic instability occurring above a critical Froude number by analyzing the temporal stability of the constant velocity flow. Here we analyze the linear, spatial stability of the shallow-water flow down an inclined plane of arbitrary slope including the first order effects of the gradients of both the velocity and the water depth. For constant water depth (parallel case) we reproduce previous results of the temporal stability analysis. Then we apply the nonparallel stability formulation to the kinematic wave approximation of the shallow-water flow down an inclined plane of arbitrary slope and characterize, analytically, the frequency and the wavelength of the most unstable waves as a function of the Froude number, slope angle, velocity and velocity gradient. We find important qualitative differences with respect to the parallel (constant depth) case. These stability results are used to discuss the numerical solution to the nonlinear shallow-water flow equations for the dam-break problem on an inclined surface of arbitrary slope. A good agreement between the waves resulting from the numerical simulations and the predictions of the stability analysis is found.

1 INTRODUCTION

A thin layer of water flowing down an inclined surface may undergo, in some circumstances, a transition to an oscillatory movement where a train of surface waves propagates downstream. The amplitude of these waves increases, and eventually break into the form of a train of hydraulic bores at quite regular intervals, as they propagate downstream. These so-called roll waves where first scientifically observed in open channel flows by Cornish in 1904 (Cornish 1934), and have been subsequently documented in many man-made and natural shallow water flows (Kenyon 1998; Chanson 2004). The presence of these waves is generally undesirable from the hydraulic engineer point of view because they can produce overflow from the channel sides and because excessive intermittency at the outlet. Therefore the interest in determining with precision the conditions under which they appear.

Since the early work of Jeffreys (1925), these roll waves are known to be originated by inertial instabilities of the turbulent shallow water flow in a channel. Particularly, this author analysed the linear, temporal stability of the St. Venant one-dimensional model for the uniform flow over a plane, including a drag term proportional to the square of the velocity, and found the instability condition $Fr > 2$, where Fr is the Froude number (see below for its definition). Subsequently, Dressler (1949) confirmed this stability result and constructed finite-amplitude roll waves by piecing together smooth solutions separated by discontinuous shocks. Experiments by Brock (1967) showed the formation of roll waves for $Fr > 2$. Further linear stability results for the uniform turbulent flow down open inclined channel include both temporal (Brock 1967; Whitham 1974; Berlamont and Vanderstappen 1981) and spatial stability analysis (Di Cristo and Vacca 2005). All these stability results do not modify Jeffrey's basic finding that the uniform flow becomes unstable for $Fr > 2$.

In this work we consider the spatial stability analysis of the shallow water flow with friction down an inclined plane. The two features introduced here that have not been considered before are that the basic flow is valid for arbitrary slope of the channel, and that nonparallel effects accounting for the slow streamwise variations of both the basic flow and the perturbation are taken into account. Earlier stability analysis of the shallow water flow down an open inclined channel used the St. Venant one-dimensional shallow-water equations, valid for small slopes of the channel (Stoker 1957; Whitham 1974). Recently, Bouchut et al. (2003) and Keller (2003) have generalized these shallow water equations for arbitrary slopes of the bottom of the channel. But, for a constant (but arbitrary) slope, the equations are formally the same as the St. Venant

Copyright © 2006 Taylor & Francis Group plc, London, UK

equations, provided that appropriate variables are used (Savage and Hutter 1991). Therefore, this generalisation to an arbitrary slope of the inclined plane does not modify, as we shall see, the basic Jeffreys's stability result. However, we find that the inclusion of nonparallel effects in the stability analysis qualitatively modify the stability properties of the flow. Therefore, the critical parameters at which roll waves are predicted in a non-uniform flow may be substantially different from those in an uniform flow.

The structure of the paper is as follows. In the next section we formulate the spatial stability problem. We consider non-parallel effects for a general non-uniform flow down an inclined plane of arbitrary slope. Then we reproduce the known stability results for a uniform flow when non-parallel effects are neglected, but for arbitrary slope of the channel. Detailed stability properties of non-uniform flows, when non-parallel effects are included, are given for the case when the kinematic wave approximation (Whitham 1974) is used for the basic flow. These stability results are then compared with the outcome of some numerical simulations for the dam-break problem on an inclined surface of arbitrary slope, and with some available experimental results. Finally, some conclusions are drawn in the last section.

2 FORMULATION OF THE PROBLEM

We consider here the one-dimensional flow over a constant slope bed. In the shallow-water approximation, the dimensionless equations for the mass conservation and momentum in the direction of the flow can be written as [see Fig. 1]

$$\frac{\partial \eta}{\partial t} + \frac{\partial \eta U}{\partial X} = 0\,, \tag{1}$$

$$\frac{\partial U}{\partial t} + U\frac{\partial U}{\partial X} + \cos\theta \frac{\partial \eta}{\partial X} = \sin\theta - \frac{s_f}{\eta}\,, \tag{2}$$

where θ is the angle between the bed and the horizontal, t is the time, X is the coordinate along the bed, η is the depth of the water measured along the coordinate Y perpendicular to the bed, U is the depth-averaged velocity component along X, and s_f is a dimensionless bed friction (see below). All the magnitudes in these equations have been non-dimensionalized with respect to a length scale η_0, corresponding to some initial depth, and a velocity scale $U_0 \equiv \sqrt{g\eta_0}$, where g is the acceleration due to gravity. Equations (1)–(2) are formally the same as the classical St. Venant equations for the shallow-water in a channel with small angle of inclination θ (Stoker 1957). However, it can be shown (Savage and Hutter 1991; Bouchut et al. 2003; Keller 2003) that these equations, written in the present coordinates X and Y (see Fig. 1), are valid for *any* slope

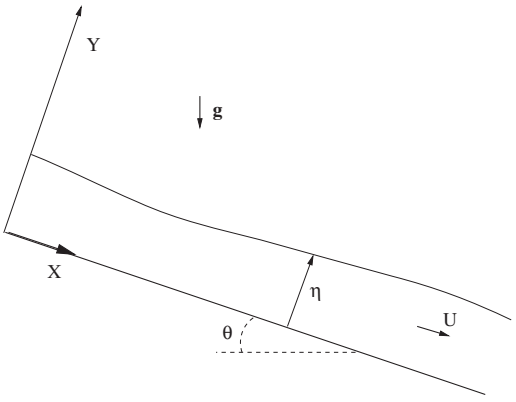

Figure 1. Sketch of coordinates and variables.

$\tan\theta$ of the *constant-slope* bed, not just for small channel slope, provided that the characteristic length scale of the flow in the direction of the coordinate X is much greater than the characteristic length scale in the Y direction.

To compute the friction term, $s_f \equiv (\tau_b/\rho U_0^2)$, where τ_b is the bed shear stress and ρ the fluid density, we shall use the Darcy-Weisbach friction factor f, so that s_f may be written as

$$s_f = \frac{f}{8}|U|U\,. \tag{3}$$

The factor f is a function of the local Reynolds number, based on the velocity U and the hydraulic diameter of the channel, and the relative height roughness of the bed. However, to simplify the present analysis we shall assume that the friction factor f is constant in what follows.

Here we shall analyse the spatial stability of a flow governed by Eqs. (1)–(2). To that end, if $\eta = H(X,t)$ and $U = V(X,t)$ is a solution to these equation, the perturbed flow is decomposed, as usual, as the sum of the basic flow solution plus a small perturbation, $\eta'(X,t)$ and $U'(X,t)$,

$$\eta = H + \eta', \quad U = V + U', \tag{4}$$

where the (non-dimensional) perturbations satisfy

$$|\eta'| \ll H, \quad \text{and} \quad |U'| \ll V\,. \tag{5}$$

We shall also assume that the streamwise variation of the basic flow is small,

$$\left|\frac{\partial H}{\partial X}\right| \ll 1\,, \quad \left|\frac{\partial V}{\partial X}\right| \ll 1\,. \tag{6}$$

Substituting (4) into (1)–(2), taking into account that $[H, V]$ is a solution to the equations, and neglecting

Copyright © 2006 Taylor & Francis Group plc, London, UK

second order terms in both the small perturbations and the streamwise derivatives of the basic flow, one is left with the following set of linear equations for the perturbations:

$$\frac{\partial \eta'}{\partial t} + \frac{\partial H U'}{\partial X} + \frac{\partial V \eta'}{\partial X} = 0, \tag{7}$$

$$\frac{\partial U'}{\partial t} + \frac{\partial V U'}{\partial X} + \cos\theta \frac{\partial \eta'}{\partial X} + \frac{f V^2}{8H}\left(\frac{2U'}{V} - \frac{\eta'}{H}\right) = 0. \tag{8}$$

The perturbation $\mathbf{s} \equiv [\eta'(X,t), U'(X,t)]^T$, where the superscript T denotes transposed vector, is decomposed in the standard form

$$\mathbf{s}(X,t) = \mathbf{S}(X)\boldsymbol{\chi}(X,t), \tag{9}$$

where the complex amplitude

$$\mathbf{S}(X) \equiv \begin{pmatrix} F(X) \\ G(X) \end{pmatrix} \tag{10}$$

depends only on the streamwise coordinate. In accordance with (6), we shall assume that $|d\mathbf{S}/dX| \ll 1$. The other part of the perturbation is of exponential form and describes the wave-like nature of the disturbance,

$$\boldsymbol{\chi}(X,t) = \exp\left[\int_{X_i}^{X} a(X')dX' - i\omega t\right], \tag{11}$$

where X_i is an initial or reference value of the coordinate X. The non-dimensional, complex wavenumber a is defined as

$$a(X) \equiv \gamma(X) + i\alpha(X). \tag{12}$$

The real part $\gamma(X)$ is the local exponential growth rate, and the imaginary part $\alpha(X)$ is the local wavenumber. A non-dimensional frequency ω has also been defined in (11).

Substituting (9)–(12) into (7)–(8), the resulting set of two linear equations may be written in the matrix form

$$\mathbf{A}\cdot\mathbf{S} + a\mathbf{B}\cdot\mathbf{S} + \mathbf{B}\cdot\frac{d\mathbf{S}}{dX} = 0, \tag{13}$$

where

$$\mathbf{A} = \begin{pmatrix} -i\omega + V_X & H_X \\ -\frac{fV^2}{8H^2} & -i\omega + V_X + \frac{fV}{4H} \end{pmatrix}, \tag{14}$$

$$\mathbf{B} = \begin{pmatrix} V & H \\ \cos\theta & V \end{pmatrix}, \tag{15}$$

and $H_X \equiv \frac{\partial H}{\partial X}$, $V_X \equiv \frac{\partial V}{\partial X}$.

The retained terms in (13) account for two different non-parallel effects on the stability of the perturbations: the effect of the non-parallelism of the basic flow and of the amplitude of the perturbations, and the effect of the history, or convective evolution, of the perturbations. This last effect is described by the d/dX terms of the stability equation. All these effects are negligible in the parallel limit of uniform basic flow with uniform perturbations.

As it stands there is some ambiguity in the partition of the perturbations (9) into two functions of the coordinate X. To close the problem one has to enforce an additional normalization condition which puts some restriction on the streamwise variation of the perturbation amplitude (Bertolotti et al. 1992). We shall perform here a local spatial stability analysis (Fernandez-Feria 2000): Given a *real* frequency ω, Eq. (13) and its X-derivative will be solved locally for each location $X = X_0$ with the *normalization* condition $[da/dX]_{X=X_0} = 0$. This condition will restrict, as required, the downstream variation of the perturbation amplitude (eigenfunction), yielding, for each $X = X_0$, the local growth rate and the wavenumber (or the phase speed of the disturbance). To that end, the eigenfunction $\mathbf{S}$ is expanded in a Taylor series about $X = X_0$, where only two terms are retained to be consistent with the approximation made in Eq. (13):

$$\mathbf{S}(X) \simeq \mathbf{S}(X_0) + (X - X_0)\left.\frac{d\mathbf{S}}{dX}\right|_{X=X_0} \equiv \mathbf{S}_0 + (X - X_0)\mathbf{S}_1. \tag{16}$$

This expansion is now substituted into (13) and its X-derivative to obtain two equations for $\mathbf{S}_0$ and $\mathbf{S}_1$ ($|\mathbf{S}_1| \ll |\mathbf{S}_0|$). Using the local normalization condition $[da(X)/dX]_{X=X_0} = 0$, one has a set of four homogeneous linear equation that may be written as

$$\mathbf{F}\cdot\boldsymbol{T} = \mathbf{0}, \tag{17}$$

where

$$\mathbf{F} = \begin{pmatrix} \mathbf{A} + a\mathbf{B} & \mathbf{B} \\ \mathbf{C} + a\mathbf{D} & \mathbf{E} + a\mathbf{B} \end{pmatrix}, \quad \boldsymbol{T} \equiv \begin{pmatrix} \mathbf{S}_0 \\ \mathbf{S}_1 \end{pmatrix}, \tag{18}$$

$$\mathbf{C} = \begin{pmatrix} 0 & 0 \\ -\frac{fV}{4H^3}(HV_X - VH_X) & \frac{f}{4H^2}(HV_X - VH_X) \end{pmatrix}, \tag{19}$$

$$\mathbf{D} = \begin{pmatrix} V_X & H_X \\ 0 & V_X \end{pmatrix}, \tag{20}$$

$$\mathbf{E} = \begin{pmatrix} -i\omega + 2V_X & 2H_X \\ -\frac{fV^2}{8H^2} & -i\omega + 2V_X + \frac{fV}{4H} \end{pmatrix}. \tag{21}$$

For a given basic flow, and given ω and $X = X_0$ (for simplicity, in the above expressions, and in what

Copyright © 2006 Taylor & Francis Group plc, London, UK

follows, we write X for the local value X_0), the homogeneous equation (17) constitutes an eigenvalue problem for the complex eigenvalue a and the complex eigenfunction $\boldsymbol{T}$. That is to say, the homogeneous equation (17) has nontrivial solutions only when the determinant of $\mathbf{F}$ vanishes, yielding a dispersion relation of the form

$$D(a,\omega;\theta,f,V,H,V_X,H_X)=0, \tag{22}$$

that determines the eigenvalue a.

One is interested in looking for convective instabilities propagating towards $X>0$, i.e. in the same direction as the basic flow. Thus, for a given positive value of the real frequency ω, one is interested in modes whose eigenvalue a has both its real and imaginary parts positive. According to (11)–(12), this ensures that the perturbation grows exponentially as it propagates towards increasing $X(\gamma>0)$, with phase velocity directed downstream (i.e. $c_{ph}\equiv\omega/\alpha>0$). As a matter of fact, one has to consider the sign of the group velocity,

$$c_g\equiv\frac{\partial\omega}{\partial\alpha}, \tag{23}$$

instead of the sign of the phase velocity c_{ph}, in order to determine the propagation direction of the perturbations. But, as we shall see, the sign of c_g always coincide with the sign of c_{ph} in all the cases considered below (all the instabilities found are convective instabilities, with both c_g and c_{ph} positive). On the other hand, the frequency range of study can be reduced to just non-negative values because the real and imaginary parts of the linear operator $\mathbf{F}$,

$$\mathbf{F}(\omega,\alpha,\gamma)\equiv\mathbf{F}_{\Re}(\gamma)+i\mathbf{F}_{\Im}(\omega,\alpha), \tag{24}$$

have the property

$$\mathbf{F}(a,\omega)=\overline{\mathbf{F}}(\overline{a},-\omega), \tag{25}$$

where $\overline{(\cdot)}$ denotes the complex conjugate, and both $\mathbf{F}_{\Re}$ and $\mathbf{F}_{\Im}$ are real functions. Thus, if a is the eigenvalue corresponding to the real frequency ω, $\overline{a}$ is also an eigenvalue of the problem, corresponding to the frequency $-\omega$. So that one has to consider only non-negative values of ω to fully analyse the linear stability of the flow.

3 RESULTS

3.1 *Parallel flow: Roll waves*

Before undertaking the non-parallel stability analysis of a non-uniform flow down an open inclined channel, it is convenient to consider first the simplest case of an uniform flow, thus reproducing previous stability results. This analysis will also serve as a reference for better understanding the results given in the next section.

For an uniform and steady basic flow, $H=constant$ and $V=constant$, one has $d\mathbf{S}/dX\equiv\mathbf{S}_1=0$ in (17)–(18). In fact, the second equation in (17) becomes unnecessary, and the linear stability equation is just (13) with $d\mathbf{S}/dX=0$. The dispersion relation (22) reduces then to

$$\det(\mathbf{A}+a\mathbf{B})=0, \tag{26}$$

with $H_X=V_X=0$ in (14).

For an uniform and steady basic flow, the solution to (1)–(3) relates the constant values of H and V by

$$H=\frac{fV^2}{8\sin\theta}. \tag{27}$$

It is convenient to use the Froude number

$$Fr\equiv\frac{V}{c}=\frac{V}{\sqrt{H\cos\theta}}=\sqrt{\frac{8}{f}\tan\theta}, \tag{28}$$

instead of the friction factor f, where $c=\sqrt{H\cos\theta}$ is the non-dimensional wave speed for small surface perturbations. Substituting (27)–(28) into (26), one obtains the following dispersion relation for the complex eigenvalue a and the real frequency ω:

$$a^2V^2\left(1-\frac{1}{Fr^2}\right)+a(3\sin\theta-2\omega Vi)-\omega^2-\frac{2\sin\theta\omega}{V}i=0. \tag{29}$$

The number of parameters may be reduced to just one, the Froude number, if one makes the following changes of variables valid for $\sin\theta\neq0$:

$$e\equiv\frac{aV^2}{\sin\theta},\quad w\equiv\frac{\omega V}{\sin\theta}, \tag{30}$$

so that (29) reduces to

$$e^2(1-\varrho)+e(3-2wi)-w^2-2wi=0, \tag{31}$$

where, for convenience, we use the inverse of the square of the Froude number,

$$\varrho\equiv\frac{1}{Fr^2}. \tag{32}$$

The new growth rate σ and wavenumber ϵ are defined as [see (12)]

$$e\equiv\sigma+i\epsilon,\quad \sigma=\frac{\gamma V^2}{\sin\theta},\quad \epsilon=\frac{\alpha V^2}{\sin\theta}. \tag{33}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

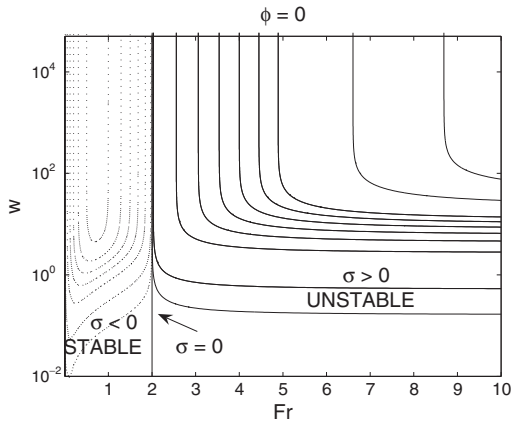

Figure 2. Contour lines for constant growth rate in the (w,Fr) plane for the parallel flow case. Continuous lines: $\sigma = 0, .001, .01, .2, .4, .6, .8, 1, 1.2, 2, 3$. Dashed lines: $\sigma = -.001, -.01, -.05, -.1, -.15, -.2, -.25$.

The neutral curve for instability, corresponding $\sigma = 0$, may be easily obtained by substituting $e = i\epsilon$ into (31). The imaginary and real parts of the resulting equation yield, respectively,

$$\epsilon = \frac{2}{3}w \quad \text{and} \quad \varrho = \frac{1}{4}. \tag{34}$$

The flow is stable ($\sigma < 0$) for $\varrho > \varrho_c = 1/4$, while it is (convectively) unstable ($\sigma > 0$) for any value of the frequency w if $\varrho < 1/4$. This obviously reproduces Jeffreys (1925) instability condition $Fr > 2$: any perturbation is unstable above the critical Froude number 2. In addition, one obtains that the phase velocity of the neutrally stable waves,

$$c_{ph} \equiv \frac{\omega}{\alpha} = \frac{wV}{\epsilon} = \frac{3}{2}V, \tag{35}$$

is three times larger that the surface wave speed c for the critical $Fr = 2$, $c = V/Fr = V/2$.

Figure 2 depicts the neutral curve in the plane (Fr, w), which is just the vertical line $Fr = 2$, together with some contour lines for constant growth rate σ. This figure qualitatively explains why Brock (1967) did not observed the formation of roll waves for Froude numbers below 3.5, approximately, in his experiments for an uniform flow in an inclined channel. For Fr close to the critical value $Fr_c = 2$ the growth rate is so small that a extremely long channel would be required for the developments of the waves (note that for $Fr < 3.5$, $\sigma < 0.5$, approximately).

To finish this section it is worth to mention that for a horizontal channel ($\sin\theta = 0$), Eq. (29) does not yield unstable solutions (i.e., solutions with $\sigma > 0$ together with $\epsilon > 0$).

3.2 *Nonparallel flow: Kinematic wave approximation*

We now turn to the general nonparallel stability formulation (17). In order to obtain some quantitative results, but without recurring to any particular basic flow, we shall consider here the 'kinematic wave approximation' to the shallow-water flow equations (Lighthill and Whitham 1955; Whitham 1974), which have proved to be very useful for approximating the long time behavior of the flow down an open inclined channel (Hunt 1983).

In the kinematic wave approximation, one neglects the left hand side of Eq. (2) and, after using the friction law (3), obtains the same relation (27) between H and V. But now, H and V are not constant, they must satisfy the continuity equation (1) and the initial and boundary condition of the particular problem under consideration. Substituting (27) into the left hand side of Eq. (2) and using (1), one obtains the following condition for the validity of this approximation:

$$\left|\frac{\partial H}{\partial X}\right| \ll \left|\frac{\sin\theta}{\cos\theta - \frac{2}{f}\sin\theta}\right|, \tag{36}$$

which in the case $f \ll 2\tan\theta$ may be simplified to $|\partial H/\partial X| \ll f/2$.

With this approximation, one can eliminate the dependence on H and on H_X of the dispersion relation (22) by using (27) and its derivative with respect to X:

$$H = \frac{fV^2}{8\sin\theta}, \quad H_X = \frac{fVV_X}{4\sin\theta}. \tag{37}$$

In addition, the explicit dependence on the angle θ and on the local flow velocity V can be eliminated from the dispersion relation by using the same change of variables (30) together with

$$\phi \equiv \frac{V_X V}{\sin\theta}. \tag{38}$$

Thus, taking the determinant of **F** (18) and using the above notation, the dispersion relation may be written as

$$D(e, w; \varrho, \phi) \equiv d_0 + d_1\phi + d_2\phi^2 + d_3\phi^3 + d_4\phi^4 = 0, \tag{39}$$

where

$$d_0 \equiv \left[e^2(\varrho - 1) + w^2 + 2iew + (2iw - 3e)\right]^2, \tag{40}$$

$$\begin{aligned} d_1 \equiv 2\big[&3iw^3 + 2e^3(\varrho - 1)^2 + 4ew^2(\varrho - 2) \\ &+7ie^2w(\varrho - 1) - 13e^2(\varrho - 1) - 12w^2 \\ &+2iew(5\varrho - 12) + (12e - 11iw)\big], \end{aligned} \tag{41}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

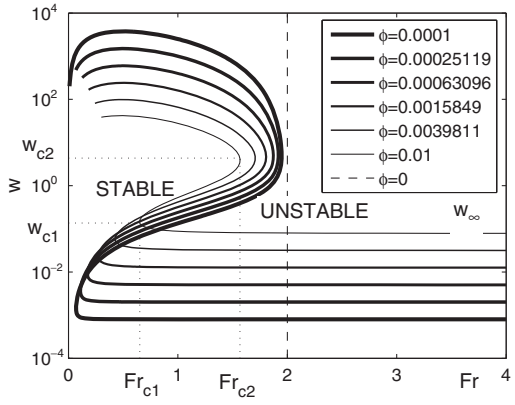

Figure 3. Neutral curves ($\sigma = 0$) for different values of $\phi > 0$ (as indicated).

$$d_2 \equiv -13w^2 + 8e^2(\varrho - 1)^2 + 4iew(4\varrho - 5) + 36 - 2[iw(27 - 4\varrho) + e(22\varrho - 25)], \quad (42)$$

$$d_3 \equiv -4[3iw + 2e(\varrho - 1) + 2(3\varrho - 5)], \quad (43)$$

$$d_4 \equiv 4, \quad (44)$$

and where use has been made of the Froude number (28) and (32). In the new variables, the validity condition (36) for the kinematic wave approximation reads

$$|\phi| \ll \left| \frac{2}{4\varrho - 1} \right|. \quad (45)$$

The neutral curves for instability, corresponding to vanishing real part of $e(\sigma = 0)$ in (39), depend on w, ϱ (or Fr), and ϕ. Figure 3 shows these neutral curves in the (Fr, w) plane for several values of $\phi > 0$. As it is observed, there exists marked differences with the neutral curve for the parallel flow case $\phi = 0$. Firstly, the flow is always stable for very small frequencies [for $w < w_\infty(\phi)$], independently of the Froude number. Secondly, the minimum, or critical, Froude number for instability, $Fr_{c1}(\phi)$, corresponding to the frequency $w_{c1}(\phi)$, is always less that 2 when $\phi > 0$. This critical Froude number tends to zero as ϕ decreases, though the frequency range around w_{c1} for which the flow is unstable is small, vanishing as $\phi \to 0$. As in the parallel case, the flow is unstable for almost any frequency when $Fr > 2$ (except for very small frequencies, as commented on above). In fact, there exists another critical value of the Froude number, $Fr_{c2}(\phi) < 2$, corresponding to the frequency $w_{c2}(\phi)$, above which the flow is always unstable provided that the frequency is not too small ($Fr_{c2} \to 2$ and $w_\infty \to 0$ as $\phi \to 0$). For high frequencies the stability region shrinks to disappear for very high w, the larger the smaller ϕ. But these very high frequencies, like the very small ones $w < w_\infty$, are too extreme to be physically meaningful. Thus, the two pairs of critical values (Fr_{c1}, w_{c1}) and (Fr_{c2}, w_{c2}) are the most significant physical results. Figures 4 and 5 show these critical values (together with w_∞) as functions of $\phi(>0)$.

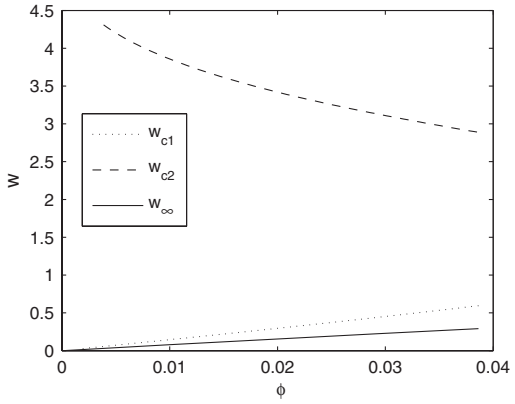

Figure 4. w_{c1}, w_{c2}, and w_∞ as functions of ϕ.

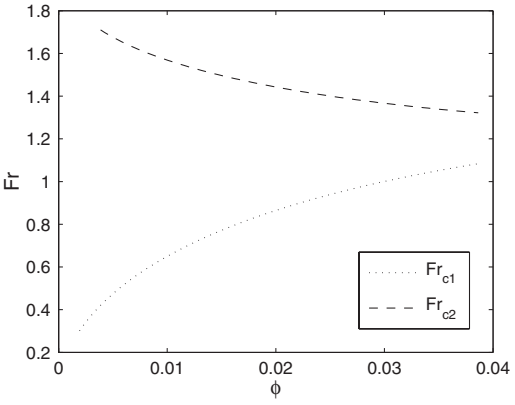

Figure 5. Fr_{c1}, and Fr_{c2} as functions of ϕ.

To have an idea of the most unstable frequencies, Fig. 6 shows contour lines of constant growth rate σ for a particular value of ϕ. It is observed that, though the critical Fr is much smaller than 2 for low frequencies, the growth rate for $Fr < 2$ is always quite small (except for very high, unrealistic frequencies). This explains why we have to use a very long channel and leave the flow evolve during a quite long time in our numerical simulations of the next section to observe the formation of roll waves for $Fr < 2$.

In all the numerical computations we have made where roll waves are formed in a nonuniform flow (some of them reported in the next section for the

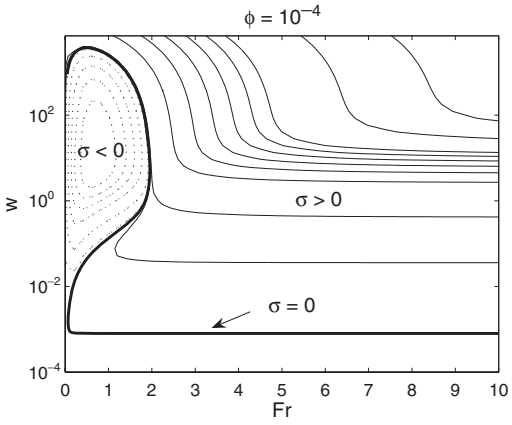

Figure 6. Contour lines of constant growth rate in the (w, Fr) plane for $\phi = 10^{-4}$. Continuous lines: $\sigma = 0$, .001, .01, .2, .4, .6, .8, 1, 1.2, 2, 3. Dashed lines: $\sigma = -.001, -.01, -.05, -.1, -.15, -.2$.

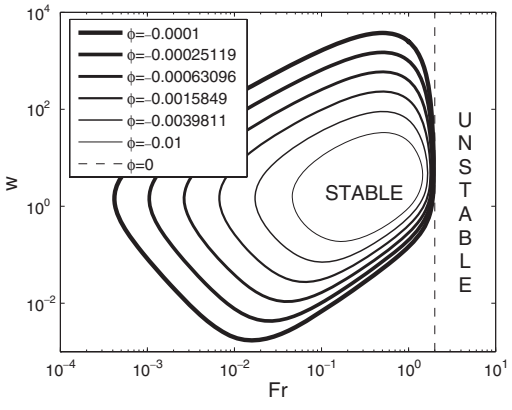

Figure 7. Neutral curves ($\sigma = 0$) for different values of $\phi < 0$ (as indicated).

dam-break problem on an inclined channel), the waves develop in regions of the flow where the kinematic wave approximation applies and where $\phi > 0$, i.e. in regions where the velocity (and the height) increases downstream. Nonetheless, we include here the stability results for $\phi < 0$ for completeness. Figure 7 shows the neutral curves in the (Fr, w) plane for several values of $\phi < 0$, while Fig. 8 depicts contour lines of constant growth rate σ for a particular value of $\phi < 0$.

As in the cases with $\phi > 0$, the flow may be unstable for $Fr < 2$ and the stability properties are very sensitive to the non-uniformities of the flow: with very small values of $|\phi|$, the region of instability changes dramatically with respect to the parallel flow case. However, the growth rates for $Fr < 2$ are very small, except for

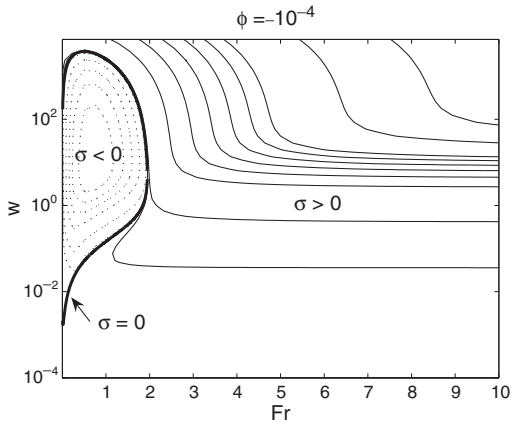

Figure 8. As in Fig. 6, but for $\phi = -10^{-4}$.

very high unrealistic frequencies (Fig. 8), as it also occurs for $\phi > 0$. There are, nonetheless, some important differences between $\phi > 0$ and $\phi < 0$. First, for $\phi < 0$ there no exists the frequency w_∞, and the flow is always unstable as $w \to 0$. In fact, the stable region in the (Fr,w) plane is closed, so that the flow is unstable for any frequency when Fr is very small (Fig. 7). However, for these very small values of the Froude number the kinematic wave approximation is no longer valid because condition (45) implies

$$Fr \gg \sqrt{\frac{4|\phi|}{2+|\phi|}} \simeq \sqrt{2|\phi|}\,. \tag{46}$$

This applies for both $\phi < 0$ and $\phi > 0$. This restriction, together with the very small growth rates for $Fr < 2$ in both cases, explain why it is difficult to observe the development of roll waves when $Fr < 2$, in spite of the fact that the critical Froude number for instability can be much smaller than 2 for both positive and negative values of ϕ.

4 COMPARISON WITH NUMERICAL RESULTS FOR THE DAM-BREAK PROBLEM

As an example on the formation of roll waves in a nonuniform flow, we have considered the dam-break problem in an inclined channel (Fernandez-Feria 2006; Bohorquez and Fernandez-Feria 2006). Actually, our interest in the present stability problem originated from the observation of roll waves in some numerical simulations for that non-uniform flow problem. Basically, a finite mass of water like that sketched in the inset of Fig. 9 is released at $t = 0$ on an inclined plane of angle θ. The equations (1)–(2)are solved numerically by using a high-resolution TVD finite-volume

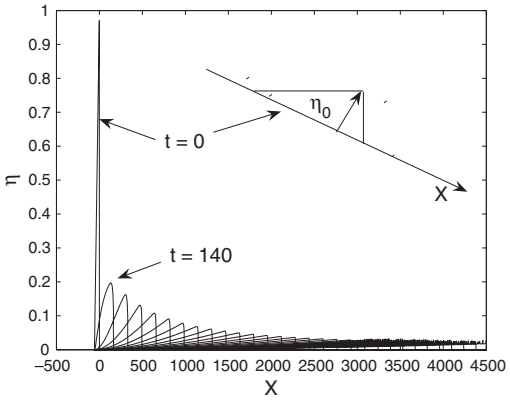

Figure 9. Water depth $\eta(X)$ for different instants of time in the dam break problem for $\theta = 1°$ and $Fr = 2.5$. The different curves are for $t = 0$, 140, 288, 454,638, 841, 1061, 1298, 1550, 1817, 2097, 2392, 2699, 3018, 3349, 3691, 4045, 4409, 4784, 5167, 5542, 5901, 6267, 6637, 7012, 7394, 7779, 8172, 8568, 8966. Also included is a sketch of the initial configuration of the dam-break problem.

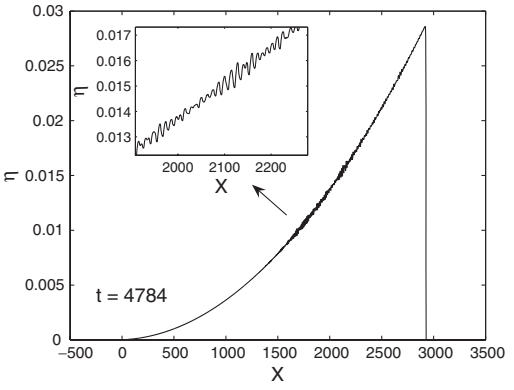

Figure 10. $\eta(X)$ for $t = 4784$ (from Fig. 9).

method like that described in Burgete and Garcia-Navarro (2001) (see the above mentioned references for the details of the formulation of the problem and the numerical method used). We have started a systematic search for the instabilities and the formation of roll waves in that flow, and we present here some preliminary results.

We have not found the spontaneous formation (i.e., with the only forcing of the round-off numerical noise) of roll waves in our numerical simulations for Froude numbers less than 2. This is explained by the small growth rate of the unstable perturbations when Fr is less than, approximately, 2 (see Figs. 6 and 8), so that a very long channel is needed for the roll waves to develop. In fact, we have observed perturbations growing downstream for $Fr < 2$ when disturbances with much higher amplitude than the numerical noise are introduced upstream. But these waves never reach the stage of a roll wave for $Fr < 2.5$ with the channel lengths used so far. In any case, to our knowledge, no roll waves have been documented before from experimental observations for Froude numbers less than approximately 3.5, whence the interest of the numerical results given below.

Figure 9 shows the evolution of the water depth η for several instants of time after the break of the dam in a channel with $\theta = 1°$ and for $Fr = 2.5$ (a sketch of the initial configuration is also shown in the figure). For $t \simeq 4400$, the instability in the free surface begins to be appreciated in the numerical simulations, originated just from numerical noise, as it is clearly evident in Fig. 10 for $t = 4784$. For these instants of time, the kinematic wave approximation is already valid in all the flow domain (in fact, it is very accurate; see Fig. 11), so that one may use the stability results obtained in the last section. Eventually, the amplitude of the instability waves grows to reach the stage where the free surface has the aspect of the classical roll waves (see Fig. 12).

The frequency of the initial waves developed after the instability of the flow can be obtained by plotting the velocity perturbation at a given location as a function of time. Figure 13 is such a plot for $X = 2342$, starting from $t = 4400$, the instant at which one begins to observe numerically the formation of the instability waves at the surface. The velocity perturbation, $U' = U - V$, has a frequency $\omega \simeq 0.1924$, which remains almost constant for a long period of time. Taking into account that during the period of time considered in Fig. 13 V and its gradient vary, in the location considered, in the ranges $0.28 < V < 0.37$ and $1.9 \times 10^{-3} < \phi < 3.3 \times 10^{-3}$, respectively, that

Copyright © 2006 Taylor & Francis Group plc, London, UK

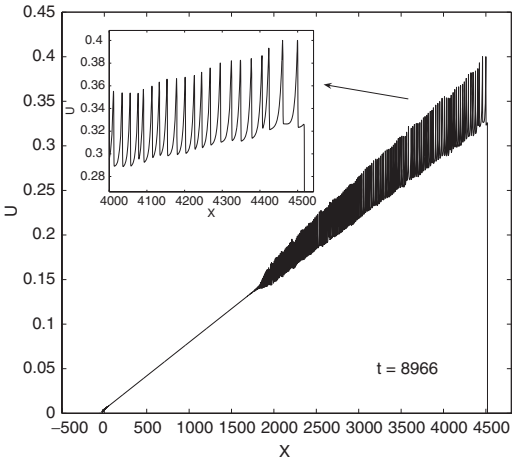

Figure 12. $U(X)$ at $t = 8966$ for the flow depicted in Fig. 9.

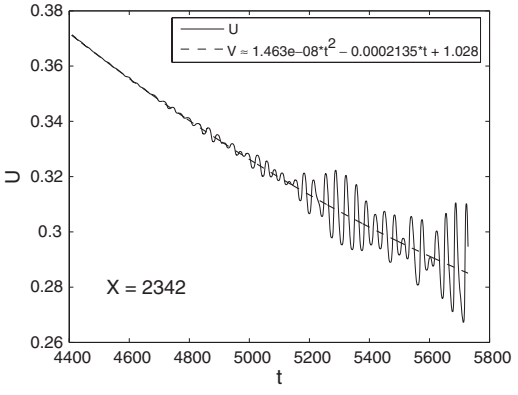

Figure 13. $U(t)$ at $X = 2342$ for the flow depicted in Fig. 9. Also shown is an extrapolation of the mean velocity without perturbation, $V(t)$ (dashed line).

frequency corresponds to $3.1 < w < 4.1$, approximately. For these values of w, ϕ and Fr, the stability analysis predicts that the eigenvalue $e = \sigma + \epsilon i$ ranges between $0.1136 + 2.163i$ and $0.1591 + 2.8922i$ ($0.0203 + 0.3687i$ and $0.0253 + 0.4814i$ in terms of $a = \gamma + \alpha i$). This corroborates, first, that the growth rate σ cannot be too small in order to observe the instabilities in the numerical simulations (σ is larger that 0.1, which in Fig. 6 only occurs if Fr is sufficiently larger than 2, if the frequency w is not too large). On the other hand, the wavelength $\lambda = 2\pi/\alpha$ given by the stability analysis ranges between 13 and 17, approximately. This agrees quite well with the wavelength in the numerical simulation, which from the inset in Fig. 10 can be estimated as the ratio between the space domain length to the number of crests to be $370/27 \approx 14$.

5 CONCLUSIONS

We have analysed the spatial stability of the shallow-water flow in an inclined surface of arbitrary slope. We have developed a local analysis that takes into account the effect of the local gradients of both the velocity and the water depth. In particular, we have considered the kinematic wave approximation, that is shown to be a very good approximation to any non-uniform and non-steady frictional flow for sufficiently long times. The stability results depend only on two dimensionless parameters: the Froude (Fr) number and a parameter ϕ characterizing the local gradient of the water depth. Since the stability analysis is a spatial one, we have characterized the frequency ranges in the parameter space (Fr,ϕ) for which instabilities develop. The main result is that the stability properties of the flow change qualitatively (substantially) when the non-parallelism of the shallow-water flow is taken into account. In particular, instabilities can be present for Froude numbers smaller than 2 in some frequency ranges that depends on ϕ (for a parallel, constant-depth flow, the instability condition is $Fr > 2$). However, the growth rate for the unstable modes is so small when $Fr < 2$ that, without artificially disturbing the initial flow, we have not observed the formation of roll waves in our numerical simulations for the dam-break problem in a inclined surface when $Fr < 2$. We have been able to simulate numerically the formation of roll waves in the dam-break problem in an inclined surface for $Fr = 2.5$. The instability waves, and the subsequent roll waves, develop from just the numerical round-off noise at this Froude number, and for larger values of Fr. This is also a relevant finding because, to our knowledge, there are no previous observations of roll waves in physical experiments for Fr less than approximately 3.5, due to the above mentioned fact that the growth rate of the perturbations is very small when Fr is close to its critical value for instability. Finally, we find that the reported numerical results compare very well with the predictions of the stability analysis.

ABSTRACT: Inundation following the breaking of a dam or a dyke are likely to occur in areas that are not subject to common river floods. In urban districts, the flow route is dictated by the layout of buildings and streets rather than by a natural river thalweg. This paper presents a study of transient flow in simplified representations of urban districts, under the circumstances of a dam-break wave, or any rapid wave following a flash flood. An experimental study was conducted on three different configurations: (i) a square city layout of 5 × 5 buildings aligned with the flow direction, (ii) a single crossroad and (iii) a square city layout of 5 × 5 buildings not aligned with the main flow direction. Measurements were obtained by means of water level gauges and digital imaging techniques. Those measurements form a complete data set that is used to validate a numerical model based on 2D shallow-water equations.

1 INTRODUCTION

Flooding of urbanised areas constitutes a major threat for populations, especially if they are not prepare to cope with the situation. This is likely to occur when the inundation happens following unexpected or uncommon events such as the breaking of a dam or a dyke, or a flash flood after a heavy rainfall. Several examples can be found in the last years events: frequent flooding in Barcelona, Spain, inundation of Nîmes, France, in 1988 following a heavy rainfall of huge intensity and the recent flooding of New-Orleans (2005) in the United States following the breaking of several protecting dykes.

In urban districts, the flow route is dictated by the layout of buildings and streets rather than by a natural river thalweg. This induces complex flow features, and water levels in the streets higher than what would have happened without the presence of the city.

This type of flow have been studied experimentally by some authors, but generally under steady flow conditions, either subcritical or supercritical. Nanía et al. (2004) presented an experimental study of supercritical flow in a crossroad, with the aim of deriving one-dimensional relationships to predict the dividing flow in crossings. A similar study was conducted by Rivière & Perkins (2004). The propagation of inundation both through the streets and through the subway network in a detailed representation of an urban area was studied by Ishigaki et al. (2003).

Experiments under dam-break flow conditions were conducted by Soares-Frazão et al. (2004), to investigate the influence of the presence of a single building in the valley.

Those experiments are generally conducted with the objective of providing valuable data sets to calibrate and validate numerical models aimed at simulating flows in urban district, for the design of flood defence structures or emergency plans.

This paper presents dam-break flow experiments in three different idealised city layouts: (i) a square city layout of 5 × 5 buildings aligned with the flow direction, (ii) a single crossroad and (iii) a square city layout of 5 × 5 buildings not aligned with the main flow direction. Measurements were obtained by means of water level gauges and digital imaging techniques. Finally, numerical results obtained with a two-dimensional finite-volume model are compared to the experiments.

2 EXPERIMENTAL SET-UP

The experimental set-up is located in the laboratory of the Civil and Environmental Engineering Department of the Université catholique de Louvain, in Belgium. The channel is 36 m long and 3.6 m wide, with a partly trapezoidal cross section as indicated in Figure 1. A gate is located between two impervious blocks in order to simulate a breach in a dam or a dyke. The initial water level in the reservoir is 0.40 m and there is a thin

layer of 0.011 m water in the channel. The Manning friction coefficient for the channel is 0.01 $sm^{-1/3}$. The flow following the rising of the gate is thus typically two-dimensional as it expands in the downstream part of the channel.

Three different layouts of simplified urban district were studied in the channel (Deswijsen & Duthoit, 2005), as sketched in Figure 2: (i) a square city layout of 5×5 buildings aligned with the flow direction (Figure 2a), (ii) a single crossroad (Figure 2b) and (iii) a square city layout of 5×5 buildings making an angle of 22.5° with the main flow direction (Figure 2c).

The buildings consist in impervious wooden blocks of $0.3\,m \times 0.3\,m$. The buildings are fixed on the channel bed using a no-slip material and heavy weight inside the blocks. This system allows an easy repositioning of the blocks in order to simulate a wide range of city layouts. The single crossroad for example is set up by placing the individual buildings next to each other as sketched in Figure 2b.

In the square city layouts (aligned and not aligned with the flow direction), the streets are 10 cm wide, while for the single crossroad, the street is 50 cm wide. This latter test was designed to observe in more details the complex flow features in the crossroads.

3 FLOW DESCRIPTION

3.1 *Measurement devices*

Several measurement devices were used to characterise the flow. First, the water level evolution was measured at different locations by means of water level gauges. Those water level measurements (about 40 different gauge locations in each case) can be combined thanks to the reproducibility of the experiment in order to observe water profiles in the streets. Figure 3 illustrates the reproducibility of the results by means of four series of measurements at a gauging point located at the entrance of the skew urban district.

The surface velocity field was obtained using digital imaging techniques (Capart et al., 2002, Spinewine et al., 2003) to track the movement of tracer particles on the free surface. Again, thanks to the reproducibility of the experiment, several locations could be imaged and combined, which allows to identify particular features of the flow such as re-circulation for example.

In this particular case of rapid transient flow, surface-velocity measurement give valuable information on the depth-averaged velocity field. Indeed, it was observed (Soares-Frazão et al., 2004) that under rapid transient flow conditions, the velocity profile in a vertical plane was close to a uniform profile, as the flow had no time to adapt to a fully developed profile.

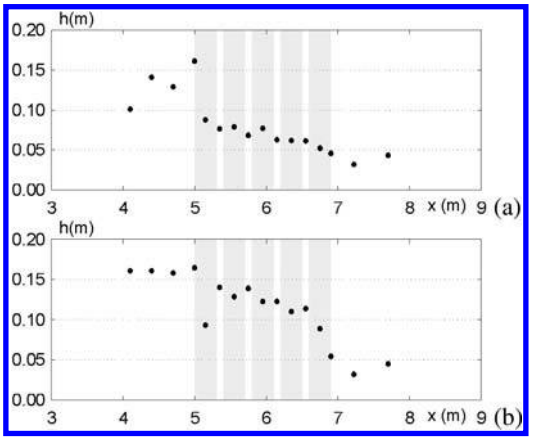

Figure 5. Experimental water profile in the left central street: (a) $t = 5$ s and (b) $t = 10$ s.

3.2 *The aligned case*

Flow observations show that after the violent impact of the wave against the buildings, the flow rises before entering the streets. A hydraulic jump forms upstream (Fig. 4), with the consequence that the water level is locally higher than without buildings. Immediately downstream from the city, a wake zone is observed. Then, further downstream, the flow slowly recovers the structure it would have had without the presence of the city (Soares-Frazão et al., 2004).

Looking at the water profile in the left central street (located at $y = 0.2$ m) obtained from the gauge measurements, we can see that after 5 s (Fig. 5a) the hydraulic jump has formed following the reflection of the flow against the buildings, and that the water depth in the urban district is still low. Then, after 10 s (Fig. 5b), the upstream hydraulic jump is still present but the water level has significantly raised in the streets. The flow in the urban district has evolved from supercritical to subcritical. Figure 6 shows the measured velocity vectors in the left central street after 5 s (Fig. 6a) and 10 s (Fig. 6b). Combining the
