A vertical two-dimensional morphodynamic model for bedform simulation

S. Giri & Y. Shimizu
Hokkaido University, Sapporo, Japan

ABSTRACT: A vertical two-dimensional morphodynamic model with non-hydrostatic, unsteady free surface flow is proposed herein. Model simulates flow and turbulence structures induced by sand waves under free surface flow condition. Furthermore, model can reproduce physically the formation and migration process of sand waves from an initially flat bed condition. A moving boundary coordinate system is employed. A state-of-the-art turbulence closure is used, known as nonlinear k-ε model with an allowance for anisotropy of Reynolds stresses in region with flow separation. A high order Godunov scheme referred to as Cubic Interpolated Pseudo-particle (CIP) numerical technique is employed to compute advection phase of Navier-Stokes equations. An Eulerian stochastic formulation of sediment exchange process as pick up and deposition function that explicitly considers the local flow variability during morphodynamic computation is incorporated to compute non-equilibrium sediment transport. The model prediction capability is verified against laboratory observations on dune evolution. In addition, prediction of dune geometry by numerical model is compared with results obtained by using some empirical relations.

1 INTRODUCTION

The microscale sand waves, particularly dunes, in alluvial streams are usually formed in lower flow regime under rough turbulent condition. Several investigations have been carried out so far that have made invaluable contributions to improve understanding on morphodynamic features of bedforms as well as flow and turbulence characteristics induced by sand waves. The complex hydraulic and morphodynamic aspects associated with bedform evolution have an important bearing on problems; however still remain poorly understood despite numerous efforts that have been made since long.

Understanding flow and turbulence induced by sand waves is of importance to explicate their formation mechanism and further development. Number of physical studies in this regard was made in the past (Bennet & Best, 1995; Nelson et al., 1993; Best et al.,1997). For instance, Nelson et al. (1993) conducted flow and turbulence measurement over two-dimensional fixed dunes, in which effects on bedform instability and finite amplitude stability along with the coupling of mean flow and turbulence were examined. Schmeeckle et al. (1999) conducted laboratory visualization of turbulence and suspended sediment transport over two-dimensional dune. Furthermore, some notable numerical studies were also carried out (Mclean & Smith, 1986; Mendoza-Cabrales, 1987). Shimizu et al. (2001) performed a three-dimensional direct numerical simulation of flow and turbulence over two-dimensional fixed dunes. The numerical model was able to reproduce the coherent structure induced by dune crest adequately. Most observations yielded strong correlation between coherent turbulence structure induced by flow separation, bed resistance and sediment transport mechanism. The flow field and bed configuration are found to be interdependent having direct and converse effect on each other that creates difficulties in appropriate physical interpretation and quantitative determination of the said problem. Numerous approaches were developed in order to quantify sand wave induced morphology of alluvial channels. Most early investigations were conducted using theoretical, semi-empirical and empirical approaches (Engelund, 1970; Engelund & Fredsoe, 1982). Among them, theoretical studies are largely based on linear stability theory which is, in effect, not appropriate approach for the determination of natural phenomena having finite amplitude features (Nelson et al.,1993). Scant attention has been given in regard to numerical modeling of sand waves morphodynamics (Fredsoe & Tjerry, 2001; Tjerry & Fredsoe, in print). Nakayama and Shimizu (2001) carried out a numerical study on suspended sediment transport over sand waves. They compared the computation result of time averaged concentration of suspended sediment with Rouse distribution curve as well as laboratory

Copyright © 2006 Taylor & Francis Group plc, London, UK

measurements. One of the significant studies was made by Onda & Hosoda (2004), in which a depth-integrated flow model was proposed with an allowance for vertical acceleration. They described bottom shear stress based on potential flow analysis considering acceleration-deceleration effect near the bed. In order to compute water surface profile, a numerical technique was used to simulate undular bore and flow over dunes with an attempt to eliminate the deficiency of hydrostatic pressure assumption by introducing a reduction factor to the vertical acceleration terms. Furthermore, they used sediment pick up and deposition function (Nakagawa & Tsujimoto, 1980) to simulate sand dune formation. Finally, they analyzed temporal variation of sand wave spectrum as well as dune geometry using their numerical results. However, this flow model cannot reproduce separation behind dune crest and, thereby, its effect on flow field and sediment transport. Recently, a comprehensive review has been conducted by Best (2005) where principal feature of mean flow and turbulence over dunes has been summarized as well as prospective areas for future research have been pointed out.

Present research has been prompted by the need to develop a more complete and reliable computational model to simulate flow and morphodynamic features of sand waves in a physically based manner. There is no doubt that earlier proposed three-dimensional model (Shimizu et al., 2001) is more complete approach for computation of flow and turbulence over bedforms. However, coupling this flow model with a morphodynamic module may inhibit it from being applied efficiently because of rather high computational effort. Consequently, aforesaid three-dimensional hydrodynamic model is simplified to be a vertical two-dimensional model and enhanced by imposing non-hydrostatic, free surface flow condition and coupled with a morphodynamic module. The model is verified against laboratory measurement of bedform geometry and visualization of dune migration process. Likewise, prediction of geometric characteristics of bedforms is validated with some relations for bedform geometry proposed by van Rijn (1983b) and Julien & Klaassen (1995).

2 HYDRODYNAMIC MODEL

2.1 *Conservation equations*

The governing equations for vertical two-dimensional flow in cartesian coordinate system reads as:

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0 \tag{1}$$

$$\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}=-\frac{1}{\rho}\frac{\partial p}{\partial x}+\frac{\partial}{\partial x}\left(-\overline{u'u'}\right)+\frac{\partial}{\partial y}\left(-\overline{u'v'}\right) \tag{2}$$

$$\frac{\partial v}{\partial t}+u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}=-\frac{1}{\rho}\frac{\partial p}{\partial y}+\frac{\partial}{\partial x}\left(-\overline{u'v'}\right)+\frac{\partial}{\partial y}\left(-\overline{v'v'}\right)-g \tag{3}$$

where x and y = coordinates in horizontal and vertical direction respectively; u and v = components of velocity in horizontal and vertical direction respectively, $-\overline{u'u'}$, $-\overline{u'v'}$ and $-\overline{v'v'}$ = Reynolds stress tensors, ρ = fluid density, g = gravitational acceleration, p = pressure.

Equations (1)–(3) are transformed from x, y, t cartesian coordinate system to a moving boundary fitted ξ, η and τ coordinate system (Shimizu & Itakura, 1994).

Pressure term in momentum equations can be computed considering non-hydrostatic component as follows:

$$p=p_0+p'=g\int_y^H \rho\,dz+p'=\rho g(H-y)+p' \tag{4}$$

Eq. (4) can be rewritten as:

$$p=\rho g(H-y)+p' \tag{5}$$

in which, p' = non-hydrostatic component of pressure, H = the elevation of free surface. Calculation is performed substituting pressure term (p) by Equation (5) in momentum equations, consequently, computing the non-hydrostatic component.

2.2 *Free surface oscillation*

Computation of time-dependent water surface change is of importance for the realistic reproduction of free surface flow over migrating bedforms. Basically, majority of morphodynamic numerical models developed earlier have assumed the rigid lid water surface condition to achieve numerically stable solution. In present study, the kinematic condition is imposed along the free surface to compute temporal water surface elevation. The kinematic condition, which constraints fluid particles to remain on the water surface at any time following the local flow velocity, is expressed as follows:

$$\frac{\partial H}{\partial t}+u\frac{\partial H}{\partial x}=v \tag{6}$$

$$H=y_b+h \tag{7}$$

where y_b = bed elevation and h = local flow depth.

2.3 *Turbulence model*

In conventional k-ε model, turbulence stress tensors are evaluated using linear relationship. In order to reproduce turbulence characteristics more accurately in shear flow with separation zone, a nonlinear term is

Copyright © 2006 Taylor & Francis Group plc, London, UK

added to the standard k-ε model as follows (Kimura & Hosoda, 2003):

$$-\overline{u_i'u_j'} = \nu_t S_{ij} - \frac{2}{3}k\delta_{ij} - \frac{k}{\varepsilon}\nu_t \sum_{\beta=1}^{3} C_\beta \left(S_{\beta ij} - \frac{1}{3} S_{\beta\alpha\alpha}\delta_{ij} \right) \tag{8}$$

$$\nu_t = C_\mu \frac{k^2}{\varepsilon} \tag{9}$$

where ν_t = eddy viscosity coefficient, δ_{ij} = Kronecker delta, k = turbulent kinetic energy, ε = dissipation rate of k. The detailed description and formulation of strain tensors S_{ij}, $S_{\beta ij}$, $S_{\beta\alpha\alpha}$, as well as coefficient C_β can be found elsewhere (Kimura & Hosoda, 2003).

k-ε equations can be expressed as follows:

$$\frac{\partial k}{\partial t} + u\frac{\partial k}{\partial x} + v\frac{\partial k}{\partial y} = \frac{\partial}{\partial x}\left(\frac{\nu_t}{\sigma_k}\frac{\partial k}{\partial x} \right) + \frac{\partial}{\partial y}\left(\frac{\nu_t}{\sigma_k}\frac{\partial k}{\partial y} \right) + P_h - \varepsilon \tag{10}$$

$$\frac{\partial \varepsilon}{\partial t} + u\frac{\partial \varepsilon}{\partial x} + v\frac{\partial \varepsilon}{\partial y} = \frac{\partial}{\partial x}\left(\frac{\nu_t}{\sigma_\varepsilon}\frac{\partial \varepsilon}{\partial x} \right) + \frac{\partial}{\partial y}\left(\frac{\nu_t}{\sigma_\varepsilon}\frac{\partial \varepsilon}{\partial y} \right) + C_{1\varepsilon}\frac{\varepsilon}{\kappa}P_h - C_{2\varepsilon}\frac{\varepsilon^2}{k} \tag{11}$$

$$P_h = -\overline{u_i'u_j'}\frac{\partial u_i}{\partial x_j} \tag{12}$$

where σ_k, σ_ε, $C_{1\varepsilon}$ and $C_{2\varepsilon}$ are standard model constants.

Boundary conditions are no slip at the bed and free flow at the surface. Following expression for near-bed region is adopted:

$$\frac{u_p}{u_*} = \frac{1}{\kappa}\ln\frac{y_p}{y_0} \tag{13}$$

where u_p = velocity at near-bed grid point, u_* = bed shear velocity, κ = Karman constant, y_p = distance from bed to nearest grid, $y_0 = k_s/30$, k_s = roughness height (=2.5d), d = sediment diameter.

Periodic boundary condition is employed in streamwise direction. Turbulent energy and its dissipation in near-bed region are evaluated as proposed by Kimura & Hosoda (2003):

$$\frac{k}{u_*^2} = \frac{1}{\sqrt{C_\mu}} \tag{14}$$

$$\varepsilon = \frac{u_*^3}{ky} \tag{15}$$

In order to account for the diminution of turbulence length scale at the free surface layer, they proposed a damping function to the eddy viscosity:

$$f_s = 1 - \exp\left(-B\frac{(h-y)\varepsilon_s}{k_s^{3/2}} \right) \tag{16}$$

where $B = 10$.

The dissipation rate of turbulent energy at the surface layer is evaluated using following equation (Sugiyama et al., 1995)

$$\varepsilon_s = \frac{C_{\mu 0}^{3/4} k_s^{3/2}}{0.4\Delta y_s} \tag{17}$$

where Δy_s = distance from water surface to first grid and coefficient $C_{\mu 0} = 0.09$

$$\frac{\partial k}{\partial y} = 0 \tag{18}$$

2.4 *Numerical method*

The transformed equations are numerically solved by splitting them into non-advection and pure advection phase. The non-advection phase is computed using central difference method. The pressure field is resolved using SOR method. The advection phase is calculated using a high-order Godunov scheme known as CIP method (Yabe et al.,1990). In this scheme, at very small time increment, the change in time of velocity components at a point in space can be split into the time evolution of the inhomogeneous terms and the time evolution at a point due to the advection of the field. A brief description of CIP numerical scheme to solve advection terms in generalized coordinate system can be found elsewhere (Shimizu, 2004).

3 SEDIMENT TRANSPORT MODEL

Some earlier investigations (Schmeeckle et al., 2003; Sumer et al.,2003) have revealed that spatially or/and temporally averaged sediment transport models are inadequate to describe the extremely inconsistent nature of sediment particle motion particularly in the region with high near-bed turbulence. In effect, a direct computation of sediment particle motion, viz. Discrete Element Model (DEM), which responds to the local and temporally variable flow field, is physically more complete approach. However, coupling this approach with an advanced hydrodynamic model, at present, seems to be rather sophisticated in view of computational complexity and expenses, in particular, for solving comparatively big scale problem.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Computationally efficient and relatively comprehensive approach is believed to be the modeling of pick up and deposition of sediment particles in terms of a stochastic formulation. Consequently, an Eulerian stochastic formulation of sediment transport proposed by Nakagawa & Tsujimoto (1980) is incorporated in our numerical code. This method yielded one of the best predictions of pick up function for fine sediment grain as described by van Rijn (1983a). Moreover, this approach was effectively used and validated in earlier investigations (Onda & Hosoda, 2004).

The dimensionless pick up rate is expressed as follows (Nakagawa & Tsujimoto, 1980):

$$p_s\sqrt{d/(\rho_s/\rho-1)g} = 0.03\tau_*(1-0.035/\tau_*)^3 \qquad (19)$$

where p_s = sediment pick up rate, ρ and ρ_s = fluid and sediment density respectively and τ_* = dimensionless local bed shear stress.

The sediment deposition rate reads as:

$$p_d = p_s f_s(s) \qquad (20)$$

where p_d = sediment deposition rate and $f_s(s)$ = distribution function of step length.

Distribution function of step length is found to be exponential as follows (Nakagawa & Tsujimoto):

$$f_s(s) = \frac{1}{\Lambda}\exp\left(-\frac{s}{\Lambda}\right) \qquad (21)$$

where Λ = the mean step length and s = the distance of sediment motion from pick up point.

The mean step length can be calculated as $\Lambda = \alpha d$, in which α is an empirical constant and proposed to be 100.

In order to consider the instability of bedforms in upper flow regime, a module to compute suspended sediment transport is also incorporated in proposed numerical model. Considering suspended sediment transport, the bed deformation rate can be computed using following sediment continuity equation:

$$\frac{\partial y_b}{\partial t} + \frac{1}{1-\lambda}\left[\frac{A_3}{A_2}(p_d - p_s)d + (q_{sui} - w_f c_b)\right] = 0 \qquad (22)$$

where y_b = bed elevation, λ = porosity of sediment particle, A_2 and A_3 = shape coefficients of sand grain with two- and three-dimensional geometrical properties, q_{sui} = upward suspended sediment flux per unit area, w_f = falling velocity and c_b = reference concentration of suspended sediment.

In case of equilibrium suspended sediment transport, the third term in Equation (22) vanishes.

q_{sui} is calculated using equation proposed by Itakura & Kishi (1980):

$$q_{sui} = K\left(\alpha_*\frac{\rho_s-\rho}{\rho_s}\frac{gd}{u_*}\Omega - w_f\right) \qquad (23)$$

in which,

$$\Omega = \frac{\tau_*}{B_*}\frac{\int_a^\infty \xi\frac{1}{\sqrt{\pi}}\exp(-\xi^2)d\xi}{\int_a^\infty \frac{1}{\sqrt{\pi}}\exp(-\xi^2)d\xi} + \frac{B_*\eta_0}{\tau_*} - 1 \qquad (24)$$

$$a = \frac{B_*}{\tau_*} - \frac{1}{\eta_0} \qquad (25)$$

where B_*, η_0, α_* and K are constants, the values of which are adopted as: $B_* = 0.143$, $\eta_0 = 0.5$, $\alpha_* = 0.14$ and $K = 0.008$.

The falling velocity is calculated using well-known Rubey's formula:

$$w_f = \sqrt{\frac{2}{3}Sgd + \frac{36\nu^2}{d^2}} - \frac{6\nu}{d} \qquad (26)$$

where S = relative density of sediment in water, namely 1.65, ν = kinematic viscosity of water.

4 MODEL VALIDATION

4.1 *Physical experiment*

An experimental investigation on sand dune formation and migration process was carried out under the department of hydraulic research of Hokkaido University. Experiments were performed in laboratory flume of CERI of Hokkaido. The total length of the flume was 30 m, width was 10 cm and height was 30 cm having 1/500 slope, regulated by automatic control system. The middle part of flume (10 m) was covered with 5 cm thick sediment layer with 0.28 mm median diameter, which was trapped by using sediment stoppers at the part of upstream and downstream having length of 10 m each. The sand feeding was done manually by filling up the space between movable bed and sand stopper in the upstream boundary, which formed because of transported sand. The migration process of sand dunes was visualized using high resolution video camera. Quantitative evaluation of bedform geometry was made at the end of each experiment. The experimental condition is listed in Table 1. In addition, experiments by Venditti et al (2005) were also used to verify model.

Copyright © 2006 Taylor & Francis Group plc, London, UK

4.2 *Simulation results*

4.2.1 *Flow and vorticity visualization*

Visualization of the flow and vorticity simulation over fixed dunes reveals the existence of flow separation behind dune crest (**Fig. 1**) which seems to be realistic as observed in most physical investigations. For the sake of comparison, same simulation was made using standard k-ε model. In this case, the instantaneous motion of vorticity behind dune crest as well as recirculation can not be reproduced well (**Fig. 1**). This evinces the reliability of nonlinear turbulence model for such a region with flow separation. More detail analysis on flow and turbulence was made by authors elsewhere (Giri & Shimizu, accepted).

4.2.2 *Bedform simulation-effect of grid resolution*

An attempt has been made to simulate sand wave formation and migration from a nearly flat sand bed for all experimental cases. It was found that grid resolution near the bed has significant impact on dune evolution. The dune geometry seems to be poorly predicted by numerical model in case when vertical grid is distributed uniformly. On the other hand, when same number of grid was exponentially stretched in vertical direction, the result appears to be changed dramatically. In this case, grid is dense near bed (**Fig. 2**). For the sake of comparison, simulation result of dune geometry for a typical case (Run A-5) with uniform grid and stretched grid spacing for a selected time increment is depicted in **Figure 3**. Moreover, simulation of temporal bedform evolution shows that model with non-uniform grid can reproduce rather realistically one of the important physical processes during dune evolution observed in natural rivers, namely amalgamation. A typical example of bedform evolution from a flat bed condition can be seen in **Figure 4**. It can be noticed in visualization of bedform migration that small size dunes migrate faster at first and become slower as bedform geometry increases.

Table 1. Experimental condition.

Run	Time (min)	Discharge ($cm^3/s \times 10^3$)	Flow depth (cm)	Froude number
A-1	250	2.0	7.0	0.34
A-2	105	4.0	9.9	0.41
A-3	90	6.0	12.1	0.46
A-4	75	8.0	15.2	0.43
A-5	60	10.0	16.7	0.47

4.2.3 *Prediction of dune characteristics*

Proposed morphodynamic model can reproduce dune geometry in physically based manner that appears to be realistic and close to physical observation. Some quantitative comparison between simulated and visualized dune geometry is depicted in **Figure 5**. In effect, the geometric characteristics of dunes for these experimental cases look similar since hydraulic and sediment conditions are related to the limited range. Nonetheless, prediction of such a phenomenon by

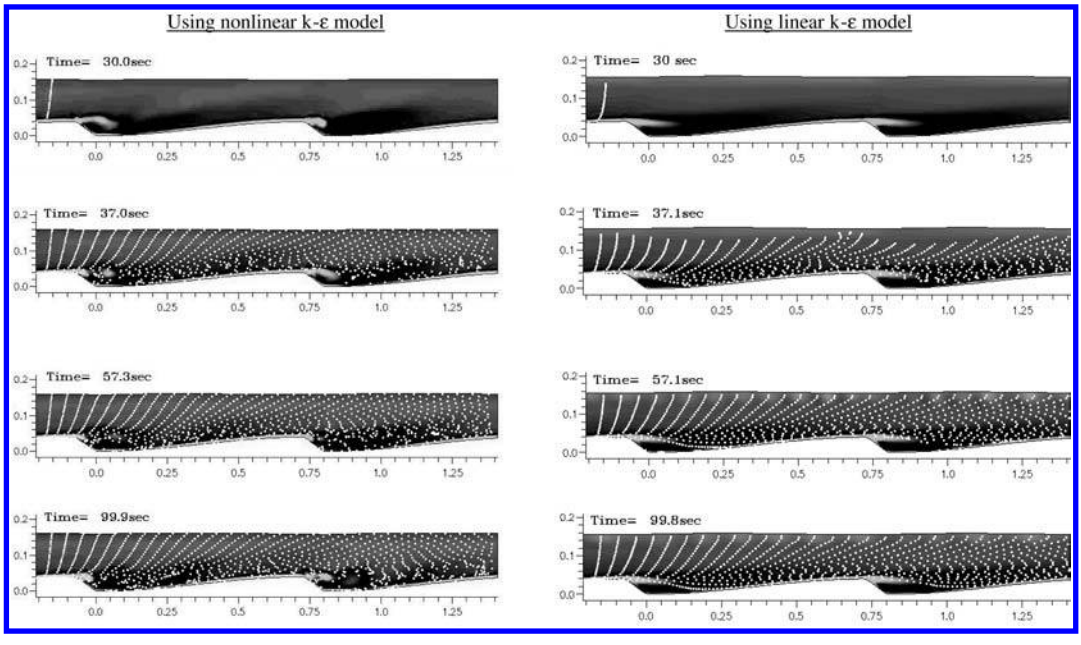

Figure 1. Instantaneous flow particle and vorticity simulation- performance of linear and nonlinear k-ε models.

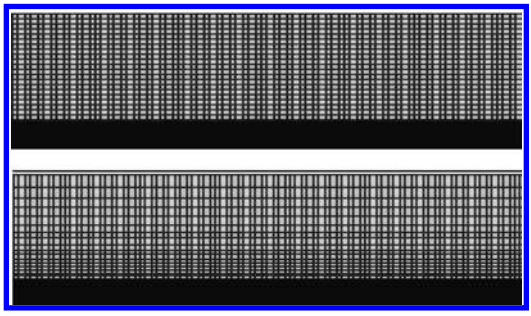

Figure 2. Grid generation- uniform & non-uniform.

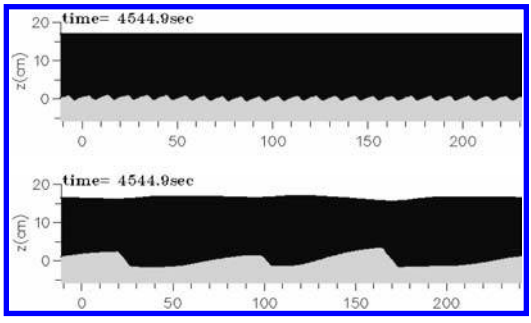

Figure 3. Typical example of instantaneous bedform evolution for uniform (upper) & non-uniform (lower) grid in vertical direction.

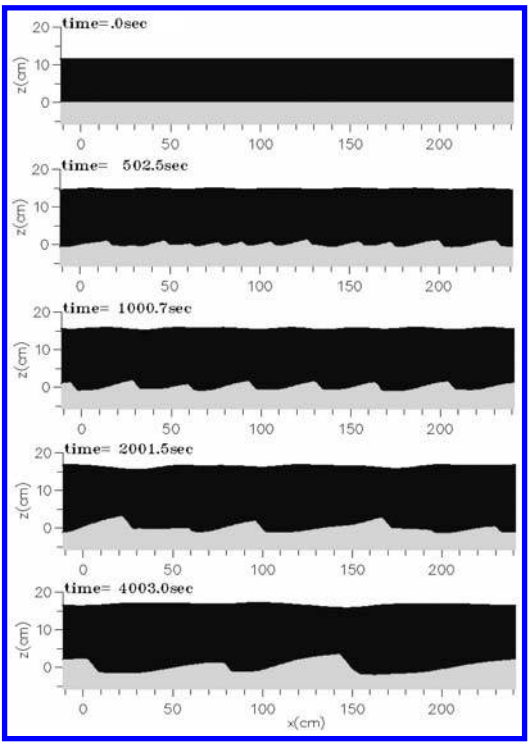

Figure 4. Typical example of bedform evolution simulated by numerical model (run A-5).

numerical model seems to be rather promising. Likewise, numerical simulation of dune migration reveals identical qualitative characteristic as in laboratory observation. Computed results show some quantitative inconsistency for prediction of bedform migration speed. However, these comparisons are subjected to further study. Simulated dune migration process is compared with the experimental visualization of Run A-2 for the qualitative assessment of model performance (see visualization).

For further validation of model prediction capabilities, empirical approach proposed by van Rijn (1983b) and Julien & Klaassen (1995) is used, which is based on large range of laboratory and field observations on dune geometry. Julien & Klaassen (1995) collected wide range of data on sand dune geometry of large rivers and revised the van Rijn's approach to predict dune geometry. We have used both relations proposed by van Rijn (1983b) and Julien & Klaassen (1995) to predict dune characteristics and compared them with numerical results as depicted in **Figures 6–7**. We have used van Rijn's method herein to predict dune length only (**Fig. 7**). Prediction of geometric characteristics of dunes by numerical model with compare to calculated results seems in trend. The discrepancy is likely to be due to the approaches used in empirical relationships as well as effect of sidewall in authors' experiment. Venditti et al. (2005) reported in their work that their experimental results are well predicted.

Model simulation on bed form migration showed some discrepancies, particularly for authors' experiments. From the simulation result, it can be identified that bed form celerity is higher in the beginning and decreases with the growth of bed form geometry. Most laboratory and field observations revealed similar feature of bed form celerity. For instance, Venditti et al.(2005) observed in their experiments decrement of migration rate with respect to the temporal development of bed form. They measured migration rates in initial as well as equilibrium stages of bed form development (Table 3 in Venditti et al., 2005). They reported that for their experiments A and B, migration rate showed a decrease from ~1.5 to 0.2 mm/s during 6000 seconds. It is also found from our computation that there is a decrease in migration rates from 1.0 to 0.3 mm/s for these experiments, which is almost of the same order. Computation result of dune migration also showed agreement with their experiments except for the case with low flow stages (**Fig. 9**). The discrepancies that were observed particularly in

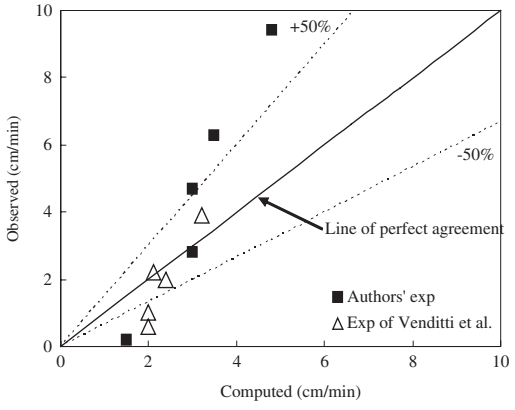

Figure 9. Numerical simulation of bedform migration in later stage (quasi-equilibrium stage).

authors' experiments can be attributed to the side wall effect.

Overall, numerical simulation of dune evolution showed fairly identical trend for characteristic of bed forms (dunes) as observed in laboratory. It can be inferred that the range of prediction capability of proposed computational model is acceptable considering sophisticated nature of the problem.

4.2.4 *Temporal change of flow resistance and flow depth simulation*

It is well-known that flow resistance is associated with skin friction of sediment particle and form drag exerted by bedforms. In case of flat bed, effective shear stress is equal to the grain shear stress. Whereas, in presence

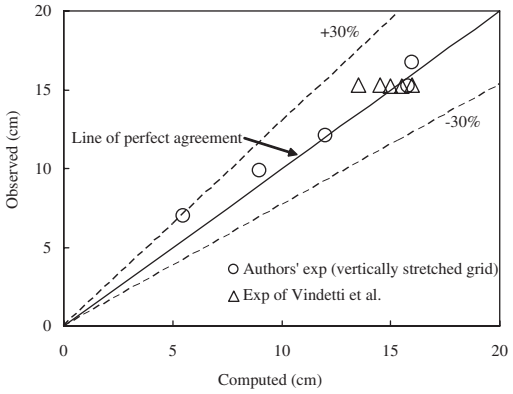

Figure 10. Comparison between observed and computed flow depth after bedform development.

of bedforms, contribution of form drag becomes significant and effective shear stress starts to increase. This phenomenon can be simulated using proposed model and thereby can be assessed deviation of bed shear stress according as bedform growth. **Figure 8** represent an instantaneous feature of total shear stress deviation (**Fig. 8a**). In the same figure, variation of Froude number (**Fig. 8b**) and depth variation **(Fig. 8c**) associated with temporal bedform growth can be assessed. In **Figure 8d** instantaneous bedform associated with given time event (3912 seconds) is depicted. Using this model, all aforementioned features can be visualized for each time step according as bedform evolution. Furthermore, quantitative comparison between observed and computed average flow depth for all experimental cases is depicted in **Figure 10**. It can be seen that model shows quite good prediction of bedform-induced flow depth. Model capability to simulate bedform-induced flow depth for given discharge could be useful in river engineering practice.

5 GENERAL CONCLUSION

A vertical two-dimensional hydrodynamic and morphologic model has been developed that can simulate flow, turbulence and morphodynamic features induced by sand waves, particularly dunes. The hydrodynamic model with a nonlinear k-ε turbulence closure has been found to be adequate to reproduce flow and turbulence characteristics as well as vorticity field in separation region behind the bedform crest. Likewise, the simulation result of water surface oscillation due to the form drag exerted by migrating bedforms seems to be realistic. The sediment transport modeling approach, namely modeling the exchange of sediment particles as pick up and deposition rate, shows fairly good performance. The proposed approach is believed to be

Copyright © 2006 Taylor & Francis Group plc, London, UK

more appropriate for non-equilibrium sediment transport with bedforms than generally used morphologic modeling approach. Additionally, module to compute suspended sediment flux could also be relevant to consider the bedform instability during upper flow regime, though still remains to be verified.

An attempt has been made here to develop a reliable and physically based modeling approach which was able to embody known concepts to characterize bedform evolution mechanism from a flat bed condition. Model can predict all physical characteristics of bedforms particularly dunes, namely height, length, shape, form drag as well as migration physically. In general, computation results seem to be realistic and promising, which demonstrate scope and usability of numerical simulation technique that could be a supplementary tool to comprehend a sophisticated river engineering phenomenon. Proposed model is not validated for upper flow regime. Moreover, effort is being made in order to incorporate in existing model the unsteady condition for flow rate and simulate hysteresis of bedform evolution.

ACKNOWLEDGEMENTS

This study was supported by Japan Society of Promotion of Science fellowship grant (Grant-in-aid 17-05093). We gratefully acknowledge Kazutake Asahi who carried out experiments as a part of his graduate study.

Experimental study on steady flow in a channel with macro-roughness at the side walls

T. Meile, J.-L. Boillat, J. Dubois & A.J. Schleiss

ABSTRACT: Water levels of rivers are influenced by the material and the form of bed and banks, which are producing skin friction and form drag. Morphological measures on banks can have an influence on the flow, especially when the flow depth becomes significant comparing to the river width. 36 configurations of the side walls producing a macro-roughness have been tested in a laboratory flume. The test configurations were formed by rectangular, local widenings with varying geometrical proprieties (widening length, widening lateral depth and distance between widenings). The analysis of the water level measurements was based on backwater curve calculations. It was possible to quantify equivalent sand roughness of the side walls including the effect of macro-roughness, effective flow widths at the enlarged sections and friction factors of the composite sections. Results reveal that macro-roughness produces rising characteristics for the relationship between friction factor and Reynolds numbers.

1 INTRODUCTION

Water levels of rivers are influenced by the roughness of the bed and the roughness of the banks. For low relative flow depths the roughness of the banks is of secondary importance. This is generally the case for wide rivers at low and moderate discharge. With increasing relative flow depths, which can be found in side-channels or streams, the influence of bank roughness becomes more significant. This leads to composite channel resistances. Different equations issuing from various researches for composite channel resistance exist. They are based on numerous assumptions summarized in Yen (2002).

In addition to the effect of bed and bank, the total resistance in a channel is depending on both, grain roughness and form roughness, for example generated by the bed forms of alluvial channels as described by several authors (Einstein & Barbarossa 1952; Graf 1984; Van Rijn 1993).

For the flow in rough conduits, Morris (1955) and Morris & Wiggert (1972) applied a concept based on skin friction, caused by the roughness of the material, and form drag. A first friction factor for smooth-turbulences corresponding to walls without macro-scale roughness and a second friction factor caused by roughness elements are considered. The importance of the second friction factor depends on size, form and spacing of the roughness elements.

More recent studies on macro-rough flow deal with flow resistance of mountain streams respectively flow over macro-scale roughness. First attempts to quantify the flow resistance in function of relative submergence, and parameters related to the geometry and density of macro-rough elements were made by Bathurst et al. (1981). Canovaro et al. (2004) relate Chezy coefficients to pebble concentrations and arrangements. A minimum of Chezy coefficients corresponds to a spatial density of pebbles of 0.1.

Recently, numerical simulations have been established for artificially roughened beds. Macro-roughness was introduced by rectangular cavities (Leonardi et al. 2003; Stoesser et al. 2004). Depending on the ratio cavity width to roughness height, they have simulated the three roughness types according to Morris (1955). The maximum total flow resistance is observed for the mentioned ratio equal to about 7 and the resistance is mainly due to the form drag of the macro-roughness elements.

The present article aims to provide information for a better understanding of the effect of macro-roughness at the side walls on steady flow in channels.

2 EXPERIMENTS

2.1 *Setup*

The experiments have been realized in a channel of the Laboratory of Hydraulic Constructions at EPFL.

The channel has a useful length of $L_{tot} = 38.25$ m and a mean slope of 1.15‰. The base width is

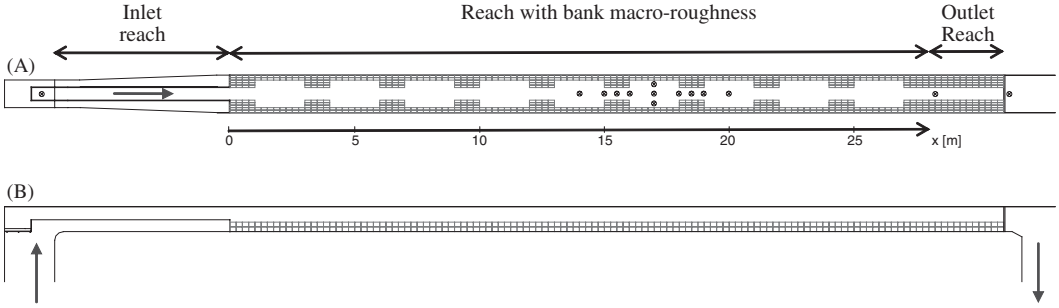

Figure 1. (A) Plan view of the laboratory channel divided in three reaches: Inlet-reach, reach with macro-roughness, outlet-reach. ⊗ level measurements with ultrasonic-probes. (B) Longitudinal section of the flume.

$B = 0.485$ m. The channel is divided in an inlet reach ($L_{in} = 7.35$ m), a reach with macro-roughness at the side walls ($L_{MR} = 26.9$ m) and an outlet reach ($L_{out} = 4$ m). The exact length of L_{MR} and L_{out} depends on the configuration of macro-roughness. The sum of both is constant.

The sidewalls of the reach with macro-roughness and the outlet reach are formed by limestone bricks (Fig. 2). The equivalent sand roughness of the limestone bricks has been determined by means of backwater curve computations in a rectangular, prismatic configuration ($k_{sw} = 0.021$ mm). The equivalent sand roughness of the bottom, also found by backwater curve computation is $k_{s0} = 0.001$ mm.

An outlet control section is placed at the end of the outlet reach. The geometry of this section is optimized in order to simulate a long channel at normal depth (Carlier 1998). The channel slope is small enough to guarantee subcritical flow at every position of the channel for the range of tested discharges.

The plan view and the longitudinal section of the laboratory channel are shown on Figure 1.

Water levels have been measured at different points along the channel axis as well as in the left and right widening of section $x = 17.0$ m. A velocity profile was measured in the axis of the channel at $x = 17.0$ m using the Ultrasonic Doppler Shift effect (Takeda 1985). Finally, at the same section the pressure on the bottom has been measured.

The channel has a fixed bed without sediment transport.

2.2 *Test configurations*

A prismatic reference configuration with constant width $B = 0.485$ m is compared to 36 geometrically different test configurations, formed by symmetric widenings (Fig. 2). The widenings, considered as a macro-roughness at the side walls, have been obtained by a modular system of limestone bricks. The bottom level is the same for the main channel and for widenings.

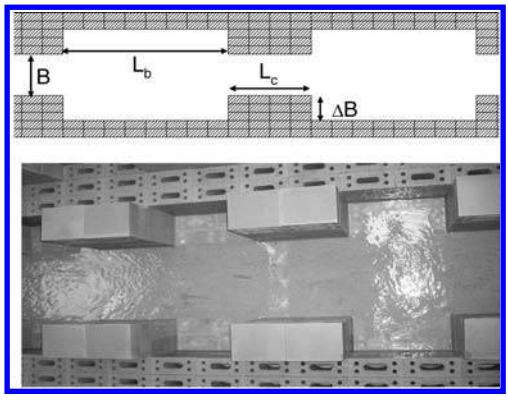

Figure 2. Definition of the geometrical parameters of the test configurations (above) and example of widenings (macro-roughness) built using the modular system of limestone bricks.

The geometrical parameters are defined on Figure 2 and the 36 different test geometries are summarized in Table 1. The base width $B = 0.485$ m remains constant during all the tests. L_b is the length of the widening. L_c is the distance between two widenings, ΔB is the depth (or lateral extent) of the widening.

A linear widening density can be defined as the ratio $D_L = L_b/(L_c + L_b)$ and a surface widening ratio as $D_S = \Delta B \cdot L_b/(B \cdot (L_c + L_b))$.

Generally, 12 different discharges within a range of about 5 l/s to max. 140 l/s have been studied. This range led to Froude numbers between 0.37 and 0.64 and to Reynolds numbers between 6,800 and 110,000 at the section $x = 17.0$ m.

3 RESULTS

3.1 *Flow behavior*

Different flow behaviors can be observed in the channel (Fig. 3). By increasing the discharge, flow depths,

mean velocities and Reynolds numbers become more important in a given channel section. Instead, Froude numbers remain more or less constant.

For relative flow depths of $h/B < 0.12$ and Reynolds numbers $Re < \sim$15,000, the water surface is smooth, flat with possible small surface waves. For relative flow depths h/B > 0.3 and Reynolds numbers $Re > \sim$50,000, the water surface gets uneven and wavy.

Observations with tracer show that the flow pattern in the widenings corresponds to the ones of emerged groin fields when flow depths and velocities remain low. As pointed out by several researches, the ratio of $\Delta B/L_b$ affects dead zones and eddies. Yossef & Vriend (2004) show a flow pattern composed by a primary, secondary and a dynamic eddy. The experiments of Weitbrecht & Jirka (2001) put in evidence that the presence of these three eddies is depending on $\Delta B/L_b$. Dye tests reveal that the region between the widening and the main channel is dynamic. The dynamic eddy at the upstream part of the widening is frequently taken by the current and migrates downstream. It does then either directly disappears in the main stream or it merges with the primary eddy.

For higher flow depths and thus higher velocities, flow structures can not be detected applying dye tests. The flow acts like an expanding jet arriving in an enlargement. If the ratio $\Delta B/L_b$ is small, reattachment of the flow seems possible. If the depth of the widening is important compared to its length, the jet directly hits the contraction of the section at the end of the widening.

Finally, in some cases, significant water surface oscillations between two opposite widenings can be observed. This has already been detected in other researches (Ohmoto et al. 2005). The phenomenon is in particular present for small and medium relative flow depths. For high relative flow depths, the flow arrives with a higher velocity in the widening and it becomes therefore stable enough to avoid the interaction between the widening on the left and right channel side wall. If transverse surface oscillations

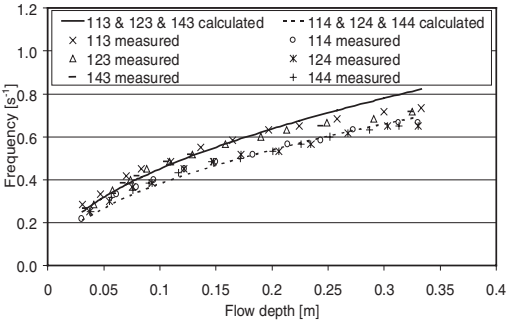

Figure 4. Calculated (from flow depths) and observed frequencies of the transverse oscillations in the widenings.

arise, the observed main period, found by spectrum analysis, corresponds to the natural period of a seiche in a rectangular basin:

$$T = \frac{2 \cdot L}{n\sqrt{gh}} \tag{1}$$

where T = period; $L = B + 2\Delta B$ = width of the basin; n = number of nodes; g = gravity constant and h = flow depth.

If the ratio $L_b/(B + 2\Delta B)$ is smaller than about 0.5 to 1, the oscillations are present for most of the discharges and their period is in good agreement with the theory of a rectangular basins (first mode, $n = 1$).

The observed frequencies are lower than the calculated ones for higher flow depths (Fig. 4). This can be explained by the coexistence of transverse and longitudinal seiches, which leads to an increase of the period according to the generalized Merian's formula (Wüest & Farmer 1998).

3.2 *Roughness quantification*

Several phenomena are responsible for the additional head loss along the channel. The major source of friction is the generation, spreading, and subsequent dissipation of vortices from the wake and separation zones following the roughness elements. According to Morris (1972), a depression, like the tested widenings, can also be considered as a roughness element. A second, minor source of energy loss is the momentum exchange caused by turbulent exchange and geometrical transfer at the interface between the widenings and the main channel (Bousmar & Zech 1999). Transverse oscillations (see Chapter 3.1) may enhance this flow exchange.

Two different calculation methods have been considered for the analysis of the water level measurements. Both are based on a water level computation from downstream upwards. Starting point is the known water level in the outlet-reach. The first method (Chapter 3.2.1) considers that the widenings produce an additional linear headloss. The computation method is a 1D prismatic approach for a non prismatic channel and should be seen as an inverse roughness modeling. The calibration of a factor related to the roughness allows fitting calculated on measured water levels. The second method (Chapter 3.2.2) considers the single head losses along the channel produced by the sudden expansions and contractions of the flow. Calculations are done based on the specific energy $H_s = h + U^2/(2g)$. A theoretically effective flow width is then used to fit calculated on measured water levels.

3.2.1 *Governing equations: Method 1*

The energy equation is used for the backwater curve computation. The standard step method leads to:

$$\left(h_{i+1} + z_{i+1} + \frac{U_{i+1}^2}{2g}\right) - \left(h_i + z_i + \frac{U_i^2}{2g}\right) = \overline{S_{fm}}(x_{i+1} - x_i) \tag{2}$$

where S_f = friction slope; h = flow depth; x = channel section; z = bottom level; U = mean velocity related to the base width B; B = base width. The subscript $_m$ indicates that the friction slope is composed of a wall friction (subscript $_w$) including effect of the macro-roughness and a bottom friction (subscript $_0$).

The friction slope is calculated by the Darcy-Weisbach formula:

$$\overline{S_{fm}} = \overline{f_m}\frac{\overline{U}^2}{8g\overline{R_h}} \tag{3}$$

where R_h = hydraulic radius; f = friction coefficient.

The channel has been considered as a composite section. If the hypothesis is made that the Einstein (1934) approach for a composite section is applicable, it can be written as follows:

$$\frac{R_{h0}}{f_0} = \frac{R_{hw}}{f_w} = \frac{R_{hm}}{f_m} = \frac{U^2}{8gS_{fm}} \tag{4}$$

where R_{h0} = hydraulic radius referred to the bottom; R_{hw} = hydraulic radius referred to the wall; R_{hm} = hydraulic radius referred to the composite section.

The friction coefficient of the composite section f_m is calculated according to Hersberger (2003) as:

$$f_m = \frac{Bf_0 + 2hf_w}{B + 2h} \tag{5}$$

where f_0 = bottom friction coefficient; f_w = wall friction coefficient including the effect of macro-roughness of the widenings.

Copyright © 2006 Taylor & Francis Group plc, London, UK

After all, the bottom and wall friction coefficients can be determined with the following logarithmic Colebrook-White laws:

$$\frac{1}{\sqrt{f_0}} = -K_1 \log\left(\frac{k_{s0}}{K_2 R_{h0}} + \frac{K_3}{4Re_0\sqrt{f_0}}\right) \quad (6)$$

$$\frac{1}{\sqrt{f_w}} = -K_1 \log\left(\frac{k_{sw}}{K_2 R_{hw}} + \frac{K_3}{4Re_w\sqrt{f_w}}\right) \quad (7)$$

where Re_0 = Reynolds number related to the bottom; Re_w = Reynolds number related to the wall; k_{s0} = equivalent bottom sand roughness; k_{sw} = equivalent wall sand roughness including the effect of macro-roughness of widenings. $K_1 = 2.03$, $K_2 = 10.95$ and $K_3 = 1.70$ are the constants used by Rouse (1946).

The hydraulic radius R_{h0}, R_{hw}, and the Reynolds numbers Re_0 and Re_w are calculated with the following formulas:

$$R_{h0} = \frac{R_{hm}}{f_m} f_0 \quad (8)$$

$$Re_0 = \frac{U R_{h0}}{\nu} \quad (9)$$

$$R_{hw} = \frac{R_{hm}}{f_m} f_w \quad (10)$$

$$Re_w = \frac{U R_{hw}}{\nu} \quad (11)$$

The equivalent sand roughness of the wall k_{sw} which includes the effect of macro-roughness of the widenings can be used to fit the calculated water levels with the observed ones and a dataset of k_{sw}-values can be obtained. The k_{sw}-values can be either determined globally for all discharges of one geometrical configuration or individually for every discharge of the geometrical configuration.

The friction coefficients of the composite section f_m can be extracted from equation (5) as second information obtained from the backwater curve computation. The f_m-values must be considered as more global information's than the k_{sw}-values. Moreover, they are practically not depending on the hypothesis made by formulas (4) to (11) and nearly constant for a given discharge and a given geometrical configuration. The equivalent sand roughness of the wall k_{sw} and the friction coefficients f_m present two different sets of values related to the macro-roughness configurations.

3.2.2 *Governing equations: Method 2*

Backwater curves can also be computed by considering the single head losses produced by the sudden expansions and contractions of the flow due to the widenings. Calculations are based on the specific energy $H_s = h + U^2/(2g)$ (Fig. 5). The skin friction is thus assumed to be compensated by the bottom slope of the channel.

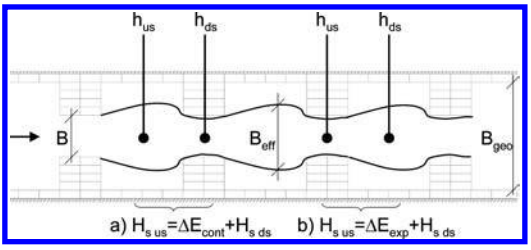

Figure 5. Scheme of backwater curve calculations for sudden contractions (a) and expansions (b).

The single head loss for an abrupt expansion ΔE_{exp} is given by (Henderson, 1966) The subscript $_{us}$ refers to the upstream section (width B) and the subscript $_{ds}$ to the enlarged section (width B_{eff}):

$$H_{s\,us} = H_{s\,ds} + \Delta E_{exp} \quad (12)$$

with:

$$\Delta E_{exp} = \frac{\left(Q/B h_{us}\right)^2}{2g}\left[\left(1 - \frac{B}{B_{eff}}\right)^2 + \frac{2 Fr_{us}^{\,2} B^3 \left(B_{eff} - B\right)}{B_{eff}^{\,4}}\right] \quad (13)$$

where H_s = specific energy; ΔE_{exp} = single headloss for the expansion; Q = discharge; B_{eff} = effective flow width at the enlarged section; Fr_{us} = Froude number at the upstream section.

The upstream flow depth h_{us} is calculated knowing the flow depth h_{ds} at the enlarged section by iterating the following formula:

$$h_{us} = h_{ds} + \frac{\left(Q/B_{eff}\, h_{ds}\right)^2}{2g} + \frac{\left(Q/B h_{us}\right)^2}{2g}\left(A - 1\right) \quad (14)$$

with:

$$A = \left(1 - \frac{B}{B_{eff}}\right)^2 + \frac{2 Fr_{us}^{\,2} B^3 \left(B_{eff} - B\right)}{B_{eff}^{\,4}} \quad (15)$$

The single head loss for the abrupt contraction ΔE_{cont} is calculated as proposed in Sinniger & Hager (1989). The downstream section (subscript $_{ds}$) has now the width B and the upsteam section (subscript $_{us}$) is enlarged:

$$H_{s\,us} = H_{s\,ds} + \Delta E_{cont} \quad (16)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

with ΔE_{cont}:

$$\Delta E_{cont} = \xi \frac{\left(Q / B h_{ds}\right)^2}{2g} \quad (17)$$

with ξ given by Matthew (1975):

$$\xi = \left(1 - B/B_{eff}\right)^{2-(\alpha/11)} \sin^2\left(\alpha/2\right) \quad (18)$$

where α = contraction angle (in the present case 90°).

Finally, the flow depth in the enlarged, upstream section is calculated by iterating the following formula:

$$h_{us} = (\xi + 1)\frac{\left(Q / B h_{ds}\right)^2}{2g} + h_{ds} - \frac{\left(Q / B_{eff} h_{us}\right)^2}{2g} \quad (19)$$

The backwater curve can be calculated moving from downstream to upstream. B_{eff} is unknown and used to fit the calculated water levels with the observed ones. Therefore it is possible to get an effective width used by the flow at the enlarged sections for every geometrical configuration. The B_{eff}-values are forming the third set of values related to the macro-roughness configurations.

Some results of the three data sets, k_{sw}, f_m and B_{eff}, are presented in the following chapters.

3.2.3 *Equivalent wall sand roughness values*

The equivalent sand roughness values of the wall k_{sw} including the effect of macro-roughness of the widenings are summarized in Table 2. The given values are global values for each geometrical configuration, which, by definition, are independent of the discharge. They allow the best fit between the calculated water-surface and the water level measurements. Δh_{ksw} is the mean absolute error resulting from measured and calculated water depths. Water depths are varying between 0.04 m and 0.3 m. The relative errors remain therefore quite small.

Nevertheless, the use of a global equivalent sand roughness value for the side walls generally leads to an overestimation of the calculated flow depths for lower discharges and an underestimation of the flow depths for higher discharges. For the analysis done by method 1 it can thus be concluded that the k_{sw} values are not only dependent on the geometrical characteristics of the widenings but also on the characteristics of the flow. This can be shown in Figure 6 where the k_{sw}-values have been determined individually for every tested discharge. For the geometrical configurations 221 to 224, it clearly appears that the found equivalent sand roughness increases in the range of Re_w-numbers between 50,000 and 120,000. For higher Re_w-numbers the k_{sw}-values become again constant. The dependence of k_{sw}-values on the Reynolds numbers is not as obvious for all tested configurations as it is in Figure 6. Nevertheless it exists in most of the cases.

Table 2. Equivalent sand roughness of the wall k_{sw} (including the effect of the macro-roughness of the widenings) and effective flow width B_{eff}.

442	70	3.7	0.898	3.0
443	84	4.7	0.961	3.9
444	82	3.3	0.953	2.5

The bigger the mean absolute error Δh_{ksw}, the more dependent is k_{sw} on the Re_w-number. Therefore the computation with a global k_{sw}-value leads to increasing errors for these cases.

It is difficult to relate the global k_{sw} values directly to the geometry of the widenings. Detected trends are increasing k_{sw}-values with increasing widening depths ΔB, increasing widening lengths L_b and decreasing distance between the widenings L_c. The increase of the geometric parameter ΔB is more important than the one of L_b for the increase of k_{sw}.

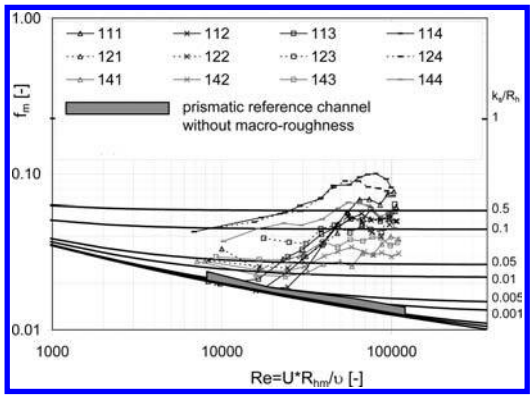

Figure 8. Friction coefficients of the composite section f_m for geometric configurations 111 to 144 (see Table 1). Widening length $L_b = B$.

3.2.4 *Flow width B_{eff} at the enlarged sections*

The values of the theoretically effective flow widths at the enlarged sections B_{eff} are given for all geometrical configurations in Table 2. Δh_{Beff} is the mean absolute error between measured and calculated backwater curves for the approach based on the single headlosses. The mean absolute errors Δh_{Beff} are similar to the Δh_{ksw}-values corresponding to the first approach. As already noticed in Chapter 3.2.2, the backwater curve is difficult to predict with a global B_{eff}-value for geometrical configurations showing high mean absolute errors (Table 2).

The effective flow widths B_{eff} can be compared to the geometric width of the widening $B_{geo} = B + 2\Delta B$. It is interesting to note that for relatively long but not too wide widenings (configurations: 411, 412, 421, 441, 442, 211, 221, 241), the geometrical width and the determined effective flow width are very close. This indicates reattachment of the flow. For ratios $\Delta B/B = 0.6$ and 0.8, the effective flow widths always remain smaller than the geometric widths.

If B_{eff} would be related to the geometry of the widenings, it can be done by taking account the ratios $\Delta B/L_b$ and L_b/L_c (Fig. 7). The ratio $\Delta B/L_b$ is more important to explain B_{eff} than L_b/L_c. Values of B_{eff}/B_{geo} fairly higher than 1.0 indicate that taking into account skin friction and single headlosses only is not sufficient to explain completely the rising of water levels in presence of macro-roughness.

3.2.5 *Friction coefficients f_m of the composite section*

The friction coefficients of the composite section f_m are presented on Figures 8–10. They have been extracted individually for each discharge from formula (5) for every geometrical configuration. The f_m-values of the prismatic reference configuration without macro-roughness are also presented on Figures 8–10.

The following points can be observed:

1 Comparing to the prismatic reference channel, macro-roughness leads to significantly increased f_m-values.
2 Macro-roughness leads to rising characteristics of the f_m-Re curves, especially for Reynolds numbers greater than 25,000 to 30,000.
3 For short widenings ($L_b = B$; Fig. 8), no further increase of f_m-values seems to be produced for Reynolds numbers greater than about 60,000. For long widenings (Figs 9–10), the increase of f_m-values is still present but reduced for Reynolds numbers greater than about 70,000.
4 According to Morris (1972), three types of flow behaviour can be observed in the channel with macro-roughness at the side walls: A) Smooth and semi-smooth (isolated roughness) flow for Reynolds numbers lower than 25,000. B) Wake interference (also called hyperturbulent) flow for Reynolds numbers greater than 25,000 to 30,000. C) Quasi-smooth flow for geometries with short

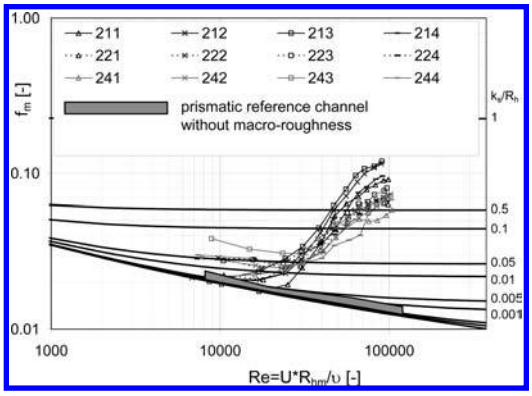

Figure 9. Friction coefficients of the composite section f_m for geometric configurations 211 to 244 (see Table 1). Widening length $L_b = 2B$.

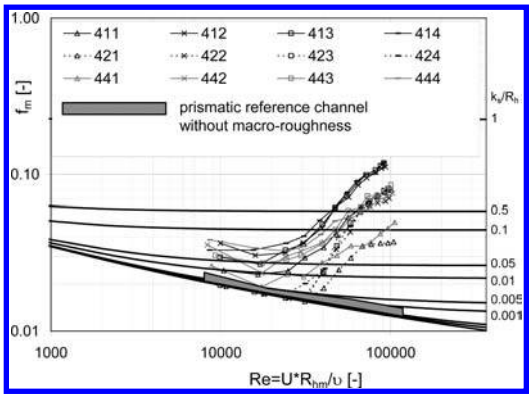

Figure 10. Friction coefficients of the composite section f_m for geometric configurations 411 to 444 (see Table 1). Widening length $L_b = 4B$.

widenings (Fig. 8) and Reynolds numbers greater than 60,000 to 70,000.

5 Differences in f_m-values between the different geometrical configurations exist although they are not as important as the difference between the prismatic reference and the configurations with macro-roughness (rectangular widenings).

Further investigations are necessary in order to quantify in detail the effect of the different geometric parameters of the rectangular widening on the flow resistance.

4 CONCLUDING REMARKS

The experiments performed in this study show the influence of macro-roughness at the side walls on steady flow in a laboratory channel. The macro-roughness (or form-roughness) was given by regular rectangular widenings on both channel side walls. 36 geometrical configurations have been tested for several discharges. The analysis of the flow and the results of backwater curve calculations with two different methods reveal that:

– The flow pattern in rectangular widenings corresponds with the ones of emerged groin-fields if the relative flow depth h/B remains lower than about 0.12 and the Reynolds number is lower than 15,000.
– The influence of the macro-roughness increases with the relative flow depth according to the theory of composite channels.
– For increasing discharges and therefore increasing velocities and Reynolds numbers, the influence of the macro-roughness at the channel side walls becomes important. The values of the friction coefficients of the composite section f_m are clearly higher than for a prismatic reference configuration. The f_m-Re curves show rising characteristics for Reynolds numbers from about 25,000 to 65,000 depending on the geometrical configuration. All of the three flow types given by the roughness concept of Morris (1955 & 1972) can be observed in the channel with macro roughness: A) smooth or isolated roughness flow for low Reynolds numbers; B) wake interference flow for intermediate Reynolds numbers; C) quasi smooth flow for some configurations at high Reynolds numbers.
– The difference of roughness between a prismatic reference configuration and the tested geometrical configurations is significantly higher than the difference of roughness between the different configurations with macro-roughness.
– The determined theoretically equivalent sand roughness of the wall k_{sw} including the macro-roughness of the different geometrical configurations is not independent of the hydraulic characteristics of the flow. Using global k_{sw}-values generally leads to an overestimation of the calculated flow depths for lower discharges and an underestimation of the flow depths for higher discharges.
– A second approach, comparing the effective flow width at the enlarged section to the geometric width of the widening, indicates that the reattachment of the flow probably produces for ratios $\Delta B/L_b$ smaller than 0.1.

In the ongoing research the detailed relationship between the different geometrical characteristics of the tested widenings and the flow resistance is identified.

NOTATIONS

The following symbols are used in this paper:

- A: section area
- B: channel base width
- B_{eff}: effective flow width at enlarged section
- B_{geo}: geometric width of the widening
- D_L: $D_L = L_b/(L_c + L_b)$; linear widening density
- D_S: $\Delta B^* L_b/(B^*(L_c + L_b))$; surface widening ratio
- f: friction coefficient
- Fr: Froude number related to B
- g: 9.81 m/s^2, gravity constant
- h: flow depth
- H_s: specific energy
- $K_{1,2,3}$: constants for logarithmic law
- k_s: equivalent sand roughness
- L: width of the basin for calculation of transverse oscillations
- L_b: widening length
- L_c: distance between widenings
- L_{in}: length of the inlet reach
- L_{MR}: length of the reach with macro-roughness
- L_{out}: length of the outlet reach
- L_{tot}: total channel length
- n: number of nodes of seiches
- Q: discharge
- Re: $Re = UR_h/\nu$; Reynolds number related to B
- R_h: hydraulic radius
- S_0: bottom slope
- S_f: friction slope
- T: period of transverse oscillations
- U: mean flow velocity related to B
- x: channel section
- z: bottom level
- α: contraction angle
- ξ: single head loss coefficient
- ΔB: widening depth (the lateral extent)
- ΔE_{cont}: single headloss for the contraction
- ΔE_{exp}: single headloss for the expansion
- Δh_{Beff}: mean absolute error between measured and calculated water depths (approach 2)
- Δh_{ksw}: mean absolute error between measured and calculated water depths (approach 1)

The following subscripts are systematically used in this paper:

- 0: concerning the bottom
- w: concerning the wall (with or without the effect of macro-roughness)
- m: concerning the composite section
- us: concerning the upstream section
- ds: concerning the downstream section
- i: positive integer designating the section

Weakly nonlinear analysis on interaction of alternate bars and double-row bars

Y. Watanabe
Civil Engineering Research Institute for Cold Region, Sapporo, Japan

K. Hasegawa
Foundation of River and Watershed Environment Management, Sapporo, Japan

ABSTRACT: This research incorporates mode interference into the weakly nonlinear analysis of sandbar growth, to improve explanation of the mode reduction process in sandbar formation. The study attempts to clarify the degree of the interference. Introduction of linear amplication into the nonlinear analysis model made it possible to examine alternate bars and double-row bars on the same order. The analysis used hydraulic conditions with large width/depth ratio in which double-row bars form. Although it did not accurately reproduce the quantitative results of the experiments, this analysis was able to explain the qualitative characteristics of the reduction process, in which sandbars of both modes cannot simultaneously occur.

1 INTRODUCTION

Toward improving flood control, studies have been conducted on the behavior of bar formation on the riverbed, because once such sand waves form, they start to cause local scouring and make the river channel meander, promoting riverbank erosion. Conventionally, the initial growth rate during sandbar development is used to classify the mesoscale riverbed configuration. Theoretical studies on bar formation have been conducted several researchers. Colombini et al. (1987), Schielen et al. (1993) and Izumi & Pornprommin (2002) conducted weakly non-linear stability analysis on bar developments in straight channel. They clarified the bar formation process. However, these analysis were not considered the interaction of two modes (alternate bars and double-row bars). Various hydraulic tests (Fujita 1989, Fujita et al. 1992) and numerical simulations (Takebayashi et al. 2001, Teramoto & Tsujimoto 2005) have reported that under the condition in which sandbars of higher mode form during the initial period, mode reduction occurs over time. This means that there may be a situation in which the sandbar mode differs from the mode predicted by the initial growth rate for that riverbed configuration. In fact, there are river sections with hydraulic conditions under which double-row bars are expected to form but where mode reduction is occurring or has occurred. This difference between the theoretical, initially predicted mode and the reduced mode that occurs over time must be addressed in planning flood control revetments and river conservation, since these are greatly influenced by riverbed microtopography.

Watanabe & Kuwamura (2004) experimented sandbar formations by setting several hydraulic conditions under which either alternate bars or double-row bars formed. They applied the weakly nonlinear analysis in describing sandbar development which was established by Colombini et al. (1987) and tried to explain the mode reduction process of double-row bars (Watanabe & Kuwamura 2005). In that experiment, alternate bars and double-row bars were examined separately, and analysis was simplified by neglecting any interference between the two modes. The experiment resulted in the conclusion that reduction from double-row bar mode to alternate bar mode could be explained even from experiments in which the two types of bars were examined separately.

This present study incorporates the interference between modes into nonlinear analysis to clarify the mutual influence of the modes in the mode reduction process.

2 GROWTH RATE EXPANSION METHOD CONSIDERING MODE INTERFERENCE

2.1 *Basic equations and dimensionless forms*

Basic equations and dimensionless forms are set in the same form as Colombini et al. (1987). Equations 1, 2, 3 and 4, respectively, are two steady two-dimensional

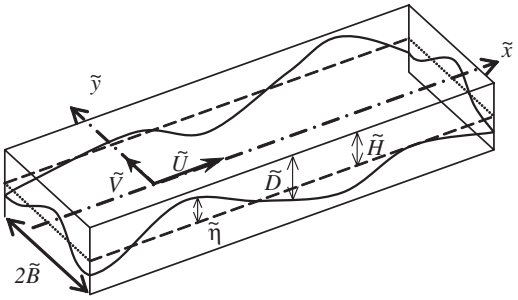

Figure 1. Definitions of coordinate system of the flow model.

shallow-water flow equations where the diffusion terms are omitted, the continuity equation, and the continuity equation of bedload, for a straight channel (width: $2\tilde{B}$) under the coordinate system shown in Figure 1.

$$\tilde{U}\frac{\partial \tilde{U}}{\partial \tilde{x}} + \tilde{V}\frac{\partial \tilde{U}}{\partial \tilde{y}} + \tilde{g}\frac{\partial \tilde{H}}{\partial \tilde{x}} + \frac{\tilde{\tau}_x}{\tilde{\rho}\tilde{D}} = 0 \quad (1)$$

$$\tilde{U}\frac{\partial \tilde{V}}{\partial \tilde{x}} + \tilde{V}\frac{\partial \tilde{V}}{\partial \tilde{y}} + \tilde{g}\frac{\partial \tilde{H}}{\partial \tilde{y}} + \frac{\tilde{\tau}_y}{\tilde{\rho}\tilde{D}} = 0 \quad (2)$$

$$\frac{\partial\left(\tilde{U}\tilde{D}\right)}{\partial \tilde{x}} + \frac{\partial\left(\tilde{V}\tilde{D}\right)}{\partial \tilde{y}} = 0 \quad (3)$$

$$\frac{\partial \tilde{\eta}}{\partial \tilde{t}} + \frac{1}{1-p}\left(\frac{\partial \widetilde{Q_{bx}}}{\partial \tilde{x}} + \frac{\partial \widetilde{Q_{by}}}{\partial \tilde{y}}\right) = 0 \quad (4)$$

where $\tilde{t}$ = time; $\tilde{x}$ = longitudinal coordinate; $\tilde{y}$ = transverse coordinate; $\tilde{U}$ = flow velocity in the $\tilde{x}$ coordinate direction; $\tilde{V}$ = flow velocity in the $\tilde{y}$ coordinate direction; $\tilde{H}$ = water level; $\tilde{D}$ = water depth; $\tilde{\eta}$ = riverbed elevation ($=\tilde{H}-\tilde{D}$); $\tilde{\tau}_x$ = shear stress in the $\tilde{x}$ coordinate direction; $\tilde{\tau}_y$ shear stress in the $\tilde{y}$ coordinate direction; $\widetilde{Q_{bx}}$ = bedload transport rate in the $\tilde{x}$ coordinate direction; $\widetilde{Q_{by}}$ = bedload transport rate in the $\tilde{y}$ coordinate direction; $\tilde{\rho}$ = density of water; $\tilde{g}$ = acceleration of gravity; and p = porosity of bed. Parameters capped with have dimensions.

Equations 1, 2, 3 and 4 are made dimensionless using the parameters of uniform flow on a flat riverbed:

$$(U,V) = (\tilde{U},\tilde{V})/\widetilde{U_0};\ D = \tilde{D}/\widetilde{D_0};\ H = \tilde{H}/(F_0{}^2\widetilde{D_0});\ (Q_{bx},Q_{by}) = (\widetilde{Q_{bx}},\widetilde{Q_{by}})/(\delta\tilde{g}\tilde{d}_s{}^3)^{1/2};\ (\tau_x,\tau_y) = (\tilde{\tau}_x,\tilde{\tau}_y)/(\tilde{\rho}\widetilde{U_0}{}^2);\ (x,y) = (\tilde{x},\tilde{y})/\tilde{B};\ t = \tilde{t}/(\tilde{B}/\widetilde{U_0});\ \text{and } F_0 = \widetilde{U_0}/(\tilde{g}\widetilde{D_0})^{1/2}\ .$$

Here, the suffix 0 indicates a value for uniform flow. $\tilde{d}_s$ = the grain size of the riverbed material; and δ = the submerged specific gravity of the riverbed material. The resultant equations are as follows:

$$U\frac{\partial U}{\partial x} + V\frac{\partial U}{\partial y} + \frac{\partial H}{\partial x} + \beta\frac{\tau_x}{D} = 0 \quad (5)$$

$$U\frac{\partial V}{\partial x} + V\frac{\partial V}{\partial y} + \frac{\partial H}{\partial y} + \beta\frac{\tau_y}{D} = 0 \quad (6)$$

$$\frac{\partial (UD)}{\partial x} + \frac{\partial (VD)}{\partial y} = 0 \quad (7)$$

$$\frac{\partial \eta}{\partial t} + Q_0\left(\frac{\partial Q_{bx}}{\partial x} + \frac{\partial Q_{by}}{\partial y}\right) = 0 \quad (8)$$

where $Q_0 = (\delta d_s{}^3)^{1/2}/[F_0(1=p)]$.

2.2 *Conventional perturbation method (Colombini et al. 1987)*

When alternate bars and double-row bars are considered separately, (U,V,H,D) in these equations are substituted by their expansions whose perturbation parameters are $\varepsilon^{1/2}$, as shown by Equations 9, 10, 11, 12 and 13.

$$(U,V,H,D) = (1,0,H_0,1) + \varepsilon^{1/2}(U_1,V_1,H_1,D_1) + \varepsilon^{2/2}(U_2,V_2,H_2,D_2) + \varepsilon^{3/2}(U_3,V_3,H_3,D_3) \quad (9)$$

$$(U_1,V_1,H_1,D_1) = \begin{cases} A_{(T)}(S_1u_{111},C_1v_{111},S_1h_{111},S_1d_{111})E_1 + c.c. & ;\text{mode} = 1 \\ A_{(T)}(C_2u_{121},S_2v_{121},C_2h_{121},C_2d_{121})E_1 + c.c. & ;\text{mode} = 2 \end{cases} \quad (10)$$

$$(U_2,V_2,H_2,D_2) = \begin{cases} A_{(T)}{}^2E_2[(C_2u_{222},S_2v_{222},C_2h_{222},C_2d_{222}) + (u_{202},v_{202},h_{202},d_{202})] + c.c. \\ +A_{(T)}\overline{A}_{(T)}[(C_2u_{220},S_2v_{220},C_2h_{220},C_2d_{220}) + (u_{200},v_{200},h_{200},d_{200})] \\ +(0,0,H_{200},0) \quad ;\text{mode} = 1 \\ A_{(T)}{}^2E_2[(S_4u_{242},C_4v_{242},S_4h_{242},S_4d_{242}) + (u_{202},v_{202},h_{202},d_{202})] + c.c. \\ +A_{(T)}\overline{A}_{(T)}[(S_4u_{240},C_4v_{240},S_4h_{240},S_4d_{240}) + (u_{200},v_{200},h_{200},d_{200})] \\ +(0,0,H_{200},0) \quad ;\text{mode} = 2 \end{cases} \quad (11)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

$$(U_3, V_3, H_3, D_3) =$$

$$\begin{cases} A_{(T)}{}^2\overline{A}_{(T)}\,(S_1u_{311}, C_1v_{311}, S_1h_{311}, S_1d_{311})\,E_1 \\ \qquad +c.c. + h.h. \qquad ;\mathrm{mode} = 1 \\ A_{(T)}{}^2\overline{A}_{(T)}\,(C_2u_{321}, S_2v_{321}, C_2h_{321}, C_2d_{321})\,E_1 \\ \qquad +c.c. + h.h. \qquad ;\mathrm{mode} = 2 \end{cases} \tag{12}$$

$$(S_m, C_m, E_m) =$$

$$\left(\sin\left(\frac{1}{2}\pi my\right), \cos\left(\frac{1}{2}\pi my\right), \exp\left[mi\left(\lambda x - \omega t\right)\right]\right) \tag{13}$$

where, $c.c.$ = the complex conjugate of the immediately preceding term; $h.h.$ = a term of high order; m = the mode number of bar formation; and $A_{(T)}$ = the amplitude of small perturbation at time T. T is a time scale introduced to express the variation of small perturbation. Its relation to the time scale of flow, t, is given by Equation 14. $\overline{A}_{(T)}$ is the complex conjugate of $A_{(T)}$.

$$T = \varepsilon t \tag{14}$$

The time scale necessary for expressing development of sandbars is much greater than that for changes of water flow. On the order of $\varepsilon^{3/2}$, a modified Landau-Stuart equation shown as Equation 15 is obtained for alternate bars and double-row bars.

$$\frac{dA_{(T)}}{dT} + \alpha_1 A_{(T)} + \alpha_2 A_{(T)}{}^2\overline{A}_{(T)} = 0 \tag{15}$$

Equation 16 is the solution of Equation 15:

$$|A| = \sqrt{\frac{-\mathrm{Re}\,(\alpha_1)}{\mathrm{Re}\,(\alpha_2) - a_0\mathrm{Re}\,(\alpha_1)\exp\left[-2\mathrm{Re}\,(\alpha_1)\,T\right]}} \tag{16}$$

where, $|A|_0$ = assumed to be the initial value of small perturbation; and a_0 = expressed by Equation 17.

$$a_0 = \frac{1}{|A|_0{}^2} + \frac{\mathrm{Re}\,(\alpha_2)}{\mathrm{Re}\,(\alpha_1)} \tag{17}$$

When the growth rate expansion method is applied to nonlinear analysis of sandbar development, the perturbation parameter, $\varepsilon^{1/2}$, is the square route of the ratio ε obtained by dividing the difference between β_c (the minimum river width/depth ratio for which the initial perturbation is neutral, i.e., whose initial growth rate Ω_0 is 0 in linear stability analysis) and β (the river width/depth ratio under the test conditions) by β_c, as shown by Equation 18:

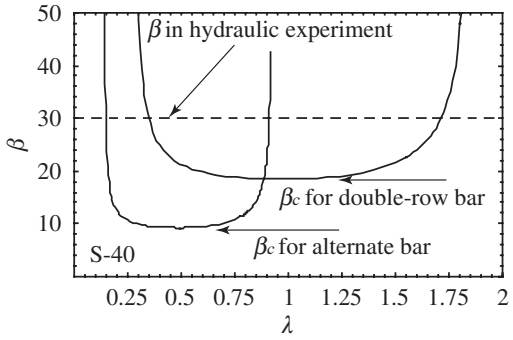

Figure 2. Neutral curves of initial growth rates calculated by the linear stability analysis.

$$\beta = \beta_c\,(1 + \varepsilon) \tag{18}$$

For application of nonlinear analysis, the river width/depth ratio β needs to be close to β_c. The wavenumber of sandbar λ is given by Equation 19. For the sake of analysis, however, here we assume that $\lambda_1 = 0$, because it does not greatly affect the analysis result.

$$\lambda = \lambda_c + \varepsilon\lambda_1 \tag{19}$$

2.3 *Mode interference method*

The growth rate expansion method was used to consider the development process of alternate bars and double-row bars on the same order. As shown in Figure 2, the critical river width/depth ratio β_c, or the minimum river width/depth ratio when the initial growth rate Ω_0 of the sandbar is 0, differ between alternate bar and doublerow bar. In the growth rate expansion method, which describes sandbar development in a channel whose width/depth ratio is close to the critical width/depth ratio, it is theoretically impossible to simultaneously examine the growth of sandbars in channels that have different critical river width/depth ratios. In addressing the mode change from double-row bar to alternate bar, one must consider the interference between the two modes. Thus, the alternate bar and the double-row bar need to be considered under conditions in which there is the same order of perturbation. Toward solving this problem, some preconditions are set as follows.

When perturbation expansion is applied to more than one type of sandbar under the condition of the same order of perturbation, a uniform perturbation parameter is required. The region in which alternate bars and double-row bars can be considered is the region that is conventionally classified as the region

Copyright © 2006 Taylor & Francis Group plc, London, UK

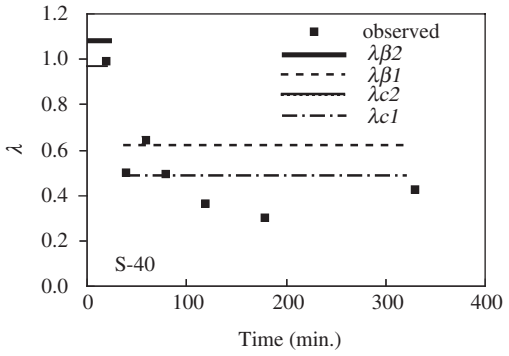

Figure 3. Changes in wavenumber of bars in hydraulic tests.

for double-row bars. Therefore, analysis is applied to a case in which the critical river width/depth ratio, or the minimum river width/depth ratio, is β_c when the initial growth rate of a double-row bar Ω_0 is 0, and a uniform perturbation parameter is used. In this case, the critical river width/depth ratio differs from that for an alternate bar, and the alternate bar has an initial growth rate that exceeds 0.

Figure 3 shows the changes in wavenumber of sand bars obtained in a previous hydraulic test on the process of reduction from double-row bar mode to alternate bar mode. The figure also contains the wavenumber λ_c at β_c obtained by linear stability analysis and the wavenumber λ_β at β obtained in the experiments. The suffix refers to the mode number. In Figure 3, the wavenumber for the alternate bar mode becomes roughly half that for the double-row bar mode as the mode reduction progresses. Thus the wavenumber for the alternate bar mode will be considered to have the fixed value of half that for the double-row bar mode.

When the above conditions are applied, it is impossible to satisfy equations on the first order for both the alternate bars and the double-row bars. Thus, the amplitude of the double-row bar continues to be $B_{(T)}$, a function of T, but for the alternate bar $W_{(t)}$, a function of t is used in addition to $A_{(T)}$, a function of T, because the alternate bar mode has an initial growth rate that exceeds 0. This is equivalent also to changing the time scale of development in the mode 1 and the mode 2.

Accordingly, Equations 20, 21 and 22 replace Equations 9, 10, 11 and 12.

$$
\begin{aligned}
&(U_1, V_1, H_1, D_1) = \\
&\quad A_{(T)} W_{(t)} \left(S_1 u_{111}, C_1 v_{111}, S_1 h_{111}, S_1 d_{111}\right) E_1 + c.c. \\
&\quad + B_{(T)} \left(C_2 u_{122}, S_2 v_{122}, C_2 h_{122}, C_2 d_{122}\right) E_2 + c.c.
\end{aligned} \tag{20}
$$

$$

where, the leftmost number of the three-digit suffix in Equations 21 and 22 is the order, the middle number is the wavenumber of small perturbation in the transverse direction, and the rightmost number is the wavenumber of small perturbation in the longitudinal direction. By substituting them into Equations 5, 6, 7 and 8, Equations 23 and 24 are obtained on the order of $\varepsilon^{1/2}$ (the first order):

$$
\begin{bmatrix}
p_{111,11} & p_{111,12} & p_{111,13} & p_{111,14} \\
p_{111,21} & p_{111,22} & p_{111,23} & p_{111,24} \\
p_{111,31} & p_{111,32} & p_{111,33} & p_{111,34} \\
p_{111,41} & p_{111,42} & p_{111,43} & p_{111,44}
\end{bmatrix}
\begin{bmatrix}
u_{111} \\ v_{111} \\ h_{111} \\ d_{111}
\end{bmatrix} = 0 \tag{23}
$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

$$\begin{bmatrix} p_{122,11} & p_{122,12} & p_{122,13} & p_{122,14} \\ p_{122,21} & p_{122,22} & p_{122,23} & p_{122,24} \\ p_{122,31} & p_{122,32} & p_{122,33} & p_{122,34} \\ p_{122,41} & p_{122,42} & p_{122,43} & p_{122,44} \end{bmatrix} \begin{bmatrix} u_{122} \\ v_{122} \\ h_{122} \\ d_{122} \end{bmatrix} = 0 \quad (24)$$

For Equations 23 and 24 to have solutions, Determinants 25 and 26 are derived:

$$\begin{vmatrix} p_{111,11} & p_{111,12} & p_{111,13} & p_{111,14} \\ p_{111,21} & p_{111,22} & p_{111,23} & p_{111,24} \\ p_{111,31} & p_{111,32} & p_{111,33} & p_{111,34} \\ p_{111,41} & p_{111,42} & p_{111,43} & p_{111,44} \end{vmatrix} = f_{111(W_{(t)},\beta_c,\lambda_c,\omega;\theta_0,d_s)} = 0 \quad (25)$$

$$\begin{vmatrix} p_{122,11} & p_{122,12} & p_{122,13} & p_{122,14} \\ p_{122,21} & p_{122,22} & p_{122,23} & p_{122,24} \\ p_{122,31} & p_{122,32} & p_{122,33} & p_{122,34} \\ p_{122,41} & p_{122,42} & p_{122,43} & p_{122,44} \end{vmatrix} = f_{122(\beta_c,\lambda_c,\omega;\theta_0,d_s)} = 0 \quad (26)$$

By adding the condition that β_c, λ_c and ω be real numbers in Equation 26, the values of β_c, λ_c and ω are determined for given values of θ and d_s. By substituting them into Equation 25, $W_{(t)}$ is obtained. That is, $W_{(t)}$ will be determined by linear analysis. When $d_{111} = 1$ and $d_{122} = 1$ in Equations 23 and 24, amplitudes on the first order, namely u_{111}, v_{111}, h_{111}, u_{122}, v_{122} and h_{122} are calculated for each wave.

Regarding the order $\varepsilon^{2/2}$ (the second order), equations in the same form as Equations 23 and 24 are obtained for the components of waves having transverse and longitudinal wavenumbers of (1, 1), (1, 3), (2, 2), (3, 1), (3, 3), (4, 4), (2, 0), (4, 0), (0, 2), (0, 4) and (0, 0) respectively.

$$\begin{bmatrix} p_{2ij,11} & p_{2ij,12} & p_{2ij,13} & p_{2ij,14} \\ p_{2ij,21} & p_{2ij,22} & p_{2ij,23} & p_{2ij,24} \\ p_{2ij,31} & p_{2ij,32} & p_{2ij,33} & p_{2ij,34} \\ p_{2ij,41} & p_{2ij,42} & p_{2ij,43} & p_{2ij,44} \end{bmatrix} \begin{bmatrix} u_{2ij} \\ v_{2ij} \\ h_{2ij} \\ d_{2ij} \end{bmatrix} = q_{2ij} \quad (27)$$

where, i and j are the transverse and longitudinal wavenumbers of small perturbation. These equations, however, are nonhomogenous, which means that the right-hand side of each equation exceeds zero. Thus, amplitudes on the second order can be obtained for u_{211} and other values of the second order by using the values obtained on the first order.

The same order can be applied to the waves of (1, 1) and (2, 2), which represent an alternate bar and a double-row bar, respectively. So, when the perturbation parameter for nonlinear analysis is ε, it is theoretically possible to determine $A_{(T)}$ and $B_{(T)}$, which represent bar formation processes on the second order, and Equations 28 and 29 are obtained. However, each equation diverges over time when they are used for calculation under the conditions of hydraulic tests described below. Therefore, nonlinear analysis was redone with a perturbation parameter of $\varepsilon^{1/2}$:

$$\frac{dA_{(T)}}{dT} + \alpha_1 A_{(T)} + \alpha_2 B_{(T)} \overline{A}_{(T)} = 0 \quad (28)$$

$$\frac{dB_{(T)}}{dT} + \alpha_4 B_{(T)} + \alpha_5 {A_{(T)}}^2 = 0 \quad (29)$$

When waves having the transverse and longitudinal numbers of (1, 1) and (2, 2) are subjected to the above on the order of $\varepsilon^{3/2}$ (the third order), then Equations 30 and 31 are obtained.

$$\frac{dA_{(T)}}{dT} + \alpha_1 A_{(T)} + \alpha_2 {A_{(T)}}^2 \overline{A}_{(T)} + \alpha_3 A_{(T)} B_{(T)} \overline{B}_{(T)} = 0 \quad (30)$$

$$\frac{dB_{(T)}}{dT} + \alpha_4 B_{(T)} + \alpha_5 {B_{(T)}}^2 \overline{B}_{(T)} + \alpha_6 B_{(T)} A_{(T)} \overline{A}_{(T)} = 0 \quad (31)$$

If these equations are solved simultaneously, the values $A_{(T)}$ and $B_{(T)}$ are obtained. Analytical solutions, however, are impossible, and thus numerical calculation is used. $W_{(t)}$ are included in the coefficients α_1 to α_6. It is shown that the fourth term on the left side of Equations 30 and 31 represents interference and that these equations have the same form as Equation 15 when the fourth term is omitted.

3 COMPARISON BETWEEN NONLINEAR ANALYSIS RESULTS AND HYDRAULIC TEST RESULTS

3.1 *Outline of hydraulic test*

To examine the results of nonlinear analysis in which mode interference is considered, those results are compared with the results of hydraulic tests (Watanabe & Kuwamura 2005) in which there was mode reduction from double-row bars to alternate bars. The experiments were conducted in a flume with a length of 50 m and a width of 0.9 m. The flume was filled with 0.76 mm silica sand, and a bed with a slope

Copyright © 2006 Taylor & Francis Group plc, London, UK

of 1/80 was formed for all experiments. In each experiment, bar height and bar wavelength were measured continuously until the bars were fully developed.

The items of hydraulic tests are shown in Table 1. In test S-30, the double-row bars that formed in the early stages of water flow transformed into alternate bars. In test S-40, although double-row bars formed in the very early stages of water flow, they soon transformed into alternate bars. For test S-50, alternate bars immediately formed in the early stages of water flow.

3.2 *Comparison result*

The bedload and the coefficient of riverbed resistance used for analysis are represented by Equations 32 and 33 below, which are respectively the equations of Meyer-Peter & Müller, and of Engelund & Hansen.

$$\phi = (\theta - \theta_{cr})^{3/2} \tag{32}$$

$$C_f = \frac{1}{\left[6 + 2.5 \ln\left(\frac{D}{2.5 d_s}\right)^2\right]} \tag{33}$$

where, $\phi =$ the dimensionless bedload transport rate for a unit width; $C_f =$ the drag coefficient of riverbed; $d_s = \tilde{d}_s / \tilde{D}_0$ (dimensionless grain size); $\theta =$ the dimensionless shear stress; and $\theta_{cr} =$ the dimensionless critical shear stress. Both equations reproduce the test results accurately and thus can be used for analysis without problems (Watanabe & Kuwamura 2005).

In Figure 4, the observed amplitudes $\acute{a}11$ and α_{22} are compared with the calculated amplitudes $|A_{(T)}W_{(t)}(F_0^2 h_{111} - d_{111})|$ and $|B_{(T)}(F_0^2 h_{122} - d_{122})|$. The amplitude α_{11} is for the wave that has the wavenumber of 1 in the transverse and longitudinal directions, and α_{22} is the amplitude of the wave that has the wavenumber of 2 in the transverse and longitudinal directions. The observed amplitude was obtained by wavenumber analysis applied to the riverbed configuration identified in the hydraulic tests. $|A_{(T)}W_{(t)}(F_0^2 h_{111} - d_{111})|$ is the calculated amplitude of the wave that has a wavenumber of 1 and $|B_{(T)}(F_0^2 h_{122} - d_{122})|$ is the calculated amplitude of the wave that has the wavenumber of 2 (the third digit of the three-digit suffix) in the transverse and longitudinal directions. The calculated wavenumber was obtained by weakly nonlinear analysis on the first order. It is shown that the calculated values are larger than the experimental values. However, as the river width/depth ratio increases, the amplitude tends to become smaller, and the general tendency of transition from double-row bars to alternate bars is represented well. Particularly well represented is the attenuation with time in the components of double-row bars, whose wavenumber is 2. In solving Equations 30 and 31, the values shown in Table 1 were used as the initial values for $A_{(T)}$ and $B_{(T)}$, for the sake of calculation stability. In analysis on the second order, waves having the longitudinal and transverse wavenumber of 1 and 2, expressed as $|\overline{A}_{(T)}W_{(t)}B_{(T)}\ (F_0^2 h_{211} - d_{211})|$ for wave number 1 and $|A_{(T)}^2 W_{(t)}^2\ (F_0^2 h_{222} - d_{222})|$ for wave number 2, appear. These waves are taken into consideration, and the calculated heights of sandbars are compared with the hydraulic test results in Figure 5. It is shown that solutions oscillate over time as the perturbation parameter $\varepsilon^{1/2}$ grows. This may suggest, as Pornprommin et al. (2004) propose, that the irregularity of the amplitude increases when the river width/depth ratio becomes large. But the time change in the value of $|W_{(t)}|$ for S-40 shown in Figure 6 suggests that $|W_{(t)}|$ tends to diverge over time. It is possible that this irregularity results from the method used in this study. In other words, although the method is originally formulated for phenomena that take place near the growth rate of 0, the linear growth rate $W_{(t)}$ was applied in this

Table 1. Hydraulic conditions of experiments and initial conditions of analysis.

Run	β	d_s	θ	$A_{(0)}$	$B_{(0)}$	β_c	$\varepsilon^{1/2}$
S-30	37.5	0.063	0.12	0.0065	0.0010	17.5	1.07
S-40	30.0	0.051	0.15	0.0020	0.0010	18.5	0.79
S-50	25.0	0.042	0.18	0.0010	0.0010	19.2	0.55

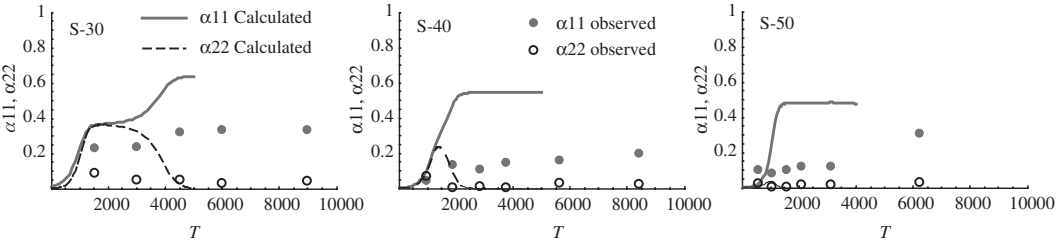

Figure 4. Experimental values and calculated solutions on the first order: temporal changes in the components of alternate bars and double-row bars.

Copyright © 2006 Taylor & Francis Group plc, London, UK

study. At the same time, the irregularity might arise as a result of applying the method to a region having a relatively large growth rate. It is also shown that each wave expressed in the equation does not diverge but instead maintains a steady value, despite $W_{(t)}$ having a relatively large value. The irregularity found in this study needs to be addressed. While the above irregularity remains to be solved, comparison between the results of Figure 4 and Figure 5 shows that the analysis results conform to test results (Watanabe 2004). Even when the amplitude $|A_{(T)}W_{(t)}\,(F_0^2 h_{111} - d_{111})|$ of a wave having a wavenumber of 1 on the fist order increases and the amplitude $|B_{(T)}\,(F_0^2 h_{122} - d_{122})|$ of the wave having the wavenumber of 2 on the first order decreases, the amplitude $|A_{(T)}^2 W_{(t)}^2\,(F_0^2 h_{222} - d_{222})|$ of the wave having the wavenumber 2 on the second order grows and the characteristics of the double-row bar are maintained.

4 DISCUSSION OF THE MODE REDUCTION PROCESS

The characteristics of transition from double-row bars to alternate bars are reproduced satisfactorily by this weakly nonlinear analysis. The mode interference working in the process of mode reduction from double-row bars to alternate bars is examined on the basis of the results of this analysis as follows.

The results of hydraulic test S-40 are used, because in S-40 the mode reduction from double-row bars to alternate bars is clearly shown and the perturbation parameter $\varepsilon^{1/2}$ is the smallest. Figure 7(a) shows the temporal changes in $|A_{(T)}W_{(t)}|$, $|B_{(T)}|$, $|A_{(T)}W_{(t)}B_{(T)}|$ and $|A_{(T)}^2 W_{(t)}^2|$ when the initial values of $A_{(T)}$ and $B_{(T)}$ are set at 0.002 and 0.001, respectively. This means that $A(T)$ exceeds $B_{(T)}$ in the early stages of development process. While $|B_{(T)}|$ grows in the early stages of water flow just as $|A_{(T)}W_{(t)}|$ does, it begins to attenuate when $|A_{(T)}W_{(t)}|$ grows to some level. This agrees well with the results of the hydraulic tests.

Figure 7(b) shows the results when the initial value is set at 0.001 for both $A_{(T)}$ and $B_{(T)}$. In this case, the results of analysis differ from the hydraulic test results: $|A_{(T)}W_{(t)}|$ attenuates, but $|B_{(T)}|$ keeps on growing.

Thus, the results shown in Figure 7(a) and (b) indicate that different initial values result in different tendencies. It is shown in the same figures that on the first order only one mode can grow. This can also be interpreted to mean that interference between the modes is almost unilateral and that one mode cannot grow when the other mode is predominant. Regarding this difference that results from different initial values, further study is needed.

5 CONCLUSIONS

In this study, weakly nonlinear analysis, which can represent mode interference, was conducted to understand phenomena in reduction of mode from double-row bars to alternate bars. Although there are some problems in terms of quantitative evaluations, the characteristics of the mode reduction process are qualitatively reproduced. It is shown that when the two modes are on the same order, they cannot grow simultaneously. The study indicates that disagreement between the calculated values and the experimental values seem to be influenced by the divergence of $W_{(t)}$, the linear growth rate introduced into analysis in this study, and also

by the difference in the initial values. This should be examined in future studies.

ACKNOWLEDGEMENTS

ABSTRACT: Our ability to numerically predict the interaction between complex topography and three dimensional flow at large scales (∼1 km) has yet to be fully developed. This is the result of our inability to design numerically stable meshes for complex topographies at these spatial resolutions. This paper deals with the numerical simulation of flow over a natural dune field located in the Rio Paraná, NE Argentina. The methodology is based upon the development and application of a new five term porosity algorithm that modifies the mass conservation equation within a regular Cartesian mesh. Bathymetric measurements were made in the field using a multibeam echo sounder which provided an unparalleled topographic dataset to test this new numerical modeling approach. Measurements of flow were made using an acoustic Doppler current profiler and are used as inlet boundary conditions and validation data. The results demonstrate simple flow acceleration due to topographic forcing over the dune stoss and expansion and deceleration over the dune lee.

1 INTRODUCTION

Dunes are one of the most common depositional bed forms in river channels, forming in a range of sediment sizes from silt and sand through to gravel (Dinehart, 1992; Best, 1996; Carling, 1999; Kleinhans, 2001, 2002; Carling et al. 2005). Their presence significantly influences both the nature of the mean and turbulent flow and consequently exerts a strong control of the entrainment, transport and deposition of sediment (Parsons et al. 2005, Best, 2005). In recent years progress has been made in our knowledge of dune dynamics due to the significant advances in our ability to monitor flow and dune morphology both in the laboratory and field (Best, 2005). Previous research has determined the main flow characteristics associated with dunes dynamics, which are; (1) accelerating flow over the dune stoss side; (2) flow separation or deceleration (Nelson et al. 1993; McLean et al. 1994; Best & Kostachuck, 2002) from the dune crest in the lee side; (2) flow reattachment at 4 to 6 dune heights downstream (Engel, 1981); (4) a shear layer between the separated flow and stream wise flow above which expands as it extends downstream and; (5) an internal boundary layer that grows from reattachment beneath the wake along the stoss slope of the next dune downstream. However, virtually all process understanding has been deduced from work that has dealt with morphologies that are essentially regular and two-dimensional, a situation that is rare in natural river channels. Records of bed morphology from natural channels show the frequent occurrence of dunes of different scales (Allen & Collinson, 1974; Allen, 1978; Rubin & McCulloch, 1980; Harbor, 1998; ten Brinke et al. 1999; Wilbers & ten Brinke, 2003; Wilbers, 2004; Parsons et al. 2005) possibly as a response to both non-uniform and unsteady flow, hysteresis effects within a flood hydrograph, or the developing internal boundary layer on the stoss side of large dunes. Although, the effect of three dimensional

Copyright © 2006 Taylor & Francis Group plc, London, UK

dune morphology on flow structures generation has been recognized for a long time (e.g. Allen, 1968), it has only recently been fully explored. Maddux et al. (2003a,b) report that the friction coefficients for 3D dunes are 50% greater compared to their 2D dunes which has the direct effect of reducing turbulence. However, the observed sinuous crest lines imply the presence of secondary circulation, which are responsible for a large percentage of the momentum flux over the dune (Maddux et al. 2003a, b). These form-induced stresses are secondary circulation and augment the low Reynolds stresses present over the 3D dunes (Maddux et al. 2003 a,b). Recent summaries on the dynamics and role of dunes (ASCE Task Force, 2002; Bridge, 2003; Best, 2005) highlighted that in order to gain a more complete understanding of the dynamics of river dunes, a fuller appreciation is needed of the complex links between turbulence, natural bed morphology and sediment transport.

One approach that has yet to be fully explored to gain an insight into the interaction between dune dynamics and morphology is through the application of numerical models. The application of Computational Fluid Dynamics (CFD) schemes have the potential, but are yet to be fully developed because of; i) our inability to collect high resolution topographic data that is required as a boundary condition for a CFD scheme and; ii) the inclusion of this topography into a CFD scheme. Recent application of multibeam echo sounding permits full quantification of river bed topography at centimeter resolution over km reach lengths. This has been applied by Parsons et al. (2005) to a natural sand bed river where three-dimensional dunes where identified over scales from superimposed bed forms ($\sim$<0.20 m high) to larger dune forms ($\sim$2 m high). This provides an unparalleled topographic dataset to test this new numerical modeling approach within a Computational Fluid Dynamics scheme. In this paper we outline a new methodology that incorporates complex topography into a CFD scheme over a river length of approximately 1 km. This allows the interaction between form and flow to be studied numerically over a naturally occurring dune field.

2 NUMERICAL METHODOLOGY

The incorporation of complex topographies within a CFD scheme has been problematic to date as the representation of the large scale topographic features has required the application of boundary fitted co-ordinates (BFC's), which involve mesh deformation in the Cartesian space (if not in the computational space). Mesh deformation may change the magnitude of numerical diffusion in the model and lead to uncertainties as to whether observed changes in process representation are due to topographic effects or grid adjustment effects. Therefore, there have been several new approaches to include complex topography into numerical schemes.

The methodology presented here is a mass flux scaling algorithm based upon a porosity approach within a regular Cartesian mesh. This approach has previously been developed and validated for high resolution applications (Lane et al. 2003; Lane et al. 2004; Hardy et al. 2005) for the inclusion of complex topography (individual gravel particles) in high resolution (spatial resolutions of 0.002 meters) CFD applications. Here a methodology is extended to consider greater spatial scales so that the approach can be used to study geomorphological problems over spatial scales of hundreds of meters. The original method was based upon a numerical porosity treatment, similar to that of Olsen and Stokseth (1995), which used a structured grid but specifies cell porosities to block out bottom topography (P = 1 for cells that are all water, P = 0 for cells that are all bed and 0 < P < 1 for partly blocked cells) with appropriate drag terms introduced into the momentum equations. The fundamental difference from the original methodology is that instead of using a single term volume approach the approach is modified to a five term porosity algorithm which includes the four vertical faces of the cell and a cell volume. This is achieved by a porosity value representing a blockage in each cell being introduced into the equations by modifying the effective cell face area. This subsequently reduces the amount of flux which can pass through each cell. Assuming the steady state case, this is represented by,

$$\begin{aligned} a &= \min\left((\rho uA),0\right) - \frac{A\Gamma}{\Delta} && \text{for upwind} \\ a &= \rho uA\frac{\delta}{\Delta} - \frac{A\Gamma}{\Delta} && \text{for linear,} \end{aligned} \qquad (1)$$

where δ = distance between the relevant face and the cell centre; Δ = distance between the cell centre and the next adjacent node in the direction normal to the face. As the area of the face appears in both terms in these expressions, the modification of face area can be considered as a multiplier of a. Therefore, for the transient case, where a includes an extra term of the form $V\rho/\Delta t$, the multiplier applies only to those terms containing A. This is represented schematically for a simple two-dimensional case in Figure 1 and simplified for diagrammatical purposes with face areas replaced by edge lengths.

In this application a Cartesian mesh is used so that the grid is rectangular, therefore A_e and A_w are replaced by Δy and A_n and A_s are replaced by Δx. The bed topography cuts through the cell in question, reducing the flux through the east (e) face to 30% and west (w) face to 60% and completely blocking the south (s) face (0%). The north (n) face is not affected

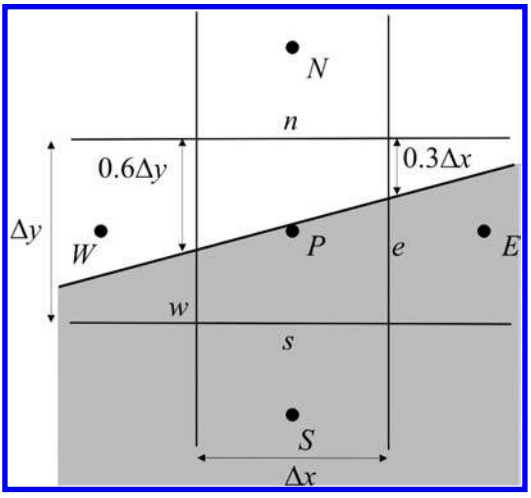

Figure 1. A schematic diagram illustrating the porosity method in two dimensions.

(100%). Therefore, the two-dimensional finite volume equation becomes:

$$a_P\varphi_P + 0.3a_E\varphi_E + 0.6a_W\varphi_W + a_N\varphi_N + 0.0a_S\varphi_S = Q_P. \quad (2)$$

The value of a_P is modified through the continuity condition:

$$a_P + 0.3a_E + 0.6a_W + a_N = 0, \quad (3)$$

For this method to work the digital elevation model which contains the topographic data must be on the same resolution as the computational grid. A computational sequence is then applied to every (i,j) location of cells to calculate the blockage term. Initially the cells which contains the interface between the bed and water is found using the mean of the four elevations at each of the cell corners and all cells below this height are assigned a volume porosity of zero, allowing no flux though the cell and effectively blocking it completely. The most complex calculations occur for the cells where the bed-water interface is located. Initially porosity values are calculated for the two vertical faces on the downstream and left sides of the cell which is based on the elevations at the cell corners. This porosity is calculated by taking the mean of the two elevations and subtracting the elevation of the base of the cell;

$$\mathrm{FP} = 1 \quad \frac{1}{\Delta z} \quad \frac{z_e + z_w}{2} \quad z_{\mathrm{cell}} \ , \quad (4)$$

where Δz is the vertical extent of the cell, z_e and z_w are the elevations of the bed at the edges of the face in question and z_{cell} is the elevation of the cell base. The elevations here are given with respect to the lower extent of the computational domain. If one or more of the bed elevations is above the elevation of the top of the cell then the bed will 'cut through' the top of the cell and a porosity is applied to restrict the flux through the top of the cell. Here linear interpolation between adjacent elevations is used to find where the bed and water interface is located along the cell edge(s). The porosity value for the face is then found by calculating the area of the triangular or trapezoidal part(s) of the face which is blocked as a proportion of the cell face area. The assumption introduced here is that the change in bed elevation between adjacent data points is linear.

The model described above still requires uses a of wall functions to model the laminar sub-layer as the method described above can only include a finite amount of information in the model. Specifically, any variation in the bed at a scale smaller than that of the computational cell cannot be represented directly. The 'roughness height' in these wall functions should therefore be set to represent the effect of the grains smaller than the grid cells on the flow itself. The wall functions used in this research are the non-equilibrium form proposed by Launder and Spalding (1974):

$$\frac{u\sqrt{k}}{u_*^2} = \frac{1}{0.25c'_\mu\kappa}\ln\left(0.25c'_\mu\frac{\sqrt{k}}{u_*}\frac{z}{z_0}\right), \quad (5)$$

where u = velocity parallel to the wall; z = distance from the wall, z_0 = roughness height; k = turbulent energy per unit mass; c'_μ = empirically derived coefficient equal to 0.09 (Lauder and Spalding, 1974); κ = von Karman constant (=0.4); ρ = fluid density; u_* = shear velocity ($u_* = \sqrt{\tau_b/\rho}$, where τ_b = the bed shear stress and ρ = density of water).

3 FIELD SITE AND DATA COLLECTION

The study area is a 0.25 km wide, 1.8 km long area of dunes in the Rio Paraná, just upstream of the confluence of the Rio Paraguay, NE Argentina. At the dune field, the Rio Paraná is 2.5 km wide and 5-12 meters deep and at the time of survey the discharge of the full river section was 11 000 $\mathrm{m^3 s^{-1}}$. Measurements of the 3D bathymetry and 3D flow have previously been discussed by Parsons et al. (2005). MBES and aDcp measurements were made along a total of 14 parallel stream wise transects, each approximately 25 m apart, and six span wise cross-sections approximately 200 m apart. The Digital Elevation model (represented in the numerical scheme through the porosity approach) used here is shown Figure 2.

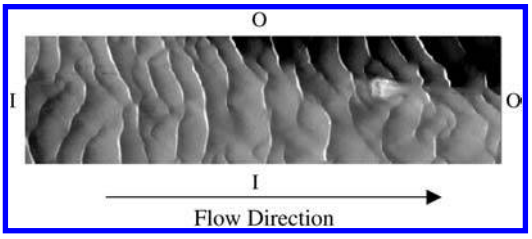

Figure 2. The digital elevation model represented in the porosity algorithm. I marks inlets, O outlets.

4 NUMERICAL SCHEME

The numerical scheme solves the full three-dimensional Navier-Stokes equations discretised using a finite-volume method. The interpolation scheme used is hybrid-upwind, where upwind differences are used in high convection areas (Peclet number >2) and central differences are used where diffusion dominates (Peclet number <2). Although this scheme can suffer from numerical diffusion, it is very stable. The pressure and momentum equations are coupled by applying SIMPLEST, a variation on the SIMPLE algorithm of Patankar and Spalding (1972). This convergence can proceed either smoothly or with damped oscillations to the final solution. To achieve relaxation either: (i) realistic maximum and minimum values may be imposed on the solution; or (ii) relaxation may be used to limit the amount of change allowed in any variable at a given iteration. Weak linear relaxation was used for the pressure correction, while weak false time step relaxation was used for the other variables. The convergence criterion was set such that the residuals of mass and momentum flux were reduced to 0.1% of the inlet flux.

Figure 2 shows the field site which the flow was modeled across. Two inlets, at the upstream end and on the south boundary, and two outlets where specified as the general flow conditions where across the domain. Inlet conditions were taken from aDcp data collected in the field which provided flow results for the u-, v- and w-component of flow. The aDcp data was collected from a moving boat along transects and therefore the flow fields are continuous in both time and space. In order to remove the highly complex nature of flow observed in this data, which may have caused instability, the inlet flow velocity was smoothed with a 3×3 box function. At the free surface, the method applied by Bradbrook et al. (2000) has been adopted, which uses a symmetry plane at the surface across which all normal resolutes are set to zero. The bed was represented by the porosity algorithm while no-slip conditions were specified at the walls. The standard RNG theory k-ε turbulence model is not modified at the sidewalls or the bed and the equilibrium wall function is used.

The computational domain was regular in the x,y directions, with a grid resolution of 2 m. In the z direction the grid resolution was increased 0.25 m. To allow inclusion of topography data using the porosity treatment, the maximum extent of the domain was set at 11 m. Thus, the computational grid was sized at $484 \times 139 \times 44$ (2 960 144 grid cells).

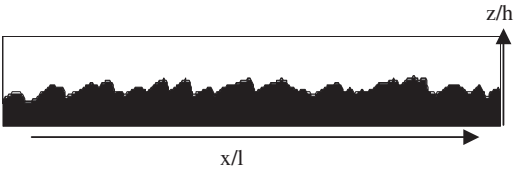

Figure 3. The dune morphology down the midline of the domain. The vertical axis has been increased by a factor of 2.

5 RESULTS

5.1 *Dune morphology*

Using the MBES, bed forms were identified over scales from superimposed bed forms ($\sim<0.20$ m high) to larger dune forms ($\sim$2 m high), providing an unparalleled topographic dataset to test this new numerical modeling approach at a large scale. Figure 2 shows the complete topography of the domain which includes a series of dune profiles down the reach. Previous analysis of this topography has calculated that dune height ranges between 1.2 to 2.5 m high and possess a range of wavelengths from 45 to 85 m (Parsons et al. 2005). This yields a range in the dune form index (or aspect ratio; height/wavelength) of 0.021 to 0.029 (Parsons et al. 2005).

In addition to this there are two main features which can be identified in the domain which will influence the flow field. The first of these is a bedrock protrusion, labeled A on Figure 2, located at 0.8 x/l down the reach. This protrudes approximately 2 meters above the surrounding bed and appears to affect the bed forms, identified in the crest line of the dunes, downstream. Secondly, there is a cross stream gradient with deeper flow located in the top right of the domain. The effect of the cross domain gradient is observed in the orientation of the crest lines which appear normal to the gradient.

The general downstream profile is observed in Figure 3 which represents the dune topography down the midline of the channel represented through the porosity algorithm. Classical low angle dunes are observed that with the majority of forms being highly asymmetric, with leeside slope angles typically around 8.5 to 18°, but with lee slopes up to 22° in individual dunes (Parsons et al. 2005). Dune stoss slope angles are much shallower, typically around 1.5° to 2.5° (Parsons et al. 2005). There is, therefore, considerable topography to determine complex flow structures.

(a) The velocity magnitude for height 0.4 z/h

(b) The velocity magnitude for height 0.5 z/h

(c) The velocity magnitude for height 0.6 z/h

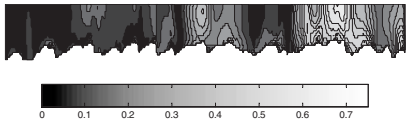

Figure 4. Plan form plots for the velocity magnitude at three successive height. Flow is from left to right.

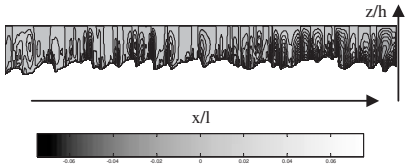
5.2 *The predicted flow fields*



In most of the analysis the velocity magnitude is used to visualize the results. This is the resolved component on the *u*-, *v*- and *w*- component of velocity. The area which is white within the graph is the region that is topography and has been blocked out of the numerical mesh with the porosity algorithm.

5.2.1 *Plan form analysis*

Figure 4 shows three velocity magnitude plots at 0.41, 0.5, 0.6 z/h above the bed where the flow direction is from left to right. Figure 4a demonstrates the prediction at a height of 0.4 z/h. There are two distinct characteristics that can be observed. The first is the effect of the deepening flow in the top right hand of the domain where faster flow is predicted ($>0.4\,\mathrm{ms}^{-1}$). The second characteristic that can be observed is the low flow ($<0.1\,\mathrm{ms}^{-1}$) located in the lee of each of the dunes. Towards the deeper part of the domain flow the flow in the lee of the dunes is steered towards the deeper water. The influence of this topographic hollow can be seen to be dominant through the flow depth. In Figure 4b only a few dune crests can be seen with a complex pattern of skimming flow being observed.

(a) The velocity magnitude down the midline

(b) The w-component of velocity down the midline

Figure 5. Velocity contour maps down the midline of the domain. The vertical axis have been increased by a factor of 2.

This can be detected in the bottom of the images where two separate bands of faster flow ($\sim 0.3\,\mathrm{ms}^{-1}$) compared to the surrounding flow ($\sim 0.1\,\mathrm{ms}^{-1}$) can be detected forming over the dune crests. This pattern is more dominant higher in the flow, (Fig. 4c). The most dominant pattern that is observed throughout the domain is the effect of the deeper flow. The topographic forcing caused by the deeper flow generates a strong process gradient that the effect of the bedrock protrusion (Fig. 2, Region A) is not clearly detectable. It would be possible to speculate that with a protrusion of this magnitude a junction vortex system would be expected to form, however this can not be detected in the velocity contours.

5.2.2 *Midline predictions*

Figure 5 shows the predicted values for the velocity magnitude (Fig. 5a) and the vertical (*w*-) component (Fig. 5b) down the midline of the domain. The velocity magnitude shows complex flow patterns with regions of both high and low flow. Classical flow separation can not be identified, which has previously been identified over 2D dunes, due to the influence of the three dimensional morphology. As previously identified in Figure 4, the effect of the deeper flow can be observed at 0.7 x/l downstream where high flow starts to move across.

A more classical flow structures over dunes can be observed when the *w*-component is studied independently, Figure 5b. This includes flow separation and reattachment with most of the generated flow structures influencing the whole flow depth. However, the complex nature of these structures increase at 0.7 x/l where the lateral process gradient determined by the movement of flow in to the deeper water influence the flow structure. This confirms the previous observations of Allen (1968).

(a) The velocity magnitude at 0.2 x/1

(b) The velocity magnititude at 0.4 x/1

(c) The velocity magnitude at 0.6 x/1

Figure 6. A series of velocity contour plots for y/w plots downstream.

5.2.3 *Cross stream plots*

Figure 6 shows a series of velocity magnitude plots for y/w at 0.2, 0.4 and 0.62 x/l downstream. The first cross section (Fig. 6a) shows the predicted velocity magnitude which is influenced by the local morphological form. A shear layer is starting to develop at approximately 0.55 y/w with very low flow ($<0.1\,\mathrm{ms}^{-1}$) contained within two higher cores of fluid. The core on the right of the image ($\sim$0.7 y/w) becomes more dominant further downstream with the effect of the deeper flow. The opposite is true for the flow on the left as the core of the fluid looses structure with more regions of alternate high and low flow forming. These appear in streaky structures which have previously been identified in Figure 4c.

6 DISCUSSION

This paper has presented a new methodology for the inclusion of complex topography into a Cartesian mesh. The methodology now enables the prediction of flow structures with the application of a three dimensional Computational Fluid Dynamics scheme over scales of 1 km. The present limitation of this methodology is that it is dependent on the quality and resolution of the topographic boundary condition. If high resolution topography does not exist the methodology is not applicable. The results from qualitative validation are encouraging and full validation of the numerical scheme is presently been undertaken with comparison against the aDcp data collected at various transects throughout the domain.

The results have demonstrated that the larger scale topography significantly influence the flow structure. Even though high resolution topographic form, such as dune height, wavelength, scour depth and crest line curvature the main are included the main flow structures are formed by the cross stream gradient located in the top right of the domain. Such enhanced topographic steering of the flow may have a significant influence on the distribution of shear stresses and sediment transport rates over the dune crests.

Effect of vegetation growth and unsteady characteristics of water supply on formative condition of mesoscale channel configuration

H. Takebayashi, M. Teraoka & T. Okabe
University of Tokushima, Tokushima, Japan

S. Egashira
Ritsumeikan University, Shiga, Japan

ABSTRACT: Braided streams and alternate bars under unsteady water and sediment supply conditions were reproduced via flume tests and numerical analysis, and the effects of the unsteady characteristics of water and sediment supply on the geometric characteristics of streams and bars are discussed. The results show that sediment deposits in smaller channels at higher locations during floods and bed at riffles is eroded during low flows. These phenomena force water to flow into larger streams. As a result, the bed elevation in streams decreases. Furthermore, the presence of vegetation enhances sediment deposition at higher bed elevation regions and contributes to a decrease in the number of streams. These results also indicate that the unsteady condition of water and sediment supply and vegetation growth in rivers are absolutely essential for formation of single thread meandering channels.

1 INTRODUCTION

Formative hydraulic conditions for mesoscale bed configurations have been studied by many researchers. A wide range of methods has been used, which include linear bed instability analyses (e.g. Fredsøe 1976, Parker 1976, Kuroki & Kishi 1982) and dimensional analyses based on field data (e.g. Muramoto & Fujita 1978). Results of those studies showed that the width-depth ratio plays an important role in determining formative hydraulic conditions for mesoscale bed configurations. As the width-depth ratio increases, the bed configuration changes in the order of No bar, Alternate bars, and Multiple row bars. Although the applicability of these studies to hydraulic conditions for generation of bed configurations and to conditions for cases in which dry bed regions like islands are not generated in the channel is clear, the applicability to the fully developed bed geometry in dynamic equilibrium state and to conditions that dry bed regions are generated in the channel remains unclear. Furthermore, with natural rivers, water and sediment supply conditions are unsteady while vegetation grows. Therefore, applicability of the previous studies to natural rivers is also unclear.

Using a mesoscale bed configuration regime criterion based on the bed instability analysis, it is assumed that the generation hydraulic condition of alternate bars are equivalent to those of a meandering stream, and that the generation hydraulic condition of a multiple row bars are equivalent to those of braided streams. It is then considered that, in the case in which alternate bars are considered for an initial bed configuration in a straight channel with erodible banks, banks are eroded alternately by alternate flows on the alternate bars, thereby forming a meandering stream (Kinoshita 1961). However, bed instability analysis that is used as the basis of mesoscale bed configuration regime criterion treats a straight channel with rigid banks only. It is not the analysis for meandering streams or braided streams. Furthermore, water and sediment supply conditions are intended for a steady state in which the entire bed is covered by water. Such a condition, which allows formation of a stream with dry bed regions within the analysis domain, is not discussed.

According to the mesoscale bed configuration regime criterion based on data from natural rivers and flume experiments, braided streams which are formed near the generation hydraulic conditions of alternate bars are hard to be discriminated from alternate bars (Egashira and Takebayashi 1999). Therefore, the possibility that these are regarded as the same cannot be denied.

The present study examines the bed and channel configurations composed of non-cohesive materials. The effect of vegetation growth and unsteady characteristics of water supply on a mechanism for determining beds and stream geometry are discussed based on

results of flume experiments and of two dimensional bed deformation analysis. In addition, it is revealed that formative hydraulic conditions of meandering streams are appeared under the larger width-depth ratio conditions.

2 METHOD OF FLUME EXPERIMENTS AND NUMERICAL ANALYSIS

2.1 *Method of flume experiments*

The channel used in the experiments is a straight rectangular one in 7.5 m length. The bed slope is 1/100 and the initial bed geometry is made flat. The bed materials are nearly uniform sediments with average particle diameter of 1 mm. Table 1 shows hydraulic conditions used in the experiments and the numerical analyses. Figure 1 shows these conditions on the mesoscale bed configuration regime criterion (Kuroki and Kishi 1982). Experiments are carried out for Case 1 and Case 2 to investigate the effects of the unsteady characteristics of water and sediment supply on geometry of braided streams. The sole difference between these two conditions is a method of supplying water and sediments. Under the unsteady conditions (Case 2), the water discharge has been changed every 30 min between 1.25 l/s and 3.75 l/s. The water supply cycle is enough short not to change bed configuration completely in a cycle. Consequently, the bed configuration differs from the bed configurations corresponding to each water discharge. Sediment is supplied so that the initial bed elevation at the upstream end might not be lowered. According to Fig. 1, hydraulic conditions in Case 1 and Case 2 (both large and small water discharges) are all within the formative regime of multiple row bars (modified to the formative regime of braided streams (Takebayashi et al. 2001)). Although a non-dimensional shear stress at a small water discharge is less than the non-dimensional critical shear stress, sediment moves if a bed configuration is generated and flows are concentrated in channels.

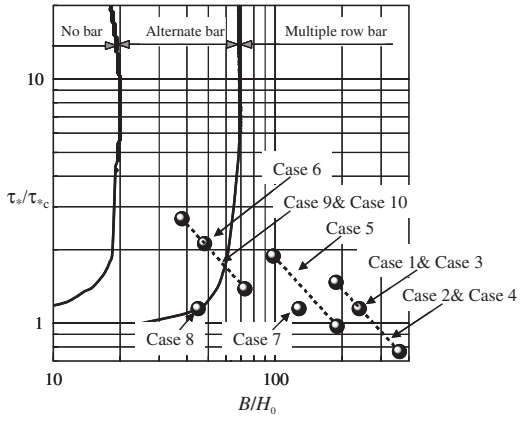

Figure 1. Hydraulic conditions of flume experiments and numerical analysis on the mesoscale bed configuration regime criterion (Kuroki & Kishi 1982), (x and y axes indicate the width-depth ratio and the shear stress normalized by critical shear stress, respectively, critical shear stress is 0.034).

Photographs are taken every hour; measurements of the bed geometry are taken 6 hr later, when no change was noticed in channel configurations.

2.2 *Method of numerical analysis*

Computation of surface flow is performed by the use of the governing equation for the horizontal two-dimensional flow averaged with depth. The conservation of mass, i.e., inflow and outflow of mass by seepage flow, is taken into consideration as shown in the following equation (Takebayashi & Egashira, 2003).

$$\Lambda\frac{\partial z}{\partial t}+\frac{\partial}{\partial x}(uh)+\frac{\partial}{\partial y}(vh)+\frac{\partial}{\partial x}(u_g h_g)+\frac{\partial}{\partial y}(v_g h_g)=0 \quad (1)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

where, t is the time and x and y are the coordinates along the longitudinal and the transverse directions, respectively. Surface flow depth is represented as h, and the seepage flow depth is h_g. u and v represent depth-averaged flow velocity along the longitudinal and the transverse directions, respectively. Depth-averaged seepage flow velocities along the longitudinal and the transverse directions are shown as u_g and v_g, respectively. z is the water surface level. Λ is a porosity parameter related to the relative elevation of bed surface and water surface, wherein $\Lambda = 1$ as $z > z_b$, and $\Lambda = \lambda$ as $z < z_b$, where z_b is the bed level and λ is the porosity of the bed material. Seepage flow is assumed to be a horizontal two dimensional saturated flow. Momentum equations of the surface water are as follows:

$$\frac{\partial}{\partial t}(hu)+\frac{\partial}{\partial x}(huu)+\frac{\partial}{\partial y}(huv) = -gh\frac{\partial}{\partial x}(h+z_b)-\frac{\tau_x}{\rho}+\frac{\partial}{\partial x}(h\sigma_{xx})+\frac{\partial}{\partial y}(h\tau_{yx})-\frac{F_{vx}}{\rho} \quad (2)$$

$$\frac{\partial}{\partial t}(hv)+\frac{\partial}{\partial x}(huv)+\frac{\partial}{\partial y}(hvv) = -gh\frac{\partial}{\partial y}(h+z_b)-\frac{\tau_y}{\rho}+\frac{\partial}{\partial x}(h\tau_{xy})+\frac{\partial}{\partial y}(h\sigma_{yy})-\frac{F_{vy}}{\rho} \quad (3)$$

where g is the gravity and ρ is the water density. The conservation of momentum, i.e., inflow and outflow of momentum by seepage flow, is not considered because their values are very small. τ_x and τ_y are the shear stresses along the longitudinal and the transverse directions, respectively, as follows:

$$\tau_x = \tau_b \frac{u_b}{\sqrt{u_b^2+v_b^2}} \quad (4)$$

$$\tau_y = \tau_b \frac{v_b}{\sqrt{u_b^2+v_b^2}} \quad (5)$$

$$\frac{\tau_b}{\rho} = u_*^2, \quad u_*^2 = \frac{u^2+v^2}{\left(6+2.5\ln\frac{h}{k_s}\right)^2} \quad (6)$$

where u_* is the friction velocity and k_s is the roughness height. u_b and v_b represent velocity near the bed surface along the longitudinal and the transverse directions, respectively. Velocities near the bed are evaluated using the curvature radius of the streamlines as follows:

$$u_b = u_{bs}\cos\alpha_s - v_{bs}\sin\alpha_s \quad (7)$$

$$v_b = u_{bs}\sin\alpha_s + v_{bs}\cos\alpha_s \quad (8)$$

$$u_{bs} = 8.5u_* \quad (9)$$

$$v_{bs} = -N_*\frac{h}{r}u_{bs} \quad (10)$$

where $\alpha_s = \arctan(v/u)$, N_* is 7.0 (Engelund, 1974) and r is the curvature radius of the stream lines obtained by the depth integrated velocity field as follows (Shimizu & Itakura, 1991):

$$\frac{1}{r} = \frac{1}{\left(u^2+v^2\right)^{3/2}}\left\{u\left(u\frac{\partial v}{\partial x}-v\frac{\partial u}{\partial x}\right)+v\left(u\frac{\partial v}{\partial y}-v\frac{\partial u}{\partial y}\right)\right\} \quad (11)$$

σ_{xx}, σ_{yy}, τ_{xy} and τ_{yx} are turbulence stresses as follows:

$$\sigma_{xx} = 2\nu\frac{\partial u}{\partial x}-\frac{2}{3}k_t \quad (12)$$

$$\sigma_{yy} = 2\nu\frac{\partial v}{\partial y}-\frac{2}{3}k_t \quad (13)$$

$$\tau_{xy} = \tau_{yx} = \nu\left(\frac{\partial v}{\partial x}+\frac{\partial u}{\partial y}\right) \quad (14)$$

$$\nu = \frac{\kappa}{6}u_*h \quad (15)$$

$$k_t = 2.07u_*^2 \quad (16)$$

where ν is the coefficient of kinematic eddy viscosity, κ is the Karman constant, and k_t is the depth averaged turbulence kinetic energy (Nezu & Nakagawa, 1993). F_{vx} and F_{vy} are the drag forces due to the vegetation along the longitudinal and the transverse directions, respectively, as follows (Shimizu & Tsujimoto, 1995):

$$F_{vx} = F_v\frac{u}{\sqrt{u^2+v^2}} \quad (17)$$

$$F_{vy} = F_v\frac{v}{\sqrt{u^2+v^2}} \quad (18)$$

$$\frac{F_v}{\rho} = \frac{1}{2}C_{dv}\lambda_v\left(u^2+v^2\right)h \quad (19)$$

where C_{dv} (=1.0) is the coefficient of form drag and λ_v is the vegetation density. Figure 2 describes the vegetation model. The vegetation density is determined so that it is increased linearly from 0 to $\lambda_{v\max}$ as follows (Takebayashi & Egashira, 2003):

$$\lambda_v = \lambda_{v\max}\left(t_d/T_f\right) \quad (20)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

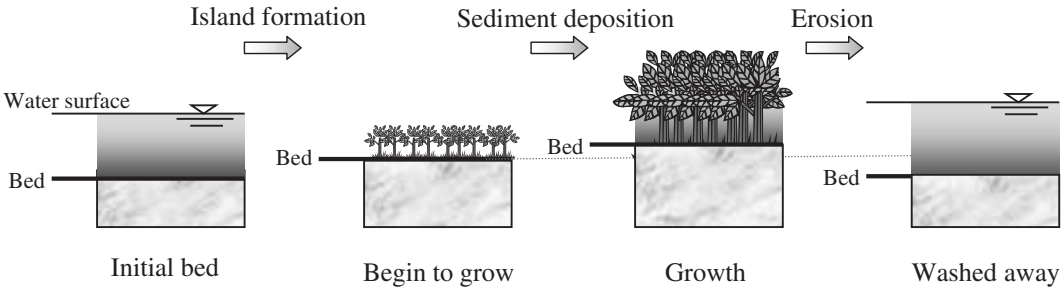

Figure 2. Vegetation model.

where $\lambda_{v\max}$ is the maximum vegetation density and should be estimated according to the kind of vegetation, t_d is the accumulated dry bed time and T_f is the time wherein the relevant region is filled with vegetation. Bed degradation is assumed to cause vegetation extinction; the vegetation is washed out when the bed level decreases lower than that at the vegetation invasion, so that the density is set to 0. Momentum equations of seepage flow are as follows:

$$u_g = -k_{gx}\frac{\partial z}{\partial x} \tag{21}$$

$$v_g = -k_{gy}\frac{\partial z}{\partial y} \tag{22}$$

where k_{gx} and k_{gy} are the coefficients of permeability along the longitudinal and the transverse directions respectively. When the water depth of surface flow becomes less than the mean diameter of the bed material, the surface flow is computed only in consideration of the pressure term and bed shear stress term in the momentum equation of surface flow (Nagata, 1999).

The temporal change in bed elevation is evaluated by use of the following equation.

$$\frac{\partial z_b}{\partial t} + \frac{1}{1-\lambda}\left(\frac{\partial q_{bx}}{\partial x} + \frac{\partial q_{by}}{\partial y}\right) = 0 \tag{23}$$

q_{bx} and q_{by} are sediment transport rates along the longitudinal and the transverse directions, respectively, as follows (Ashida & Michiue, 1972, Liu, 1991, Kovacs & Parker, 1994):

$$q_{bx} = q_b \cos\beta \tag{24}$$

$$q_{by} = q_b \sin\beta \tag{25}$$

$$q_b = 17\frac{\rho u_{*e}^3}{(\rho_s - \rho)g}\left(1 - \sqrt{K_c}\frac{u_{*c}}{u_*}\right)\left(1 - K_c\frac{u_{*c}^2}{u_*^2}\right) \tag{26}$$

Here ρ_s is the sediment density and u_{*e} is the effective shear velocity as follows:

$$u_{*e}^2 = \frac{u^2 + v^2}{\left(6 + 2.5\ln\dfrac{h}{d_m(1+2\tau_*)}\right)^2} \tag{27}$$

where d_m is the mean diameter of the bed material and u_{*c} is the non-dimensional critical friction velocity. u_{*c} is evaluated by using the Iwagaki's formula (Iwagaki, 1956) which is formulated for uniform bed material.

K_c is a correction factor due to the influence of bed inclination on sediment motion:

$$K_c = 1 + \frac{\left[\left(\dfrac{\rho}{\rho_s - \rho} + 1\right)\cos\alpha\tan\theta_x + \sin\alpha\tan\theta_y\right]}{\mu_s} \tag{28}$$

$$\theta_x = \arctan\left(\partial z_b/\partial x\right) \tag{29}$$

$$\theta_y = \arctan\left(\partial z_b/\partial y\right) \tag{30}$$

The angle of deviation of the near bed flow from the longitudinal direction is as follows:

$$\alpha = \arctan\left(v_b/u_b\right) \tag{31}$$

The coefficient of static friction is μ_s. The deviation angle of the bed load to the depth averaged flow direction (β), which depends on the flow near the bed and the inclination of the bed, is calculated by the following relations

$$\tan\beta = \frac{\sin\alpha - \Pi\Theta_y\left(\dfrac{u_{*c}^2}{u_*^2}\right)\tan\theta_y}{\cos\alpha - \Pi\Theta_x\left(\dfrac{u_{*c}^2}{u_*^2}\right)\tan\theta_x} \tag{32}$$

$$\Pi = K_{id} + 1/\mu_s \tag{33}$$

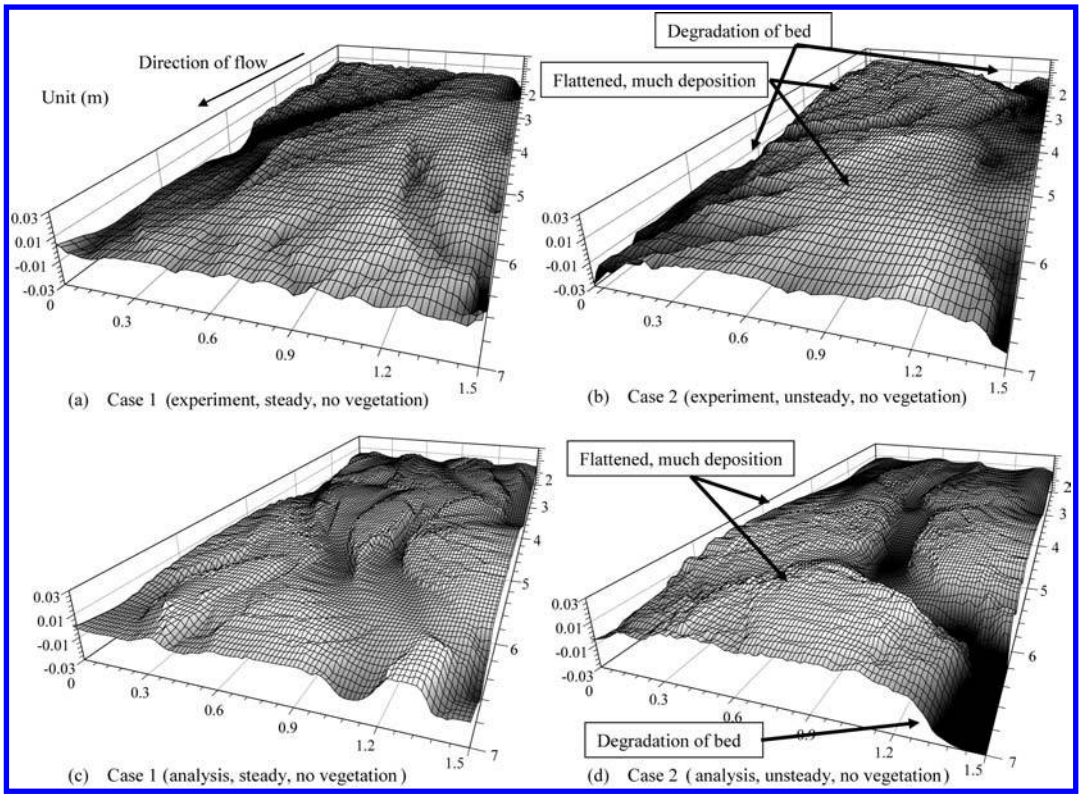

Figure 3. Bed geometry (flume experiment and numerical analysis in Case 1 and Case 2).

$$\Theta_x = \Theta_y + \frac{\rho}{\rho_s - \rho}\cos^2\theta_x \tag{34}$$

$$\Theta_y = \frac{1}{1+\tan^2\theta_x + \tan^2\theta_y} \tag{35}$$

where K_{ld} (=0.85) is the ratio of the lift force to the drag force. The local bed slope is adjusted to be smaller than the angle of repose (Michiue et al 1995).

Hydraulic conditions used in the analysis are also shown in Table 1 and Fig. 1. The bed slope is 1/100. The bed materials are treated as uniform sediment with a particle diameter of 1 mm. Case 1 and Case 2 have the same conditions used in flume experiments. Vegetation growth is taken into account in Case 3 and Case 4. The flow hydraulic conditions of Case 3 and Case 4 are identical to those of Case 1 and Case 2. Water discharge under Case 5 is the same as that under Case 4, but the width is different. Water discharge under Case 6 is the same as that under Case 3, but the width is different; it is in the formative regime of alternate bars that are approximately in the formative region of multiple row bars. In Case 7 and Case 8, the width is changed with same unit width water discharge conditions as those used in Case 3. In Case 9 and Case 10, Case 6 is converted to unsteady conditions that are used as the formative hydraulic conditions of alternate bars at a large water discharge and as the formative hydraulic condition of multiple row bars at a small water discharge. Vegetation growth is not considered in Case 9.

3 EFFECTS OF UNSTEADY CHARACTERISTICS OF WATER SUPPLY ON BED AND CHANNEL CONFIGURATION

Figure 3 shows bed geometries obtained through flume experiments and numerical analysis under steady water and sediment supply conditions (Case 1) and unsteady water and sediment supply conditions (Case 2), where vegetation growth is ignored. These hydraulic conditions are in the formative regime of multiple row bars. Although some parts of the bed geometries by flume experiments are not reproduced well by numerical analyses, the bed elevation of dry bed regions during low flow is higher and flattened under unsteady water and sediment supply conditions in both flume experiments and numerical analyses. In addition, the bed elevation in the stream is lowered

Copyright © 2006 Taylor & Francis Group plc, London, UK

further in unsteady conditions than in steady conditions. This lowering is due to the fact that, at a large water discharge, sediment is transported to and deposited on bars, thereby choking smaller scale streams. At a small water discharge, flows are concentrated to larger scale streams with the deepest bed, thereby developing streams further.

Numerical analyses clearly revealed that the streams are fewer in unsteady conditions than they are in steady conditions. However, bed geometries obtained by flume experiments did not confirm that fact. This matter should be judged using a steady water supply on the rigid bed obtained by unsteady conditions.

Figure 4 shows bed geometries obtained through numerical analyses under steady water and sediment supply conditions where vegetation growth is neglected (Case 6), unsteady water and sediment supply conditions where vegetation growth is neglected (Case 9), and unsteady water and sediment supply conditions where vegetation growth is taken into account (Case 10). These hydraulic conditions are in the formative regime of alternate bars. The wavelength of bars in unsteady water and sediment supply conditions is longer than that in steady conditions as reported by the previous study (Watanabe et al. 2001). Furthermore, it is noticed that in unsteady conditions, the water surface slope becomes steeper from a riffle towards a pool during low flow, and the riffles are eroded and its bed elevation is lowered. Case 10 will be discussed in section 4.

4 EFFECTS OF VEGETATION GROWTH ON BED AND CHANNEL CONFIGURATIONS

Figure 5 shows bed geometries obtained by numerical analysis under steady water and sediment supply conditions (Case 3) and unsteady water and sediment supply conditions (Case 4). These hydraulic conditions are in the formative regime of multiple row bars. A comparison of Case 1 and Case 2 is made with the

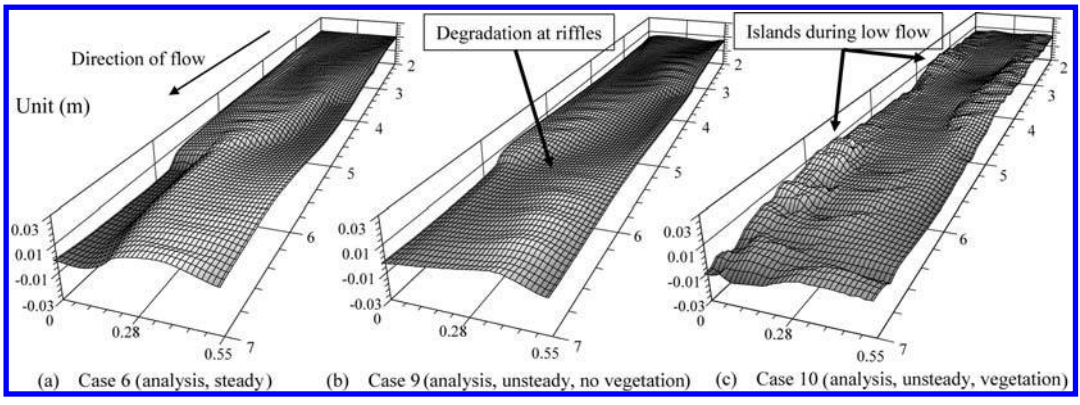

Figure 4. Bed geometry (numerical analysis in Case 6, Case 9 and Case 10).

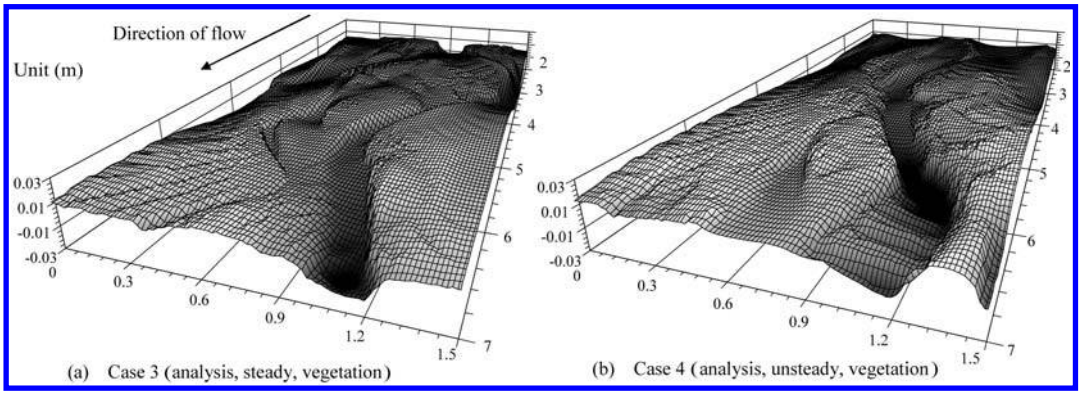

Figure 5. Bed geometry (numerical analysis in Case 3 and Case 4).

Copyright © 2006 Taylor & Francis Group plc, London, UK

same conditions, but ignoring the vegetation growth. If the vegetation growth is considered, the sediment deposition at the area of higher bed elevation is accelerated. Furthermore, the bed elevation in the stream is lowered in both steady and unsteady conditions. Simultaneously, the number of streams decreases. In the unsteady condition (Case 4), it is noted that one meandering stream with smaller anabranches is formed. This result shows that the formative region of a meandering stream appears with greater width-depth ratio in the field with rigid banks, if both vegetation growth and unsteady characteristics of water and sediment supply are considered. The definition of width is very important here. Under formative hydraulic conditions of alternate bars, no dry bed region is formed with steady water and sediment supply conditions. Hence, the width of a flow is equal to the width of analysis domain. On the other hand, under formative hydraulic conditions of multiple row bars, the stream width is not the same as the width of analysis domain, because a dry bed region is formed even under steady water and sediment supply conditions. Hence, the width of the analysis domain becomes braiding width or flood plain width. With previous linear bed instability analysis, the treatment of the dry bed regions within the analysis domain is difficult. For this reason, formative mechanism of bars with dry bed regions has not been studied well. As a result it is considered that the concept that "formative hydraulic conditions of alternate bars are equivalent to formative hydraulic conditions of meandering streams" has been confirmed.

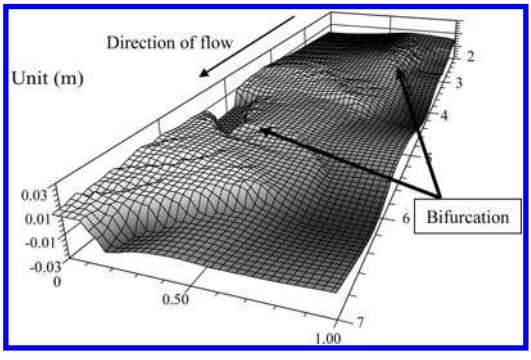

Figure 6. Bed geometry (numerical analysis in Case 5).

Figure 6 shows bed geometries obtained through numerical analysis of Case 5 using a smaller width-depth ratio, in which unsteady water and sediment supply conditions, where effects of vegetation growth are considered. This condition is in the formative region of multiple row bars. Compared with Case 4 shown in Fig. 5, in Case 5, despite a smaller width-depth ratio, the main stream is bifurcated and the number of streams with largest stream scale is greater than that of Case 4. These differences contradict the previous findings derived from linear bed instability analysis. It is considered that vegetation growth produces these differences. Figure 7 shows a horizontal distribution of the degree of vegetation growth obtained from Case 4 and Case 5. The degree of vegetation growth 0 is for no vegetation and 1 is for perfect growth. Figure 7 shows that, compared with Case 4, the vegetated area is narrowed with regard to the total area of the analysis domain in Case 5

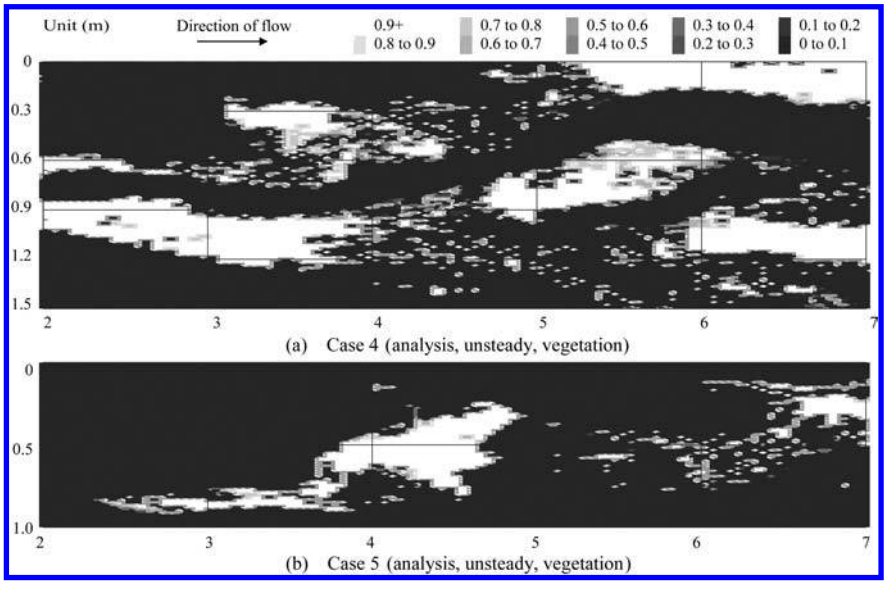

Figure 7. Vegetation growth rate (numerical analysis in Case 4 and Case 5, 0: no vegetation, 1: perfect growth).

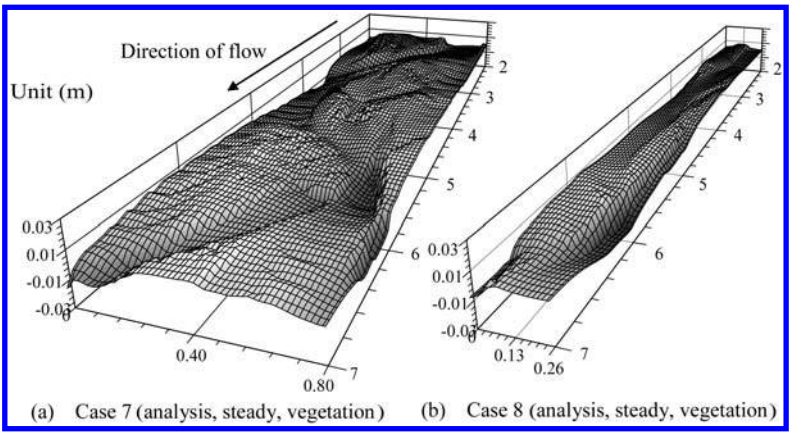

Figure 8. Bed geometry (numerical analysis in Case 7 and Case 8).

with a smaller width depth ratio. This is due to the high shear stress by narrowing the analysis width. Disturbances to bars by flowing water are increased and vegetation growth is suppressed. It is considered that suppression of vegetation growth enhanced stream deformation and accelerated generation of stream bifurcations.

Figure 8 shows bed geometries obtained through numerical analysis of Case 7 and Case 8 with a smaller width-depth ratio under steady water and sediment supply conditions, in which effects of vegetation growth are considered and the non-dimensional shear stress is the same as that of Case 3. Comparison of Case 3 and Case 7 shows that, despite a greater width-depth ratio, the number of main streams in Case 3 is only 1–2, which is nearly equal to that of Case 7. The same description used for Case 4 and Case 5 are also applicable here. Bifurcation of streams is suppressed by the vegetation growth, even with increased width-depth ratio and where the number of streams is not increased significantly. Furthermore, the bed geometry in Case 8 shows a formation of nearly one stream flowing from bank to bank alternately. In other words, under the formative condition for braided streams the number of streams is determined by a balance between instability of the bed surface and resistance characteristics of vegetation. Under the condition in which resistance characteristics of the vegetation are low, the number of streams increases as the width-depth ratio becomes greater, thereby forming braided streams. With greater resistance characteristics of vegetation, the number of streams reaches a maximum value at a certain level of width-depth ratio: the meandering stream is formed with a greater width-depth ratio.

Figure 4 shows bed geometries obtained through numerical analysis of Case 10 under unsteady water and sediment supply conditions in which effects of the vegetation growth are considered. The hydraulic conditions are in the formative region of alternate bars. Although bars are formed alternately along with the right and left banks, it is noticed that by considering the unsteady characteristics of water and sediment supply, and vegetation growth, a channel configuration is formed that has entirely different geometric characteristics from those of well-known alternate bars. These differences are from the fact that the riffles are eroded during low flow. In addition, vegetation grows on areas where the bed elevation is higher during low flow, sediment is deposited only on the vegetated area resulting in increased bed elevation further, and flows are concentrated to the main stream with lower bed elevation. Concentration of flows to lower bed elevation areas because of vegetation growth is similar to such a field in which the dry bed regions are formed. It is therefore considered that under formative hydraulic conditions of alternate bars close to formative hydraulic conditions of multiple row bars and phenomena in natural rivers tend to be shifted to a greater width-depth ratio side.

The vegetation effect to reduce sediment transport rate is expected to cohesive materials in the flood plain. Therefore, it is expected that a meandering stream is formed, if cohesive material exists, even if vegetation does not grow (Ashida & Sawai 1977).

5 CONCLUSIONS

Based on results of flume experiments and of two dimensional bed deformation analysis in which beds are composed of non-cohesive materials, effects of the unsteady characteristics of water and sediment supply and of vegetation growth on the formative mechanisms of meso-scale channel configuration were

Copyright © 2006 Taylor & Francis Group plc, London, UK

investigated. Results obtained through this study are summarized as follows:

(1) Both flume experiments and numerical analysis showed that, compared with steady conditions, the bed elevation on dry bed regions at low water flow is elevated and flattened under formative hydraulic conditions of multiple row bars and unsteady conditions. In addition, compared with steady conditions, the bed elevation in the stream is lowered under unsteady conditions. These phenomena are due to the fact that sediment is brought to and deposited at such areas where the bed elevation is high during high flow, thereby smaller scale streams are choked. In addition, flows are concentrated to a larger scale stream where the bed elevation is low, thereby developing the stream further.
(2) In the formative region of alternate bars, compared with steady hydraulic conditions, the wavelength of bars is lengthened under unsteady conditions. Furthermore, under unsteady conditions, the water surface slope becomes steeper from a riffle toward a pool during low flow, thereby bed elevation becomes lowered at riffles.
(3) Under both steady and unsteady conditions, if the vegetation growth is taken into account, deposition of sediment on a higher bed elevation area is accelerated and the bed elevation in the stream is lowered. In addition, under unsteady conditions, number of streams is reduced and nearly one meandering channel is formed with the large width-depth ratio. This suggests that in a field with rigid banks, the formative region of meandering streams appears in the condition with larger width-depth ratio if vegetation grows and water and sediment supply condition are unsteady.
(4) Because of the fact that opportunities for bifurcation of streams are suppressed by vegetation growth even if the width-depth ratio is increased, the number of streams does not increase remarkably. This fact suggests that under formative hydraulic conditions of braided streams, the number of streams is determined by the balance between the instability of bed surface and the resistance of vegetation. The number of streams increases as the width depth ratio increases with small vegetation resistance. On the other hand, with large vegetation resistance, the number of streams reaches a maximum value, resulting in a meandering stream in a large width-depth ratio region.
(5) Even if mean hydraulic conditions are in the formative region of alternate bars, a channel configuration is formed that has entirely different geometric characteristics from those of well-known alternate bars because of the vegetation growth during low flow under unsteady conditions. It is therefore considered that under formative hydraulic conditions of alternate bars close to formative hydraulic conditions of multiple row bars, phenomena in natural rivers tend to be shifted to a larger width-depth ratio side.

Location of hills and deeps in meandering streams: An experimental study

A.M. Ferreira da Silva
Associate Professor, Department of Civil Engineering, Queen's University, Kingston, Ontario, Canada

T. El-Tahawy
Assistant Professor, Department of Civil Engineering, Helwan University, Cairo, Egypt

ABSTRACT: The effect of geometric and flow related parameters on the location in flow plan of the laterally adjacent erosion "deeps" and deposition "hills" of meandering streams is investigated. The centerlines of the regular meandering streams follow sine-generated curves; the banks are rigid; the flow is turbulent and sub-critical. A series of experimental runs carried out in a channel having a deflection angle $\theta_0 = 70°$ is presented. The results of these runs are analysed together with those from runs reported in previous works by other authors. It is found that the location of deeps and hills is strongly dependent on θ_0 (i.e. on the stream sinuosity), and to a smaller extent also dependent on the ratio of the meander wavelength to flow width and possibly the flow friction factor. For the same remaining conditions, the location of hills and deeps continuously moves upstream from the crossovers to the apexes as θ_0 increases from small to large.

1 INTRODUCTION

1.1 *General*

This paper concerns the nature of the deformed bed in regular meandering streams. The centerlines of the streams follow sine-generated curves (see Section 2, paragraph (i)); the banks are assumed to be rigid. The work is restricted to turbulent, sub-critical and "wide" streams, "wide" stream being defined for the present purposes as a stream having a width-to-depth ratio $B/h_{av} > \approx 10$. The elements of bed topography under consideration are those brought into being by the curvature of the stream. Elements due to other reasons, namely bed forms (ripples, dunes, bars, etc.) are not considered here. The paper is an extension of previous experimental studies by Losiyevskii (reported by Makaveyev 1975), Hooke (1974), Hasegawa (1983), Whiting & Dietrich (1993a,b), and Termini (1996), who investigated the nature of the developed (or equilibrium) bed topography in laboratory sine-generated streams having movable beds. Table 1 presents a summary of the hydraulic conditions used by these authors. Here θ_0 = deflection angle, Λ_M = meander wavelength (see the definition sketch in Figure 1, where the geometry-related notation is introduced), Q = flow rate, D = average grain size, B = flow width, h_{av} = channel-averaged flow depth, S_c = bed slope along the channel centerline, $(c_f)_{av}$ = dimensionless (Chézy) flow friction factor, Re = flow Reynolds number, Fr = Froude number, and Re_* = roughness Reynolds number (see also the List of Symbols). The quantity λ is introduced in Sub-Section 1.2. All runs were carried out starting from a flat movable bed at $t = 0$, the bed subsequently being allowed to deform until the equilibrium state (or the equilibrium bed topography) was achieved. From Table 1, it should be clear that in most of the experiments carried out to date, the channels used had mainly small or large values of θ_0.

As is well known, the bed in meandering streams deforms so as to acquire laterally adjacent erosion "deeps" and deposition "hills". In the case of the periodic (along x) sine-generated streams, each deep+hill complex forms a large-scale erosion-deposition zone having the length $L/2$. The largest erosion-deposition occurs somewhere in the midst of the erosion-deposition zone. From experiment (the laboratory experiments in Table 1 as well as field measurements), it is known that the location in flow plan of hills and deeps is not "standard", i.e. it is not the same or approximately the same for every meandering stream. Indeed, consider Figures 2 and 3, showing the bed in actual streams, and observe that in Figures 2a and 3a, where θ_0 is "small", the deeps and hills are centered approximately around the crossover-sections O, while in Figures 2b and 3b, where θ_0 is "large", they are centered around the apex-sections a.

On the basis of their own experimental observations, as well as those of other authors, Whiting & Dietrich (1993b) indicated that the location of the

erosion-deposition zones varies depending on the plan shape of the stream, i.e. depending on the values of the initial deflection angle θ_0 and Λ_M/B. According to these authors, "the larger the bend angle (i.e. θ_0) and the narrower the channel with respect to the cartesian wavelength, the further upstream is the pool" (Whiting & Dietrich 1993b, p. 3610). Using dimensional analysis, Yalin & da Silva (2001) have shown that, in addition to θ_0 and Λ_M/B, the location of the erosion-deposition zones may be expected to vary also depending on flow-related parameters, namely the channel-averaged values of the flow width-to-depth ratio B/h_{av} and the dimensionless (Chézy) flow friction $(c_f)_{av}$ (which reflects the influence of the granular skin roughness as well as of the grain size Reynolds number). However, no attempt has been made to date to determine how exactly does the location of

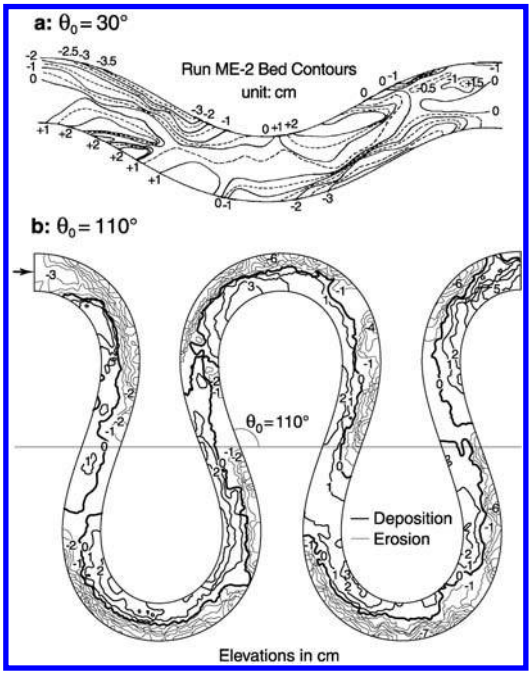

Figure 3. Examples of measured bed topography. a) Measured by Hasegawa (1983) in a 30°-channel (Run ME-2); b) Measured by Termini (1996) in a 110°-channel.

erosion-deposition zones depend on the geometric and flow-related parameters. This paper is the authors' contribution to this end.

1.2 *Aims of the paper and approach*

In order to define a quantity to characterize the type of distribution in flow plan of the $L/2$-long erosion-deposition zones, consider any meander loop between two consecutive crossovers (O_i and O_{i+1}, or O_{i+1} and O_{i+2}, etc. – see Figures 1 and 2). Within such a meander loop, locate the $L/2$-long erosion-deposition zone where deposition (D) occurs at the inner bank and erosion (E) at the outer bank. As can be inferred from Figure 4 (showing a schematic representation of the erosion-deposition zones in channels having "small" and "large" θ_0), the aforementioned $L/2$-long erosion-deposition zone may be only partially located in the meander loop (O_i and O_{i+1}, say) as in Figure 4a ($\theta_0 \rightarrow 0$), or fully located within it as in Figure 4b ("large" θ_0). Let $\tilde{l}_c$ be the distance from the apex a (a_i if the meander loop under consideration is $O_i\,O_{i+1}$; a_{i+1} if the meander loop under consideration is $O_{i+1}O_{i+2}$; etc.) to the mid-section of the aforementioned erosion-deposition zone, as shown in Figure 4a. Clearly, the location in flow plan of the erosion-deposition zones occurring in any given sine-generated stream can be

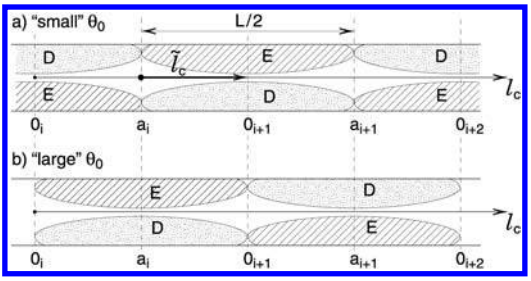

Figure 4. Schematical representation showing the location of L/2-long erosion-deposition (E-D) zones in sine-generated streams (streams "straightened" for the sake of simplicity); definition of $\tilde{l}_c$.

fully characterized by $\tilde{l}_c$ – or, equivalently, by its dimensionless counterpart $\lambda = \tilde{l}_c/L$. In other words, each different distribution in plan of the erosion-deposition zones is associated with its "own" value of λ. (For example, for the distribution in Figure 4a, $\lambda \approx 0.25$; for that in Figure 4b, $\lambda \approx 0$.) Following Whiting & Dietrich (1993b) and Yalin & da Silva (2001), in this paper $\lambda = \tilde{l}_c/L$ is treated as the following function of four dimensionless variables:

$$\lambda = \varphi_\lambda\left(\theta_0, \frac{\Lambda_M}{B}, \frac{B}{h_{av}}, (c_f)_{av}\right). \qquad (1)$$

The present paper has the following two aims:

1. to present the results of a series of experiments carried out by the authors in order to reveal the bed topography in a sine-generated channel having an intermediate value of θ_0. This value of θ_0 is selected so as to extend the range of θ_0-values investigated by previous authors; and
2. to investigate the form of the functional relationship (2), and thereby gain some insight into how the location of erosion-deposition zones depends on the relevant geometric and flow-related parameters. For this purpose, the λ-values resulting from the present measurements are analysed together with all the available data from previous works.

Throughout the paper, the position of a point P in the flow plan will be specified by the channel-fitted coordinates l_c and n (see insert in Figure 1) or by their dimensionless counterparts $\xi_c = l_c/L$ and $\eta = n/B$.

2 PERTINENT ASPECTS OF THE PLAN AND BED GEOMETRY IN SINE-GENERATED STREAMS

Before proceeding to the description of the experimental runs and their results, the following pertinent

Copyright © 2006 Taylor & Francis Group plc, London, UK

aspects of the geometry of sine-generated streams and their deformed beds – invoked throughout this paper – should be mentioned:

(i) The centerlines of sine-generated streams are given by the following equation (due to Leopold & Langbein 1966, Langbein & Leopold 1966)

$$\theta = \theta_0 \cos\left(2\pi \frac{l_c}{L}\right). \tag{2}$$

Eq. (2) appears to have become generally accepted as best representing the path of the channel centerline of natural regular meandering streams. Owing to this reason, current laboratory and numerical research on the mechanics of alluvial meandering flows and related processes is often carried out by idealizing the stream centerline as a sine-generated curve (see Smith & McLean 1984, Chang 1988, Nelson & Smith 1989, Shimizu 1991, Lyness et al. 2001, Jia & Wang 1999, Termini 2004, etc.).

(ii) The sinuosity $\sigma = L/\Lambda_M$ of sine-generated streams is uniquely determined by θ_0 as

$$\sigma = \frac{1}{J_0(\theta_0)} \tag{3}$$

(see Yalin 1992, Yalin & da Silva 2001). Here $J_0(\theta_0)$ is the Bessel function of first order and zero-th kind of θ_0. Fig. 5 shows how the computed sinuosity σ $(= L/\Lambda_M)$ of sine-generated channels corresponding to various θ_0 compares with its values measured in large Russian lowland rivers.

Note that the maximum possible value of θ_0 is $\approx 138^\circ = 2.41$ *rad*. This corresponds to $J_0(\theta_0) = 0$ and $L, \sigma \rightarrow \infty$. However, in practice, this can never occur, for when θ_0 reaches the value $\approx 126^\circ = 2.20$ rad ($\sigma \approx 8.5$), the meander loops come into contact with each other and the meandering pattern is destroyed.

(iii) It has since long been established that the meander wavelength Λ_M is proportional to the flow width B. Yalin (1992), Yalin & da Silva (2001) have shown that the relation

$$\Lambda_M \approx 2\pi B \tag{4}$$

best characterizes the average behaviour of natural streams. However, as pointed out by these authors, "the random element in natural meandering streams is rather strong; hence the coefficient of B in (3) may, in some cases, deviate substantially from $\approx 2\pi$, which is to be considered as the average value only" (Yalin & da Silva 2001, p. 103). This explains why Λ_M/B is included in the set of variables in Eq. (3) and also why different authors carried out their experiments in channels where this quantity differed somewhat from $\approx 2\pi$ (see Table 1).

(iv) Sine-generated streams consist of a sequence of anti-symmetrically identical loops conveying anti-symmetrically identical flows. Thus the sediment transport rates entering and leaving a meander loop are equal. But this means that the bed deforms with the passage of time around an unchanging average bed surface, which is the same as the flat initial bed at time $t = 0$ (+ and – areas at any section are the same for any t, as shown in Figure 6 (see e.g. Levi 1957, Ikeda & Nishimura 1986, Yalin & da Silva 2001)). In other words, the channel-averaged flow depth h_{av}, and thus B/h_{av}, can be regarded as constant throughout the process of bed deformation (and $h_{av} \approx h_0$).

In the following, the difference between the bed surface elevation at equilibrium, $(z_b)_T$, and the elevation of the initial bed surface, $(z_b)_0$, will be termed $(\Delta z_b)_T$ (see Fig. 6):

$$(\Delta z_b)_T = (z_b)_T - (z_b)_0. \tag{5}$$

3 EXPERIMENTAL SETUP AND RUNS

The present runs were carried out in a sine-generated meandering channel having $\theta_0 = 70°$ (which corresponds to a sinuosity $\sigma = 1.52$ (Eq. (3)). The flow width B was 0.80 m. The meander wavelength Λ_M and B were related by the proportionality (3). The channel had the total extent, L_T, of two meander lengths ($L_T = 2L = 15.2\,m$), its first and last sections coinciding with apex-sections (see Figure 7). The upstream-end of the meandering channel was connected to a 2 m-long straight approach channel. The vertical channel walls were made of 5 mm-thick plywood sheets, painted with an Epoxy paint; the channel bed consisted of a well-sorted silica sand having an average grain size (D_{50}) of 0.65 mm. The granular skin roughness $k_s \approx 2D_{50}$ (Kamphuis 1974) was 1.3 mm. The specific density of the sand was 2.65.

In total six runs were carried out. In each run, the flow rate Q was constant (steady flow). All runs started from a bed having zero radial slope and a specified longitudinal slope S_c (flat initial bed at $t = 0$). A tailgate was used to set the water elevation at the downstream-end of the channel so that the free surface slope was identical to the longitudinal bed slope S_c ("uniform" flow conditions). No sediment was fed to the channel throughout the duration of the runs. At the end of each run, the water was drained from the channel very slowly in order to ensure that the resulting deformed bed was not disturbed. The bed topography was measured only after the channel was completely drained.

The channel-averaged flow depth h_{av} was identified with the (identical) flow depth h_0 at the centreline of the four consecutive crossovers 1_1, 1_2, 1_3 and 1_4 – see Section 2, paragraph (iv). The flow depth h_0 at each crossover was obtained as the difference between the free surface elevation measured immediately after the "uniform" flow conditions were established and the elevation of the surface of the flat initial bed $(z_b)_0$. Measurements of the elevation of the deformed bed surface $(z_b)_T$ (see Figure 6) were carried out in three consecutive loops Λ_1, Λ_2, Λ_3, and in each loop in sixteen equally spaced cross-sections 1_i to 16_i ($i = 1$ to 3) as shown in Figure 7. The distance between two adjacent measurement cross-sections along the channel centerline was $\delta l_c = 23.8\,cm$ (or $\delta\xi_c = 0.03125$, where $\delta\xi_c = \delta l_c/L$). In each cross-section, the bed surface was measured at twenty-two equally spaced points (from $n = -36.75\,cm$ to $n = 36.75\,cm$). The bed surface elevation measurements were carried out by using as reference level (datum) a horizontal plane located 30 cm below the top of the channel walls.

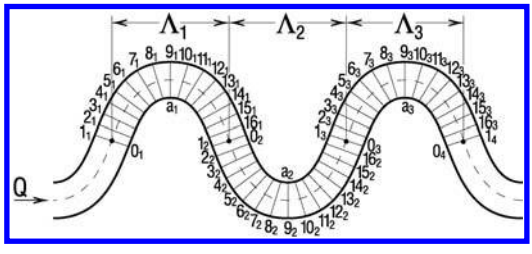

Figure 7. Experimental sine-generated channel and cross-sections for measurement of bed surface elevation.

A complete description of the experimental installation and the measurement techniques is given elsewhere (see El-Tahawy 2004).

The hydraulic conditions in each run are summarized in Table 2. Table 3 shows the values of the pertinent dimensionless variables for each run. Following Grishanin (1979), Kondratiev et al. (1982), Nelson & Smith (1989), etc., the values of the channel-averaged friction factor $(c_f)_{av}$ of gradually convergent (in both longitudinal sections and plan) meandering flows are invariably identified with those of the corresponding uniform flows. In accordance with this, $(c_f)_{av}$ was calculated from the following well-known equation (of uniform flows):

$$(c_f)_{av} = \frac{1}{\kappa}\ln\left(0.368\frac{h_{av}}{k_s}\right) + B_s, \qquad (6)$$

where κ = von Karman constant, k_s = granular roughness of the bed surface, and $B_s = \varphi(\mathrm{Re}_*)$ = roughness function (determined in this paper with the aid of Eq. (1.10) in Yalin & da Silva 2001). The values of

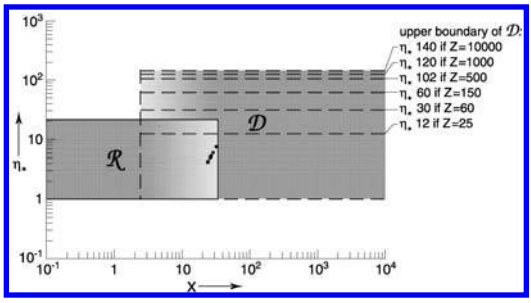

Figure 8. Existence regions of ripples (R) and dunes (D) in the $(\eta_*; X)$-plan of Yalin & da Silva (2001); dots mark the present runs.

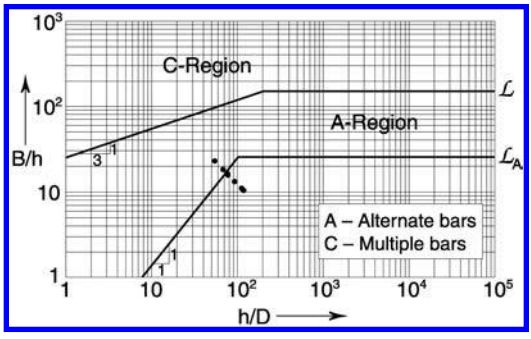

Figure 9. Existence regions of alternate bars (A) and multiple bars (M) in the $(B/h; h/D)$-plan of da Silva (1991); dots mark the present runs.

$(c_f)_{av}$ were similar in all runs, their average value being 15.6, while the values of B/h_{av} were increased from 10.7 in Run 1 to 22.9 in Run 6. Therefore, in the present series of runs, the values of $(c_f)_{av}$ can be regarded as fixed ($(c_f)_{av} \approx const = 15.6$), B/h_{av} being the only parameter in the functional relationship (2) that was varied.

The conditions in the experimental runs were selected so as to eliminate the possibility of occurrence of bed forms (ripples, dunes, alternate bars), or at least to ensure that eventual bed forms were small enough so as not to obscure the bed features under investigation. Consider Figure 8, showing the $(\eta_*; X)$-plan defining, according to Yalin & da Silva (2001), the existence regions of ripples (R) and dunes (D). Consider also Figure 9, showing the $(B/h;\ h/D)$-plan defining, according to da Silva 1991 (see also Yalin & da Silva 2001), the existence regions of alternate bars and multiple bars. The present runs are plotted as black dots in both of these Figures. Note from Figure 8 that the runs are located very near the vertical line implying the upper X-boundary of the region of ripples superimposed on dunes – where ripples are virtually non-existent. Four of the runs (namely runs 1 to 4) are located outside the alternate bar region in the $(B/h; h/D)$ in Figure 9. Runs 5 and 6 are within the A-region, but relatively near its lower boundary (especially Run 5), where alternate bars are the least prominent. During the runs, only small dunes were occasionally observed in some parts of the bed – which is consistent with the plots in Figures 8 and 9. The dune length varied from approximately 15 to 30 *cm*, the dune height typically being less than 1 to 1.5 *cm*.

4 EXPERIMENTAL RESULTS AND OBSERVATIONS

As examples, the bed topography maps at the end of Runs 1, 3 and 5 are shown in Figure 10a, b and c, respectively. These maps were produced from the measured $(\Delta z_b)_T$-values (see Figure 6 and note that $(\Delta z_b)_T > 0$ implies deposition, and $(\Delta z_b)_T < 0$ implies erosion).

The deformation of the bed was observed to progress very rapidly at the early stages of a run, and then to gradually slow down with the passage of time. The bed deformed by developing bars and pools, which over time grew in their prominence (magnitude), their location in flow plan remaining essentially the same.

As should be clear from Figure 10a to c, the deposition bars were always asymmetric. That is, the maximum deposition was not at, or near, the centre (mid-section) of the bar, but rather at a location further upstream, somewhere in the first half of the bar. As a bar grew in prominence, it deflected more and more the flow towards the pool at the opposite bank, which continued to deepen. The bars grew in their height until they became nearly exposed. At the later stages of a run, the flow was being strongly deflected by the bars towards the deeps.

Runs 1, 2 and 3 were stopped at times 75, 45 and 60 minutes, respectively, when the bottom of the channel became exposed at the locations of most intense erosion. Since the bed changes over time had already slowed down considerably, the measured deformed beds in these runs can be regarded as being near, although not exactly, at equilibrium. Runs 4, 5 and 6 were stopped at times 170, 180 and 120 minutes, respectively, some time after bed changes became no longer noticeable. Therefore, the measured deformed beds in these runs can be regarded as being in equilibrium.

From Figures 10a to c, it should be clear that in the present 70° -channel, the beginnings of the erosion-deposition zones do not coincide with the apexes a_i as in the case of small sinuosity (see Figures 2a and 3a), and also not with the crossovers O_i as in the case of large sinuosity (see Figures 2b and 3b). Rather, their beginnings occur somewhere in between the crossovers O_i and apexes a_i. In order to determine the exact location (i.e. the beginnings and ends) of

Copyright © 2006 Taylor & Francis Group plc, London, UK

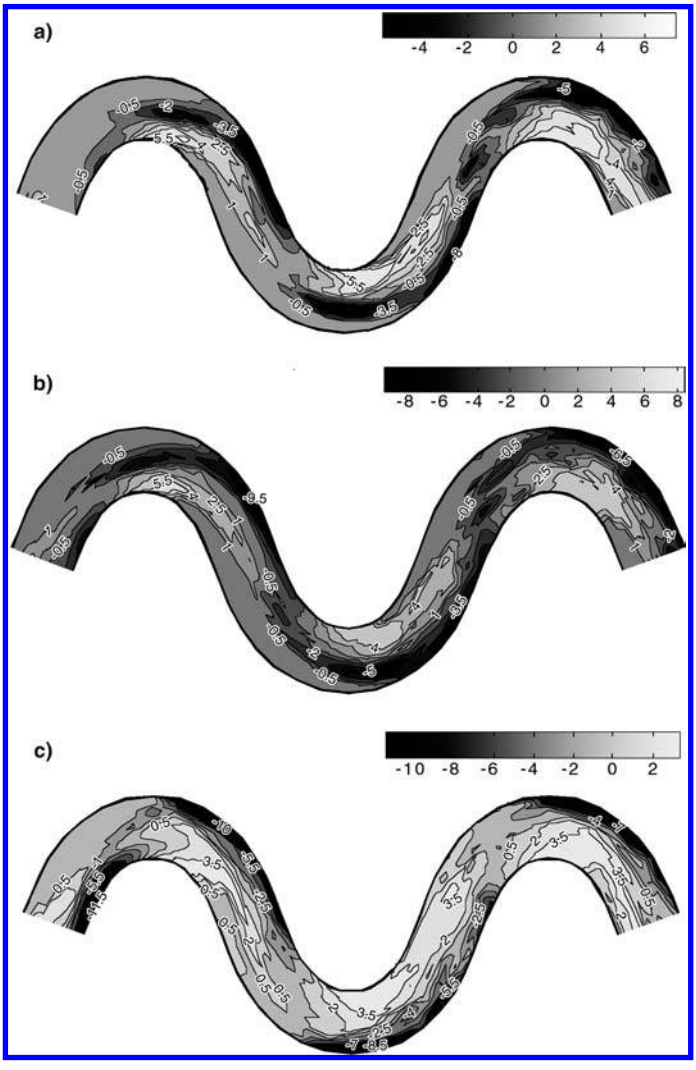

Figure 10. Bed elevation contour maps (contours based on $(\Delta z_b)_T$-values; units are cm; flow from left to right.) (a) Run 1; (b) Run 3; (c) Run 5.

the deformed beds and, consequently, the values of λ, plots of E_V and D_V versus ξ_c $(=l_{c/L})$ were produced for each run. Here E_V is the volume of space between any two consecutive measurement cross-sections which became void of sand over the duration of the run (i.e. from $t=0$ to $t=T_b$), and D_V the volume of space which became filled with sand over the same period of time. Clearly, no erosion or deposition occurs at the cross-sections coinciding with the beginning (i.e. upstream-end) and end (downstream-end) of each erosion-deposition zone, and therefore at these cross-sections $E_V;D_V \rightarrow 0$. The $E_V;D_V$-plot corresponding to Run 5 is shown, as example, in Figure 11. In this Figure, the cross-sections where $E_V;D_V \rightarrow 0$, corresponding to the beginnings (and ends) of each erosion-deposition zone, are marked by the vertical dashed lines labelled "Beginning of nth E-D zone" (with $n=1$, 2, 3).

The dimensionless length of the first erosion-deposition zone was systematically less than the expected (theoretical) value of 0.50 (its average value for the six runs being 0.43). On the other hand, the downstream end of the third erosion-deposition zone was invariably located after the last measurement cross-section. Considering this, the values of λ were determined for the second erosion-deposition zone (where λ is to be measured from the apex-section a_2 (i.e. 5_2 – see Figure 7). The resulting values are $\lambda=0.125$, 0.120, 0.100, 0.135, 0.135 and 0.145 for Runs 1 to 6, respectively.

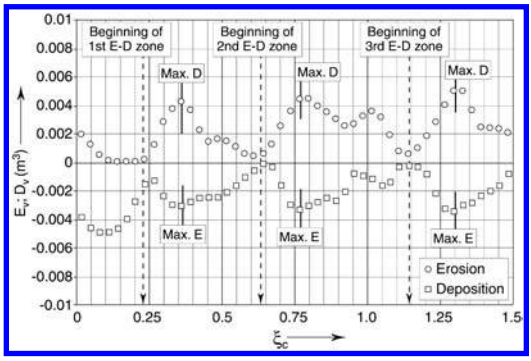

Figure 11. Plot of E_V (eroded volume) and D_V (deposited volume) versus ξ_c: Run 5.

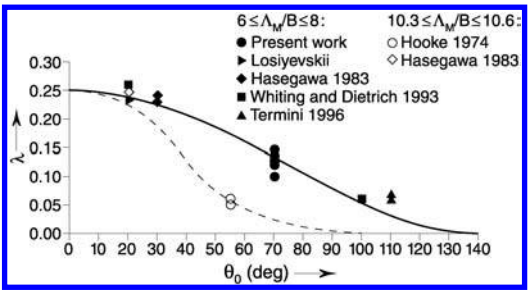

Figure 12. Plot of λ versus θ_0.

The location in flow plan of the $L/2$-long erosion-deposition zones was remarkably similar in all runs, irrespective of their values of B/h_{av}. Indeed, for all runs the topographic maps and the E_V;D_V-plots show a $L/2$-long erosion-deposition zone starting approximately at cross-section 5_2 and another approximately at cross-section 5_3, with $\lambda \approx const = 0.125$.

5 EFFECT OF PLAN SHAPE AND FLOW RELATED PARAMETERS

Using the topographic maps produced by Losiyevskii, Whiting & Dietrich (1993a,b), Hasegawa (1983), Hooke (1974) and Termini (1996), values of λ were estimated also for each of the runs in Table 1. The resulting values of λ are shown in the last column in this Table. (The three values shown for the run by Termini 1996 correspond to measurements in three consecutive meander loops).

The width-to-depth ratio was varied in the series of runs by Hasegawa (1983), Hooke (1974) and the present runs. For the range of B/h_{av}-values investigated by these authors, B/h_{av} had no significant effect on the values of λ (and thus on the location of the erosion-deposition zones). The parameter B/h_{av} thus will be disregarded in the discussion below.

No single author has substantially varied $(c_f)_{av}$ for constant θ_0, Λ_M/B and B/h_{av}. Therefore no definite conclusions can be drawn from the experiments carried out to date on the effect of $(c_f)_{av}$.

It is clear that the values of λ are strongly dependent on θ_0. A plot of the measured values of λ versus θ_0 is shown in Figure 12. The "black" data-points correspond to runs where $6 \leq \Lambda_M/B \leq 8$ and $12.4 \leq (c_f)_{av} \leq 16.4$. The solid line in this Figure represents the trend followed by these data-points. This line thus gives the variation of λ for specified values of Λ_M/B, $(c_f)_{av}$ and B/h_{av}, namely $\Lambda_M/B = const \approx 7$, $(c_f)_{av} = const \approx 14.5$ and $\approx 10 \leq B/h_{av} \leq \approx 30$. Here the values 7 and 14.5 are the average-values of the ranges of Λ_M/B- and $(c_f)_{av}$-values of the aforementioned data.

The "white" circles in Figure 12, which correspond to the runs by Hooke (1974), plot substantially below the aforementioned solid line. In these runs, the values of Λ_M/B and $(c_f)_{av}$ were 10.3 and ≈19, respectively. Given these data, it appears reasonable to expect the variation of λ for these values of Λ_M/B and $(c_f)_{av}$ (i.e. $\Lambda_M/B = 10.3$, $(c_f)_{av} = 19$ and $\approx 10 \leq B/h_{av} \leq \approx 30$) to be approximately as indicated by the dashed line in Figure 12. The deviation between the solid and dashed lines can be due entirely to differences in the values of Λ_M/B, or partially to differences in the Λ_M/B-values and partially to differences in the $(c_f)_{av}$-values. This is a point which can be clarified only through further research in the future. In spite of this, the results of the present analysis suggest that there is a trend for the location of the erosion-deposition zones to move further upstream for larger values of Λ_M/B (other conditions remaining the same) – as apparently first suggested by Whiting & Dietrich (1993b).

6 CONCLUDING REMARKS

From the analysis in this paper, it follows that:

1. The location of the erosion-deposition zones is strongly dependent on θ_0 (i.e. on stream sinuosity). For the same remaining conditions, the location of the erosion-deposition zones which are centered around the crossovers O_{i+1} for small θ_0, continuously moves upstream so that for large θ_0 they are centered around the apexes a_i.
2. Accordingly, for specified values of Λ_M/B, B/h_{av} and $(c_f)_{av}$ the quantity λ reflecting the distribution in flow plan of the erosion-deposition zones plots as an inverted S-curve (see Figure 12).
3. The present analysis suggests that the location in flow plan of erosion-deposition zones is affected also by Λ_M/B and possibly by $(c_f)_{av}$. For a specified θ_0, the larger Λ_M/B (and perhaps also $(c_f)_{av}$), the

Copyright © 2006 Taylor & Francis Group plc, London, UK

further upstream will the erosion-deposition zones be located.

4. Within the range of B/h_{av}-values of the data used in this work (namely $\approx 10 \leq B/h_{av} \leq \approx 30$), B/h_{av} did not play any detectable role in determining the location of the erosion-deposition zones.

LIST OF SYMBOLS

B	flow width
$(c_f)_{av}$	dimensionless (Chézy) friction factor
D_V	volume of space between any two consecutive measurement cross-sections that became filled with sand over the total duration of a run
D_{50}	representative grain size
E_V	volume of space between any two consecutive measurement cross-sections that became void of sand over the total duration of a run
Fr	Froude number ($= u_{av}/\sqrt{gh_{av}}$)
g	acceleration due to gravity
h_{av}	channel-averaged flow depth
h_0	flow depth at time $t = 0$, over the flat initial bed
$J_0(\theta_0)$	Bessel function of first kind and zero-th order (of θ_0)
k_s	granular roughness of bed surface ($k_s \approx 2D_{50}$)
l	longitudinal coordinate; $l = 0$ at the crossover O_i (see Figure 1)
L	meander length (measured along l_c)
l_c	longitudinal coordinate along the centreline of a meandering flow; $l_c = 0$ at the crossover O_i (see Figure 1)

$\tilde{l}_c$ distance measured along the channel centreline from the apex-section a to the mid-section of a $L/2$-long erosion-deposition as shown in Figure 3a

n radial coordinate of a meandering flow; $n = 0$ at the flow centreline (see insert in Figure 1)

Q flow rate

r radial coordinate of a meandering flow; $r = 0$ at the centre of channel curvature (see Figure 1)

R local radius of curvature

Re flow Reynolds number ($= u_{av}\, h_{av}/\nu$)

Re_* roughness Reynolds number ($= v_*\, k_s/\nu$)

S_c bed slope along the centreline of a meandering flow

t time

T_b duration of development of the deformed bed of a meandering stream

u_{av} channel-averaged flow velocity

v_* shear velocity ($= \tau_0/\rho = \sqrt{g h_{av} S_c}$)

X grain size Reynolds number ($= v_*\, D/\nu$)

z_b bed elevation measured with regard to an arbitrary reference datum (see Figure 6)

γ_s specific weight of grains in fluid

Δz_b local difference between the elevations of the deformed bed surface and the initial flat bed surface ($\Delta z_b = z_b - (z_b)_0$)

η dimensionless counterparts of n ($\eta = n/B$)

η_* relative flow intensity ($\eta_* = Y/Y_{cr}$, where Y is the mobility number (Shields parameter) and Y_{cr} is the value of Y at the stage of initiation of sediment transport

θ, θ_0 deflection angle of a meandering flow at any l_c and at $l_c = 0$, respectively (see Figure 1)

λ dimensionless counterpart of $\tilde{l}_c$ ($\lambda = \tilde{l}_c/L$)

Λ_M meander wavelength

ν fluid kinematic viscosity

ξ_c dimensionless counterpart of l_c ($\xi_c = l_c/L$)

ρ fluid density

σ sinuosity of a meandering flow ($\sigma = L/\Lambda_M$)

τ_0 bed shear stress

Subscripts:

av marks the channel-averaged value of a quantity

T marks the value of a quantity at time $t = T_b$

0 marks the value of a quantity at time $t = 0$

On the bed deformation in meandering streams

A.M. Ferreira da Silva
Associate Professor, Department of Civil Engineering, Queen's University, Kingston, Ontario, Canada

M.S. Yalin
Emeritus Professor, Department of Civil Engineering, Queen's University, Kingston, Ontario, Canada

ABSTRACT: The bed deformation in meandering streams is explained in the light of the sediment transport continuity equation and the convective behaviour of the vertically-averaged flow: the width-to-depth ratio is "large", the meandering channel is sine-generated. The plan shape of the channel and flow rate are assumed to remain constant during the bed formation process. It is shown that each erosion-deposition zone of the *developed* (or equilibrium) *bed* at time $t = T$ is brought into being by a corresponding convergence-divergence zone of the vertically-averaged *initial flow* over the flat (movable) bed at time $t = 0$. A series of experimental runs involving the systematic variation of the channel's deflection angle θ_0 is used to establish how the location of the convergence-divergence zones of the vertically-averaged initial flow varies with θ_0. The implications regarding the variation with stream sinuosity of the location in flow plan of erosion-deposition zones are discussed.

1 INTRODUCTION; FUNDAMENTALS

(i) This paper concerns the bed development in meandering streams. Following Leopold & Langbein (1966) (see also Langbein & Leopold 1966), the centerlines of the streams (in plan view) are idealized as sine-generated functions, where

$$\theta = \theta_0 \cos\left(2\pi \frac{l_c}{L}\right), \tag{1}$$

the different plan shapes being due to the different values of the deflection angle θ_0 only (see the schematic Figure 1, where a meandering stream having a "large" θ_0 is used to introduce the geometry-related notation). As shown by Yalin (1992), the deflection angle θ_0 and the stream sinuosity $\sigma (= L/\Lambda_M)$ of sine-generated channels are uniquely interrelated:

$$\sigma = \frac{1}{J_0(\theta_0)} \quad \left(= \frac{L}{\Lambda_M}\right). \tag{2}$$

here $J_0(\theta_0)$ is the Bessel function of the first kind and zero-th order (of θ_0).

(ii) In accordance with the majority of current publications on the topic, the present study rests on the following assumptions:

1. The stream is imbedded in a cohesionless alluvium which is homogeneous and isotropic;
2. The B/h_{av}-ratio of the stream is "large" (larger than ≈ 20, say, as in most of the large natural streams);
3. The flow is rough turbulent.

The implications of assumption 2 are of particular significance, and they are outlined below.

Assumption 2 gives the possibility to replace the study of an actual 3D-stream by that of its *vertically-averaged* 2D counterpart, where the location of a point in the flow plan can be specified by the "channel-fitted" polar coordinates $(l_c; r)$ or $(l_c; n)$ (Figure 2). This approach, which seems to have been first introduced in Smith & McLean (1984), Nelson & Smith (1989a), Struiksma et al. (1985), Shimizu & Itakura (1989) (see also Shimizu 1991), is adopted in the present text.

Assumption 2 also implies that the bank-friction is negligible. Considering this, one can express the Chézy resistance formula in the following manner

$$u_{av} = c_{av}\sqrt{g S_c h_{av}}\,. \tag{3}$$

here the dimensionless resistance factor c_{av} is related to the original (dimensional) Chézy's C_{av} by $c_{av} = C_{av}/\sqrt{g}$. [In order to save the space, the Symbols are not always defined where they appear, and the reader is invited to consult the "List of Symbols" at the end of the text.] It should be noted that since the energy losses due to the channel curvature are insignificant in

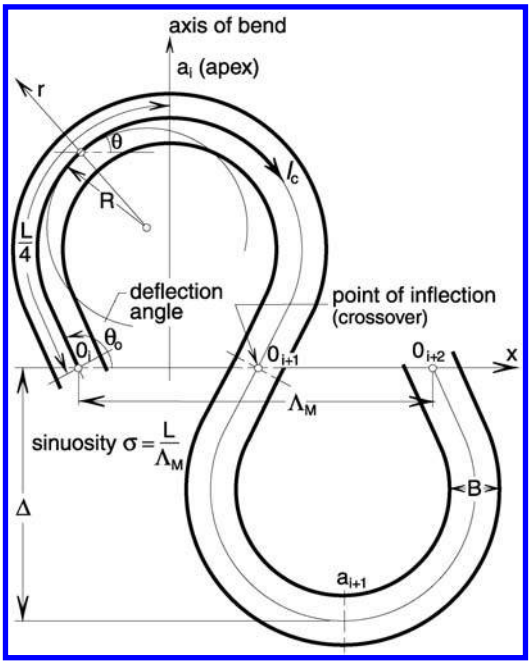

Figure 1. Definition sketch.

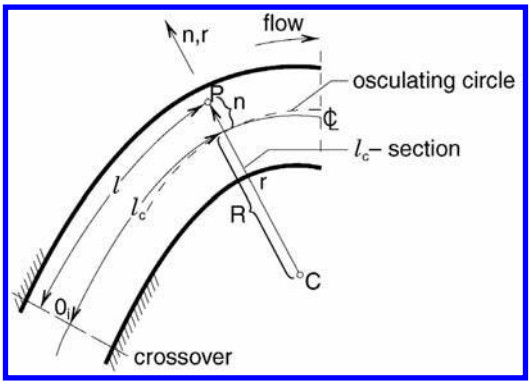

Figure 2. Channel-fitted polar coordinates.

comparison to the bed-friction losses (Leopold et al. 1960, Rozovskii 1957, Chang 1983; see also James 1994), the value of the resistance factor c_{av} does not differ appreciably from the value of the friction factor $(c_f)_{av}$: i.e. $c_{av} \approx (c_f)_{av}$.

Finally, assumption 2 conveys that the role of the cross-circulation (Γ) is negligible with regard to the present study. Indeed the relation

$$\left(\frac{\bar{v}'_\Gamma}{\bar{u}}\right)^2 = \alpha c_{av}^2[\theta_0 J_0(\theta_0)]\sin\left(2\pi\frac{l_c}{L}\right)\cdot\frac{h_{av}}{B} \qquad (4)$$

(derived in Yalin & da Silva 2001, pp. 136 to 140) indicates that $\bar{v}'_\Gamma/\bar{u} \to 0$ when $B/h_{av} \to \infty$, and thus

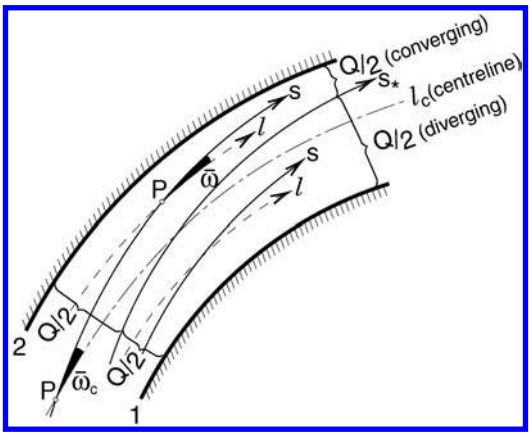

Figure 3. Laterally adjacent convergence-divergence flow zones in a meandering flow.

that Γ ($\sim \bar{v}'_\Gamma$) can be ignored when B/h_{av} is "large". The irrelevance of Γ with regard to the formation of wide natural streams has been independently pointed out in the past by many eminent field-research engineers (such as Leliavskii 1959, Matthes 1948, 1941, Kondratiev et al. 1982, Velikanov 1955 and Makaveyev 1975). [More on the topic in Chapter 5 of Yalin & da Silva 2001; see also Hooke 1974 and Hooke 1980.]

2 CONVECTIVE FLOW AND SEDIMENT TRANSPORT

(i) Consider the flow in a wide meandering channel at the beginning of experiment (at the time $t = 0$): the channel bed is *flat* (it is the graded surface of a mobile bed). The vertically-averaged streamlines s of this (initial) flow are not parallel: in some parts of the flow-plan they converge, in some others they diverge from each other (Figure 3). Let s_* be the streamline separating two (laterally adjacent (inner and outer)) zones, each conveying half the flow rate ($Q/2$). It can be demonstrated, on the basis of longitudinal periodicity of meandering flow (see Yalin & da Silva 2001), that s_* is at the same time the line which separates the laterally adjacent zones of converging and diverging flows. e.g. in Figure 3, s_* separates the converging (convectively accelerating) flow-zone on the side of the Bank 2, from the diverging (convectively decelerating) flow-zone on the side of the Bank 1.

In sine-generated streams, the pattern formed by the streamlines in plan view varies periodically along l_c: the flow characteristics in the cross-sections separated by the length L are identical, those in the cross-sections separated by $L/2$, are antisymmetrically identical.

Copyright © 2006 Taylor & Francis Group plc, London, UK

(ii) Since the local sediment transport rate q_s is an increasing function of the (local) vertically-averaged flow velocity $\overline{U}$, the convective variation of $\overline{U}$ in a flow zone must inevitably cause the corresponding convective variation of q_s in that zone; i.e. it must cause the scalar $\nabla \mathbf{q}_s$ to acquire a non-zero value. But $\nabla \mathbf{q}_s \neq 0$ must, in turn, induce the displacement of the bed surface in vertical direction (z) – as required by the sediment transport continuity equation

$$W = (1-p)\frac{\partial z_b}{\partial t} = -\nabla \mathbf{q}_s , \tag{5}$$

where W is the vertical displacement velocity of the bed surface. This equation indicates that if $\nabla \mathbf{q}_s > 0$, then $W < 0$ (erosion), and if $\nabla \mathbf{q}_s < 0$, then $W > 0$ (deposition). Only in the locations where the flow is parallel, and thus $\nabla \mathbf{q}_s = 0$, the elevation z_b of the bed surface can remain unchanged ($W = 0$).

Let T be the duration of bed development. Integrating (5) over $0 < t < T$, we obtain

$$(z_b)_T \sim -\int_0^T \nabla \mathbf{q}_s dt \tag{6}$$

i.e.

$$(z_b)_T \sim -(\nabla \mathbf{q}_s)_m T = W_m T . \tag{7}$$

This relation conveys that the (total) displacement $(z_b)_T$ of the bed surface at a location of flow plan is an increasing function of $-(\nabla \mathbf{q}_s)_m = W_m$, i.e. of the intensity of convective behaviour of flow at that location. At this stage it may also be mentioned that for the same remaining conditions, the plan-geometry of the streamlines s and thus of the converging-diverging flow zones varies depending on the plan shape of the meandering stream, i.e. with the value of the deflection angle θ_0.

3 BED DEVELOPMENT

The deformed bed of a meandering stream consists of a longitudinal sequence of laterally adjacent "deeps" and "hills" (see Figure 4a, where, as example, an intermediate value of θ_0 is used). Each (deep) + (hill) complex can be viewed as one erosion-deposition zone (in short [ED]). From the preceding section it should be clear that each [ED] is brought into being by a (corresponding) convergence-divergence zone (in short by [CD]) of the initial flow. Hence the length of each [ED] must be the same as that of each [CD], viz $L/2$. The channel cross-sections separating the successive [CD]'s (and [ED]'s) are identifiable by the fact that the streamlines s at those sections must be parallel to each other, i.e. we must have at those sections, $\overline{\omega} = 0$ (see Figure 3). Moreover, the deeps and

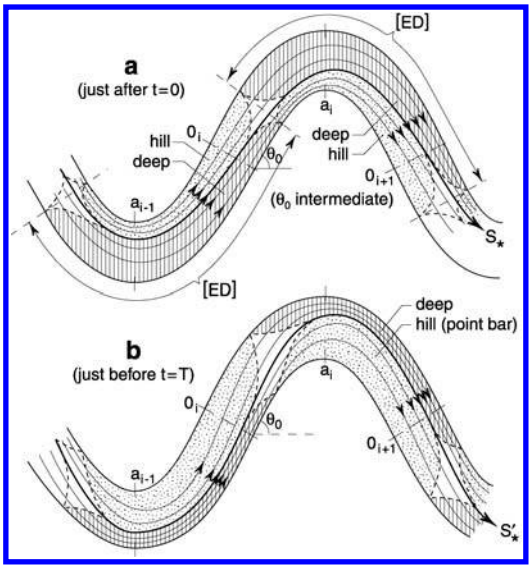

Figure 4. Schematical representation of convergence-divergence zones [CD]'s and corresponding erosion-deposition zones [ED]'s.

hills forming an [ED] of infinitesimal amplitude, just after $t = 0$, must be expected to be separated from each other by the same streamline s_* which separates the convergence-divergence zones of the initial flow (Figure 4a). The meandering streams under study are periodic along x, and therefore the consecutive [ED]'s are anti-symmetrically identical.

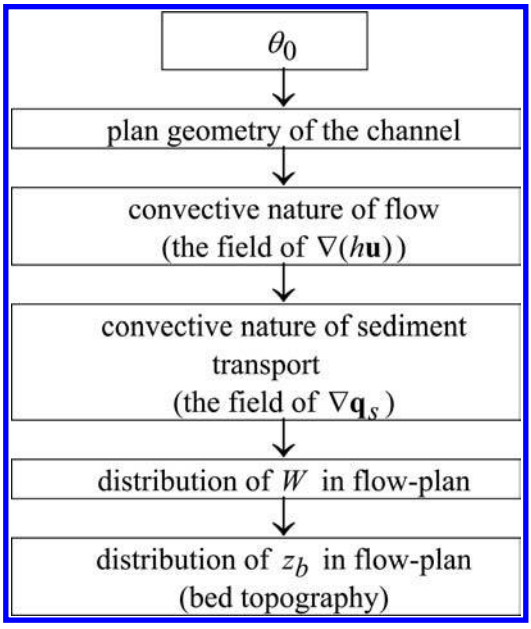
Both hills and deeps are rather flat (non-prominent) at any t ($\in[0; T]$). Their longitudinal and radial steepnesses can be expressed as

$$S_l \approx \delta/(L/2) < 2h/L \tag{8a}$$

and

$$S_r \approx \delta/(B/2) < 2h/B , \tag{8b}$$

respectively. Here $\delta(=\delta_H$ or $\delta_D)$ implies the height of hills and the depth of deeps (at a time t), respectively. Since δ_H and δ_D are comparable, we can write roughly



$$S_l / S_r \approx \frac{B}{L} . \tag{9}$$

The process of bed deformation is solely due to the transfer of bed material from the area of deeps to the area of hills (as effected by the convective flows over these areas). These locally transferred transport rates, which occur only during $0 < t < T$, are superimposed on the (always present) "transit" transport rate. In wide natural meandering streams, the material eroded from a deep (and/or banks) is deposited predominantly on the next hill (bank) on the *same* side of the flow: "only

Copyright © 2006 Taylor & Francis Group plc, London, UK

a small portion of eroded material crosses the channel" (Leliavskii 1959, Matthes 1941, 1948, Kondratiev et al. 1982, Velikanov 1955, Makaveyev 1975).

The cause-effect sequence embodied in the present approach can be summarized as follows:

From laboratory measurements of sine-generated meandering flows having a flat bed (see Whiting & Dietrich 1993a,b, da Silva 1995, Termini 1996) it follows that:

If θ_0 is "small" (Figure 5a), then a [CD] extends between the apex-sections a_i and a_{i+1} (where $\overline{\omega} = 0$), the most intense convergence/divergence ($\overline{\omega}_{\max}$) being at the crossover-section O_{i+1};

If θ_0 is "large" (Figure 5b), then the analogous [CD] extends between the crossover-sections O_i and O_{i+1} (where $\overline{\omega} = 0$), the most intense convergence/divergence ($\overline{\omega}_{\max}$) being at the apex-section a_i.

Hence the deepest erosions and highest depositions must be expected to occur around the crossovers O_i if θ_0 is "small", and around the apex-sections a_i if θ_0 is "large". The examples of actual streams shown in Figure 6 appear to validate these expectations.

The following two assertions can be made on the basis of the aforementioned:

1. Every different plan geometry of a meandering stream (i.e. every different θ_0) possesses "its own" type of convective flow and thus its own distribution of [CD]'s in the flow plan. (There is no "standard" pattern of streamlines of a meandering flow).
2. The locations (in plan view) of [ED]'s of a deformed bed are approximately in coincidence with the locations of [CD]'s of the initial flow past the flat bed. ([ED]'s are the "imprints" of [CD]'s).

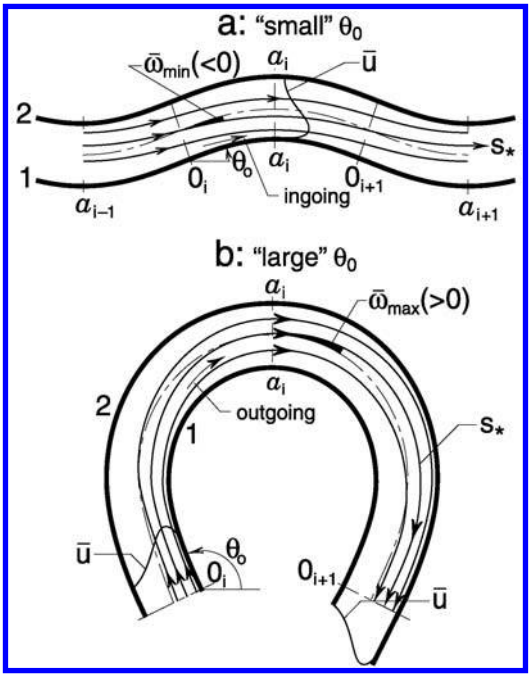


Figure 5. Convergence-divergence zones of initial flow in channels having "small" and "large" θ_0.

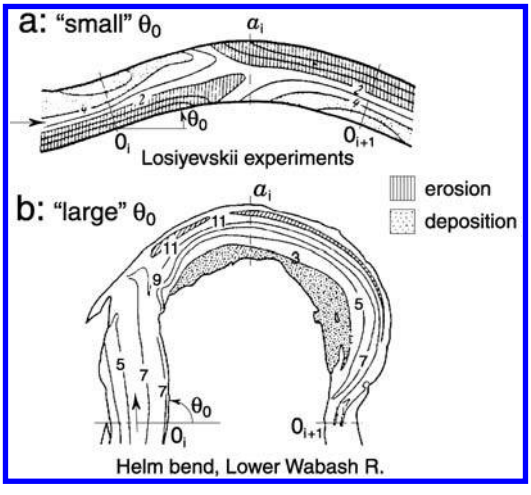

Figure 6. Bed topography in actual streams. a) Measurements reported by Makaveyev 1975; b) Measurements carried out by Jackson 1975.

The second assertion may not sound readily acceptable: "perhaps [ED]'s are moving (migrating) in longitudinal direction l_c during T, their locations at $t = T$ thus becoming different from those at $t = 0$ (i.e. from the locations of the initial [CD]'s)". With regard to this point, it should be mentioned that the displacement of

Copyright © 2006 Taylor & Francis Group plc, London, UK

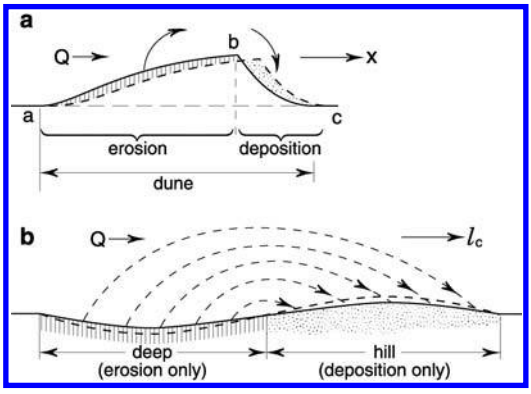

Figure 7. Migrating versus non-migrating "bed forms".

a bed feature can take place only if while one part of the feature is eroded, its remaining part is deposited. e.g. the ripples and dunes are moving (migrating) because while their upstream part $\overline{ab}$ is eroded, their (remaining) downstream part $\overline{bc}$ is deposited (Figure 7a). This is not the case of deeps and hills under study. Indeed, not a part, but the whole surface of a deep is subjected only to erosion, while that of a hill, only to deposition (by definition of these features). Hence, the deeps and hills can grow and deform, but they cannot move in longitudinal direction (Figure 7b).

The hills impede and thus repel the flow. By contrast, the deeps "invite" it. Hence the continual growth of the amplitude of hills and deeps during T causes a progressive "shift" of the flow from hills to deeps ("topographic steering" (Nelson & Smith 1989a,b)). In the process the flow velocity over the hills decreases, that over the deeps increases: hills themselves widen, deeps become narrower. As a result, the initial s_*-line approaches more and more to the bank on the side of the deep (s'_* in Figure 4b). The bed formation process stops (at $t = T$) when

$$W = (1-p)\frac{\partial z_b}{\partial t} = -\nabla \mathbf{q}_s = 0 \qquad (10)$$

is reached.

As mentioned earlier, in previous works the location of [CD]'s has been established experimentally only for the cases of "small" and "large" θ_0. From the considerations in this paper, it follows that if θ_0 is "intermediate", then the [CD]'s must necessarily be located in an intermediate position between that of "small" and "large" θ_0. However, it is not known at the present how exactly does the location of [CD's] in a meander loop vary as a function of θ_0. The following Section, where a series of flow measurements involving the systematic variation of θ_0 is used to establish the location of [CD]'s in streams of varying θ_0, is the authors' contribution to this topic.

4 LABORATORY INVESTIGATION ON LOCATION OF [CD]'S; VARIATION WITH θ_0

4.1 *Description of experimental setup and runs*

The measurements reported below were carried out in five sine-generated channels having $\theta_0 = 30°$, 50°, 70°, 90°, and 110°.

In all channels, the flow cross-section was rectangular, the flow width being $B = 0.40\,m$. In agreement with the conditions present in natural alluvial streams, and following Yalin 1992, Yalin & da Silva 2001, the flow width B and the meander wavelength Λ_M were related as $\Lambda_M \approx 2\pi B$. For the present flow width, this gives $\Lambda_M = 2.51\,m$. Each channel had the total extent of two meander lengths, viz $2L$, with the entrance- and exit-sections being in coincidence with apex-sections. The upstream-end of each channel was connected to a $0.8\,m$-long straight approach-channel; the downstream-end to a $0.6\,m$-long straight exit-channel leading to a return channel. The channel walls were made of Plexiglas; the channel beds were formed by sand having $D_{50} = 2.2\,mm$. The bed surface was scraped so as to have along the channel centerline the desired slope S_c; the bed slope in radial direction was zero. The grains of the uppermost layers were then immobilized by spraying the bed surface with a (50%) diluted varnish. The flow rate Q was kept constant throughout the duration of each run (steady flow). The free surface slope was adjusted by means of a tailgate until the flow depth h at the centerline of the four consecutive crossover-sections (sections 1_1, 1_2, 1_3, and 1_4 in Figure 8 later on) became identical.

The pertinent parameters characterizing the plan geometry and hydraulic conditions in each channel are summarized in Table 1. Here $h_{av} =$ channel-averaged flow depth, $S_c =$ bed slope along the channel centerline, $u_{av} =$ channel-averaged flow velocity ($=Q/(Bh_{av})$). Table 1 also displays the values of the following channel-averaged quantities: $v_* =$ shear velocity, $c_{av} =$ dimensionless (Chézy) resistance factor, $B/h_{av} =$ width-to-depth ratio, $Re =$ flow Reynolds number, $Fr =$ Froude number, and $Re_* =$ roughness Reynolds number. The values of Fr and Re_* in Table 1, which fall in the ranges $0.271 < Fr < 0.363$ and $71 < Re_* < 78$, indicate that the flow was subcritical and rough turbulent in all experimental runs. The values of B/h_{av} and c_{av} were similar in all runs: $B/h_{av} \approx 13$; $c_{av} \approx 10$.

The effective (or measurement) region in each channel consisted of three consecutive meander loops Λ_1, Λ_2, and Λ_3, as shown in Figure 8. In each loop $\Lambda_i (i = 1, 2, 3)$, the values of $\overline{u}$, h and $\overline{\omega}$ were measured in eight equally spaced sections 1_i, 2_i, …., 8_i. In each of these "l_c-sections", $\overline{u}$ and h were measured, with the aid of a traversing mechanism, at several points along the cross-section; $\overline{\omega}$ was measured only at the centreline (i.e. only $\overline{\omega}_c$ was measured). For complete

Copyright © 2006 Taylor & Francis Group plc, London, UK

details on equipment and measurement techniques, see da Silva 1995 and Tape 2001.

The value of η_* at each l_c-section was calculated from the measured values of $\overline{u}$ and h (at that l_c-section).

4.2 *Experimental results*

(i) The distribution of the convergence-divergence flow zones in flow plan can be revealed with the aid of the "$\overline{\omega}_c$-curve", which indicates how the deviation angle $\overline{\omega}_c$ (at the channel centerline) varies along ξ_c. On the other hand, these zones can be revealed also by means of the streamline s_*, i.e. by means of the function $\eta_* = \varphi_{\eta_*}(\xi_c)$, where $\eta_* = n_*/B$ is the (positive or negative) lateral dimensionless deviation of s_* from the centerline ξ_c. In the following, the plan distribution of convergence-divergence zones of the experimental meandering flows will be revealed by determining both, their η_*- and $\overline{\omega}_c$-curves.

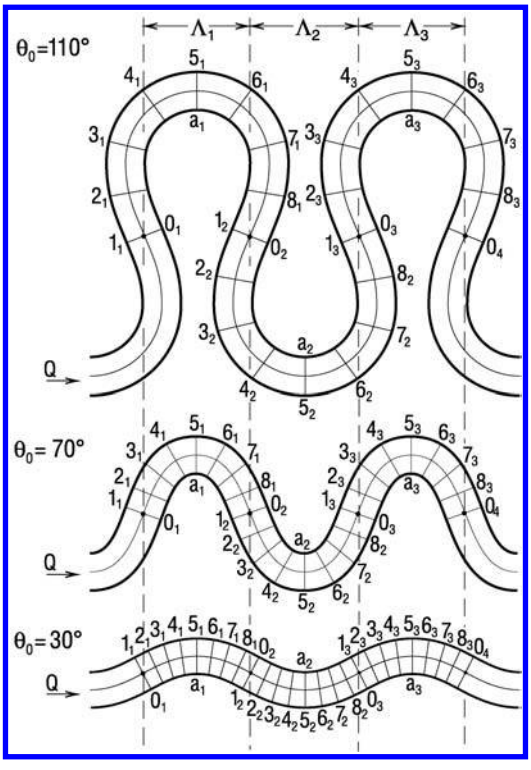

Figure 8. Schematical representation of the experimental channels having $\theta_0 = 30°$, 70° and 110°.

Before proceeding to the presentation and discussion of the results of the measurements, it may be useful to consider first the relation between the η_*- and $\overline{\omega}_c$-curves. For this purpose, consider the behaviour of the streamline s_* and of $\overline{\omega}$ for the cases of "small" and "large" θ_0 (see Figures 5a and b). Clearly, at the cross-sections (l_c-sections or ξ_c-sections) where $\eta_* = n_*/B = 0$, then $\overline{\omega}_c$ is either max or min, while at the sections where η_* is max or min, then $\overline{\omega}_c = 0$. It follows that, for any given θ_0, the curves representing the variation of the normalized $\overline{\omega}_c/(\overline{\omega}_c)_{\max}$ and $\eta_*/(\eta_*)_{\max}$ along ξ_c must be expected to be two (likely similar) sinusoidal curves separated from each other by the horizontal distance $\Delta\xi_c = 1/4$, the $\overline{\omega}_c/(\overline{\omega}_c)_{\max}$-curve always lying to the left of the $\eta_*(\eta_*)_{\max}$-curve.

(ii) Figures 9a to e show the plots of the (normalized) measured $\overline{\omega}_c$-data versus ξ_c and η_*-data versus ξ_c^* ($= \xi_c - 1/4$) for the channels having $\theta_0 = 30°$, 50°, 70°, 90° and 110°, respectively. The values of $\eta_*/(\eta_*)_{\max}$ are plotted versus ξ_c^*, rather than versus ξ_c, so that the $\overline{\omega}_c$- and η_*-point patterns overlap (see paragraph (i) above).

The solid line in each of Figure 9a to e is the best visual "sine-like" fit to the point-pattern formed by both, the plot of measured $\overline{\omega}_c/(\overline{\omega}_c)_{\max}$ versus ξ_c and $\eta_*/(\eta_*)_{\max}$ versusξ_c^*. (The utilization of one single "sine-like" curve to fit the two data sets in each of Figure 9a to e is justified on the basis of paragraph (i).)

(iii) For the sake of clarity, in this paragraph we will focus exclusively on the $\overline{\omega}_c/(\overline{\omega}_c)_{\max}$-curves. However, a discussion similar to the one below could equally well be carried out on the basis of the $\eta_*/(\eta_*)_{\max}$-curves.

The solid lines in Figures 9 represent, for the present experimental conditions, the distribution of $\overline{\omega}_c/(\overline{\omega}_c)_{\max}$ along three consecutive [CD]'s. The

occurrence of $\overline{\omega}_c = 0$ and thus $\overline{\omega}_c/(\overline{\omega}_c)_{\max} = 0$ signify simultaneously the end of one [CD], and the beginning of a new one. More specifically, a transition from $\overline{\omega} < 0$ to $\overline{\omega} > 0$, say, indicates a transition from a $L/2$-long *convergence-divergence* zone to a $L/2$-long *divergence-convergence* zone. In these figures, ξ_{c0} is the value of ξ_c where the first transition from $\overline{\omega} < 0$ to $\overline{\omega} > 0$ occurs.

Consider first Figure 9a, which corresponds to $\theta_0 = 30°$. In this Figure, $\overline{\omega}_c$ maintains its (positive or negative) sign throughout [CD]'s whose upstream- and downstream-ends are slightly upstream of two consecutive apex-sections (a_i and a_{i+1}, say). In particular, $\overline{\omega} > 0$ nearly between a_1 and a_2. In Figure 9e, which corresponds to $\theta_0 = 110°$, $\overline{\omega}_c$ maintains its (positive or negative) sign throughout flow regions of the length $L/2$ whose upstream- and downstream-ends are slightly downstream of two consecutive crossover-sections (O_i andO_{i+1}, say). In particular, $\overline{\omega} > 0$ nearly between O_1 and O_2. In Figures 9b to d, which correspond to $\theta_0 = 50°$, 70° and 90°, respectively, $\overline{\omega}_c$ maintains its sign in $L/2$-long flow regions situated somewhere between those for $\theta_0 = 30°$ and $\theta_0 = 110°$, with the $\overline{\omega}_c$-curves clearly shifting more and more to the left as θ_0 increases (note from Figures 9a to e how ξ_{c0} decreases as θ_0 increases).

The gradual shifting-to-the-left of the $\overline{\omega}_c$-curves observed in Figures 9a to e is summarized in the conceptual Figure 10. It is postulated that the upstream- and downstream-ends of the decelerated region at the inner bank 1 (defined as shown in Figure 3) coincide *exactly* with the apex-sections a_i and a_{i+1} in the limit $\theta_0 \to 0$ ($\sigma \to 1$); and that the upstream- and downstream-ends of the decelerated region (at the bank 1) coincide *exactly* with the crossover-sections O_i and O_{i+1} when $\theta_0 \to 138°$ ($\sigma \to \infty$). Thus, in Figure 10, the curves C_0 and C_{138} are the limiting curves corresponding to $\theta_0 = 0$ and $\theta_0 = 138°$. [It should be noticed that the maximum possible value of θ_0 is $\theta_0 \approx 138° = 2.41$ rad, which corresponds to $J_0(\theta_0) = 0$ and $L, \sigma \to \infty$ (see Eq. (2)). However, in practice, this can never occur, for when θ_0 reaches the value $\approx 126° = 2.20$ rad ($\sigma \approx 8.5$), the meander loops come into contact with each other and the meandering pattern is destroyed.]

(iv) Consider now two consecutive meander loops $O_iO_{i+1}O_{i+2}$ (where O_i is a crossover-section as shown in Fig. 1), and let L be the [CD] within these two loops where $\overline{\omega}$ is positive, say (and thus

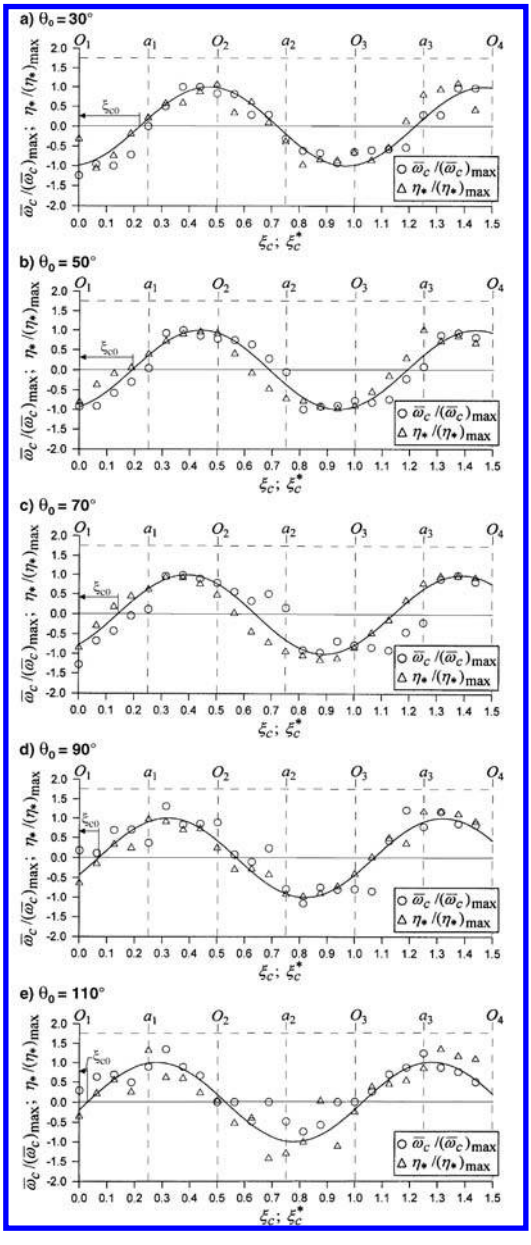

Figure 9. Plots of measured $\overline{\omega}_c/(\overline{\omega}_c)_{\max}$ versus ξ_c and $\eta_*/(\eta_*)_{\max}$ versus ξ_c^* ($= \xi_c - 1/4$).

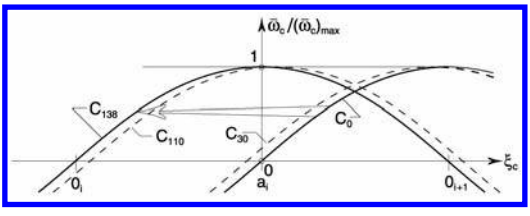

Figure 10. $\overline{\omega}_c/(\overline{\omega}_c)_{\max}$-curves corresponding to different values of θ_0 (e.g. C_0 corresponds to $\theta_0 = 0$, etc.).

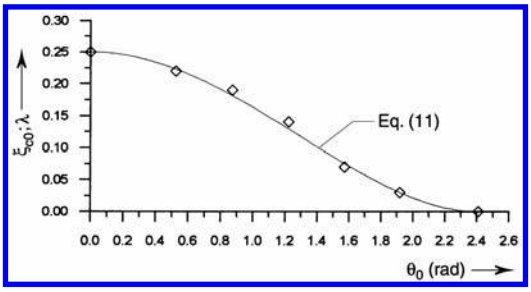

Figure 11. Plot of $(\xi_c)_0$ and λ versus θ_0.

where the flow diverges from bank 1 and converges to bank 2 (banks 1 and 2 being as defined in Figure 2)). It should be clear that the gradual shifting-to-the-left of the $\overline{\omega}_c$-curves described above implies that the location of L in the flow plan gradually shifts upstream as θ_0 increases. Observe that ξ_{c0} is but the (normalized by L) longitudinal coordinate of the ξ_c-section coinciding with the upstream-end of L. From Figures 9 and 10, it follows that ξ_{c0} gradually decreases from 0.25 to 0 as θ_0 increases from 0° to 138°. [It should be noted that from the knowledge of ξ_{c0} alone, it is possible to infer the distribution in plan of flow convergence-divergence zones of flow throughout the entire flow domain (the entire length of the channel). For the aforementioned [CD] where $\overline{\omega} > 0$ (region L) is preceded and followed by [CD]'s where $\overline{\omega} < 0$, which in turn are preceded and followed by [CD]'s where $\overline{\omega} > 0$, etc.).]

(v) The $(\xi_c)_0$-values supplied by the diagrams in Figures 10a to e are plotted versus θ_0 in Figure 11. Since in the limits $\theta_0 \to 0$ and $\theta_0 \to 138°$, the value of $(\xi_c)_0$ is expected to approach 0.25 and 0, respectively, these values of $(\xi_c)_0$ are also included in Fig. 11.

The resulting point-pattern is well approximated by the fourth degree polynomial

$$(\xi_c)_0 = 0.0033\theta_0^4 + 0.0198\theta_0^3 - 0.1100\theta_0^2 + 0.25 \ , \qquad (11)$$

where θ_0 is in radians.

Using dimensional analysis, Yalin & da Silva 2001, pp. 134 to 136, have shown that the convective nature of meandering flows must be expected to depend on θ_0, B/h_{av} and c_{av}. This implies that $(\xi_c)_0$ – and thus the distribution of [CD]'s in flow plan – is a function of three variables: $(\xi_c)_0 = \varphi(\theta_0, B/h_{av}, c_{av})$. The solid line in Figure 11 represents the variation of $(\xi_c)_0$ with θ_0 for specified B/h_{av} and c_{av} (namely $c_{av} \approx 10$ and $B/h_{av} \approx 13$ of the present experiments). Future research involving the systematic variation of B/h_{av} and c_{av} for specified values of θ_0, and directed towards the determination of the function $(\xi_c)_0 = \varphi(\theta_0, B/h_{av}, c_{av})$ would be worthwhile. In particular, it would be relevant to establish the extent to which variations in B/h_{av} and c_{av} lead to deviations form the solid line in Fig. 11.

(vi) Within a meander loop $O_i a_i O_{i+1}$, let λ be the dimensionless coordinate, measured with regard to the apex-section a_i, of the ξ_c-section where maximum erosion-deposition must be expected to occur (erosion at the outer bank, deposition at the inner bank). Since the [CD]'s of the vertically-averaged initial flow are approximately in coincidence with the [ED]'s of the developed bed, the graph of $(\xi_c)_0$ versus θ_0 is, at the same time, the graph of λ versus θ_0 (which explains why in Fig. 11, both $(\xi_c)_0$ and λ are used as ordinate). But this means that, for the same remaining conditions, the location of "deeps" and "hills" continuously moves upstream from the crossover O_{i+1} to the apex a_i as θ_0 increases from "small" to "large". The study on the location of erosion-deposition zones in da Silva and El-Tahawy 2006 (paper in these Proceedings) confirms that this is indeed the case.

5 CONCLUDING REMARKS

The approximate coincidence between the location of the convergence-divergence zones of the initial flow (over the flat (moveable) bed surface at $t = 0$) and the location of the erosion-deposition zones of the developed (equilibrium) bed (at $t = T$) is explained on the basis of the sediment transport continuity equation. It is concluded that the "information" needed for a flow to (subsequently) generate its deformed bed surface at $t = T$ is already locked in the convective structure of the (vertically-averaged) meandering flow at its initial stage at $t = 0$ (when the bed is still flat).

It follows that the nature of bed topography can be inferred from the structure of the initial flow. In particular, the "property" ξ_{c0} of the initial-flow can be used as a (rough) estimate of the dimensionless coordinate λ, measured with regard to the apex-section a_i, of the ξ_c-section where maximum erosion-deposition must be expected to occur (erosion at the outer bank, deposition at the inner bank).

Gravitational effects on river morphodynamics

ABSTRACT: In the present work an experimental study devoted to investigate the effects of transversal slopes on the bedload sediment transport and on the morphodynamic evolution of a mobile bed was carried out. The general aim of such investigation is the experimental observation of the evolution of a laterally tilted bed from the initial configuration to the final one, laterally flat, under conditions of uniform flow. The bottom topography was measured at the beginning and during the experiments for different time lengths; complementary data regarding the applied shear stresses and the particle velocity are inferred from a previous experimental activity on bedload transport over an non-erodible bed. The experimental results about the evolution of the bed were interpreted theoretically by solving numerically the 3-D governing morphodynamic problem employing the non linear theoretical model for bedload transport over sloping beds proposed by Parker, Seminara and Solari (2003). The experimental observations are compared to the results obtained from the numerical model in terms of the evolution of the bed topography, applied shear stress and sediment transport rate in longitudinal and transversal directions. In the present contribution, both experimental and numerical results are presented and discussed.

1 INTRODUCTION

The evaluation of the bedload transport on an arbitrarily sloping bed is one of the crucial aspects in any morphodynamic model that considers the evolution of the bed: when the bed is tilted in both longitudinal and transversal direction the gravity plays an important role on particle dynamics and on bedload transport (Sekine and Parker 1992; Kovacs and Parker 1994; Nino and Garcia 1994a; Nino and Garcia 1994b; Talmon et al. 1995).

This problem has been recently tackled by Parker et al. (2003) through a non-linear theoretical model which provides a vectorial description of the bedload transport on arbitrarily sloping beds at low Shields stress. The results of this model were verified by Francalanci & Solari (2005) by means of an experimental activity devoted to study the sediment motion over a plane, non-erodible, artificially roughened bed tilted longitudinally and laterally. The latter experimental observations on the non-erodible bed showed a good agreement with the theoretical model, and an interpolated equation for bedload transport was then derived by Francalanci & Solari (2006) to employ Parker et al. (2003) model, which may increase the computational costs of the morphodynamic modeling.

In the present work an experimental study devoted to investigate the effects of transversal slopes on sediment transport dynamics and on the morphodynamic evolution of a mobile bed is presented. The experimental observation of the evolution of a laterally tilted bed from the initial configuration to the final one, laterally flat, under conditions of uniform flow, was monitored and measured.

The whole experimental activity here presented was based on experiments on both non-erodible and mobile sloping bed in longitudinal and transversal direction: the experiments on the non-erodible bed revealed the bed shear stress, the particle velocity and the bedload transport rate, while the experiments with mobile bed revealed the gravitational effects on the bed evolution.

The evolution of the bed was monitored and interpreted theoretically by solving numerically the three-dimensional morphodynamic problem with the help of the sediment transport relationship inferred both from the non-linear model of Parker et al. (2003) and from the linear model of Ikeda (1982). The experimental observations are compared to the results obtained from the numerical model in terms of the evolution of bed topography, applied shear stress at the bed and sediment transport rate in longitudinal and transversal directions. This comparison suggests that the evaluation of the transversal component of the bedload transport is crucial to describe the morphodynamic evolution of the bed.

2 EXPERIMENTAL SET-UP

2.1 *Experimental apparatus*

The evolution of the mobile bed was investigated in a free surface laboratory flume. The experiments were carried out in a tilting, recirculating flume, 10 m long, 0.365 m wide and 0.45 m deep, equipped for clear water flows up to 28 l/s and slope adjustment up to 5°. In order to obtain higher bed inclinations, a 2 m long 0.23 m wide plane was built inside the flume with inclination adjustable up to 15°. Due to entrance effects the length of the measuring reach was about 1 m. Water flow was supplied at one end of the flume from a centrifugal pump and the water discharge was monitored by an electromagnetic flow-meter. The sediment particles were fed at a constant discharge by means of a sediment feeder.

2.2 *Sediment material*

The employed particles satisfied the following requirements in all the range of investigated bed slopes: mobility at low Shields stress; ratio of water depth to particle size sufficiently high to allow particle saltation, even in the case of high bed slope; relatively high friction angle. The selected material was represented by steel particles with a density of 7850 kg/m^3, shaped like disks with almost uniform size of 3 mm of maximum diameter and of 0.6 mm thickness. The use of steel particles with a higher density, compared to the common fluvial sediments, allowed one to perform sediment transport experiments on a free surface laboratory flume with high local inclinations of the bed and sufficiently high water depth. The not spherical shape allowed particles disposition according to a given transversal inclination, for performing the mobile bed experiments.

2.3 *Mobile bed set-up*

The mobile bed was disposed according to a given longitudinal α and transversal φ inclination. The cross-section was constant and the flow was uniform. Two zones of fixed bed were located upstream and downstream of the mobile bed which was 5 m long. A sketch of the experimental set-up is shown in Figure 1. Along the mobile bed the bed elevation was measured in different cross-sections. The measuring cross-sections were located at a distance of 50 cm at the beginning of the mobile bed and of 25 cm closer to the end, where the equilibrium configuration was reached, as shown in Figure 2.

For each cross-section, the bed elevation was measured using a pointgage in 7 verticals, spaced about 3 cm.

3 EXPERIMENTAL PROCEDURE

At the beginning of each experiment, the mobile bed was arranged according to the given longitudinal and transversal inclination and the initial configuration of the bed elevation was measured.

After the preparation, the experiments were performed according to the following procedure. First the flow discharge was adjusted to the assigned value: during this transient period the bed was not allowed to evolve. Then the experiment was started and the evolution of the bottom topography was observed, using a video recorder. Different experiments with different time length were performed in order to measure the bed elevation at the end of each run, in dried condition. The transient period at the end of the run was such that it did not influence the bed configuration. The bottom topography was measured at the beginning and at the end of the experiments for different time lengths; additional data regarding the applied shear stresses and the particle velocity are inferred from the previous experimental activity of bedload transport on non erodible bed.

4 MOBILE BED EXPERIMENTS

The initial experimental conditions for the performed runs are reported in Tab. 1, in particular the longitudinal inclination of the bed is from 1.72° to 10° while the transversal inclination is 5° and 10°. In order to relate the initial conditions of the mobile bed with the complete set of measurements collected during the non-erodible bed experiments, the initial conditions for the present experiments were selected among the whole set of configurations for which the experiments on the non-erodible bed were performed. In this way the quantities bed shear stress, flow velocity profile, particle velocity and bedload transport rate were known at the beginning of each experiment. The experiments Run 2b and Run 4 were performed with a shorter mobile bed reach, 1.5 m instead of 5 m.

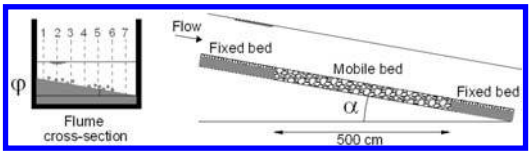

Figure 1. Sketch of the set-up for the mobile bed experiments.

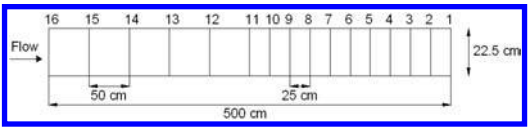

Figure 2. Plan view of the mobile bed, the numbers specify measuring cross-section locations.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Moreover, the all cross-sections needed to be invaded by the flow as phenomena such as bank collapse were not addressed in this study.

To underline the equilibrium configuration that the cross-section is able to reach, the bottom evolution of Run 2a is shown here (Fig. 3). After 30" an erosion phenomenon can be observed at the beginning of the mobile bed due to the transition from fixed to mobile bed, and the laterally tilted bed started to evolve from the initial configuration. After 60" the mobile bed is close to the equilibrium configuration, which can be observed for the bottom profile measured after 210": the erosion phenomenon at the beginning of the mobile bed is increased due to the difficulties on maintaining the sediment feeding in equilibrium with the bedload transport capacity, while at the end of the mobile bed the equilibrium cross-section laterally flat can be observed.

The Run 1 was performed with a relative low longitudinal inclination. The initial bottom topography showed a transversal inclination. The topography of the bed was measured for 4 different time lengths. The beginning of the mobile bed was affected by a local

Table 1. Initial experimental conditions for the mobile bed experiments.

Run Code	α [°]	φ [°]	Q_w $[l/s]$	Time [″]
Run 1	1.72	10	15.4	180–270–360–540
Run 2a	5	5	5.98	30–60–210
Run 2b	5	5	7.5	30–180
Run 3	5	10	7.02	30–60–150–210
Run 4	10	5	4.5	20–40–72

erosion phenomenon, but the equilibrium mobile bed was achieved at the end of the reach. The measured cross-sections are averaged at the end of the measuring reach. The mobile bed reached the transversal equilibrium configuration after about 540", as shown in Figure 4(a).

The Run 2 was performed with two different flow discharges. The experimental results of the Run 2a are reported in Figure 4(b). The Run 2b showed a faster evolution of the mobile bed because the intensity of the bedload transport was increased along the cross-section (Fig. 4(c)).

The Run 3 was performed with a higher transversal inclination than Run 2: the mobile bed reached the equilibrium configuration and then a slow average erosion phenomenon is observed in the equilibrium cross-section, due to the changing of the bedload discharge according to the flow (Fig. 4(d)).

The Run 4 was performed with a high longitudinal inclination ($\alpha = 10°$), and the mobile bed reach was 1.5 m long. In this experiment the time evolution of the observed phenomenon was rapidly changing and hence the bottom topography was difficult to control and monitorate. The final profiles along the cross-section are shown in Figure 4(e).

5 EVOLUTION OF A LATERALLY TILTED MOBILE BED

The evolution of the bed was monitored and interpreted theoretically by solving the three-dimensional morphodynamic problem with the help of the sediment transport relationship proposed by Francalanci & Solari (2006), derived by the theoretical model of Parker et al. (2003) and verified by means of the experimental observations on a non-erodible sloping bed. The experimental observations on the mobile bed are here compared to the results obtained from the numerical model that employs the verified theoretical model, in terms of the evolution of bed topography, applied shear stress and sediment transport rate in longitudinal and transversal directions.

5.1 *3D numerical model*

The numerical model adopted in the present analysis is the one proposed by Vignoli (2004) suitable modified in order to employ Parker et al. (2003) non linear model. The model is here briefly summarized. The model considers a straight channel with vertical banks, characterized by cohesionless bed and constant width $2B^*$.

The dimensional variables are made dimensionless adopting suitable scales: the channel half width B^* to scale the planimetric coordinates; a reference flow depth H_o^* to scale the vertical coordinate z^*, the local free surface elevation h^*, bed elevation η^* and flow depth H^*, a reference flow velocity U_o^* to scale the velocity components. Furthermore a characteristic time scale $T_o^* = B^*/U_o^*$ is introduced. The reference values U_o^* and H_o^* can be readily defined in the river case as the depth averaged velocity and depth of the uniform flow, for given discharge, bed slope and sediment size. In dimensionless form such reference state is completely determined once the following dimensionless parameters are given:

$$\beta = \frac{B^*}{H_o^*} \tag{1}$$

$$D_s = \frac{D^*}{H_o^*} \tag{2}$$

$$\tau_{*o} = \frac{(U_o^*)^2 C_{fo}}{(s_g - 1)\, g D^*} \tag{3}$$

$$R_p = \frac{\sqrt{(s_g - 1)\, g D^{*3}}}{\nu} \tag{4}$$

where D^* is sediment diameter, s_g is the specific density of sediment, ν is the kinematic viscosity of water, and C_{fo} is the friction coefficient of the reference uniform flow.

In dimensionless form, and keeping only significant turbulent flux, the Reynolds equations along the longitudinal and transversal direction, the flow continuity equation and the sediment continuity equation read:

$$\frac{\partial U}{\partial t} + U\frac{\partial U}{\partial x} + V\frac{\partial U}{\partial y} + \beta W\frac{\partial U}{\partial z} - \\ -\gamma\frac{\partial}{\partial z}\left(\nu_T\frac{\partial U}{\partial z}\right) + \frac{1}{F_o^2}\frac{\partial h}{\partial x} + \frac{i_F}{F_o^2} = 0 \tag{5}$$

$$\frac{\partial V}{\partial t} + U\frac{\partial V}{\partial x} + V\frac{\partial V}{\partial y} + \beta W\frac{\partial V}{\partial z} - \\ -\gamma\frac{\partial}{\partial z}\left(\nu_T\frac{\partial V}{\partial z}\right) + \frac{1}{F_o^2}\frac{\partial h}{\partial y} = 0 \tag{6}$$

$$\frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} + \beta\frac{\partial W}{\partial z} = 0 \tag{7}$$

$$(1 - \lambda_p)\frac{\partial \eta}{\partial t} + Q_o\left(\frac{\partial Q_{bx}}{\partial x} + \frac{\partial Q_{by}}{\partial y}\right) = 0 \tag{8}$$

where (U, V, W) denote the three-dimensional velocity field and F_o is the Froude number of the reference flow.

The model yields the following boundary conditions for the flow field: the dynamic condition is satisfied imposing the vanishing stress at the free surface, which yields the zero vertical derivatives of longitudinal and transversal flow velocity; the kinematic conditions at the bed and at the free surface are automatically satisfied provided zero values of the vertical velocity and imposing no slip at the bottom, which yields zero velocity at the bed.

Closure assumption for the eddy viscosity ν_T is introduced assuming that the slowing varying character of the flow field both in space and in time leads to a sequence of equilibrium states. The eddy viscosity is evaluated using an algebraic approach, namely involving the local values of the shear velocity and of the flow depth; for the vertical distribution of the eddy viscosity we adopt the formulation given by Dean (1974).

A closure for the bedload transport need to be introduced. In the original implementation of the model, bedload transport $\mathbf{Q}_b$ is quantified in terms of the local and instantaneous value of the Shields stress, the intensity of bedload transport is evaluated using Parker (1990) formula. The gravitational effects on bedload transport are taken into account through a simplified semi-empirical approach which is formally justified only for small values of local bed slopes (Ikeda 1982;

Copyright © 2006 Taylor & Francis Group plc, London, UK

Kovacs and Parker 1994):

$$Q_{bx} = \frac{|\mathbf{Q}_b|}{|\boldsymbol{\tau}|}\left[\tau_x cos\left(\psi\right) - \tau_y sin\left(\psi\right)\right] \quad (9)$$

$$Q_{by} = \frac{|\mathbf{Q}_b|}{|\boldsymbol{\tau}|}\left[\tau_x sin\left(\psi\right) + \tau_y cos\left(\psi\right)\right] \quad (10)$$

$$tan\left(\psi\right) = -\frac{r}{\beta\sqrt{\tau_*}}\frac{\partial\eta}{\partial n} \quad (11)$$

where s is directed as the local bed shear vector, while n is orthogonal to the above direction, and ψ is the deviation angle of the bedload transport vector from the applied bed shear stress. Finally bedload intensity $|\mathbf{Q}_b|$ is assumed to be a function of $(\tau_* - \tau_{*c})$, with

$$\tau_{*c} = \left(\tau_{*co} + \frac{r_1}{\beta}\frac{\partial\eta}{\partial s}\right)\sqrt{1 - \frac{\left(\partial\eta/\partial n\right)^2}{tan^2\left(\phi\right)}} \quad (12)$$

According to experimental observations the empirical constants r and r_1 fall in the range (0.3–0.6) and (0.1–0.2), respectively. The bedload transport equation has been modified according to the bedload transport equations on arbitrarily sloping bed proposed by Francalanci and Solari (2006), to employ Parker et al. (2003) formulation.

The proposed equation has a simple polynomial expression of the bedload transport rate as a function of the applied Shields stress:

$$|Q_b| = A_q\left(\alpha,\varphi\right)\cdot\left(\frac{\tau_*}{\tau_{*co}}\right)^2 + B_q\left(\alpha,\varphi\right)\cdot\left(\frac{\tau_*}{\tau_{*co}}\right) + \\ + C_q\left(\alpha,\varphi\right) \quad (13)$$

while the direction of the bedload transport with respect to the direction of the applied bed shear stress is evaluated with the following expression:

$$\psi = A_\psi\left(\alpha,\varphi\right)\cdot\left(\frac{\tau_*}{\tau_{*co}}\right)^{B_\psi(\alpha,\varphi)} \quad (14)$$

where A_q, B_q, C_q, A_ψ and B_ψ are polynomial functions of α and φ.

The model follows the numerical semi-implicit procedure proposed by Casulli and Cattani (1994), according to which the non-linear terms appearing in the momentum equations are discretized using a Lagrangian approach, while the pressure term and the viscous term are solved implicitly; the approach has been modified to account for the no slip condition at the bed. In the present model a suitable logarithmic vertical coordinate is introduced such that the grid density decreases from the bed to the free surface: the logarithmic vertical coordinate minimizes the numerical truncation errors and achieves a better accuracy with the same number of grid points.

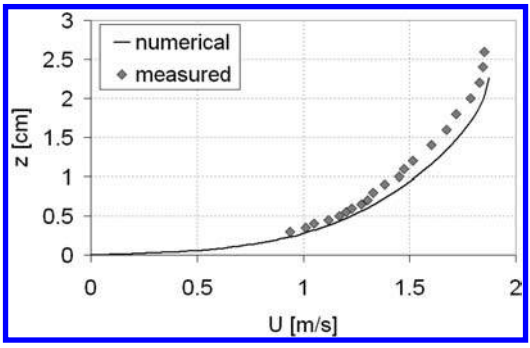

Figure 5. Fitting of the simulated flow velocity profile with the measured one, taken at a distance of 5 cm from the wall, Run 2a.

The solutions for the flow field are obtained using finite-differences technique. The solution for the bed elevation is evaluated from Exner's equation, solved with a decoupling algorithm between the hydrodynamics and the morphodynamics. The spatial mesh adopted in the numerical solution is a staggered grid and consists of rectangular boxes. The resulting numerical scheme seems sufficiently accurate and efficient to represent adequately the flow on fluvial system and their role in the development of bed topography.

5.2 *Comparison of experimental and numerical results*

The measurements of the mobile bed profiles are here compared to the results of the three-dimensional numerical model.

The numerical model simulated the experimental conditions in the flume, reproducing the measured quantities, such as the bed shear stress and the bedload transport intensity. The roughness coefficient was set such that the velocity flow profiles measured in the experimental activity on the non-erodible fixed bed were fitted to the profiles numerically simulated at the beginning of the run. The measured flow velocity profile compared to the numerically estimated ones is shown in Figure 5, in the experimental conditions of Run 2a; a similar fit was obtained for the other experimental conditions.

The measured profiles of the bed elevation are compared to the numerically computed ones, for different time length of the experiments, for Run 2a in Figure 6. The time evolution of the phenomenon is well reproduced, as well as the final equilibrium configuration in the cross-section. The numerical model is able to reproduce the equilibrium bedload transport, which is changing during the experiment; vice versa during the experimental Run the fed bedload discharge was adjusted to the changing stresses along the cross-section: this induced a net erosion phenomenon of the

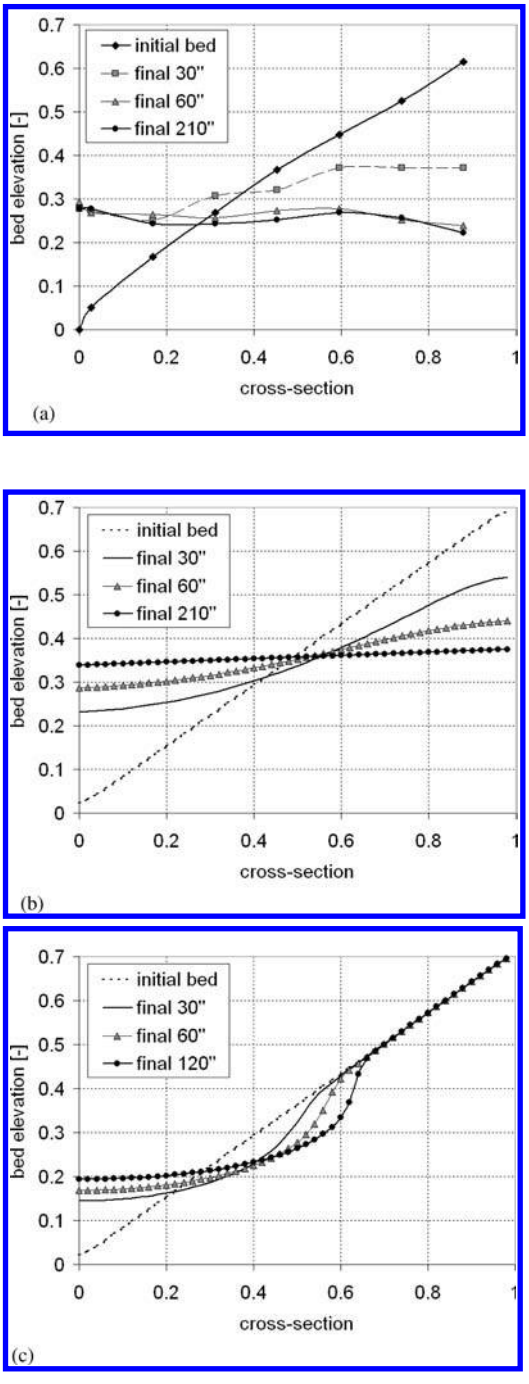

Figure 6. Comparison between the measured dimensionless bed elevation profiles and the numerically computed ones (Run 2a). (a) Measured bed profiles; (b) Numerical bed profiles employing the non-linear bed load transport of Parker et al. (2003). (c) Numerical bed profiles employing a linear bedload transport of Ikeda (1982).

average elevation within the cross-section. However, this phenomenon did not affect the transversal evolution of the bottom topography which reached a flat configuration.

The numerical results obtained employing Parker et al. (2003) formulation are compared with the results obtained employing Ikeda (1982) formulation: the comparison of the bed profiles reveals a different time and spatial evolution of the phenomenon, due to the under-estimation of the transversal bedload transport and of the bedload intensity estimated with the Ikeda (1982) formulation. In particular, the under-estimation of the lateral bedload transport with the linear formulation did not allow the bed to evolve in the upper part of the cross-section, while the flattening process is limited to a narrow region of the cross-section.

6 CONCLUSIONS

In the present work the experimental observations of the evolution of a mobile bed from the initial arbitrarily sloping configuration to the final laterally flat equilibrium configuration are presented and discussed.

The measured bed profiles are compared with the results obtained from a three-dimensional numerical model employing both the linear (Ikeda 1982) and the nonlinear formulation (Parker et al. 2003) to evaluate the bedload transport over an arbitrarily sloping bed. Results suggest that the linear formulation lead to a great underestimation of the lateral bedload transport which prevents the model to adequately describe the evolution of the bed whereas in the case of the non linear formulation the time and spatial morphodynamic evolution of the bed is well reproduced.

ABSTRACT: Equilibrium meander bends shift downstream with a constant speed while maintaining a coherent form. Based on a dynamical description of flow in alluvial river bends and a kinematic description of continuous bank erosion, Parker et al. (1983) derived a class of equilibrium meander planform shapes known as Kinoshita curves. These equilibria were found to be unstable, which has lead to the common idealized view that meanders alternately elongate by gradual bend erosion and shorten due to cut-off, and do not reach a true equilibrium. It is herein argued that the extremely slow rate of change of near-equilibrium meanders in conjunction with neglected aspects such as time variation of the threshold of sediment motion can be the reason why most undisturbed meanders found in nature are in fact near-equilibrium. It is therefore worthwhile to further examine and describe equilibrium meanders, which is the subject of the present study. Starting from the hypothesis that for equilibrium meanders the variance of entropy production is minimized, most probable planform parameter values are derived that determine how fattening and skewing (parameterized by c_f and c_s, respectively) of an equilibrium meander depend on sinuosity. Sinuosity, in turn, is mainly externally controlled. It is shown how the hypothesis ofminimumvariance of entropy production practically boils down to the assumption ofminimization of channel morphology change rates, revealing the mechanistic interpretation of the theory. The validity of our hypothesis is elucidated by a comparison with twenty four meander reaches of various geographical locations, and by the fact that for arbitrary sinuosities a unique minimum for the variance of entropy production in the (c_f, c_s)-plane exists.

1 INTRODUCTION

Present-day understanding of the mechanistic evolution of river meanders is captured by idealized models derived from the shallow water equations and the continuity equation of sediment. These meander bend models go back to the work of Ikeda et al. (1981), who delineated a bend equation by coupling the flow theory of Engelund (1974) for river bends to a kinematic treatment of bank erosion. Subsequent progress was due to Johannesson and Parker (1989), who added the effect of convective transport of primary flow momentum by the secondary flow, as formulated by Kalkwijk and De Vriend (1980). Zolezzi and Seminara (2001) further increased the level of detail of modelling the flow in their meander bend model, by extending the flow decomposition proposed by Kalkwijk and De Vriend (1980) with the aim to preserve the memory of the centrifugally induced secondary flow. Recently, Camporeale et al. (2005) performed long-term simulations with the three models mentioned above, for various river parameter configurations. They showed that each of the three models predict the same long-term statistics for geometrical planform parameters, indicating that the bend model by Ikeda et al. (1981) already contains all the necessary ingredients to describe the long-term dynamics.

In the research line described above, the existence of an equilibrium in which a meander shifts downstream with a constant speed while maintaining a coherent form was shown to exist for the model by Ikeda et al. (1981) (Parker et al. 1983), albeit an unstable equilibrium (Parker and Andrews 1986). Seminara et al. (2001) found that there are no equilibrium solutions to the model equations by Zolezzi and Seminara (2001). River meanders are hence considered to evolve towards a dynamical state, characterized by alternating phases of elongation induced by the local bend erosion and sporadic shortening caused by cutoff events. This gives an idealized view of alluvial river behavior on a millennial timescale, suggesting that neglected aspects such as discharge variation and associated variation

Copyright © 2006 Taylor & Francis Group plc, London, UK

of the threshold of sediment motion are irrelevant to the long-term behavior. Herein it is argued that it is worthwhile to elaborate on the equilibria described by Parker et al. (1983), despite their instability. Parker and Andrews (1986) showed that the rate of change of meanders near their equilibrium is markedly low, as the corresponding characteristic timescales are an order of magnitude longer than the timescales of meanders with the same parameter settings at a non-equilibrium stage. Meander bends of longer as well as smaller bend angle amplitude can evolve more than an order of magnitude faster. Considering this and the fact that slowly evolving rivers are prone to consolidate, which further retards or even halts their natural evolution by the increased threshold of incipient sediment motion, it is not surprising that many river meanders found in nature are nearequilibrium.

The equilibrium solutions admitted by the bend equation formulated by Ikeda et al. (1981) were termed Kinoshita curves, defined by:

$$\Theta(s) = \Theta_0 \cos\phi - \Theta_0^3(c_f \cos 3\phi + c_s \sin 3\phi) \qquad (1)$$

where Θ denotes the bend angle between the tangent to the curve and the downvalley x-axis, $\phi = 2\pi s/L$ with s the coordinate along the curve and L the meander length measured along the curve, and Θ_0 is the bend angle amplitude (see Fig. 1). The coefficients c_f and c_s respectively determine fattening and skewing of the equilibrium meander. The infinitesimal distances along the curve ds and in the downvalley direction dx relate as in $dx = \cos\Theta ds$. The sinuosity k, defined as the ratio of distance along the curve and downvalley distance averaged over a single wave length, proceeds from Eq. 1:

$$k = \overline{(1/\cos\Theta)} \qquad (2)$$

where the overbar denotes averaging over a wave length. Parker et al. (1983) found that for equilibrium meanders the bend angle amplitude Θ_0 is imposed by sinuosity according to:

$$k = 1 + \frac{1}{4}\Theta_0 \qquad (3)$$

Hence, for a given sinuosity, which is in turn largely controlled by valley slope (Schumm et al. 1972; Nakagawa and Scott 1984), near equilibrium meanders are parameterized by two unknown coefficients c_f and c_s.

The theory by Parker et al. (1983) indicates that c_f and c_s relate to scour, expressing the role of secondary currents, and to the Froude number, but no means was presented to evaluate their value for an arbitrarily sinuosity. The present paper shows that starting from the hypothesis that in equilibrium meanders the variance of entropy production is minimized, most probable values of c_f and c_s can be found for a given sinuosity.

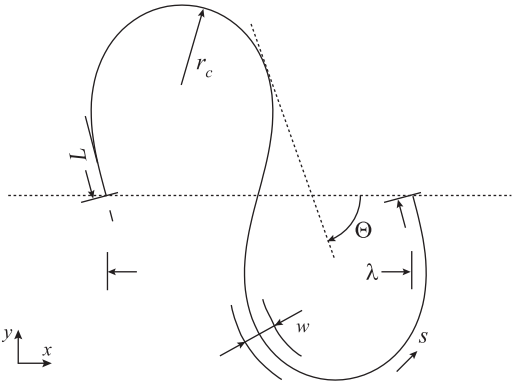

Figure 1. Sine-generated curve and definition of planform parameters.

For a specified value of k a unique minimum for the variance of entropy production is shown to exist in the (c_f, c_s)-plane. Both the existence of this unique minimum and comparison with meander reaches of various geographical locations support the hypothesis presented herein, which is based on the second law of thermodynamics (cf. Prigogine and Stengers 1985).

Section 2 explains how minimum variance of entropy production can be quantified from the velocity gradients in a flow model and gives a mechanistic interpretation of the theory based on thermodynamics. Section 3 describes the flow model used in this paper, which was developed by Odgaard (1986a), and it explains the way in which the state of minimum variance of entropy production is found for a given sinuosity. In Section 4 results are presented, showing how fattening and skewing of near-equilibrium meanders in which the variance of entropy production is minimized depend on sinuosity, and on three additional model parameters. In Section 5 the results are discussed.

2 ENTROPY PRODUCTION IN A MEANDERING RIVER

In an near-isothermal system such as a river, entropy production is caused by irreversible friction losses within the fluid. For incompressible fluids, the entropy production per unit volume and unit time (σ), reads (Yang 1992):

$$T\sigma = -(\tau : \nabla \mathbf{v}) \qquad (4)$$

in which T is the absolute temperature, τ is the stress tensor and $\mathbf{v}$ is the velocity vector. Eq. 4 can be obtained by combining the first law of thermodynamics with the equation of motion for an isothermal system and incompressible fluid. It is assumed that the stress tensor for turbulent flow in a river can be written

Copyright © 2006 Taylor & Francis Group plc, London, UK

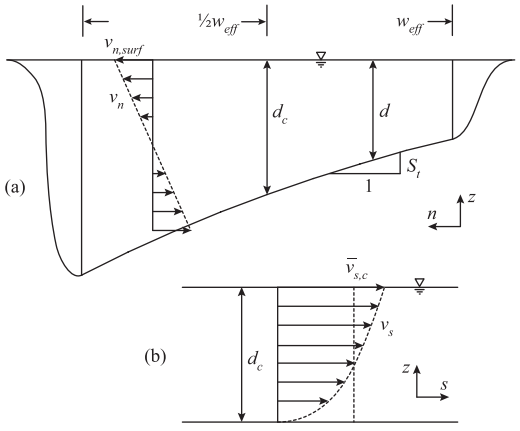

Figure 2. Longitudinal and transverse vertical velocity profiles, transverse depth distribution and definition of model parameters. Vertical scale is exaggerated.

in terms of a rate of strain tensor and a kinematic eddy viscosity, ϵ. This implies that the influences of turbulent flow on themeander planformis neglected (Smith and McLean 1984; Odgaard 1986a). The stress tensor may then be written as:

$$\tau_{ij} = -2\rho\epsilon\psi_{ij} \tag{5}$$

in which ρ the density of the fluid and ψ_{ij} the rate of strain tensor. The rate of strain tensor is given by:

$$\psi_{ij} = \frac{1}{2}(\nabla v_{ij} + \nabla_{ji}) \tag{6}$$

in which i and j represent the directions s, n and z. The components of the rate of strain tensor proceed from Eq. 4. The velocity gradient tensor will be expressed in a right-handed, orthogonal, curvilinear coordinate system with a downstream s-axis, a cross-stream n-axis and a vertical z-axis. The physical (Cartesian) space and the computational space resulting from the transformation of Cartesian into curvilinear coordinates are illustrated in Fig. 2. In curvilinear coordinates, the velocity gradient tensor is given by:

$$\nabla v_{ij} = \begin{bmatrix} N\frac{\partial v_s}{\partial s} - \frac{v_n}{r_c - n} & \frac{v_s}{r_c - n} + N\frac{\partial v_s}{\partial s} & \frac{v_s}{r_c - n} + N\frac{\partial v_z}{\partial s} \\ \frac{\partial v_s}{\partial n} & \frac{\partial v_n}{\partial n} & \frac{\partial v_z}{\partial n} \\ \frac{\partial v_s}{\partial z} & \frac{\partial v_n}{\partial z} & \frac{\partial v_z}{\partial z} \end{bmatrix} \tag{7}$$

in which r_c is the radius of curvature of the river centerline and $N = 1/(1 - n/r_c)$. As the situation of a moderately meandering, shallow river with steady, subcritical flow is considered, several components can be neglected. Under the assumption of incompressible fluid, the contribution of the normal stresses can be neglected. Moderate meandering justifies omission of terms depending on $\partial v_s/\partial n$ and $\partial v_n/\partial s$. Finally, in a shallow river flow near the banks is small and relatively unimportant, so when bankflow is neglected, the gradients of vertical velocity $\partial v_z/\partial s$ and $\partial v_z/\partial n$ can also be neglected. The effective width of a river, w_e is introduced as the part of the river not influenced by bankflow (see Fig. 2). After these simplifications, calculation of the tensor product (Eq. 4) results in an expression for only dependent on the vertical gradients of the longitudinal and transverse velocity. Because the main interest is in the distribution of the entropy production along the river, this expression is integrated over a cross section of the river. This yields:

$$\sigma_{cs} = \frac{\rho}{T}\int_{-\frac{1}{2}w_e}^{\frac{1}{2}w_e}\int_0^d \epsilon\left(\left(\frac{\partial v_s}{\partial z}\right)^2 + \left(\frac{\partial v_n}{\partial z}\right)^2\right) dz dn \tag{8}$$

in which σ_{cs} is the entropy production for a cross-section of a river, w_e is the effective river width and d is the local depth. To determine σ_{cs} the distribution of the longitudinal and transverse velocities in a meander bend have to be known.With the assumption of steady flow it is implied that the meander planform is determined by one unique discharge (see e.g. Chang (1979), Chang (1984), Ikeda et al. (1981), Parker et al. (1983), Odgaard (1986a), Odgaard (1986b)).

The product of temperature (T) and entropy production per unit volume (σ) is equal to the energy dissipation rate per unit volume (E). Minimizing the variance of entropy production is hence equivalent to minimizing the variance of energy dissipation. Energy dissipation, in turn, bears a direct relation with the capacity of a local flow volume to carry sediment in suspension, and hence sediment transport (Yang 1991; Yang 2005). As a consequence of conservation ofmass (Exner equation), morphological changes are driven by gradients in depth-mean total sediment transport. In our analysis, the hypothesis of minimum variance of entropy production thus boils down to the assumption that the most likely equilibrium river meanders are the ones in which the (steady state) channel morphological change rates are minimal, which reveals the mechanistic interpretation of the entropybased hypothesis.

3 FLOW MODEL

The meander flow model developed by Odgaard (1986a) is used here for its compatibility with the

Copyright © 2006 Taylor & Francis Group plc, London, UK

assumptions made in the former section. The constraints in the model are (1) the effective river width is constant; (2) the centerline radius of curvature is large compared to width; (3) the width to depth ratio is large; (4) transverse velocity components are small compared to longitudinal ones; (5) turbulence is isotropic. The meander flow model is slightly modified for a dimensionless treatment. The dimensions present in the problem are length, time, mass and temperature. Since the entropy production in Eq. 8 will be written times temperature and per unit mass, only characteristic scales for length and time have to be de- fined. For both quantities a suitable reference value is present in the model. Both effective width and centerline depth are assumed constant in the model, as well as the averaged centerline longitudinal velocity. Therefore all lengths are normalized with respect to width and all velocities are normalized with respect to the averaged centerline longitudinal velocity $\overline{v}_{s,c}$. The dimensionless downstream direction and transverse velocity s̃ and transverse velocity are taken as:

$$\tilde{s} = \frac{s}{w_e} \tag{9}$$

$$\tilde{v}_n = \frac{v_n}{\overline{v}_{s,c}} \tag{10}$$

in which the tilde denotes a dimensionless variable. Because the bed topography and the longitudinal velocity profile are dependent of the actual velocity and friction coefficient, a fully dimensionless treatment is not possible. However the scale-dependent parameters are found to have only small effect on the results.

The analytical relationships for velocity profiles in Odgaard's model allow to solve the first integral of Eq. 8. This results in an expression independent on vertical changes in velocity. The general power law is used to describe the vertical distribution of the longitudinal velocity (Odgaard 1986a):

$$\frac{\tilde{v}_s}{\overline{\tilde{v}}_s} = \frac{m+1}{m}\left(\frac{\tilde{z}}{\tilde{d}}\right)^{\frac{1}{m}} \tag{11}$$

in which the dimensionless velocity-profile exponent m is a linear function of the Chézy coefficient. The vertical transverse velocity profile is assumed to be linear. Since we only use the differentiated form of the velocity profiles in Eq. 11, this relation can be described in its simplest form (Odgaard 1986a):

$$\frac{\tilde{v}_n}{\tilde{v}_{n,surf}} = 2\left(\frac{\tilde{z}}{\tilde{d}} - \frac{1}{2}\right) \tag{12}$$

in which $\tilde{v}_{n,surf}$ is the transverse surface velocity. Again the interaction with the riverbed is not accounted for. Therefore the violation of the no-slip condition on the riverbed is legitimate. Examples of the velocity profiles described by Eqs. 11 and 12 are given in Fig. 2. With Eqs. 12 and 2 and the assumption of a parabolic profile of the eddy viscosity ϵ it is possible to solve the first integral of (10). Normalizing by the temperature, density, effective width and averaged centerline longitudinal velocity, integrating and rearranging of terms yields:

$$\begin{aligned}\tilde{\sigma}_{cs} &= \frac{T\sigma_{cs}w_e}{\rho\overline{v}_{s,c}^3} \\ &= \kappa^2 \int_{-\frac{1}{2}}^{\frac{1}{2}} \left(\frac{(m+1)^2}{4m^3+2m^4}\tilde{\overline{v}}_s^{\,3} + \frac{4\tilde{v}_s\tilde{v}_{n,surf}^2}{6m} \right) d\tilde{n}\end{aligned} \tag{13}$$

The entropy production is now only dependent of the transverse surface velocity and the averaged centerline longitudinal velocity. A complicated determination of the three-dimensional velocity field is thus avoided.

The central equation of the meander flow model describes the longitudinal or streamwise variation of the centerline transverse bedslope $S_{t,c}$. This equation is derived from a combination of the equation of motion for the transverse velocity component, a parabolic eddy viscosity profile, a parabolic velocity profile, the mass balance at the centerline to compensate for mass-shift and a simple linear relationship between the transverse bedslope and the transverse velocity at the bottom. At the centerline of the river this yields (Odgaard 1986a):

$$\frac{d^2D_{t,c}}{d\tilde{s}^2} + c_1\frac{dS_{t,c}}{d\tilde{s}} + c_2S_{t,c} = \frac{c_3}{\tilde{r}_c} \tag{14}$$

in which c_1, c_2 and c_3 are functions depending on sediment characteristics and cross section geometry. In Eq. 14, only the centerline radius of curvature $\tilde{r}_c$ is a function of $\tilde{s}$. From the centerline transverse bedslope, the local transverse depth distribution can be calculated from the simple relationship (Odgaard 1986a):

$$\frac{S_t}{S_{t,c}} = \frac{\tilde{d}}{\tilde{d}_c}\frac{\tilde{r}_c}{\tilde{r}} \tag{15}$$

in which $\tilde{d}_c$ is the (constant) centerline depth and $\tilde{r}$ is the local radius of curvature. The convex transverse depth distribution described by Eq. 15 is illustrated in Fig. 2. The depth distribution is needed to calculate the longitudinal velocity distribution. From the equation of motion in longitudinal direction, written in terms of the average longitudinal velocity and with the use of the parabolic eddy viscosity profile, it follows

Copyright © 2006 Taylor & Francis Group plc, London, UK

that the change in average longitudinal velocity along a path of constant distance from the centerline can be approximately written as (Odgaard 1986a):

$$\frac{d(\tilde{\bar{v}}_s)^2}{d\tilde{s}} + c_4 \frac{\tilde{d}_c}{\tilde{\bar{d}}} (\tilde{\bar{v}}_s)^2 = c_4 \frac{\tilde{r}_c}{\tilde{\bar{r}}} \tag{16}$$

in which the function c_4 is again depending on sediment characteristics and cross section geometry. Finally it is assumed that the local transverse bedslope is proportional to the transverse bottom velocity. Since it follows from Eq. 12 that the transverse surface velocity has the same absolute value (but different sign) as the transverse bottom velocity, the transverse surface velocity can be written in terms of the centerline transverse bedslope as (Odgaard 1986a):

$$\tilde{v}_{n,surf} = c_5 S_{T,c} \frac{\tilde{\bar{d}}}{\tilde{d}_c} \frac{\tilde{r}_c}{\tilde{\bar{r}}} \tag{17}$$

in which the function c_5 depends on sediment and flow characteristics and cross section geometry. We now define ξ as the dimensionless variance of cross-sectional entropy production along arbitrary meander bends:

$$\xi = \frac{1}{p-1} \sum_{i=1}^{p} \left(\tilde{\sigma}_{cs,i} - \tilde{\bar{\sigma}}_{cs} \right)^2 \tag{18}$$

in which p is the discrete number of cross-sections. As a necessary boundary condition it is imposed that a change in shape of the meander bend does not lead to a change in the meander length and wavelength. From Eq. 1, the longitudinal variation in the centerline radius of curvature can be determined as in:

$$\frac{1}{\tilde{r}_c} = \frac{d\Theta}{d\tilde{s}} \tag{19}$$

The values of c_f and c_s are taken between -0.1 and 0.1, with intervals of 0.01. Higher or lower values result in physically unlikely curves. For a constant sinuosity, the curves that minimize entropy production are thus determined out of 441 possible curves. Since the meander flow model is dimensionless, the number of parameters that influences the result is strongly reduced. The spatial dimensions are all expressed with respect to the effective width, so only three spatial ratios remain to be chosen: the ratios of wavelength, meander length and centerline depth to effective width. The ratio of effective width to centreline depth shows considerable variations in natural rivers. A reference value of 10 is chosen, and the influence of this variable is investigated. To close the geometry problem (Hey 1976), we assume the wavelength to equal eleven times the width, following Davy and Davies (1979). In terms of effective width and in dimensionless notation:

$$\tilde{\lambda} = \frac{\lambda}{w_e} = 13.2 \tag{20}$$

Regarding sinuosity, a maximum value of 5 is considered. Above this value cut-offs are likely to occur. The depth/width ratio also shows considerable variations in natural rivers. A reference value of 0.1 is chosen, but the influence of this variable is also studied. According to Odgaard (1986a) bankflow influences the flow pattern to a distance of approximately one time the depth. With a depth/width ratio of 0.1, neglecting bankflow thus leads to a ratio of the wavelength to effective width of 13.2.

Besides the geometrical parameters mentioned above also two parameters related to flow and sediment characteristics are dependent on scale. Although the velocity profile exponent and the particle Froude number are both dimensionless, their value cannot be determined because the velocity profile exponent is a function of the scale dependent Chézy coefficient and the particle Froude number is a function of the actual velocity and sediment size. The values of the velocity profile exponent and the particle Froude number are taken as 2.8 and 6.78 (respectively), the average values of the two river sites tested in Odgaard (1986b). On both parameters a sensitivity test is performed.

4 RESULTS

The variance of the entropy production per cross section for different Kinoshita curves with a constant sinuosity clearly shows one unique minimum. This is shown in Fig. 3, where ξ is plotted in the (c_f, c_s)-plane.

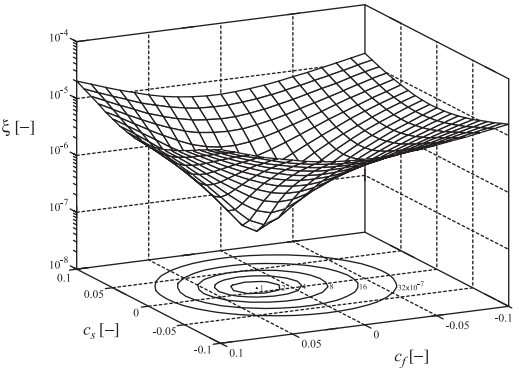

Figure 3. Variance of the entropy production per cross-section (vertical axis) versus fattening and skewing parameters for the Kinoshita curve ($k = 3$).

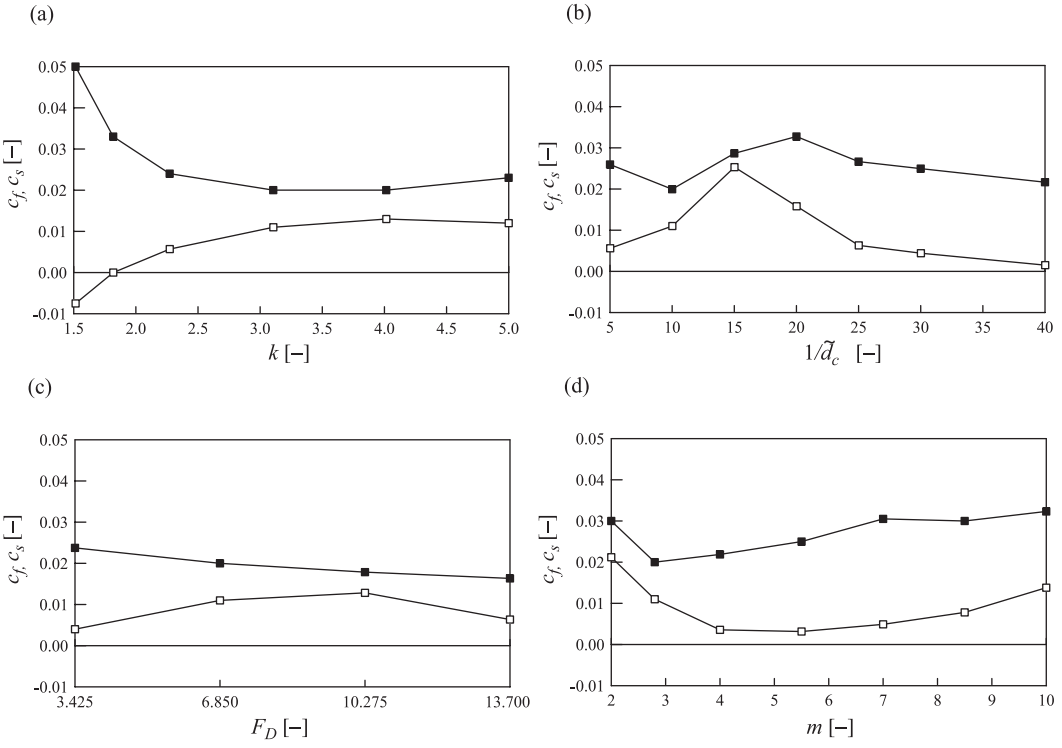

Figure 4. Effect of model parameters on the values of fattening (dotted line) and skewing (solid line). (a) Sinuosity, (b) Ratio of effective width to centerline depth, (c) Particle Froude number, (d) velocity profile exponent.

The location of the minimum clearly differs from the first order sine-generated curve (located at $c_f = 0$ and $c_s = 0$), which would result if the entropy production would be a simple linear function of the curvature. Linear interpolation shows that the minimum is located at $c_f = 0.020$ and $c_s = 0.011$. This leads to a fattening and upvalley skewing in comparison with the first order sine-generated curve.

The results depend on two geometrical parameters and two flow parameters, as discussed earlier. The effect of the sinuosity and the depth/width ratio on the result is shown in Fig. 4a and b. The upvalley skew in meanders is the most pronounced at higher sinuosities. At a sinuosity of 1.8, the model predicts a symmetric meander as the most probable one, while at an even lower sinuosity the most probable meander shows a slight downvalley skew. The influence of the sinuosity on the most probable meander planform is illustrated in Fig. 5. The depth of the river also influences the most probable combination of fattening and skewing parameters. From Fig. 4b it can be seen that theres a maximum upvalley skew at a centerline depth of 1/15 times the effective width. The effect of the particle Froude number and the velocity profile exponent on the result is shown in Fig. 4c and d. The particle Froude number shows to have only little effect on the result. Skewing is more pronounced at low and high values of the velocity profile exponent, while at median values skewing is less pronounced.

We selected regular meanders and confronted these meanders with our optimalized equilibrium curves. Only few examples of undisturbed meanders have been documented, as many meandering rivers are found in remote areas or have been straightened in the past century. Consequently, we also selected meanders from satellite images and old maps. Fig. 6 compares these meanders with one complete wavelength of our optimized equilibrium curves. No quantitative comparison was made for several reasons. First natural meanders are not necessarily in equilibrium. The starting point of the curve and the location and direction of the downvalley axis is a subjective matter. This is also true for scale and sinuosity of the curve to be fitted, as a good comparison can only be made between curves of the same sinuosity. However as can be seen in Fig. 6, a visual comparison is based on shape rather than on sinuosity. Furthermore the exact centreline of the river depends on unknown depth distribution and stage. Because of this lack of data, average parameter values as discussed in the previous section were used for the curves in Fig. 6.

The old and distinct meanders of the Mississippi River near Greenville (Fig. 6a) are perhaps the most cited in literature. They have been used to illustrate earlier theories on meander planform (Langbein and Leopold 1966; Parker et al. 1983) or just to illustrate the typical meander planform (Chitale 1973; Jefferson 1902; Chitale 1973; Davies and Tinker). Where the first order sine generated curve gave a reasonable agreement (Langbein and Leopold 1966) with the Mississippi meanders, the equilibrium curve for which the variance of entropy production is minimized matches almost exactly. A large aerial photograph of the incised San Juan River (Fig. 6b) was used by Leopold and Langbein (1966) to introduce their Theory of minimum variance. Langbein and Leopold (1966) concluded that during incision, irregularities apparently tend to be averaged out and only the regular form is preserved. This is confirmed by the good agreement with our optimized equilibrium curve. Examples of smaller scale used by (Langbein and Leopold 1966) are Baldwin Creek (Fig. 6j) and the Popo Agie River (Fig. 6r), which was by far the most symmetrical and uniform meander reach they had ever seen. Again the curves obtained here show good agreement.

Some of the most extensive meandering systems are found in tectonically stable Precambrian shield areas like the Amazon basin and the Congo basin. Satellite images available from the Global Rain Forest Mapping Project allowed easy analysis of larger rivers. Meandering rivers in these areas often show remarkable regularity in their planform. Nice examples of 'approximately free and unforced meandering' rivers (Stø lum 1998) are the Juruá River (Figs. 6c,g,u,x) and Jutai River (Figs. 6f,i,k) in Brazil. Even the large meanders in the Solimões River (Fig. 6w) show a regular pattern. One of the finest examples of regular meanders was found along the reaches of the Maringa River in Congo (Fig. 6m). Satellite images where also used to identify regular reaches along the freely meandering Kahayan River in Kalimantan (Figs. 6e,q) and Salonga River in Congo (Fig. 6t). The regular meanders found in these areas can be assumed close to an equilibrium in which variance of entropy production is minimized.

In, or close to The Netherlands we found three examples of regular meandering rivers of different scale. The River Rhine (Figs. 6l,d,o) and the River Meuse (Fig. 6h) once were freely meandering rivers, but many meandering reaches have been straightened in the past century. Abandoned meanders and old maps however show that before the straightening these too were rivers close to equilibrium. The Geul Brook (Fig. 6s) is generally considered as one of the finest examples of a meandering brook in The Netherlands, as it remained largely untouched by human influence (Overmars et al. 1996). Other examples of regularly meandering rivers were found in the literature, such as the River Myittha in Myanmar. The Muddy Creek was used by Odgaard (1986b) as a validation site for the meander flow model (see previous section).

A first glance of Fig. 6 already reveals a large geometric similarity in meander planforms, which seems to be independent of geographical location or scale. The scale of the meanders in Fig. 6 ranges over four orders of magnitude, from 1 m (Fig. 6p) to 10 km (Fig. 6w). At large sinuosities (3–4) the same upvalley skewing is apparent for rivers of four different continents. At mediate sinuosities (2–3) most meanders are symmetric. At lower sinuosities (1.5–2) some meanders show a slight downvalley skew. This behaviour is in correspondence with our theoretical findings (Fig. 4). A good overall correspondence is found between equilibrium meanders in which variance of entropy production is minimized and meanders with the same sinuosity encountered in nature.

5 DISCUSSION

The use of thermodynamic principles in fluvial geomorphology is not new. The concept that landscapes or landscape elements evolve towards a state of maximum probability was already used by Davis in the end of the 19th century (Davis 1899). Leopold and Langbein (1966) introduced the use of entropy in fluvial geomorphology. Thermodynamic principles were also applied byWoldenberg (1966), Scheidegger (1967) and Yang (1971). Recently, similar concepts have provided new insights in the structure and development of drainage networks and hydraulic geometry (Kapoor 1990; Ijjász-Vásquez 1993; Rodríguez-Iturbe and Rinaldo 1997; Molnár and Ramírez 1998; Huang and Nanson 2000).

At the same time the use of extremal hypotheses related entropy in fluvial hydraulics has often been a subject to debate, and can even be considered controversial (Griffiths 1984; Lamberti 1992;Mosselman 2000). For this reason the mechanistic interpretation of the hypothesis of minimal variance of entropy production was included in Section 2, showing that minimization of entropy production of water is largely equivalent to minimization of channel morphology change rates, leading to a near-uniform dissipation of kinetic energy. It is acknowledged that the correct application of the second law of thermodynamics to an open dissipative system as a river meander is not straightforward, yet the law itself is not under dispute and equally fundamental as Newton's second law that provides the basis for the equations of motion.

A contestable assumption made in this paper is that entropy production of water only is to be minimized, whereas suspended sediment particles also produces entropy. Especially since bankfull discharge conditions are considered normative for meander formation, the focus on entropy production by water only may not be justified, as the sediment discharge may be significant in mass and energy. Furthermore, the constraints implied by the flow model leave room for improvement, as the level of detail of the flow description is limited. Despite these remarks, the existence of unique minimum of the variance of entropy production for arbitrary sinuosities and the favorable comparison with a variety of field situations strongly suggest a basic validity of the theory presented.

Downstream stable channel configuration: Preliminary analysis

Beatrice Mengoni & Enio Paris
CERAFRI (CEntre of Research and Advanced education For hydrogeological RIsk prevention), Retignano (LU), Italy
DIC (Department of Civil Engineering, University of Florence), Florence, Italy

ABSTRACT: A new analytical method for determinating stable channel configuration of self formed river is presented. The method is based on a downstream approach and includes spatial variability along the river reach of quantities related to hydrological and sedimentological river basin characteristics. It combines one-dimensional steady water and sediment continuity equations, friction factor and sediment transport laws together with given analytical expressions of river basin input quantities along the river reach. A differential equation is obtained and solved to calculate the downstream equilibrium geometric and hydraulic variables.

1 INTRODUCTION

Since the beginning of the previous century the determination of the equilibrium configuration of a river has fascinated many Authors that have developed both empirical methods (e.g. Blench 1957, Simon and Albertson 1963), extremal hypothesis method (e.g. Chang 1979, White et al. 1982), mechanistic method (e.g. Parker 1978, Diplas and Vigilar 1992, Kovacs and Parker 1994), and experimental methods (e.g. Ikeda 1981, Diplas 1990).

All the above cited methods, have been developed following an approach at station, where the entire spatial variability of quantities related to river basin characteristics is not considered but instead averaged and represented by a single value of water discharge and sediment load. This assumption is associated with a channel forming discharge concept: where a single theoretical discharge and sediment load if maintained indefinitely, would produce the same channel geometry as the one modelled by the entire-long term discharge cycle.

Nowadays the determination of the equilibrium configuration following a downstream direction approach seems, instead, not to have been investigated in similar details. For this reason, in the present work the stable configuration of self formed river has been studied developing a new method in downstream direction, based on an extensive basin scale approach. The method combines one-dimensional steady water and sediment continuity equations, friction factor and sediment transport laws together with given analytical expressions of river basin input quantities such as longitudinal bed profile, sediment size, water and sediment discharges distributions along the river reach. A differential equation is obtained and solved to calculate the downstream geometric and hydraulic variables.

A first example of application procedure is presented mainly to show potential applicability of the method that looks very promising especially to predict downstream stable configuration and to help to provide a rational interpretation of relationships of the regime theory that still need further clarifications.

2 FORMULATION OF THE MODEL

The form of a fluvial system results from the complex interaction between variables superimposed by the river basin (independent) and variables that the system is able to modify and adjust (dependent). The independent variables are essentially related to the hydrological, physiographic and sedimentological river basin characteristics and usually include water discharge (Q), sediment load (Q_s) and the sediment size distribution (D_s) whereas the dependent variables are generally related to the geometry and planimetric-altimetric configuration of the river such as cross section shape (water depth H and surface width W) and longitudinal profile (slope i). It is know how by adjusting the dependent variables the system tries to reach a quasi-steady state configuration, indicated as equilibrium (or stable) configuration.

In order to reproduce the spatial variability along the stream length of both dependent and independent variables, the present method is developed assuming a

Copyright © 2006 Taylor & Francis Group plc, London, UK

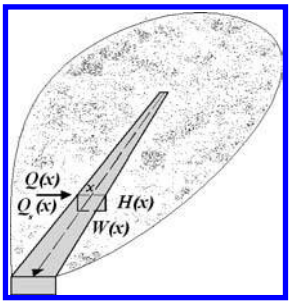

Figure 1. Simplified river system: the river is assumed rectilinear with rectangular cross section and the hydraulic variables are function of downstream coordinate x.

1D approach along river length. In particular the distributions along the river reach of water discharge Q, sediment load Q_s and sediment size D_s are considered as input variables. Because vertical variations of bed level profile usually occur on a time scale that is much greater than the variations of other variables, by considering an appropriate time scale (e.g. graded time scale, Schumm and Lichty 1965), the bed level profile can also be considered as an independent variable.

The method intends to obtain the river system configuration that is able to carry in each cross section along the river axis the superimposed values of water discharge and sediment load without generating any erosion or deposition and hence variations in bed level profile.

Time-averaged steady flow conditions, with reference to dominant discharge, along the entire river axis, are considered; as consequence all variables are function only of their position along the river axis x (in the following x-coordinate dependence is omitted, e.g. $Q(x)=Q$; $Q_s(x)=Q_s$; $D_s(x)=D_s$; $i(x)=i$; $H(x)=H$; $W(x)=W$).

The mechanical processes through which the river achieves the stable configuration are not reproduced. Only the equilibrium relationships between independent and dependent variables are modelled by employing the basic laws of flow motion and sediment transport.

Assuming the simplified conditions of rectangular cross section shape composed by homogeneous and non cohesive bed and banks material, the method has been developed combining the *1D steady flow equation* (Eq. 1) with the 1D flow and sediment continuity equation at equilibrium condition (Eq. 2 and Eq. 3):

$$\frac{d}{dx}\left(H+\frac{U^2}{2g}\right)=i-j \tag{1}$$

$$\frac{dQ}{dx}=q \tag{2}$$

$$\frac{dQ_s}{dx}=q_s \tag{3}$$

(where U = flow velocity; j = energy gradient loss; q = downstream unit length inflow water discharge; q_s = downstream unit length inflow sediment discharge).

Among the several relations available in literature, the following general power function formulation has been chosen as flow resistance formula:

$$C=K_c\left(\frac{H}{D_s}\right)^{\alpha} \tag{4}$$

(where K_c and α are dimensionless constants), together with the following general expression of *sediment transport formula*:

$$Q_s=K_{q_s}(\vartheta-\vartheta_{cr})^n W\sqrt{g(s-1)D_s^3} \tag{5}$$

(where K_{q_s} and n are dimensionless constants).

Under the assumption of wide rectangular cross section shape, velocity U, energy gradient loss j and dimensionless shear stress ϑ assume the following expressions:

$$U=\frac{Q}{WH} \tag{6}$$

$$j=\frac{U^2}{gC^2H}=\frac{1}{g}\frac{Q^2}{W^2H^3C^2} \tag{7}$$

$$\vartheta=\frac{U_*^2}{g(s-1)D_s}=\frac{1}{g(s-1)D_s}\cdot\frac{Q^2}{W^2C^2H^2} \tag{8}$$

which substituted in Eq. 1 lead to the well know *1D backwater equation*:

$$\frac{dH}{dx}=\frac{-\frac{1}{g}\frac{Q^2}{W^2H^2}\left(\frac{1}{Q}\frac{dQ}{dx}-\frac{1}{W}\frac{dW}{dx}\right)-\frac{dZ_b}{dx}-\frac{1}{g}\frac{Q^2}{W^2H^3}}{\left(1-\frac{Q^2}{gW^2H^3}\right)} \tag{9}$$

and substituted in Eq. 5, under the assumption of fully developed sediment transport conditions ($\vartheta >> \vartheta_{cr}$), lead to the following:

$$Q_s=\frac{K_{q_s}}{[g(s-1)]^{n-\frac{1}{2}}}\cdot\frac{Q^{2n}D_s^{\frac{3}{2}-n}}{C^{2n}H^{2n}W^{2n-1}} \tag{10}$$

Substituting flow resistance formula (Eq. 4) in Eq. 10 the following expression is obtained:

$$Q_s=\frac{K_{q_s}}{[g(s-1)]^{n-\frac{1}{2}}K_c^{2n}}\cdot\frac{Q^{2n}D_s^{2n\alpha+\frac{3}{2}-n}}{H^{2n(\alpha+1)}W^{2n-1}} \tag{11}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

Assuming the classic flow resistance formula exponent $\alpha = 1/6$ (Strickler 1923), Eq. 11 becomes:

$$Q_s = \frac{K_{q_s}}{[g(s-1)]^{n-\frac{1}{2}} K_c^{2n}} \cdot \frac{Q^{2n} D_s^{\frac{9-4n}{6}}}{H^{\frac{7}{3}n} W^{2n-1}} \tag{12}$$

For sediment transport exponent $n = 3/2$ (e.g Meyer-Peter and Muller 1948, Shields 1936, Ashida and Michiue 1971), the sediment transport capacity is function of the sediment size D_s only only through the flow resistance formula (see Eq. 10). This is due the assumed simplifying hypothesis of wide rectangular cross section shape and fully developed sediment transport conditions.

Subsequently width W is obtained by Eq. 10, Eq. 11 and Eq. 12 as follow:

$$W = \frac{K_{q_s}^{\frac{1}{2n-1}}}{\sqrt{g(s-1)}} \cdot \left(\frac{Q^{2n} D_s^{\frac{3}{2}-n}}{Q_s H^{2n} C^{2n}} \right)^{\frac{1}{2n-1}} \tag{13}$$

$$W = \frac{K_{q_s}^{\frac{1}{2n-1}}}{\sqrt{g(s-1)} K_c^{\frac{2n}{2n-1}}} \cdot \left(\frac{Q^{2n} D_s^{\frac{3}{2}-n+2n\alpha}}{Q_s H^{2n(\alpha+1)}} \right)^{\frac{1}{2n-1}} \tag{14}$$

$$W = \frac{K_{q_s}^{\frac{1}{2n-1}}}{\sqrt{g(s-1)} K_c^{\frac{2n}{2n-1}}} \cdot \left(\frac{Q^{2n} D_s^{\frac{9-4n}{6}}}{Q_s H^{\frac{7}{3}n}} \right)^{\frac{1}{2n-1}} \tag{15}$$

Let us notice how adopting an *approach at a station* width W and water depth H are inversely proportional to each other (Eq. 13, 14, 15) and thus characterized by opposite behavior with respect to input variables (under the admissible condition of $n > 1/2$). This disagrees with the behaviour showed by *classical* regime formula, according to which the hydraulic variables are characterize by the same proportionality against input variables (e.g. Blench 1957, Bray 1982). As consequence, in order to obtain the same proportionality, it seems necessary to include the downstream variation of the input variables.

Starting from Equation (15) the derivative of width W is obtained (Eq. 16) and subsequently included in Equation (9).

$$\frac{1}{W}\frac{dW}{dx} = \frac{2n}{2n-1} \cdot \frac{1}{Q}\frac{dQ}{dx} - \frac{1}{2n-1} \cdot \frac{1}{Q_s}\frac{dQ_s}{dx} + \frac{9-4n}{6(2n-1)} \cdot \frac{1}{D_s}\frac{dD_s}{dx} - \frac{7n}{3(2n-1)} \cdot \frac{1}{H}\frac{dH}{dx} \tag{16}$$

Expressing everything as function of water depth H, the following 1st order, variable coefficient, ordinary differential equation is achieved:

$$\frac{dH}{dx} = \frac{F_2 H^{\frac{2(n+3)}{3(2n-1)}} + F_3 H^{\frac{10-6n}{3(2n-1)}} + i}{1 + F_1 H^{\frac{9-4n}{3(2n-1)}}} \tag{17}$$

where F_1, F_2, F_3 are the variable coefficients of the differential equation, defined as:

$$\begin{cases} F_1 = \frac{n+3}{3(2n-1)} A_s \left(\frac{Q_s}{Q}\right)^{\frac{2}{2n-1}} \frac{1}{D_s^{\frac{9-4n}{3(2n-1)}}} \\ F_2 = \frac{A_s}{2n-1} \left(\frac{Q_s}{Q}\right)^{\frac{2}{2n-1}} \frac{1}{D_s^{\frac{9-4n}{3(2n-1)}}} \cdot \left(\frac{1}{Q}\frac{dQ}{dx} - \frac{1}{Q_s}\frac{dQ_s}{dx} + \frac{9-4n}{6}\frac{1}{D_s}\frac{dD_s}{dx} \right) \\ F_3 = -\frac{A_s}{K_c^2} \left(\frac{Q_s}{Q}\right)^{\frac{2}{2n-1}} \frac{1}{D_s^{\frac{10-6n}{3(2n-1)}}}. \end{cases} \tag{18}$$

and where A_s is a constant defined as:

$$A_s = (s-1) \left(\frac{K_c^{2n}}{K_{q_s}} \right)^{\frac{2}{2n-1}} \tag{19}$$

It is know that when the Froude number ($Fr = U/\sqrt{gH}$) is equal to 1, a critical flow condition occurs since the denominator of Eq. 9 tends to 0.

It is interesting to observe that the denominator of Equation (17) is always positive and thus no critical flow condition is found along the entire river length. Analytical investigations confirm that the validity of this result is not affected by both employed values of sediment transport exponent n and flow resistance formula exponent α.

This result could be explained noticing that natural system usually tries to smooth local discontinuities reaching a configuration where critical flow condition does not occur.

The hydraulic variables obtained by means of Equation 17 are then employed to calculate exponents E_H and E_W (see Equation 20). The obtained exponents are then investigated in order to find rational interpretation of classical *Regime formula* exponents.

$$H = K_H Q^{E_H} \tag{20}$$

$$W = K_W Q^{E_W} \tag{21}$$

3 BOUNDARY CONDITION ANALYSIS

In order to solve the 1st order variable coefficients ordinary differential equation (17) a boundary condition is needed. Uniform flow condition at boundary cross section is assumed by imposing equality between channel slope i and energy gradient loss j (Eq. 6) that gives the following:

$$H = \left[\left(\frac{i}{s-1} \right) \left(\frac{K_{q_s}}{K_c} \frac{Q}{Q_s} \right)^{\frac{2}{2n-1}} \right]^{\frac{2n-1}{2\alpha-2n+3}} D_s \tag{22}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

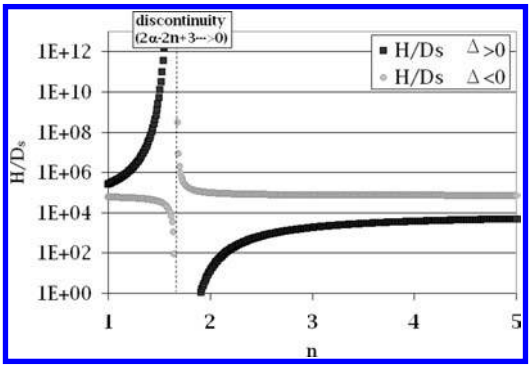

Figure 2. Dual behavior of H/D_s against n (input quantities: $Q = 10\,m^3/s$; $Q_s = 10^{-4}\,m^3/s$; $\alpha = 1/6$ (for $\Delta > 0$, $i = 1.2 * 10^{-5}$; for $\Delta < 0$, $i = 2.3 * 10^{-6}$).

Analytical investigations of Eq. 22 show how water depth H (and thus all related hydraulic variables) are strongly influenced by chosen value of both input variables Q, Q_s, D_s, i and exponents n and α.

In particular it can be analytically demonstrated that H behavior against n and α depends on the sign assumed by the following quantity:

$$\Delta = \left[\left(\frac{i}{s-1}\right)\left(\frac{K_{q_s}}{K_c}\frac{Q}{Q_s}\right)^{\frac{1}{\alpha+1}} - 1\right] \tag{23}$$

An example of H function against n, considering both positive and negative Δ cases, is presented in Figure 2. The plot shows how H function is characterized by dual behavior depending on Δ sign.

Furthermore let us also notice the existence of a specific combination of exponents α and n for which a discontinuity characterized by duality of H depending on quantity Δ, occurs in Equation (22) as:

$$\lim_{(2\alpha-2n+3)\to 0^+} H = \begin{cases} 0 & \text{if } \Delta > 0 \\ +\infty & \text{if } \Delta < 0 \end{cases}$$

$$\lim_{(2\alpha-2n+3)\to 0^-} H = \begin{cases} +\infty & \text{if } \Delta > 0 \\ 0 & \text{if } \Delta < 0 \end{cases}$$

Taking advantage of Equation (22), the expression of uniform flow Froude number is obtained (Eq. 24) and then employed to investigate physical explanation of H discontinuity. In particular as the quantity $(2\alpha - 2n + 3) \to 0$ a passage between supercritical and subcritical flow is detected: according to above introduced limits if the flow is subcritical H tends to 0 whereas if the flow is supercritical H tends to infinite.

$$Fr = \frac{U}{\sqrt{gH}} = C\sqrt{i} = K_c\left(\frac{H}{D_s}\right)^{\alpha}\sqrt{i}$$

$$= K_c\sqrt{i}\left[\left(\frac{i}{s-1}\right)\left(\frac{K_{q_s}}{K_c}\frac{Q}{Q_s}\right)^{\frac{2}{2n-1}}\right]^{\frac{2\alpha(2n-1)}{2\alpha-2n+3}} \tag{24}$$

The present analysis underlines how approaching to the limiting value of $(2\alpha - 2n + 3) \to 0$, the solution can be strongly affected by employed exponents α and n. The sign of quantity $(2\alpha - 2n + 3)$ influences both quantitatively and qualitatively the solution.

As example let us assume the classical case of $\alpha = 1/6$ (Strickler 1923). The limiting value of n that determine the sign of quantity $(2\alpha - 2n + 3)$ can be easily calculated as follow:

$$n = \tfrac{3}{2} + \alpha = \tfrac{5}{3}$$

In this case the proportionality of dependent variables against independent is the opposite employing sediment transport formula with exponent $n < 5/3$ (e.g. Meyer and Peter 1948, Shields 1938) or formula with exponent $n > 5/3$ (e.g. Engelund and Hansen 1967, Brown 1950). Hence also the exponents E_H and E_W are influenced by the employed value of sediment transport formula exponent n.

These considerations developed for uniform flow condition *at a station* can be extended also to 1D steady flow condition *in downstream direction*. Therefore awareness about the choice of exponents α and n is then recommended.

4 APPLICATION OF THE METHOD

In the present section a first example of application procedure is presented mainly to introduce potential applicability of the method such as rational derivation of exponents of river regime equations.

The method is applied to a real case study: a reach of the Italian river Ombrone-Grossetano (Grosseto-central Italy). In the recent decades no consistent artificial modifications have been performed on the Ombrone-Grossetano river, as consequences the river is almost in natural conditions. Moreover since there are not very pronounced erosion or deposit processes, the river can be assumed to be approximately in equilibrium conditions.

4.1 *Model set up*

The case study reach, approximatively 56.4 Km long, is located between the head of the river and the confluence with the Trasubbie river.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The distributions of input variables along the river axis are calculated employing simple power functions, which are obtained directly from regression equations of Ombrone-Grossetano river field data (Paris 1991; Paris and Billi, 1996).

In particular the water discharge distribution Q (return period = 2 years), is calculated from:

$$Q = 16.133 \cdot x^{0.3841} \tag{25}$$

The total sediment discharge distribution Q_s, which increases in downstream direction, is calculated from:

$$Q_s = 4 \cdot 10^{-5} \cdot x^{0.4241} \tag{26}$$

The fining sediment size distribution D_s is calculated from:

$$D_s = -10^{-6} \cdot x + 0.1244 \tag{27}$$

The downstream decreasing bed slope i is calculated by employing the following:

$$i = -10^{-8} \cdot x + 0.0015 \tag{28}$$

Downstream relationships between independent and dependent variable are investigated by means of two cases:

- *Case 1*: all input functions (Q, Q_s, D_s) except bed slope i, are variable in downstream direction;
- *Case 2*: all input functions (Q, Q_s, D_s, i) are variable in downstream direction;

The value of dimensionless input quantities (at initial and final cross sections) employed in the application test are summarized in Table 1.

Strickler (1923) flow resistance formula and Brown (1950) sediment transport formula are employed to perform the calculations ($\alpha = 1/6$, $K_c = 21.1/\sqrt{g}$, $K_{q_s} = 100$, $n = 3$).

The non linear differential equation (Eq. 17) is solved, assuming the uniform flow at boundary condition introduced in Equation (22) and numerically integrated employing a *predictor corrector* method. Integration is performed according to flow characteristics which are verified by means of Fr number introduced in Equation (24).

4.2 *Results*

In Figures 3 and 4 dimensionless water depth H/H_{in} and dimensionless width W/W_{in} , obtained by means of Equations (15) and (17), are shown against corresponding dimensionless water discharge Q/Q_{in}. Let us obverse how the inclusion of whole variability of all input variable looks necessary in order to guarantee an increasing behavior in downstream direction of both H and W.

Table 1. Dimensionless input quantities for application case (Ombrone-Grossetano river: Paris 1991, Paris and Billi 1996).

$\frac{x_{fin}}{x_{in}}$	$\frac{Q_{fin}}{Q_{in}}$	$\frac{Q_{sfin}}{Q_{sin}}$	$\frac{D_{sfin}}{Q_{sin}}$
8.79	2.30	2.50	0.52

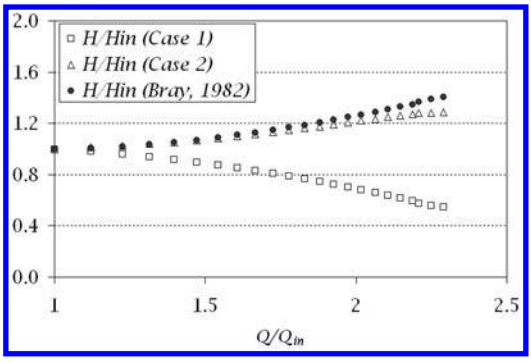

Figure 3. Dimensionless water depth H/H_{in} against dimensionless water discharge Q/Q_{in} (Bray 1982 formula; Case 1: Q, Q_s, D_s variable and i constant; Case 2: Q, Q_s, D_s, i variable).

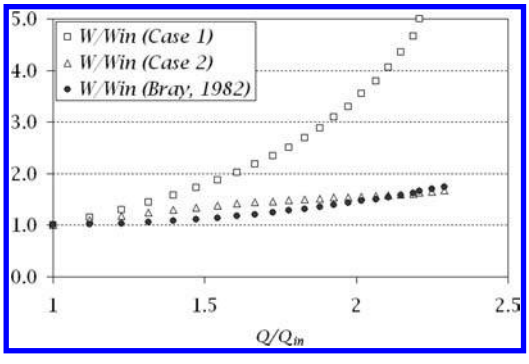

Figure 4. Dimensionless width W/W_{in} against dimensionless water discharge Q/Q_{in} (Bray 1982 formula; Case 1: Q, Q_s, D_s variable and i constant; Case 2: Q, Q_s, D_s, i variable).

In order to compare the results with classical *Regime equations exponents* the obtained hydraulic variables are subsequently interpolated by means of power functions previously introduced (Eq. 20): a comparison between obtained exponents and Blench (1957) and Bray (1982) formula is shown in Table 2. Case 1, where slope variability is not included, induces downstream decreasing water depth H (Fig. 3) and consequently negative E_H exponent, whereas Case 2 is

Table 2. Application case: comparison of power function exponents with Regime formula of Bray (1982) and Blench (1957).

	Bray	Blench	Case 1	Case 2
E_H	0.33	0.33	−0.79	0.36
E_W	0.50	0.50	2.17	0.55

characterized by complete analogy behavior predicted by regime formula.

These considerations underline the importance of including the whole entire spatial variability of river basin input quantities which can be achieved only employing an approach in downstream direction.

5 CONCLUSIONS

A new analytical method based on a '*downstream*' approach for determination of equilibrium configuration of self formed channel has been presented.

The approach includes the spatial variability along the river reach of the quantities related to hydrological, morphological and sedimentological river basin characteristics, assuming as input variables water discharge, sediment size and sediment load distributions together with longitudinal bed slope along the river axis.

The stable configuration is obtained under the hypothesis of steady flow condition and no change in the bed level. To this aim 1D steady flow equation, 1D sediment continuity equation has been combined with two general expression of flow resistance formula and sediment transport formula obtaining a 1st order variable coefficients ordinary differential equation. The obtained differential equation points out that at the equilibrium configuration no critical flow condition occurs along the entire river length: the result is found valid for every combination of sediment transport and flow resistance formula exponents α and n. Further inspections on the possible physical justification of such phenomena are recommended.

It has been pointed out also how adopting an *approach at a station* width W and water depth H are inversely proportional to each other (Eq. 13, 14, 15) and thus characterized by opposite behavior with respect to input variables: this result suggests that in order to obtain *classical* hydraulic variables regime exponents (e.g. Blench 1957, Bray 1982) it is necessary to include downstream variation of the input variables.

Furthermore, analytical investigation has pointed out how hydraulic variables are both quantitatively and qualitatively strongly influenced by the chosen value of exponents n and α, in particular when the quantity $(2\alpha - 2n + 3)$ is approaching to zero.

A preliminary application test (Ombrone-Grossetano river, Italy) has been carried out, mainly to show the application procedure of the present method. The results show the importance of including the whole entire spatial variability of river basin input quantities and thus the appropriate characteristics of the proposed downstream method, that looks promising, especially to find rational explanation to *Regime formula* exponents.

ACKNOWLEDGEMENTS

The authors wish to thank Alberto Pistolesi (University of Florence, Italy) and Dr. Bruno Volzone (Department of Mathematics and Applications 'R. Caccioppoli', University of Naples, Italy) for the precious help concerning the analytical developments of the present method.

Two-layer approach for transcritical flow on mobile bed: Nickpoint migration

C. Savary, M. Bellal & Y. Zech
Dept. of Civil and Environmental Engineering, Université catholique de Louvain, Louvain-la-Neuve, Belgium

ABSTRACT: The transcritical flow presented in the paper consists in a transition from a mild to a steep bed slope, with a change in the flow regime from subcritical to supercritical at the transition (nickpoint). Experiments were carried out in the UCL sediment flume with uniform non-cohesive sediment under various hydraulic and geometric conditions. A two-layer model is proposed, able to cope with intense transport and severe transients. The Chezy-like friction coefficients of the model are calibrated on uniform flows conditions. Then the way to handle the boundary conditions is exposed, with a comparison between the common (Saint-Venant-Exner) and the two-layer approaches. The numerical and experimental results are successfully compared (bed and water levels) and the numerical evolution of the solid transport with time and space is analysed. Finally, evolution in time of the boundary conditions is presented.

1 INTRODUCTION

Transcritical flows over mobile bed are challenging to model due to the rapid variation in space and time of the solid transport and to the specific treatment required for boundary conditions. The experiment carried out by Bellal (Bellal et al. 2004) illustrates the morphological changes due to a transition from a mild to a steep bed slope. A change is observed in the flow regime from subcritical to supercritical at the transition (nickpoint). Such a transition generates a critical section moving upwards with regressive erosion. The nickpoint is associated with an important increase in bed shear stress and transport rate.

The common Saint-Venant-Exner approach (Rahuel 1988, Correia 1990, Correia et al. 1991) may fail in reproducing such sudden variation of transport due to the discontinuities in regime. A two-layer approach (Capart, 2000) is proposed, where the bed-load transport layer is explicitly considered. Moreover, it offers more possibilities to deal with boundary conditions including those associated to morphodynamics, above all if transcritical flow is expected. The solid discharge depends on the shear stresses applied at each layer interface. These shear stresses are linked to Chezy-like friction coefficients, which are calibrated in uniform flows conditions using the Meyer-Peter-Müller and Manning formulae. Then the way to handle the boundary conditions is exposed, with a comparison between the common (Saint-Venant – Exner) and the two-layer approaches. Afterwards, the water and bed profiles computed with the two-layer model are compared with measurements. The evolution of the solid transport with time and space and the displacement of the control section are analysed numerically. Finally, the change in time of the boundary conditions and the occurrence of a mixed control section are presented.

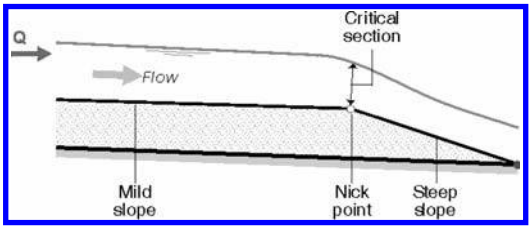

Figure 1. Initial condition.

2 EXPERIMENT

A control section over a changing erodible slope has been experimented by Bellal et al. (2004). The experiment represents the transition from a subcritical flow (water profile M_2) to a supercritical one (water profile S_2), transition from a mild slope to a steep slope (Fig. 1). A nickpoint is defined as the point of abrupt change in the longitudinal bottom profile of the channel. The control section is located at the nickpoint, the time-evolution is represented on Figure 2. The nickpoint and the control section propagates upwards, there is an erosion wave. The toe of the steep slope is non

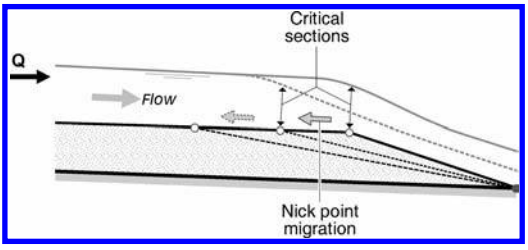

Figure 2. Nickpoint migration.

Table 1. Experimental data.

Test #	Q (l/s)	S_0^{up}(%)	S_0^{dwn} (%)
Run 1	4.90	0.4	2.02
Run 2	6.15	0.47	2.03
Run 3	7.33	0.45	2.00
Run 4	5.01	0.42	3.02
Run 5	6.18	0.44	5.03

erodible, it corresponds to the downstream end of the channel. The level of the toe of the steep slope thus remains the same during the regressive erosion.

In initial conditions, the nickpoint is pre-formed, it is located at 1 m (Table 1, run 1–3) or 1.1 m (Table 1, run 4–5) from the downstream end of the flume. The sediment bed is saturated with a small liquid discharge. Afterwards, the liquid discharge is progressively increased up to the experimental value. No sediment supply is furnished upstream.

At the end of the experiment, the control section and the nickpoint vanish as a supercritical flow takes place. As there is no sediment supply, no equilibrium state is reached.

Several experiments were performed within the following ranges of initial parameters reported in Table 1.

The experiment modelled below is run 1 (Table 1), the liquid discharge is 4.9 l/s, there is no sediment supply upstream. The upstream slope is 0.004 and the downstream slope is 0.02, these values respectively correspond to a mild and a steep slope.

3 NUMERICAL MODEL

To simulate such transient fluvial flows, a two-layer model developed by Capart (2000) and improved by Capart & Young (2002) in which boundary conditions treatment is introduced, is proposed. In this paper a one-dimensional model is used. Assuming the shallow-water hydrostatic pressure distribution, the flow is divided in two layers constituted of incompressible fluid. The main variables are the thickness of the water layer h_w and of the transport layer h_s, the

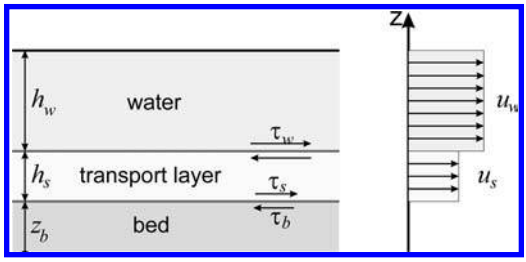

Figure 3. Two-layer model.

velocity in each layer u_w and u_s, respectively, and the level of the interface between the transport layer and the bed z_b (Fig. 3).

The transport layer and the fixed bed are constituted of a water-sediment mixture with a sediment concentration C, assumed as constant in time and in space. The volumetric density of this transport layer is $\rho_s' = (1-C)\rho_w + C\rho_s$ where ρ_w and ρ_s are the water and the grain density, respectively. In fact sediment mobilisation often requires a decrease of concentration (Spinewine, 2005) but, by seek of simplicity, this is not taken into account in the model here presented. The velocity in the transport layer u_s is allowed to be distinct from the velocity in the water layer u_w, but both are assumed to be uniform in their layer. As only the bed load is modelled, there is no mass and momentum exchange between the transport layer and the water. The only possible mass exchange occurs between the bed and the transport layer. The five-equation system proposed by Capart & Young (2002) results from mass (Equations 1–2) and momentum (Equations 4–5) conservation in each layer and from the definition of the erosion rate e_b(3).

$$\frac{\partial h_w}{\partial t} + \frac{\partial h_w u_w}{\partial x} = 0 \tag{1}$$

$$\frac{\partial h_s}{\partial t} + \frac{\partial h_s u_s}{\partial x} = e_b \tag{2}$$

$$\frac{\partial z_b}{\partial t} = -e_b \tag{3}$$

$$\frac{\partial h_w u_w}{\partial t} + \frac{\partial\left(h_w u_w^2 + \frac{1}{2} g h_w^2\right)}{\partial x} + g h_w \frac{\partial\left(z_b + h_s\right)}{\partial x} = -\frac{\tau_w}{\rho_w} \tag{4}$$

$$\frac{\partial h_s u_s}{\partial t} + \frac{\partial\left(h_s u_s^2 + \frac{1}{2} g h_s^2\right)}{\partial x} + g h_s \frac{\partial\left(z_b + \frac{\rho_w}{\rho_s'} h_s\right)}{\partial x} = \frac{\tau_w}{\rho_s'} - \frac{\tau_b}{\rho_s'} \tag{5}$$

where the erosion rate e_b depends on the shear stresses τ_s and τ_b:

$$e_b = \frac{\tau_s - \tau_b}{\rho_s' u_s} \tag{6}$$

The shear stress between the water and the transport layer τ_w and the shear stress applied on the fixed bed τ_s are assumed to follow a Chézy-like friction law:

$$\tau_w = \rho_w C_{f,w} |u_w - u_s| (u_w - u_s) \quad (7)$$

$$\tau_s = \rho'_s C_{f,s} |u_s| u_s \quad (8)$$

where $C_{f,w}$ and $C_{f,s}$ are water and sediment friction coefficients. The resistance shear stress to the flow, exerted by the fixed bed, is expressed by a Mohr–Coulomb relation.

$$\tau_b = \tau_{crit} + tg\,\varphi(\rho'_s - \rho_w) g h_s \quad (9)$$

where τ_{crit} is the threshold value of τ_s allowing erosion and φ is the angle of repose of the soil. This two-layer numerical scheme is documented in more details in Chen et al. (in press), where it is applied to flows involving water and mud layers.

A finite-volume approach is adopted to discretise the system. The system is solved in two steps (Capart & Young, 2002), the first solving the hyperbolic part of the system and the second the source terms. The hyperbolic part of the system is integrated using the Godunov scheme developed by Harten et al. (1983). This method allows to solve the conservative part of the system, it was extended by Fraccarollo et al. (2003) to take into account the non conservative products (pressure on the sloping interface) as additional terms (called lateralised terms) of the fluxes.

4 CALIBRATION

The friction coefficients are calibrated on base of uniform flow conditions. In uniform steady flow conditions, Equations (1–5) simplify since the partial derivatives $\partial/\partial t = 0$ and $\partial/\partial x = 0$, except $\partial z_b/\partial x = -S_0$. The solid transport is in equilibrium, which means that neither erosion nor deposition occurs; thus $\tau_s = \tau_b$.

The calibration consists in finding the friction coefficients corresponding to a flow described by five parameters, for given slope and water discharge, the uniform depth is calculated with the Manning formula and the solid discharge and the critical shear stress are evaluated with the Meyer-Peter-Müller formula. The calibration conditions depend on the flow characteristics. In the present application, the solid transport takes place mainly in the supercritical part of the flow, downstream the nickpoint. It was thus chosen to calibrate the friction coefficients using the parameters (q_w, h_w, q_s, S_0 and τ_{crit}) of a flow corresponding to a Froude number:

$$\mathbf{Fr}_w = \frac{u_w}{\sqrt{g h_w}} = 1.2 \quad (10)$$

which is a good average of the observed Froude number. If the calibrated friction coefficients are acceptable, the computed solid discharge should be close to Meyer-Peter-Müller predictions (Fig. 4) and the Manning coefficient should be close to the measurements (Fig. 5).

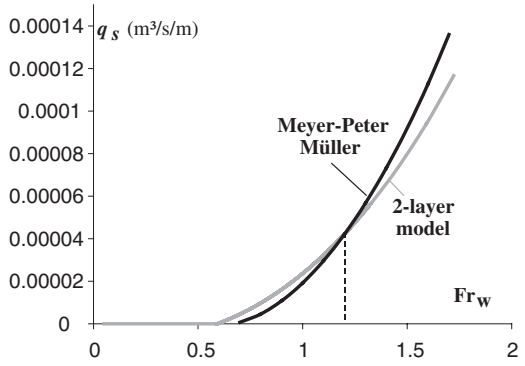

Figure 4. Evolution of solid discharge q_s with Froude number $\mathbf{Fr_w}$: comparison between two-layer model and Meyer-Peter-Müller formula (run 1 (Table 1), $C_{fw} = 0.02$, $C_{fs} = 0.128$).

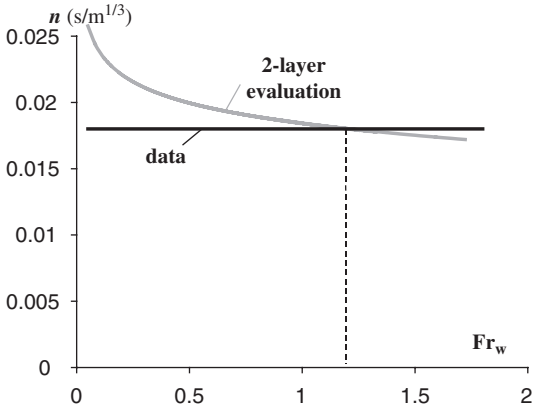

Figure 5. Evolution of roughness Manning coefficient n with Froude number $\mathbf{Fr_w}$: comparison between two-layer model and datas (run 1 (Table 1), $C_{fw} = 0.02$, $C_{fs} = 0.128$).

The solid discharge q_s is overestimated for Froude numbers lower than the calibration value ($\mathbf{Fr_w} = 1.2$) and underestimated for higher Froude numbers. In the range of $\mathbf{Fr_w} = 1 \ldots 1.4$, where the most important solid transport is noticed during the experiment, the estimations of the two-layer model and the Meyer-Peter-Müller formula are close. The Manning coefficient (labeled as data) is an estimation of the average experimental Manning coefficient. The main difference between this constant coefficient and the one deduced from the two-layer model is due to the difference between Manning formulation, used for calibration, and Chezy form, used to express the shear stresses.

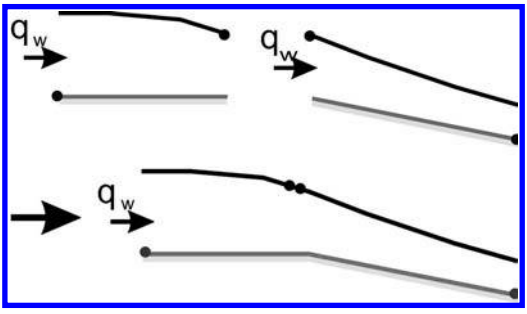

Figure 6. Classical boundary conditions in the case of the nickpoint migration transcritical case.

5 BOUNDARY CONDITION

First, the way the boundary conditions are treated with a classical model based on the Saint-Venant-Exner equations is exposed. Then the characteristic method (Abbot 1979) is applied to the two-layer model which is used here to model the nickpoint migration.

5.1 *Classical approach*

The main unknowns of the Saint-Venant-Exner equations are the water depth h_w, the water discharge q_w and the bed level z_b. Contrarily to the two-layer model, the transport layer is not explicitly considered in this approach. The boundary conditions have to be expressed as functions of the main unknowns h_w, q_w and z_b. As the solid discharge is calculated with a closure relation and is not one of the unknowns, it can not be imposed as a boundary condition. The Saint-Venant-Exner system of equations (Cunge et al. 1980) have three eigenvalues, for each Froude number, two of them are positive and one is negative (Vreugdenhil & de Vries 1967). It is usually stated that in supercritical flows, the two upstream conditions (linked to the positive eigenvalues) concern the hydrodynamic variable (h_w and q_w) and the downstream one (linked to the negative eigenvalues) concerns the sediments (z_b). By the same way, in subcritical flow, conditions on hydrodynamic have to be imposed upstream (q_w) and downstream (h_w), the second upstream condition concerns the sediments (z_b).

The flow is divided into two parts (Fig. 6), the reach located upstream the nickpoint (subcritical) and the one located downstream (supercritical). In each reach two conditions have to be imposed upstream and one downstream. As the two parts are joined, the bed level z_b should be imposed upstream and downstream and the water discharge q_w should be imposed upstream.

Of course, in the experiment, the bed level at the upstream reach can not be constant as there is no sediment supply. The boundary condition on the bed level is not adapted to this case, it would have been better to be allowed to impose the solid discharge instead of the bed level.

5.2 *Two-layer model*

Boundary conditions have to be expressed as functions of the main unknowns (h_w, h_s, z_b, q_w, q_s) of the five-equation system (1–5). In opposition with the previous classical approach, it is possible to express boundary conditions on the solid discharge q_s. Neglecting the source terms, the five-equation system (1–5) can be written

$$\frac{\partial \mathbf{U}}{\partial t}+\frac{\partial \mathbf{F(U)}}{\partial x}+\mathbf{H(U)}\frac{\partial \mathbf{U}}{\partial x}=\frac{\partial \mathbf{U}}{\partial t}+\frac{\partial \mathbf{F(U)}}{\partial \mathbf{U}}\frac{\partial \mathbf{U}}{\partial x}+\mathbf{H(U)}\frac{\partial \mathbf{U}}{\partial x}$$

$$=\frac{\partial \mathbf{U}}{\partial t}+\mathbf{A(U)}\frac{\partial \mathbf{U}}{\partial x}+\mathbf{H(U)}\frac{\partial \mathbf{U}}{\partial x}=\frac{\partial \mathbf{U}}{\partial t}+\mathbf{A'(U)}\frac{\partial \mathbf{U}}{\partial x}=0 \quad (11)$$

where $\mathbf{A(U)}$ is the Jacobian matrix and $\mathbf{A'(U)}=\mathbf{A(U)}+\mathbf{H(U)}$ a kind of pseudo-Jacobian matrix.

The five-equation system has five eigenvalues, one of them is equal to zero. To analyse the sign of the other four eigenvalues, the characteristic polynomial (12) and the product (13) of the non-zero roots λ_i, $i=1\ldots4$ are written ($\mathbf{I}$ is the identity matrix):

$$\left|\mathbf{A'}-\lambda\mathbf{I}\right|=0 \Rightarrow \lambda\left(a\lambda^4+b\lambda^3+c\lambda^2+d\lambda+e\right)=0 \quad (12)$$

$$\prod_{i=1}^{4}\lambda_i=\frac{e}{a}=c_s^2c_w^2\left(1-\frac{\rho_w}{\rho_s'}\right)+u_s^2u_w^2-\left(c_w^2u_s^2+c_s^2u_w^2\right) \quad (13)$$

with $c_w=(gh_w)^{1/2}$ and $c_s=(gh_s)^{1/2}$, respectively the celerity in the water and the transport layer. The sign of the non-zero eigenvalue product (13), and thus of the characteristics, changes when

$$\mathbf{Z_{sw}}=\frac{c_s^2c_w^2\left(1-\frac{\rho_w}{\rho_s'}\right)+u_s^2u_w^2}{c_w^2u_s^2+c_s^2u_w^2}=\frac{\left(1-\frac{\rho_w}{\rho_s'}\right)+\mathrm{Fr}_s^2\mathrm{Fr}_w^2}{\mathrm{Fr}_s^2+\mathrm{Fr}_w^2}=1 \quad (14)$$

where $\mathbf{Fr_s}=u_s/c_s$ is the sediment Froude number. The non-dimensional number $\mathbf{Z_{sw}}$ is a kind of two-layer Froude number describing the interference between water and sediment wave celerities. According to Equations (13–14), if $\mathbf{Z_{sw}}>1$, the number of negative characteristics is even (0 or 2 negative characteristics) while if $\mathbf{Z_{sw}}<1$, this number is odd (1 negative characteristic). If the transport layer vanishes ($h_s\rightarrow 0$), $\mathbf{Z_{sw}}$ becomes equivalent to the square of the water Froude number $\mathbf{Fr_w}$. If the water layer disappears ($h_w\rightarrow 0$), $\mathbf{Z_{sw}}$ becomes equivalent to the square of the sediment Froude number $\mathbf{Fr_s}$. If $\mathbf{Z_{sw}}=1$ there is a kind of control section, which corresponds to a relation between the depths (h_w and h_s) and the discharges (q_w and q_s) in each layer.

The non-dimensional number $\mathbf{Z_{sw}}$ (Fig. 7) is calculated for a range of water Froude numbers with the friction coefficients calibrated above.

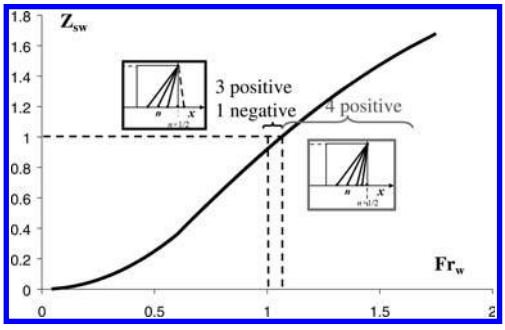

Figure 7. Evolution of the number Z_{sw} computed with the water Froude number Fr_w (run 1 (Table 1), $C_{fw} = 0.02$, $C_{fs} = 0.128$).

Three areas have to be distinguished:

Subcritical flow

– $\mathbf{Fr_w} < 1$: ($\mathbf{Z_{sw}} < 1$) three positive eigenvalues and one negative imply three upstream boundary conditions (e.g.: q_w, q_s, h_s) and one downstream (e.g.: h_w or control section)

Supercritical flow

– $1 < \mathbf{Fr_w} < 1.07$: ($\mathbf{Z_{sw}} < 1$) three positive eigenvalues and one negative imply three upstream boundary conditions (e.g.: q_w, q_s, h_s) and one downstream (e.g.: h_w or control section)

– $\mathbf{Fr_w} > 1.07$: ($\mathbf{Z_{sw}} > 1$) four positive eigenvalues imply four upstream boundary conditions (e.g.: q_w, q_s, h_w, h_s)

Till the control section vanishes, the flow at the upstream boundary remains subcritical and three upstream boundary conditions have to be imposed. The flow at the downstream boundary is always supercritical during the experiment, the number of downstream boundary conditions will depend on the Froude number. Till the Froude number is higher than 1.07, there is a total transmission without any downstream boundary condition. If the Froude number decreases below 1.07, the downstream end may influence the flow and a boundary condition has to be imposed (Fig. 8).

The eigenvalues are ranked from the highest to the lowest. The unknowns at the upstream interface ($h_{w,1/2}$, $h_{s,1/2}$, $z_{b,1/2}$, $q_{w,1/2}$, $q_{s,1/2}$) are obtained by the solution of the system composed of the three boundary conditions

$$q_{w,1/2} = q_{w,up} \tag{15}$$

$$q_{s,1/2} = q_{s,up} = 0 \tag{16}$$

$$h_{s,1/2} = 0 \tag{17}$$

one compatibility relation linked to the vertical (18) characteristic (eigenvalue equal to zero λ_4).

$$\left(z_{b,1/2}^{t+dt} - z_{b,1/2}^{t}\right)_{\lambda_4} = 0 \tag{18}$$

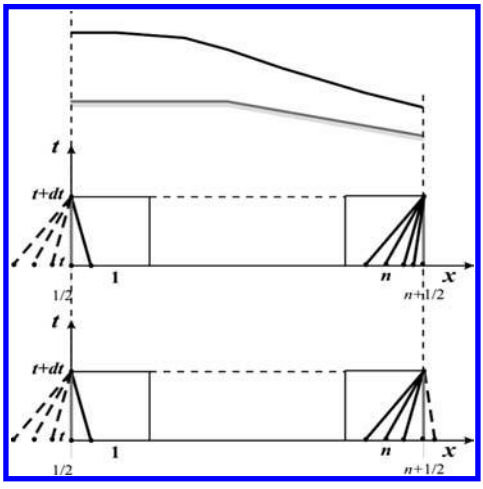

Figure 8. Two-layer boundary conditions in the case of the nickpoint migration transcritical case.

and another compatibility relation linked to the negative characteristic (negative eigenvalue λ_5) (Savary & Zech, submitted).

In the case of 4 positive eigenvalues downstream, the unknowns at the downstream interface ($h_{w,n+1/2}$, $h_{s,n+1/2}$, $z_{b,n+1/2}$, $q_{w,n+1/2}$, $q_{s,n+1/2}$) are obtained by the resolution of the system composed of the five compatibility relations which can be simplified to express a total transmission.

$$h_{w,n+1/2} = h_{w,n} \qquad h_{s,n+1/2} = h_{s,n} \qquad q_{w,n+1/2} = q_{w,n}$$

$$q_{s,n+1/2} = q_{s,n} \qquad z_{b,n+1/2}^{t+dt} = z_{b,n+1/2}^{t} \tag{19}$$

In the case one of the eigenvalue is negative downstream, even if the flow is supercritical, a boundary condition has to be imposed at the downstream end, this case will be exposed below.

6 COMPARISONS

The experimental and numerical initial conditions are plotted on Figure 9. The numerical initial bed level is compound of two constant slopes, contrarily to the experimental one, which is more irregular, due to difficulty to realise a perfect slope in a flume. Some differences between the numerical results and the experimental data are due to this initial dicrepancy. The non erodible bed (bottom of the flume) is set to level 0.11 m.

Figure 10 illustrates the evolution with time of water and bed levels. The regressive erosion induces the slope upstream the nickpoint increases as the slope downstream decreases till the two slopes become identical in order that the nickpoint and the control section

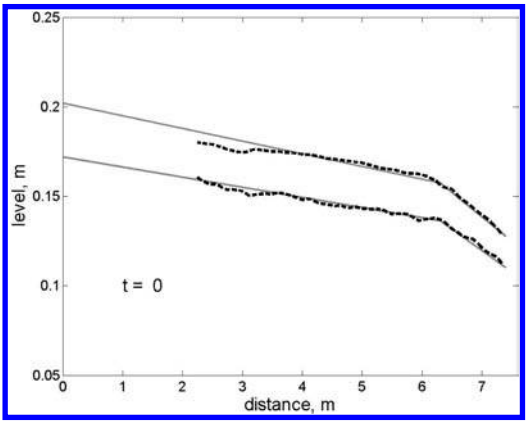

Figure 9. Comparison between experimental (.....) and numerical (—) levels: initial conditions.

vanish. The bed level at the downstream end remains the same during all the computation, the downstream slope decreases taking this fixed point as tilting point. There is no sediment supply upstream, the flow thus erodes a part of the bed at the upstream part to constitute a transport layer. The erosion in the upstream end stops when the shear stress applied to the bed decreases below the critical treshold. The erosion area enlarges downwards with time. In the downstream part, the computed bed level is a little higher than the experimental one. As exposed in the calibration section (Fig. 4), for high Froude numbers, the computed solid discharge is a little lower than the one estimated by Meyer-Peter-Müller inducing a lower erosion. Moreover, when the Froude number is lower than 1.2 (mainly upstream the nickpoint), the solid discharge is overestimated in comparison with Meyer-Peter-Müller predictions. An overestimated solid discharge coming from the upstream reach induces an overestimated deposition in the downstream reach. As the bed and water levels are not measured there, no comparison near the upstream boundary is possible.

The evolution of the solid discharge along the flume with time is plotted in Figure 11. In initial conditions, there is no transport layer, thus the solid discharge is equal to zero everywhere. The evolution with time allows to identify three areas.

– First, the upstream part of the flow (distance $<\sim$1.8 m) corresponds to the creation of the transport layer. The slope and the solid discharge decrease with time in this area. At the upstream end, as it is imposed like a boundary condition, the solid discharge is zero. Once the shear stress applied to the bed decreases below a threshold value, no solid transport occurs. The area without any solid discharge enlarges with time, the solid discharge inquiring some space to increase.
– The second area (1.8 $<\sim$ distance $<\sim$ 6 m) is the part of the flow located between the nickpoint and the upstream area. At the beginning of the experiment, a water profile M_2 develops from the critical depth at the nickpoint. As the length is important enough and till the slope is quite regular, it reaches the uniform depth upstream. For the two or three first computation times, there is an area ($\sim$=2 m or 2.5 m) where the flow is close to uniform and the solid discharge is close to equilibrium. The solid discharge increases approaching the nickpoint. The solid discharge also increases with time inducing a rise of slope in this area.
– The last zone is the part of the flow, downstream the nickpoint, where the flow is supercritical. At the beginning of the experiment, the solid discharge increases sharply in this area. Due to the regressive erosion, the solid discharge and the bed slope decrease with time in this part of the flow.

At the end of the experiment/computation, the nickpoint vanishes and the different areas become less distinguishable.

The transport layer depth h_s is set to zero at the upstream interface, however the flow generates a transport layer in the first cell. Even if the solid discharge is equal to zero, the proximity of the threshold leads to a small fictitious transport layer depth but with a velocity equal to zero (Fig. 12).

The water Froude number (Fig. 13) and the solid discharge (Fig. 11) are closely linked, the three areas described above appear in both figures. In the upstream area, the flow becomes more and more subcritical with time, the slope and so the Froude number decrease. In the middle area the slope and the Froude number increase with time. Downstream the nickpoint, the regressive erosion makes the slope and the Froude number decrease. During all the experiment, the flow remains transcritical, the movement of the control section is depicted in Figure 14, the control section propagates first upwards and then downwards in a space interval smaller than 1 m (during the experiment). When the non-dimensional number $\mathbf{Z_{sw}}$ becomes lower than 1 (589 s and 851 s) (Fig. 15), the downstream end influences the flow and the nickpoint stops propagating upwards to move downwards. The intuition, mentioned before, that the nickpoint propagates upwards is thus only partly confirmed by the numerical results. Unfortunately the profiles are not smooth enough to observe the displacement of the control section experimentally. If the computational time was longer, the nickpoint would reach the downstream end and the flow would become subcritical all along the flume.

For the two last computation times (589 s and 851 s), the non-dimensional number $\mathbf{Z_{sw}}$ (Fig. 15) is lower than 1 at the downstream end ($\mathbf{Fr_w} < 1.07$). It implies,

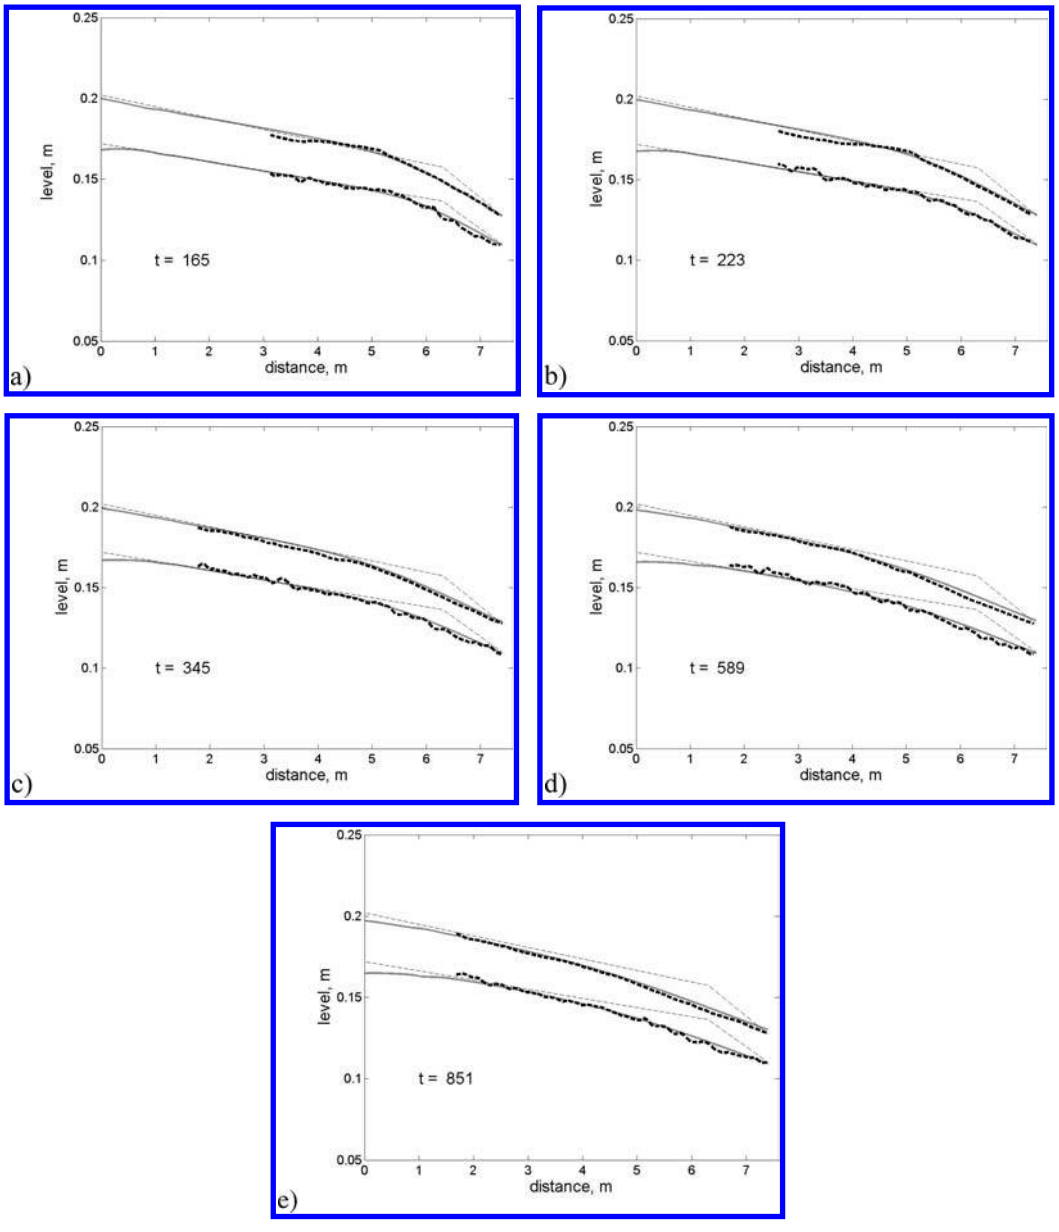

Figure 10. a–e. Comparison between experimental (…..) and numerical (—) levels: time evolution (108 s–851 s) (initial conditions (- - - -)).

as illustrated in Figure 7, one boundary condition has to be imposed at the downstream end. Looking at the experiment, the choice of which condition to impose is not obvious. A parallelism is made with a pure hydrodynamic example (Fig. 16). A supercritical water profile S_2 develops on a steep slope flume, if the slope decreases under the critical slope, the flow becomes subcritical, the water profile becomes M_2. The location of the control section changes from the upstream to the downstream end. If the slope decreases again, the downstream condition remains a critical section $\mathbf{Fr_w} = 1$ (corresponding to a eigenvalue equal to zero). In the case of a two-layer flow, when the slope decreases, the non-dimensional number $\mathbf{Z_{sw}}$ decreases till it reaches 1 at the downstream end. Then, the influence on the flow moves from the upstream to the

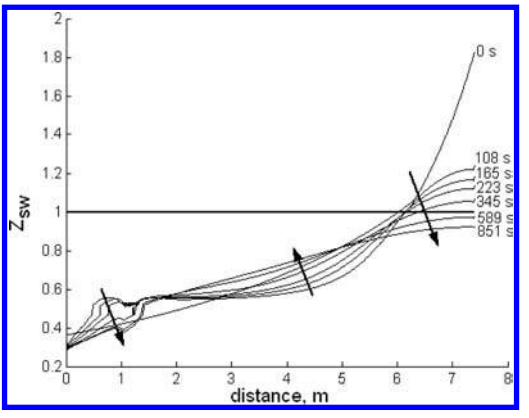

Figure 15. Variation of the computed non-dimensional number $\mathbf{Z_{sw}}$ along the flume with time.

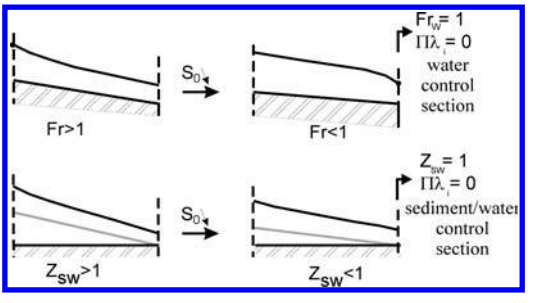

Figure 16. Comparison between hydrodynamic case, control section.

downstream end. If the slope decreases again, there is a kind of mixed control section at the downstream end, the non-dimensional number $\mathbf{Z_{sw}}$ remains equal to 1 (corresponding to a eigenvalue equal to zero).

In this case, one of the compatibility relation has to be replaced by a mixed control section condition. $\mathbf{Z_{sw}}$ is fixed to 1, implying one of the eigenvalue is equal to zero.

7 CONCLUSIONS

The case of a transcritical flow over a changing bed slope was discussed. A two-layer model was proposed as an alternative to common models based on Saint-Venant-Exner equations. After a short description of the experimental conditions and the two-layer model proposed (Capart & Young, 2002), the friction coefficients appearing in the model were calibrated using Manning and Meyer-Peter-Müller formulations. Then, the way to treat the boundary conditions was exposed for both, classical and two-layer, models. Concerning boundary conditions, the two-layer approach revealed to be more flexible and closer to real conditions. A good agreement was observed between the two-layer model and the experiment the boundary conditions treatment revealed a mixed water-sediment control section downstream. It would be interesting to test and compare various boundary conditions to observe their influences on the results.

ACKNOWLEDGEMENTS

The authors would like to thank H. Capart for his advices about using the eigenstructure to handle the boundary conditions and for the access to his two-layer software. The authors are thankful to the laboratory staff for his help during the measurement campaign.

On the effect of the bed morphology on the river confluence hydrodynamics

D. Đorđević & M. Jovanović
Faculty of Civil Engineering, University of Belgrade, Belgrade, Serbia & Montenegro

ABSTRACT: A river confluence is known for the strong three-dimensional flow effects. The confluence hydrodynamics is significantly influenced by the river bed morphology. Two morphological features are typical for river confluences: a discordance of the two river bed elevations at the entrance to the confluence and presence of a scour hole in the post-confluence channel. The objective of this paper is to examine the influence of these morphological features on the flow structure by using a three-dimensional numerical model. The confluence of the Sava and Danube Rivers (in the city of Belgrade) offers excellent possibilities for this investigation, as both bed elevation discordance and scour hole are present. The results of numerical simulations for this case are compared to the results obtained for the three hypothetical bed configurations of the same confluence: a) concordant bed elevations and the scour hole, b) concordant bed elevations and no scour hole, and c) discordant bed elevations and no scour hole. An attempt is made to generalise the results of numerical simulations. Results are discussed in terms of the secondary flow pattern and the distribution of the turbulent kinetic energy.

1 INTRODUCTION

A river confluence has always been a challenging subject for river hydrodynamics and morphodynamics investigations due to complex flow phenomena and processes occurring in both the confluence and the post-confluence channel. The complexity of the phenomena and processes arises from the strong three-dimensional flow effects resulting from the interaction of the incoming flows and the interaction thereof with the river bed. In the last decade, new methods and tools for investigation of complex flows were developed and/or the existing methods and tools were improved, offering opportunities to shed more light on the processes characteristic for a river confluence. The majority of investigations were, however, concerned with the laboratory models of confluences (Best & Reid 1984, Biron et al. 1996b, 2004, Bradbrook et al. 2000, 2001, Huang et al. 2002). There are only a few field investigations, mostly on the small rivers (Biron et al. 1996b, Bradbrook et al. 2000, Rhoads & Sukhodolov 2001).

Unlike a river confluence, a laboratory model of a confluence assumes a simplified plan-form and cross-section geometry of the main river, tributary and post-confluence channels. Hence, not all relevant factors necessary for complete understanding of the confluence hydrodynamics can be encountered for with a laboratory model of a confluence. Field investigations have shown, for instance, that transition between the shallower tributary bed and the main river bed at the entrance to the confluence of alluvial rivers is not as vertical as considered in the laboratory models of confluences (Rhoads & Sukhodolov 2001, Jovanović et al. 2005). Also, no significant increase in the width of the post-confluence channel was observed. Confluences are observed to have a form of the scour hole, too (Rhoads & Sukhodolov 2001), the position and size of which are influenced by the plan-form of the confluence, geological composition of the river bed and the upstream hydrologic regimes of the confluent streams.

The confluence of the Sava and Danube Rivers in the city of Belgrade is a typical example of an asymmetrical confluence with the shallower channel of the Danube river, no significant increase in the post-confluence channel width, and presence of the scour hole. With such a complex plan-form and bed morphology it was interesting to investigate how different river bed configurations may influence the confluence hydrodynamics. Therefore numerical simulation results of the three-dimensional flow at the confluence with the observed bed topography were compared to the results for three hypothetic river bed morphologies: a) concordant beds and the scour hole, b) discordant beds and no scour hole and c) concordant beds and no scour hole. Simulations were performed for various combinations of the upstream hydrologic regimes of the confluent streams.

2 PROBLEM DESCRIPTION

The confluence of the Danube and Sava Rivers in the city of Belgrade is depicted in Figure 1. The

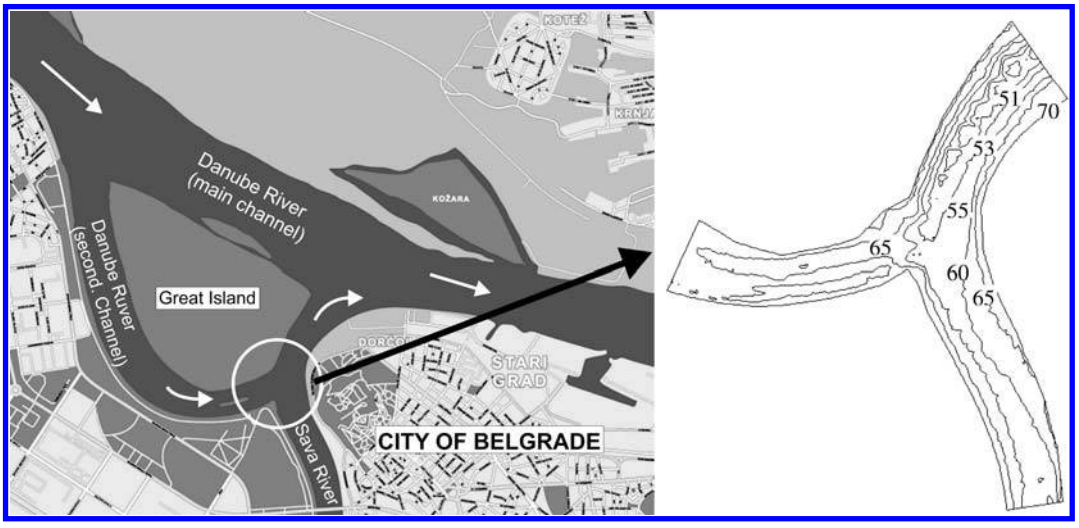

Figure 1. Site location (left) and bed elevation contours (right).

characteristic shape of the network is caused by the presence of the Great Island which divides the Danube River into the so called "Main channel" with the wider, almost straight channel, and a narrower secondary channel. The later one forms a bend in its downstream reach. Upstream from the confluence the channel of the Sava River is almost straight, while downstream from the confluence it forms a bend of radius R = 700 m.

The subject of the present study is a portion of the confluence encircled in Figure 1. It includes the Sava River (the main river in this case), and the branch of the Danube River (the tributary in this case). The junction angle at the confluence is 78°. Surveys of the river network bathymetry indicate that the bottom of the tributary channel is approximately 10 m above the bottom of the main river at the entrance to the confluence, and that there is a bar along the right bank of the main river immediately upstream from the confluence. In addition, scour hole is formed in the central part of the post-confluence channel with the deepest region of approximately 10 m in the vicinity of the cross-section D (Figs. 1 and 2). The widths of all three channels are almost the same varying in the range between 275 m and 290 m (Tab. 1).

Bathymetries for the other three river bed configurations (Tab. 2) were defined either by lowering the bottom of the tributary channel to match the bed level of the main river channel (case 3), or by "filling" the scour hole in the post-confluence channel (cases 2 and 4) to the level of 54 m.

The effect of the bed morphology on the confluence hydrodynamics can be analysed by covering a range of possible hydrological conditions at the confluence. A set of considered discharge combinations

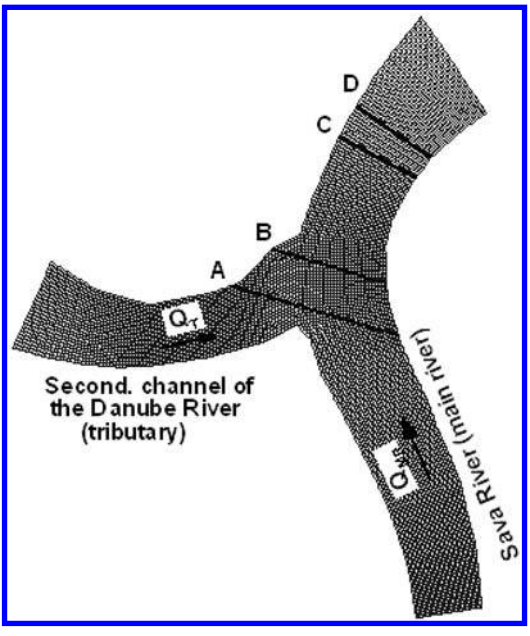

Figure 2. Computational mesh and position of the analysed cross-sections.

is given in Table 3. For the sake of simplicity, non-deformable bed was assumed for all considered river bed configurations.

A momentum-flux ratio ($M_R = \rho V_{MR} Q_{MR} / \rho V_T Q_T$) differs for different river bed configurations. The two values of M_R correspond to each D_R value, since two combinations of the bed morphology at the entrance to the confluence (concordant and discordant beds) were

supposed (Tab. 4). The M_R values for concordant and discordant beds differ by 13% at most. This should be kept in mind during the results discussion, since the discharge-ratio value was chosen as a common parameter for the comparison of the results.

3 NUMERICAL MODELLING

The three-dimensional numerical model (SSIIM2) used for the modelling is described elsewhere (Olsen 2000, 2002, 2004). The model solves the three-dimensional Reynolds averaged Navier-Stokes equations, with the standard k-ε turbulence-model closure. As this model assumes isotropic eddy viscosity, it should to be calibrated when considering strongly anisotropic flows, such as those occurring in river confluences (Bradbook et al. 2000). Since the field measurements of the flow field at the confluence of the Sava and Danube Rivers are still under way, no calibration is possible yet. Therefore, the original values of the k-ε model constants (C_μ, $C_{\varepsilon 1}$, $C_{\varepsilon 2}$, σ_k, and σ_ε) were used. For this reason, numerical simulation results obtained for the four considered bed configurations can only be used for the qualitative comparative analyses. As will be shown later, these comparative analyses provide a ground for some general conclusions.

The SSIIM2 model solves the governing equations using the finite-volume method on a three-dimensional non-orthogonal unstructured grid. This type of grid allows for flow simulation in dendritic channel networks with complex bathymetry, characteristic for river confluences. The model uses

SIMPLE method for the pressure term modelling and the second-order upwind scheme for discretisation of the convective terms. A wall law is used along solid boundaries.

In the present study, steady flow conditions were assumed. Symmetric boundary conditions were used for all variables at the surface and the outflow boundary. The water surface was fixed, which can be justified by the fact that the confluence of the Sava and Danube Rivers is under the strong influence of the Iron Gate Dam backwaters and the water level may be considered nearly horizontal. At the inflow boundaries constant fluxes were specified. To ensure mass continuity, a constant flux was prescribed at the outflow boundary.

Computational domain included channels of the main river and the tributary in the length of 1 km each and 1 km of the post-confluence channel. The length of 1 km along each confluent stream ensured no influence of the upstream boundary condition on the flow pattern in the confluence. The non-orthogonal unstructured grid consisted of two non-orthogonal structured grids – one along the main river and the post-confluence channel (block1) and the other along the tributary (block 2). After detailed grid sensitivity analysis, a grid with the following dimensions was used for all considered river bed configurations: $201 \times 31 \times 11$ for block 1 and $91 \times 26 \times 11$ for block 2 (Fig. 2).

Bed material in the tributary is finer than bed material in the main river ($d_{50,T} = 2$ mm, $d_{50,MR} = 8$ mm). Therefore, non-uniform roughness was used. The roughness was defined according to the given grain sizes.

4 RESULTS AND DISCUSSION

The effect of the bed morphology on the confluence hydrodynamics is analysed by observing the forms of *secondary circulation* and the change in the *turbulent kinetic energy* distribution at chosen cross-sections at

the confluence and in the post-confluence channel. Secondary circulation shall be discussed, first.

Depending on the D_R (M_R) value, magnitudes of the cross-stream velocity vectors in the post-confluence channel may be an order or two orders of magnitude lower than the intensities of the main stream velocity vectors. Therefore, cross-section surface streamlines were used to illustrate secondary circulation for all the considered D_R (M_R) values.

Four cross-sections were chosen, two of which are situated at the very confluence, and the other two in the scour hole (Fig. 2). All cross-sections are viewed in the downstream direction and perpendicular to the cross-section.

Development of the secondary circulation through the confluence and the post-confluence channel is presented on Figures 3–6, for the case when two secondary circulation counter-rotating vortices are formed in the

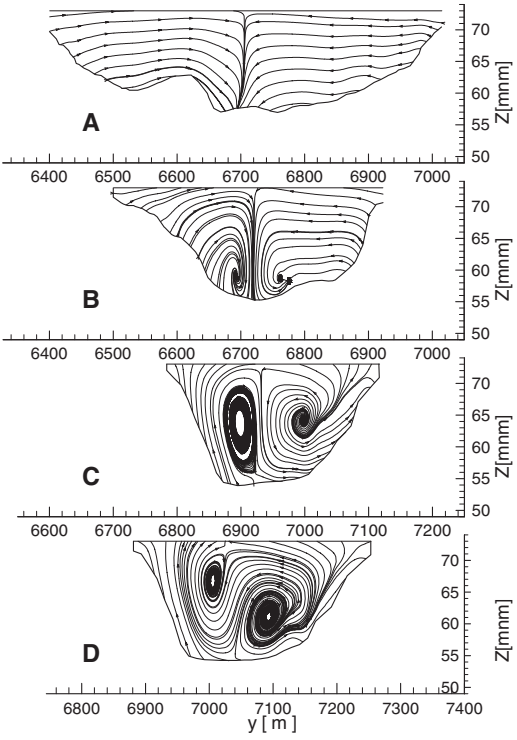

Figure 5. Streamlines at chosen locations showing secondary circulation in the cross-section (case 3 – discordant beds and no scour hole) for $D_R = 2.11$.

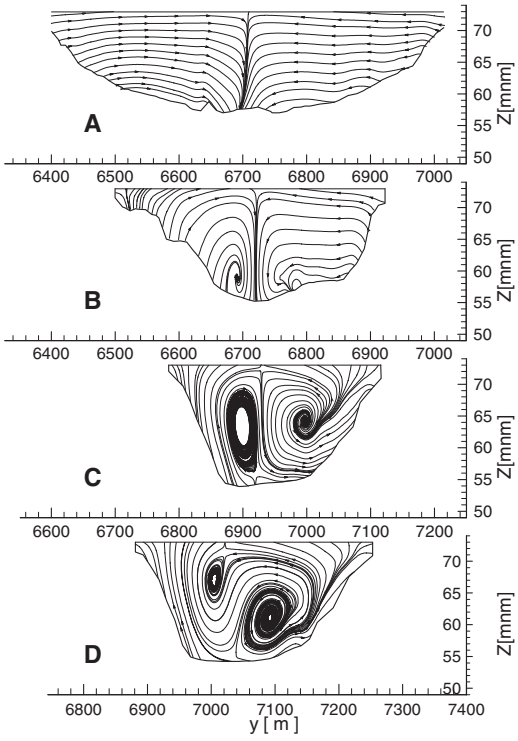

Figure 6. Streamlines at chosen locations showing secondary circulation in the cross-section (case 4 – concordant beds and no scour hole) for $D_R = 2.11$.

post-confluence channel ($D_R = 2.11$). At the cross-section closest to the confluence apex (cross-section A), cross-stream velocity vectors from the confluent streams converge to each other, as was observed in all investigated confluences (Biron et al. 1996b, Bradbrook et al. 2000, Rhoads & Sukhodolov 2001). In the cases 1 and 3 (discordant bed cases – Figs. 3 and 5) deflection of the streamlines from the vertical towards the sloping backstep at the mixing interface is a result of topographic steering at the back-step. Similar circulation pattern characterises the cross-section B.

However, flow patterns at the cross-sections C and D differ from case to case. Generally, two counter-rotating vortices are formed for all cases at both cross-sections. In the cases 3 and 4 (Figs. 5 and 6), no difference between the secondary flow patterns at C can be noticed for the considered D_R value. The same holds for the cross-section D, which leads to a conclusion that in the absence of the scour hole, the bed discordance at the entrance to the confluence does not influence the secondary circulation far downstream in the post-confluence channel.

In the cases with a scour hole (Figs. 3 and 4) the bed discordance (Fig. 3) weakens the right vortex at the section C and strengthens the left one, which now occupies more vertical space in the cross-section. At the cross-section D, a single right vortex, which rotates close to the bottom in the central part of the section, is lifted from the bottom, moved towards the right bank and its core is split into two smaller ones. The left vortex is moved towards the water surface. All these differences indicate that for a specific D_R value, the flow pattern in the scour hole is strongly governed by the momentum-flux ratio at the confluence (Tab. 4). In the cases 3 and 4 (Figs. 5 and 6) the right vortex is less elongated in the vertical direction as the dynamic pressure at the bottom is greater in the absence of the scour hole. The size of the left vortex decreases between the sections C and D due to better realignment of the dominant-flow streamlines (flow in the main stream direction).

Changes in the secondary circulation with respect to the change in the discharge-ratio value D_R are shown only for the cross-sections C and D (Figs. 7 and 8). As was observed for $D_R = 2.11$, in the absence of the scour hole (cases 3 and 4 – Figs. 7 and 8), change in the M_R value due to the discordance at the confluence does not influence the flow pattern in the post-confluence channel for neither of analysed combinations of the

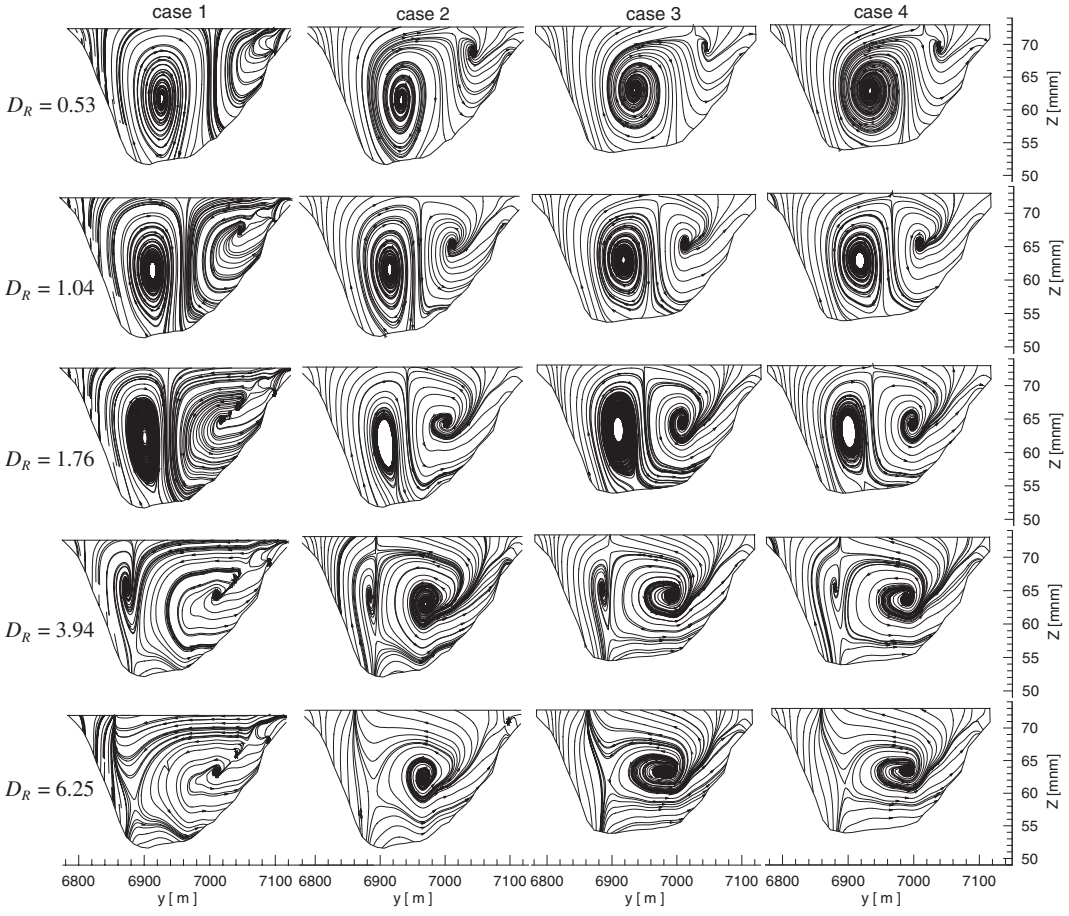

Figure 7. Streamlines showing change in the secondary circulation at the cross-section C with respect to change in the discharge-ratio value (D_R) for the four analysed river bed configurations.

hydrologic regimes of the confluent streams. However, this is not true when the scour hole is formed downstream from the confluence (cases 1 and 2).

Generally, the cases 2, 3 and 4 are characterised by the same type of secondary circulation. The only difference is in the dimensions and shape of the vortices. When there is a scour hole (cases 1 and 2), the vortices are more elongated in the vertical direction as a consequence of the topographic steering and resulting lower dynamic pressure. In contrast to the other three cases, in the case 1, decrease in the momentum-flux ratio value at the confluence due to the bed discordance, results in complete or almost complete diminishing of the vortex core on the right side of the channel at the cross-section C (Fig. 7). At the cross-section D, changes in flow patterns due to decrease in M_R depend on the D_R value (Fig. 8). For $D_R < 1.0$ the right vortex is isolated from the rest of the flow in the cross-section; for $D_R \approx 1.0$ the right vortex is larger than the one pertaining to the case 2. For the D_R values 1.76 and 2.11, the core of the vortex is split into two smaller ones, while for the higher D_R values ($D_R \geq 3.94$) the right vortex is moved to the centre of the cross-section and consists of one big and one very small core.

Changes in the D_R value influence the flow pattern at the cross-section C in the following (Fig. 7). For $D_R < 1.0$ a single large dominating clockwise vortex forms in the centre of the channel due to fast realignment of the streamlines that describe the dominant flow. This fast realignment of the streamlines results from the fact that the M_R value is still less than unity, which is in accordance with similar investigations (Bradbrook et al. 2000) (Tab. 4). For $1.0 < D_R < 2.5$ dominant-flow streamlines are not completely aligned by the cross-section C, and two counter-rotating vortices are formed. The stronger one to the left is formed above the deepest part of the cross-section. With further increase in D_R, the main river

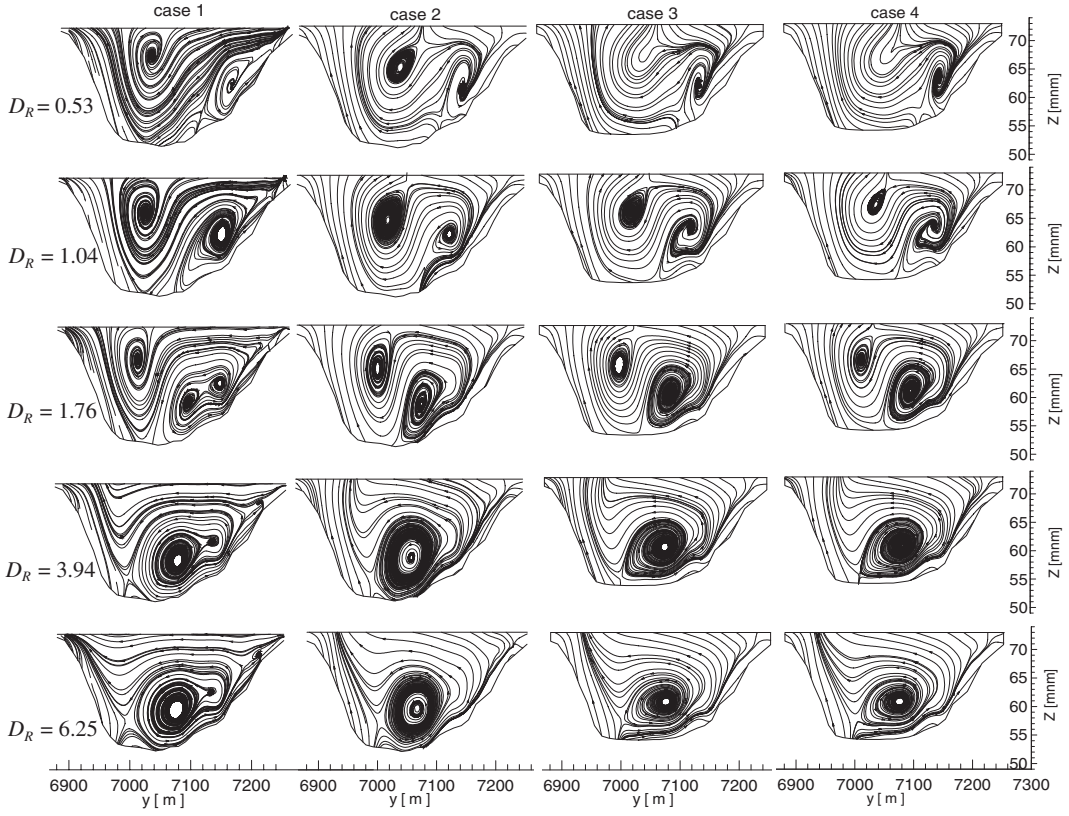

Figure 8. Streamlines showing change in secondary circulation in the cross-section D with respect to change in the discharge-ratio value (D_R) for four analysed river bed configurations.

dominates ($M_R > 10$). The strength of the left vortex gradually diminishes, but there is still a clear dividing line which moves towards the left bank.

In contrast to the cross-section C, at the cross-section D, which is depicted in Figure 8, alignment of the dominant-flow streamlines is better and dimensions of the vortices are either decreased ($D_R < 1.0$), or "redistributed" between the vortices ($1.0 < D_R < 1.76$), including additional splitting of the right vortex core into two smaller ones. For $D_R \geq 3.94$ the same can be claimed as for the cross-section C, but there is an evident increase in the dimensions of the vortex. This could be explained by additional widening of the channel and entering the deepest zone of the scour hole.

The presented secondary flow patterns are the time-averaged flow structures. In addition to the time-averaged structures, confluences are observed to have periodical flow structures, too (Bradbrook et al. 2000, Kapor 1997). These structures cannot be dealt with the numerical models of a time-averaged flow. However, distribution of the turbulent kinetic energy k, obtained by such models, may indicate where periodical flow structures may be expected to form. As Bradbrook et al. (2000) claim, the stagnation zone where the two converging flows meet, may be the source of these structures. The stagnation zone is characterised by a strong shear between the flows, formation of the shear layer which allows momentum exchange, and high values of the turbulent kinetic energy. Therefore, it was decided to investigate how the river bed morphology influences intensity and distribution of the turbulent kinetic energy at the confluence cross-section A.

Change in the k distribution at this cross-section is presented in Figure 9 in a form of contour lines for all considered D_R values. It can be noticed that the greatest values of the turbulent kinetic energy are attained in the case 1 when the scour hole is present and the beds are discordant. In the cases 2 and 4 distributions of k are almost identical for all D_R values. The only notable difference is for $D_R < 1.0$, which probably results from minimal differences in the cross-section slicing process. There is also quite a resemblance between the case 3 and the cases 2 and 4, for $D_R \geq 2.11$. Close observation reveals that similarities between the cases 1 and 3 exist in the form of contour lines in the

Copyright © 2006 Taylor & Francis Group plc, London, UK

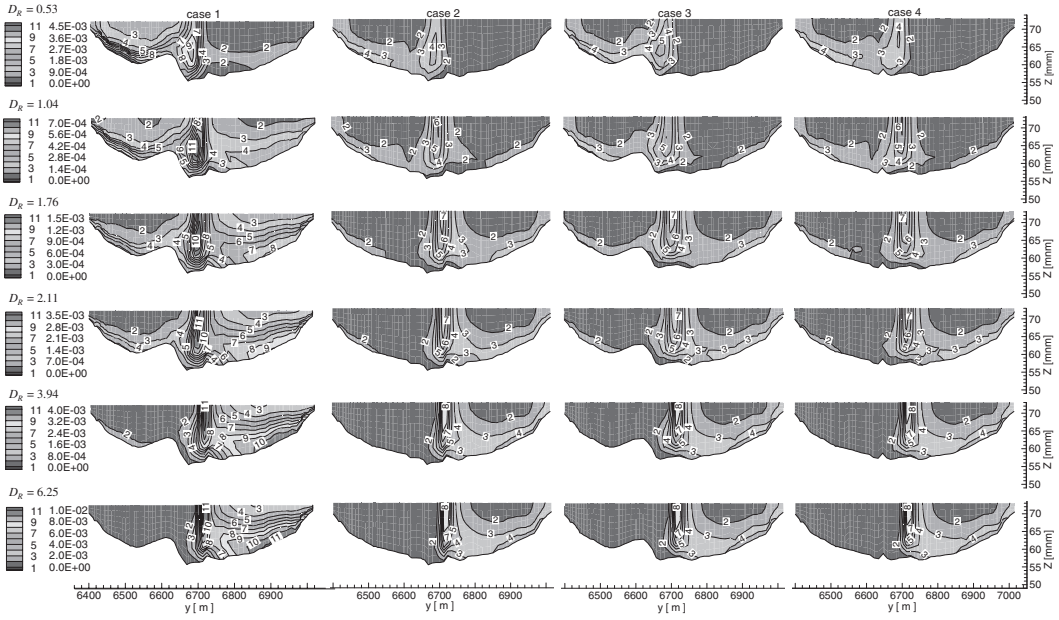

Figure 9. Contour lines showing change in the turbulent kinetic energy distribution at the cross-section A with respect to change in the discharge-ratio value (D_R) for the four analysed river bed configurations. The left bank belongs to the tributary whereas the right bank belongs to the main river.

stagnation zone. However, there is a difference in the k intensities. This proves the importance of a combined effect of the topographic steering and the changes in the upstream hydrologic regimes of the confluent streams on the confluence hydrodynamics.

There is no significant transfer of the turbulent kinetic energy from the tributary into the main river for $D_R < 1.0$. Contributions of the main river and the tributary are, as expected, almost equal when $D_R \approx 1$. For the D_R values ranging between 1.0 and 2.11 some of the turbulent kinetic energy is transferred from the main river to the tributary, whereas for the higher D_R values there is no transfer of k to the tributary.

Finally, the effects of the bed discordance and the scour hole on the distribution of the turbulent kinetic energy in the post-confluence channel were analysed for the cross-section C (Fig. 10). Results for $D_R < 1.76$ show resemblance between the cases 1 and 3 and between the cases 2 and 4. This means that in the range of D_R values less than, say 1.8, the bed discordance at the entrance to the confluence plays a key role in the distribution of the turbulent kinetic energy in the post-confluence channel. Again, the absence of the scour hole in the case 3, results in the lower k intensities when compared to the case 1. Transition area in which the influence of the bed discordance still cannot be neglected, but the effect of the scour hole (topographic steering) is yet not strong enough to overcome the influence of bed discordance, is characteristic for $2.11 < D_R < 3.94$. For the higher D_R values, distribution of k in the absence of scour hole is not influenced by the bed discordance (cases 3 and 4). When the scour hole is present, k distribution depends on the bed discordance – intensities of k are lower for the concordant bed case (case 2).

5 CONCLUSIONS

The aim of this paper was to analyse effects of the bed morphology on the confluence hydrodynamics by modifying the original bathymetry of the field confluence. Therefore, numerical simulations of the three-dimensional time-averaged flows for different combinations of the upstream hydrologic regimes of the confluent streams and four possible river bed configurations were performed. Changes in the bathymetry violate equilibrium between the flow and the bed, which can lead to the bed deformation. However, the paper only aims at investigating the effect of different bed morphologies on the flow process. Therefore, non-deformable bed was assumed. The influence on the secondary flow circulation in the post-confluence channel and distribution of the turbulent kinetic energy in the confluence, and the post-confluence channel were analysed. Comparison of the results led to the following conclusions.

(1) A change in the M_R value due to the bed discordance at the entrance to the confluence is 13% at most for all considered D_R values. The difference

Copyright © 2006 Taylor & Francis Group plc, London, UK

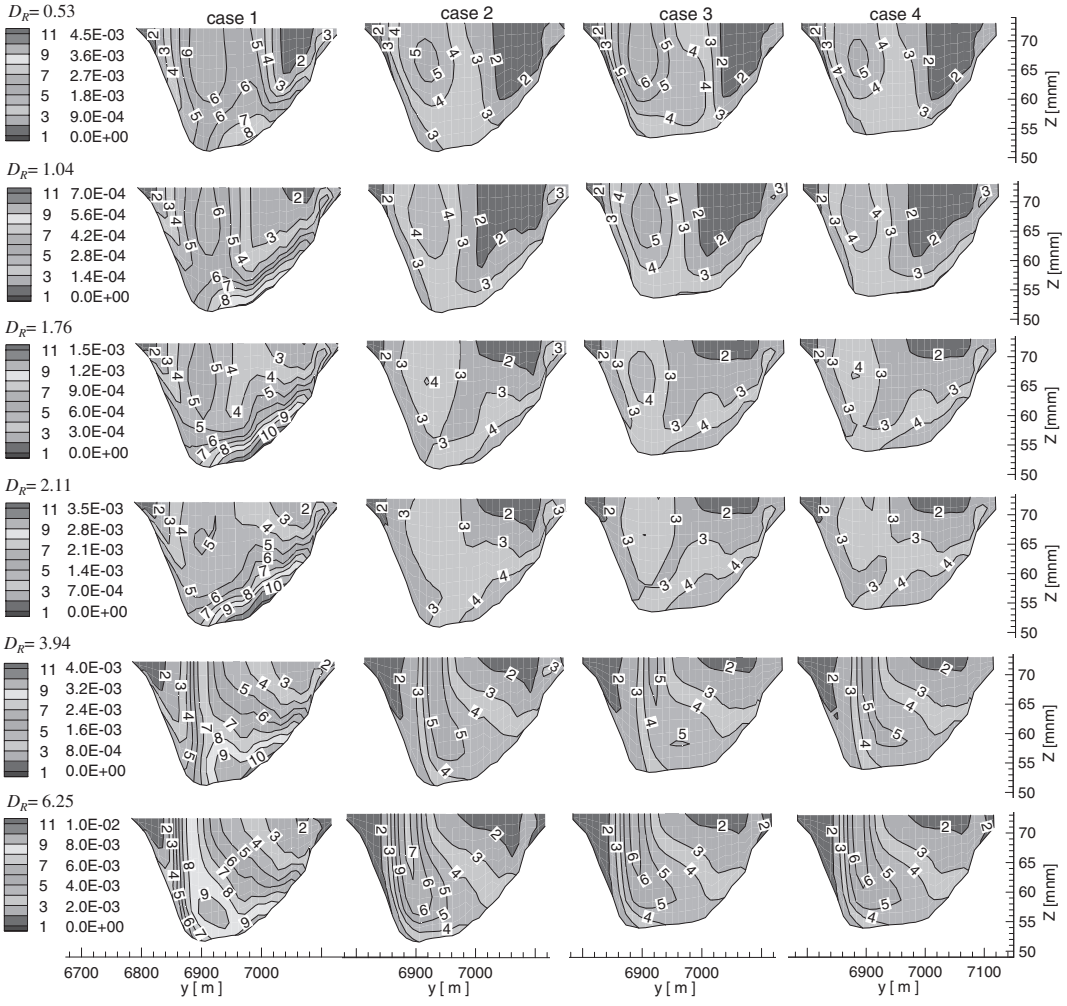

Figure 10. Contour lines showing change in the turbulent kinetic energy distribution at the cross-section C with respect to change in the discharge-ratio value (D_R) for the four analysed river bed configurations.

for the majority of combinations is less than 10%, which justifies the use of the discharge ratio (D_R) as a common parameter for the comparison.

(2) In the absence of the scour hole, the bed discordance at the entrance to the confluence has no influence on the secondary circulation in the post-confluence channel for any combination of the upstream hydrologic regimes of the confluent streams. In this case it means that the secondary flow patterns are only governed by the confluence plan-form and the discharge-ratio value and some topographic steering due to presence of other bed forms.

(3) When the scour hole is formed in the post-confluence channel, the secondary flow circulation is influenced by the presence of the bed discordance at the confluence and the D_R value. For a D_R value, a secondary flow pattern is strongly governed by the simultaneous action of the confluence plan-form and topographic steering at the confluence and in the post-confluence channel.

(4) Decreasing the D_R value below 1.0 and increasing above 4.0, causes, for the considered plan-form of the confluence, a significant increase in the k value in the stagnation zone at the confluence which may be an indicator for the development of some periodic flow structures.

(5) Generally, the highest values of k are observed for the case with the bed discordance and the scour hole in the post-confluence channel, which

Copyright © 2006 Taylor & Francis Group plc, London, UK

suggests that the intensity of k and its distribution at the confluence is influenced by the overall topography of the confluence and the post-confluence channel and, of course by the D_R value.

(6) As for the post-confluence channel, the influence of the bed discordance on the distribution of k depends on the D_R value. For D_R values less than approximately 1.8 the distribution of k is strongly governed by the bed discordance at the confluence, while topographic steering due to presence of the scour hole has no influence on the k distribution. In the range of D_R values between 1.8 and 4.0 the distribution of k is influenced by both, the bed discordance and the presence of the scour hole. For $D_R > 4.0$, the bed discordance has no effect on the k distribution when there is no scour hole, whereas in the presence of the scour hole, the bed discordance influence is significant.

The overdeepening theory in river morphodynamics: Two decades of shifting interpretations

Erik Mosselman
Delft University of Technology & WL/Delft Hydraulics, Delft, The Netherlands

Marco Tubino & Guido Zolezzi
Dipartimento di Ingegneria Civile e Ambientale, University of Trento, Italy

ABSTRACT: Theoretical analysis of mathematical equations is complementary to numerical solution as it offers additional insights into the fundamental behaviour of the corresponding physical system. An example is the theory of overdeepening in river morphodynamics. This theory explains why outer-bend pools can be locally deeper than the equilibrium outer-bend water depth in infinitely long river bends. Its essence lies in the superimposition of a steady alternate bar pattern on a streamwise uniform river bed topography. The same steady alternate bar pattern arises in a straight channel in response to a local permanent geometrical disturbance. Basically, the overdeepening theory describes river bed topography by a double-periodic function with an amplitude decaying exponentially along the river. This function yields two problems of interpretation. First, certain parameter combinations produce a growing rather than a decaying amplitude. Which phenomena are related to this situation? Originally, the growing amplitudes were explained as an indication of incipient braiding, but this interpretation was soon discarded because growing bed deformations in a linear theory may still reach a finite amplitude by nonlinear effects. The second problem of interpretation was whether the double-periodic function holds upstream or downstream of the local disturbance, or both. Originally it was assumed to hold only downstream, because of the very short adaptation length of the upstream flow accelerating towards a local constriction. Later upstream influence was revealed to occur as well, albeit with initially differing opinions on the corresponding parameter ranges. We review the history of the shifting interpretations of the overdeepening theory. In this way we seek to demonstrate that mathematical analyses of physical systems do not produce straightforward answers or predictions, but inherently require interpretations based on experimental evidence and a thorough understanding of the underlying physical processes.

1 INTRODUCTION

Theoretical analyses of mathematical equations are complementary to numerical solutions, as they offer additional insights into the fundamental behaviour of the corresponding physical system. Designing numerical models requires theoretical analyses to determine the appropriate numerical scheme and the type and location of the boundary conditions to be imposed. Theoretical analyses also help the optimization of calibration strategies for numerical models, as they reveal which parameters are responsible for different aspects of the solution. They help the interpretation of results from numerical models as well, because numerical solutions may exhibit spurious wiggles, phase lags or attenuation that in this way can be distinguished from real physical phenomena. Furthermore, analytical solutions provide exact solutions for certain idealized cases that may serve as validation cases for numerical models. Finally, analytical solutions can be used as rapid assessment models or rules of thumb.

However, the interpretation of results from mathematical analyses of physical systems is not always straightforward. Often a thorough understanding of the physical processes, rooted in observational or experimental evidence, is required to arrive at a correct interpretation. We seek to demonstrate this on the basis of the overdeepening theory in river morphodynamics (Struiksma et al, 1985), which has undergone several shifting interpretations in the past two decades. Part of the shifts resulted from debates between the two research groups that Parker & Johanneson (1989) have called the "Delft School" and the "Genova School". Here we review the history of the shifting interpretations. To that end, we review the theory only briefly. Seminara (1998) presents a more thorough overview of mathematical analyses in river morphodynamics. We use the dimensional notations of the Delft School

Copyright © 2006 Taylor & Francis Group plc, London, UK

because they are closer to the notations that are familiar to river engineers. From a mathematical point of view, the nondimensional notations of the Genova School might have been preferable.

2 STRUIKSMA'S THEORY

Struiksma et al (1985) derived a linear model from the basic depth-averaged equations for water flow and sediment transport. They found that this model could be simplified to a second-order system for parameter ranges that are representative for the branches of the Rhine delta in the Netherlands. For clarity, we review their analysis by *a priori* assuming the validity of these simplifications.

The simplified linear equation for conservation of streamwise flow momentum retains only a convective term and a friction term, because pressure gradient perturbations are neglected and because the flow is assumed to be quasi-steady. The assumption of quasi-steadiness is valid as long as morphological changes operate on a much slower time scale than adaptations of water flow to changing conditions (De Vries, 1965). The resulting linear equation reads

$$u_0 \frac{\partial u}{\partial x} + \frac{g u_0^2}{h_0 C^2}\left(\frac{2u}{u_0} - \frac{h}{h_0}\right) = 0 \tag{1}$$

where u denotes the perturbation of streamwise flow velocity with respect to the reach-averaged (zero-order) streamwise flow velocity, u_0. Similarly, h denotes the flow depth perturbation with respect to the reach-averaged (zero-order) flow depth, h_0. Furthermore, x is the streamwise co-ordinate, g the acceleration due to gravity and C the Chézy coefficient for hydraulic roughness. Equation (1) can be interpreted as a relaxation equation for u with a source term depending on h and a characteristic length scale, λ_w, given by $\lambda_w = h_0 C^2/2g$. Substitution yields

$$\frac{\lambda_w}{u_0}\frac{\partial u}{\partial x} + \frac{u}{u_0} - \frac{h}{2h_0} = 0 \tag{2}$$

A rigid-lid assumption is applied to the sediment balance, which means that water level perturbations are neglected. This implies that all bed level perturbations are equal, though with opposite sign, to perturbations in flow depth. The linear sediment balance reads

$$\frac{\partial h}{\partial t} = \frac{b q_{s0}}{u_0}\frac{\partial u}{\partial x} + q_{s0}\frac{\partial}{\partial y}\left(\frac{v}{u_0} + \frac{1}{f_s}\frac{\partial h}{\partial y}\right) = 0 \tag{3}$$

where t denotes time, y is the cross-stream co-ordinate, q_{s0} is the reach-averaged (zero-order) volumetric sediment transport rate per unit width, b is the degree of nonlinearity in $q_{s0}(u)$ defined by $b = (u_0/q_{s0})\mathrm{d}q_s/\mathrm{d}u$, v is the perturbation of cross-stream flow velocity and f_s is a function weighing the effect of gravity pull along transverse bed slopes on the direction of sediment transport. The first term in the right-hand side of equation (3) represents streamwise gradients in streamwise sediment transport, the second term cross-stream gradients in cross-stream sediment transport. The effect of helical flow has been neglected. Always $b > 3$ (e.g. Mosselman, 2005).

Generally, the equations (2) and (3) can have periodic solutions in both x and y direction, i.e. they allow solutions in the form of double-periodic functions $\exp(ikx + ik_B y)$, where k is the streamwise wave number and k_B is the cross-stream wave number. The wave numbers of periodic solutions in streamwise direction have a continuum of possible values, but the wave numbers of solutions in cross-stream direction can only assume integer multiples of half the river width due to the boundary conditions at the banks: $k_B = m\pi/B$ with $m \in \{1, 2, ..\}$. Here B denotes river width. The lowest mode ($m = 1$) is the most unstable. This implies

$$\frac{\partial^2 h}{\partial y^2} = -k_B^2 h \tag{4}$$

This can be substituted in the last term of equation (3). Furthermore, the cross-stream flow velocity can be eliminated by using the quasi-steady linear continuity equation for water flow ($v_0 = 0$):

$$h_0\frac{\partial u}{\partial x} + u_0\frac{\partial h}{\partial x} + h_0\frac{\partial v}{\partial y} = 0 \tag{5}$$

The substitutions (4) and (5) transform equation (3) into

$$\frac{h_0}{q_{s0}}\frac{\partial h}{\partial t} = \frac{h_0(b-1)}{u_0}\frac{\partial u}{\partial x} - \frac{\partial h}{\partial x} - \frac{k_B^2 h_0}{f_s}h \tag{6}$$

where h and u now refer to perturbations along a bank (Figure 1). The steady-state version of this equation ($\partial h/\partial t = 0$) can be interpreted as a relaxation equation

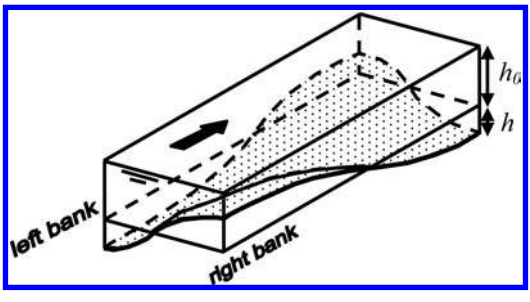

Figure 1. Near-bank flow depth perturbation, h, with respect to reach-averaged flow depth, h_0, as an indicator of cross-sectional bar-pool deformation.

Copyright © 2006 Taylor & Francis Group plc, London, UK

for h with a source term depending on $\partial u/\partial x$ and a characteristic length scale, λ_s, given by $\lambda_s = f_s/k_B^2 h_0$.

Solutions of the form $u = U \exp\{ikx - i\omega t\}$ and $h = H \exp(ikx - i\omega t)$ (+ complex conjugates) are substituted into equations (2) and (6). Here U and H are complex amplitudes, k is the complex streamwise wave number and ω is the complex frequency. All complex quantities consist of a real and an imaginary part. Thus the complex amplitudes consist of the real amplitudes and the phases. The complex wave number consists of the real wave number, $Re(k) = 2\pi/L_P$, where L_P denotes streamwise wave length, and the damping coefficient, $Im(k) = 1/L_D$, where L_D denotes damping length. The real frequency, $Re(\omega)$, can be used to calculate the propagation speed, c, of bars through $c = Re(\omega)/k$. The imaginary part, $Im(\omega)$, describes the growth or attenuation of the amplitude in time. These substitutions result in a system with the following characteristic equation:

$$\begin{vmatrix} ik\lambda_w + 1 & -\frac{1}{2} \\ (b-1)k & \frac{h_0}{q_{s0}}\omega - k + \frac{i}{\lambda_s} \end{vmatrix} = 0 \qquad (7)$$

For the steady state of non-propagating and non-developing bars ($\omega = 0$), equations (2) and (6) can be combined into the following single second-order equation:

$$\frac{\partial^2 h}{\partial x^2} + 2\,\mathrm{Im}(k)\frac{\partial h}{\partial x} + \left(\mathrm{Re}^2(k) + \mathrm{Im}^2(k)\right)h = 0 \qquad (8)$$

with

$$\mathrm{Re}(k) = \frac{2\pi}{L_P} = \frac{\sqrt{(b+1)\frac{\lambda_w}{\lambda_s} - \left(\frac{\lambda_w}{\lambda_s}\right)^2 - \left(\frac{b-3}{2}\right)^2}}{2\lambda_w} \qquad (9)$$

and

$$\mathrm{Im}(k) = \frac{1}{L_D} = \frac{\frac{\lambda_w}{\lambda_s} - \frac{b-3}{2}}{2\lambda_w} \qquad (10)$$

The ratio of λ_s to λ_w arises as a key parameter for this second-order system. Struiksma called it the "*interaction parameter*", because it stems from the interaction of two first-order relaxation equations with length scales λ_s and λ_w. It is defined by

$$\frac{\lambda_s}{\lambda_w} = \frac{2gf_s}{C^2\left(k_B h_0\right)^2} = 2\pi^2 f_s \frac{g}{C^2}\left(\frac{B}{h_0}\right)^2 \qquad (11)$$

The dominant contribution to this parameter is the width-to-depth ratio, B/h_0. Its role is therefore similar to the role of the Genova School's key parameter, β, defined as $\beta = B/2h_0$.

The second-order equation (8) makes the morphodynamic system analogous to a mass-spring-damper system (Figure 2). The latter is described by the same equation, but with derivatives to time instead of space.

The decaying oscillation of a mass-spring-damper system after an initial excitation finds its analogy in a steady pattern of spatially decaying alternate bars downstream of a local permanent geometrical disturbance (Figure 3). Examples of such disturbances are spur dikes, abrupt variations of river width or discontinuities in channel curvature. The steady bars downstream of a local permanent disturbance represent a free response to the upstream disturbance and yet they are forced to remain at the same location. They thus form an intermediate class of "*spatial bars*" between truly *free bars*, that spontaneously develop and migrate, and truly *forced bars*, that can be produced by a channel curvature distribution along the river. Struiksma et al (1985) found that the bed topography in the Waal branch of the Rhine delta in the Netherlands could be understood as a superimposition of forced bars and pools (axisymmetric bend profiles) and spatial bars and pools. The spatial bars and pools appeared as an overshoot that made outer-bend pools locally deeper than the equilibrium outer-bend water

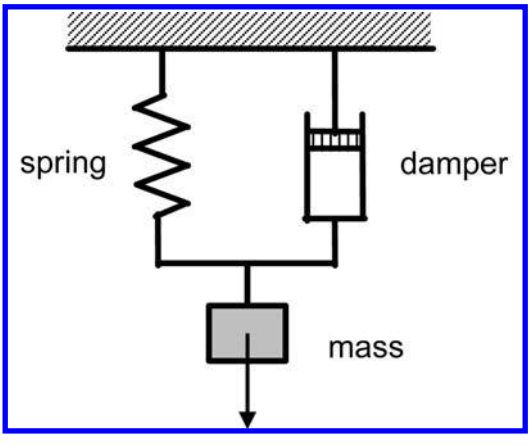

Figure 2. Mass-spring-damper system as an analogy for Struiksma's second-order model for river morphodynamics.

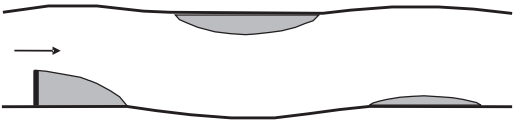

Figure 4. Incipient meandering induced by underdamped spatial bars.

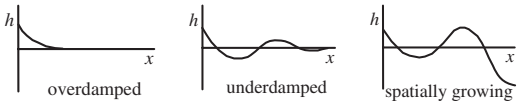

Figure 5. Near-bank flow depth perturbation for three solution regimes of equation (8).

depth in infinitely long river bends of constant curvature. Parker & Johanneson (1989) introduced the term "*overdeepening*" for this overshoot. They also showed that the independent analyses of Blondeaux & Seminara (1985) and Struiksma et al (1985) have many elements in common.

The Genova and Delft Schools proposed more or less simultaneously that spatial bars rather than migrating alternate bars could explain for many rivers why straight channels with erodible banks tend to develop into meandering water courses (Figure 4). A review by Rhoads & Welford (1991) confirmed this, with the noteworthy implication that helical flow, unlike previous widespread belief, is not a necessary ingredient to explain river meandering.

3 INTERPRETATION OF SPATIALLY GROWING BARS

The analogy with mass-spring-damper systems has proven to be useful. Blondeaux & Seminara (1985), for instance, identified the existence of *resonance* for vanishing values of the damping coefficient. However, the analogy also poses questions. In mass-spring-damper systems, the damping coefficient cannot be negative, but the damping coefficient in equation (10) does allow negative values. The solutions of equation (8) can thus fall in a *subresonant* regime for relatively narrow rivers ($\lambda_s/\lambda_w < 2/(b-3)$) or a *superresonant* regime for relatively wide rivers ($\lambda_s/\lambda_w > 2/(b-3)$). The superresonant regime corresponds to bars that grow spatially downstream in the sense that they are higher as the distance to the local permanent disturbance upstream is longer. The question is which phenomena are related to this regime. Struiksma & Klaassen (1988) attempted to answer this question by realizing that solutions of equation (8) actually have three regimes: overdamped bars, underdamped bars and spatially growing bars (Figure 5).

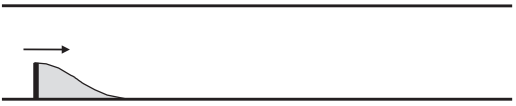

Figure 6. Overdamped bars.

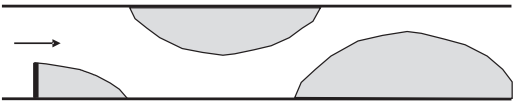

Figure 7. Spatially growing bars.

The corresponding ranges for the interaction parameter are:

$$\begin{aligned} &\frac{\lambda_s}{\lambda_w} \le \frac{2}{b+1+2\sqrt{2b-2}} \quad : \text{ overdamped} \\ &\frac{2}{b+1+2\sqrt{2b-2}} < \frac{\lambda_s}{\lambda_w} \le \frac{2}{b-3} \quad : \text{ underdamped} \\ &\frac{\lambda_s}{\lambda_w} > \frac{2}{b-3} \quad : \text{ spatially growing} \end{aligned} \tag{12}$$

The solution has no periodic components if the system is overdamped (Figure 6). It does have periodic components, leading to overdeepening, if the system is underdamped (Figure 3). The overdamped and underdamped regimes correspond to the subresonant regime, whereas the spatially growing regime corresponds to the superresonant regime (Figure 7).

Struiksma & Klaassen (1988) linked the overdamped regime to straight rivers, the underdamped regime to meandering rivers and the spatially growing or superresonant regime to braiding, in analogy to the classical three river channel patterns of Leopold & Wolman (1957). They took this as the basis for a discriminator between meandering and braiding. The Genova School pointed at the fallacy of this, because a linear prediction of exponential growth does not necessarily imply that the bars will actually reach the water level, as nonlinear effects may prevent growth beyond a finite amplitude. A better way to assess the transition from meandering to braiding is an analysis of the stability of higher modes in transverse direction, such as the pattern for $m = 2$ ($k_B = 2\pi/B$) in Figure 8. This was subsequently accepted by the Delft School (e.g. Mosselman, 1992). A weakly nonlinear analysis by Seminara & Tubino (1992) confirmed that bars in superresonant channels do not grow beyond a finite amplitude.

4 DIRECTION OF INFLUENCE

4.1 *Problem statement*

The concepts for overdamped, underdamped and spatially growing regimes in the previous sections are all based on the implicit assumption that the influence of a local geometrical disturbance extends in downstream direction alone. This is definitely true in the analogous mass-spring-damper system, where the influence of a perturbation at a certain moment can only have an effect forward in time, not backward. The spatial direction of influence for the morphodynamic system, however, is not that obvious. A solution decaying in downstream direction equally satisfies a growing solution in upstream direction and *vice versa*. It is not immediately clear whether a certain solution applies to the river upstream of the perturbation, downstream of the perturbation, or both.

4.2 *Struiksma's arguments for downstream influence*

Struiksma thought of the second-order system expressed by equation (8) as a combination of two first-order relaxation equations, i.e. equation (2) and the steady-state part of equation (6). The very concept of relaxation to an unperturbed flow and bed topography implies for these equations that the direction of influence must be downstream. Hence it was not expected that the combined system could produce an influence upstream of the local disturbance. An additional argument was that equation (2) represents a friction-dominated redistribution of the flow, whereas the flow upstream of the disturbance was assumed to be accelerating over a short distance only, without dissipation and characterized by equations from potential theory. The possibility of a larger zone of upstream influence due to morphological feedback was not taken into consideration. Accordingly, Struiksma & Crosato (1989) did not carry out any measurements upstream of the local disturbance in their laboratory experiment to verify the overdeepening theory.

4.3 *Discovery of upstream influence*

Zolezzi & Seminara (2001) discovered the possible existence of upstream influence when revisiting the linear theories of river meanders with the initial aim of deriving an exact solution of the flow field and the bed topography in arbitrarily curved channels. A main concern was the appropriate location of the boundary conditions to be imposed in the longitudinal domain. This led to the question whether the presence of curvature discontinuities could be felt in the upstream direction under suitable conditions. A physical explanation was sought in the migration of free bars, as free bars in subresonant channels migrate invariably downstream and free bars in superresonant channels might migrate upstream, at least in a linear context. The interpretation of the direction of influence thus became closely related to the interpretation of spatially growing spatial bars.

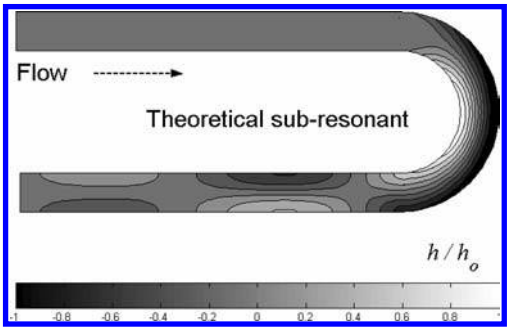

Figure 9. Theoretical bed topography in curved flume under subresonant conditions.

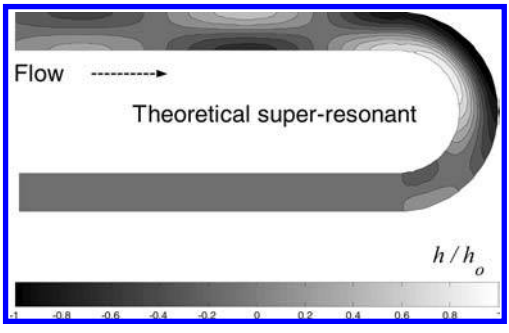

Figure 10. Theoretical bed topography in curved flume under superresonant conditions.

Figures 9 and 10 show Zolezzi & Seminara's (2001) theoretical predictions of overdeepening under sub- and superresonant conditions, the hydraulic and granulometric conditions of the subresonant case (Figure 9) being those of experiment T2 by Struiksma et al (1985). The straight-curved-straight channel sequence is characterized by two discontinuities in channel curvature. Both discontinuities trigger overdeepening, downstream in Figure 9, upstream in Figure 10.

4.4 *Analysis of characteristics*

The Delft School accepted the possibility of upstream influence in general, for instance through backwater

Copyright © 2006 Taylor & Francis Group plc, London, UK

effects, but Mosselman questioned the explanation by the Genova School that upstream influence for spatial bars is related to the migration direction of free bars, as well as the apparent implication that downstream influence would disappear under superresonant conditions. He argued that, formally, the direction of influence should be determined by means of an analysis of characteristics. Such an analysis assesses how infinitesimal perturbations propagate through a mathematical system, thus revealing the direction in which information is transmitted. Conceptually, the infinitesimally small size of the perturbations in a characteristics analysis refers not only to the amplitude of the perturbations, as in a linear analysis, but to their length as well. Hence an analysis of characteristics for spatial bars can be derived roughly from the linear analysis by rewriting equation (7) as

$$\begin{vmatrix} i\lambda_w + \frac{1}{k} & -\frac{1}{2k} \\ (b-1) & \frac{h_0}{q_{s0}}\frac{\omega}{k} - 1 + \frac{i}{k\lambda_s} \end{vmatrix} = 0 \qquad (13)$$

and subsequently taking the limit as $k \to \infty$. The result reads

$$\begin{vmatrix} i\lambda_w & 0 \\ (b-1) & \frac{h_0}{q_{s0}}\frac{\omega}{k} - 1 \end{vmatrix} = 0 \qquad (14)$$

The solution of this simplified equation is that the celerity of infinitesimally small perturbations is equal to

$$c = \frac{\omega}{k} = \frac{q_{s0}}{h_0} \qquad (15)$$

in downstream direction.

Mosselman hinted that a more complete analysis of characteristics might reveal that upstream influence is actually related to supercritical flow, in analogy to the upstream influence for infinitesimal bed perturbations in the 1D analysis of characteristics by De Vries (1959).

4.5 *Latest findings*

The actual occurrence of upstream overdeepening has been verified in laboratory flumes by Zolezzi et al (2005). Figures 11 and 12 show the patterns of spatial bars under subresonant and superresonant conditions respectively. In the subresonant case (Figure 11), overdeepening takes place both within the bend and in the downstream straight reach, whereas the upstream reach is characterized by an almost complete absence

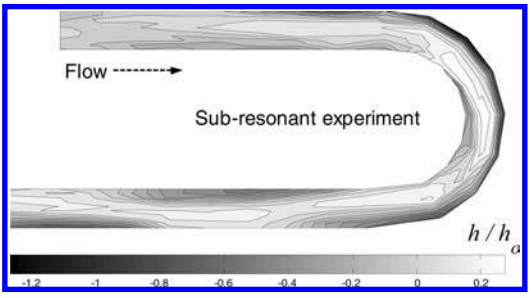

Figure 11. Observed bed topography in curved flume under subresonant conditions.

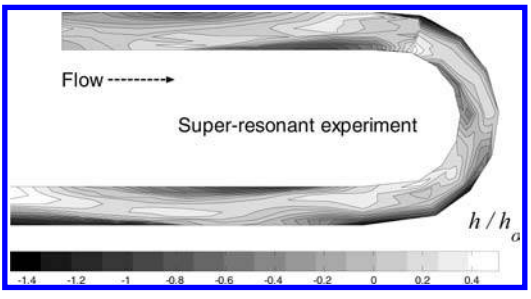

Figure 12. Observed bed topography in curved flume under superresonant conditions.

of steady bed deformations. This complies with Struiksma's original ideas on downstream influence.

Upstream overdeepening is observed under superresonant conditions (Figure 12), both in the upstream straight reach and in the bend, triggered by the two curvature discontinuities. This confirms the theoretical findings of Zolezzi & Seminara (2001). The observed wave length of the perturbations is closely reproduced by the linear theories. The most evident difference between the theoretical predictions and experimental observations, however, is that downstream overdeepening is also found to occur in the superresonant regime. This complies with Mosselman's argument that downstream influence does not necessarily disappear if free bars migrate upstream.

The experimental test of upstream influence by Zolezzi et al (2005) has also revealed how difficult it is to reproduce superresonant conditions in laboratory channels, since this requires to combine high channel width-to-depth ratios with values of the Shields stress high enough for sediment transport to occur at almost every location in the flume. The flume width is often limited by the requirement of reproducing the relatively long overdeepening wave (about 15–20 channel widths long), which implies the necessity to reduce the average water depth in order to meet superresonance. The resulting small water depth reduces sediment mobility. These difficulties explain

Copyright © 2006 Taylor & Francis Group plc, London, UK

why upstream influence had never been observed before and needed a specifically focused experimental activity.

The concept of upstream influence calls for a sound reproduction by 2D and quasi 3D numerical models that are increasingly employed for river engineering and management purposes. Despite some first attempts (Ferriani, 2003; Federici & Solari, 2004), satisfactory results are still to be achieved.

Finally, evidence of upstream influence in a broader sense is suggested by both experimental observations (Tubino & Bertoldi, 2006) and numerical simulations (Kleinhans et al, 2006) of the dynamics of channel bifurcations, which may imply unforeseen consequences also for the dynamics of braided streams.

5 CONCLUSIONS

The shifting interpretations of the overdeepening theory in river morphodynamics demonstrate that mathematical analyses of physical systems do not always produce straightforward answers or predictions, but inherently require interpretations based on experimental evidence and a thorough understanding of the underlying physical processes.

Upstream influence has been demonstrated to occur under superresonant conditions, but superresonant conditions do not imply that downstream influence disappears. The main challenge is now to obtain a sound reproduction of superresonant phenomena in 2D and quasi 3D numerical modelling.

Prevalent morphodynamic regime and short-term dynamics of meandering rivers

Guido Zolezzi, Rossella Luchi & David Marchiori
Department of Civil and Environmental Engineering, University of Trento, Italy

ABSTRACT: The role of factors such as flow discharge, valley slope, and sediment size on meander morphodynamics has been often reported referring to individual cases but lacks generality. Moreover recent observations of upstream and downstream influence in river morphodynamics still wait for close comparisons with observed features in the field. We seek to provide a unified description of how variations in relevant natural and anthropogenic controls affect the morphology of meandering rivers. We focus on the short-term planimetric evolution of a "Kinoshita curve" before cutoff, of most interest for management purposes. The examined gravel bed meandering river reaches are mainly super-resonant with dominant upstream influence at this time scale. A relatively narrow threshold range seems to distinguish between sub- and super-resonant rivers. Predicted properties of regular meander loops satisfactorily agree with field observations, supporting the use of the present model to support restoration projects involving re-meandering of channelized streams.

1 INTRODUCTION

Rapid changes undergone by our society in the last decades are reflected also in the evolution of classical approaches to river management, which progressively shifts towards philosophies of river and floodplain restoration that aim to keep the river and its surroundings fit for multiple functions, such as navigation, risk mitigation, ecosystem productivity and recreational use. The implementation of restoration measures and of those associated with traditional river engineering often implies changes in river morphology at different spatial and temporal scales. These interventions must be accompanied with an improved understanding of and ability to model the river response to both anthropogenic and natural factors (De Vriend 2002).

In the case of single thread, meandering rivers, the morphological response to variations in different types of environmental controls has been widely documented since decades (e.g. Hickin 1977, Hooke 1995, Amsler and Ramonell 2002 among others). A considerable advance in process understanding in the last two decades has led to the generation of physically based simulation models that can predict the planimetric evolution of the channel axis at much different time and spatial scales, including those significant for river management purposes (for a recent review see Seminara 2006).

A major point is that related to morphodynamic influence (Zolezzi and Seminara 2001), including its implications for the planimetric evolution of river meanders (Seminara et al. 2001). Theoretical and experimental (Zolezzi et al. 2005) analysis indicate that two well distinct regimes characterize meander dynamics, whereby the effect of geometrical disturbances, related to both anthropogenic and natural causes, can dominantly be felt in the downstream (upstream) direction essentially depending on the width to depth ratio of the channel falling below (above) a threshold value. Such value coincides with the resonant value of Blondeaux and Seminara (1985), and the morphodynamics in both regimes (therefore called suband super-resonant respectively) strongly affects the planimetric evolution at different time scales (Lanzoni et al. 2006).

Despite the large amount of available field observations and the considerable theoretical improvements, however, at least two major issues still need to be clarified.

First, a quantitative field evidence of the correspondence between sub- and super-resonant regimes with dominant downstream and upstream influence has never been reported so far. Which morphodynamic regime characterizes real rivers? Can a prevalent regime be detected? Can any clear distinction be made based, for example, on the prevalent mechanism of sediment transport or on other geomorphic controls, such as the valley slope?

Second, despite the great detail of planimetric evolution models, only qualitative comparisons with observed natural features has been reported at present. Are state-of-the-art evolution models able to reproduce

the well known field observations concerned with meander migration rate (Nanson and Hickin 1983) and sinuosity (e.g. Bridge 2003)? Assessing model performance in closer comparison with field data is now necessary to make a step forward and it is the main goal of the present work.

We have employed a model already developed in previous works (Seminara et al. 2001) in order to attempt a first answer to the above questions. The formulation of the mathematical problem of meander morphodynamics is synthetically recalled in §2 and the solution procedure is summarized in §3. §4 is devoted to illustrate the field data set and the procedure developed to adapt dimensional data to the dimensionless input parameters required by the model. Results are widely discussed in §5 and 6, while §7 shows a quantitative comparison with field observations. A summary of the open issues for future work finally concludes the paper in §8.

2 OVERVIEW OF THE PROBLEM FORMULATION

A meander evolves planimetrically on a much larger time scale (years or tenth of years) compared to that typical of the altimetric evolution of its bed topography, which is usually rearranged within a single flood event, and therefore evolves over periods of hours or days. The driving mechanism of meandering planform change is commonly assumed to be the excess near bank longitudinal velocity (e.g. Hasegawa 1989), determined by the interaction between the flow and the bed topography field.

A mathematical model of meander morphodynamics commonly consists of a planimetric evolution equation (Seminara et al. 2001) whose time integration assumes that the flow and bed topography instantaneously adapt to planform changes. We follow this approach and refer the analysis to a constant width meandering channel with constant cross-sectional width that flows along a floodplain lying on the (x^*, y^*) plane whose longitudinal slope S_v is assumed to be constant over the time scale of meander evolution (Figure 1).

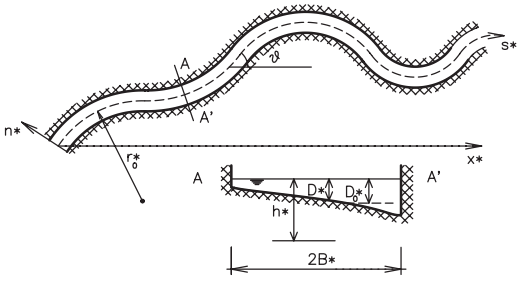

Figure 1. Sketch of a meandering channel and notations.

Several models have been proposed by far to study the flow field and bottom topography in meandering streams: for our purpose it is appropriate to employ steady, depth averaged models (e.g. Seminara and Tubino 1989) able to retain three dimensional information associated with bottom stresses and momentum redistribution due to secondary flows with vanishing depth average that develop in curved channels due to centrifugal effects and longitudinal variations of streamlines curvature. Several models have been proposed that incorporate these characteristics: based on recent comparative studies (Camporeale et al. 2005, Lanzoni et al. 2006) we choose to employ the $2.5D$ model proposed by Zolezzi and Seminara (2001) which reads:

$$UU_{,s}+VU_{,n}+H_{,s}+\beta\frac{\tau_s}{D} = \nu_o f_{11}\,, \tag{1}$$

$$UV_{,s}+VV_{,n}+H_{,n}+\beta\frac{\tau_n}{D} = \nu_o g_{11}\,, \tag{2}$$

$$(DU)_{,s}+(DV)_{,n} = \nu_o m_{11}\,, \tag{3}$$

$$q_{s,s}+q_{n,n} = \nu_o n_{11}\,, \tag{4}$$

where:

$$(\tau_s,\tau_n') = C_f(U,V)|\mathbf{U}|;\ \ \tau_n = \tau_n' + \tau_H; \tag{5}$$

with boundary conditions imposing vanishing water and sediment flux at lateral walls. The dimensionless differential system $(1,\ldots,4)$ is referred to the curvilinear orthogonal coordinates (s,n) with s measured along the channel axis and n orthogonal to s lying in the (x,y) plane. Flow and geometric variables have been made dimensionless with respect to an ideal condition referring to the same discharge Q^* flowing uniformly with an average velocity U_o^* in a straight channel characterized by the same longitudinal slope S, width $2B^*$ and mean sediment diameter d_{50}^*, the star denoting dimensional variables. In $(1,\ldots,4)$ (τ_s,τ_n) and (q_s,q_n) represent the bottom stress and the bedload discharge vector respectively; the $3D$ effect associated with secondary flows are retained in the τ_H component of the lateral bottom stress. The dimensionless flow field $\mathbf{U}=(U,V)$, the free surface elevation and water depth (H,D) and the planimetric coordinates (s,n) have been obtained from the corresponding dimensional quantities through a classical scaling procedure (Zolezzi and Seminara 2001). The relevant dimensionless parameters of the analysis read:

$$\nu_o=\frac{B^*}{R_o^*},\quad \beta=\frac{B^*}{D_o^*},\quad d_s=\frac{d_{50}^*}{D_o^*},\quad \tau_*=\frac{S}{\Delta d_s}.$$

In the above expression ν_o is the curvature ratio, β denotes the width ratio, d_s the relative roughness and

τ_* the shields stress. The friction factor is computed through classical logarithmic formulas and the sediment rate is assumed to be dominantly carried as bedload, which has been computed through the formula of Parker (1990) for gravel bed rivers in the plane bed case and through the expression of Engelund and Hansen (1967) in the case of sandy channels with dune covered bed.

The forcing terms $(f_{11}, \ldots, n_{11})$ are related to channel curvature $C(s) = -(1/v_o)d\vartheta/ds$ and redistribution coefficients related to the interaction between the main and secondary flows. $\vartheta(s,t)$ denotes the angle that the local tangent to the channel centerline forms with the x direction.

The planimetric evolution of the channel is described by the following integro-differential equation (Seminara et al. 2001):

$$\vartheta_{,t} - \vartheta_{,s} \int_0^s \zeta \vartheta_{,s} ds = \zeta_{,s}. \tag{6}$$

In (6) $\zeta(s)$ represents the erosion rate in the n direction at a given cross section s and its longitudinal distribution is assumed to adapt almost instantaneously to changes in meander planform. It is widely recognized that the appropriate measure of flow perturbations determining channel shift is the excess near bank longitudinal velocity u related to the transverse rate of meander migration by the following linear relationship (e.g. Ikeda et al. 1981):

$$\zeta = E\left[u|_{n=1} - u|_{n=-1}\right], \tag{7}$$

with E erodibility coefficient depending on the bank properties.

3 QUASI-ANALYTICAL SOLUTION

We will herein only recall the most relevant assumptions and steps of the solution procedure, for whose details the interested reader is referred to Zolezzi and Seminara (2001) and to Seminara et al. (2001). The observation that v_o is typically a small parameter allows to linearize the governing differential system through the following perturbation expansion:

$$(U, V, D, H) = (U_o, 0, D_o, H_o) + \nu_o(u, v, d, h) \tag{8}$$

where $(U_o, 0, D_o, H_o)$ refer to uniform flow conditions. The solution for the flow – bed topography field is obtained on substituting (8) into (1, . . . , 4) and then performing a Fourier expansion of the linear perturbations (u, v, d, h) in the transverse direction. The governing system is then transformed into the following fourth order ordinary differential problems for the amplitude of the m^{th} Fourier harmonic of the near bank excess longitudinal velocity u_m (m = 0, 1, 2, . . .):

$$\mathcal{L}^{(IV)} u_m = -A_m \sum_{j=o}^{6} \varrho_{j+1} \frac{d^{(j)}\mathcal{C}}{ds^{(j)}} \tag{9}$$

with

$$\mathcal{L}^{(IV)} = \left(\sum_{i=o} \sigma_i \frac{d^{(i)}}{ds^i} \right) \tag{10}$$

The recurrence of regular meandering patterns in natural rivers (Figure 2) (Kinoshita 1961, Langbein and Leopold 1964) suggests to look for periodic solutions of the above system, corresponding to a theoretically indefinite sequence of identical and periodic meander loops with wavenumber $\lambda = 2\pi/(L^*/B^*)$ and L^* intrinsic meander wavelength. Under these conditions channel curvature is described by the classical "Kinoshita curve":

$$\mathcal{C}(s) = \mathcal{C}_o \left[cos(\lambda s) + \mathcal{C}_F cos(3\lambda s) - \mathcal{C}_S sin(3\lambda s) \right] \tag{11}$$

where (C_F, C_S) are used to quantify the "fattening" and "skewing" properties of individual meander loops. The periodic solution of the system corresponding to the periodic curvature distribution (11) then takes the form:

$$\begin{aligned} u_m &= \sum_{k=1}^{3} u_{mk}(t) \exp(i\lambda_k s + c.c.)]; \\ u_{mk}(t) &= \vartheta_k(t) A_m \frac{\sum_{j=1}^{7} \varrho_j (i\lambda_k)^j}{\sum_{j=0}^{4} \sigma_j (i\lambda_k)^j}, \end{aligned} \tag{12}$$

with $\lambda_k = k\lambda$. The periodic solution of (9) displays the typical features of linear damped oscillators: namely resonance occurs when the meander wavenumber

Figure 2. Classical regular forms of natural meanders: Red River, Manitoba, Canada.

and width ratio coincide with the values (λ_R, β_R) that depend on (τ_*, d_s) such that β_R increases with the Shields parameter and decreases for higher relative channel roughnesses. Zolezzi and Seminara (2001) have shown that the condition $\beta = \beta_R$ discriminates between two markedly different morphodynamic regimes (Zolezzi et al. 2005), characterized by dominant upstream (downstream) morphodynamic influence when the width ratio exceeds (lowers) the resonant value.

Under the above assumptions the planimetric evolution equation reduces to the following ordinary differential system for the first and the third harmonic of the inflection angle ϑ and for meander wavenumber λ:

$$\begin{aligned} \frac{d\vartheta_1}{dt} &= \mathcal{F}_1(u_{m1}, u_{m3}, \vartheta_1, \vartheta_3, c.c.) \\ \frac{d\vartheta_3}{dt} &= \mathcal{F}_3(u_{m1}, u_{m3}, \vartheta_1, \vartheta_3, c.c.) \end{aligned} \tag{13}$$

$$\frac{d\lambda}{dt} = \lambda^2 \left[i(3\bar{\zeta}_3 \vartheta_3 \bar{\vartheta}_3 + \bar{\zeta}_1 \vartheta_1 \bar{\vartheta}_1) + c.c. \right] \tag{14}$$

where an overbar denotes the conjugate of a complex number and $\mathcal{F}_1, \mathcal{F}_3$, are complex algebraic expressions reported in Seminara et al. (2001).

4 THE INPUT DATA SET

We seek to compare model-based predictions of meander properties with field observations and to detect how these features are affected by changes in relevant geomorphic controls such as the valley slope and the flow discharge. To these aims suitable data sets have been employed to provide field based input for the simulation model described in the previous sections. Model-based prediction of meander properties is commonly pursued on the basis of non dimensional input data; dimensional analysis applied to river morphodynamics indicates that an appropriate input data set is provided by specifying reach-averaged values of the width ratio, of the Shields parameter and of the relative roughness (β, τ_*, d_s) together with the bank erosion coefficient E. Most theoretical investigations of meander behavior focus on the dependence of meander dynamics on a single dimensionless parameter, while the other are kept fixed; for instance this allows to isolate the role of the channel aspect ratio β (and of τ_* and of d_s). Typical results also refer to given parameter configurations and describe how meander properties vary with time.

In the present work we want to isolate the effect of different geomorphic controls such as the river discharge or the valley slope: therefore we have calculated the dimensionless input data sets from directly

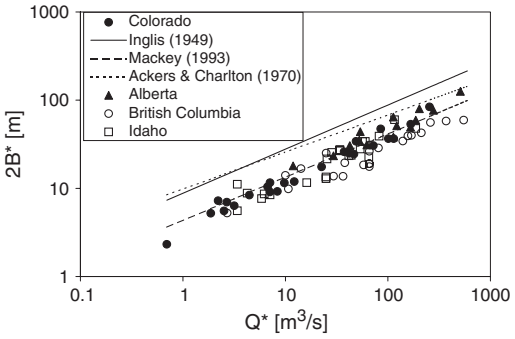

Figure 3. Comparison between different bankfull width estimations and field data relative to single thread, meandering gravel bed rivers.

measurable quantities (Q^*, S, d_{50}^*) by letting one of them to vary while keeping the others fixed. A major requirement is that the input data must reflect hydraulic conditions actually observed in natural rivers.

In order to quantitatively check the consistency of the input data with actual river conditions we have referred to the data set relative to single-thread rivers reported in Gary Parker's e-book (Parker 2004). The data set includes reach averaged characteristics of gravel and sand bed rivers, namely bankfull discharge (Q^*), channel width $(2B^*)$, longitudinal slope (S) and representative sediment size (d_{50}^*). In the present work we have mainly focussed on gravel bed rivers for essentially two reasons. First, the simulation model described in §2 assumes sediment transport to occur mainly as bedload; moreover, the number of data concerning sand bed rivers is relatively too small (<10) for the purpose of describing typical ranges of Q^*, S, d_{50}^* and their correlation properties.

Figure 3 shows the relationship between flow discharge and bankfull river width for the considered gravel bed river reaches. We have compared the field data with empirical relationships proposed by several authors (Inglis 1949, Carlston 1965, Ackers and Charlton 1970, Dury 1976, Mackey and Bridge 1993) for gravel bed, meandering rivers: only the best performing predictors have been reported. Figure 3 suggests that the formula of Mackey and Bridge (1993) most adequately reproduces observed channel widths and reads:

$$B^* = 2.165 Q^{*0.49}. \tag{15}$$

Equation (15) has therefore been used to calculate variations in (β, τ_*, d_s) values corresponding to variations in bankfull discharge with constant values of valley slope and sediment size. Examination of the field data has also suggested that the mean sediment diameter d_{50}^* should be chosen in the range $20 \div 170$ mm with valley slopes not to exceed 0.03. The upper S limit is

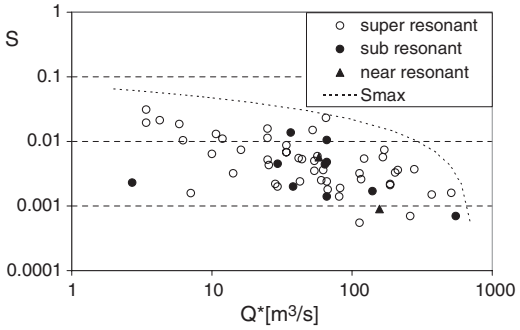

Figure 4. Sub- and super-resonant regimes in gravel bed rivers with different bankfull discharges and longitudinal slopes. The dotted line defines the upper S limit imposed in the input data set for a given flow discharge.

actually bounded by the value of flow discharge, and it has been calculated through an envelope curve based on the given data. Such curve is reported in Figure 4 and can be obtained through the following expression:

$$S_{max} = 2\left[-0.0055 \ln(Q) + 0.0363\right]. \qquad (16)$$

The input dimensionless parameters (β, τ_*, d_s) have been computed for any given combination of (Q^*, S, d_{50}^*) and B^* (from equation (15)) through the same closure relationships employed to evaluate flow resistance indicated in §2 and 3. A further check on the input data has been performed in order to ensure that sediment transport dominantly occur as bedload. We have referred to the classical marginal condition $(W_s^*/u_*^* = 1)$ for the occurrence of suspended load, where W_s^* represents the particle fall velocity, evaluated through the recently proposed expression of Jimenez and Madsen (2003), and u_*^* is the friction velocity. The minimum calculated value of the longitudinal slope corresponding to incipient suspended load is in fairly good agreement with the limit empirically defined by expression (16).

5 PREVALENT SUPER-RESONANT REGIME OF SINGLE THREAD, GRAVEL BED RIVERS

We have calculated the resonant conditions for approximately 60 gravel bed river reaches reported in the reference data set. Sub-resonant (super-resonant) reaches correspond to $\beta < \beta_R$ ($\beta > \beta_R$), while we have referred to near-resonant river reaches when the absolute value of the difference $(\beta - \beta_R)$ is lower than 10% β_R. Results are reported in Figure 5, where each point refer to a given reach: open circles (○) denote super-resonant river reaches, closed circles (●) refer to sub-resonant reaches while near-resonant reaches are represented by black triangles. Several interesting observations arise.

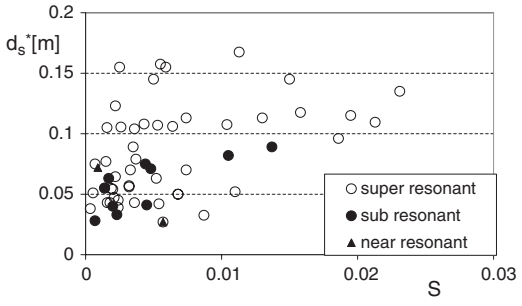

Figure 5. Sub- and super-resonant regimes in gravel bed rivers with different sediment sizes and longitudinal slopes.

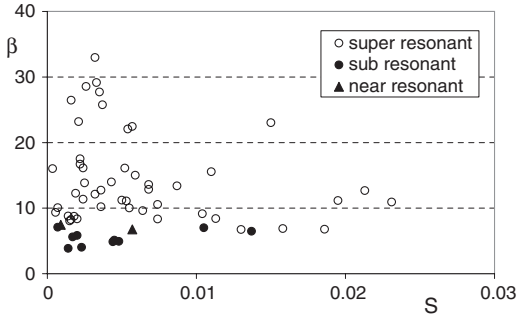

Figure 6. Bankfull width ratios and longitudinal slopes of the examined gravel bed river reaches.

First, it appears that most (~75%) gravel bed river reaches fall under super-resonant conditions. Indeed most sub-resonant rivers seem to occur only for relatively mild longitudinal bed slopes ($S < 0.005$) except for two cases. Sub-resonant conditions are not met also for mean sediment size d_{50}^* exceeding 9 cm. The observations are somewhat confirmed by the typical values of bankfull discharge in sub-resonant channels, which almost invariably exceed 30 $m^3 s^{-1}$ (Figure 4); indeed reaches with high slopes and large sediments are usually found in the upper part of river basins where bankfull discharges tend to keep relatively small. We have plotted the values of β and of β_R for the examined river reaches in Figures 6 and 7 respectively. The picture arising from Figure 6 is somewhat surprising: a sharp threshold appear to separate river reaches falling in the two regimes. Indeed every sub-resonant reach displays values of the width ratio that do not exceed 7; in addition no super-resonant river reach can be found for $\beta < 6.5$. The existence of such thin range of the width ratio separating sub- and super-resonant regime is not obvious at all, since resonant values for the examined reaches cover a much wider interval, with values of β_R for sub-resonant rivers falling between 6 and 10. If confirmed, however, the above observation might provide a simple

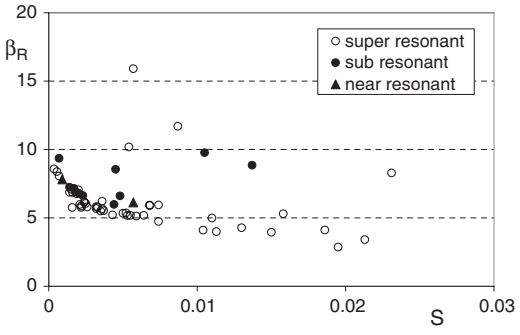

Figure 7. Resonant values of the width ratio as function of the longitudinal slope for the examined gravel bed river reaches.

width-ratio-based criterion for an expedite assessment of the morphodynamic regime of a river reach. It is worth noticing that, especially for low river slopes, a close relationship appears between β_R and S. This can be understood through a careful investigation of the effects that contribute to resonance conditions, which are mainly related to the nonlinearities in the closure relationships employed to evaluate the bedload transport. The choice of Parker (1990) formula implies that at low values of the Shields parameter the quantity $\phi_T = (\tau_{*o}/\phi_o)(\partial\phi/\partial\tau_*)$ keeps constant, thus determining a close relationship between S and d_s which gives rise to the observed biunique correspondence between β_R and S at low slopes. All the above observations seem to support the idea that sub-resonance could be an exception for gravel bed rivers, mostly characterized by relatively large values of their bankfull width ratio normally exceeding the resonant value β_R that keeps generally quite low (below 10) due to the effect of the large relative roughness typical of gravel bed streams. Sub-resonance might be more frequent in sand-bed streams, but this has not been investigated in detail in the present paper. The only supporting argument in this direction might be provided by the observed occurrence of sub-resonant gravel bed rivers in correspondence of relatively small sediment size and mild bottom slopes.

6 SHORT TERM MEANDER DYNAMICS IN GRAVEL BED RIVERS

We have examined the role of variations in bankfull discharge and of the alluvial valley slope on the planimetric evolution of gravel bed meandering rivers, performing simulations in the super-resonant regime which has been identified as the most typical for gravel bed rivers. Simulations started from a slightly perturbed straight channel whose wavelength corresponded to the maximum linearly unstable meander

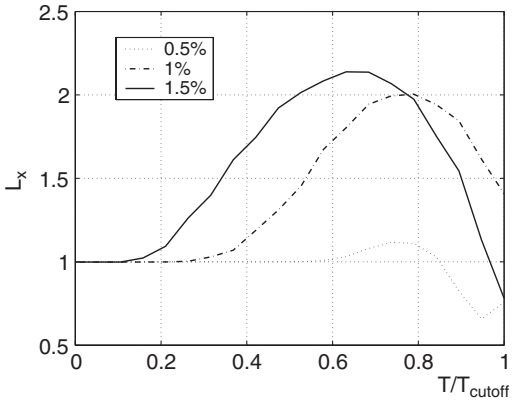

Figure 8. Time evolution of the cartesian meander wavelength L_x for different values of the valley slope, expressed in %.

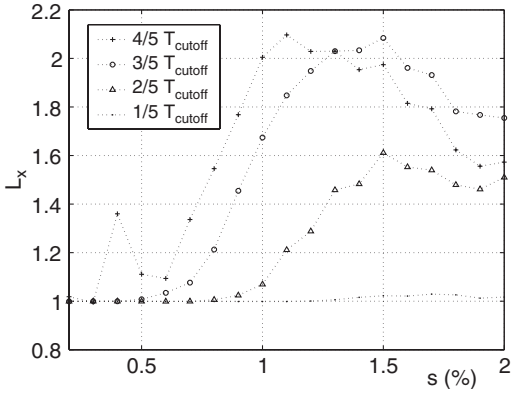

Figure 9. Variation of the cartesian meander wavelength L_x with the valley slope.

wavenumber (e.g. Ikeda et al. 1981, Blondeaux and Seminara 1985). We have investigated the evolution of channel planform until the first cutoff event, concentrating our attention to the short term dynamics of major interest for engineering applications.

We have focussed on the time evolution of meander wavelength and sinuosity as well as on the characteristics of channel planform, described through the fattening and skewing coefficients $(\mathcal{C}_F, \mathcal{C}_S)$ of the Kinoshita curve (11).

The time evolution of the cartesian dimensionless wavelength L_x, scaled with its initial value, is reported in Figure 8: it invariably appears that in the short time span the cartesian wavelength evolves up to a maximum and then decreases before cutoff; a similar tendency also appears when examining the dependence of L_x from the valley slope (Figure 9) at different

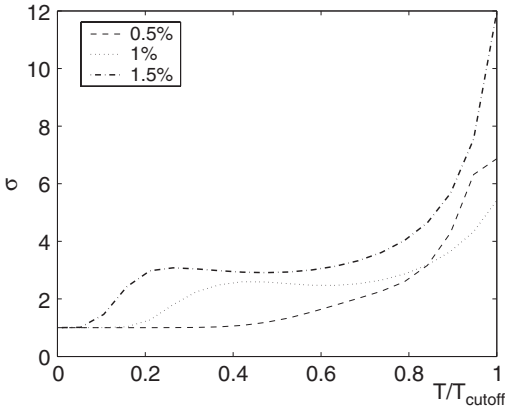

Figure 10. Time evolution of meander sinuosity for different valley slopes.

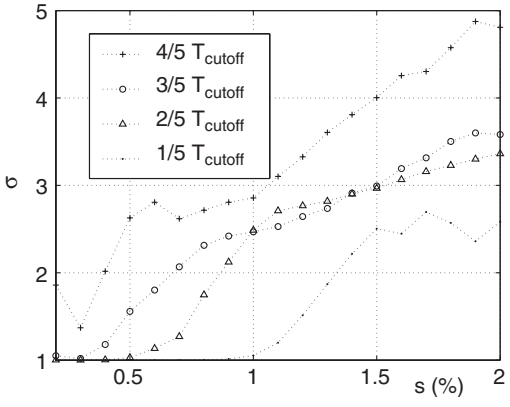

Figure 11. Variation of meander sinuosity with valley slope, at different stages of meander evolution.

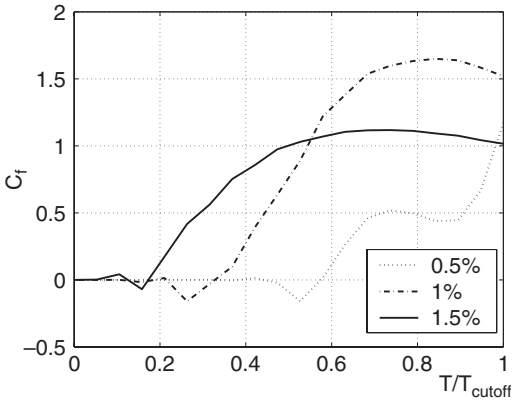

Figure 12. Temporal evolution of the fattening coefficient C_F for different values of the valley slope S.

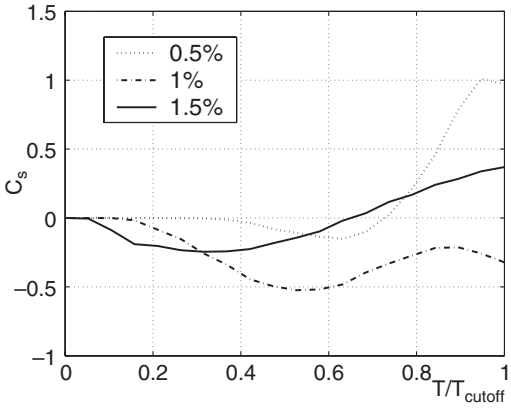

Figure 13. Temporal evolution of the skewing coefficient C_S for different values of the valley slope S.

evolution stages, measured by their relative distance to the occurrence of the first neck cutoff.

Such behavior is reflected in the evolution of channel sinuosity $\sigma = L/L_x$: Figure 10 indeed indicates that the temporal evolution of meander sinuosity is characterized by three distinct stages: an initial growth is followed by a substantially constant region which finally ends up increasing towards cutoff. Indeed the intrinsic wavelength invariably increases until the occurrence of the first neck cutoff (e.g. Seminara et al. 2001), while the presence of a maximum in the evolution of L_x accounts for the nearly constant value of the sinuosity observed in middle stages of meander growth. The highest sinuosities occur only at later stages when L_x is decreasing (Figure 8).

Figure 11 shows that meander sinuosity invariably increases with valley slope. This result confirms similar experimental tendencies reported by various authors (e.g. Bridge 2003) that indicate similar $(\sigma - S)$ relationships for meandering rivers; sinuosity is experimentally observed to sharply decrease for higher slopes which correspond to the shift to the braided morphology.

The planform evolution of a Kinoshita curve (11) can be described in terms of the fattening ($\mathcal{C}_F$) and skewing ($\mathcal{C}_S$) coefficients that can be obtained from the complex Fourier harmonics (ϑ_1, ϑ_3, solution of 13, 14). Figure 12 indicates that fattening is almost invariably positive during meander evolution, except for very short time intervals in the intermediate stages. Fattening of meander loops develops in a relatively short time compared to that needed for the first neck cutoff to occur; once reached a maximum, $\mathcal{C}_F$ keeps almost constant or slightly decreases until the neck cutoff, whose occurrence seems mainly related to the progressive skewing of meander shape, whose indicator, $\mathcal{C}_S$ displays more distributed variations along the whole evolution period. This is shown in Figure 13,

indicating also a more pronounced tendency towards oscillations of the values and the sign of $\mathcal{C}_S$: a persistence in the sign of $\mathcal{C}_S$ cannot be detected, which implies a possible temporal shift from upstream to downstream skewed meander loops (and viceversa) under super-resonant conditions.

Finally note that the dependence of meander properties from flow discharge has not revealed any clear tendency and related results have not been reported here for the sake of brevity.

7 MEANDER MIGRATION IN THE BEATTON RIVER, CANADA

We have performed a comparison of model predictions with the field data related to a widely studied meandering river, the Beatton River in British Columbia, Canada (Hickin and Nanson 1975). The analyzed river reach is approximately 50 km long and has a mean sediment size $d_{50}^{*} = 2.5$ mm, longitudinal slope $S = 0.0003$, formative discharge ranging between 60 and 200 $m^3 s^{-1}$ and bankfull width in the range $20 \div 30$ m. A series of field observations carried out in the late '70s and in the early '80s (Hickin and Nanson 1975, Hickin 1977, Nanson 1979, Nanson and Hickin 1983) have focussed on the migration properties of several meander loops along the freely evolving river reach. It appears that the migration speed of meanders, measured along the n direction, peaks when the curvature ratio ν approximates $0.15 \div 0.20$. Despite several qualitative features of such behavior have been already reproduced (Seminara et al. 2001), a close comparison with meander model predictions is still absent.

We have pursued such comparison for the meander bends analyzed by Nanson and Hickin (1983) employing different values of the flow discharge falling in the formative range and evaluating sediment transport with the formula of Engelund and Hansen (1967) in order to account for the possible coexistence of both bedload and suspended load, the Shields parameter ranging between 0.12 and 0.2.

Model predictions show good qualitative and quantitative agreement with field observations. The reach under investigation falls in the sub-resonant regime. Indeed within the given discharge range, β falls between 11 and 10 while β_R keeps always greater than 13; this picture is independent from the choice of the sediment transport formula. This finding is consistent with the typical shape displayed by the bends reported by Nanson and Hickin (1983), consisting of mature, upstream skewed bends, and with the observed tendency of meander loops to migrate downstream (Nanson 1979). Figure 14 shows the measured migration speed (in channel widths per year) for the investigated meander bends together with the computed maximum values displayed by the same bends over time. It appears that the model correctly predicts the value of the curvature ratio corresponding to peak migration rates.

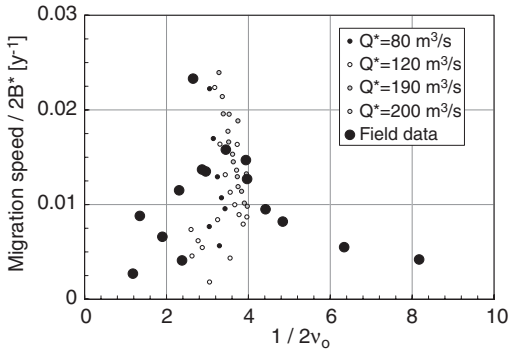

Figure 14. Computed and measured migration speed of several meander loops along the Beatton River.

8 CONCLUSIONS

A first assessment of the ability of a simulation model for river meanders to reproduce field observations has been performed and yielded fairly satisfactory results. Moreover the implications of the morphodynamic influence regimes (sub- and super-resonant, see Zolezzi and Seminara 2001) have been extensively examined in the case of gravel bed rivers for the first time. The present analysis has been carried out under some simplifying assumptions which allowed to focus on the most relevant processes for meander dynamics in the short time span, preceding the first neck cutoff. Results indicate previously undetected features of meander evolution and open promising perspectives for future work. A few interesting issues are summarized. The classical planform of mature meander loops, whose upstream skewness typically allows to detect the flow direction in meandering rivers by simply looking at an aerial picture, seems to occur quite seldom among gravel bed rivers; this might imply that such shape be typical of sand bed rivers, an assessment that requires a suitable morphodynamic model of river meanders able to account for the effect of suspended load. The fact that very few rivers display near-resonant conditions might indicate a tendency for river evolution to keep far from resonance conditions. Moreover the existence of a very narrow threshold between the width ratios of sub- and super-resonant rivers may also suggest that the evaluation of regime properties of gravel bed rivers could be affected by their morphodynamic regime.

Improvements of the present work shall incorporate a wider and more detailed field data set, especially for

sand bed rivers; moreover the present findings need to be verified with more complete numerical models accounting for arbitrary distribution of channel curvature.

ABSTRACT: Extraction of sediments in a riverbed is currently operated to regulate its profile equilibrium. The excavation pit is submitted to a migration process characterized by successive convection and diffusion phases. This phenomenon has been investigated in a case study of gravel exploitation on the Rhone River in Switzerland. A first approach was conducted on a physical model in order to quantify the impact of the main geometrical parameters of the pit, particularly its length, width and depth. The experimental results have then been used for the development and calibration of a numerical model simulating transient flow on a non-cohesive mobile bed. Numerical simulations allowed proceeding to a sensitivity analysis of the pit migration related to its depth, length and width as well as to the riverbed material gradation. The results highlight the erosion processes which develop upstream and downstream of the excavation zone.

1 INTRODUCTION

Disruption of sediment transport in rivers caused by sand and gravel pits modify the bed geometry and can endanger the stability of the banks and structures, e.g. bridges. Sediment transport is affected by a sudden change in the riverbed geometry and consequently erosion is anticipated downstream of the pit. Therefore, geomorphic and also environmental effects of material extraction are one of the main concerns in river training projects (Kondolf, 1994).

The 3rd correction enterprise of the Rhone River is a project at national scale, which deals with all kind of hydraulic activities and structures in the Swiss part of the river, upstream of Lake Geneva. Sand and gravel extraction is carried out at particular locations along the river, among which the Rarogne Region.

The evolution of the bed geometry due to this mine pit was examined. A 1:45 scale physical model with mobile bed was submitted to experimental tests in order to investigate the pit migration and the downstream erosion resulting from the dredging activity. The main goal was to define the depth and extend of the erosion in the affected zone in order to establish the criteria for the dredge operator.

Although research was carried out in the past based on laboratory tests and numerical modeling (Lee & Song, 1993, Bianco et al., 1997 and Gill, 1993), due to the complexity of this phenomenon, scale hydraulic modeling is necessary for each particular case in order to obtain appropriate results. For a first approximation, Lee & Song (1993) proposed formulas derived from experimental results as a general solution to this problem. This set of formulas was obtained for a rectangular mining pit with uniform sediments over the whole river width and in a limited range of Froude numbers (0.40–0.47).

Its application is limited to cases presenting no lateral contraction and only within the range of the original study. Referring to these investigations, two different stages can be distinguished in the mining pit migration process, the convection and the diffusion phases (Fig. 1). The transition occurs when the lowest point of the pit coincides with the downstream extremity of the pit.

2 PHYSICAL MODELING

2.1 *Model boundaries and characteristics*

The simulated river reach extends to some 800 m (Fig. 2), which was modeled at a geometrical scale 1/45 giving the length and width of the model as 16 m to 2.4 m, respectively.

In order to find out the impact of the dredging pit during different flood events, a series of tests was carried out for three discharges listed in Table 1.

The hydraulic model constructed for this study is schematically shown in Figure 3. In order to meet the similarity laws in case of mobile bed modeling, the grain diameter has been chosen considering the riverbed roughness and type of the bed form. The total roughness coefficient can be computed taking into account the grain size roughness and the bed form. Based on the empirical formulas and charts determining the bed form (Larras, 1972, Yalin & Ferreira, 2001) the Rhone River is characterized by a regime of dunes and bars. Considering the total roughness, uniform graded fine sand of 0.2 mm diameter was adopted as bed sediment.

Sediment feeding was evenly done at the upstream limit of the model during tests. The sediment discharge has been computed for each case based on the empirical relations of Smart & Jaeggi (Jaeggi, 1994) and Schoklitsch (Graf & Altinakar, 1998). Average values issued from the mentioned methods were applied as sediment discharge (Table 2).

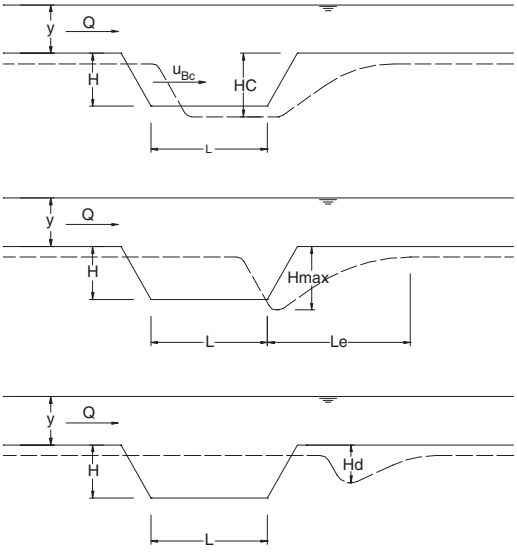

Figure 1. Migration of a rectangular mining pit composed of uniform sediments according to Lee & Song (1993).

2.2 *Instrumentation*

Four UVP (Ultrasonic Velocity Profiler) transducers were mounted on a mobile measurement platform moving along the model length (Fig. 4).

A series of 2 MHz transducers were adopted for the test taking into account the following three parameters:

- Measurement distance range.
- Maximum estimated velocity range.
- Required accuracy in terms of width of the measurement channel and velocity resolution.

Velocity profile measurements were conducted every 25 cm close to the pit and every 50 cm in the other parts.

In each measurement station, 100 profiles were measured by each of the four probes, having one second delay to activate the next probe. One full measurement set over the model was performed at an interval of half an hour. Additional detailed information about

Table 1. Discharge values used in the study.

Return period (yr)	10	50	100

Figure 2. Limits of the hydraulic model and available cross sections of the Rhone River used in this study.

the transducers and measurement interpretation can be found in Nilipour et al. (2004) and Hersberger (2002).

2.3 *Tested configurations*

The analysis of systematically repeated bathymetric measurements, performed at different periods of the mine operation during the last 14 years, reveals important variations of the riverbed configuration between cross sections BWW57 and BWW58 (Fig. 2).

Furthermore, temporary material deposits causing a contraction of the river could be observed periodically on the operation site (Fig. 2). Based on this information, three different configurations of the dredging pit geometry were considered:

– Big dredging pit, 2 m long, 10 cm deep.
– Big dredging pit with contraction, 2 m long, 10 cm deep.
– Small dredging pit, 1 m long, 10 cm deep.

The river contraction has a maximum being half of the width at the beginning of the pit and reaches until zero at the end of the pit. In all cases, the pit extent occupies the total available width of the river bed, as presented in Figure 5.

2.4 *Experimental results*

As expected Yalin & Ferreira (2001), bed forms developed with a predominant influence of multiple bars caused by horizontal turbulence (Fig. 6). Inside the mining pit, dune formation can be observed due to the water depth increase (Fig. 6).

The temporal migration of the mining pit and the velocity field inside the excavation were measured for the three steady state flow conditions given in Table 1. An example of results is presented on Figures 7 and 8 for configuration (a) of the mining pit (Fig. 5) and a flow discharge corresponding to a 50 years return period. Values are given at model scale with the following characteristics:

– The longitudinal distance grows in flow direction starting from the upstream end of the model;
– The longitudinal profile of the mining pit is given at three different instants in order to illustrate the progression of the upstream front and the downstream erosion of the pit;

Table 2. Sediment feeding discharge.

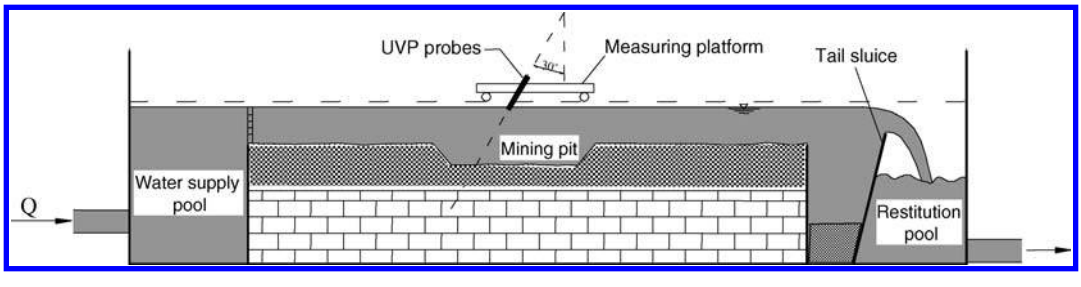

Figure 3. Schematic profile of the hydraulic model.

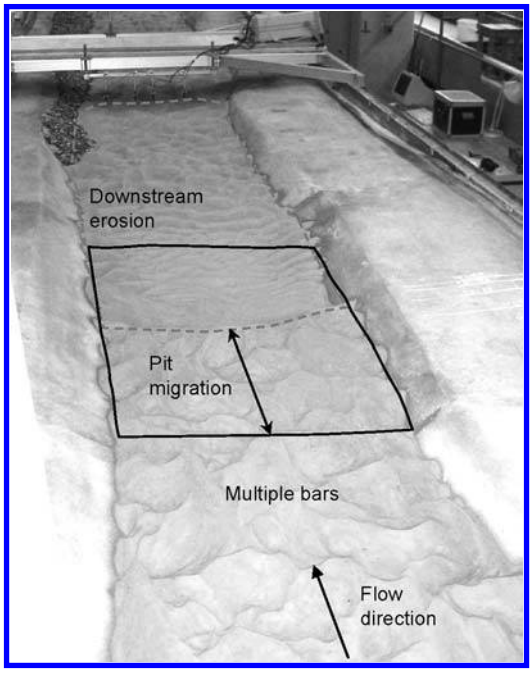

Figure 6. Migration of a rectangular mining pit with formation of bed forms on the mobile bed.

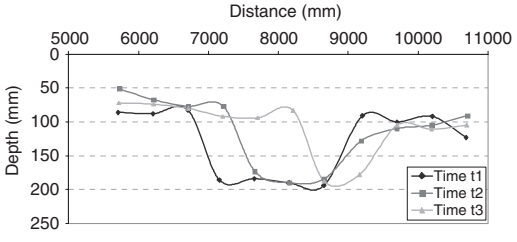

Figure 7. Migration of the big dredging pit for a 50 years return period discharge.

– Velocity profiles are given on five vertical axis uniformly distributed along the initial configuration of the pit at time t_1;
– Mean velocity and standard deviation are given on 128 vertically distributed points;

The observed migration process, illustrated by Figure 7, corresponds fairly well to the stages described in Figure 1, however with some particularities:

– The pit fills from upstream and the downstream erosion is clearly observed but without any deepening of the initial bottom;
– The multiple bars bed forms which develop on the river bed upstream of the mining pit have a significant influence on the upstream flow boundary condition; during filling up, a dune regime develop over the pit (Fig. 6);
– The velocity profiles clearly show the influence of the pit, particularly in the deepened section where a dead zone exists.

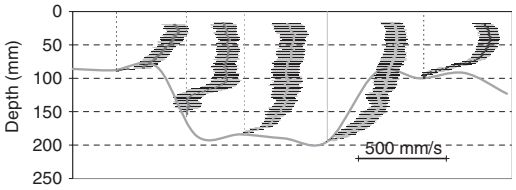

Figure 8. Velocity profiles measured by UVP probes in different sections at time t_1.

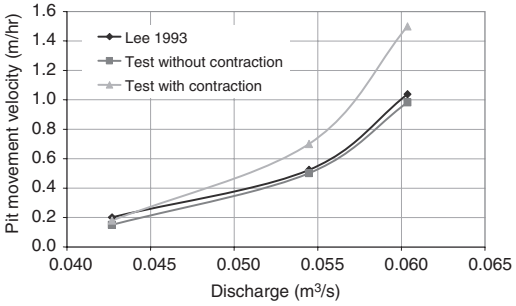

Figure 9. Comparison of the pit movement velocity for different discharges.

2.5 *Summary*

The advancing velocity of pit movement of the big dredging pit was determined for each discharge tested (Fig. 9). Measurements carried out with configuration 1, i.e. without contraction, are compared with the calculated values using the theory of Lee (1993). The movement of the big dredging pit with contraction is faster, particularly for the high discharges. This can be explained by having a smaller excavated volume as well as head losses due to sudden deepening at the beginning of the dredging pit.

The zone submitted to erosion downstream of the pit is not significantly influenced by the discharge (Fig. 10). Its extent is only 25% greater for Q_{100} compared with that of Q_{10}. The effect of the contraction leads to a reduction in the range of 7 to 8% of the erosion extent.

During saturating and filling of the model, it was observed that the bed is deepened at the upstream front of the pit. This phenomenon is particularly perceptible with the contracted configuration where the additional hole reaches 1.5 m at prototype scale for Q_{100}.

It should be mentioned that the results of the experimental model study are used as a first approximation

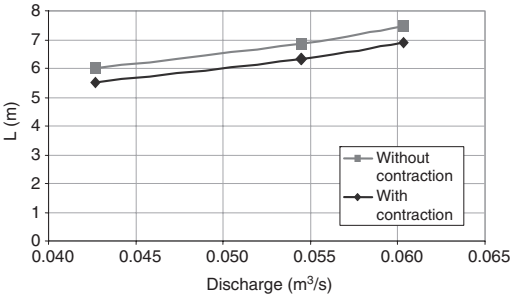

Figure 10. Comparison of the extent of downstream erosion for different discharges.

of the pit migration phenomenon. In order to examine in detail this phenomenon and to show the influence of the different main parameters, the experimental results were used to calibrate a numerical model with mobile bed for transient calculation. This model allows performing a sensitivity analysis on the main parameters, particularly the size of the pit and the gradation of the bed material.

The tests on the model reveal a multiple bars bed regime, which influences the filling of the pit. In fact, the length of the dunes is reduced above the pit with an increased steepness.

It is also interesting to see that the velocity of the pit movement was higher at the beginning of the test, when the initial bed has not yet reached its dune regime.

These different impacts of the bed forms as well as initial condition during the temporal evolution are not modeled in the numerical tool, where a flat bed is considered.

3 NUMERICAL MODELING

3.1 *Mathematical equations*

For the purpose of the project, a new computational model has been developed inside the Excel programming environment. This numerical tool performs the coupled hydrodynamic simulation of 1D flow behavior and bed load transport. The main theoretical aspects of numerical modeling are presented below.

The basic continuity and momentum equations are expressed in the form

$$\frac{\partial A}{\partial t}+\frac{\partial Q}{\partial x}=S \tag{1}$$

$$\frac{\partial Q}{\partial t}+\frac{\partial}{\partial x}\left(\frac{Q^2}{A}+gI_1\right)=gA\left(\frac{\partial z}{\partial x}-J_f\right)+gI_2 \tag{2}$$

$$(1-p)\frac{\partial z}{\partial t}+\frac{\partial q_s}{\partial x}=0 \tag{3}$$

Where A is the wetted surface, Q the discharge, S a source term, J_0 the bed slope, z the bottom elevation of the cross section, I_1 the term of pressure in the wetted cross section, I_2 the term of pressure taking into account the non prismatic geometry of the reach and q_s the bed load unit discharge. The two terms of pressure are computed using the following relations:

$$I_1=\int_0^h (h-\eta)\,b(\eta)\,d\eta \tag{4}$$

$$I_2=\int_0^h (h-\eta)\left.\frac{\partial b}{\partial x}\right|_{h=\eta} d\eta=\frac{\partial I_1}{\partial x}+A\frac{\partial h}{\partial x} \tag{5}$$

An additional semi-empirical closure relation is necessary for coupling the bed load discharge and the hydraulic parameters. In the present case, the equation of Smart and Jaeggi (Jaeggi, 1984) has been implemented:

$$Q_s=\alpha\frac{B_z}{B}2.5QJ_f^{0.6}\left(J_f-\frac{d_m}{12.1h}\right) \tag{6}$$

Where α is a calibration parameter, B_z and B are widths as defined in the schematic cross section of Figure 11, d_m is the mean diameter of the sediments and h the water depth.

Finally, the friction head loss is computed according to the equation of Manning-Strickler:

$$J_f=\frac{Q^2}{K^2A^2R_h^{4/3}} \tag{7}$$

Where K is the Strickler coefficient and R_h the hydraulic radius of the cross section.

3.2 *Cross section geometry*

The coupled 1-D simulation between hydrodynamics and sediment transport has to be able to consider the cross sectional variations induced by deposition and erosion processes. When conceiving the model, the hypotheses related to 1-D modeling have to be kept in mind, in particular that only one value describes the flow or the geometry in any point along the river axis.

By definition, if hydraulics is modeled at 1-D, the same approach has to be applied for the bed load transport. Consequently, the mobile bed elevation must be defined by one single value, considering a horizontal movable bed in the cross sections as described by equations (2) and (3).

Regarding the general morphology of the Rhone River, the trapezoidal cross section presented in Figure 11 was adopted for the study.

Where B_0 is the reference width of the bed at reference elevation z_0, B_z the bed width at elevation z, B the

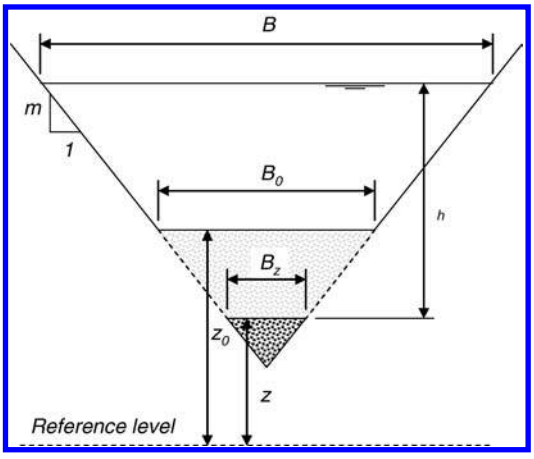

Figure 11. Geometrical model of the cross section.

width at the free water surface and m the inverse slope of the riverbanks. The knowledge of B_0 at elevation z_0 and the inclination m of the riverbanks is sufficient for the definition of the cross section.

3.3 *Numerical solution*

Equations (1) and (2) describe the conservative form of the 1-D St-Venant equations and Equation (3) the sediment continuity, also known as "equation of Exner". In matrix form, this system can be written like:

$$\frac{\partial \mathbf{u}}{\partial t} + \frac{\partial \mathbf{f}}{\partial x} = \mathbf{s} \tag{8}$$

with:

$$\mathbf{u} = \begin{bmatrix} A \\ Q \\ z \end{bmatrix} \tag{9}$$

$$\mathbf{f} = \begin{bmatrix} Q \\ \frac{Q^2}{A} + gI_1 \\ \frac{q_s}{1-p} \end{bmatrix} \tag{10}$$

$$\mathbf{s} = \begin{bmatrix} S \\ gA\left(\frac{\partial z}{\partial x} - J_f\right) + gI_2 \\ 0 \end{bmatrix} \tag{11}$$

Where the vector **u** represents the primary variables (unknown), the vector **f** represents the fluxes (mass, momentum and sediments) and the vector **s** contains the source terms (likewise mass, momentum and sediments).

Equation (8) being hyperbolic, the propagation of perturbations from the primary variables follows characteristic lines. In order to take into account this propagation along characteristic directions in the numerical scheme, the spatial derivates are discretized in a decentralized manner. However, as the characteristic velocities don't have the same sign at subcritical flow conditions, the moving off center of all derivates in the same way is not acceptable. It is necessary to separate the flux judiciously and to move it partially off center in both upstream and downstream directions. This type of scheme is physically based and allows avoiding the appearance of oscillation characteristics of centered schemes.

Two families of methods propose adequate taking off center ways:

- Flux difference splitting: this type of method (Roe, Osher, HLL…) integers directly the notions of wave celerity for the weigthening of the spatial derivates.
- Flux vector splitting: this technique of fractioning fluxes consists in separating the fluxes vector in two parts and taking off center each in a different way. For the present study, the original algorithms of fractioning fluxes developed by Prof. Michel Pirotton at the University of Liège, Belgium, (http://www.hach.ulg.ac.be/), has been used.

3.4 *Model calibration*

When using a numerical model, the first step is devoted to calibration. For hydraulics, the single calibration parameter is the Strickler coefficient in each cross section. The well-documented flood occurred in October 2000 could be used for calibration but no other event was available for validation. According to this procedure, a rather good result was obtained with only two values of the Strickler coefficient: 35 $m^{1/3}/s$ between cross sections P10 and P7, and 24 $m^{1/3}/s$ between P7 and the downstream end of the model (Fig. 2).

The reach located upstream of the mining pit is calibrated with a very classical value for the Rhone river. Nevertheless, the morphological changes due to the pit induce an additional head loss, which has repercussions on the reduction of the Strickler coefficient in this sector. The sediment transport calibration in the present study could be achieved with reference to the experimental results issued from the physical model. This operation refers to the parameter α of Equation (6), which allows weighting the bed load discharge computed from the Smart and Jaeggi equation.

According to the experimental tests, the coefficient α needs to be nearly 3 in order to reproduce all

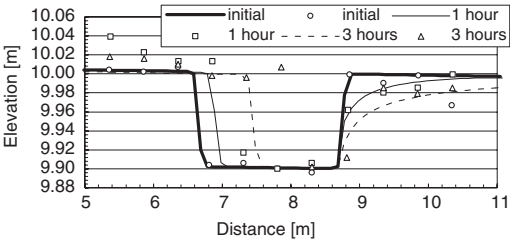

Figure 12. Sediment transport calibration of the numerical model by comparison with measured points of the physical model.

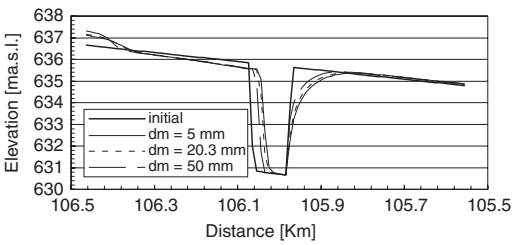

Figure 13. Influence of mean grain size.

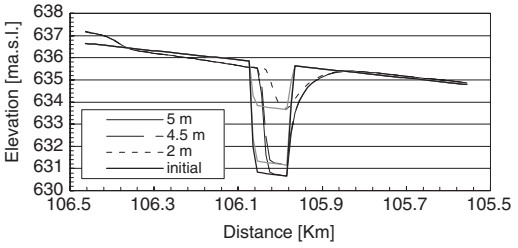

Figure 14. Influence of pit depth after 20 hours.

observed phenomena as good as possible (Fig. 12). Some comments are useful at this point:

- The mean slope of the Rhone River is about 2‰ in this reach, which corresponds to the lower application limit of the equation of Smart and Jaeggi.
- Due to the progressive modification of the initial equilibrium state in the upstream part of the model the progression velocity of the front of the pit was not constant.
- A dune regime developed on the movable bed of the physical model. These bed forms which cannot be reproduced numerically have a significant influence on the energy slope and consequently on the bed load transport.

3.5 *Sensitivity analysis*

Different scenarios were then simulated with the numerical model. The sensitivity analysis refers to the following parameters:

- Flow discharge.
- Grain size distribution.
- Depth of the pit.
- Width of the pit.
- Length of the pit.

Finally, the historical event of October 2000 was simulated in order to examine the behavior of the dredged pit during a high flood.

3.5.1 *Influence of flow discharge*

Three characteristic values of the flow discharge corresponding to high return periods, $Q_{10} = 580\,m^3/s$, $Q_{50} = 740\,m^3/s$ and $Q_{100} = 820\,m^3/s$, have been simulated.

For this range of flow discharge, no significant differences can be mentioned. The flood duration, considered as 20 hours in all cases, reveals as main factor for the filling rate.

3.5.2 *Influence of grain size*

Three different mean grain sizes were used for simulation. The first considered of $d_m = 20.3$ mm, which corresponds to the mean diameter of the extracted sediments, the two other are $d_m = 5$ mm and $d_m = 50$ mm. The profiles obtained after 20 hours for a constant discharge of $740\,m^3/s$ are presented in Figure 13.

It can be observed that the grain size doesn't have a great influence on the pit migration. However, this effect is more noticeable than the previous one related to the discharge.

3.5.3 *Influence of the depth of the pit*

Three different depths of the pit have been investigated, being 5 m, 4.5 m and 2 m. The discharge was kept constant at $740\,m^3/s$ during 20 hours and the mean grain size was 20.3 mm. The computational results are presented in Figure 14.

The influence of the initial depth of the pit is well marked. The sediment transport capacity in the upstream reach is identical in all cases, but the storage capacity of the pit differs. For a 2 m depth it can be observed that the transition phase is ended after 20 hours and the diffusion phase will start at this time.

In order to define the influence of the pit migration on the maximal erosion of the riverbed, the simulation duration was extended up to 10 days. Although maintaining a flow discharge over such a long time is not reasonable in reality, the results give a long-term idea of the pit migration. The envelope curves of the maximal erosion depth are presented in Figure 15.

3.5.4 *Influence of pit width*

Two different widths of the pit were considered in a same manner than in the physical model. The widths are $B = 40$ m and $B = 26.6$ m. The simulation results obtained after 20 hours with a flow discharge of

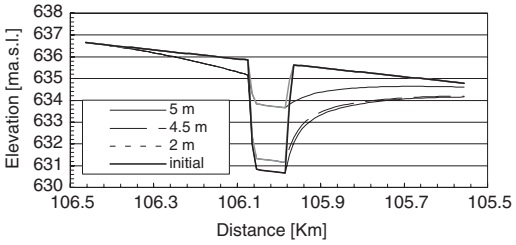

Figure 15. Envelope curves of the maximal erosion for three initial depths of the pit.

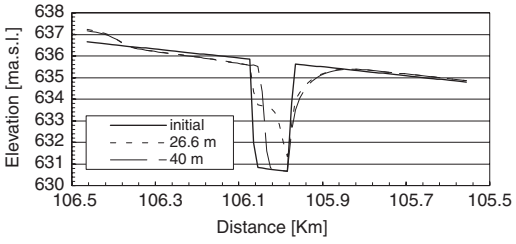

Figure 16. Influence of the pit width after 20 hours.

740 m^3/s and a mean grain size of $d_m = 20.3$ mm are presented in Figure 16.

As expected, the front moves more rapidly in the contracted pit. For the flow discharge of 740 m^3/s, the filling process reaches the downstream end of the pit after 20 hours. The form of the front is different in this particular case with an intermediate landing about two meters below the river bed.

As shown in the previous case, simulations over a long time were performed for both widths of the pit. The envelope curves of the maximal erosion depth (Fig. 17) show that a contraction of the cross section reduces the influence on the downstream erosion. This effect is noticeable for the depth as well for the distance. Thus the diffusion phase of the pit can be significantly damped.

3.5.5 *Influence of pit length*

Simulations with two different lengths of the big dredging pit (Fig. 5), $L = 100$ m and $L = 50$ m, were accomplished. The simulation results obtained after 20 hours with a flow discharge of 740 m^3/s and a mean grain size of $d_m = 20.3$ mm are presented in Figure 18. The envelope curves of the maximal erosion depth resulting from simulations over a long time are given in Figure 19.

The influence of pit length of the on erosion is similar to that related to width. A short pit will have less impact on the downstream erosion than a longer one.

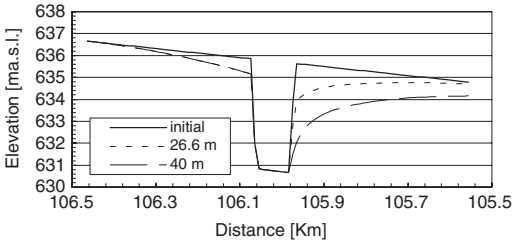

Figure 17. Envelope curves of the maximal erosion depth for two different widths of the pit.

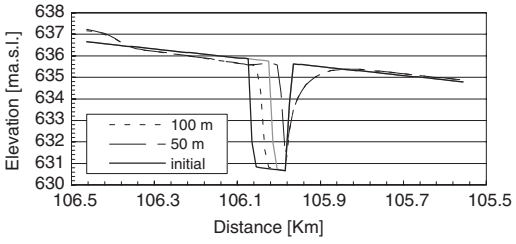

Figure 18. Influence of the length of the big dredging pit after 20 hours.

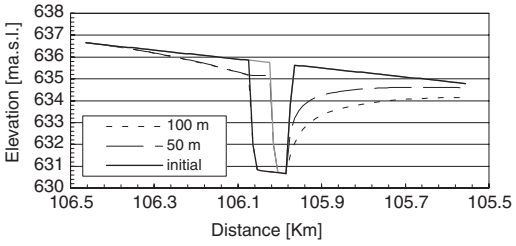

Figure 19. Envelope curves of the maximal erosion depth for two different lengths of the big dredging pit.

3.5.6 *Simulation of the 2000 flood event*

Finally, in order to illustrate the dynamic behavior of the pit during a real flood event, the hydrograph measured on the Rhone River in October 2000 has been simulated (Fig. 20). The return period of the peak discharge is estimated to be approximately 100 years. The initial configuration of the pit has a length of 100 m, a depth of 5 m and two different widths, 26.6 m and 40 m. The mean grain size of the sediments is 20.3 mm.

The temporal evolution of the profile with the broad cross section is presented in Figure 21, respectively with the reduced cross section in Figure 22.

With the broad cross section, the filling process nearly reaches the downstream limit of the pit at the end of the flood. Concerning sediment management, it is interesting to note that this important flood event was not able to completely fill the dredged pit.

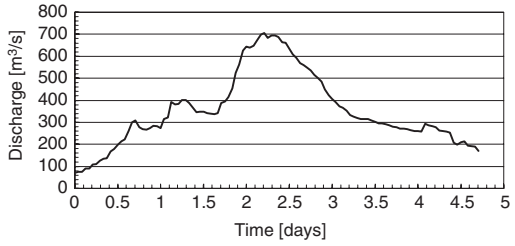

Figure 20. Hydrograph of the 2000 flood event.

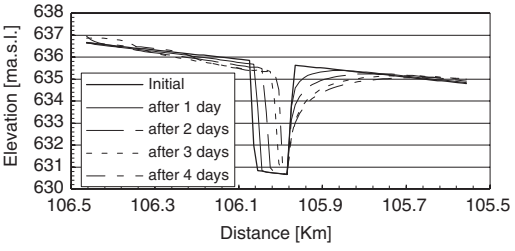

Figure 21. Temporal evolution of the profile during the 2000 flood event with the broad cross section.

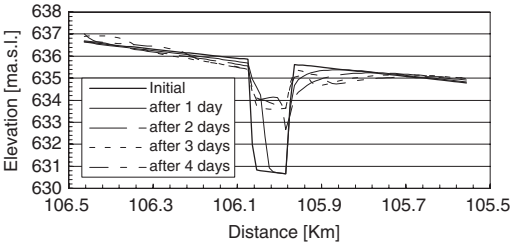

Figure 22. Temporal evolution of the profile during the 2000 flood event with the contracted cross section.

In the case of a pit with contracted cross section, the convection progress takes about 2 days before the beginning of the diffusion phase. It is worthy to note that the reduction of the cross section results in a local dredging effect at the downstream end of the pit.

4 CONCLUSIONS

Extraction of sand and gravel from a river causes a disruption of bed load supply in the downstream part of a mining pit. As a consequence, erosion occurs at that place and the dredged pit itself is submitted to a diffusion process following the filling process. Different parameters influence the evolution and extent of erosion in the affected zone. Among the most important, the depth, the width and the length of the pit, the sediment size and the discharge could be analyzed using a combination of experimental and numerical approaches.

The presented models were developed for application to the particular case of the mining pit of Rarogne on the Rhone River in Switzerland. Nevertheless, the obtained results can be used in a general way for similar situations.

The main goal was to define the depth and extent of erosion in the affected zone in order to establish criteria for the mine operator.

The experimental results obtained for different configurations of the dredged pit were used for the development and calibration of a 1D numerical model for non-steady flow simulation on mobile bed. This model was then used for a sensitivity analysis of the main parameters mentioned above, whose main results can be summarized as follows:

- The discharge doesn't significantly influence the erosion profile in the upstream as well as in downstream part of the dredged zone;
- The uncertainty related to the sediment size only has a weak influence on the downstream erosion and no perceptible effect upstream of the pit;
- The initial depth of the pit has a significant impact on the downstream erosion depth; this influence is proportional to the initial depth; however, no difference can be observed on the erosion upstream;
- The width of the pit has a direct influence on its filling velocity which is obviously related to the available volume; however, a width reduction has a significant effect on the downstream erosion; this effect is reduced the more the pit is narrow;
- The length of the pit exerts a significant influence on the erosion depth in the downstream reach. This influence increases with the length of the pit;
- The numerical simulation of the flood of October 2000 highlights the temporal evolution of the filling process during a real event; it is noticeable that a dredged pit with 100 m length and 4.5 m depth over the total width of the Rhone River could not be completely filled during the four days of the flood event; obviously, the pit with a reduced width fills more rapidly.

The experimental and numerical results confirm that the erosion which develops upstream and mainly downstream of a dredged pit has a negative effect on the stability of the riverbanks and the civil works built in the riverbed. This influence increases with the length and the depth of the pit. However, a pit of a reduced width diminishes the erosion depth downstream.

The results obtained in the case study of Rarogne help to quantify the impact of different configurations of the mining pit on the riverbed. The analysis of these results will be useful for defining an exploitation strategy according to the hydrological regime of the river.

However, it has to be mentioned that the experimental and numerical results are overestimated to a certain extent due to the fact that uniform grain size distribution used for the study impeaches the formation of a protective armoring layer in the eroded zones. This fact places the designer on the safe side.

Bed levelling investigations on transverse sloped beds

Jens-Uwe Wiesemann, Peter Mewis & Ulrich Zanke
Institute of Hydraulic and Water Resources Engineering, Darmstadt University of Technology, Darmstadt, Germany

ABSTRACT: An experimental investigation on the sediment transport process on transverse sloped beds is presented. Experiments were conducted in a 60 m long laboratory tilting flume which is 1 m wide and 0.5 m deep. During the experiments bed levels have been measured at several positions of the cross section with a non-touch method. Longitudinal bed profiles were continuously measured from the chosen positions of the cross section to observe the bed levelling process. Based on the experimental data an accurate characterization of the bed morphology and the prevailing bed forms is given. With respect to the prevailing bed forms the experiments were conducted under different hydraulic and sedimentologic conditions to develop ripples and dunes. The presented work illustrates some new experimental results for the description of the transverse transport process. The transverse transport is an important process in morphologic evolutions. The knowledge of this component of the general, total sediment transport and the development of a useful approach are essential for testing as well as improving and applying numerical models.

1 INTRODUCTION

The sediment transport in transverse direction to the main flow is a very important factor in numerical computations with morphodynamic models. The transport direction differs from the direction of main flow affected by an inclined bed. Following the gravity force the sediment particle moves downwards the bed slope. The quantitative knowledge of this effect is relevant for simulations of scouring and river morphology with numerical models. This transverse transport process is a phenomenon which is not sufficiently investigated and described yet. The inclined bed affects the beginning of sediment transport and also the general transport process over a wide range of hydraulic and sedimentologic parameters. The still existing lack of exact experimental data describing the sediment transport in downslope direction transverse to the main flow field makes some further investigations necessary to develop and to verify approaches which are suitable for numerical investigations.

The transverse directed downslope transport is a very important factor for the appearance and development of bed forms and scours, particularly in river bends. The interaction between downslope transport and secondary flow is described in literature (e.g. Zimmermann & Kennedy (1978). This interaction reaches an equilibrium condition at the final developed scour. The relevance for the implementation of a downslope transport approach in a morphodynamic numeric model is shown e.g. in Mewis (2002) or Rüther & Olsen (2005) among others.

In the present study experiments on sediment transport on a transverse sloped bed were conducted. Different grain materials were used and the experiments were carried out with various hydraulic and morphodynamic conditions, like bed shear stress and given bed forms. The results are compared with those reported in the technical literature. For analyzing the downslope transport and the sediment transport direction a similar arrangement like that used by Talmon et al. (1995) was applied (Wiesemann et al. (2004)).

2 TASK COMPLEX

2.1 *Workflows and conditions*

The investigation, conducted in a 60 m long tilting flume, include experiments with prevailing bed-load transport and experiments with a noticeable fraction of suspended load. The laboratory tilting flume is 1 m wide and 0.5 m deep. Figure 1 shows the sediment characteristics and the prevailing conditions and parameters are given in table 1.

The mobile bed was preformed previous to every experiment. The profile of the bed can be described with a cosine function (Talmon et al. (1995), Wiesemann et al. (2004)). An important advantage of this geometry is the conservation of the bed's shape throughout the experiment. Only the amplitude

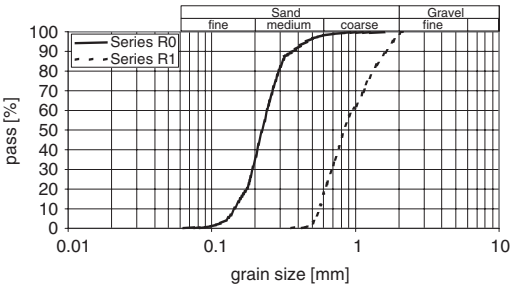

Figure 1. Sediment characteristics of experimental series R0 and R1.

Table 1. Conditions and parameters.

Experiment	d_m [mm]	h [m]	U [m/s]	Θ [–]
Series R0	0.25	0.3	0.22–0.64	0.11–0.57
Series R1	0.96	0.3	0.48–0.77	0.12–0.53

decreases with time according to equation (3). This provides an improved accuracy in the measurements of the decaying amplitude, especially if bed forms occur.

The bed levels at different positions in the cross section, the water levels and the total sediment transport rate were measured. The location of the bed level measurements was chosen in accordance with the requirements of the bed morphology. In this investigation it is necessary to conclude from five bed profile values on the cross sectional shape of the flume bed. For data acquisition five Laser-Distance-Sensors (LDS) were used to detect the bed levels and two Ultrasonic-Distance-Sensors (UDS) were used to detect the water levels. Figure 2 shows the positioning of the Laser-Distance-Sensors. The sensors were positioned at the transversal coordinates 0.96 m, 0.79 m, 0.5 m, 0.21 m and 0.06 m with placing the origin at the right side of the flume (see fig. 3).

In figures 3 and 4 a typical process of transverse located bed levels is given. The sediment transport rates were measured by gathering the material at the end of the flume and for the experiments with prevailing dunes by analysing the movement of bed forms. The experimental setup and the used devices enables a high resolved simulation of the movable flume bed. The experiment was controlled by adjusting the tilt of the flume, adjusting the flow discharge and positioning the sliding panel at the outlet of the flume.

Some disturbances caused by the inflow and the outflow conditions affect the evolution of the bed morphology. By locating the measurement section in a sufficiently long distance from the boundaries these interferences could be regarded as negligible. Every run includes several measurements of longitudinal bed

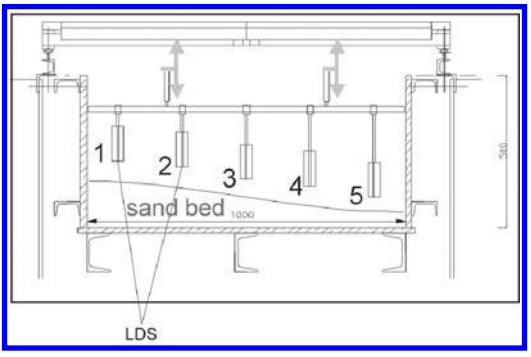

Figure 2. Cross sectional view of measuring carriage with mounted LDS.

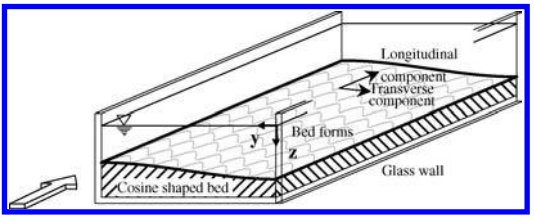

Figure 3. Extract of experimental setup with prevailing bed forms.

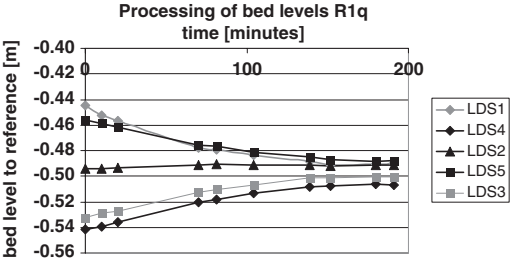

Figure 4. Depicted bed levels over time (example run r1q). The decay of the bed level difference is visable.

profiles of 30 m length, which were measured by moving the devices on a measuring carriage with mean flow velocity to minimize the disturbances to the flow conditions. Each run is short because the main goal was the bed levelling. No feeding of sediment at the inflow was necessary.

During an experiment bed forms evolved from the initially plain bed. The evolution of bed forms continues until the geometry of bed forms is fully developed or reaches an quasi-equilibrium-condition.

2.2 *Direction of sediment transport on a transverse sloped bed*

Based on the work of van Bendegom (1963) the force balance of transport in longitudinal and transverse

Copyright © 2006 Taylor & Francis Group plc, London, UK

direction specifies the actual sediment transport direction. The balance of forces on a grain which moves on a transverse sloped bed includes the fluid drag force and the gravity force. Gravity force affect the movement of the sediments. The inclined bed turns the resulting force in downslope direction (see also Mewis (2002), Wiesemann et al. (2004).

Regarding the experimental setup in this investigation the longitudinal transport rate is as necessary as the transverse component of transport in order to get some information about the transport direction. Because of the nonlinearity of this process a separated analysis of longitudinal and transverse transport is not suitable. Measured data of downslope transport leads to reliable results if the longitudinal transport is known, because the longitudinal transport rate includes information about the hydraulic and sedimentologic conditions.

Figure 3 shows an extract of the used experimental setup. A transversely to the main flow direction inclined bed with prevailing bed forms is in accordance with a cosine function inserted in the straight flume. A separation in a longitudinal and a transverse component of the sediment transport is defined by observing the transport direction.

3 DOWNSLOPE TRANSPORT APPROACHES

3.1 *Basis of approaches*

A general approach to describing the sediment transport direction was presented by van Bendegom (1963) based on the longitudinal coordinate of the flume. This formulation can be simplified for the case where no general longitudinal direction of the channel or flume exists and the longitudinal slope is negligible. This leads to the following formula:

$$\frac{q_y}{q_x} = \tan(\alpha) = -\frac{1}{f(\Theta)}\frac{\partial z_r}{\partial y} \tag{1}$$

with α = angle between sediment transport direction and longitudinal direction, $f(\Theta)$ = weight-function to be determined, Θ = Shields parameter, y = longitudinal direction or main flow direction, x = direction orthogonal to longitudinal direction or main flow direction, q_y = sediment transport in transverse direction, q_x = sediment transport in longitudinal direction, z_r = depth under reference level.

3.2 *Overview of downslope transport approaches*

In table 2 an overview over some downslope transport approaches is given. The approaches consist of formulations which include the Shields parameter and the critical shear stress. The variation in the approaches is the different exponent of the Shields arguments and a deviating factor. The general formulation for the downslope transport $f(\Theta)$ has to be determined with regard to equation 4. The analysis of this investigations based on the general formulation

$$f(\Theta) = \mathrm{a}\,\Theta^{\mathrm{m}}. \tag{2}$$

Table 2. Downslope transport (from Mewis (2002) and Sekine & Parker (1992) respectively).

Author/ Source	$f(\Theta)$	m (exponent of Θ)

4 BED LEVELLING EXPERIMENTS IN THE LABORATORY

4.1 *Experimental procedure and analysis*

The determination of experimental series with the experimental arrangement, described in Wiesemann et al. (2004), yields bed level data which gives information about the transverse transport. The initial bed slope inside the flume, which was preformed at the initial state of $t = 0$, decays with time. This decay was checked by measuring longitudinal bed profiles with laser distance sensors (non-touch method) and compared with the results of the mathematical formulation:

$$h(y) = \hat{h} + a_i \cdot e^{-t/T}\cos\left(\pi\frac{y}{B}\right) \tag{3}$$

$$T = \left((1-p)\left(\frac{B}{\pi}\right)^2\frac{f(\Theta)}{q_s}\right) \tag{4}$$

where B = width of the flume, h = water depth, a_i = amplitude of bed slope, $\hat{h}$ = *mean water depth;*

Copyright © 2006 Taylor & Francis Group plc, London, UK

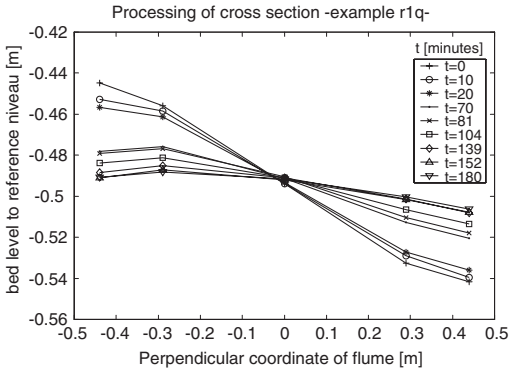

Figure 5. View of cross section with representation of different bed slopes decreasing with time.

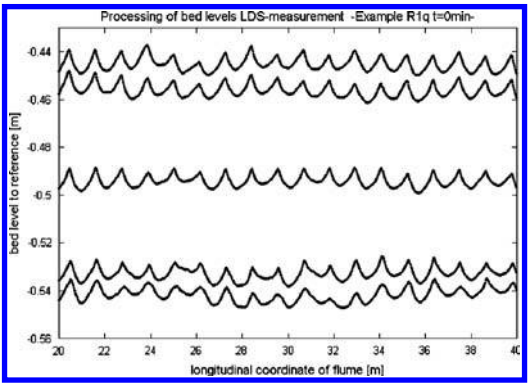

Figure 6. Depiction of longitudinal bed profiles of run r1q at the initial state (t = 0 min). Filtered profiles to smooth the original data for illustration.

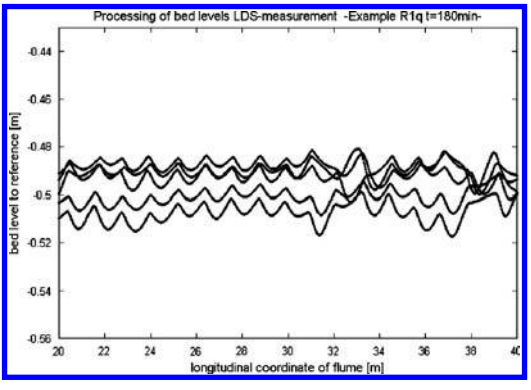

Figure 7. Depiction of longitudinal bed profiles of run r1q at the point of time t = 180 min. Filtered profiles to smooth the original data for illustration.

p = porosity of bed material, q_s = longitudinal transport rate and $f(\Theta)$ = function for the transverse transport.

Based on this comparison the general formulation for downslope transport (eq. 2) could be modified and adapted to the measured data. To analyze the data the measured total sediment transport rate was used.

In the following depictions the decay of the initial bed level differences is visible. As a representative example for a typical run of the series R1 the bed level process of run R1q is given in figures 4 and 5. The localisation of the LDS is described in section 2.1 and in figure 3. The progression of the bed levels is illustrated by plotting the asymptotic merging of the bed levels (fig. 4), the rotation of the inclined bed about the center of the flume (fig. 5) and the merging of the measured longitudinal bed profiles in the analyzed measurement section (fig. 6 and fig. 7).

The longitudinal bed profiles at two different time steps are given in figures 6 and 7. The transversal located LDS-measurements yield the bed level at five points in the cross section. The transverse slope is given with the bed level difference of the bed profiles. With comparison of figures 6 and 7 the merging of the bed profiles is visible which indicates the decay of the transverse bed slope. The bed profiles proceed quasi-parallel.

Above the longitudinal bed profiles of run R1q are given. The decay of the initial bed slope (amplitude of inserted cosine function) is clearly observed.

The measured longitudinal bed profiles in figures 6 and 7 were smoothed due to a better illustrating. The vertical oscillation is here only about 2 cm whereas the real dune heights were bigger. The tilting of the flume is not included in this depictions.

In figure 5 the pivot is placed in the center of the flume, so there was no general erosion in the measurement section. By monitoring the water levels and the flume inclination the normal flow condition could be checked or achieved, which leads to a quasi equilibrium state of transport in the measuring section. The normal flow conditions avoid the occurrence of a net erosion. That means that the average bed level in the cross section is constant during the experiments and no general raise or descent of the flume bed appears.

In the presented experimental series a sand feeding at the beginning of the sand bed was not necessary. Additionally a faulty sand feeding at the inlet leads to an incorrect assessment, particularly in experiments in shorter flumes.

In figures 8, 9 and 10 the decay of the initial amplitude of a run of the experimental series R0 is visible. The initial smooth bed changes into a ripple bed. In the depicted three time steps the decay of the transverse bed inclination and the evolving bed forms are observable.

The experimental series R1 with the coarse sand is depicted in figures 11, 12 and 13. Comparable with the bed evolution of the runs of the experimental series

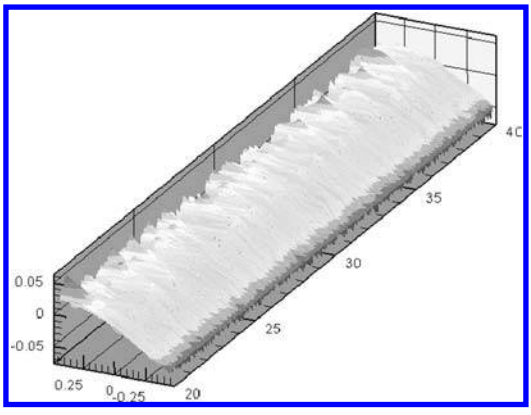

Figure 9. Depiction of the bed of the experimental series with fine sand ($d_m = 0.25$ mm) after running time t = 41 min.

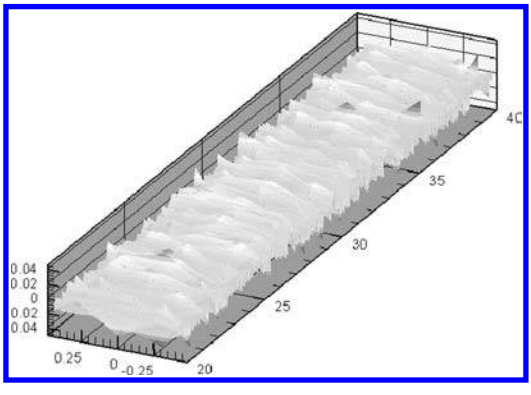

Figure 10. Depiction of the bed of the experimental series with fine sand ($d_m = 0.25$ mm) after running time t = 302 min.

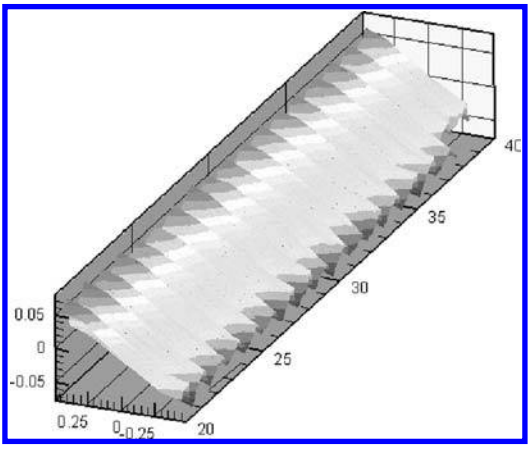

Figure 11. Depiction of initial dune bed of the experimental series with coarse sand ($d_m = 0.96$ mm).

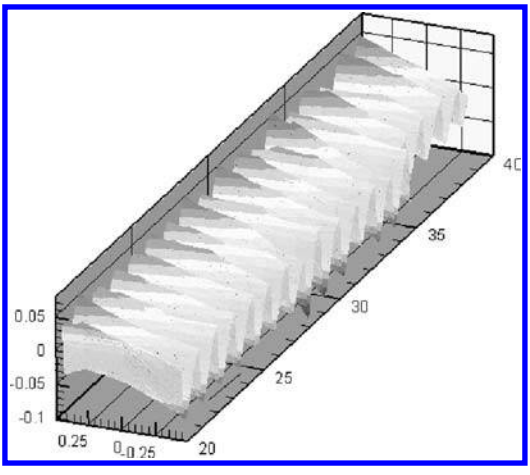

Figure 12. Depiction of the dune bed of the experimental series with coarse sand ($d_m = 0.96$ mm) after running time t = 70 min.

R0 the decay of the initial transverse sloped bed is visible. At the initial state of the bed in this exemplary run the dunes already exist. These bed forms were preformed in order to accelerate their evolution. It is observable that the preformed bed forms are stable over the running of the experiment. The profile of the dunes remains similar, only the height of the dunes increases, while the transverse bed slope decreases.

4.2 *Experimental results*

Figure 14 shows the measured data of the experimental series R0 and literature data. Plotted is Θ versus $1/f(\Theta)$. The Shields parameter for this measurement series is in the range from 0.1 to 0.6. A good correlation is observed.

Copyright © 2006 Taylor & Francis Group plc, London, UK

With increasing Shields parameters there were two experiments observed which yield different values for the existing downslope transport approach. Remarkably dunes were present at this two runs whereas in all other runs a three dimensional ripple bed evolved.

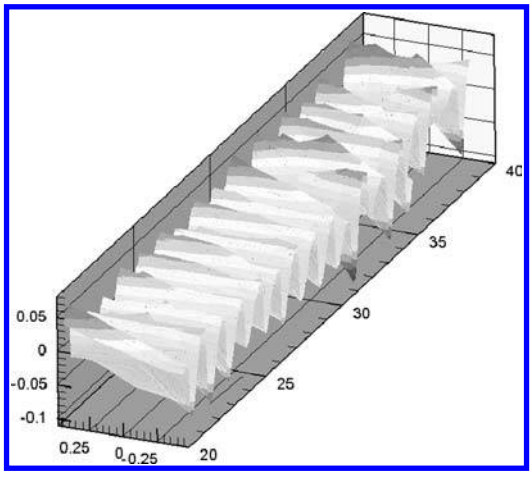

Figure 13. Depiction of the dune bed of the experimental series with coarse sand ($d_m = 0.96$ mm) after running time $t = 180$ min.

The quite good correlation for a three dimensional ripple bed is no longer existing for a condition where dunes evolved from the bed. This leads to the conclusion that the bed forms have an important effect on the transverse transport.

In the region with small shear stresses, where some two dimensional ripple formations were observable, one measurement deviates from the line of best fit too. This has to be investigated in further experiments to confirm this first impression.

An adaption of the general downslope transport approach (eq. 2) in the region of Shields parameters from 0.16 to 0.5 according to the measurement data leads to the following downslope transport approach (Wiesemann et al. (2004)):

$$f(\Theta) = 1.0\,\Theta^{\frac{1}{2}}. \tag{5}$$

In the experimental series R1 with coarse sand ($d_m = 0.96$ mm) dunes were present at the bed.

In figure 15 particularly the deviating gradient of the fit is remarkable, which leads to a differing exponent in the downslope transport approach.

The aforementioned adaption to measurements leads for this experimental series with a 960 µm sand

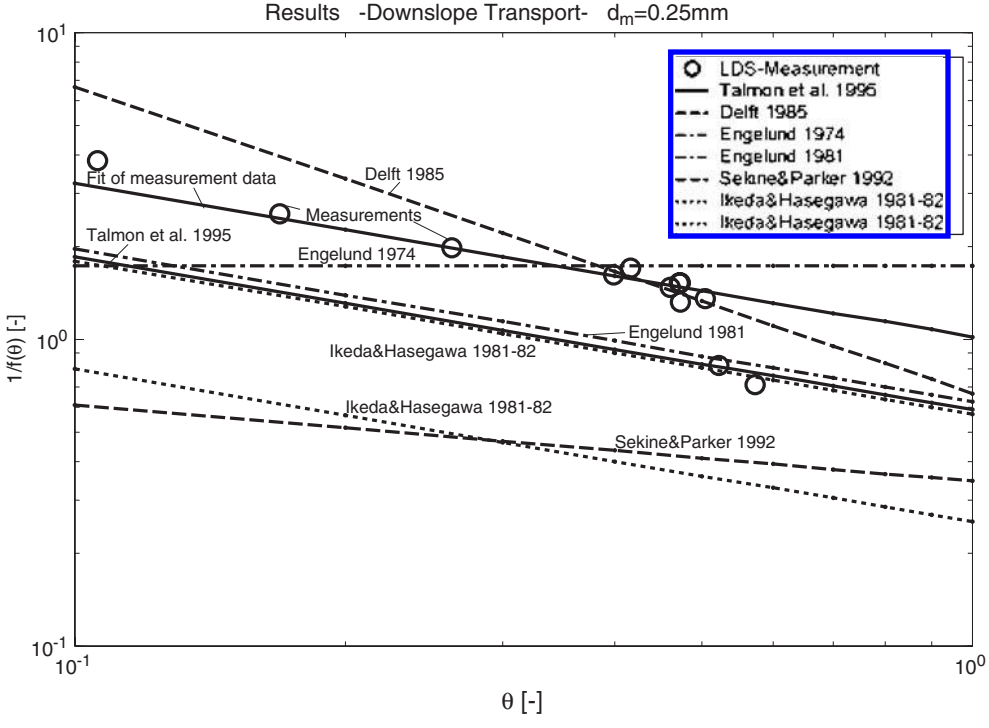

Figure 14. Comparison of results and existing approaches depending on Θ. Fine sand (0,25 mm).

Copyright © 2006 Taylor & Francis Group plc, London, UK

to the following downslope transport approach:

$$f(\Theta) \approx 0.9 \quad . \tag{6}$$

This tendency of the downslope transport function was already proposed by Engelund (1974) however there was a different magnitude of $f(\Theta)$ given. Engelund revised his first proposal in 1981 and found a similar tendency as Talmon et al., Ikeda and Hasegawa.

An interpretation of the deviating formulation of this experimental series cannot be given at the moment. A verification of these new results and the arising approach for the downslope transport (eq. 6) is aspired in following investigations.

5 DISCUSSION AND CONCLUSIONS

The results given in fig. 14 as well as in eq. 5 yield an exponent of ½ in the downslope transport approach. So the exponents proposed already by Engelund, Ikeda and Hasegawa and Talmon et al. could be verified. In contrast to the other formulations a different factor in the function $f(\Theta)$ was obtained. The factor a is 1, as given in equation 5. This relationship is valid for a bed with ripples.

Additionally to that conclusion a difference in the factor a was observed for different bed form conditions. It seems to be necessary to consider the bed forms, because results of some more recent experiments with dunes lead to other values of parameter a. The experiments of the first experimental series lead to a separation of results depending on the bed forms. For a nearly 2D-ripple bed the results are different from a 3D-ripple bed and for a condition with prevailing dunes the results differ and are closer to the results from Talmon et al. (1995). This first estimation was partly verified with the second experimental series. The investigation with a 960 μm sand yields a different order of magnitude of the downslope transport.

An important new output of these experimental series is the different exponent in the downslope transport approach. This differing tendency of the transverse transport approach has to be investigated in further experimental series. In addition the transport on a smooth bed should be investigated for a better understanding of the downslope transport.

There is not enough experimental data about the influence of the suspended load on the transverse transport present yet. A more specific investigation could be helpful in order to understand the role of the suspended load. This should be considered in future investiga-

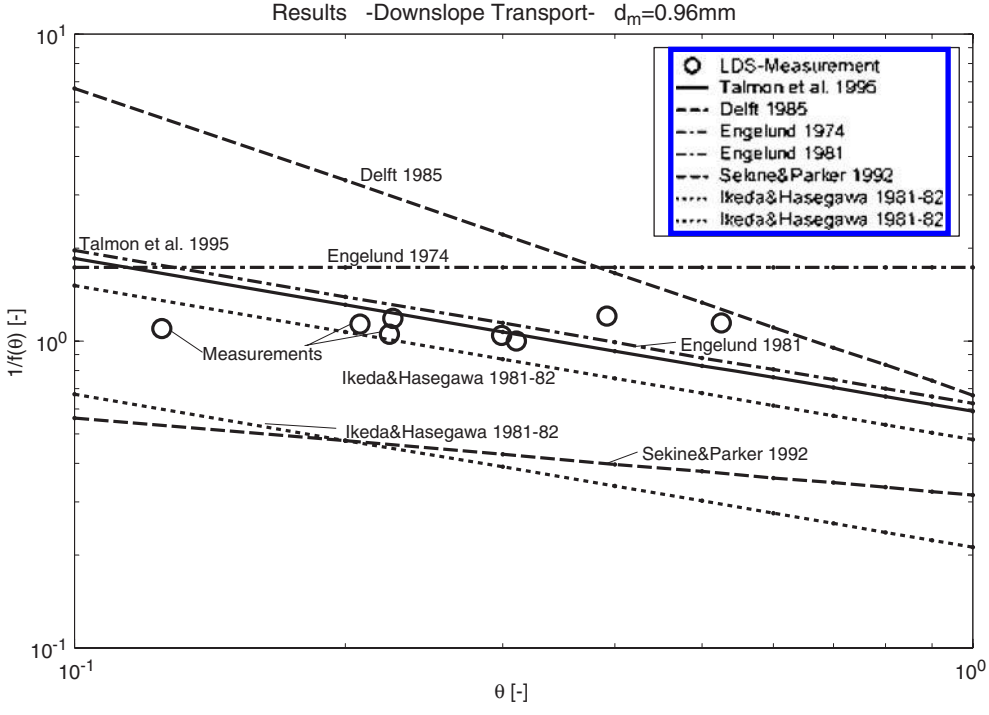

Figure 15. Comparison of results and existing approaches depending on Θ. Coarse sand (0,96 mm).

tions. A new proposal to investigate fine sand with a recent part of suspended load is formulated.

Furthermore there are no experiments available about the investigation of bed material with a different density. Important results with regard to the influence of the density were expected from experiments with a synthetic material bed. The gravity force component, which drives the downslope transport, is smaller than that in the available experiments. Simultaneously the less weight leads to an increasing longitudinal transport rate. Resulting from this inspection a more general formulation for the transverse directed downslope transport can be expected. If necessary the form factors for such an intention should be adapted. Normally the form of synthetic material is different from the natural sand material one.

Effective use of non-erodible layers for improving navigability

C.J. Sloff & E. Mosselman

ABSTRACT: By constructing a non-erodible layer in the pool of a river bend, the distribution of flow and sediment discharge can be modified such that the shallow inner bend will degrade to a certain extent. This results in a larger width for navigation. The approach has been successfully applied in two river bends in the Waal River in the Netherlands. We analyzed the governing processes to estimate the effectiveness of these non-erodible layers. We also applied a 2-D morphological model to laboratory experiments and to the Waal River with a special sub-model for simulating the effect of non-erodible layers. The results have been compared with measurements of bed development, water motion and bed form propagation. A conceptual analytical approach verifies the answers from the more advanced 2D model. From the analysis of field data and model approaches it is concluded that in most conditions the non-erodible layer can be used effectively to reduce the bed level in the inner bend. However, in certain situations such as narrow rivers like the IJssel River in the Netherlands, the flow re-distribution in the cross-section is such that the net degradation of the point bar does not occur.

1 INTRODUCTION

The shallow point bar developing in meander bends often leads to unfavorable conditions for navigability. The available width is reduced, and safety is threatened (chance to run aground, danger of collision). With the busy navigation on the lower Rhine River in the Netherlands and Germany this issue has become quite an important problem for the river managers. To provide a safe and fast fairway for cargo traffic between the port of Rotterdam and the German hinterland a long term investment has been made to deal with the bottlenecks that are caused by shallow point bars and other types of shoals. In the Dutch part of the Rhine River, particularly the Waal River part, two types of measures have been taken or planned:

(a) Durable measures (low maintenance) by using structures in the river bed (non-erodible layers, bendway weirs, bottom vanes) or changing the river alignment (groynes, bend cut-off).
(b) Dredging strategies that aim at removing the shoals without disrupting the sediment balance (i.e. with dumping near the dredge location)

Although various types of measures have been applied in the Dutch and German rivers with varying degrees of success, the application of non-erodible layers in the Waal River has been found to be quite successful in permanently lowering the point bar, and increasing the available navigation width. The effect is induced by filling the pool of a meander bend and covering it with a non-erodible rip-rap, as shown in Figure 1. A redistribution of flow then causes an increase of flow velocity on the point bar, forcing an erosion of the inner bend.

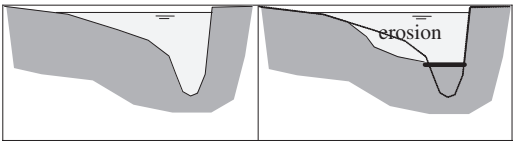

Figure 1. Lowering of the point bar by applying a non-erodible layer in the outer bend.

In the Netherlands erodible layers have been applied in two bends of the Waal River, at St. Andries and at Nijmegen (see Figure 2).

The non-erodible layer at Nijmegen:

- was constructed between 1986–1988 in the sharp river bend at Nijmegen, between chainage km 883.18 and km 885.1.
- has a depth below the low flow reference OLR of 3.50 m, a length of about 2 km, and a width of about 150 m.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Figure 2. Locations of non-erodible layers in the Waal River at St. Andries and Nijmegen.

The non-erodible layer at St. Andries:

- was constructed between 1997 and 1999, in the sharp river bend at Sint Andries, between chainage km 925 and 928.
- has a depth below the low flow reference OLR of 3.50 m, a length of about 3.1 km, and a width of 140 m.

For the design and evaluation of these measures several modelling approaches have been applied in the past, ranging from laboratory scale models to physically based mathematical models. These studies have led to the development of a computational modelling approach, which has been implemented in one-dimensional (1D) and two-dimensional (2D) computational models. In this paper the modelling approach, following Struiksma (1999), is presented and discussed. Also the results are shown of the evaluation of the computational approach by a comparison with recent high-resolution multi-beam data.

The success of this measure depends on a sufficient increase of flow velocities in the inner bend to induce erosion. However, the layer also increases the amount of sediment transport through the inner bend (as the helical flow sweeps all sediment from the non-erodible layer). This decreases the effectiveness of the measure. An analysis of model applications in this paper shows that the increased sediment transport makes that this measure will not be effective in the IJssel River (one of the Rhine branches).

2 MODELLING THE EFFECT OF NON-ERODIBLE LAYERS IN BENDS

2.1 *General*

The non-erodible layer in an outer bend reduces its depth. This causes an increase of discharge and flow velocity in the inner bend. This effect is enhanced when the non-erodible layer is rougher than the alluvial bed, which is often true when riprap is used.

At the upper edge of the non-erodible layer sediment is supplied (by the river) over the full width of the river bed and the layer. This sediment is transported downstream over the non-erodible layer, but it is gradually swept towards the inner bend by helical flow effects. As no sediment is added from the non-erodible layer, theoretically after some distance the layer is 'swept clean', and all sediment is moving through the inner bend.

In the final equilibrium situation all sediment supplied from upstream is transported (after some distance) through the inner bend. Compared to the original situation without non-erodible layer this means a substantial increase of transport through the inner bend.

The main characteristic of the relation between sediment transport and flow velocity can be expressed by a power law, in which the transport rate is a function of flow velocity:

$$s = m \cdot u^n \tag{1}$$

where m is a coefficient (depends on roughness, grain size, etc.); n is the power of the transport formula (always larger than 3, in practice 4 to 5); s is the sediment-transport capacity per unit of width; and u is the local flow velocity.

On basis of this general sediment-transport relation for the transport capacity three possible morphological equilibrium conditions can be defined:

Equilibrium 1	Equilibrium 2	Equilibrium 3
Supply = Transport capacity	Supply < Transport capacity	Supply > Transport capacity
Bed level inner bend remains unchanged	Erosion in inner bend (until supply = capacity)	Sedimentation in inner bend (until supply = capacity)

Erosion is therefore only expected if the redistributed flow velocities will increase the transport capacity more than the increase in sediment supply through the inner bend. The probability of occurrence of this equilibrium increases when the power n in equation (1) is high, which is typical for conditions with bed-load transport at low shear stresses. For example, and increase of flow velocity of 10% will lead to an increase of transport capacity of 50% for $n = 4$, and an increase of almost 100% if $n = 7$.

Side effect of the increased sediment transport rate through the inner bend is a local increase of amplitude of migrating bed forms (dunes), and of bar patterns which are forced by the alignment (by groynes). These effects have been observed in laboratory experiments and recent field observations. The amplified bed forms will oppose the actual gain of navigation depth.

Furthermore, the lack of transport over the non-erodible layer causes a scour hole in the river bed just downstream of this layer. This effect is clearly visible downstream of the non-erodible layers at St. Andries and at Nijmegen (see Figure 3).

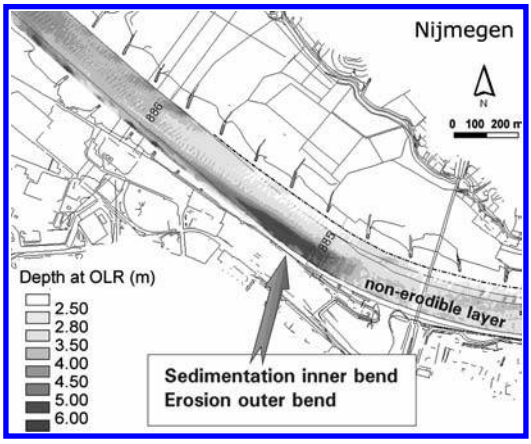

Figure 3. Measured water depth (multi-beam sounding) at lower edge of non-erodible layer at Nijmegen (flow is from East to West).

2.2 *Modelling concept*

The model concept for non-erodible layers has been defined in the early 1980s, and is based on a correction of bed-load transport capacity. The model concept was subsequently implemented in the numerical models SOBEK and Delft3D. The theoretical backgrounds and experimental verification of this approach have been presented in a conference paper of Struiksma (1999).

Usually bed load is modeled with a simple predictor in which sediment transport is a function of the local transport capacity of the flow. However, when transported over a non-erodible layer, no sediment can be supplied from the bed when the capacity increases. The sediment transport thus becomes supply-limited rather than capacity-limited. At first glance, this might seem to necessitate an entirely different computational approach in which volumes of sediment supplied at the boundaries are followed as they travel over the non-erodible layer. However, the model concept of Struiksma (1999) retains the relation with local transport capacity. This model concept accounts for the transport limitations on non-erodible layers through a reduction of the transport layer thickness on the bed.

In this concept the volumetric sediment transport per unit width (according to a customary transport predictor), s_f, is modified with a correction factor, ψ, to obtain the actual sediment transport per unit width, s, over the non-erodible layer (including pores):

$$s = \psi\left(\frac{\delta}{\delta_a(h)}\right) s_f(u) \tag{2}$$

in which δ is the thickness of alluvium on the non-erodible bed, δ_a is the maximum thickness of alluvium at which the non-erodible layer affects the sediment transport, h is the local water depth and u is the local depth-averaged flow velocity. The bed is non-alluvial ($\psi < 1$) if $\delta/\delta_a < 1$ and alluvial ($\psi = 1$) if $\delta/\delta_a \geq 1$ (Fig. 4). The correction factor, ψ, accounts for the reduction of the transport capacity due to a thinner transport layer and hindered bed-form development. Basically, the information on the reduction is carried by the sediment layer thickness, δ. Local increases in s_f are counteracted by decreases in δ and ψ in such a way that the resulting erosion cannot reach below the surface of the non-erodible layer. This limits the supply of sediment from the bed. The supply of sediment from upstream is limited by the occurrence of similar reductions upstream. The maximum alluvium thickness for influence of the non-erodible layer, δ_a, corresponds to the thickness of the transport layer on an alluvial bed. It can be taken equal to half the bed-form height and is therefore primarily a function of the local water depth.

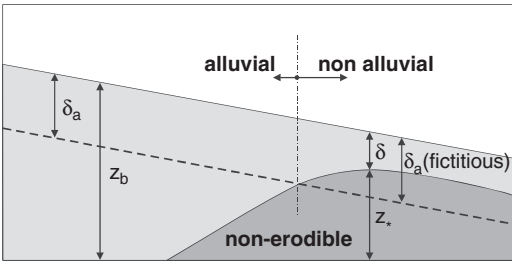

Figure 4. Definition sketch (Struiksma, 1999).

Indicating the level of the top of the non-erodible layer with z_*, the alluvium thickness satisfies $\delta = z_b - z_*$, where z_b represents the bed level which is equal to the level of the top of the layer of alluvium. Using this relation, equation (2) is substituted into the one-dimensional sediment balance

$$\frac{\partial z_b}{\partial t} + \frac{\partial s}{\partial x} = 0 \tag{3}$$

where t denotes time and x denotes the streamwise co-ordinate. This yields

$$\frac{\partial z_b}{\partial t} + \psi \frac{\mathrm{d}s_f}{\mathrm{d}u}\frac{\partial u}{\partial x} + \frac{s_f}{\delta_a}\frac{\mathrm{d}\psi}{\mathrm{d}(\delta/\delta_a)}\left(\frac{\partial z_b}{\partial x} - \frac{\delta}{\delta_a}\frac{\mathrm{d}\delta_a}{\mathrm{d}h}\frac{\partial h}{\partial x}\right) = \frac{s_f}{\partial_a}\frac{\mathrm{d}\psi}{\mathrm{d}(\delta/\delta_a)}\frac{\partial z_*}{\partial x} \tag{4}$$

which shows that the correction factor, ψ, modifies the free morphodynamic behaviour and that the level of the non-erodible layer, z_*, acts as an external forcing of the system.

The dependence of the correction factor, ψ, on the relative alluvium thickness, δ/δ_a, is represented by an assumed function which increases monotonously from

Copyright © 2006 Taylor & Francis Group plc, London, UK

zero to unity for $0 \leq \delta/\delta_a < 1$ with a smooth transition to the constant value of $\psi = 1$ for $\delta/\delta_a \geq 1$. In the one-dimensional numerical model SOBEK, this function reads

$$\psi = \sin\left(\frac{\pi}{2}\frac{\delta}{\delta_a}\right) \quad \text{for} \quad \frac{\delta}{\delta_a} < 1 \tag{5}$$

In the two- and three-dimensional modelling system Delft3D, the function reads

$$\psi = \frac{\delta}{\delta_a}\left(2 - \frac{\delta}{\delta_a}\right) \quad \text{for} \quad \frac{\delta}{\delta_a} < 1 \tag{6}$$

On basis of a characteristic analysis of the governing equations Struiksma (1999) concluded that a non-erodible layer significantly increases the celerities of bed perturbations. This implies that the numerical stability of computations requires smaller time steps.

The concept presented above has been implemented in Delft3D modelling software, which is a tool that can be used to compute morphology in 2D-mode (depth-averaged flow and sediment transport) and 3D-mode (fully 3D hydrodynamics and 3D sediment transport processes). The algorithm is applied in the bed-level update module, and satisfies the principles of conservation of mass. A comparable algorithm for non-erodible layers can be found in Hanson & Militello (2005), but they approach the reduction of the transport capacity in a physically different way than Struiksma.

In practice most river-morphology applications are run in 2D, for which the 3D helical flow in bends has to be approached using a parameterization. In 2D mode, the Delft3D system the flow is calculated according to De Vriend (1981). The bed slope effect on sediment transport is calculated according to Koch & Flokstra (1981), see also Talmon et al. (1995).

$$\tan(\alpha_s) = \frac{\sin(\alpha_f) + \frac{1}{f(\theta)}\cdot\frac{\partial z_b}{\partial y}}{\cos(\alpha_f) + \frac{1}{f(\theta)}\cdot\frac{\partial z_b}{\partial x}} \tag{7}$$

In this equation α_f and α_s are the angle of bed-shear stress (flow) and bed-load transport respectively, and θ is the Shields parameter (defined as $u^2/[C^2 \Delta D]$ with Δ is the relative density of sediment equal to about 1.65). The function $f(\theta)$ determines the effect of bed-slope, and can be approximated by the following relation:

$$f(\theta) = A_{shld} \cdot \theta^{1/2} \tag{8}$$

In which A_{shld} is a coefficient, which is found to be in the order of 0.85 in natural rivers, and 1.7 in laboratory experiments. The parameterized effect of spiral flow is used to adapt the flow angle α_f in eq. (7).

Figure 5. Photograph of curved flume experiment in 1987.

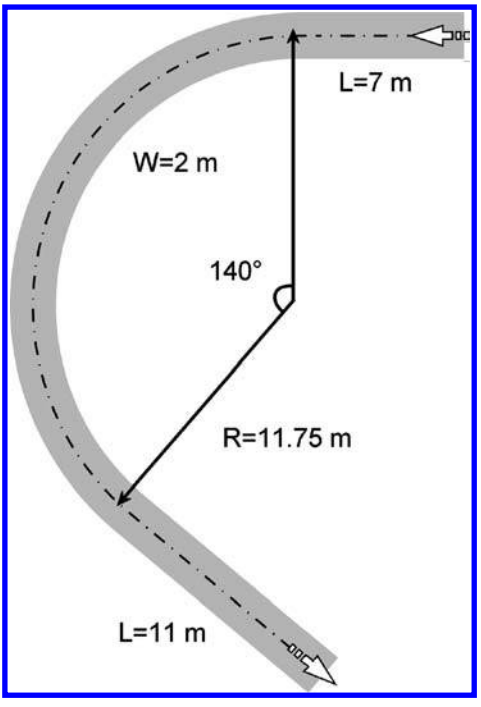

Figure 6. Dimensions of curved flume.

2.3 *Experimental verification of the modelling concept*

In 1987 experiments have been carried out in a curved flume at WL | Delft Hydraulics to verify the presented theoretical model. Figure 5 shows a photograph of the model looking in downstream direction. The actual dimensions of the flume are presented in Figure 6. The flume was equipped with a sand recirculation system. The sediment in these experiments has a median grain size D_{50} of 780 μm.

Copyright © 2006 Taylor & Francis Group plc, London, UK

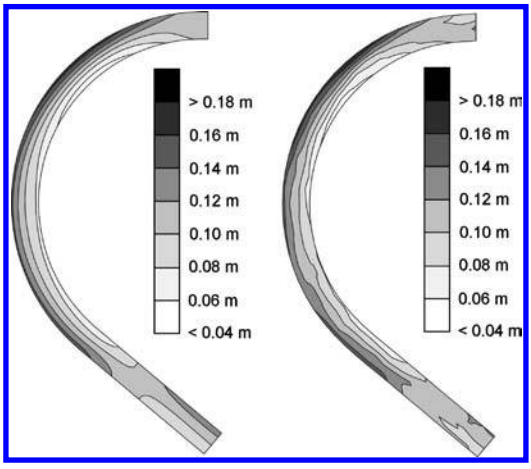

Figure 7. Water depth simulated with Delft3D (left) and in the laboratory flume (right) for reference simulation T2.

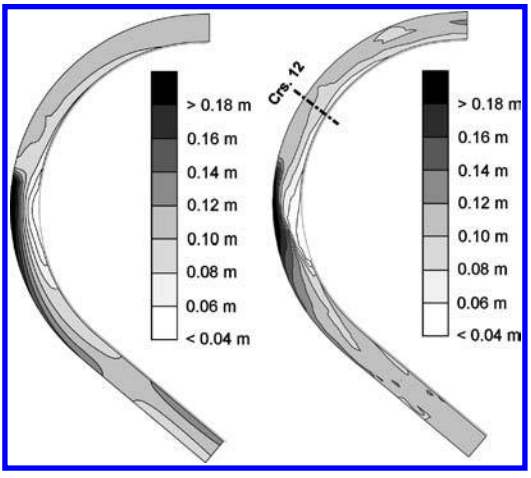

Figure 8. Water depth simulated with Delft3D (left) and in the laboratory flume (right) for non-erodible layer experiment.

Several types of experiments have been carried out, among which the experiment T2 (reference situation without measures) and experiment T3 with non-erodible layer. The non-erodible layer in T3 was placed in the upper part of the curved section over a length of 15 m, and was composed of sediment with coarse sediment having a grain size $D_{50} = 13.4$ mm. Some other characteristics of the experiments are listed in the table below:

Discharge	0.09 m^3/s
Chézy roughness value	27.66 $m^{1/2}/s$
Slope	$2.46 \cdot 10^{-3}$ m/m
Average depth	0.106 m
Average velocity	0.425 m/s
Average sediment transport	60 to 70 l/hr
Dune height	0.03 m
Duration of experiment	6 days
Transport formula	Engelund & Hansen (1967)

For the analysis only the final equilibrium situation has been considered. Simulations with Delft3D have been carried out for both the reference experiment T2, and the fixed-layer experiment T3.

Figure 7 shows the computed bed levels for the calibration simulation of the reference experiment T2. For calibration a coefficient $A_{shld} = 2.1$ combined with a reduction factor of 0.5 for spiral flow intensity has been chosen to obtain the best reproduction of transverse slopes, wavelength of point bar, and overshoot (effect of overshoot causes two peaks on the point bar). A comparison of the two plots in Figure 7 shows an excellent agreement.

In Figures 8 and 9 the results are plotted for experiment T3 with the non-erodible layer. In the Delft3D simulation the maximum alluvium thickness for influence of the non-erodible layer, δ_a, is set to 0.02 m

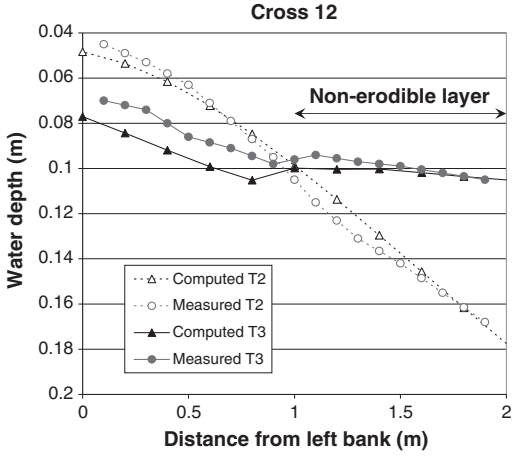

Figure 9. Water depth in cross-section 12 (indicated in Figure 8), in computational model and laboratory experiment, and with and without non-erodible layer.

(based on the observed bed-form height in experiment T2). Other parameters are maintained from run T2, hence no change in roughness has been used for the non-erodible layer and inner bend (so no further calibration has been applied).

The results show that the effect of the non-erodible layer is reproduced quite well, although the increase of depth in the inner bend is slightly overestimated in the computations. Note that this might be influenced by applying a transverse variation in roughness.

Furthermore it has been found that just downstream of the non-erodible layer a quite strong bed-tilting is triggered. In both the experiment and in the computational model a scour hole develops just downstream

Copyright © 2006 Taylor & Francis Group plc, London, UK

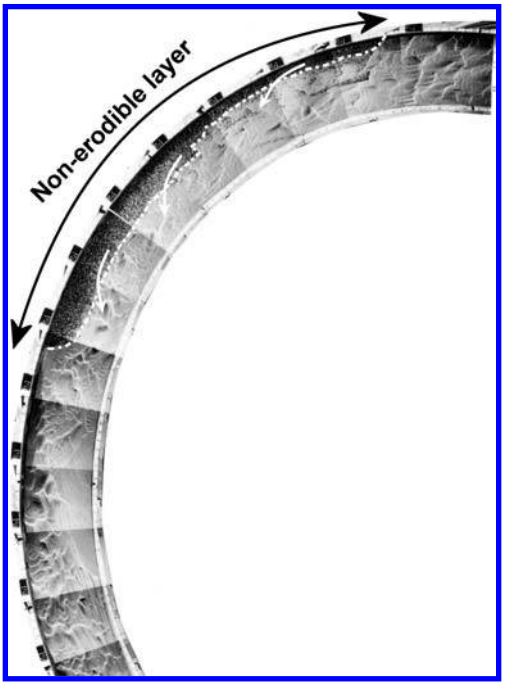

Figure 10. Photograph of bed in flume with non-erodible layer exposed (indicated by dashed line) showing how sediment is swept towards the inner bend (arrows).

of the non-erodible layer (in the outer bend), whereas a strong deposition occurs on the opposite side of the river (in the inner bend), see Figure 8. The responses in both models are quite similar with respect to maximum scour depth and bar height, but the width of the scour hole appears to be slightly narrower in the laboratory experiment.

In both the computation and the experiment it has been found that the non-erodible layer is swept clean from the sediment after some distance. In Figure 10 the area of the non-erodible layer that is uncovered is indicated by a dashed line. Arrows indicate the sweeping process that is induced by the spiral flow effect.

Only at the upstream part some barchan shaped dunes travel over the non-erodible layer, after which they migrate gradually towards the inner bend. In a more or less similar way small patches of sediment supplied from upstream travel in a similar way over the non-erodible layer in the computational model. These patches of sediment are the mechanism in which bed-load is transport over the non-erodible layer, but it is not a physically correct representation of the dunes mentioned above (dimensions and propagation of these patches do not correspond to bed forms).

It should further be noted that the dune heights in the model cannot be scaled up to prototype conditions, because then they are too high. The dunes may therefore overestimate the roughness in the experiment when compared to the prototype.

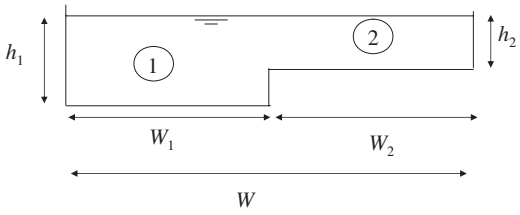

Figure 11. Schematization of a cross section into two sections.

2.4 *Analytical approach*

Based on the modelling concept presented before, it is possible to derive a simple analytical approach for simplified conditions. Consider the cross-section to be represented by two sections: a deep section "1" (outer bend) and a shallow section "2" (inner bend) as shown in Figure 11.

In the following we assume that the time-average morphology of the cross-section can be determined from conditions at a characteristic mean discharge (e.g. the discharge that produces the same yearly transport rate as the full hydrograph). Assuming an axi-symmetric cross-section in a bend, the depth of the sections can be written as:

$$\begin{aligned} h_1 &= h_{avg} + \frac{1}{2}(W - W_1) I_n \\ h_2 &= h_{avg} - \frac{1}{2} W_1 I_n \end{aligned} \tag{9}$$

in which h_{avg} = average depth, and I_n is the average transverse slope in an axisymmetric bend profile. The slope I_n is computed from:

$$I_n = \frac{2\varepsilon}{\kappa^2}\left(1 - \frac{\sqrt{g}}{\kappa C}\right) \cdot \mathrm{f}(\theta) \cdot \frac{h_{avg}}{R} \tag{10}$$

in which f(θ) is the transverse slope function expressed by equation (8), R is the radius of curvature (at the axis), κ is the Von Karman coefficient (~0,4), and ε is a spiral flow coefficient. It is assumed that the surface slope for both sections are identical, i.e. assuming a weak curvature, hence using the Chézy formula for the sections it is found that:

$$\frac{u_1^2}{C_1^2 R_1} = \frac{u_2^2}{C_2^2 R_2} \quad with \quad R_1 = \frac{h_1 W_1}{h_1 + W_1}; R_2 = \frac{h_2 W_2}{h_2 + W_2} \tag{11}$$

where R_1 and R_2 are hydraulic radii of the sections. We can assume roughly that $R_1 \approx \xi_{R1} \cdot h_1$ and $R_2 \approx \xi_{R2} \cdot h_2$

Copyright © 2006 Taylor & Francis Group plc, London, UK

with $\xi_{R1,2} \approx 0{,}9$ if $W_1 = W_2$. Furthermore it is assumed that sediment transport can be expressed by a power law, as in equation (1). A power function $s = au^n/C^k D^l$ (with a is a factor, D is grain size, and k,l,n are powers) is applied. Furthermore we assume that the reference situation (situation without non-erodible layer) is denoted by variables having a subscript 0, and in the situation with non-erodible layer with subscript n.

$$\left\{\frac{u_{10}}{u_{20}}\right\}^n \left\{\frac{C_{20}}{C_{10}}\right\}^k = \left(\frac{\xi_{R10}}{\xi_{R20}}\right)^{n/2} \left(\frac{h_{10}}{h_{20}}\right)^{n/2} \left(\frac{C_{10}}{C_{20}}\right)^{n-k} \tag{12}$$

Considering the part of the bend where all sediment is transported through the inner bend, and assume that this transport rate is equal to the total rate of the reference situation, then we find that ($S_{2n} = S_0$):

$$\frac{u_{2n}^n}{C_{2n}^k} = \frac{u_{20}^n}{C_{20}^k}\left(\frac{W_{10}}{W_{20}}\left\{\frac{\xi_{R10}}{\xi_{R20}}\right\}^{n/2}\left\{\frac{h_{10}}{h_{20}}\right\}^{n/2}\left\{\frac{C_{10}}{C_{20}}\right\}^{n-k}+1\right) \tag{13}$$

Approximating that the alluvial roughness is constant in the sections $C_{2n} = C_{10} = C_{20}$ it is found that:

$$\frac{u_{2n}}{u_{20}} = \left(\frac{W_{10}}{W_{20}}\left\{\frac{\xi_{R10}}{\xi_{R20}}\right\}^{n/2}\left\{\frac{h_{10}}{h_{20}}\right\}^{n/2}+1\right)^{1/n} \tag{14}$$

and with $B_1 = B_2$, using equations (9) and (12) it can be derived that:

$$\frac{u_{2n}}{u_{20}} = \left(1+\left\{\frac{h_{avg}+\frac{1}{4}W\cdot I_{n0}}{h_{avg}-\frac{1}{4}W\cdot I_{n0}}\right\}^{n/2}\right)^{1/n} \tag{15}$$

in which u_{2n}, and u_{20} are the velocities in the inner bend in the situation with and without non-erodible layer respectively. Note that u_{2n} in this formula is highly influenced by the power n of the transport formula.

To determine the depth of the inner bend h_{2n} after construction of the non-erodible layer, equations (13), (11) and a continuity equation ($u_{2n}h_{2n}W_2 + u_{1n}h_{1n}W_1 = Q_{total}$) are used. Assume that roughnesses are known, and depth h_{1n} is given (because the elevation of the non-erodible layer is known).

$$h_{2n}\left(h_{2n}^2u_{2n}^2W_2^2 - 2h_{2n}u_{2n}W_2Q_{totaal} + Q_{totaal}^2\right) = h_{1n}^3W_1^2u_{2n}^2\left(\frac{C_{1n}}{C_{2n}}\right)^2\frac{\xi_{R1n}}{\xi_{R2n}} \tag{16}$$

Solution of this 3rd order polynomial gives for the depth at the inner bend:

$$h_{2n} = \frac{2}{3}\left(\frac{Q_{totaal}}{u_{2n}W_2}\right)\left\{\cos\left[\frac{1}{3}\text{asin}\left(1-\frac{27}{2}\Pi\right)-\frac{\pi}{2}\right]+1\right\} \tag{17}$$

We have applied the relations above to the existing non-erodible layers in the Waal River, as well as to a non-existing non-erodible layer in the IJssel River (the Rhine River branch that flows to the North in the Netherlands).

The analysis for the non-erodible layer at Nijmegen is based on data from the prototype and data from Delft3D simulations for this reach, as summarized (and translated to the schematized cross-section of Figure 11) in table 1. From the last column can be read that the water depth in the inner bend has increased between 1.2 and 1.5 m. Note that the effective width (uncovered) of the non-erodible layer is only 80 m in this cross section.

In table 2 the result from the calculation using the analytical model is presented. The values for the reference depths are obtained from the axisymmetric solution, equation 10, with a mean grain size of 1 mm, a characteristic discharge of 1600 m^3/s, a h_{avg} of 4.5 m, an ε of 1.45, and a radius of curvature of 750 m. The increase of depth at the inner bend is 1.3 m, which is in close agreement with the results from table 1.

Using the analytical relationships it can be analysed how certain parameters in this model influence the efficacy of the non-erodible layer. For instance in Figure 12 is shown how with an increasing value of the power n the lowering effect at Nijmegen is decreasing.

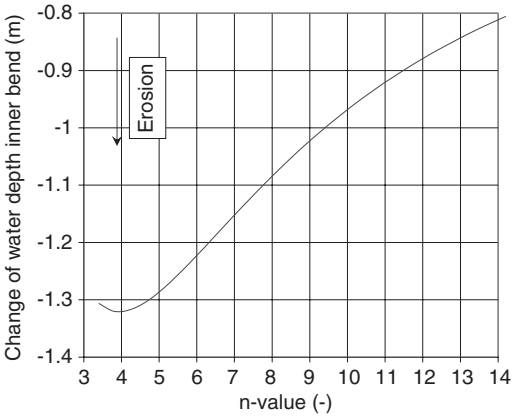

Figure 12. Influence of power n in transport formula on effect of non-erodible layer in Nijmegen (analytical approach).

Table 3. Effect of non-erodible layer ($h_{20} - h_{2n}$) determined from analytical model, St. Andries.

h_{10} (m)	h_{20} (m)	C_{1n}, C_{2n} ($m^{1/2}/s$)	h_{1n} (m)	n	u_{20} (m/s)	u_{2n} (m/s)	h_{2n} (m)	$h_{20} - h_{2n}$ (m)
6.5 ($B_1 =$ 120)	4.8 m ($B_2 =$ 140)	35, 50	5.85	5	1	1.23	5.72	−0.9

For the non-erodible layer in St. Andries a similar result has been obtained. In table 3 the result from the calculation using the analytical model is presented. The increase of depth at the inner bend is 0.9 m, which is also in close agreement with the observations and the 2D model computations.

In relation with improvement of navigability of the IJssel River, the possibility of applying non-erodible layers in some sharp bends has been considered. Simulations with Delft3D modelling system revealed unexpectedly that the effect of the non-erodible layers appeared to be opposite: the inner bend showed some aggradation instead of erosion, see Figure 13. Clearly the increase of transport rate through the inner bend cannot be compensated by an increase of velocity.

The deposition can also be predicted from the analytical model as shown in table 4. However, the analytical model appears to underestimate the effect in most cases.

The reason of this unexpected sedimentation of the inner bend is the relatively narrow main channel of the IJssel River, with protected banks. In comparison to the much wider Waal River, the fixed sloping bank sections in the IJssel River cover a rather large part of the cross-section as shown in Figure 14. Analysis of the transverse distribution of flow velocities shows

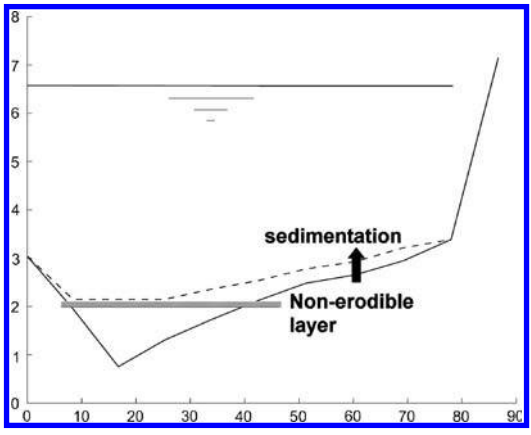

Figure 13. Cross-section with computed bed level in IJssel River with and without non-erodible layer.

that after the pool is filled with a non-erodible layer, the increase of velocities in the remaining cross-section is absorbed by the bank sections, and the increase on the alluvial part of the inner bend is limited.

3 SIMULATIONS AND OBSERVATIONS IN PROTOTYPE

In the past years multi-beam soundings have become available for the river bed of the Waal River. The resolution of these soundings (as shown in Figure 3) is sufficiently high to analyze the bed forms and indirectly assess the bed-load transport rate from bed-form migration. After all, bed-load transport and bed forms are coupled phenomena in this river. In the statistical analysis the observed bed-forms can be considered as the standard deviation of bed-level variations

Copyright © 2006 Taylor & Francis Group plc, London, UK

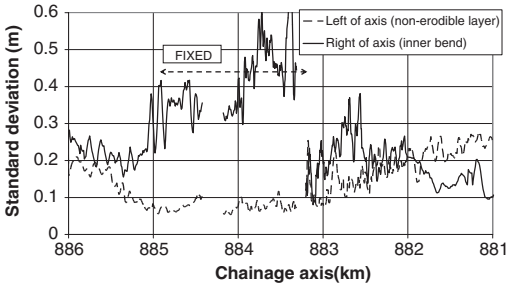

Figure 15. Standard deviation of bed-levels on the non-erodible layer at Nijmegen at two longitudinal sections.

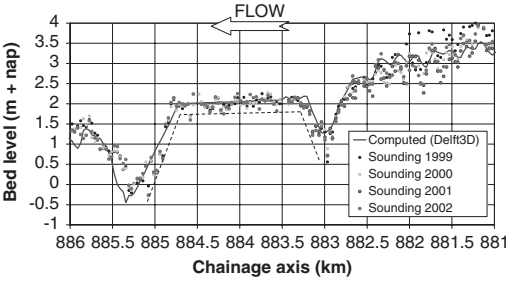

Figure 16. Measured and computed bed level at a grid line left of the river axis. Dashed line indicates expected position of non-erodible layer.

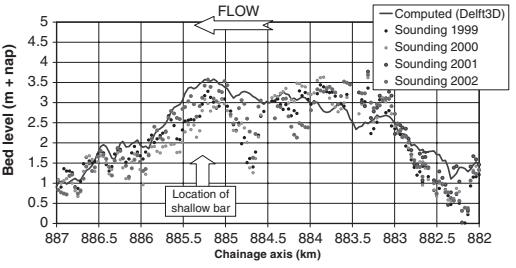

Figure 17. Measured and computed bed level at a grid line right of the river axis.

around the spatially averaged bed level (averaged on 500×20 m cells). The standard deviation scales with the bed form height. Figure 15 shows how the standard deviation varies along two longitudinal sections at Nijmegen, at the non-erodible layer and through the inner bend respectively.

The standard deviation disappears rapidly on the non-erodible layer (it reduces to 0.06 m, which is the inaccuracy of the sounding). On the other hand it increases significantly in the inner bend. This behaviour proves that all bed-load transport is passing through the inner bend such that the non-erodible layer is practically clear of sediment. It should be noted that the scour and deposition pattern forced by the groynes in the inner bend has also been amplified by the increase of transport.

Also recently developed 2D morphological models (used to ongoing Rhine flood-protection and navigation studies) have profited from analysis of the high-resolution multi-beam soundings.

For instance the resulting bed-levels computed with Delft3D for the river bed at Nijmegen are shown in Figure 16 (section at outer bend, non-erodible layer) and Figure 17 (section at inner bend). The simulations have been carried out with a 2D flow and uniform sediment approach (i.e. sediment of one size fraction). It has been concluded that the present level of the non-erodible layer was lower than the design level, which is probably due to consolidation after placement. The exact position can only be guessed.

Furthermore, it was found in the simulations that the scour depth downstream of the layer, and in response the associated bar in the inner bend, was overestimated. This could be fixed by locally increasing the sediment grain size of the bed in the scour hole. This can be justified from an armouring of the river bed in the scour hole that is expected for the relatively graded sediment in this reach (although also parts of the rip rap have shown up in the scour hole). Indeed, both in the much more uniform sediment bed at the river bend of St. Andries, and in the scale model with uniform sediment, the computed scour depth matches better. Note that sediment-sorting effects might also explain differences in length of the scour holes at Nijmegen and St. Andries. For instance Mosselman et al. (2004) show how lateral sorting effects increase the length scales, which explains the longer scour hole at Nijmegen.

4 DISCUSSION

Application of non-erodible layers in outer bends have proven to be quite effective in lowering the inner bend in two sharp bends of the Waal River. However, the experiences from these cases and simulations for the IJssel River have resulted in a few points of caution:

- As at the lower end of the non-erodible layer a scour hole and deposition occurs, it is necessary to extend the layer in such a way that the deposition will not lead to a new bottleneck for navigation.
- In relatively narrow rivers, in which bank-sections form a large part of the cross-section the effect of non-erodible layers may be reversed because the increase of transport rate through the inner bend cannot be compensated by an increase of velocity (increases of velocity are absorbed by the bank sections). The inner bend will then aggrade instead of erode.

Copyright © 2006 Taylor & Francis Group plc, London, UK

- Non-erodible layers are made of coarse material, and therefore they have a higher hydraulic roughness (v.d. Zwaard, 1974).

The model concept presented in this paper properly describes the observed physical processes. Strictly speaking, the model concept holds only for bed load. Transport predictors based on local conditions alone, however, are also utilized for the total load when the characteristic adaptation lengths of the suspended part of the transport are small compared to the meshes of the computational grid. This can be justified for the present model concept as well. A different approach is required, however, for suspended sediment transport with significantly long adaptation lengths. Such cases require the solution of a convection-diffusion equation with a proper source term for the exchange of sediment with the bed load layer. The formulation of this exchange above non-erodible layers is a topic for further research.

The bed of the Rhine River shows a gradual degradation as a consequence of river-training, sediment mining and reduced sediment inflow in the past and present. At locations with non-erodible layers this erosion will be amplified, as the erosion is restricted to the inner bend. The outer bend is fixed by the non-erodible layer, but this layer is usually restricted in width. The accelerated erosion does not only lead to a much higher erosion depth that can reach far below the non-erodible layer level, but also appears to increase the degradation rate upstream. Furthermore, as the surrounding river reaches are lowering, the non-erodible layer can become an obstruction for navigation by itself.

5 CONCLUSIONS

Non-erodible layers in outer bends can be effectively used to lower the inner bend, such that navigability in river bends can be improved. By the non-erodible layer both transport rate and flow velocity in the remaining alluvial part in the inner bend are increased. A net lowering of the bed is achieved provided that increased flow velocity mostly contributes to the shear stress in the inner bend, and is not absorbed by wide bank sections (e.g. in narrow rivers like the IJssel river).

The mathematical approach presented in this paper for modelling bed-load transport over non-erodible layers has been successfully applied to simulate laboratory experiments and for the non-erodible layers at Nijmegen and St. Andries in the Waal River. The observed processes by which through helical flow effects the sediment is swept from the non-erodible layer towards the inner bend is simulated correctly, and such that the final lowering of the inner bend is well reproduced. Also the development of a scour hole downstream of the non-erodible layer is simulated with the 2D (Delft3D) morphological model. A simplified analytical approach can be derived that can be used to analyze the effect of different parameters on the effect of the non-erodible layer.

The simulations and prototype observations show that it is necessary to extend the non-erodible layer past the bend, such that the sedimentation facing the downstream scour hole does not result in a navigation problem. Furthermore it is found that general degradation of the river bed can be amplified in the inner bend next to a non-erodible layer, and that this might increase degradation upstream.

Morphodynamic modeling of sand bar evolution under unsteady flow

K. Kobayashi, Y. Shimizu & S. Giri
Hokkaido University, Sapporo, Japan

Y. Watanabe
Civil Engineering Research Institute of Hokkaido, Sapporo, Japan

ABSTRACT: This paper presents investigations on sand bar formation and evolution process in consequence of unsteady flow. Firstly, experiments have been carried out to investigate the sand bar response to the unsteady flow under laboratory condition. Observations have revealed some notable outcomes, which indicate the effect of unsteady flow condition on sand bar development mechanism. Sand bar evolution in unsteady flow appears to be altered in comparison with sand bar formation under steady flow condition. Furthermore, a two-dimensional morphodynamic model has been developed to reproduce sand bar evolution under unsteady flow condition. Proposed model solves depth-averaged flow equations with a simplest turbulence closure in a generalized coordinate system. A Cubic Interpolated Pseudo-particle (CIP) numerical technique is employed to solve advection phase of momentum equations. Likewise, model solves two-dimensional sediment continuity equation for bedload sediment transport considering the effect of secondary current. Computation has been performed for variety of boundary conditions in upstream and downstream end to evaluate their effect on ultimate results. Results of numerical computation have been verified against laboratory observations. Numerical simulation of aforesaid phenomenon using proposed model has been found to be reasonably consistent.

1 INTRODUCTION

Morphodynamic behavior of meso-scale bedforms like sand bar in alluvial rivers is of importance from practical engineering point of view. Several investigations were conducted in the past that have provided essential insight into the channel evolution mechanism induced by sand bars. Amongst the pioneer works, Leopold and Wolman (1957) and Kinoshita (1961) are noticeable. They made significant studies that enabled some key features of alternate bar to be identified. Some noticeable laboratory observations were performed by Fujita and Muramoto (1985), Lazoni (1999). Kinoshita and Miwa (1974) investigated the bar migration in straight and curved channel. Shimizu and Itakura (1989) were able to replicate this phenomenon using a morphologic numerical model. Some researchers performed theoretical analysis on bar formation (Parker, 1976; Fredsoe, 1978; Kuroki and Kishi, 1984; Columbini et al., 1987; Garcia and Nino, 1993; Tubino et al., 1999). Some recent works on weakly nonlinear analysis have appended some supplementary knowledge as well (Izumi et al., 2002; Watanabe & Kawamura, 2005).

Most of these studies explored features of alternate bars under steady discharge condition. Consideration of sand bar evolution under unsteady discharge, for instance during flood event, is of importance. Moreover, behavior of downstream morphology induced by several control structures is also subjected to the consideration of unsteady flow. The significance of unsteady discharge on channel evolution was figured out by Tubino (1991). He conducted a weakly nonlinear analysis to formulate a model to investigate the development of the amplitude of alternate bars in unsteady flow. Recently, some notable laboratory observations were made by Watanabe et al. (2001). They found significant distinction between bar characteristics developed under steady and unsteady discharge conditions. They concluded that hysteresis effect of flow condition must be taken into account to analyze sand bar evolution under unsteady discharge. Additionally, they conducted a linear stability analysis to formulate development of bar amplitude under unsteady flow.

In this research, we performed some laboratory investigations on sand bar evolution under unsteady discharge in addition to those performed by Watanabe et al. In effect, it is rather difficult to conduct this kind of physical study for range of hydraulic conditions. Consequently, we propose herein a numerical model that can be used to reproduce sand bar formation

Copyright © 2006 Taylor & Francis Group plc, London, UK

under unsteady discharge. To authors' knowledge, no numerical work has been done so far that can simulate bar formation under unsteady discharge (except for the work conducted by our group of researchers, e.g. Yokoyama et al., 2004).

2 MODEL DEVELOPMENT

2.1 *Hydrodynamic equations*

The two-dimensional, unsteady, incompressible flow has been calculated using the following continuity and momentum equations in a generalized coordinate system (Shimizu & Itakura, 1991).

$$\frac{\partial}{\partial t}\left(\frac{h}{J}\right)+\frac{\partial}{\partial \xi}\left(\frac{hu^{\xi}}{J}\right)+\frac{\partial}{\partial y}\left(\frac{hu^{\eta}}{J}\right)=0 \tag{1}$$

$$\frac{\partial u^{\xi}}{\partial t}+u^{\xi}\frac{\partial u^{\xi}}{\partial \xi}+u^{\eta}\frac{\partial u^{\xi}}{\partial \eta}+\alpha_1 u^{\xi}u^{\xi}+\alpha_2 u^{\xi}u^{\eta}+\alpha_3 u^{\eta}u^{\eta}$$
$$=-g\left[\left(\xi_x{}^2+\xi_y{}^2\right)\frac{\partial H}{\partial \xi}+\left(\xi_x\eta_x+\xi_y\eta_y\right)\frac{\partial H}{\partial \eta}\right]$$
$$-\frac{C_b u^{\xi}}{J}\sqrt{\left(\eta_y u^{\xi}-\xi_y u^{\eta}\right)^2+\left(-\eta_x u^{\xi}+\xi_x u^{\eta}\right)^2}+D^{\xi} \tag{2}$$

$$\frac{\partial u^{\eta}}{\partial t}+u^{\xi}\frac{\partial u^{\eta}}{\partial \xi}+u^{\eta}\frac{\partial u^{\eta}}{\partial \eta}+\alpha_4 u^{\xi}u^{\xi}+\alpha_5 u^{\xi}u^{\eta}+\alpha_6 u^{\eta}u^{\eta}$$
$$=-g\left[\left(\eta_x\xi_x+\eta_y\xi_y\right)\frac{\partial H}{\partial \xi}+\left(\xi_x{}^2+\xi_y{}^2\right)\frac{\partial H}{\partial \eta}\right]$$
$$-\frac{C_b u^{\eta}}{J}\sqrt{\left(\eta_y u^{\xi}-\xi_y u^{\eta}\right)^2+\left(-\eta_x u^{\xi}+\xi_x u^{\eta}\right)^2}+D^{\eta} \tag{3}$$

in which, x, y are orthogonal coordinate axis, t is time, ξ, η is plane coordinate axis in generalized coordinate, h is water depth, H is water level, u^{ξ}, u^{η} is contravariant tensor in ξ or η direction, J is Jacobian determinant in coordinate transformation, C_b is bed friction coefficients. Other coefficients and diffusion terms are as follows:

$$\alpha_1=\xi_x\frac{\partial^2 x}{\partial \xi^2}+\xi_y\frac{\partial^2 y}{\partial \xi^2} \tag{4}$$

$$\alpha_2=2\left(\xi_x\frac{\partial^2 x}{\partial \xi\partial \eta}+\xi_y\frac{\partial^2 y}{\partial \xi\partial \eta}\right) \tag{5}$$

$$\alpha_3=\xi_x\frac{\partial^2 x}{\partial \eta^2}+\xi_y\frac{\partial^2 y}{\partial \eta^2} \tag{6}$$

$$\alpha_4=\eta_x\frac{\partial^2 x}{\partial \xi^2}+\eta_y\frac{\partial^2 y}{\partial \xi^2} \tag{7}$$

$$\alpha_5=2\left(\eta_x\frac{\partial^2 x}{\partial \xi\partial \eta}+\eta_y\frac{\partial^2 y}{\partial \xi\partial \eta}\right) \tag{8}$$

$$\alpha_6=\eta_x\frac{\partial^2 x}{\partial \eta^2}+\eta_y\frac{\partial^2 y}{\partial \eta^2} \tag{9}$$

$$D^{\xi}=\frac{\partial}{\partial \xi}\left[\frac{\tau_{\xi\xi}}{\rho}\right]+\frac{\partial}{\partial \eta}\left[\frac{\tau_{\eta\xi}}{\rho}\right] \tag{10}$$

$$D^{\eta}=\frac{\partial}{\partial \xi}\left[\frac{\tau_{\xi\eta}}{\rho}\right]+\frac{\partial}{\partial \eta}\left[\frac{\tau_{\eta\eta}}{\rho}\right] \tag{11}$$

in which, τ_{ab} is component of a shear force along b-axis (the plane normal to a-axis), ρ is density of water.

Bottom friction was determined as follows:

$$C_b=\frac{gn^2}{h^{1/3}},\quad n=\frac{d^{1/6}}{6.8\sqrt{g}} \tag{12}$$

A simple zero equation model was used as turbulence closure.

2.2 *Sediment transport model*

The continuity equation of two-dimensional bedload transport in a general coordinate system reads as:

$$\frac{\partial}{\partial t}\left(\frac{Z}{J}\right)+\frac{1}{1-\lambda}\left[\frac{\partial}{\partial \xi}\left(\frac{q^{\xi}}{J}\right)+\frac{\partial}{\partial \eta}\left(\frac{q^{\eta}}{J}\right)\right]=0 \tag{13}$$

where Z is bed elevation, λ is porosity of the bed material, q^{ξ} and q^{η} are contravarient components of the bedload transport rate per unit width in the ξ and η directions. The sediment transport of q^{ξ} and q^{η} in two-dimensional general coordinate (ξ,η), depend on the velocity vector specifically near the bed, therefore:

$$q^{\xi}=q_b\left[\frac{u_b^{\xi}}{V_b}-\gamma\left(\frac{\partial Z}{\partial \xi}+\cos\theta\frac{\partial Z}{\partial \eta}\right)\right] \tag{14}$$

$$q^{\eta}=q_b\left[\frac{u_b^{\eta}}{V_b}-\gamma\left(\frac{\partial Z}{\partial \eta}+\cos\theta\frac{\partial Z}{\partial \xi}\right)\right] \tag{15}$$

in which,

$$\gamma=\sqrt{\frac{\tau_{*c}}{\mu_s\mu_k\tau_*}} \tag{16}$$

where u_b^{ξ} and u_b^{η} are flow velocities near the bed in the ξ and η directions, V_b is resultant velocity near the bed, q_b is bedload sediment transport rate, θ is intersection angle between ξ and η axes, γ is a correction coefficient to account for the bed slope, μ_s is static coefficient of Coulomb friction (=1.0), μ_k is dynamic coefficient of Coulomb friction (=0.45). The

Copyright © 2006 Taylor & Francis Group plc, London, UK

sediment transport rate was calculated based on the Ashida and Michiue's formula.

$$\frac{q_b}{\sqrt{s_g g d^3}} = 17\,\tau_*^{3/2}\left(1-\frac{\tau_{*c}}{\tau_*}\right)\left(1-\frac{u_{*c}}{u_*}\right) \tag{17}$$

in which,

$$\tau_* = \frac{hI}{s_g d} = \frac{C_f V^2}{s_g g d} = \frac{n^2 V^2}{s_g d h^{1/3}} \tag{18}$$

$$V = \sqrt{u^2 + v^2} \tag{19}$$

where s_g is specific weight of grain in fluid, d is grain diameter, τ_* is non-dimensional shear stress, τ_{*c} is critical non-dimensional shear stress obtained by Iwagaki's formula, u_* is bed shear velocity.

2.3 *Flow velocities near the bed*

The streamwise velocity component near the bed can be defined as:

$$u_b^s = \beta V \tag{20}$$

Assuming that the parabolic distribution of the flow over depth, β can be defined as:

$$\beta = 3(1-\sigma)(3-\sigma), \quad \sigma = \frac{3}{\phi\kappa+1} \tag{21}$$

where ϕ is velocity factor $(=V/u_*)$, κ is von Karman constant $(=0.4)$.

Secondary flow is generated by the variation of centrifugal force caused by streamline curvature. The effect of secondary flow on near-bed transverse velocity can be estimated as follows:

$$u_b^n = u_b^s N_* \frac{h}{r_s} \tag{22}$$

where r_s is radius of curvature of the streamline and N_* is coefficient that takes into account the strength of secondary flow $(=7.0)$. The radius of streamline curvature is determined by:

$$\frac{1}{r_s} = \frac{1}{V^3}\left[\begin{array}{l} u^2\left(\xi_x\frac{\partial v}{\partial \xi}+\eta_x\frac{\partial v}{\partial \eta}\right)+uv\left(\xi_y\frac{\partial v}{\partial \xi}+\eta_y\frac{\partial v}{\partial \eta}\right) \\ -uv\left(\xi_x\frac{\partial u}{\partial \xi}+\eta_x\frac{\partial u}{\partial \eta}\right)-v^2\left(\xi_y\frac{\partial u}{\partial \xi}+\eta_y\frac{\partial u}{\partial \eta}\right) \end{array}\right] \tag{23}$$

In the Eq. (14) and (15), u_b^ξ and u_b^η are given by:

$$u_b^\xi = \frac{1}{\xi_r}\left\{\begin{array}{l} (\cos\theta_s\xi_x + \sin\theta_s\xi_y)u_b^s \\ +(-\sin\theta_s\xi_x + \cos\theta_s\xi_y)u_b^n \end{array}\right\} \tag{24}$$

$$u_b^\eta = \frac{1}{\eta_r}\left\{\begin{array}{l} (\cos\theta_s\eta_x + \sin\theta_s\eta_y)u_b^s \\ +(-\sin\theta_s\eta_x + \cos\theta_s\eta_y)u_b^n \end{array}\right\} \tag{25}$$

where θ_s is the angle between x- and s-axis. With compare to u_b^s, u_b^n is small by an order thus can be neglected, then the resultant near-bed velocity V_b reads as

$$V_b = \sqrt{u_b^{s\,2} + u_b^{n\,2}} \approx u_b^s \tag{26}$$

In the Eq. (14) and (15), the longitudinal and transverse channel bed slopes are determined by following equations:

$$\frac{\partial Z}{\partial s} = \frac{\partial Z}{\partial \xi}\left(\xi_x\frac{\partial x}{\partial s}+\xi_y\frac{\partial y}{\partial s}\right)+\frac{\partial Z}{\partial \eta}\left(\eta_x\frac{\partial x}{\partial s}+\eta_y\frac{\partial y}{\partial s}\right) \tag{27}$$

$$\frac{\partial Z}{\partial n} = \frac{\partial Z}{\partial \xi}\left(\xi_x\frac{\partial x}{\partial n}+\xi_y\frac{\partial y}{\partial n}\right)+\frac{\partial Z}{\partial \eta}\left(\eta_x\frac{\partial x}{\partial n}+\eta_y\frac{\partial y}{\partial n}\right) \tag{28}$$

in which,

$$\begin{array}{l} \frac{\partial x}{\partial s} = \frac{u}{V} = \cos\theta_s, \quad \frac{\partial y}{\partial s} = \frac{v}{V} = \sin\theta_s \\ \frac{\partial x}{\partial n} = -\frac{v}{V} = -\sin\theta_s, \quad \frac{\partial y}{\partial n} = \frac{u}{V} = \cos\theta_s \end{array} \tag{29}$$

2.4 *Calculation condition*

Numerical computation was performed for two experimental cases (U30 and U50).

A periodic boundary condition can be applied with a random field of initial bed perturbation. On the other hand, a non-periodic boundary condition can be imposed with some perturbation added to the flow at the upstream end.

The periodic boundary condition might be suitable in case of dynamic equilibrium bed evolution. However, this condition may not work well when temporal change of the wavelength takes place. In this case, non-periodic boundary condition is desirable. The shortcoming of this boundary condition is that it requires long calculation domain, which affects the calculation time.

We performed computation using both boundary conditions for the sake of comparability. In case of non-periodic boundary condition,, a non-periodic perturbation of all but ±5% was added to upstream flow. Likewise, a random field of bed perturbation was also added for both conditions.

Total calculated domain was 80 m long. However, we presented here calculation result for 15 m long domain in the middle.

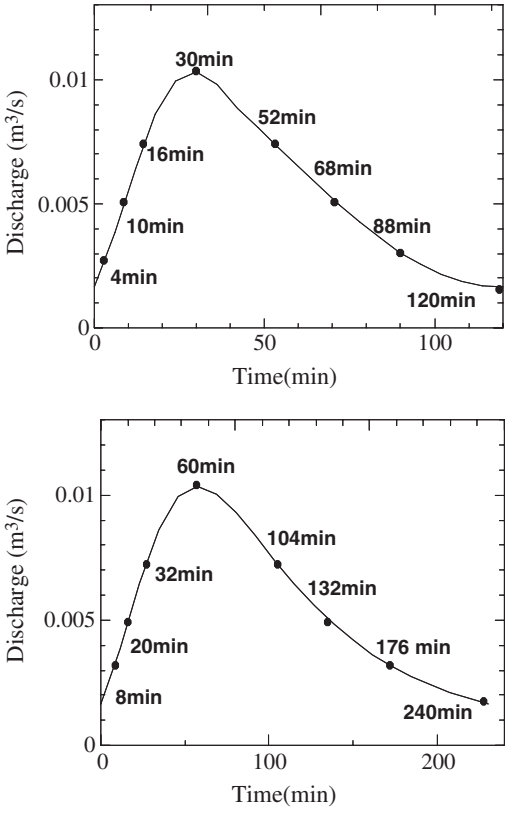

Figure 1. Stage hydrograph for flume experiment case U-50 (upper) and U-30 (lower).

3 MODEL VALIDATION

3.1 *Experiment*

Experiment was conducted in a laboratory fume of CERI. The width of flume was 0.9 m and the length of the flume was 50 m. The diameter was 0.76 mm. The slope of flume was 1/80. At the downstream end, the weir of the same height as water depth was set. Two typical experimental cases are reported herein (U30 and U50). Figure 1 shows the hydrograph in the flume experiment for both of the cases. The peak discharge is 10.3(l/s) for both cases. The experiment was performed for 2 hours for U50 and 4 hours for U30. One case with steady discharge has also been incorporated in this study.

3.2 *Result and discussion*

3.2.1 *Sand bar characteristics*

Calculation result of bed topography was compared with experimental data which is depicted in Figure 2. Moreover, computed temporal evolution of sand bar characteristics (height and wave length) was compared with observation. Calculation was performed for non-periodic boundary condition. Comparing the calculation result with the experimental one, we found that sand bar formation in numerical computation is slower than in observed case. For this particular case, results are not identical until 30 min of calculation. However, after 30 minutes the bed topography reproduced by numerical model appears to be in good agreement with observed quantities (Fig. 2).

With regard to the temporal evolution of bar height, from depicted result (Fig. 3) it can be seen that computed result match well with experimental one. It was revealed that the peak of hydrograph does not coincide with the maximum bar height. The bar height evolution shows some lag with respect to discharge variation. The maximum bar height was observed in falling stage. This can be attributed to the hystereris effect of the flow. Interestingly, numerical model was able to reproduce this phenomenon rather realistically.

With the increment of time, the shape of alternate bar was found to be somewhat irregular. In Figure 3, a quantitative comparison of wavelength growth is depicted. In this case, the variation of wavelength is not so clear. Nonetheless, it can be seen that the maximum wavelentgh is deflected from the point of maximum discharge. The model overestimated the wave length, though within the satisfactory range. The wavelength was apperaed to be increased with time.

3.2.2 *Computation with periodic boundary condition*

For the sake of comparison, we performed calculation for these cases using periodic boundary condition. We revealed that the sand bar wavelength in this case significantly alters due to the decrease of wavenumber in latter stage of calculation. We attempted to increase the length of calculation domain. However, no noteworthy difference was found. Some comparison between computed results using periodic and non-periodic boundary conditions can be seen in Figure 4. From this figure, one can see that the predicted wave length is somewhat similar in initial stage of calculation. However, it became all but twice bigger in case of periodic boundary condition after 80 minutes and 120 minutes of calculation for U30 and U50 respectively. This leads to the conclusion that the periodic boundary condition is not appropriate for sand bar growth simulation under unsteady flow.

3.2.3 *Comparison between computational results for steady and unsteady flow conditions*

An attempt was made to evaluate the distinction between physical characteristics as well as bar evolution under steady and unsteady flow conditions. We performed calculation for steady flow case for each particular discharge that we used for unsteady simulation.

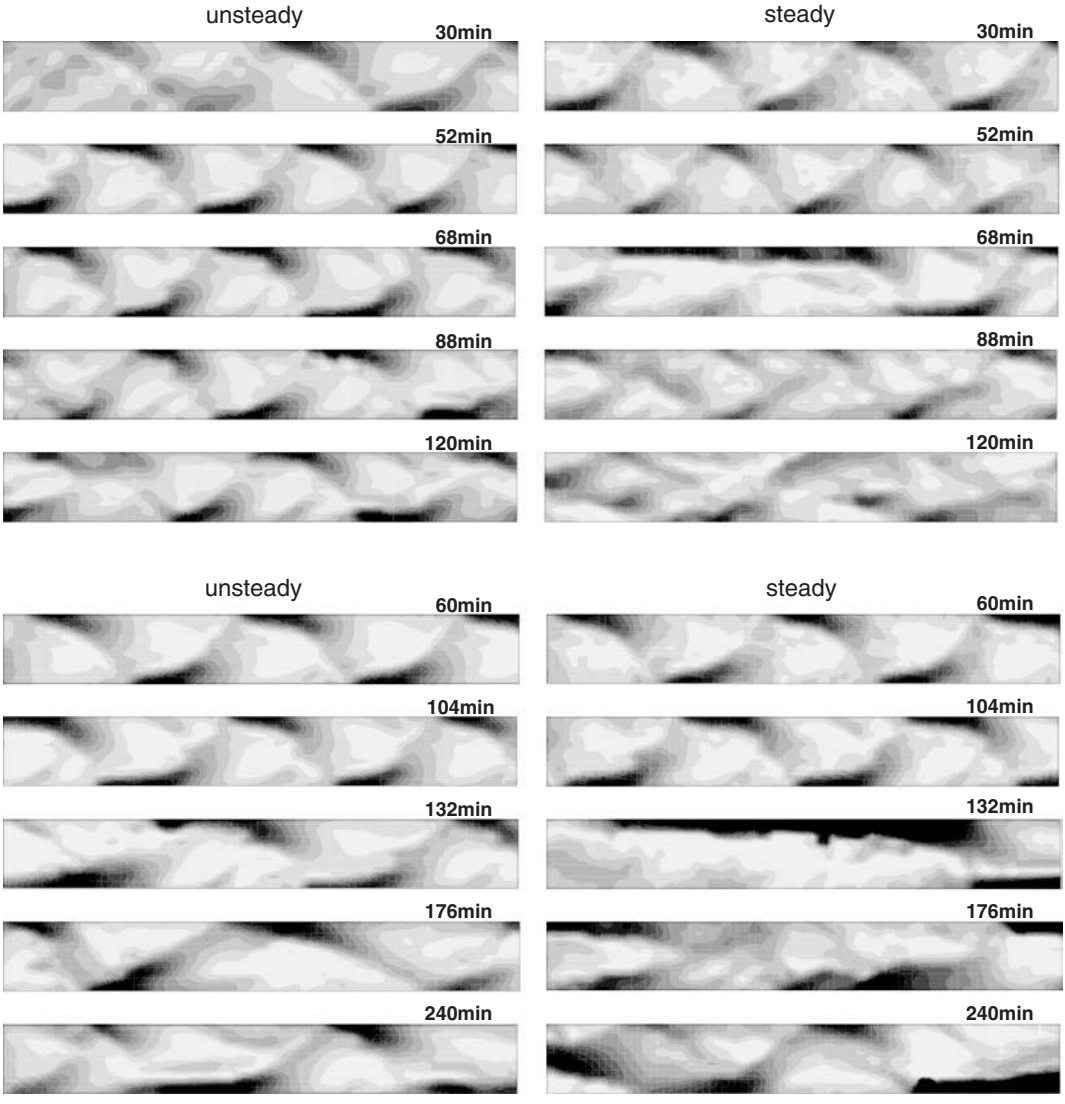

Figure 5. Comparison between computed results of sand bar evolution for steady and unsteady cases (U-30 upper figures and U-50 lower figures).

A qualitative comparison between computed results under these conditions has been depicted in Figure 5. It can be seen that feature of sand bar evolution is different for these two cases. The sand bar evolution appears to possess clear trend in case of unsteady flow. Likewise, quantitative comparison between sand bar characteristics for both cases depicted in Figure 6. From this figure, it can be seen that bar heigth increased with time and then became constant in latter stage for the case of unsteady condition. While, it is unclear (practically constant) for steady case. With regard to wavelength, the trend doesnot seem to be so clear. Most notable result is that the wavelength is similar in the region with maximum discharge for both cases but differs significantly in falling stage. For the sake of verification, comparison between calculation and experiment for one of the steady cases was also made that is depicted in Figure 7.

Overall, for each stage of discharge, the sand bar characteristics were found to be altered depending on the flow condition. Moreover, it can be noticed that for similar discharge in rising and falling stages, bar evolution shows distinctive characteristics. This evidence

points out towards the histeresis effect induced by unsteady flow condition.

4 CONCLUSION

A state-of-the-art morphodynamic model was developed that can simulate meso-scale bedforms under unsteady flow condition in physically based manner. Model was able to capture most physical characteristics of sand bar.

It is evident that the behavior of sand bar under unsteady flow condition is different in comparison with steady flow condition. Consideration of hysteresis characteristics of sand bar evolution under unsteady flow condition appears to be essential. The hysteresis

Copyright © 2006 Taylor & Francis Group plc, London, UK

effect of unsteady flow was replicated realistically by proposed numerical model. Furthermore, periodic boundary condition was found to be inappropriate for the computation under the conditions similar to the ones presented in this work. It can be inferred that the model performance is fairly satisfactory taking into account the complicated nature of the phenomenon.

ABSTRACT: We present experimental evidence on the occurrence of large angles of flow expansion with no flow separation over depositional fans. The evolution of a number of self-formed experimental fans was analyzed using overhead images and detailed topographic surveys taken from a run of the Experimental EarthScape basin at St Anthony Falls Laboratory. Instability phenomena produce narrow, upstream migrating channels coupled to lobes with large opening angles and sheet flow over them. Most of deposition appears to occur relatively rapidly during the initial perturbed expansion phase. Our analysis confirms that steady conditions can develop over large angles of expansion (half angle over 20 degrees). The steady condition is maintained with the help of a downstream-decreasing transverse bed curvature (with a normalized average value of 0.1). The bed curvature transfers flow momentum toward the banks, preventing flow separation and maintaining the high divergence angle. The bed curvature thus appears sufficient to explain the common occurrence of unchannelized, simple fans with opening angles, and hence rates of bedload divergence, much larger than would be predicted from jet theory. Furthermore, at equilibrium conditions, the deposit displays a conical shape, well described by a linear relation. We have also analyzed fan development. An initial channel perturbation causes an upstream migrating scour, which leads to an abrupt downstream increase in width and a consequent heart-shaped deposit. In this phase, flow shows the largest divergence angles values (half angle up to 50 degrees) in the upstream fan part. The fan then reaches a final cone-shape, developing an unchannelized low depth-width ratio flow.

1 INTRODUCTION

The evolution of flow expansions is important because represents a primary mechanism of deposition in many fluvial and submarine environments. Water flow, expanding, decreases its momentum and therefore its transport capacity, allowing large deposition and fans self-formation. Understanding this mechanism can aid to understand the general evolution of the larger depositional system, with practical applications in the land management and, with the support of stratigraphic investigations, in the estimation of the volume of subsurface reservoirs.

Different alluvional architectures, like channels, bifurcations, junctions and fans, forming on the surface of a depositional system directly influence the stratigraphic structure, affecting the entrapment of subsurface fluids, as oil and water.

In this work we analyzed fluvial fans that were observed to form over the surface of the eXperimental EarthScape basin (XES). This experimental feature, located at the St. Anthony Falls Laboratory (University of Minnesota), is designed to study the evolution of a fluvial depositional system under conditions of net deposition produced by steady basement subsidence and base level variation. This feature allows also further stratigraphic elaborations of the fluvial deposit. This basin presents some peculiar experimental parameters to take into account in this analysis, including the absence of vegetation, non-cohesive material, high water discharge, high slope. These parameters are related to a high activity depositional environment which leads to an easier formation of different alluvional architectures and, in particular of fluvial fans. We believe that at least some aspects of fan mechanics are sufficiently general to allow a future extension to submarine cases as well.

Several instability phenomena over the surface of the XES produce upstream perturbation waves along channels causing a significant water flow widening

and the development of large angles of expansion which leads to the formation of fan deposits. Subjected to further deposition, deposits can be recognized in stratigraphic analysis through the presence of laterally extensive depositionally based strata with convex tops.

Theory states that flow expansions over flat beds with half angles over 5–6° develop flow separation. From a preliminary analysis of the images taken during this experiment, expansion angles seem to show values significantly larger than this threshold. Water is also observed to cover the whole fan deposit with an unchannelized, low depth-width ratio flow with no occurrence of separation. The leading hypothesis investigated in this work is that the presence of a transverse curvature of the bed of the deposit transfers flow momentum toward the banks, suppressing separation and maintaining the high divergence angle. In this case the flow expansion would be dominated by the bed topography, opening up the possibility of finding consistent geometric relations, e.g. between local deposit curvature and deposit length, that can be used for subsurface prediction.

In this paper, a data analysis of experimental fans is presented. We emphasize measurement of flow expansion angles and detailed description of the deposit topography. We then study fan development from the instability phenomena occurring along a channel, through the formation of a concave-shaped deposit, to the cone-shaped equilibrium condition. Deposition seems to decrease with the development of the fans, which appear to reach an asymptotic sediment bypass condition during the equilibrium stage in which liquid and solid discharge remain constant down the fan. This is an unexpected situation for a diverging body, in particular if, as observed in the present case, the fans originate as self-formed depositional phenomena.

Further work on this problem will include analytical and numerical investigations of unchannelized flow over a cone-shaped body under conditions of complete fluid and solid bypass.

2 EXPERIMENTAL DESIGN

Data analyzed here come from the XES basin run XES02-1, performed at the St. Anthony Fall Laboratory. The XES basin develops strata under clearly defined variations in sediment discharge, rates and geometries of subsidence, and absolute base-level change. XES02-1 is designed to investigate the effect of slow, rapid, and superimposed base level cycles on shoreline migration and stratigraphic response, under conditions of passive margin type subsidence. The XES02-1 run had a basin area 5.72 m long and 2.98 m wide, one quarter of the entire basin.

A more detailed description of the XES facility is available at http:// www.geo.umn.edu/orgs/seds/ and it has been reported in Paola (2000), Heller et al. (2001), Paola et al. (2001), Sheets et al. (2003), and Kim et al. (in press). Sediment and water were mixed and fed from a single point source. The sediment feed rate was 0.0182 m^3/hr, the water discharge was 1.5 m^3/hr, and their rates were kept constant throughout the experiment. The sediment mixture comprised 63% quartz sand (110 μm), 27% coal sand (bimodal: 460 and 190 μm), and 10% kaolinite. The coal has a specific gravity of 1.3, whereas quartz has a specific gravity of 2.65, so the coal grains are substantially more mobile than the quartz grains and serve as a proxy for fine-grained clastics. Subsidence rate increases linearly downstream in the basin so as to produce simple linear-hinge type subsidence.

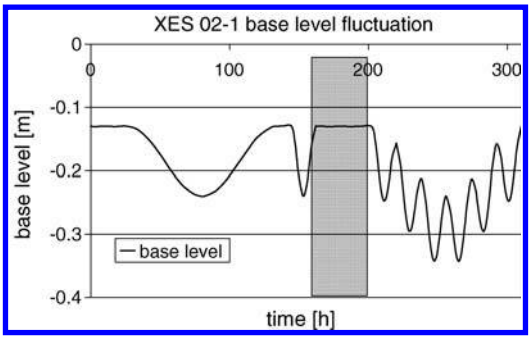

Figure 1. Base level fluctuation. The equilibrium period analyzed in this work is highlighted in the box.

Absolute base-level changes (i.e., absolute change of water surface level in the downstream "ocean" part of the basin) during the XES 02-1 experiment included sinusoidal base-level cycles with two time scales. The first slow base level cycle lasted 108 hours, beginning at runtime hour 26. It was followed by a rapid base level cycle lasting 18 hours beginning at runtime hour 144. Base level was stable before the first slow cycle and between the slow and rapid base level cycles. The second part of the experiment comprised six rapid cycles superimposed on one slow cycle beginning at runtime hour 202 (Fig. 1). All data analyzed in this work come from the equilibrium period between stages one and two (162–202 hours runtime). During this 40 hr equilibrium period base level was constant. The analysis was performed during the equilibrium period to exclude any effect of variable base-level on fan development.

3 PLAN-VIEW ANGLES OF EXPANSION AND BED TOPOGRAPHY INVESTIGATION

Consistently with what stated in the introduction, the first step of this work is to investigate large angles of expansion without flow separation, i.e. involving

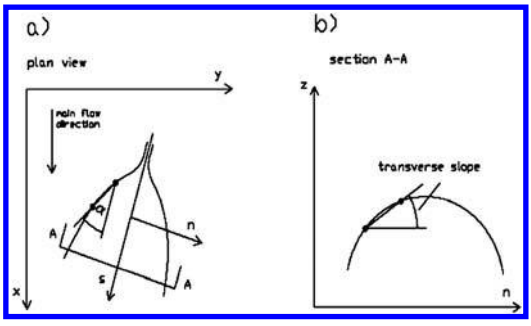

Figure 2. Sketch of the reference frames and notation.

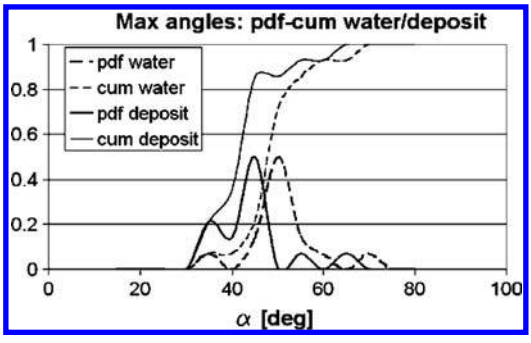

Figure 3. Maximum plan-view angles of expansion: pdf and cumulate curve for water and deposit. x-axis: plan-view angles in degrees; y-axis: dimensionless pdf-cumulate.

half-angles larger than 5–6 degrees. We analyzed fans during their development through a series of time intervals.

Plan-view angles were computed as the local first derivative of the plane shape border with respect to the longitudinal direction. This procedure is performed both for water and deposit expansion. A sketch of the coordinate systems utilized in this work is shown in Figure 2.

The maximum plan-view angles found for each fan are plotted in Figure 3. It was common for the flow to have a somewhat different geometry than the fan surface, so the solid line indicates the deposit, and the dashed line the water expansion. The plotted values represent the maximum angle along the whole longitudinal extension when considering all time intervals. The plot in Figure 3 clearly shows the presence of large angles of expansion with average values of 45 degrees for the deposit and 50 degrees for the water (values refer to half angles).

Overhead images taken during the experiment suggest the presence of a transverse curvature of the deposit that could support the high divergence angles. Topography data for the whole basin, taken every four

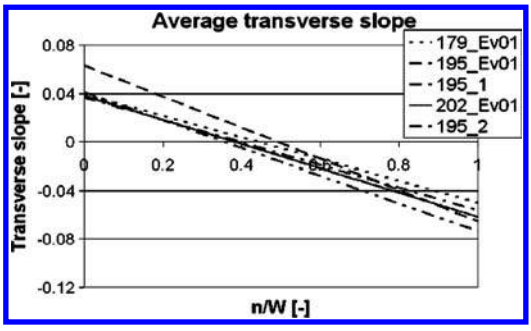

Figure 4. Average width normalized transverse slope. x-axis: transverse coordinate normalized by the local transverse width (n/W); y-axis: average transverse slope.

hours through a high resolution grid, were analyzed for this purpose. Five fans are available for investigation, with consistent and interesting results. A qualitative analysis of the fan bed shape shows a central upstream feeder channel that slowly disappears further downstream, leaving space for a regular concave curved bed. Transverse slope and curvature are then calculated from the topography grid along the direction perpendicular to the midline.

Transverse curvature is always present in all the analyzed fans as shown in Figure 4, where the average transverse slope of the downstream third of each fan is plotted with respect to the local fan width normalized by the transverse direction. The transverse slope decreases from positive to negative values, suggesting a negative curvature (slope of the slope), which, for a varieties of fans, averages around 0.1, when normalized by the local width.

Furthermore, the transverse slope at the deposit boundaries often reaches values of 0.04 with peaks of 0.06. Those values are of the same order of magnitude as the longitudinal slope over the deposit and, from simple further calculations, of the average longitudinal slope of the whole experimental basin. Thus lateral gravitational forces are comparable to downstream ones, and the curvature could transfer enough flow momentum toward the banks to prevent flow separation and maintain the high divergence angle. The bed curvature thus appears to play an important role in the physics of the phenomenon, sufficient to explain the common occurrence of unchannelized simple fans with opening angles, and hence rates of bedload divergence, much larger than would be predicted from jet theory (Hoyal et al. 2003, Van Wagoner et al. 2003).

Local transverse curvature values are summarized in Figure 5, where they are plotted against the length normalized longitudinal direction over the fan (s/L). The absolute value of the curvature clearly shows a consistent decreasing pattern in the downstream direction.

4 FAN DEVELOPMENT ANALYSIS

From observation of fans during their experimental evolution, we find that: the process starts with a perturbation of the bed; a scour then forms and migrates upstream, changing the pre-existent substrate. Once an "equilibrium" is reached and the bed is conveniently modified, migration stops. Downstream of an inertial-dominated region, water flows following the deposit topography with an unchannelized low depth-width ratio motion field. Furthermore, young fans appear to show a concave shape, while old fans a cone shape. A qualitative fan evolution is shown in Figure 6 through a series of images representing successive temporal steps.

A quantitative description of the plan-view border evolution is given in Figures 7, 8 where the border is plotted with respect to the midline. Data in Figure 8 are normalized by the length of the deposit (x-axis) and by its final width (y-axis). Here it is clearly possible to observe the translation from the concave to the conic shape even if any scale information is lost.

A further parameter investigated in fan evolution analysis is the fan length-final width (aspect) ratio. This parameter is generally observed to decrease in time and, in particular, during equilibrium phase, the aspect ratio drops below 4. In these conditions, fans seem to tend to reach an asymptotic equilibrium shape characterized by a status of sediment bypassing, in which liquid and solid discharge remain constant.

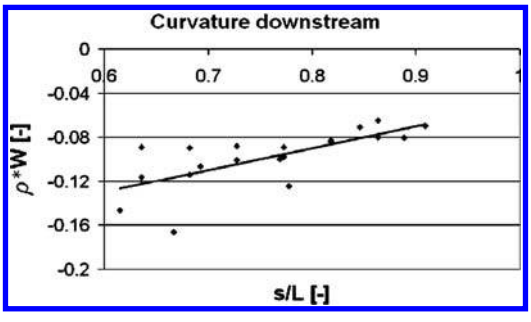

Figure 5. Downstream tendency of the local transverse curvature. x-axis: longitudinal coordinate normalized by the deposit length, y-axis: dimensionless local transverse curvature.

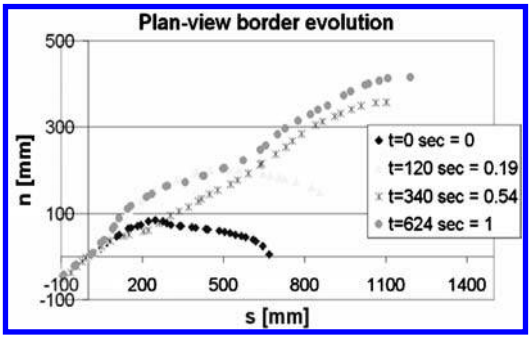

Figure 7. Plan-view border evolution. x-axis: longitudinal direction over the fan (s); y-axis: transverse direction (n).

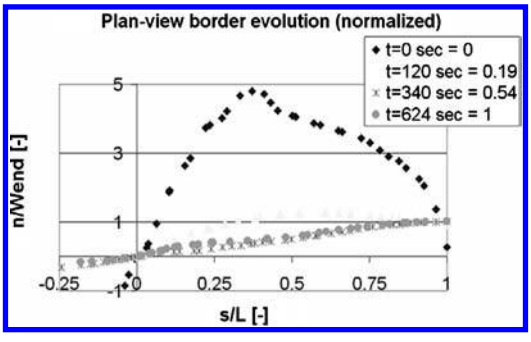

Figure 8. Plan-view border evolution (normalized). x-axis: longitudinal direction over the fan normalized by the fan length (s/L); y-axis: transverse direction normalized by the fan final width ($n/Wend$). The translation from a concave to a conic shape is clear proceeding with time.

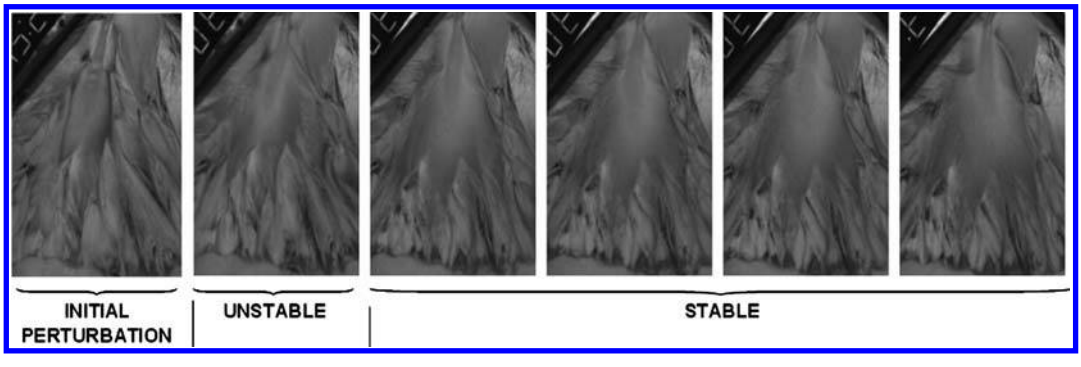

Figure 6. Fan evolution. From left to right: bed initial perturbation and concave shape, unstable phase, stable phase when the fan reaches a conic shape with uniform unchannelized low depth-width ratio flow over the downstream area of the deposit.

All of the deposit plan-view shapes of the fans that reached this stadium are then collected and fitted with a linear relation (1), as shown in the plot in Figure 9:

$$n/L = 0.365\, s/L \; ; \qquad R^2 = 0.92 \qquad (1)$$

where s represents the streamwise direction and n is perpendicular to s; both coordinates are normalized by the deposit length. Plan-view deposit border follows a linear relation which, in association with a transverse curvature, suggests a conical deposit equilibrium shape.

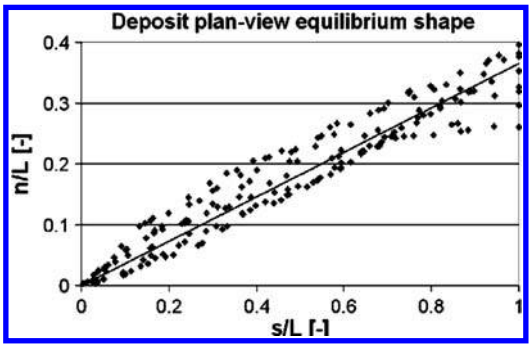

Figure 9. Deposit plan-view shape at equilibrium conditions. x-axis: longitudinal coordinate normalized by the deposit length; y-axis: transverse coordinate also normalized by the deposit length.

Finally, Figure 10 shows a potential application of the results of this work to estimate the shape and hence the volume of a subsurface fluids reservoir when only few data are available, which represents the main goal of this project. For example, knowing the transverse curvature and the deposit width, e.g. from a stratigraphic section, (Fig. 10, top left) it is possible to calculate the dimensionless transverse curvature. Knowing the downstream tendency of the transverse curvature (Fig. 10, top right) one can determinate the corresponding dimensionless longitudinal coordinate. At this point, the plan-view equilibrium shape chart (Fig. 10, bottom right) gives the dimensionless width. From the dimensional width it is hence possible to determinate the surface and hence the volume of the subsurface deposit (Fig. 10, bottom left).

Further analysis in this sense represents the direction of future work. It would be interesting to understand how a self-formed depositional structure evolves tending to become a bypassing body, and, in particular, what is the deposit equilibrium shape and how an unchannelized low depth-width ratio flow field could be maintained over it. In the near future numerical simulations and stability analysis are planned in this direction. The main idea is of investigating the

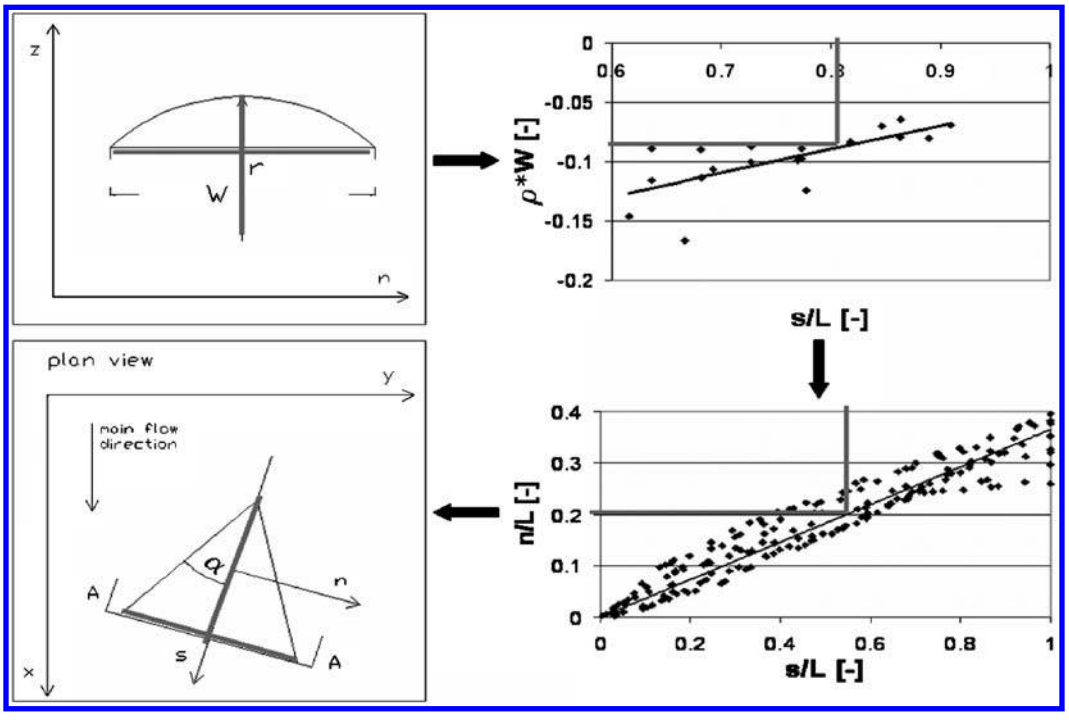

Figure 10. Subsurface deposit geometry determination.

influence of the variation of the deposit transverse curvature on the motion field, under the conditions of conserved liquid and solid discharge. We believe that this procedure can aid to verify if there is an equilibrium shape of the deposit, what this would be, and if the topography of the deposit is the single leading parameter in the occurrence of large angles of expansion and the consequent unchannelized, low depth-width ratio flow over the deposit.

5 CONCLUSIONS

This work shows evidence of the occurrence of large flow expansion angles over fans. Maximum values are found to range between 40–50 degrees half-angle. This phenomenon is made possible by a consistent deposit transverse curvature of around 0.1 when normalized by the fan width. Plan-view expansion angles seem to be independent of the curvature. Fan development analysis shows that an initial channel perturbation causes an upstream migrating scour, which leads to an abrupt downstream increase in width and a consequent concave-shaped deposit. The fan then reaches a final cone-shape, where the aspect ratio maintains approximately constant in the range of 2–4. The consistency of the depositional shapes opens up the possibility of using local shape measures to estimate downdip sandbody extent.

ACKNOWLEDGMENT

This work is supported by the National Center for Earth-surface Dynamics (NCED), a Science and Technology Center funded by the Office of Integrative Activities of the National Science Foundation (under agreement Number EAR- 0120914) and by the Industrial Oil Consortium. We also thank the XES staff for running the experiment and for providing all the useful data and Chris Paola's research group at the SAFL (St. Anthony Falls Laboratory) for the appreciated advice.

ABSTRACT: Dominant discharge is the one of most important parameters in rivers, the determination of which is of common difficulty in river engineering. This parameter depends on many subjects like the river nature, sediment supply & transport, plan and cross-section of the river and other morphologic and physiographic Specifications of river and its basin. Human affairs, made for exploiting the river, are a leading issue affecting the dominant discharge. DEZ is one of the greatest Iranian rivers with annual flow of 8400 MCM and average discharge of 258 m^3/sec. In this article we are going to determine the dominant discharge in four hydrometric station, that one of them located upstream of DEZ Dam. So with comparing and analysis of results in different stations we can obtain the effect of dam on dominant discharge.

1 INTRODUCTION

Rivers are one of the most important components of the nature, knowing which requires deep insight into their behaviors. For almost all of the projects related to river flow engineering and hydraulic structures, defining the design dominant discharge is of great importance. What we are going to explain in this paper is a brief about the defining of the dominant discharge and then, as a case study, paying attention to DEZ River in Iran and defining the so called factor in its different stations.

1.1 *DEZ River in brief*

Located on the western plains of Iran, DEZ River is one of the longest and most important Iranian rivers. Dez originate from Zagros Mountains and Oshtorankooh heights, and its mean annual flow is 8400 MCM and its annual discharge exceeds 258 m^3/s at Harmaleh station (in the flat plain of Khuzestan). A great dam (DEZ Dam) is located, in the north of Dezfoul, before the river reaches to the plain and there is also an old diversion dam (Dezful Dam) on the downstream of the great dam.

Finally DEZ River contributes the great Karun River at the place of Gheer ancient weir, 40 km far from the north of Ahwaz City then flows towards Persian Gulf. The length of this river is about 510 km from the upstream of DEZ Dam to its contribution with Karun River. Refer to Figure 1 the Dez watershed reaches 22755 km^2 including the cities of Boroojerd, Dorood, Azna, Aligoodarz, Andimeshk and Dezful (Al-e- Yasin, 2000).

2 THE STUDIED HYDROMETRIC STATIONS

There are several hydrometric stations on DEZ River four of which have been studied in this research. The so-called stations include Tale-Zang, Dezful, Harmaleh and Bamdej.

The locations of these four stations are seen in Figure 2 and their specifications are presented in Table1. As seen in the figure, Tale-Zang is the only station located on the upstream and the other ones are on the downstream of DEZ Dam. Among the three Dezful station is located just after the Dezful diversion dam.

Also presented in Table 2 are the hydrometric data acquisition periods of the studied stations. As easily

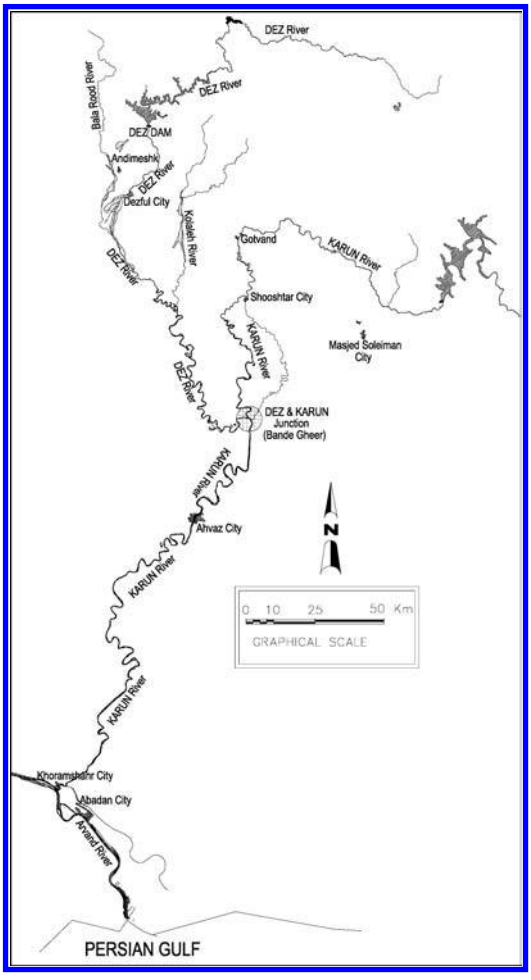

Figure 1. DEZ & KARUN Rivers in the west of Iran.

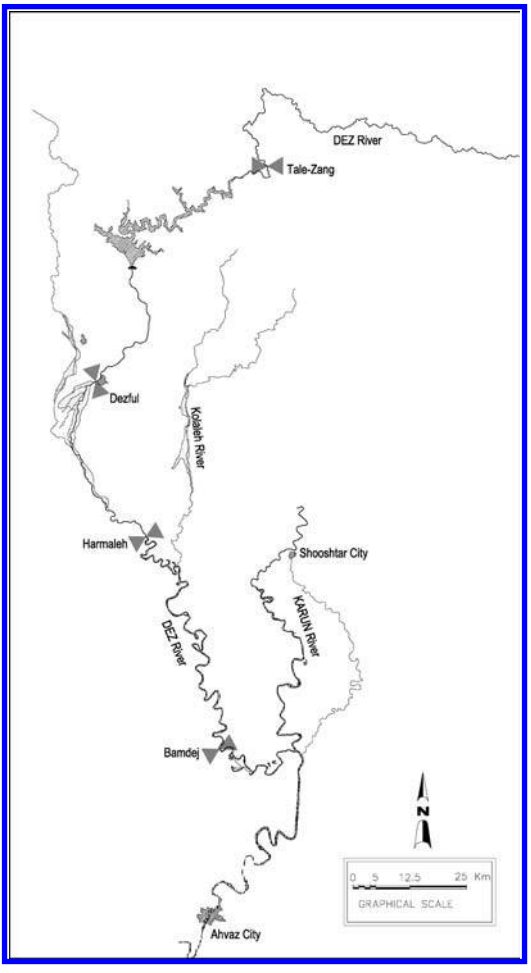

Figure 2. The location of studied hydrometric stations.

seen, we find longer records for Tale-Zang station which is located on the upstream of DEZ Dam. Other records belong to after 1962 which was the end of DEZ Dam construction date.

3 THE DOMINANT DISCHARGE AND HOW TO FIND IT

The rivers dimension and geometry are influenced by different floods, but the only floods that can affect the river physiologic specifications are the ones that exceed the threshold discharge. The main question is that when does the river reach to a dynamic equilibrium. By the means of physical models, Inglis (1941) concluded that rivers can reach the dynamic equilibrium in a specific range of floods and this specific flood range can not only vary from one river to another one, but also in different reaches of a single river. He also found in 1949, following a series of laboratory researches on incohesive bed, that the amount of dominant discharge is about 80% of Bank-full discharge.

Continuing his research, Inglis mentioned the importance of width, depth, longitudinal slope and bed and bank material grain size and related these parameters to flow and sediment discharge. In fact the dominant discharge is a flow that can cause the river equilibrium like a natural flood (Tabatabai & Jaydari, 2002)

Dominant discharge is one of the following three parameters and can be chosen through investigating the physical and morphological specifications of the river:

1. Mean Annual Flood Discharge (MAF)
2. Bank-full Discharge (BF)
3. Effective Discharge

Table 2. Hydrometric and sediment data acquisition period of the studied stations.

Station	Hydrometry measured fata	Sediment measured data
Tale-Zang	1955–2004	1970–2004
Dezful	1950–2004	1970–2004
Harmaleh	1992–2004	1962–2004
Bamdej	1962–2004	1968–2004

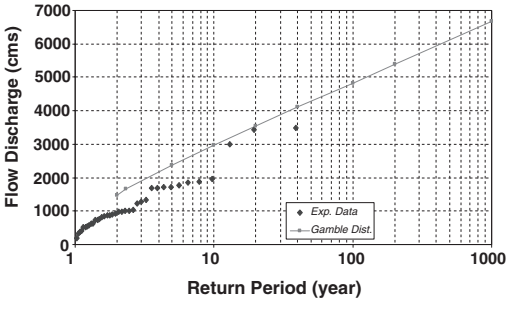

Figure 3. Hydrologic frequency analysis results of annual max series in Harmaleh station.

3.1 *Mean Annual Flood Discharge (MAF)*

The MAF discharge can be obtained by means of hydrologic frequency analysis (HFA) of annual max series (AMS). If the Gamble distribution is the dominant distribution of AMS and we know that the mean value of this distribution is when it's reduced value (y) is 0.5772, then the return period of MAF discharge will be 2.33 years. Obviously if we consider the dominant distribution to be normal or log-normal then the return period will become half year. In our research we found the Gamble distribution to be dominant. Figure 3 shows the HFA of annual Seri in the Harmaleh station. The amounts of MAF discharge of the four stations are presented in Table 4.

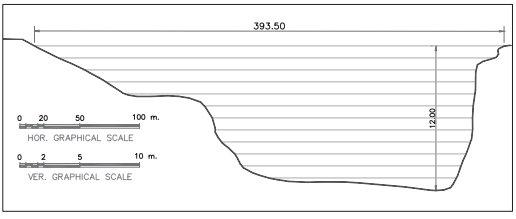

Figure 4. The section of DEZ River in Harmaleh station.

3.2 *The bank-full discharge*

The bank-full discharge is the maximum capacity of the river main channel and any discharge that exceeds this amount will enter the flood plain. It should be mentioned that in many cases, the boundary between the main channel and the flood plain can not be clearly distinguished.

The studies show that the meanders wave length is related to the bank-full discharge. The experimental regime equations also show that the river width has more correlation with instant flow than mean daily discharge (Tabatabai & Hey, 1998). Further more, many researchers have used the bank-full discharge for obtaining the experimental regime equations (Ackers & Charlton, 1970). Regarding these reasons we can imagine the bank-full discharge as one of the candidates for the dominant discharge. For finding the boundary between main channel and the flood plain, we have used the Wolman (1955) method in which we analyze the width to depth ratio versus depth diagram. The minimum point of this diagram shows the depth corresponding to the maximum channel capacity. Having obtained this point and by the usage of flow rating curve of the station, we can determine the bank-full discharge (Osterkamp & Hedman, 1982). Shown in Figures 4 and 5 are the section of DEZ River at Harmaleh station and the determining of the depth corresponding to the bank-full discharge. Using the Wolman method, the bank-full discharge of the four studied stations are determined and the results are shown in Table 4.

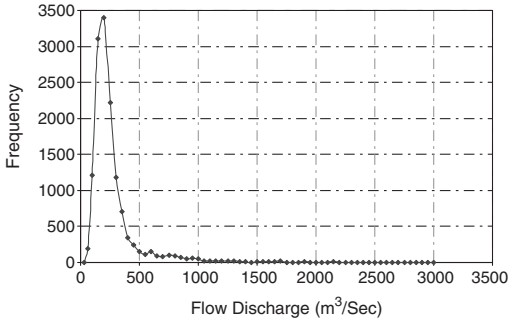

Figure 6. Daily discharge histogram of Harmaleh station.

3.3 *The effective discharge*

The effective discharge is the amount of flow that can supply the maximum rate of sediment during the data acquisition period. For finding the effective discharge we must obtain the daily discharge histogram. In Figure 6 the daily discharge histogram of Harmaleh station is shown.

Then by the means of sediment measured data, the sediment rating curve equation is determined. These equations are generally in the form of:

$$Q_s = a.Q_w^b \quad (1)$$

In this equation Q_s and Q_w are the suspended sediment discharge (ton/day) and the flow discharge (m^3/sec) respectively. Also a and b are constant coefficients. Shown in Figure 7 is the suspended sediment rating curve of Tale-Zang station. The suspended sediment rating curves of the four stations are presented in Table 3.

By using this equation, the sediment supply power of each discharge histogram class can be calculated.

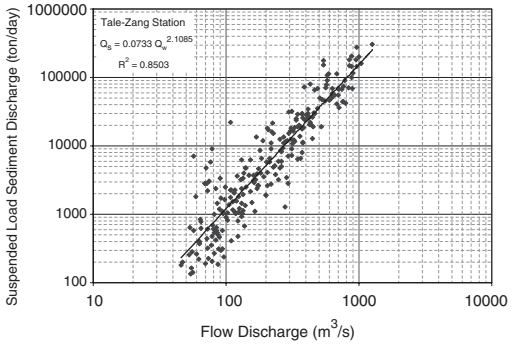

Figure 7. Tale-Zang station suspended sediment rating curve.

Table 3. Suspended sediment rating curve equations of studied stations.

Station name	Sediment rating-curve equation
Tale-Zang	$Q_s = 0.0733\ Q_w^{2.1085}$
Dezful	$Q_s = 1.089\ Q_w^{0.5738}$
Harmaleh	$Q_s = 0.9975\ Q_w^{1.5363}$
Bamdej	$Q_s = 0.2189\ Q_w^{1.8424}$

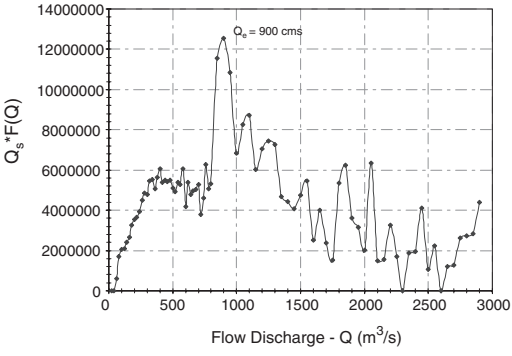

Figure 8. The total suspended sediment histogram and the effective discharge for Tale-Zang station.

By multiplying the frequency of each discharge histogram class in its corresponding sediment discharge ($F(Q)^*Q_s$) and drawing the results versus the discharge histogram classes, the total suspended sediment histogram will be obtained. The discharge corresponding to the maximum of recent histogram will be the effective discharge.

Figure 8 shows the total sediment discharge histogram of Tale-Zang station. Also shown in Table 4 are the results of effective discharge calculations.

Table 4. Summary of the results.

Station	Mean annual flood discharge m^3/sec	Bank-full discharge m^3/sec	Effective discharge m^3/Sec	Comparison
Tale-Zang	2444	2720	900	$Q_e < Q_{MAF} < Q_{BF}$
Dezful	1575	1670	250	$Q_e < Q_{MAF} < Q_{BF}$
Harmaleh	1650	1640	220	$Q_e < Q_{bF} < Q_{MAF}$
Bamdej	1363	1320	200	$Q_e < Q_{bF} < Q_{MAF}$

4 DETERMINING THE DOMINANT DISCHARGE AND DEZ DAM EFFECTS

4.1 *Decision making on the dominant discharge*

A brief of the results are shown in table 4. As seen in this table, the amount of the effective discharge is much less than annual and the bank-full discharge in all four stations. The number of DEZ River floods shows that this river has reached a dynamic equilibrium under the effect of these floods. The little difference between the mean annual flood and the bank-full discharge also admits this idea.

Figure 9 is used for clarify the DEZ River dominant discharge in different stations. In this figure the sediment supply to total sediment discharge ratio for each daily discharge histogram classes is drawn due to the calculations of effective discharge. The vertical axis is cumulative and is shown in percents. This figure shows that the sediment supply to total sediment discharge ratio for Tale-Zang, Harmaleh and Bamdej is a little fraction of total suspended sediment supply for low classes (less than 250 m^3/sec – approximately effective discharge). At Dezful station which is located close to DEZ Dam, more than 80% of the sediment is supplied in less than 350 m^3/sec, while in Tale-Zang, Harmaleh and Bamdej; the same amount of sediments is supply with 1550, 1300 and 1050 m^3/sec of discharge respectively. So it can be concluded that in only a short distance from its down stream, the DEZ Dam has stabilized and the river is influenced by low level flows (close to effective discharge). In the downstream stations (Harmaleh and Bamdej) the river geometry is still highly affected by long return period floods. It can be said as a result that in the Dezful station, the effective discharge should be considered to be dominant but in the other stations, the dominant discharge is mean annual flood or the bank-full discharge.

4.2 *The effect of DEZ Dam on the river sediment supply mechanism*

As seen in figure 9, DEZ Dam has only reduced the dominant discharge in a short reach of its downstream and the rest of downstream; the geometry of the river is affected by the dam spilled flow (artificial floods) or the flows of other branches which pour in the river after the dam in the south of Dezful and Andimeshk. The important branches that pour in are Balaroud and kalaleh River and are shown in figure 1. The dominant discharge in the upstream of the DEZ Dam is almost four times than in the downstream and it's a proof to the dam's great influence on the river dominant discharge.

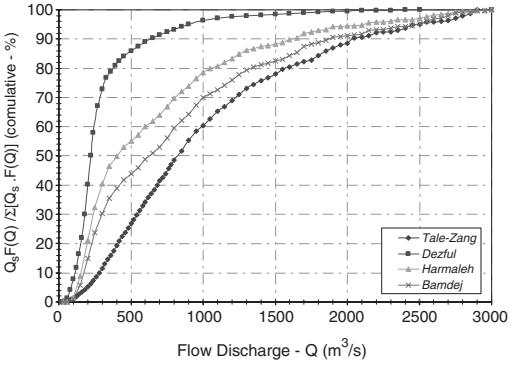

Figure 9. The sediment supply to total sediment discharge ratio for each daily discharge histogram classes.

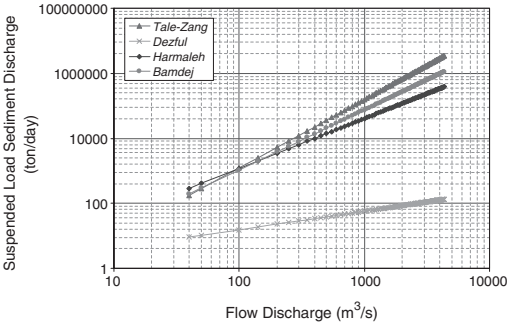

Figure 10. The effect of DEZ Dam on the sediment supply mechanism.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Other point to be mentioned is the great influence of DEZ Dam on sediment trapping and supplying in the downstream reaches. A comparison is done between the sediment rating curve diagram of the stations and the results are shown in Figure 10. By comparing Tale-Zang and Dezful stations it can be said that more than 95 percent of the sediment is settled in DEZ Dam reservoir and astonishingly the same amount of sediment is supply along the rive until Bamdej station and this shows the high erosion potential of DEZ River in the downstream reach of dam.

Large-scale turbulence and river morphology

M.S. Yalin
Department of Civil Engineering, Queen's University, Kingston, Ontario, Canada

ABSTRACT: The paper shows, on a theoretical as well as experimental basis, that dunes are the products of the vertical turbulent bursts, while all the periodic in the flow-direction bars, are the "imprints" of horizontal bursts. The paper also demonstrates, on the basis of congruence of plan-configurations and wavelengths, that the initiation of meandering and braiding is also due to the large-scale horizontal turbulence. One-row horizontal bursts originate meandering, multiple-row bursts, braiding.

1 INTRODUCTION; FUNDAMENTALS

i) Following Hussain (1983), the term "coherent structure" (CS) is used in this paper to designate the largest conglomeration of turbulent eddies which has a prevailing sense of rotation, the term burst, to designate the evolution of a CS during its life-span T. The bursts can be vertical (V) or horizontal (H). The CS's of the former rotate in the $(x;z)$-planes, those of the latter, in the $(x;y)$-planes (Figure 1).

A burst-forming CS originates (rolls-up) at a point O_i near the flow boundary – if V, near the bed; if H, near the bank. A rolled-up (at O_i) CS moves away from the flow boundary while it is transported by the flow downstream: in the process it is continually enlarging. The conceptual Figure 2a shows (in a stationary frame) a V-burst cycle of an open-channel flow; the cine-record in Figure 2b shows (in a convective frame) an instantaneous view of two consecutive CS's. The analogous is valid, *mutatis mutandi*, for an H-burst.

The present paper intends to demonstrate that the size and plan-configuration of the large-scale (periodic along x) alluvial forms generated by a flow, are in coincidence with those of the bursts of that flow – which would justify the longstanding view of many eminent researchers that the large-scale alluvial forms are due to the large-scale turbulence.

It is assumed throughout this text that the "experiment" commences, at $t = 0$, in a trapezoidal wide initial channel ($B/h > \approx 15$, say): the channel bed and banks are flat, the initial turbulent flow is uniform.

ii) Some pertinent conditions, which follow from recent research on turbulence, are summarized (in a highly idealized manner) below.

If O_i and O_{i+1} are the "birth-places" of two consecutive bursts of a burst-sequence (Figure 2a), then the distance $\overline{O_i O_{i+1}} = \lambda_V$ or λ_H is the burst-length, the life-span of a burst being $T_V = \lambda_V/u_m$ or $T_H = \lambda_H/u_m$ (for CS's are transported by the flow with the velocity

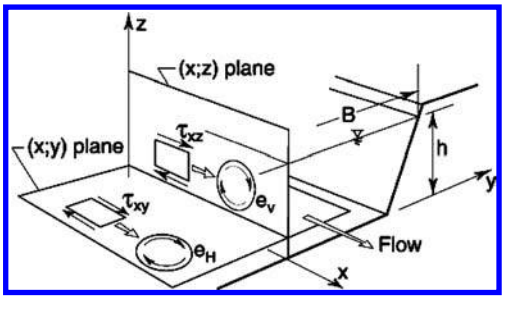

Figure 1. Vertical and horizontal planes of rotation of CS's.

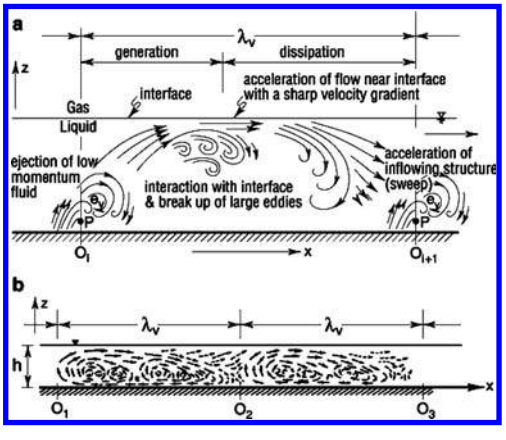

Figure 2. a) Conceptual representation of a V-burst cycle (after Rashidi & Banerjee 1988); b) Cine-record showing instantaneous view of two consecutive CS's (from Klaven 1966).

$\approx u_m$). Let O_0 be the origin of the first burst of a burst-sequence. If O_0 is fixed (e.g. if O_0 is the location of the "local discontinuity" δ in the sense of Yalin (1992)), then the rest of O_i's must also be considered as fixed, for each of them is distant from O_0 by a integer number of the constant lengths λ_V and λ_H. But this means that the straight time-average initial flow is subjected to a perpetual action of bursts "fired" from the (ideally speaking) same location O_i. This action must inevitably render the flow to acquire a sequence of periodic (along x and t) non-uniformities, which, in turn, must cause, by virtue of the transport continuity equation, the emergence of the periodic (along x) bed- and/or bank-forms (j). These initial forms must grow with the passage of time (by coalescence) until they acquire their developed length Λ_j that is the same as the burst length:

$$\Lambda_j = \lambda_V \text{ or } \lambda_H . \tag{1}$$

iii) The burst lengths λ_V and λ_H are found to be independent of the inner variables $v_* k_s/\nu$ and k_s/h: they scale, respectively, with the outer variables h and B (see e.g. Nezu & Nakagawa 1993, Gad-el-Hak & Hussain 1986, Cantwell 1981). Indeed, as can be noted e.g. from Figures 3a and 3b, the data-points of λ_V/h cluster at the level $\approx$6, irrespective of what the value of $\mathrm{Re} = u_m h/\nu$ ($=c(h/k_s)(v_* k_s/\nu)$) might be. Thus

$$\frac{\lambda_V}{h} \approx 6 . \tag{2}$$

Similarly, the oscillograms recorded by Yokosi (1967) in Uji River (Japan), and those obtained by Dementiev (1962) in Syr-Darya River (former U.S.S.R.) indicate that the dimensionless λ_H, viz λ_H/B, can also be expressed as

$$\frac{\lambda_H}{B} \approx 6 . \tag{3}$$

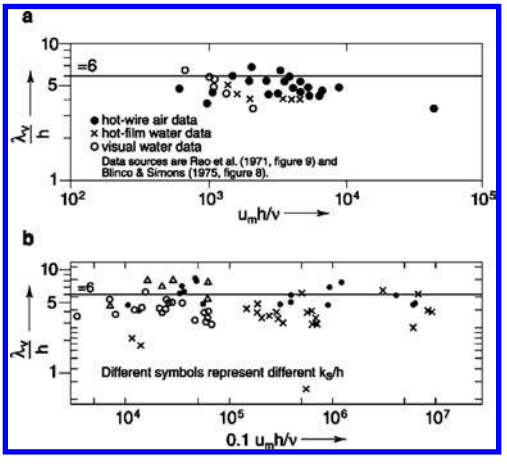

Figure 3. Plots of λ_V/h versus Reynolds number (after Jackson 1976).

However, as will be presently clarified, the relation (3) is valid only if the aspect ratio (B/h) of the flow does not exceed a certain upper limit.

2 DUNES AS BED-FORMS DUE TO V-TURBULENCE

i) If the uniform initial flow can be treated as two-dimensional, then the length Λ_d of the developed dunes produced by this flow can be expressed (Yalin 1992, 1977, Yalin & da Silva 2001) as

$$\frac{\Lambda_d}{h} = 6 \cdot \phi_d(X, Z). \tag{4}$$

From the experimental family of curves implying (4) (Figure 7.28 in Yalin 1977 or Figure 2.8 in Yalin & da Silva 2001), it is clear that if the initial flow is rough turbulent, i.e. if $v_* k_s/\nu \approx 2X > \approx 70$, then $\phi_d(X, Z) \to \approx 1$ and (4) becomes

$$\frac{\Lambda_d}{h} = 6 , \tag{5}$$

as to justify the validity of (1) and (2). The multiplier $\approx$6 in (4) and (5) was determined on a purely experimental basis. It is only recently that it has been demonstrated theoretically, by D. Zhou and C. Mendoza (2005), that $\approx$6 is, in fact, the rounded-up value of 2π. This gave the author the impetus to produce the following (more direct and precise) explanation for $\Lambda_d/h \approx 2\pi$.

ii) Figures 4 and 5 show the classical neutral stability curves which are due to W. Tollmien (1929) and S.F. Shen (1954), respectively. These curves indicate how the range of the wave numbers $\alpha\delta^* = 2\pi\delta^*/\lambda$,

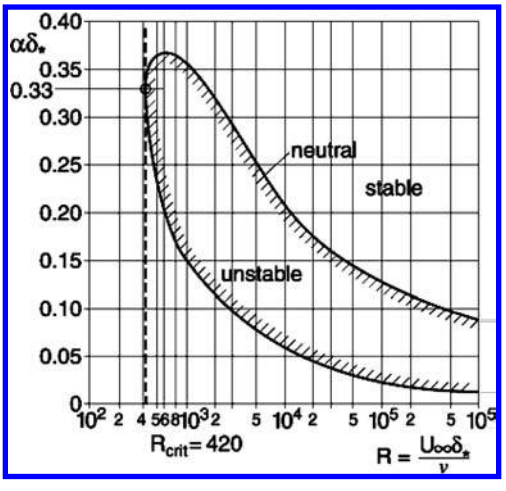

Figure 4. Neutral stability curve (after Tollmien 1929).

Copyright © 2006 Taylor & Francis Group plc, London, UK

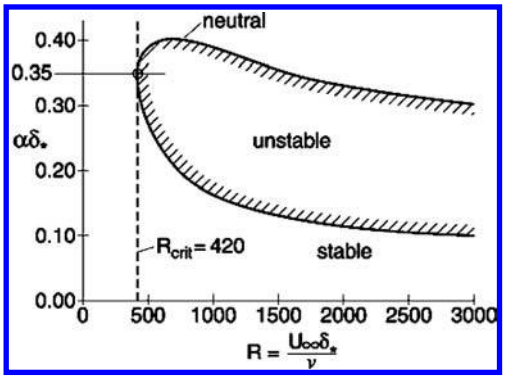

Figure 5. Neutral stability curve (after Shen 1954).

which are capable of converting a laminar boundary layer flow into a turbulent one, varies with the Reynolds number $R = U_\infty \delta^*/\nu$. No analogous curves were computed so far, to the author's knowledge, for open-channel flows. Hence, there is no alternative but to use the above mentioned curves by interpreting δ $(=3\delta^*)$ as h, U_∞ as u_m, and $R = U_\infty \delta^*/\nu$ as Re/3.

Observe from Figures 4 and 5 that only when $R = R_{cr} = 420$ $\mathrm{Re}_{cr} = 1260$) do the ranges of $\alpha\delta^*$, and thus of λ, become reduced into the single values $(\alpha\delta^*)_{cr}$ and λ_{cr}, say. Identifying the disturbance wavelength λ_{cr} at R_{cr} with the burst length at R_{cr} – or, to that matter, with the length (λ_V) of bursts at any Re (for λ_V is practically the same for any Re (Figures 3a and b)) we can write

$$\lambda_{cr} = \lambda_V \,. \tag{6}$$

Now, for $R_{cr} = 420$ (and $\lambda = \lambda_V$) the curve in Figure 4 gives

$$\alpha\delta^* = 2\pi \frac{h}{3\lambda_V} = 0.33 \tag{7a}$$

and thus

$$\frac{\lambda_V}{h} = 2\pi \cdot 1.01 \approx 6.346 \,, \tag{7b}$$

while the curve in Figure 5 gives

$$\alpha\delta^* = 2\pi \frac{h}{3\lambda_V} = 0.35 \tag{8a}$$

and thus

$$\frac{\lambda_V}{h} = 2\pi \cdot 0.95 \approx 5.969 \,, \tag{8b}$$

which indicate that ≈ 6 must indeed be the rounded-up value of 2π.

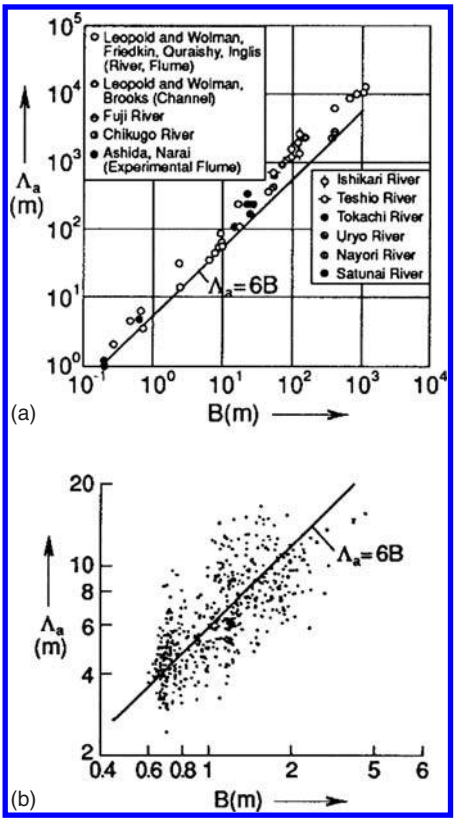

Figure 6. Plots of alternate bar length versus flow width a) from JSCE (1973); b) from Hayashi (1971).

3 BARS AS BED FORMS DUE TO H-TURBULENCE

i) The coherent structures forming the H-bursts of a wide open-channel flow have the shape of the horizontally positioned disks. These "disks" extend (along z) throughout the flow thickness h and they are *rubbing the bed*, with their lower-faces. Hence they are capable of producing "their" bed forms. Since $h \ll B$, the variation of their characteristics along z is negligible, and therefore they are usually referred to as two-dimensional coherent structures (2DCS) (Jirka & Uijttewaal 2004).

It will be assumed throughout the present Section that only the bed is mobile (the banks are "rigid").

ii) From a very large number of field and laboratory measurements (carried out mostly by the Japanese researchers) it follows that the length Λ_a of alternate bars (or of one-row bars) can be expressed as $\Lambda_a \approx 6B$ (Figure 6). Combining this expression with (3), we obtain

$$\Lambda_a \approx \lambda_H \approx 6B \,, \tag{9}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

which strongly suggests that alternate bars are the "imprints" of the H-bursts "fired" alternatively from the burst-points O_i and O'_i (Figure 7).

Consider the $(B/h;h/D)$-plan in Figure 8, from which the existence-regions of various alluvial forms caused by the H-turbulence can be observed. Note that with some few exceptions (due to experimental scatter), the alternate bar points A remain *below* the line $\mathcal{L}$. This is to be expected, for the disk-like 2DCS's of the H-bursts are rubbing the bed, and therefore their rotational kinetic energy is continually undermined by the bed friction:

1. If B/h is smaller than the ordinates $(B/h)_{1,2}$ of the line $\mathcal{L}$, then 2DCS's "are able" to grow indeed up to the size B, i.e. as to reach the opposite bank, and we have *one-row* horizontal bursts and thus *one-row* bars – each of the length $\approx 6B$ (Figure 7).
2. If, however, $B/h > (B/h)_{1,2}$, then 2DCS's emitted from one bank will not be able to grow as to reach the opposite bank (for they will be destroyed before that by friction). In this case the 2DCS's issued from both banks meet each other in the midst of the stream, and we have *2-row horizontal bursts* and thus *2-row bars*: the width of each row is $B/2$, the length of each bar being $\Lambda_2 \approx 6B/2 = 3B$ (Figure 9a).
3. Similarly, if $B/h > (B/h)_{2,3} > (B/h)_{1,2}$, where $(B/h)_{2,3}$ are the ordinates of the (so far unknown) line separating the zones of the 2- and 3-row bars, then the bursts issued from each bank will not be able to meet each other in the midst of the stream and we will have *3-row horizontal bursts* and thus *3-row bars*: the width of each row is $B/3$, the length of each bar being $\Lambda_3 \approx 6B/3 = 2B$ (Figure 9b).

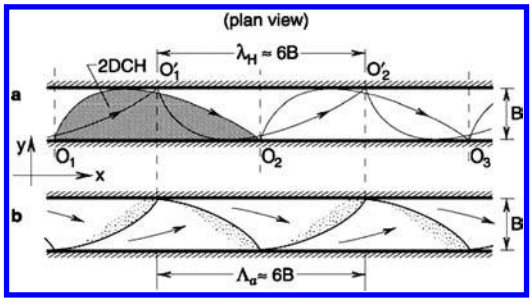

Figure 7. Occurrence of alternate bars as the "imprints" of H-bursts.

iii) Extrapolating the aforementioned, one may erroneously conclude that every open-channel flow, no matter how wide, can have an appropriate number n of burst-rows and thus n-row bars on its mobile bed: the width of each row is B/n, the length of each bar is $\approx(6B)/n$. This is not so, for if the stream is *very wide* it does not manifest itself as a "correlated totality" across its width B: the flow at the left bank "does not know" what the flow at its right bank is doing. Under

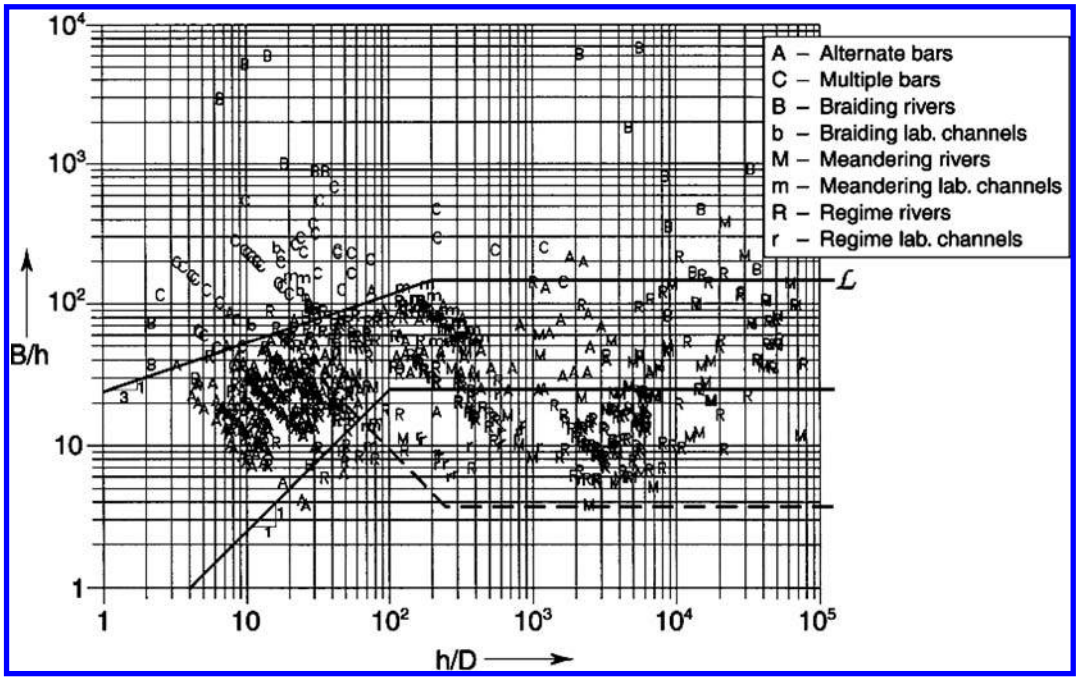

Figure 8. $(B/h;h/D)$-plan (from Yalin & da Silva 2001); existence regions of alluvial forms due to H-turbulence.

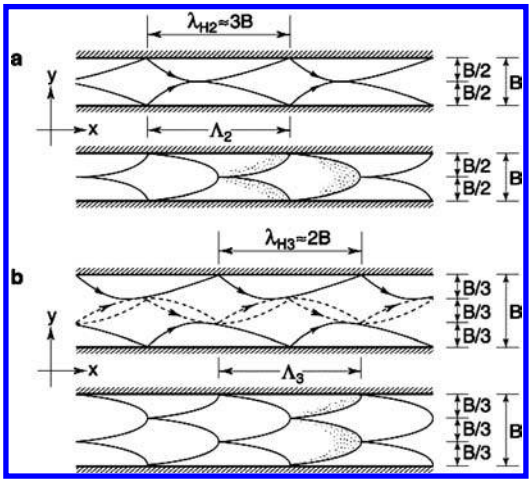

Figure 9. Multiple-row horizontal bursts and related bed forms. a) 2-row; b) 3-row.

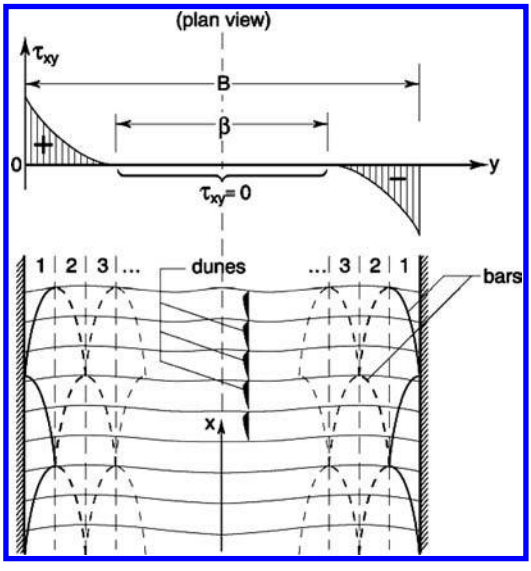

Figure 10. Conditions in very wide streams.

idealized conditions, such streams have $\tau_{xy} \equiv 0$, at any level z, throughout their central regions β (Figure 10). Moreover, it is only the "first" burst-rows adjacent to the banks which consist of the *factual* bursts issued by the banks (Figure 10): the remaining 2DCS-rows are *induced* rows. The farther from the bank, the weaker is the "induction-capacity", and the less prominent are the bar-rows. In reality only two or three rows of bars can be observed along the banks of a very wide stream. In the midst (β) of such streams only the vertical turbulence, and thus only dunes and ripples are present.

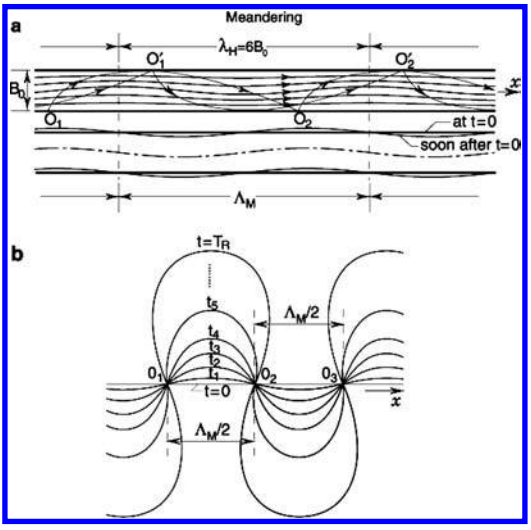

Figure 11. Initiation and subsequent development of meanders.

4 MEANDERING AND BRAIDING AS PLAN-FORMS DUE TO H-TURBULENCE

It will be assumed in this Section that both bed and banks are deformable.

i) Note from Figure 8 that the line $\mathcal{L}$ implying the upper limit for the formation of alternate bars (points A) can also be taken as the upper limit for the formation of meanders (points M and m). Indeed, with few exceptions, the points A, M and m are situated below the line $\mathcal{L}$. This is not surprising, for both alternate bars and meanders are caused by the same agent, viz one-row H-bursts. These bursts, as has already been mentioned, cause the flow to acquire the periodic (along x and t) non-uniformities, which in turn, deform correspondingly the bed and banks. Figure 11a shows the initiation of the periodic (curve-like) deformation of banks. The amplitude of the so initiated meandering grows in the flow plan so that (under ideal conditions) the meander wave length $\Lambda_M \approx \overline{O_i O_{i+2}}$ remains constant (Figure 11b).

But if Λ_a and Λ_M are thus the bed- and bank-"imprints" of the same $\lambda_H \approx 6B$, then we must have

$$\Lambda_M = \Lambda_a = \lambda_H \approx 6B\,, \tag{10}$$

which is the augmented (9). The plot in Figure 12 justifies the validity of $\Lambda_M \approx 6B$.

ii) From Figure 8 one also infers that the bulk of multiple bar points C and the points B and b of the braiding streams remain above the line $\mathcal{L}$ – which can thus be taken as their lower limit. Consider e.g. the 2-row bars generated by the two-row H-bursts in Figure 13. The bars cause the time-average flow to diverge

Copyright © 2006 Taylor & Francis Group plc, London, UK

and converge with the longitudinal period $\Lambda_2 \approx 3B$. Since the banks are erodible, B progressively increases (as in A-A), while h decreases. Consequently, the central bars emerge as "islands" and the single-channel stream turns into a braiding stream.

5 CONCLUDING REMARKS

1) Although the initiation of meandering and braiding is due to the large-scale horizontal turbulence (and so are their wavelengths and geometric nature), the subsequent growth of the "amplitude" (in lateral direction y) of these plan-forms is due to the regime-trend (see Yalin & da Silva 2001). Each stream, "if it is left alone", tends to increase its entropy (Second Law of Thermodynamics) and consequently it tends to reduce its flow velocity u_m (its kinetic energy). In the case of meandering, the reduction of u_m is achieved by the increment of flow length, i.e. by the reduction of S; in the case of braiding by the increment of the number n of branches.

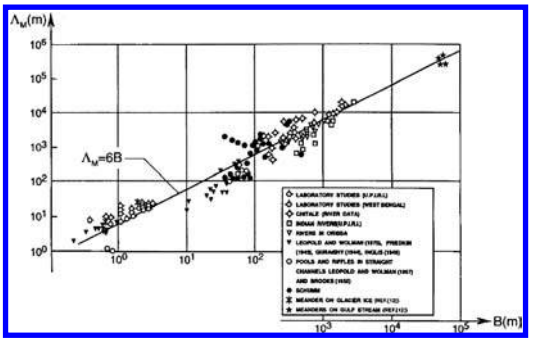

Figure 12. Plot of meander wavelength versus flow width (after Garde & Raju 1977).

The purpose of this remark is to remind the future researchers that the aforementioned growth of the amplitude is due to the Second Law, and it cannot be explained by turbulence.

2) No reference to ripples has been made in this paper. And although they may also be due to the turbulence, they are certainly not due to the turbulent bursts, for, unlike $\lambda_V \approx 2\pi h$, their length $\Lambda_r = D \cdot \varphi_r(v_* D/\nu)$ scales with the inner variables.

A special research directed towards the clarification of the origin of ripples would certainly be very desirable.

Analysis of water and sediment flows over an alternate bar in a gravel bed river

M. Jodeau & A. Paquier
Cemagref, Hydrology and Hydraulics Research Unit, 3 bis quai Chauveau, Lyon Cedex, FRANCE

ABSTRACT: Bars are present in most gravel bed rivers and exert a strong influence on flow and sediment processes. We focused on topographic changes of an alternate bar in a gravel bed river with high suspended sediment concentration. This phenomenon was studied on the river Arc (French Alps). The area of interest was approximately 600-meter long and quite straight with a gravel bar along the left side of the channel. Bar bed material was gravel and, due to high suspended sediment concentration in this river, fine sediments were found on the bed surface and included in the bed.

To understand how water and sediment flows organized around this alternate bar, a series of measurements was performed in the proximity of the gravel bar during a flushing operation from upstream dams. Topographic surveys helps to identify deposition and erosion areas. During the operation that was equivalent to a one year period return flood, suspended sediment concentration, flow depth and water velocity were monitored. Field measurements were compared with two-dimensional hydrodynamic modeling which permitted to identify zones and times of high/low velocities.

1 INTRODUCTION

Many studies emphasize the effect of bars in river flows. Gravel bars develop in natural rivers and in straight embanked channels with sufficient width to depth ratio (Schielen et al. 1993). In order to control the development of vegetation in the active channel of the river, managers have to deal with bars that constitute one of the areas in which fine sediment deposits are located. Gravel bars represent important instream habitat features at the aquatic terrestrial interface. Besides the establishment of vegetation depends on the evolution of the water level (amount of time the bar is flooded or dry) and if the bar gravels are subject to movement or not. In this case the river is the main factor determining vegetation development (Edwards et al. 1999) but the composition of the river bed is part of the factors determining the establishment of plants (Langlade and Décamp 1995).

Fine and coarse sediment interaction over alternate bars had been studied in laboratory flume (Diplas 1994), which shows an effect of the bed topography: fine sediments were deposited first and removed last from the downstream side of the bar and from the pool area. Experiments also highlighted bed movement is required to remove fine sediments from the subpavement.

1.1 *Objectives*

The objective of this work is to provide a relevant description of water and sediments flows in a reach with alternate bars using in situ measurements. The final purpose is to predict the temporal evolution of the bar in function of water flow, and to specify if vegetation may remain and develop on the bar.

In a first step, we focused on a single reach where there is a sequence of four alternate bars. We performed field surveys during a flushing operation and topographic campaigns. Next we compared field measurements to results from a two-dimensional hydrodynamic modeling. Finally, we expect to be able to extrapolate the results to estimate where and to what extent fine sediments will deposit along a river reach with alternate bars.

2 SITE DESCRIPTION

The field work was conducted on a reach of the Arc river. The total catchment area of the Arc River is 1957 km^2 located in the French Alps. It is a mountain stream which undergoes two different types of hydrological regimes which produce floods, one from west, which is oceanic perturbation, generates small

Copyright © 2006 Taylor & Francis Group plc, London, UK

floods, the other one is from south from Italy and generates the biggest floods. Otherwise the hydrological regime is nival, natural discharge is higher during snow melt. The ten year return period flood is approximately 300 m^3/s.

The river bed is made of gravel, the slope of the bed along the river varies from 1 to 6%. The flow is regulated by several dams and restitutions of clear water along the river, all for hydroelectricity. Only 5% of the river Arc remains with its natural flow and morphology. Tributaries throw lots of fine sediments in the river, the main ones are Arvan and Glandon streams which supply black Lias schists predominantly. Because of dams, the solid flow is stopped in reservoirs. The substantive part of fine sediment discharge occurs during snow-melt (May to July), but most of sediments trapped in the reservoir during the year are flushed downstream when the reservoirs are drained. The three reservoirs on the middle part of the river are flushed every year, otherwise they would be full of fine sediments. Flushing flows are completed as counterpart to mechanical dam cleaning.

The study area was selected because it offers a succession of alternate bars which are reachable and wadable. In the following this place will be named site A. The study site is a 600 m long reach located 33 km upstream of the confluence with the Isére River, and downstream from the city of Saint Jean-de-Maurienne; its altitude is 450 m. Figure 1 shows the location of the reach of investigation. It is a very straight reach with 1 m boulder embankments, the width between dikes is approximately 50 m (Figure 2). The water discharge of this reach is controlled by upstream dams, the discharge is almost constant around 5–15 m^3/s and varies with the upstream water releases. It is the downstream part of a series of alternate gravel bars, we focused on the last downstream bar. This bar is located 200 m upstream from a bridge. The mean slope of this reach is near 0.6%. The bed is made of gravel (mean diameter 10 cm) and fine sediments (sand and silt).

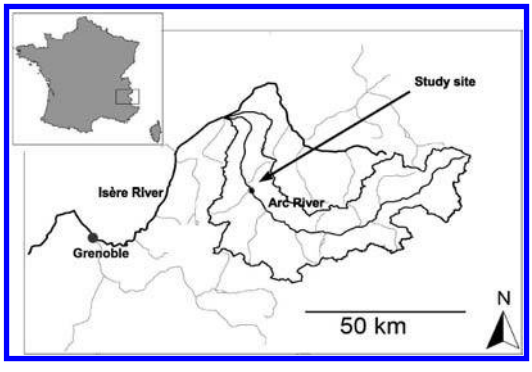

Figure 1. Location of the study reach.

This series of alternate bars fits with the existence criteria established by M. Jaeggi (Jaeggi 1984). This criteria defined the minimum slope for bar formation:

$$S_c = exp(1.07 Z_B^{0.15} + M) * 1/(12.9 Z_B) \quad (1)$$

In which $Z_B = B/d_m$, S is the slope, B the channel width, d_m mean grain size of the bed material and M a factor increasing from 0.34 to 0.7 with increasing sediment gradation.

In this case $B \approx 60$ m, $d_m \approx 0.1$ m which lead to S_c from 0.29% to 0.42% depending on M. In this part of the river Arc, the mean slope is near 0.6% which is higher than the limit for bar-forming range.

Since year 2000, no major flood has occurred and as it is complicated to anticipate floods on the Arc River we focused on the major hydraulic event on the Arc River, that's to say the dam release performed by EDF (Électricité De France) during the beginning of the summer. The last dam release occurred on June, 16th 2005. Three reservoirs were flushed. Table 1 gives the relevant features of these reservoirs. The flushing event began with a warning release, i.e. a clear water release of 10 m^3 from the flap gates, then discharge was increased gradually to reach the maximum discharge in 6 hours, the peak discharge was maintained during 2 hours and eventually the water discharge was decreased gradually. Figure 6 gives the theoretical hydrograph followed by engineers at the dams. Maximum peak discharge was equivalent to a one year period return flood.

Figure 2. Downstream view of the study reach, water flows from the back to the front of the photograph.

Table 1. Reservoirs on the Arc River flushed on 06-16-2005.

Reservoir	Live storage (m^3)	Distance upstream the study from area (km)
Freney	165 000	36.5
Pont des Chèvres	1 200 000	30.25
St Martin la Porte	125 000	18.55

Copyright © 2006 Taylor & Francis Group plc, London, UK

The dam release was significant on two accounts: first it produced an artificial flood, and the water flow from the reservoir had a very high fine sediment concentration.

3 FIELD MEASUREMENTS

In order to evaluate the different flow parameters, we performed very simple measurements. The field work was divided into three phases: topographic data were first collected the day before the event; hydrometric measurements were performed during the flushing flow; after the flushing day a series of topographic data and field observations were made.

3.1 *Morphologic surveys*

Concrete reinforcing bars of 12 mm diameter were used to observe erosion/sedimentation patterns at ten specific places on the alternate bar. The day before and the day after the event, brief topographic surveys were performed in order to identify more precisely erosion/sedimentation areas. Figure 3 is the topographic map after the flushing flow.

3.2 *Flow measurements*

Very basic measurements were performed. The water level was followed on a staff gauge located on the central bridge pier 200 m downstream, meanwhile it was measured and recorded with the help of a pressure transducer (DIVER, Van Essen, The Netherlands) near the right bank in the middle of the reach.

An assessment of surface flow velocities was obtain following floating objects (logs, plastic bottles…). Two series of measurements were performed at 10:00 and 12:00. We assessed the mean surface velocities (v_{surf}), $v_{surf}^{10:00} = 3.7 \pm 0.3$ m/s and $v_{surf}^{12:00} = 4.8 \pm 0.5$ m/s.

3.3 *Sediment and grain size measurements*

Samples of water were taken with a bucket from the bridge. It gave an assessment of fine sediment concentration in the middle of the channel and in the surface of the flow. Suspended sediment concentrations were measured in the laboratory using vacuum filtration on 0.45 µm filters and drying. The graphic on Figure 4 gives the evolution of suspended sediment concentration (ssc) during the flushing event. Note that the concentration reaches 15 g/l, that's why we could not use our turbidimeter on the field, samples needed a dilution. We had also accessed to the measurements made by IRAP (consulting engineer) for EDF downstream every dam.

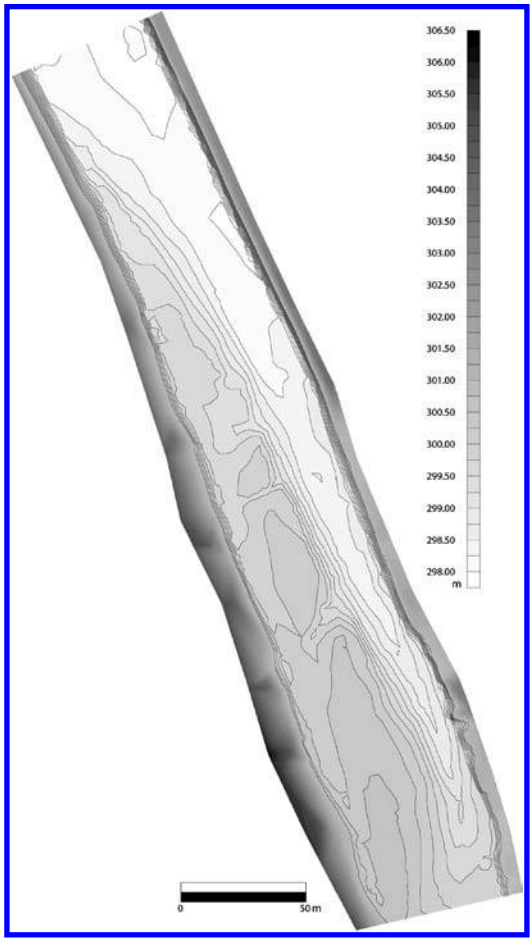

Figure 3. Topography of the study reach as determined by field survey and regular grid interpolation, water flows from the bottom to the top of the picture.

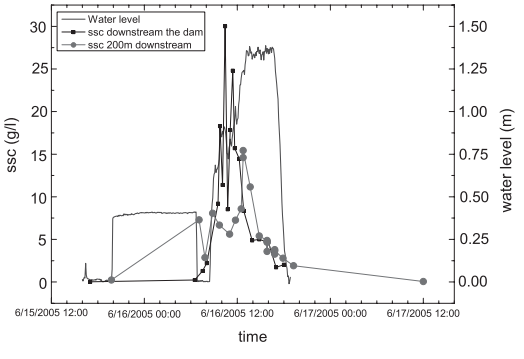

Figure 4. Suspended sediment concentration (ssc) measured just downstream from site A (disks), ssc measured 18 km upstream from site A, downstream the last dam (small squares) and water level measured by the DIVER.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Turbidity was measured in the lab after dilution, turbidity is linked with ssc but the relation is not straightforward.

We made a grain size analysis on three samples to gain insight on the features of suspended sediments. The bulk of fine sediments had a diameter smaller than 50 μm and the composition was quite constant along the flushing event.

4 MODELING TOOLS

4.1 *Model*

Water Flow in the reach was modeled with the two-dimensional model Rubar20. The code Rubar20 used a finite volume scheme that is explicit, Godunov-type and second order accurate (Paquier 1995). It solves the 2-dimensional shallow water equations which are written below:

$$\frac{\partial h}{\partial t} + \frac{\partial hu}{\partial x} + \frac{\partial hv}{\partial y} = 0 \tag{2}$$

$$\frac{\partial hu}{\partial t} + \frac{\partial (hu^2 + gh^2/2)}{\partial x} + \frac{\partial huv}{\partial y} = - gh\frac{\partial Z}{\partial x} - g\frac{u\sqrt{u^2+v^2}}{K_s^2 h^{1/3}} + K\left(\frac{\partial}{\partial x}\left(h\frac{\partial u}{\partial x}\right) + \frac{\partial}{\partial y}\left(h\frac{\partial u}{\partial y}\right)\right) \tag{3}$$

$$\frac{\partial hv}{\partial t} + \frac{\partial huv}{\partial x} + \frac{\partial (hv^2 + gh^2/2)}{\partial y} = - gh\frac{\partial Z}{\partial y} - g\frac{v\sqrt{u^2+v^2}}{K_s^2 h^{1/3}} + K\left(\frac{\partial}{\partial x}\left(h\frac{\partial v}{\partial x}\right) + \frac{\partial}{\partial y}\left(h\frac{\partial v}{\partial y}\right)\right) \tag{4}$$

In which u and v are velocities along respectively x and y axis, h water depth, Z bottom level, g gravity acceleration, K_s Manning Strickler coefficient, K the viscosity coefficient.

4.2 *Mesh, topography and friction coefficient*

The mesh may be constituted of quadrangles or triangles which have 0 or 1 common edge. To build the mesh we used linear interpolation in the stream direction and finer cells where the topography was complex. The reach is approximately 600 m long and 50 m wide, the mesh (named *final mesh*, Figure 5) has 1124 cells, in average the dimensions of cells are 5 m × 5 m, with smaller cells where topography had to be more precise.

The Manning Strickler coefficient of each cell, K_s, came from a survey of the surface grain size composition of the bed. At each topographic point we assessed the main grain size class, then measurements were converted in Manning Strickler coefficients using the formula (from Modeleur, INRS-ete):

$$K_s = \begin{cases} 19.6 & \text{if } d_{50} > 0.7 \text{ m} \\ 34.9(log(\frac{1}{d_{50}}))^{0.31} + 0.0017 & \text{else} \end{cases}$$

where d_{50} is the weighted average of diameters of each of the p grain size class: $d_{50} = \sum_{i=1}^{p} w_i d_i$, and d_i is estimated owing to the bound diameters of grain size class i: $d_i = \sqrt{b_i b_{i+1}}$.

Then K_s was linearly interpolated on a regular mesh made of triangles of 2 m side and interpolated again on the final mesh.

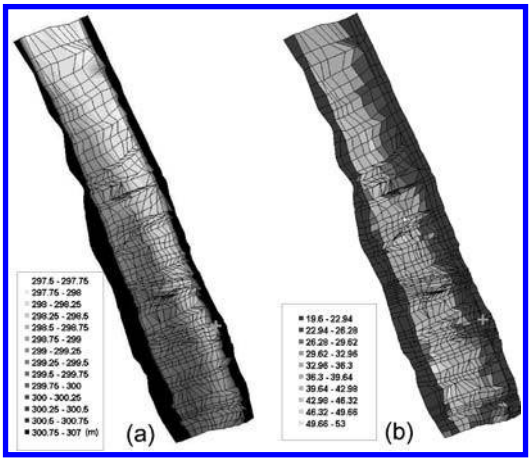

Figure 5. Mesh used for the numerical simulation (*final mesh*). (a) Topography and (b) Friction coefficient map. The cross mark locates the DIVER.

4.3 *Boundary conditions*

One-dimensional model Rubar3 was used to convey the hydrograph from the downstream dam to the reach of interest 18 km downstream. This model has been developed by Cemagref, it solves one-dimensional St Venant equations (Paquier 1995). Cross sections are based on previous topographic campaigns (2000–2001) and the model was calibrated and validated on two major floods (September 1993 and October 2000). Figure 6 shows the hydrographs at the dam, at the upstream boundary of the reach and the simplified hydrograph used as upstream boundary condition.

Water levels at upstream and downstream limits were fitted according to water level measurements made in the middle of the reach (near the right bank, DIVER measurements) and at the bridge. Water level at the downstream boundary has a limited impact on the flow features upstream.

Some simulations were also run at permanent discharges fitting with some times of the hydrograph.

5 RESULTS

5.1 *Sediment transport, erosion and deposit patterns*

The topography of the bar changed during the flushing flow. Our visual observations showed a widening of the main channel, i.e. where flow concentrates along the right bank, deposition of small gravels ($d_{50} \approx 1$ cm) on the upper left part of the bar, and several cross-bar channels appeared due to high erosion processes. Owing to the fixed marks (concrete reinforcing bars) erosion was observed near the left dike (up to 40 cm of gravel erosion) and downstream the bar. At a particular point in the middle of the bar we noted 20 cm of gravel deposit. We tried to use our topographic survey to specify these few observations. Topographic data of the bar before and after the flushing event were interpolated on the same grid. Unfortunately our topographic survey did not contain enough points to enable an accurate comparison between both states. Nevertheless it confirms fixed marks measurements.

We were also interested in the evolution of the suspended sediment concentration (Figure 4). The ssc evolution at site A is almost similar to ssc evolution downstream the nearest dam. Shape of both graphs are comparable except for a time lag of 2:20 between peak concentrations and higher values of ssc at site A in the rising phase of the flushing event. The time lag is close to the time lag of the maximum peak discharge estimated by the 1D simulation. In addition, at site A, the peak of ssc was reached approximatively at the same time as the maximum discharge. It means that at this point of the river there was no time lag between ssc peak and discharge peak.

According to common sens, the ssc peak (15.43 g/l) 18 km downstream from the dam at site A was lower than the ssc peak (30.02 g/l) at the dam. There may be some deposits in between, but suspended sediment concentrations remained high compared with the concentration before the event (less than 1 g/l).

Higher values of ssc in the rising phase of the flushing event may be due to some contribution from the Arvan tributary. This stream is a significant source of fine sediments. The first high values of ssc may be due to re-erosion of previous deposits in elevated parts of the river channel as well.

Before the flushing event fine sediments were mainly found along the left bank where water flow was stiller, on the bar tail and in the wake of vegetation. Our observations following the event showed a quasi-uniform deposit of fine sediment on the whole surface of the bar, some large (several cm) and localized deposits along the right side of the bank at the boundary with the flow, no deposit along the left bank, large deposits in the wake of vegetation and in the wake of prominent gravels and deposits on the bar tail. These observations fit with the typology of fine sediment deposits developed in (Wood and Armitage 1999). They classified deposits into five classes:

- Marginal deposits associated with reduced flow velocities at the channel margin (most stable and permanent deposits).
- Depression deposits where topography created a small hollow(relatively unstable).
- Macrophyte deposits associated with the presence of plants.
- Obstruction deposits in the lee of larger substrate clasts or debris and extensive deposits located downstream of macrophyte beds
- Fine surficial laminae deposits associated with baseflow conditions.

5.2 *Simulation Results*

We compared the results from the 2D calculation with the measurements from the DIVER (Figure 7). A spatial and a time lag can be observed. The time lag may come from the routing of hydrograph by the one-dimensional model; the friction coefficient for the 1D model will be adjusted to take into account this time lag. There are three possible reasons to explain the spatial lag between hydrographs. First, the discharge hydrograph, and particularly the peak discharge, could have been underestimated because the rating curve at the gates of the dam was not calibrated when there is a transition between subcritical and supercritical flows. That would explain an under-evaluation of the peak discharge value. Second the friction bed coefficient (K_s) in the main channel can be too low although it was fitted with grain size of bed sediments; to test this hypothesis further calculations will be done with higher Manning Strickler coefficient for the part of the bed where the flow concentrates (near the right bank). Third there may be some minor errors due to

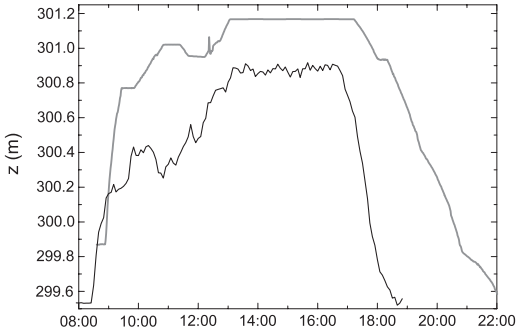

Figure 7. Water level measurements from the DIVER (thin black line) and water level from 2D simulation in cell 324, topographic location of the DIVER (bold gray line).

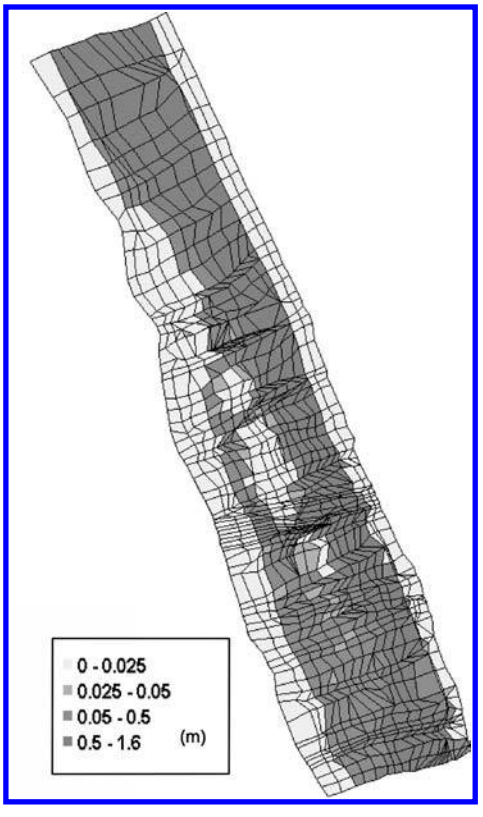

Figure 8. Water depth at 9:02 ($Q \approx 19 m^3/s$), water pattern fits with observations.

interpolation of the topography leading to reduced widths of the channel, which consequently leads to an over-evaluation of the water level.

Moreover the 2D calculation well reproduced water patterns observed during the flushing event. Figure 8 is the water depth at 9:02, it highlights the effect of

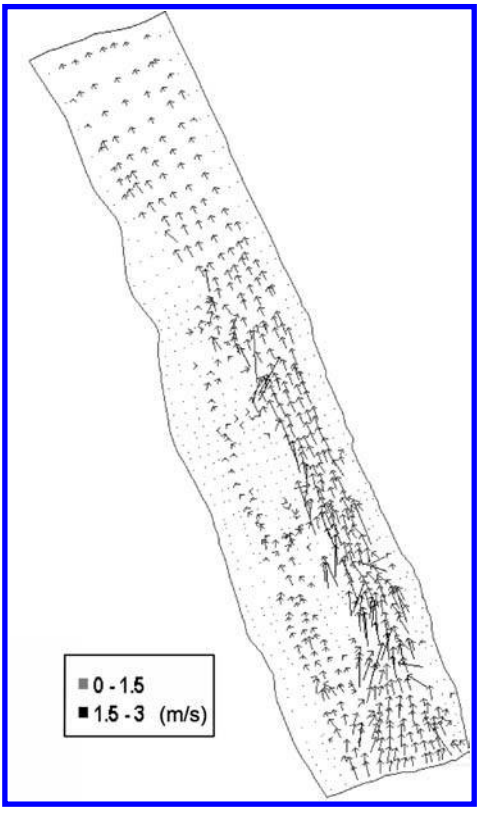

Figure 9. Velocity field at 8:59, during the rising phase, $Q \approx 19 m^3/s$.

cross-bar channels linking the upper left side of the bar with the main channel.

Velocity fields from the two-dimensional simulation were analyzed. At peak discharge, velocities in the river are lower than 6 m/s, but the mean velocity is approximately 3 m/s (Figure 10); maximum simulated water depth at this time is 2.5 m, all the channel is underwater. It fits with the observations: at 12:00 we estimated the mean surface velocities around 4.8 m/s (paragraph 3.2). It must be kept in mind that these velocities represented an assessment of the mean surface velocity of floating objects; they may be characteristic of water surface velocity in the main channel, but it is quite difficult to extrapolate from these values the mean velocity of the flow. These high velocities and high depths involve high shear stress, which explains why we observed gravel movement (see previous paragraph 5.1 for gravel erosion/deposition patterns). During the falling phase of the flushing event (Figure 9), we observed low velocities on the left side of the bar; it explains that the grain size of gravels we found in this part of the study area was lower.

Copyright © 2006 Taylor & Francis Group plc, London, UK

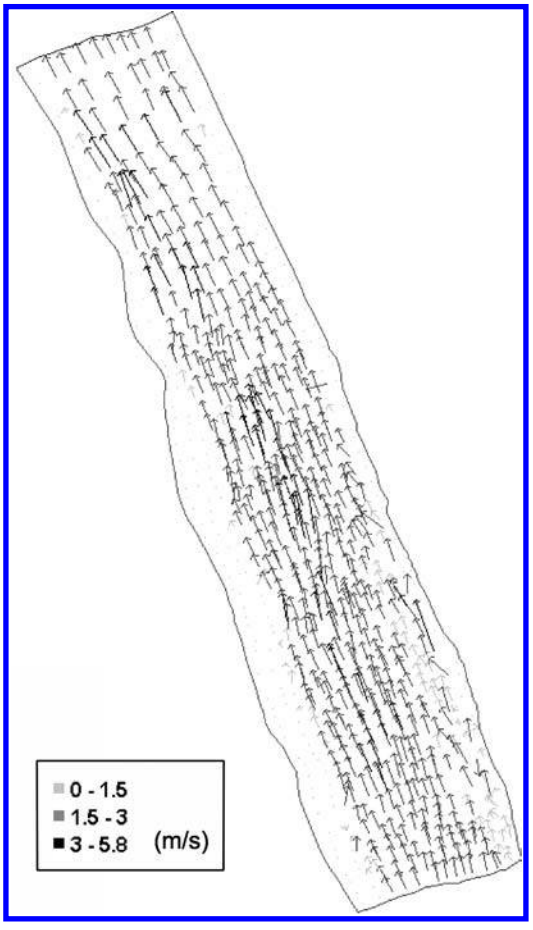

Figure 10. Velocity field at 13:54, at the peak discharge, $Q \approx = 139\,m^3/s$. Note that, for the sake of clarity, velocity field is not scaled the same way as previous figure.

6 CONCLUSION

This paper is essentially based on in situ measurements, visual observations made during a flushing event and comparisons with 2D simulation. Our field measurements provided evidence that the gravel bar we focused on underwent topographic and grain size change. Analysis of the topographic measurements revealed gravel erosion and deposition patterns along the bar. Along the right bank, there was erosion while deposition occurred along the left margin of the bar. More precisely, deposition patches of fine sediments were observed at several places along the bar. This first field campaign rise our awareness on the point that it requires more accurate measurements. Our field survey will be improved to quantify additional parameters, several discharges will be measured from the bridge, topographic surveys will contain more points.

Two-dimensional hydrodynamic modeling permits to reproduce the flushing event in the studied reach. We identify times and zones of high/low velocities. Results from the two-dimensional calculations seem to match with observations of gravel and fine sediment erosion and deposition areas. To improve our understanding of sediment processes, we consider using 2D hydrodynamical modeling with sediment transport modeling.

This presentation is one step toward a more comprehensive study of the phenomena that occur in the vicinity of an alternate bar during flows with high fine sediment concentration. In rivers, bars constitute a place where fine sediments could be stocked, consequently they may be an important component of the river suspended sediment budget. The intent of this study will be to project our observations and conclusions at the bar scale to the whole river.

ACKNOWLEDGMENTS

Authors would like to thank to EDF GEH Maurienne for providing the discharge data and flushing event reports, Cemagref technicians (G. Dramais and F. Thollet) for the field work and J. Lelouvetel for having set up the one-dimensional model of the Arc River.

ECOMSED – Three dimensional modeling in rivers

M.A. Mekonnen & B. Dargahi
KTH, Royal Institute of Technology, Stockholm, Sweden

ABSTRACT: The 3-D hydrodynamic and sediment transport model ECOMSED was adapted to simulate flow and sediment transport in rivers. A bed load transport model was included in the code. Improvements in treatment of river roughness parameterization, bed form effects, and automatic update of flow depth due to bed evolution were also made. The model was applied to 1-km long reach of the River Klarälven, located in the county of Värmland, Sweden. The model successfully predicted the general flow patterns and sediment transport characteristics of the river reach.

1 INTRODUCTION

Recent research works on 3-D river flow modelling include: Weerakoon and Tamai (1989), Olsen and Stokseth (1995), Weiming *et al*. (1997), Sinha *et al*. (1998), Lane *et al*. (1999), Bradbrook *et al*. (2000), and Chau and Jiang (2001). Olsen and Stokseth (1995) carried out a 3-D simulation of an 80-m long reach of the river Sokna in Norway. The model successfully simulated the flow features and its results were in good agreement with observed data. Sinha *et al*. (1998) did a comprehensive numerical study of the flow through a 4-km reach of the Columbia River. They succeeded in modelling rapidly varying bed topography and the presence of multiple islands. The results agreed well with experiments and field measurements. In a recent study, Bradbrook *et al*. (2000) used Large Eddy Simulation (LES) to model the flow in a natural river channel confluence. The model simulated periodic flow features in river confluences and agreed well with experimental data.

Some recent applications on use of 3-D sediment transport models are those by Gessler *et al.* (1999), Holly and Spasojevic (1999), Fang (2000), Rodi (2000), Weiming *et al*. (2000), Nicholas (2001), and Dargahi (2004). Gessler *et al*. (1999) applied the U.S. Army Corps Engineering code CH3D-SED to the Deep Draft Navigation project on the lower Mississippi River. The code predicted the sediment deposition in the river with an accuracy of less than 13% in comparison with the observations. Holly and Spasojevic (1999) applied and verified the CH3D-SED code to study water and sediment diversion at the Old River Control complex on the lower Mississippi river. Dargahi (2004) predicted secondary flows and the general flow and sediment transport patterns in a river that agreed well with field measurements. A brief review of the major developments in 3-D modeling and the limitations is given by Lane *et al*. (2002).

In this study ECOMSED, 3-D hydrodynamic and sediment transport model by Blumberg and Mellor (1987), was improved and adapted for modeling flow and sediment transport in rivers. The model was originally developed for large water bodies such as lakes and oceans. ECOMSED solves the RANS equations along with a second order turbulence model. A bed load transport model was included in the code. Improvements were also made in the treatment of river roughness parameterization, bed form effects, and automatic update of flow depth due to bed evolution. The improved model was applied to 1-km long reach of the River Klarälven, located in the county of Värmland, Sweden. The water surface and the flow division in the channels were made to agree with field data by specifying a spatially variable bed roughness depending on the local grain size distribution of the river reach and the local flow. The erosion and deposition patterns agreed with observed trends in the river reach.

2 MODIFICATIONS AND IMPROVEMENTS

2.1 *Roughness parameterization*

ECOMSED uses the logarithmic law of the wall as the bottom velocity boundary condition. The bed roughness for the whole computational domain is represented by a constant roughness parameter z_0, distance from the bed where the velocity assumes a zero value. However, in rivers bed roughness varies both spatially and temporally. Model calibration and model

Copyright © 2006 Taylor & Francis Group plc, London, UK

validation of a river reach was found difficult with a constant z_0 value. The specification of the parameter z_0 was modified in the ECOMSED code to vary spatially depending on the local bed roughness and local flow condition. The local bottom roughness is represented by the local equivalent sand roughness (k_s) that is composed of grain and bed form roughness. The grain roughness was taken as αD_{90} where D_{90} is particle diameter for 90% finer of bed material; and the coefficient α was varied between the recommended values of 3 to 5 during calibration of the water surface profile. Field studies showed that the bed of the river reach is composed of three dimensional ripples. The equivalent sand roughness due to ripples was calculated according to Grant and Madsen (1982)

$$k_s = 27.7\frac{\Delta^2}{\lambda} \quad (1)$$

In which Δ is bed form height; and λ is bed form length.

2.2 *Shear stress partitioning*

The other modification made was shear stress partitioning to extract the effective part of the stress that contributes to sediment transport. The effective shear velocity (u'_*) for the lower flow regime (ripples and dunes) was calculated by using the flow resistance relationship by Engelund and Hansen (Yang 1996).

$$u_*' = \left(0.06g(s-1)D_{50} + 0.4\frac{u_*^4}{g(s-1)D_{50}}\right)^{0.5} \quad (2)$$

In which D_{50} is particle diameter for 50% finer of bed material; g is the gravitational acceleration; and s is specific density. The transport stage parameter, T which is used for the computation of suspended and bed loads was calculated using the effective shear velocity (van Rijn 1984a and van Rijn 1984b)

$$T = \left(u_*' / u_{*cr}\right)^2 - 1 \quad (3)$$

In which u_{*cr} is the critical bed shear velocity which was calculated using the Shields curve for initiation of motion. The critical shear velocity was also corrected for the bottom and side slopes according to Chien (1999).

2.3 *Bed load transport and bed evolution*

ECOMSED considers only suspended sediment transport as the contribution of bed load movement in large water bodies such as lakes and oceans is insignificant. However, the bed load contribution can be considerable in the case of rivers. Thus a realistic modeling of sediment transport would require the implementation of the bed load transport. This was done by including the bed load in the sediment mass-balance equation for the bed evolution.

$$(1-p)\frac{\partial z_b}{\partial t} + E - D + \frac{\partial \alpha_{b\xi_1} q_b}{\partial \xi_1} + \frac{\partial \alpha_{b\xi_2} q_b}{\partial \xi_2} = 0 \quad (4)$$

In which E – D is the sediment flux at the water sediment interface which is calculated using the van Rijn (1984a) procedure; q_b is the actual bed load transport; p is the porosity of the bed material; $\alpha_{b\xi 1}$ and $\alpha_{b\xi 2}$ are the direction cosines in the orthogonal curvilinear coordinates ξ_1 and ξ_2, respectively. Rodi's (2000) formulation was used for the bed deformation.

$$(1-p)\frac{\partial z_b}{\partial t} = \frac{1}{L_s}(q_b - q_{b*}) \quad (5)$$

In which $q_b{}^*$ is the equilibrium bed load transport; and L_s is the non-equilibrium adaptation length for bed load transport. According to van Rijn (1984a)

$$q_{b*} = 0.053[(s-1)g]^{0.5} D_{50}^{1.5} \frac{T^{2.1}}{D_*^{0.3}} \quad (6)$$

$$L_s = 3D_{50}D_*^{0.6}T^{0.9} \quad (7)$$

$$D_* = \left[\frac{(s-1)g}{\upsilon^2}\right]^{1/3} D_{50} \quad (8)$$

In which D_* is the dimensionless grain size; and υ is the fluid dynamic viscosity. First order upwind scheme discretization of the equation produced by the combination of equations (4) and (5) resulted in a tri-diagonal matrix which was solved using the modified strongly implicit procedure of Stone (1968). The bed evolution was evaluated using the leap-frog method using equation (5).

3 MODEL APPLICATION

The improved model was applied to the River Klarälven. The River Klarälven enters Sweden in the north of the county of Värmland. Its course in Värmland is south down to the river mouth on lake Vänern at the city of Karlstad where it bifurcates into an east and west channels. A one kilometre long reach of the river was modelled that extends 0.5 km upstream of the bifurcation (Figure 1). To insure uniform inlet boundary conditions, the upper limit of the reach was placed in a straight river section. The river topography was measured in April 2004 at 11312 points through the

Copyright © 2006 Taylor & Francis Group plc, London, UK

river reach. The mean measurement resolution range was 2 m–6 m.

The flow discharges at the inlet and the two outlets defined by east and west channels were measured. Point velocity measurements were also taken at the inlet at 10 m spanwise intervals and at 0.5 m intervals in the vertical direction (all field measurements were taken by the local authorities of the Karlstad city municipality). The wake law was used both to determine the bed shear velocities and to specify the velocity profiles. The observed water levels at the outlet of the east and west channels were specified. Equilibrium bed load and zero suspended sediment concentration were used at the inlet boundary as sediment load data was not available.

3.1 *Grid generation*

The numerical model was built using the interpolated bottom topography (Figure 1). The horizontal orthogonal curvilinear grid was generated by CCHE2D mesh generator using the Poisson scheme with smoothness and orthogonality of 91 and 95%, respectively. The average grid spacing in the computational domain was about 6.0 m. The grid spacing around the bifurcation and around the bends was made finer with an average spacing of 2.0 m.

3.2 *Model calibration*

The model was calibrated for a discharge of 285 m^3/s using the measured water surface profiles and discharge division between the two river channels. The percentage of the discharge into west and east channels were 42% and 58%, respectively. Model calibration was done for a grid number of $126 \times 48 \times 9$ by spatially varying the roughness to satisfy both the water division and the water surface profile. The normalized error in the computed flow division was 0.8% (West channel) and 0.6% (east channel) while the normalized error in the water surface varied from 0.14% to 3%.

3.3 *Grid independence*

A grid dependency study was carried out to minimize numerical errors due to coarse discretization. In the horizontal direction the number of grids was constrained by the available resolution of the bottom topography. The deviation of results from the corresponding observed values is summarized in Table 1 for different number of layers. The normalized errors for a resolution of $126 \times 48 \times 9$ were found to be acceptable.

Table 1. The change in the normalized errors as the number of vertical layers is increased.

Number of layers	Normalized error in water surface [%]	Normalized error in flow [%]		Normalized error in bed shear stress
		West	East	
5	0.20–5.0	0.60	0.40	
7	0.17–4.0	0.66	0.48	>= 10%
9	0.23–5.0	0.58	0.42	>= 3%

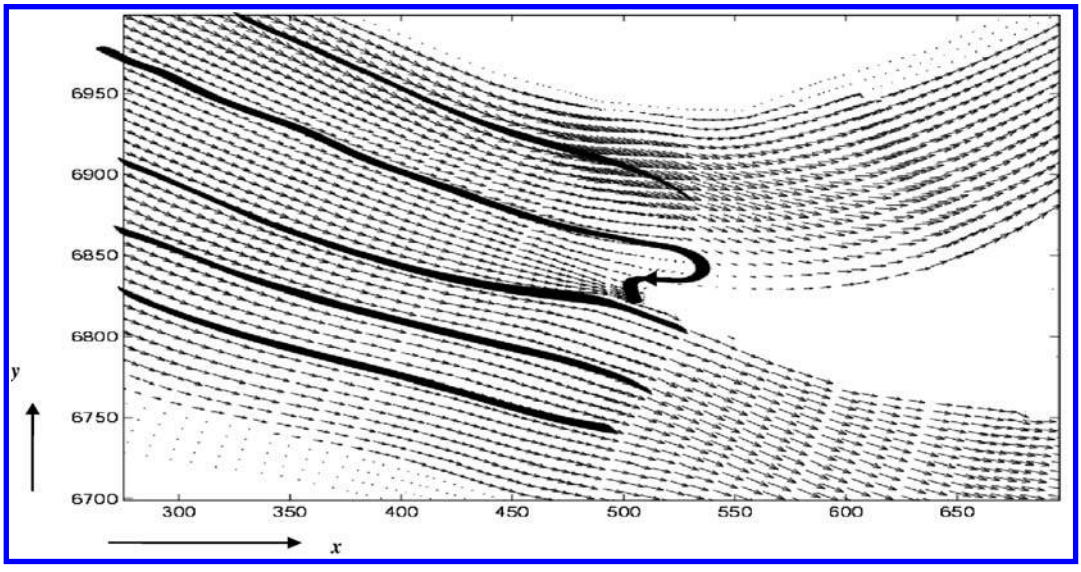

Figure 2. Simulated velocity vectors and observed tracer path lines (solid lines) used for model validation (x, y in meters).

3.4 *Validation*

A comprehensive validation of the model would require extensive field data on water surface profiles, velocity profiles, secondary flow structures and flow circulation regions. For this study limited data were available at two different discharge values of 285 m^3/s and 136 m^3/s. The model was validated with the field data for 136 m^3/s by using the roughness distribution obtained during the calibration analysis. In comparison with field data, the normalized error in the observed water surface profile varied from 0.11% to 1.33%. The normalized error in the flow division was 2.44% for the west channel and 1.56% for the east channel. Regarding the flow field, stream lines and the local flow circulation region upstream of the river bifurcation agreed with the field observations (Figure 2).

4 RESULTS AND DISCUSSION

Flow field: The flow field in the river was successfully simulated by the improved model that included the water surface profiles, velocities, secondary flows, and bed shear stresses. Figure 3 shows the contour lines of the water surface profiles. In the bifurcation region the local increase in water surface elevation is shown. The model also predicted the transverse water-surface slope at the river bend in agreement with the physics of the helicoidal secondary flows. A general flow diversion from the main channel to the east channel was detected that explains the larger portion of the total flow entering the east channel.

Secondary flows: The general patterns of the secondary flows in the vertical planes are given in Figures 4(a-d) where the velocity vectors, velocity contours and the interpolated secondary flows are shown. The spiral motions (helical cells) are shown by circles with rotation direction indicated by arrow. The number of cells increases as the river bifurcation region is approached. In comparison with the other regions of the flow, the bifurcation sections had a greater spatial variation implying an increase in secondary flow cells. The general patterns agree with Dargahi's (2004) finding, although he reports a higher number of cells especially in the river bends. The difference between the present results and his results can be explained partly by a higher grid resolution, and partly by his use of different turbulence model.

Sediment transport: Data for discharge hydrographs were not available and the sediment transport simulation was made for an observed steady flow of 285 m^3/s. The bed shear stresses were computed both as total and as effective stresses. Figures 5 and 6 show the two cases, respectively. The distributions of shear stresses are similar for both cases although the magnitudes of total shear stresses are about four times higher than the effective shear stresses. As the bed shear stress is the primary agent for sediment transport, the difference in magnitude is important. The results emphasize the need of shear stress partitioning for realistic sediment transport computations. In comparison with west channel, the shear stresses are higher in the east channel as well as in the deep region of upstream channel. The lower shear stress regions correspond to the area with little sediment transport activities.

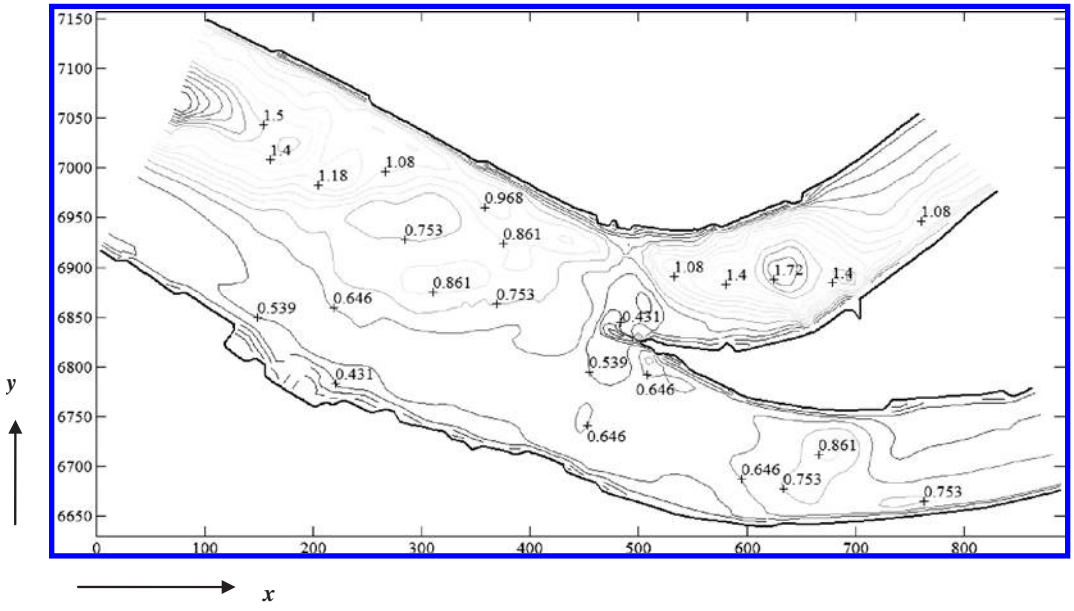

Figure 6. Effective shear stress distribution in Pascal (x, y in meters).

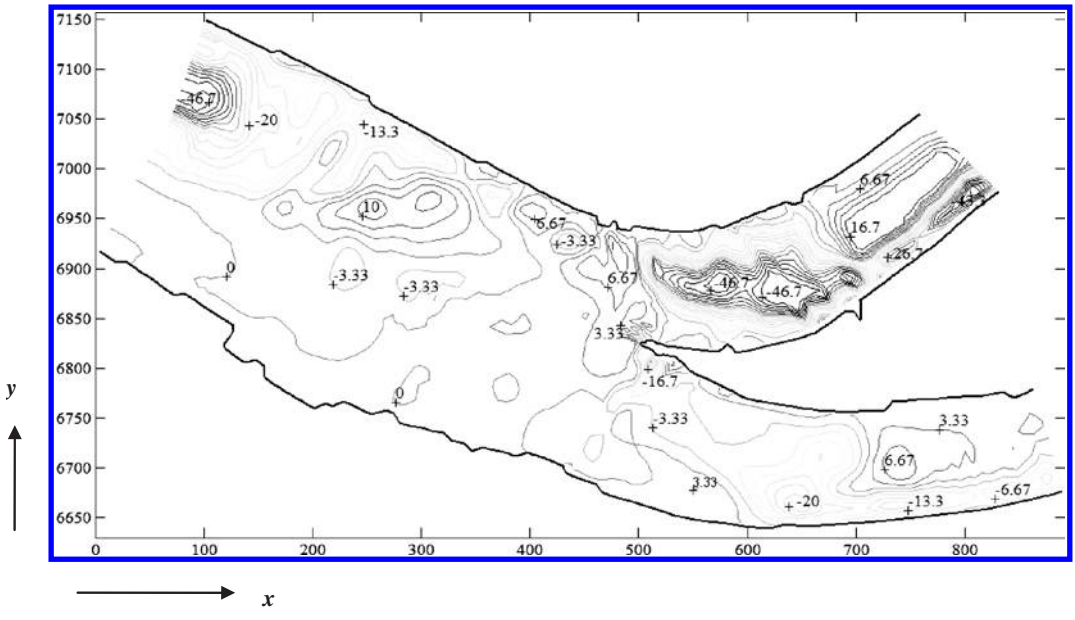

Figure 7. Predicted bed level changes in mm after 2 hours, -ve sign indicates erosion (x, y in meters).

The sediment transport simulation was run for 2 hours which was enough to reach a 'quasi' steady state solution. The general pattern of bed changes after 2-hours is shown in Figure 7. The figure shows the contour lines expressed in the units of millimeter (erosion in negative sign). The main features are the tendency for formation of a new sandbank at the entrance to the east channel and the division of the main channel into two regions of erosion and deposition. The model predicted the classical erosion patterns observed in the river bends. The maximum erosion depth was 46.7 mm, which occurred in the east channel

Copyright © 2006 Taylor & Francis Group plc, London, UK

near the concave curve. A similar trend was found in the west channel bend although the maximum erosion was 20 mm.

5 CONCLUSION

The study led to a number of improvements that should increase the applicability of ECOMSED model to rivers. These are

- Treatment of river roughness parameterization.
- Bed shear stress partitioning.
- Addition of bed load transport model.
- Automatic update of bed evolution.

The improved model successfully predicted the general flow patterns and sediment transport characteristics of the river reach. The adapted model is shown to be a useful tool for determining alluvial-channel response to changes in flow and bed sediment conditions. The model can also be a potential alternative to the expensive CFD commercial codes that have two main disadvantages: commercial codes are not primarily developed for rivers, and they give only a "black box" approach that hampers detailed adjustment of the code.

3D modeling of transient bed deformation in a sine-generated laboratory channel with two different width to depth ratios

N. Rüther & N.R.B. Olsen
Department of Hydraulic and Environmental Engineering, Norwegian University of Science and Technology in Trondheim, Norway

ABSTRACT: A three dimensional numerical model is presented to calculate the sediment transport rate and the corresponding transient bed changes in sine-generated meandering laboratory channels. Transient flow pattern as well as bed movements in simple bended laboratory channels have been successfully modeled with 2D and 3D numerical models before. However, when it comes to the successive formation of meander bends, the spatial propagation of the helical flow and its effect on the bed deformation is not fully understood yet. It is strongly depending on the deflection angle Θ of the meander bend and the width to depth ratio of the channel. In addition to this geometric characteristic, bed forms were prevailing in the experiments. The present study showed how a three dimensional numerical model is able to calculate the flow field and the sediment transport in a sine-generated laboratory channel with two consecutive meander bends and occurring bed forms.

1 INTRODUCTION

Water flow and sediment transport in meandering river is of high interest in the field of river engineering. The major local erosion in river bends under steady or unsteady flow conditions is causing huge problems to the riverine structures. Prediction of the time-dependent bed changes and the lateral bed load transport with the corresponding lateral migration with the help of computer programs is becoming more and more popular. The major problem herein is the fact that the flow field in river bends is highly three-dimensional. The flow is dominated by transverse secondary currents. The sediments are eroded by the accelerated flow at the outer part of the bend and transported by the secondary currents to the inner part. Here they tend to deposit due to the reduced velocity and shear stress, forming a so called point bar. This effect is highly depending on the geometry of the channel, e.g. deflection angle of the bends or number of consecutive bends, and also on the width to depth ratio of the channel. With the increasing computer power over the last 15 years, it is now possible to carry out fully 3D computations for such cases. Demuren & Rodi (1986) used a three dimensional model where the turbulence was predicted by the k-ε model, to calculate the flow and the transport of a neutral tracer in a meandering channel. Recently, Wilson et al (2003) computed the fully developed three dimensional velocity distributions in a meandering channel over a fixed natural bed and showed good agreement with measurements. Ruether & Olsen (2005) computed the bed changes over time in a sharply bended 90° channel with special respect to steep transversal slopes. Wu et al (2000) computed the flow in a 180° bend including suspended and bed load transport. Zeng et al (2005) computed the bed changes in a 180° bend, too. All of the results showed good agreement with measured data. Bed forms did not occur in any of the previous studies.

The present study focused on the simulation of the bed changes in a laboratory channel with sine-generated consequent bends, deflection angle $\Theta = 70°$, and prevailing bed roughness caused of bed forms, like dunes and ripples.

2 SEDIMENT TRANSPORT IN MEANDERING CHANNELS; EXPERIMENTAL DATA

The laboratory data used in the present study were taken from da Silva & Tarek (2006). Movable bed experiments were carried out in a sine generated channel. The 0.8 m wide flume was filled with sand of the size of $D_{50} = 0.65$ mm of about 0.2 m and steady, uniform flow was established. The sediments were relatively well sorted with a ratio of D_{60} to D_{10} of 1.89. There was not sediment feed at the inflow. The measured data for two experimental runs were then compared to the numerical simulation. The two different experiments were denoted Run 1 und Run 5 where the bed changes were measured after 60 min and 170 min for Run 1 and 5, respectively.

Table 1. Hydraulic conditions of the experiments.

	Exp-1	Exp-5		Exp1	Exp-5
Q [m^3/s]	0.011	0.0076	u^* [m/s]	0.04	0.042
B [m]	0.8	0.8	B/h_{av} [−]	10.67	18.18
h_{av} [m]	0.075	0.044	Re^* [−]	53	54
S [−]	1/450	1/250	Re [−]	13750	9475
u_{av} [m/s]	0.18	0.22	T [min]	60	170

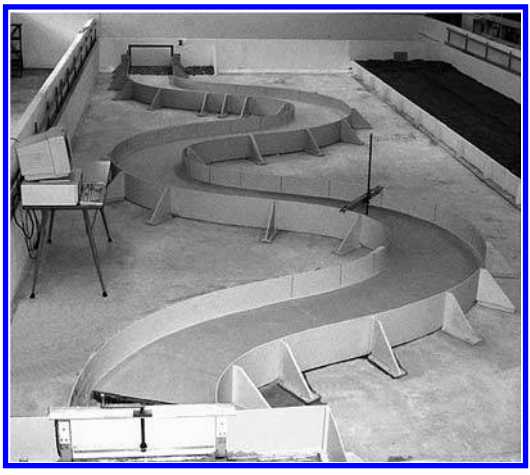

Figure 1. Experimental set up (da Silva & Tarek, 2006).

As it can be seen from table 1, the most significant difference of the two experiments is the width to depth ration of 10.67 and 18.18, respectively. For both experiments, the hydraulic conditions are listed in table 1. Figure 1 shows the experimental setup. The flow is top to bottom. (In the then following Figures the flow is from left to right). In order to establish uniformity, a tailgate at the downstream end of the channel was slightly adjusted. The water level was then controlled at the centerline in three cross sections of the geometry. The bed changes were observed to develop in the early beginning of each run.

According to the different hydraulic setups, two different bed patterns were observed. The bed deformation in Run 1, depicted in Figure 3 can be described in the following way: The locations of the deepest erosion were determined to be in the two cross over parts of the flume. Point bars developed at the inner side of each of the apex, growing with the increasing downstream coordinate. The magnitude of the bed changes over time was in the range of −0.12 m and +0.4 m. In addition one can see that the location of the maximum erosion and deposition in each of the bends were not located in the same cross section.

The bed deformation in Run 5 is depicted in Figure 5. The areas of maximum erosion are located at the outside end of each of the bends with a maximum

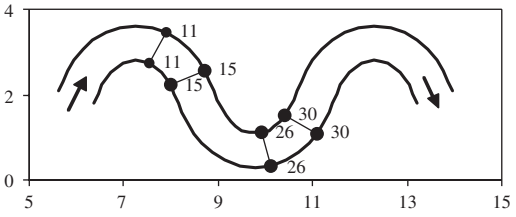

Figure 2. Location of the compared cross section.

bed change of −0.12 m. Similar to Run 1, the characteristic point bars developed and grow with the downstream, increasing coordinate. Where as the scour in the most downstream cross section was with −0.08 m less deep than the scours further upstream. In opposite to Run 1, the location of the maximum erosion and deposition were found to be in the same cross section, just slightly downstream of the apex.

Figure 2 shows the location of the cross section being compared. Cross section 11 and 15 are located right after the first bend and cross section 26 and 30 right after the second bend.

3 NUMERICAL SIMULATION OF TRANSIENT BED DEFORMATION

3.1 *Numerical model*

The flow field for the three-dimensional geometry is determined by solving the continuity equation and the Reynolds averaged Navier-Stokes equations:

$$\frac{\partial U_i}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial U_i}{\partial t} + U_j \frac{\partial U_j}{\partial x_i} = \frac{1}{\rho}\frac{\partial}{\partial x_i}\left(-P\delta_{ij} - \rho\overline{u_i u_j}\right) \tag{2}$$

U is the velocity averaged over the time t, x is the spatial geometrical scale, ρ is the water density, P is the pressure, δ is the Kronecker delta and u is the velocity fluctuation over time during one time step Δt. The control volume method was used as discretization method (Olsen 2004). The Reynolds stress term was modeled by the k-ε turbulence model. The model computed the turbulent stresses $\overline{u_i u_j}$, using the eddy viscosity relation:

$$-\overline{u_i u_j} = \nu_t\left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i}\right) - \frac{2}{3}k\,\delta_{ij} \text{ with } \nu_t = \frac{c_\mu \cdot k^2}{\varepsilon}, \tag{3}$$

where the turbulent kinetic energy k and its dissipation rate ε determining the eddy viscosity ν_t were obtained from the following equations:

$$\frac{Dk}{Dt} = \frac{\partial k}{\partial t} + U_j\frac{\partial k}{\partial x_j} = \frac{\partial}{\partial x_j}\left[\left(\nu + \frac{\nu_t}{\sigma_k}\right)\frac{\partial k}{\partial x_j}\right] + P_k - \varepsilon \tag{4}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

$$\frac{D\varepsilon}{Dt}=\frac{\partial\varepsilon}{\partial t}+U_j\frac{\partial\varepsilon}{\partial x_j}=\frac{\partial}{\partial x_j}\left[\left(\nu+\frac{\nu_t}{\sigma_\varepsilon}\right)\frac{\partial\varepsilon}{\partial x_j}\right]+C_{\varepsilon 1}\frac{\varepsilon}{k}P_k-C_{\varepsilon 2}\frac{\varepsilon^2}{k} \quad (5)$$

The production of turbulent kinetic energy P_k was defined as:

$$P_k=\nu_t\frac{\partial U_i}{\partial x_j}\left(\frac{\partial U_j}{\partial x_i}+\frac{\partial U_i}{\partial x_j}\right) \quad (6)$$

An implicit method was used for transient terms and the pressure field was computed with the *SIMPLE* method (Patankar, 1980). The Rhie and Chow interpolation (Rhie and Chow, 1983) was applied to compute the velocities and the fluxes at the cell surfaces. Zero gradient boundary conditions were used for all variables at the outflow boundary. The upstream velocities were defined by a Dirichlet boundary condition. Wall law functions for rough boundary introduced by Schlichting (1979) were used for the side walls and the bed. In the default configuration the model computes the bed roughness as a function of the grain size distribution on the river bed. This worked well in cases where the roughness is dominated by influence of the grain form. In cases where fine bed material prevailed and bed roughness is affected by bed forms such as dunes and ripples, this approach was not giving appropriate results. Instead, reasonable results were obtained by using the following approach. First the bed form height was calculated with an equation developed by v. Rijn (1984c). The value was depending mainly on the water depth y, the characteristic sediment grain d_{50} and the prevailing shear stress τ.

$$\frac{\Delta}{y}=0.11\cdot\left(\frac{d_{50}}{y}\right)^{0.3}\cdot\left(1-e^{-0.5\left(\frac{\tau-\tau_{c,s}}{\tau_{c,s}}\right)}\right)\cdot\left(25-\left(\frac{\tau-\tau_{c,s}}{\tau_{c,s}}\right)\right) \quad (7)$$

where Δ is the bed form height and $\tau_{c,s}$ the critical shear stress for each fraction. Then the bed form height is converted into bed roughness ks with the following equation.

$$ks=3.0\cdot d_{90}+1.1\cdot\Delta\cdot\left(1.0-e^{\left(\frac{-25\cdot\Delta}{7.3\cdot y}\right)}\right) \quad (8)$$

The bed forms calculated with Eq. 7 were not assumed to be equally distributed over the cross section. That fact resulted in a varying roughness in the plan form. A non-hydrostatic pressure approach was implemented, so the water surface elevation was determined from the computed pressure field, resulting in an authentic computation of lateral slope of the water surface in the bends.

Similar to the upstream boundary condition of the velocities, the boundary conditions for the inflowing sediment transport was specified with a Dirichlet boundary condition and zero gradients for the water surface, the outlet, and the sides. In the present study no sediment inflow was used; neither in the experiments nor in the numerical simulation. The boundary conditions at the bed are given by the sediment transport relations for bed load. In the default configuration of the model, fractional sediment transport was computed by the bed load transport formulas of v. Rijn (1984a) applied individually for each fraction.

$$\frac{q_{b,s}}{d_s^{1.5}\cdot\sqrt{\frac{(\rho_S-\rho_W)\cdot g}{\rho_S}}}=\zeta\cdot\frac{\left(\frac{\tau-\tau_{c,s}}{\tau_{c,s}}\right)^{1.5}}{d_s^{\,2}\left(\frac{\rho_S/(\rho_W-1)\cdot g}{\nu^2}\right)^{0.1}} \quad (9)$$

where $\zeta=0.053$ is used as the default value in the original equation.

The computational domain was subdivided into three layers, a water layer near the river bed, with a mixture of water and sediments, an upper sediment layer were the bed load is calculated, denoted active layer and a lower sediment layer, denoted inactive layer. When fractional transport was computed, sorting mechanisms were considered to happen in the active layer. The height of the active layer was kept constant, equally to the size of the largest grain in the sediment mixture. The height of the inactive layer is set to a large value in order to supply the active layer with the sufficient amount of sediments. The grain size distributions in the two bed layers were obtained by considering sediment continuity for each fraction.

Finally the bed changes were computed from sediment continuity in the bed cell, as the difference between the inflowing and out flowing sediment fluxes. The defect was converted into a vertical bed elevation by dividing it by the submerged density of the sediments, 1320 kg/m^3, to find the volume of the deposits for each time step. This volume was then transformed into bed level changes for the grid. Both the sedimentation and the erosion processes were modeled using the same approach.

For the simulation of the laboratory experiments described in chapter 2, the geometry needed to be discretized. A three-dimensional structured, non-orthogonal, vertically adaptive and curvilinear grid with a non-staggered variable placement was generated. 173 hexahedral cells in the stream wise, 16 cells in the lateral and 5 cells in the vertical direction were used. A time step of 5 seconds was chosen. After each time step, the water and the bed surface were updated.

For discretization of the initial sediment distribution the continuous bed sediment sieve curve was decomposed into five size fractions. Starting with the smaller fraction, the sediment mixture contains of 10% with a size of 0.3 mm. 20% of 0.45 mm, 20% of 0.58 mm, 20% of 0.7, 20% of 0.82 and 10% of 1 mm.

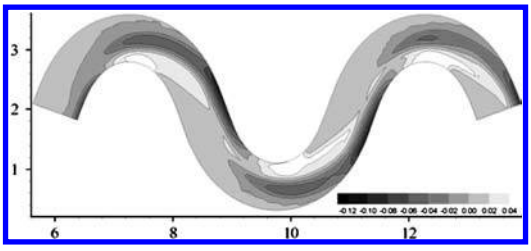

Figure 4. Calculated bed changes in Run 1.

3.2 *Results and discussion*

3.2.1 *Simulation results of Run 1*

Since the hydraulic performance of the present model was tested intensively in meandering channels (Wilson et al., 2003), the present study was focusing on the performance of predicting bed deformation only.

Two different laboratory setups were simulated. The hydraulic conditions of each experiment are described in chapter 2. The results are presented herein. Comparing the plan view of Run 1, depicted in Figure 3 for the experiments and in Figure 4 for the simulation, one can see the overall agreement with the measured data. The first two bends are characterized by a typical point bar at the apex, accompanied by a small scour in the center of the channel. The maximum scour was located further downstream, almost at the cross over, on the outside of the channel. Looking at simulated bed changes in the first two bends, one can see that the bed deformation was predicted well. The location of the maximum scours and bar positions matched. However there was some disagreement in the pattern of the last bend. In the experiment, the scour was located far more at the outside of the bend as in the previous two bends. This characteristic was not found in the results of the numerical run. So far there is no physical explanation for this longitudinal asymmetric bed development (da Silva, 2006).

The bed pattern observed in the plan view can also be shown in a longitudinal view. Figure 9 and Figure 12 show the left and the right side, respectively. One can see that the position of the maxima match well, but the absolute magnitude of the scours is slightly overestimated.

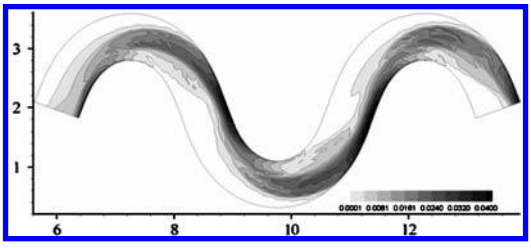

Figure 5. Calculated bed form height in Run 1.

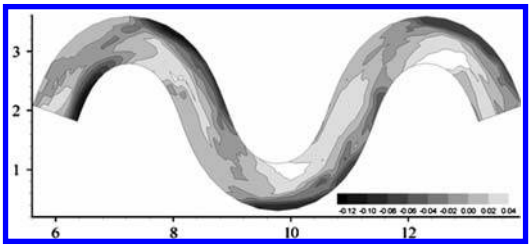

Figure 6. Measured bed changes in Run 5.

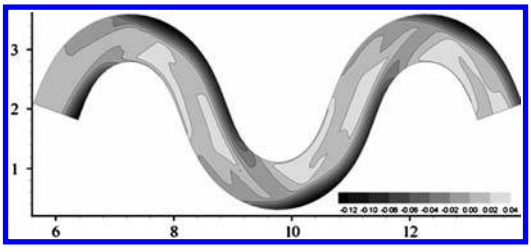

Figure 7. Calculated bed changes in Run 5.

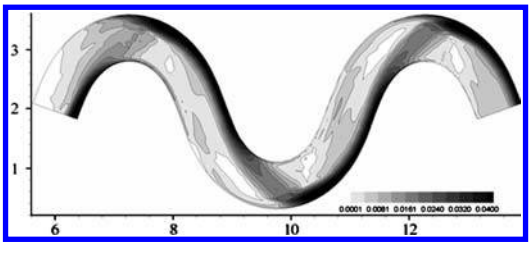

Figure 8. Calculated bed form height in Run 5.

The Figures 10, 11, 13 & 14 show the comparison of the data to the numerical results in the cross sections. Four cross sections are depicted. The locations of the cross section are shown in Figure 2. These cross sections were chosen since they were located where the maximum erosion was found in the experiments. One can see that especially in cross section 15 & 30 the calculated bed changes matched the measurements very well. In the Figures 10 & 11, one can see that the simulated scour locations were shifted towards the left channel side. The calculated bed form height is

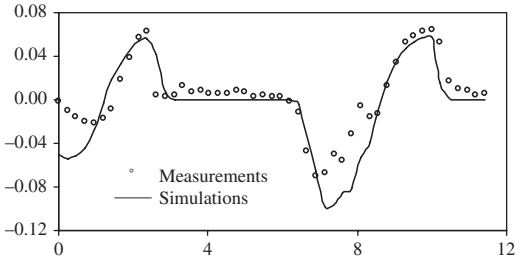

Figure 12. Run 1; Longitudinal view, right channel side.

illustrated in Figure 5. The bed form heights are not equally distributed over the width. The height varied from 0.1 mm to more than 4 cm. The highest values are simulated to be around the places where the maximum erosion occurred.

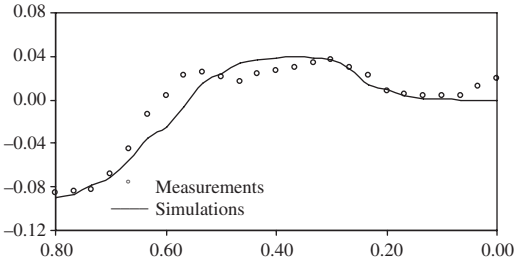

Figure 13. Run 1; Crossectional view, #15.

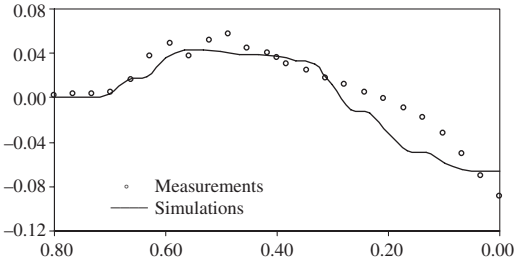

Figure 14. Run 1; Crossectional view, #30.

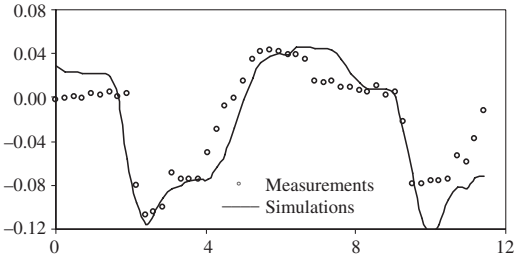

Figure 15. Run 5; Longitudinal view, left channel side.

3.2.2 *Simulation results of Run 5*

The plan views of the bed changes from the experimental and from the numerical model are depicted in the figures 5 and 6, respectively. As well as for the results in Run 1 one can see that the overall pattern matched. The magnitude of the bed changes also matched. However, the scouring in the longitudinal direction was over estimated. The scour spread too far downstream.

Figure 13 shows that the scour in the last bend is not as deep as the previous two bends. This characteristic is not reproduced by the numerical results. Otherwise one can see that the positions of the maxima are calculated to be at the same locations as in the physical model. From Figures 14, 15, 17 & 18 it is observed that the computed bed elevations at cross section 26 match particularly well with the measured data. Figure 14 & 17 show that the deposition pattern is slightly overestimated, but still being in reasonably good agreement

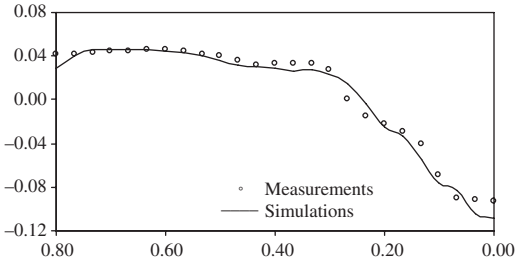

Figure 17. Run 5; Crossectional view, #26.

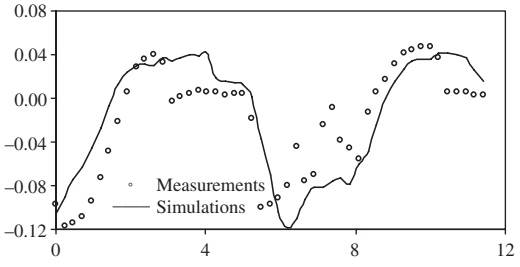

Figure 18. Run 5; Longitudinal view, right channel side.

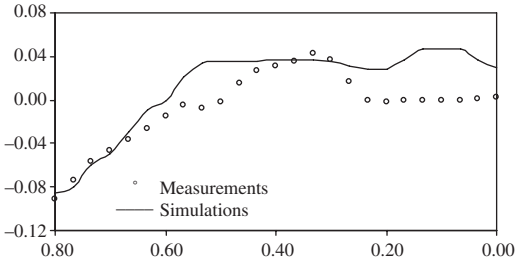

Figure 19. Run 5; Crossectional view, #15.

with the measured data. The distribution of the calculated bed form height in run 5 is depicted in Figure 8. Similar to Run 1, the bed form heights range between 0.1 mm and 4 cm. In areas with strong erosion, values of the more than 4 cm have been observed.

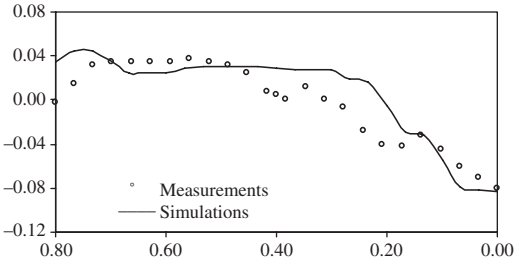

Figure 20. Run 5; Crossectional view, #30.

For Run 5, in the sediment transport capacity formula, the default value of $\zeta = 0.053$ was changed to $\zeta = 0.009$. This means that the sediment transport capacity had to be reduced to get reasonable results. One possible explanation could be the fact that the calculated bed forms are highly over predicted and consequently the bed load capacity, too. This is because the bed shear stress increases with increasing bed roughness. Sediment transport formulas and bed form predictors have uncertainties due to their empirical origin. Their prediction quality is strongly depending on the data the formulae were calibrated on. Since the roughness induced by bed forms and sediment transport are interacting, it would have been possible to modify the bed form predictor instead of modifying the ζ-coefficient in the transport capacity formula. However, more investigations about bed form development and their occurrence in meandering channels have to be done before any speculation about the physical process behind this phenomenon can be defined and adopted by a numerical model.

4 CONCLUSION AND RECOMMENDATIONS

The transient bed changes of a meandering laboratory channel with two different width to depth ratios have been successfully modeled. The calculated bed changes are in good agreement with the measurements for both cases. The numerical model was enhanced with a roughness approach taking into account the presence of bed forms. The results were very sensitive to the formulas for bed form height and bed roughness. The roughness approach seemed to be strongly connected to the development stage of a bed form and therefore to the sediment transport capacity. In the opinion of the authors there is more research needed for the universal implementation of a roughness approach taking bed form roughness into account. Furthermore, a wider range of the width to depth ratio should be tested in order to validate the present results. It seems that the width to depth ratio has a larger influence on the bed pattern in meandering channels as it is believed in literature today. To make any reliable

conclusion, the model should be tested on data from experiments with different deflection angles Θ, too.

ACKNOWLEDGEMENT

The authors would like to thank Dr. A.M. da Silva who was so kind to distribute the data used in this study and giving fruitful advices for a successful modeling of the data. In addition, the first author likes to thank the Norwegian Research Council for their support through the BeMatA Program.

ABSTRACT: Confluence-diffluence units are key elements within many river systems and present a complex and linked pattern of flow and sediment transport between these two nodes. Past work has seen much progress in our modelling of river confluences, and increasing attention is being paid to bifurcations and the important role of bifurcation asymmetry. However, most of these studies have been conducted in laboratory flumes or within small rivers (depths less than 3 m and widths <100 m). This paper presents a study of the bed morphology and 3D flow within a very large confluence-diffluence unit in the Rio Paraná, Argentina. The paper details the central scour within the reach and reveals that the flow within the confluence-diffluence is dominated largely by the bed roughness, and that the coherent secondary flow cells, that have been identified in smaller channels and assumed to be present within large rivers, are generally absent in this reach.

1 INTRODUCTION

The splitting and joining of channels is a fundamental and common process in many types of multi-channel rivers. Indeed this so called 'confluence-diffluence' unit is a key element within many fluvial networks and they are fundamental forms within braided, anastomosed, and distributary systems such as alluvial fans and river deltas (Slingerland & Smith, 2004). Such sites present a complex and linked pattern of flow and sediment transport though individual channel reaches. Indeed, channel confluence-diffluence units give rise to channel patterns themselves, and within meandering systems diffluences lie at the heart of the process of channel avulsion (e.g. Garcia & Nino, 1993).

The past 25 years has witnessed substantial efforts to understand flow processes, mixing, sediment transport and the influence of channel geometry at confluences (e.g. Ashmore et al. 1992, Best 1987, 1988, Best & Reid 1984, Best & Roy 1991, Biron et al. 1993, 1996, Bradbrook et al., 1998, 2000, 2001, Lane et al. 2000, Mosley 1976, Rhoads & Kenworthy 1998, Rhoads & Sukhodolov 2001). This focus has reflected the importance of river channel junctions as key components of both dendritic drainage networks and braided river systems, including their associated importance for sediment transport and channel change (Mosley 1976, Best 1987, 1988, Ashmore et al. 1992). There has been recent recognition that in the braiding process, the formation and control exerted by diffluences in governing the downstream partitioning of flow could be as, if not more important, than upstream confluence zones (e.g. Pittaluga et al. 2001, Frederici & Paola 2003). Indeed, all braided fluvial systems contain the fundamental confluence-diffluence unit (e.g. Southard et al. 1984, Davoren & Mosley 1986, Nicholas & Smith 1999) and despite extensive research into confluences, there is a far

Copyright © 2006 Taylor & Francis Group plc, London, UK

poorer understanding of flow and sediment dynamics within the confluence-diffluence unit as a whole, including the areas upstream and downstream of confluences. Crucially, very little is known about the transition from confluence to diffluence, and particularly the flow characteristics that are inherited at, and downstream of, these sites (e.g. Richardson & Thorne 2001). Additionally, the nature of the diffluence will also control the character of flow in the downstream distributaries, and therefore will play a critical role in the movement of sediment through the confluence-diffluence unit as a whole, governing the development and maintenance of mid-channel bars, which are central to the unit itself.

Perhaps most importantly, the vast majority of the past work outlined above on both confluences and diffluences has been conducted in laboratory flumes, within small rivers (depths less than 3 m and widths <100 m), and in a range of models based on boundary conditions of these scales. There is therefore little knowledge of how the processes observed at these smaller sites scale to larger rivers. This is a fundamental gap in the current understanding of continental scale river systems. This paper therefore has two main aims. It presents a study of the bed morphology and related 3D flow structure within a very large confluence-diffluence unit in the Rio Paraná, Argentina, and compares the features of mean flow identified with studies from smaller river channel units.

2 FIELD SITE AND FIELD METHODS

The study area is a confluence diffluence unit in the Rio Paraná, downstream of the major Paraguay River confluence and 16 km north of the city of Corrientes, NE Argentina (Figs 1 and 2). The Paraná River is the sixth largest in the world by water discharge and the mean annual discharge of the Rio Paraná is circa 17,000 m^3/s (Orfeo & Stevaux 2002). Its basin occupies some 2,600,000 km^2, mostly within Southern Brazil and Argentina. At the field site, the mean width of Rio Paraná is about 2.5 km and its mean depth at a section varies from 5–12 meters. At the time of surveying in May 2004, the discharge of the full river section was $\sim$12,000 m^3/s^{-1}.

The field methodology employed involved digital, dual frequency single beam echo-sounder surveys of the bed from a small survey vessel along 36 cross-stream traverses approximately perpendicular to the true channel banks. These bed surveys were accompanied by simultaneous acoustic Doppler current profiling (aDcp) surveys using an RDInstruments^{TM} RioGrande® 600 kHz unit. This aDcp has a 4 beam (transducer) system, each with an orthogonal angle of 20 degrees in the vertical, and emits acoustic pulses of energy that are backscattered by particles in the water column. The backscattered signal was set to split into 98 equally spaced 0.5 m bins in the vertical, and the Doppler shift principle used to convert the change in frequency into weighted averages of components of flow velocity within each depth range bin. The aDcp was set to pulse (or 'ping') at 5 Hz, although measurements were then averaged over 36 pulses to increase the signal: noise ratio, and yield 3D velocity profiles averaged over $\sim$ 0.2 Hz. The aDcp was used to trace the pattern of velocity magnitude, vertical velocity and flow direction within the confluence-diffluence unit. Both the bed echo sounder surveys and aDcp survey were located using a Real-Time Kinematic (RTK) Digital Global Positioning System

(dGPS) that allowed accurate differential positioning of the survey lines. This method produced an accuracy in relative position (dGPS base station to rover) of +/− 0.02 m and +/− 0.03 m in the horizontal and vertical positions respectively.

Since all flow velocities measured by the aDcp are relative to the aDcp, and hence the boat velocity (approximately 1 m/s^{-1}), the measured aDcp velocities must be corrected for this boat motion by removing the dGPS-derived boat velocity, thereby producing measurements of the flow velocity (cf. Yorke and Oberg, 2002). Averaging the aDcp profiles over ~ 0.2 Hz therefore produced velocity profiles that were averaged over approximately 5 meters of channel width. The derived flow velocities were finally converted from beam co-ordinates into an Earth referenced co-ordinate system, using the simultaneous measurements made by the aDcp's 'on-board' attitude and gyro sensor. The boat velocity and track position along the survey lines were monitored online and were held as constant as possible during surveying.

3 RESULTS AND DISCUSSION

3.1 *Bed morphology*

River bed surveys show that the maximum depth at the confluence, and through the nodal area of maximum flow constriction, is up to 22 m (Fig. 3), with a scour of up to 12 m compared to upstream bed levels.

There is a pronounced bed discordance at the confluence with the true right, smaller, tributary being up to 6 meters shallower than the deeper true left. This forms a discordant confluence with a mouth bar extending from the smaller tributary and dipping steeply into the central scour. The deeper channel thalweg crosses the main channel downstream of the confluence and is found to extend further into the larger diffluent (true right) channel, which is on the opposite side of the reach to the upstream confluence.

3.2 *Flow structure*

At the flow stage investigated (12,000 m^3/s), the true left channel is dominant in its discharge contribution at the confluence (Figs 4 and 5), with a discharge ratio (minor/major confluent channels) of 0.15. As the flows combine through the confluence there is a slight overall acceleration of flow produced by the reduced cross-sectional area of the downstream nodal constriction. As the deeper channel thalweg crosses the main channel downstream of the confluence, most of the flow discharge is routed into the true right diffluent channel, which is at the opposite side of the channel to the dominant channel at the upstream confluence. The diffluence discharge ratio is approximately 0.6 (true left/true right), showing a more equal division of flow than the two confluent channels upstream.

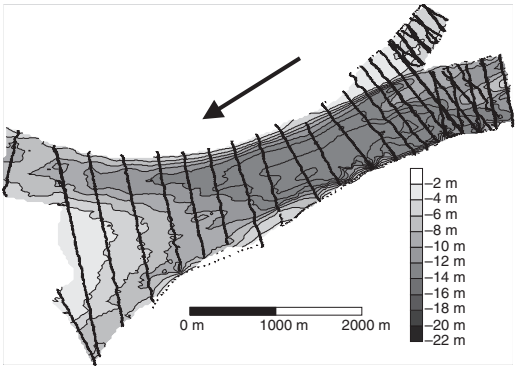

Figure 3. Bed morphology of the confluence-diffluence unit. Black lines show the survey lines. Black arrow shows flow direction.

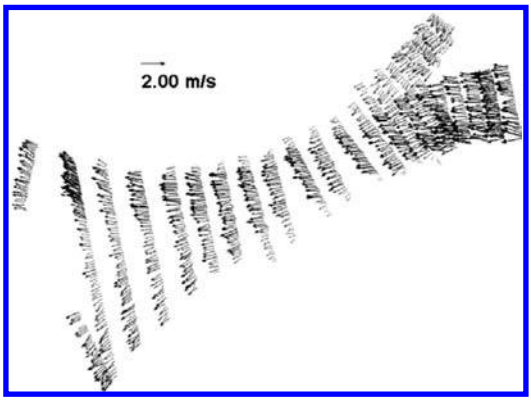

Figure 4. Planform view of the depth averaged flow velocity vectors through the confluence-diffluence unit.

Interestingly, the aDcp surveys show the progressive division of flow upstream of the diffluence. Figure 6 shows the horizontal directions of the flow vectors along each of the surveyed transects. This indicates that the division of the flow begins close to where the central scour begins to shallow, well before the mid-channel bar downstream. As this division of flow begins well before the actual diffluence, the control of the central scour position and orientation would seem to both link and govern the confluence-diffluence unit, with particular regard to the downstream division of flow. Given this finding, linkage to how sediment is routed though these scour holes would provide greater insight into the processes of flow division at diffluences more generally.

3.3 *Secondary circulation*

Secondary flows along each cross-sectional transect were calculated using the Rozovskii (1957) method.

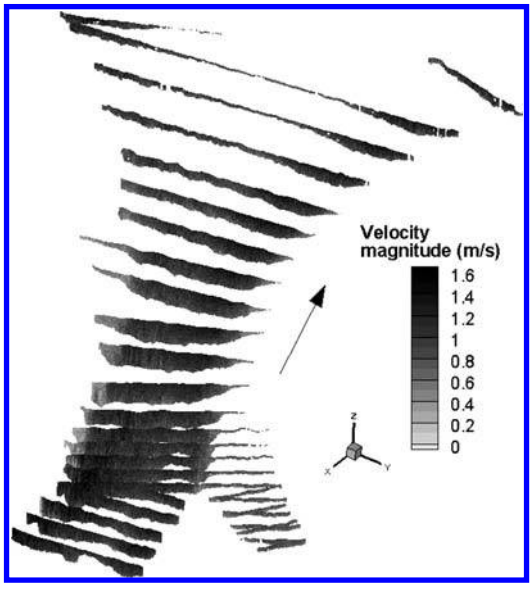

Figure 5. Perspective view of transect contoured velocity magnitude through the confluence diffluence unit.

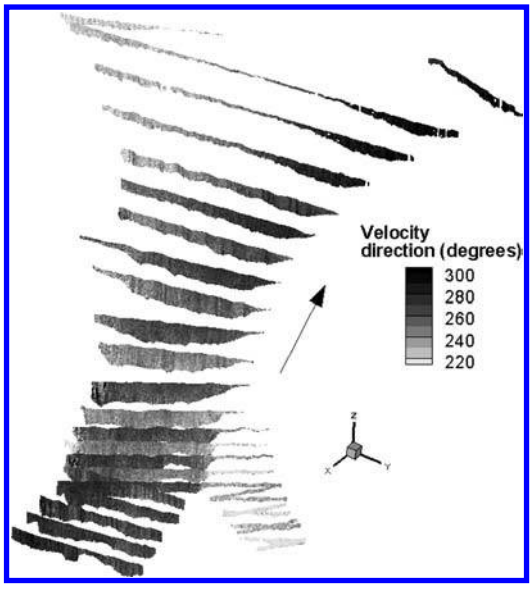

Figure 6. Perspective view of transect contoured velocity vector horizontal direction through the confluence-diffluence unit.

This involves integrating the velocity profile through the depth to obtain a depth averaged vector. The differences from this depth averaged velocity for all measurement within the profile are then computed to provide an indication of secondary motions in the plane perpendicular to the average velocity direction in the profile.

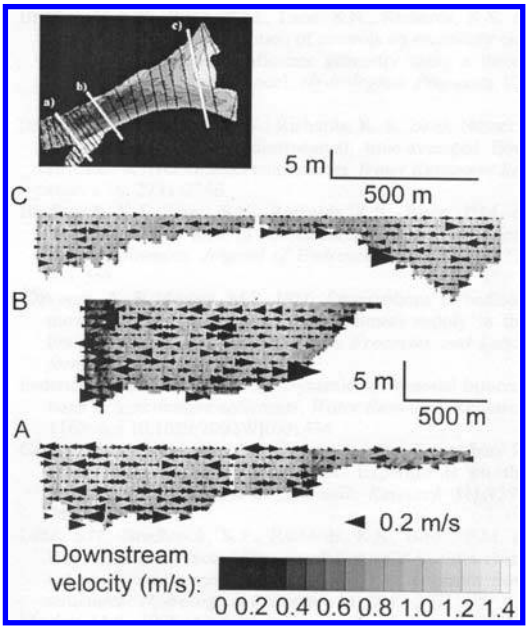

Figure 7. Secondary flow velocity vectors derived using the Rosovskii method for three sections through the confluence-diffluence. Section *a* is close to the confluence, *b* is through centre of the scour and *c* is in the true left side channel at the diffluence.

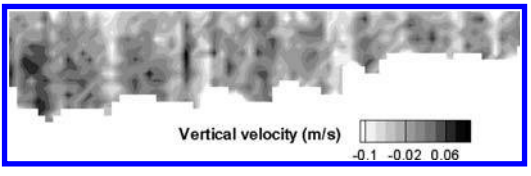

Figure 8. Vertical flow velocities for subset section c. Positive vertical velocities denote flow towards the bed. Note the profile of the bed indicating the presence and locations of dune bedforms.

Figure 7 shows the secondary flow at three sections through the confluence-diffluence unit. Section *a* is close to the confluence zone but shows no real pattern of secondary flow structure. There is some semblance of a definable pattern in section *b*, which is within the central scour, with flow generally moving towards the right bank at the bed and towards the left at the surface. However, no back-to-back cells are apparent as have been found in previous studies at smaller channel confluences (e.g. Rhoads & Kenworthy 1998). At section *c*, which shows flow in the left portion of the diffluence, again no channel scale pattern of secondary flow is present (Fig. 7).

Figure 8 shows the vertical velocities in the left channel at the diffluence (see Fig. 7 for location) and

Copyright © 2006 Taylor & Francis Group plc, London, UK

indicates a strong correlation of upwelling zones with dune bedforms. It therefore seems likely that the presence of any major coherent channel scale secondary flows is curtailed by the function of form roughness in large rivers, where the width: depth ratios are often very high.

4 CONCLUSIONS

The findings presented within this paper indicate that caution must be applied in assuming that processes observed in small channels scale linearly with channel size. The results show a large central scour between a discordant confluence and a downstream diffluence. This scour, its position and orientation in particular, seems to play a crucial role in governing flow division at the downstream diffluence.

The flow field is dominated by the convergence and divergence through this nodal area and at this flow level and discharge ratio no coherent, channel scale, secondary flow cells seem to exist at the confluence. Although there is hint of one full width cell over the central scour, there is no evidence of coherent secondary cells as flow shallows at bifurcation. It is therefore concluded in this wide, shallow river reach, flow mixing and secondary flow is almost completely dominated by bed form roughness, which prevents any coherence existing and that the coherent secondary flow cells that have been identified in smaller channels and assumed to be present within large rivers, are generally absent.

There is, however, the obvious need to repeat these measurements at different flow levels and at different discharge ratio values.

ACKNOWLEDGEMENTS

This research was enabled through award of grants NER/A/S/2001/00445 and NER/B/S/2003/00243 from the UK Natural Environment Research Council for which we are extremely grateful. We would like to gratefully acknowledge the outstanding and full support of Reson Offshore Ltd. (www.reson.com), and John Fraser in particular. We also acknowledge an award a Discovery Grant from the Natural Sciences and Research Council of Canada. Additionally, we also extend thanks to the staff of CECOAL-CONICET (Corrientes, Argentina), and in particular Lolo Roberto and Luis Bonnetti, for their field support. Mark Franklin, Pam Montgomery, Mat Roberts, and Dan Shugar are thanked for their assistance in the field. JLB would like to acknowledge the Leverhulme Trust for award of a Research Fellowship, which facilitated completion of this paper, and Marcelo García and the Ven Te Chow Hydrosystems Laboratory, University of Illinois at Urbana-Champaign, for hosting his stay.

Unsteadiness effects on the morphological behaviour of gravel-bed river bifurcations

S. Miori
University of Trento, Trento, Italy

R. Repetto
University of L'Aquila, L'Aquila, Italy

M. Tubino
University of Trento, Trento, Italy

ABSTRACT: In recent works (Bolla Pittaluga et al. 2003a, Miori et al. 2005) the equilibrium configurations of a simple channel division and their stability have been investigated within the context of a one dimensional approach. Physically based relationships for sediment distribution have been employed by the authors at the channel division point, which allow to model the effect of transverse bed slope at the bifurcation on bed load transport. Both works are based on the assumption of steady forcing conditions. Recent experimental observations on gravel-bed channel divisions (Bertoldi et al. 2005) have shown that bar migration along the upstream channel induce time fluctuations in water and sediment feeding of the downstream branches, which significantly affect the morphological behaviour of the system. In the first part of this paper we extend the model proposed by Bolla Pittaluga et al. 2003a to account for such an effect. In the second part of the paper we also investigate the effect of water discharge fluctuations, which are invariably observed in gravel-bed streams in mountain regions, on the time evolution of a channel bifurcation. Results show that both sources of unsteadiness lead to significantly different and richer scenarios of the possible solutions of the system with respect to the steady case conditions.

1 INTRODUCTION

Gravel-bed braided rivers are highly complex natural systems. Such a complexity arises from the coexistence of many morphological structures with different spatial dimensions which evolve on different time scales, interacting in a strongly nonlinear way with each other. Braided river networks are originated and maintained by the tendency of a stream flowing over a non-cohesive sediment bed to bifurcate, generating a channel division. Much research effort has been devoted to study the conditions leading to the generation of a bifurcation, both through experimental approaches (see for instance the classical work by Ashmore (1991) and the more recent study by Bertoldi & Tubino (2005)) and theoretical analyses (Repetto et al. (2002), Slingerland & Smith (1998), Hall (2005)).

Many researches have also studied already formed river bifurcations, trying to characterise their morphological behaviour, the understanding of which is a fundamental step to predict the evolution of the entire network. Experimental observations by Federici & Paola (2003), Bertoldi & Tubino (2005) and field observations by Zolezzi et al. (2005) have brought very informative insight on the characteristics of river bifurcations in gravel-bed rivers. Among the observations reported by the authors we recall here that gravel-bed channel bifurcations are highly unstable systems, particularly at low values of the Shields parameter, and often tend to close one of the two branches. Moreover, even when the two branches keep open over time, the configuration of the bifurcation is typically strongly asymmetrical with one of the tributaries carrying most of the water and sediment discharges. Observations also suggest that the transverse exchange of sediments just upstream of the bifurcation, due to locally significant values of transverse gradient of bottom elevation, plays a key role on the morphological evolution of the system.

Bolla Pittaluga et al. (2003a), Miori et al. (2005) and (2006) have proposed models based on a one dimensional description of the flow, which, in spite of their simplicity, successfully reproduce the aforementioned features. Their models are essentially based on the use of physically based nodal point conditions at the bifurcation, which allow to reproduce the effect

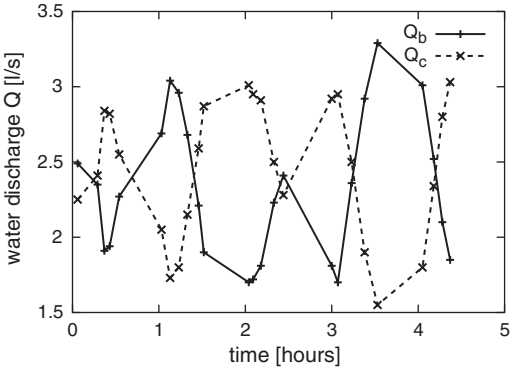

Figure 1. Water discharges measured in the two branches of a bifurcation versus time, in the presence of alternate bars migrating along the upstream channel (from Bolla Pittaluga et al. 2003a).

of transverse bed slope at the bifurcation on bed load transport.

The above models assume steady forcing conditions, however, such conditions are never met in natural braided networks. Unsteadiness may arise, among other effects, from water discharge fluctuations, migration of large scale bedforms along the channels, continuous rearrangements of the network, backwater effects due to changes in downstream boundary conditions of each channel. Experiments performed by Bertoldi et al. (2005) on bifurcations with fixed banks and movable bed have shown that if alternating bars form in the upstream channel their migration towards the bifurcation may induce time fluctuations of water and sediment distribution into the two downstream branches, thus strongly affecting the morphological behaviour of the system. The authors also observed that the complete abandonment of one of the two bifurcating channels, i.e. the obliteration of a bifurcation, is almost invariably associated with the highly non-symmetrical distribution of water and sediment supply into the downstream branches due to the migration of a bar towards the bifurcation. The importance of bars migration in the upstream channel was also recognised by Bolla et al. (2003a) who performed experiments in a straight flume whose downstream part of was divided into two parts of equal width, through a longitudinal panel, thus simulating a simple bifurcation. This is shown in figure 1, from Bolla Pittaluga et al.'s (2003a) paper, in which the measured water discharges into the downstream branches are shown to fluctuate periodically due to bars migration in the upstream channel.

Water discharge fluctuations may also play an important role in governing the morphology of natural river bifurcations, however, to our knowledge no experimental or theoretical studies focused on the role of discharge unsteadiness on bifurcation development yet exist.

With the present paper we extend the model proposed by Bolla Pittaluga et al. (2003a) to account for various unsteadiness forcing effects on bifurcations morphological behaviour. The main aim of the work is to provide some informations on the time evolution of bifurcations in natural environments. Results should not be regarded as quantitatively significant but bear, in our opinion, a conceptual value. Obviously, they will have to be corroborated by field or laboratory observations not yet available. Theoretical results may also help to set up proper experiments to understand the dynamics of river bifurcations, an endeavour which is presently being carried out.

In the first part of the paper we introduce in the model the effect of migration of alternating bars along the upstream channel. This is done in a very simple way by letting the transverse distribution of sediment discharge in the upstream channel fluctuate with time. Even with such a simple forcing, the adopted nodal point conditions reproduce a very sensible behaviour of the bifurcation, leading to the generation of an inlet step, i.e. a difference between bed levels at the mouths of the downstream branches, which fluctuates in time and affects in a complex way the behaviour of the system. Results obtained are in qualitative good agreement with experimental observations by Bertoldi et al. (2005). The model shows that the effectiveness of alternating bars in governing the behaviour of the bifurcation essentially depends on the ratio between the characteristic time scale of bars migration and the intrinsic time scale of evolution of the bifurcation. If such a ratio is small, bar migration does not strongly modify the morphological behaviour of the bifurcation while it becomes of major importance as this ratio is progressively increased. The model also predicts that migration of large and slow enough alternate bars may lead to the complete abandonment of one of the two branches; this was never observed by Bolla Pittaluga et al. (2003a).

In the second part of the paper we account for water discharge variations in time. We consider a simple hydrograph consisting of sinusoidal water discharge fluctuations superimposed to a steady flow. This hydrograph roughly models the feeding of a proglacial braided river in which formative conditions are mainly due to snow melt and water discharge variations are almost periodical, being strictly related to daily temperature variations. A very good example of this kind of hydrograph is found in the Sunwapta river (Jasper National Park, Alberta, Canada) during the ice melting season, as reported by Chew & Ashmore (2001). The model shows how such an unsteady forcing leads to time dependent equilibrium configurations of a bifurcation which may be either symmetrical, with both branches being fed with the

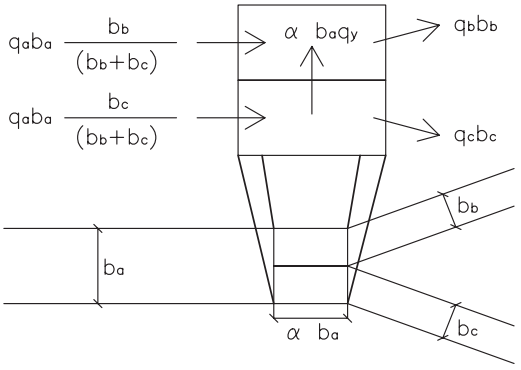

Figure 2. Sketch of the nodal point conditions proposed Bolla Pittaluga et al. (2003a).

same water and sediment discharges, or strongly non symmetrical.

2 FORMULATION OF THE PROBLEM

In the present paper we model morphological behaviour of a gravel-bed river bifurcation with fixed banks through a one dimensional approach. To this end we employ the nodal point conditions originally proposed by Bolla Pittaluga et al. (2003a), whose essential aspects are briefly recalled below; the reader is referred to Bolla Pittaluga's (2003a) and (2003b) papers for a fully detailed description of the model. Let us denote with the subscript letter a the upstream channel of the bifurcation and with b and c the downstream branches, respectively. The nodal point conditions are based on the following ideas. The most downstream part channel a is thought of as being divided into two longitudinal cells of length αb_a, with α an order one parameter and b_a the width of the upstream channel (see figure 2). The authors assume that at an upstream distance of αb_a from the bifurcation the flow in the upstream channel is not affected by the presence of the bifurcation. The nodal point conditions are obtained applying the Exner equation to both such cells and are written by the authors as

$$\frac{1}{2}(1-p)\left(1+\frac{b_a}{b_b+b_c}\right)\frac{\mathrm{d}\eta_i}{\mathrm{d}t} + \frac{q_i - q_a\left(\frac{b_a}{b_b+b_c}\right)}{\alpha b_a} \mp \frac{q_y}{b_i} = 0 \qquad (i=b,c). \tag{1a,b}$$

In the above equations p is sediment porosity, η_i is bed elevation, q_i is the sediment discharge per unit width in channel i, t is time and q_y represents the transverse exchange of sediments per unit width between the two cells. The latter term is evaluated in analogy to the two dimensional case: both the transverse flow velocity effect and the gravitational effect due to the transverse bed slope, which is responsible for the deviation of particle trajectories from flow direction, are accounted for. All the above terms are evaluated through gross relationships involving channels widths b_i, water depths D_i, bed elevations η_i and water discharges Q_i of each branch i. Such relationship are not reported here for the sake of brevity.

Equations (1a,b) are coupled with a water discharge balance and water level constancy relationships at the nodal point to obtain the five nodal point conditions required for the problem to be well posed.

To evaluate the time evolution of a bifurcation system we employ a "local approach" following Miori et al. (2005) and (2006). In fact, we couple the five nodal point conditions with rate-discharge relationships (in the form of uniform flow equations) for the two downstream branches b and c and prescribe a value of the ratio S_b/S_c between the slopes of the two branches, under the assumption that such a ratio is likely to be controlled by the mechanism of generation of the bifurcation and by the topographical characteristics of the network rather than by the evolution of the bifurcation itself. We thus solve 8 equations for the unknowns Q_b, Q_c, D_b, D_c, η_b, η_c, S_b and S_c. Notice that the time scale of system evolution is set by the nodal point conditions (1a,b); this justifies the use of the adjective "local" for this approach. Physically this means that we are neglecting the influence exerted on the bifurcation morphology by downstream conditions. Miori et al. (2006) stress the importance of adopting such an approach to correctly model the time scale of evolution of the bifurcation.

3 THE CASE OF STEADY FORCING CONDITIONS

Before proceeding it is worth while to briefly recall the main results obtained by Bolla Pittaluga et al. (2003a) in the case of a simple channel bifurcation, with downstream branches of equal width, subject to steady forcing conditions (as discussed by the authors, the assumption of $b_b = b_c$ is not essential for the validity of the results discussed below and will be adopted in the rest of the present paper). Bolla Pittaluga et al. (2003a) identify the equilibrium configurations of the system and analyse their stability. For given values of channel slope S_a and width ratio $\beta_a = b_a/(2D_a)$ in the upstream channel their model predicts the existence of a unique equilibrium solution for large enough values of the Shields parameter ϑ_a in the upstream channel. This solution is symmetrical, i.e. both branches are fed with the same water discharge. In this case the solution is stable. As the value of the Shields parameter is decreased two further solutions appear, one

Copyright © 2006 Taylor & Francis Group plc, London, UK

reciprocal to the other, according to which the configuration of the bifurcation is strongly unbalanced and one of the two channels is fed with a much larger discharge than the other. When three solutions exist the unbalanced ones are stable and the symmetrical one is, on the other hand, unstable. In figure 3 the curve in the plane (β_a, ϑ_a) separating the regions where one and three equilibrium solutions exist is plotted for different values of the upstream channel slope S_a.

In figures 4a,b two examples of time behaviour of a bifurcation are shown in terms of the ratio $r_Q = Q_b/Q_c$ between water discharges into the downstream branches. Each line in the two plots refers to a different initial state of the system. Moreover, in the figures T denotes a dimensionless time, scaled with the morphological time scale of the system as

$$T = \frac{t}{D_a b_a / q_a}. \qquad (2)$$

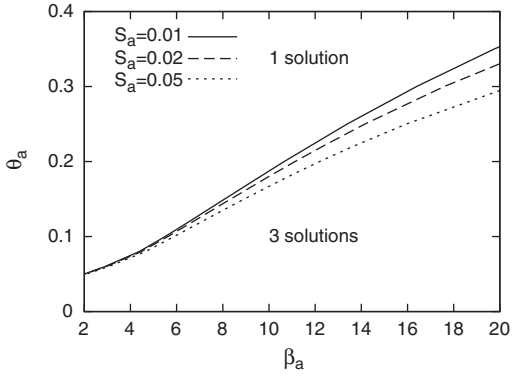

Figure 3. Curves in the plane (β_a, ϑ_a) separating the regions where the model predicts the existence of one or three equilibrium solutions. Each curve corresponds to a different value of the upstream channel slope S_a.

In the case of figure 4a the symmetrical solution is stable and the ratio r_Q tends to 1, whatever the initial condition. On the other hand in figure 4b the situation is represented in which three solutions exist. As in this case the symmetrical solution is unstable the bifurcation evolves towards either one of the unbalanced equilibrium configurations, depending on the initial value of r_Q.

4 THE EFFECT OF BARS MIGRATION ALONG THE UPSTREAM CHANNEL

Bolla Pittaluga et al. (2003a) assume that at an upstream distance αb_a from the bifurcation point, i.e. at the inlet of the two longitudinal cells depicted in figure 2, flow characteristics and bed topography are not affected by the presence of the bifurcation. Consequently, the authors impose that sediment discharge is uniformly distributed in the transverse direction at the entrance of the two cells. This implies that each cell is fed by a fraction of the total sediment discharge which is proportional to its upstream width (see labels in figure 2). This is obviously not true if alternating bars are migrating along the upstream channel: in this case one should expect the transverse distribution of sediment discharge to periodically vary in time as bars approach the bifurcation. In the light of the scheme of the nodal point conditions proposed by Bolla Pittaluga et al. (2003a) this implies that the longitudinal cells of figure 2 are alternatively fed with an excess or a defect of sediment discharge, with respect to the average value.

In the following we use the above observations to include the effect of migrating bars in the model. If we assume that the two downstream branches have equal width and assume that transverse time variations of sediment discharge are purely sinusoidal we can write

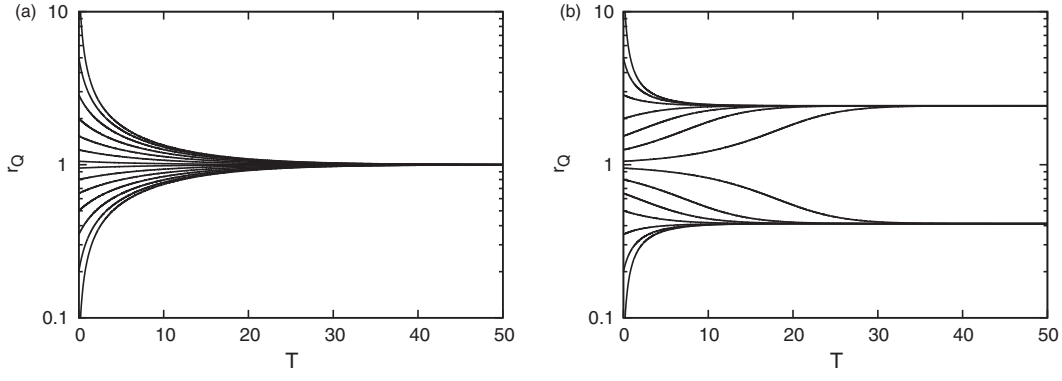

Figure 4. Time evolution of the ratio $r_Q = Q_b/Q_c$ between water discharges into the two branches starting from different initial conditions, in the case of steady forcing. (a) The symmetrical solution is stable ($\vartheta_a = 0.2$, $\beta_a = 10$, $S_a = 0.01$); (b) the symmetrical solution is unstable and the unbalanced solutions are stable ($\vartheta_a = 0.175$, $\beta_a = 10$, $S_a = 0.01$).

the sediment discharge Q_s^{in} feeding the each of the two cells as

$$Q_{s\,b}^{in} = \frac{1}{2} b_a \left[q_a + A \sin(\omega_b t) \right], \tag{3a}$$

$$Q_{s\,c}^{in} = \frac{1}{2} b_a \left[q_a - A \sin(\omega_b t) \right], \tag{3b}$$

where A is the amplitude of sediment discharge variations due the presence of alternate bars and ω_b is the frequency of bar migration. The above relationships can be easily extended to the case of channels with different widths simply by assuming a sensible transverse distribution of sediment discharge. This endeavour, however, does not add any conceptual novelty to the present analysis and is not pursued in the following. Notice that, according to the philosophy of the nodal point conditions adopted, the sediment discharges feeding the two cells is assumed independent of the state of evolution of the bifurcation since the length of such cells (equal to αb_a, with α of order 1) is defined as the upstream distance from the bifurcation at which flow conditions and bed topography are not affected by the presence of the bifurcation.

Figure 5a shows the time behaviour of the bifurcation subject to the above time dependent forcing conditions in terms of the parameter $\Delta = (\eta_c - \eta_b)/D_a$, which represents the dimensionless height of the bed inlet step between the two downstream branches. As in the case of figures 4a,b, and in all the following figures, each line refers to a different initial condition of the system. It appears that, due to the time-dependent non-uniform transverse distribution of sediment discharge imposed upstream of the bifurcation, the nodal point conditions generate perturbations of the bed elevations at the inlets of the downstream branches which suitably model the presence of alternating bars close to the bifurcation.

Once established that the use of equations (3a,b) to describe the sediment feeding of the two cells provides a simple way to suitably include the effect of bar migration in the model let us now turn to a more substantial matter: how do migrating bars influence the morphological behaviour of a bifurcation?

In our model the characteristics of migrating bars are fixed by prescribing the values of the parameters ω_b and A. Let us first investigate the role of bars celerity. We may define a characteristic time scale of bar

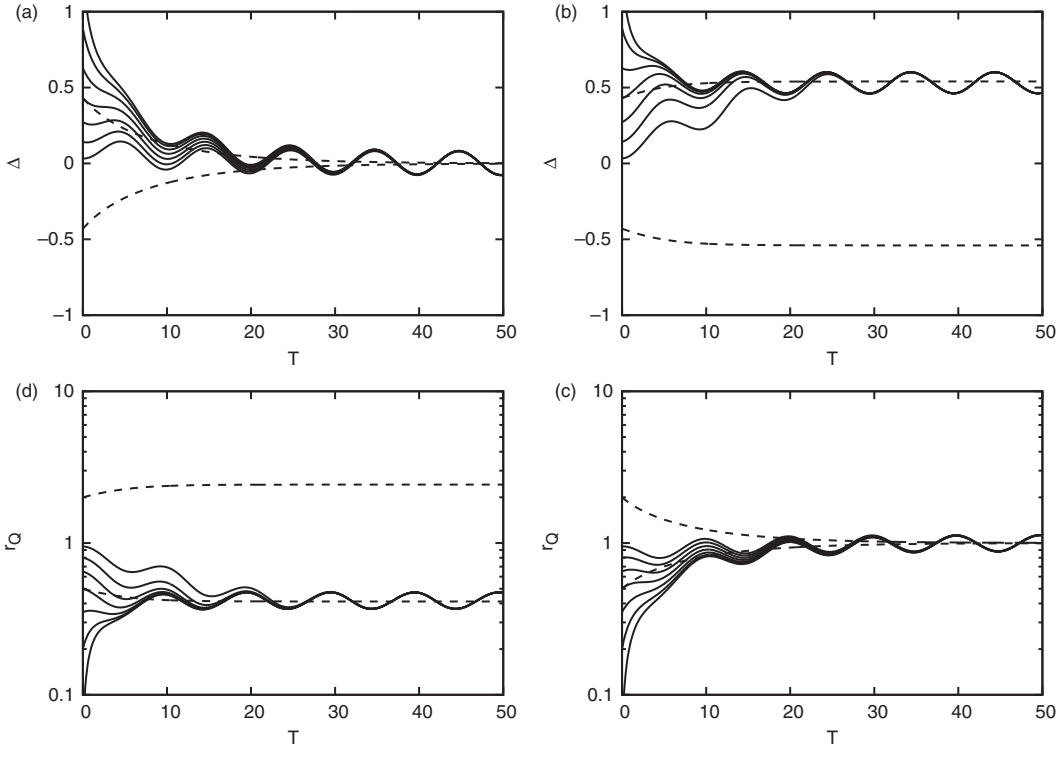

Figure 5. Time evolution of $\Delta = (\eta_c - \eta_b)/D_a$ (a,b) and $r_Q = Q_b/Q_c$ (c,d) starting from different initial conditions in the presence of alternate bars migrating along the upstream channel (continuous lines) and in the case of steady forcing conditions (dotted lines). $T_b/T^* \sim 10$, $\beta_a = 10$, $S_a = 0.01$, (a) and (c) $\vartheta_a = 0.2$, (b) and (d) $\vartheta_a = 0.175$.

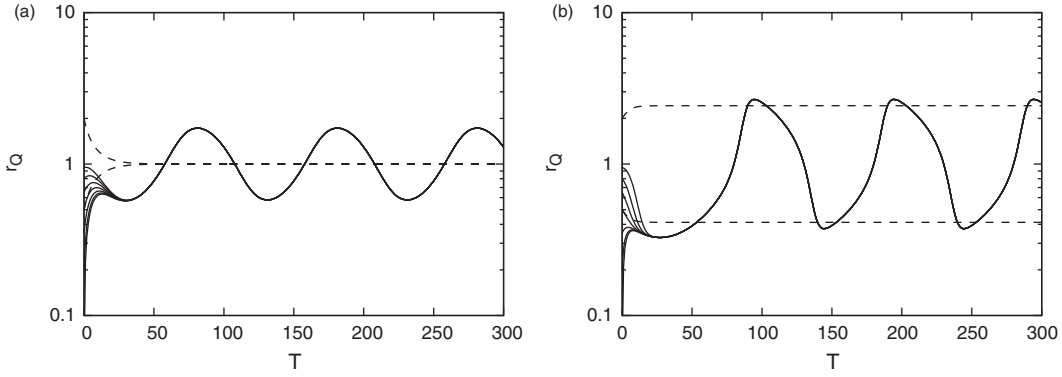

Figure 6. Time evolution of $r_Q = Q_b/Q_c$ starting from different initial conditions, in the presence of alternate bars migrating along the upstream channel (continuous lines) and in the case of steady forcing conditions (dotted lines). $T_b/T^* \sim 100$, $\beta_a = 10$, $S_a = 0.01$, (a) $\vartheta_a = 0.2$, (b) $\vartheta_a = 0.175$.

migration as $t_b = 2\pi/\omega_b$, that can be made dimensionless as $T_b = \frac{t_b}{D_a b_a/q_a}$. The other (dimensionless) time scale which plays a role in the problem is the intrinsic time scale of evolution of the bifurcation, say T^*. Such a time scale is set by the nodal point conditions and can be readily obtained fitting the asymptotic behaviour of any variable characterising the state of the bifurcation, say f (for instance r_Q in figures 4a,b), towards the stable equilibrium configuration f_{eq} with an exponential function of the kind $f_{eq} - C\exp(-T/T^*)$. Considering the upstream flow conditions of figure 4b, it is found that T^* is of order 10. It is reasonable to expect the effect of bar migration on the dynamics of the system to depend on the ratio T_b/T^*.

Figures 5a–d are obtained using a low value of such a parameter ($T_b/T^* \sim 1$), i.e. they represent the effect of fairly rapidly migrating bars (the value of A is also small). In figures 5a,c the parameters adopted are the same as in figure 4a, i.e. in the absence of alternate bars the model predicts that the symmetrical solution is stable (in all the following figures the time evolution of the system in the case of steady forcing conditions is plotted with dotted lines). It appears that, in this case, whatever the initial conditions of the system, the bifurcation evolves towards a time dependent solution which oscillates about the symmetrical configuration. Similarly, figures 5b,d depict the case of a bifurcation in which the symmetrical equilibrium configuration is unstable in the case of steady forcing conditions (figure 5d can be directly compared to figure 4b). Again it appears that the system evolves towards a periodic solution in which each variable oscillates about the the value it assumed in the case of steady forcing conditions. In other words, if alternate bars are fairly small and fast, it is still possible for the system to evolve towards either the symmetrical configuration or towards unbalanced solutions, depending on the dimensionless parameters which characterise the flow in the upstream channel (namely ϑ_a, β_a and S_a). Obviously, when the effect of migrating bars is included such solutions are not steady but periodic in time.

The scenario of the possible solutions is dramatically modified if the ratio T_b/T^* is progressively increased, leaving unchanged the amplitude A, i.e. if alternate bars migration is slowed down. This is shown in figures 6a,b which are obtained for the same values of ϑ_a, β_a and S_a adopted in the previous figures and for $T_b/T^* \sim 10$. In this case the effect of bars completely dominates the behaviour of the system. Indeed, in both cases, the system oscillates about the symmetrical configuration, alternatively feeding preferentially one of the two branches, no matter if, in the case of steady forcing conditions, the symmetrical solution is stable or not. Notice that a gross calculation relative to the case of a gravel bed mountain river, based on a linear stability analysis for bar formation (Colombini et al. (1987)), suggests that T_b/T^* attains a value of order 1. However, preliminary experimental observation conducted in the Hydraulic Laboratory of the University of Trento have also shown that, when migrating bars approach a bifurcation, they tend to significantly slow down their migration speed. Thus the model suggests that, if alternate bars are present in the upstream branch, they may crucially affect the behaviour of the system.

Finally, if we keep fixed such the ratio T_b/T^* and increase A, i.e. simulate the migration bars with a larger amplitude, the scenario is further modified, as shown if figures 7a,b. In this case the system rapidly evolves towards the complete abandonment of one of the two branches. This is in good agreement with the observations of Bertoldi et al. (2005) according to which the closure of one of the two branches is almost invariably associated with the presence, close to the bifurcation, of a strong transverse

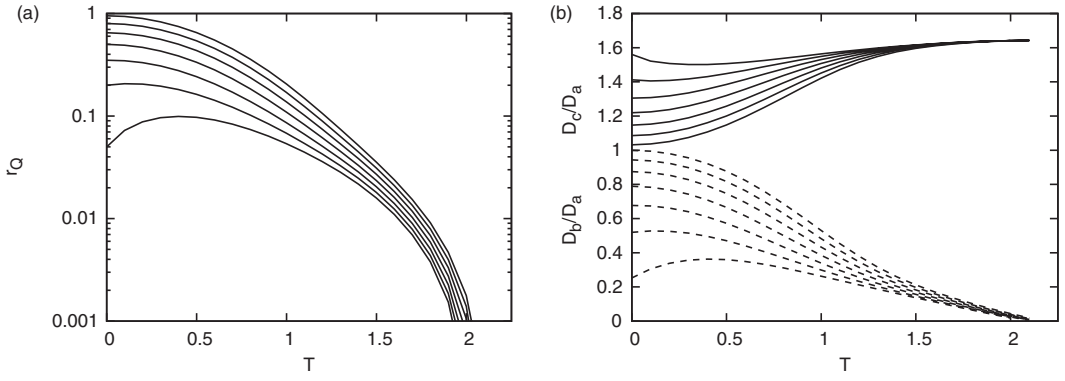

Figure 7. Time evolution of $r_Q = Q_b/Q_c$ (a) and of the dimensionless water depths $D_i/D_a (i = b, c)$ starting from different initial conditions, in the presence of alternate bars migrating along the upstream channel. $T_b/T^* \sim 100$, large amplitude bar, $\vartheta_a = 0.175$, $\beta_a = 10$, $S_a = 0.01$.

bed deformation induced by the presence of a slowly migrating alternate bar.

5 WATER DISCHARGE FLUCTUATIONS

In the present section we consider the effect of discharge variations on the morphological behaviour of a bifurcation. In particular, we focus our attention on the following simple hydrograph

$$Q(t) = Q_0 \left[1 + A_Q \sin(\omega_Q t)\right], \tag{4}$$

consisting of periodic discharge fluctuations of relative amplitude A_Q superimposed to a constant discharge Q_0. Equation (4) roughly models the feeding of a proglacial braided river in which formative conditions are mainly due to snow melt and water discharge variations are almost periodical, being strictly related to daily temperature variations.

The inclusion of discharge fluctuations into the model is straightforward. As in the case of alternate bars, there are two parameters that characterise the unsteady part of the hydrograph: the relative amplitude A_Q and the frequency ω_Q. Following the discussion developed in the previous section, we define the characteristic time scale of discharge variations as $T_Q = 2\pi/\omega_Q$ and compare it with the intrinsic time scale of evolution of the bifurcation T^*.

In figures 8a–d we report, for two different sets of the governing parameters ϑ_a, β_a and S_a (computed using the average discharge Q_0), the time evolution of the ratio r_Q between the discharges into the downstream branches. Results obtained with a constant discharge equal to Q_0 are reported with dotted lines. In each plot the time evolution of water discharge is also shown (right axis scale) to make results more easily readable.

In the case of figures 8a,b, if the discharge is kept constant and equal to Q_0, the system evolves towards the symmetrical solution while in the case of figures 8c,d such a solution is unstable and the bifurcation eventually develops to an unbalanced solution. When the discharge varies in time the situation is more complicated. Indeed, as recalled in section 3, the symmetrical equilibrium configuration, which is stable at large values of the Shields parameter (i.e. for large discharges), may become unstable as ϑ_a decreases (i.e. when the discharge falls). This seems to suggest that the stability properties of the symmetrical solution may vary during a single hydrograph, with consequences on the morphological behaviour of the bifurcation which are difficult to predict by simple means. Moreover, the time evolution of the system is, obviously, faster for large values of the water discharge as the sediment transport is larger in such conditions and, consequently, the bifurcation is morphologically more active.

Let us consider figures 8a,b first, which are obtained setting $A_Q = 0.25$ and $T_Q/T^* \sim 15$ and 60, respectively. The ratio T_Q/T^* does not seem to play an important role in this case: in both situations the bifurcation evolves towards the symmetrical solution. Notice, however, that such a solution is not steady because, even if the ratio $r_Q = Q_b/Q_c$ tends to unity, water discharges in each branch are time dependent. For the chosen values of the parameters, the symmetrical solution is, presumably, not stable for all values of the water discharge reached during the hydrograph, as it seems to be suggested by the time oscillations that r_Q displays in figure 8a. It is so, however, for most part of the hydrograph and, since the time evolution of the system is much slower for low values of the water discharge, the system is unable to leave the symmetrical configuration once it has reached it. Such

Copyright © 2006 Taylor & Francis Group plc, London, UK

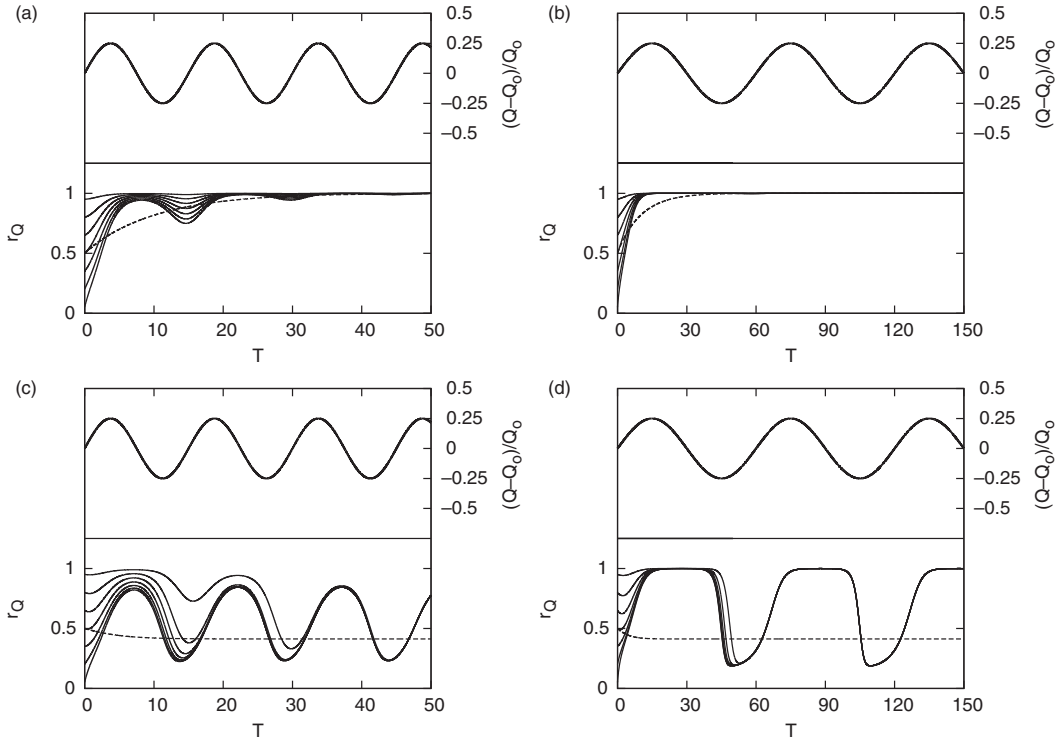

Figure 8. Time evolution of $r_Q = Q_b/Q_c$ starting from different initial conditions, in the case of water discharge fluctuations (continuous lines) and in the case of steady forcing conditions (dotted lines). In each plot the value of the water discharge is also plotted (right axis scale). $A_Q = 0.25$, $\beta_a = 10$, $S_a = 0.01$; (a) $T_Q/T^* \sim 15$, $\vartheta_a = 0.2$; (b) $T_Q/T^* \sim 60$, $\vartheta_a = 0.2$; (c) $T_Q/T^* \sim 15$, $\vartheta_a = 0.175$; (d) $T_Q/T^* \sim 60$, $\vartheta_a = 0.175$.

a solution is thus approximatively maintained during the entire cycle.

In figures 8c,d the counterpart situation is shown, in which, for $Q = Q_0$, the symmetrical solution is unstable and the two unbalanced solutions are stable. Again figure 8c is obtained for $T_Q/T^* \sim 15$ and figure 8d for $T_Q/T^* \sim 60$; in both cases $A_Q = 0.25$. It appears that, during each cycle of the hydrograph, the bifurcation configuration oscillates about some unbalanced state. In the case of slow water discharge fluctuations, however, the system reaches and maintain for a certain time the symmetrical configuration, which is the only state of the bifurcation to represent a stable solution of the system for more values of the discharge during the hydrograph.

6 CONCLUSIONS

In the present paper we have extended the model proposed by Bolla Pittaluga et al. (2003a) to account for the effect of unsteady forcing conditions. In particular we have considered both bar migration along the upstream channel and water discharge fluctuations. Both sources of unsteadiness are very likely to affect the morphological behaviour of bifurcations in gravel-bed braided rivers.

The effect of bar migration has been included into the model through a simple approach which is based on the assumption that the sediment discharge in the upstream channel has a time dependent transverse distribution. The effectiveness of the presence of bars on the dynamics of the bifurcation is found to depend on the ratio between the characteristic time scale of bar migration and the intrinsic time scale of evolution of the bifurcation, which is set by the nodal point conditions. If such a ratio is large enough the presence of bars dominates the morphological behaviour of the system, no matter what such a behaviour would be in the absence of bars. The model also shows that the migration through the bifurcation of large amplitude bars may induce the complete closure of one of the two branches.

Water discharge variations have also been considered in the paper, assuming a simple hydrograph consisting of sinusoidal fluctuation superimposed to a

Copyright © 2006 Taylor & Francis Group plc, London, UK

steady condition. The model shows that the dynamics of the system in this case is much more complicated and richer with respect to the case of steady forcing conditions.

Sediment dynamics in anabranched channels of the Loire River: The study case of Ingrandes (France)

S. Rodrigues & J.N. Gautier
Equipe Pluridisciplinaire Plan Loire Grandeur Nature, Agence de l'Eau Loire-Bretagne, Orléans, France

J.J. Peters
Bruxelles, Belgique

ABSTRACT: Engineering works were carried out on the Loire River (France) in order to stop the incision of its main channel at the site of Ingrandes characterized by a bifurcation. Topo-bathymetric data collected during and between floods on two channels of the site (main and secondary channel) evidenced an impact of the works on the sediment budgets of the main channel while their impact on the secondary channel seems low. For this secondary channel, the first results show that the morphological evolution of the secondary channel is governed by the growth and migration of large sandwaves. The first results presented here suggest that the dynamic behaviour of bars and dunes is strongly influenced by the morphological configuration and by variation in bedload pulses and discharge. A displacement of the thalweg of the anabranch is also highlighted and linked to the migration of large sandwaves. Scour chains show that reworking of the sediments previously deposited can be significant and can precede sediment deposition. Data presented here constitute the first step of the study and will be completed in order to analyse the behaviour of the anabranched channels system in the Loire.

1 INTRODUCTION

The rapid intensification of the incision of river beds over the last 200 years (Arnaud-Fasseta, 2003) was noted on several European (Petts et al., 1989) and French rivers (Peiry, 1987, Bornette et al. 1996, Bravard et al. 1997, Piégay et al. 2000). The largest river of France, the Loire River, was subjected to this phenomenon. Particularly, a severe deepening of its main channel (with maximum values ranging from 2 to 5 m) was recorded on the reach between Angers and Nantes. This incision is one of the consequences of human activities. Dyke raising since the Middle Ages and construction of oblique groynes during the 19th and 20th century have substantially reduced the width of the river, and thus, have contributed to its incision. Moreover, recolonisation of the upper basin by vegetation, constructions of dams, and intense sediment extraction between 1950 and 1995 (Dambre & Malaval 1993, Belleudy 2000) have reduced the quantity of sediments delivered to the river and thus, accentuated the incision process. Concurrently, a rapid colonization of the shallow secondary channels by woody vegetation and a significant sediment aggradation (Rodrigues et al. 2006) of these areas have caused a reduction of the flow conveyance capacity (increasing the flooding risk). The incision of the main channel contributed to weaken the foundations of bridges and dykes, to dry up the water wells and to decrease the habitat diversity.

In order to stop the incision on the downstream reaches of the river, different kinds of operations have been considered. Particularly, two artificial sills were constructed in the site of Ingrandes where the river bed is asymmetrical and divided into two channels (a deep main channel and a shallow secondary channel). The sills were inserted in the main channel during summers 2002 and 2003 in order to increase the water level during low flows and activate consequently the flow in the secondary channel. An environmental survey was carried out before, during, and after, the construction of the sills in order to monitor the evolution of the stream bed in this area and to improve the knowledge concerning flow and sediment transport processes in the Loire (Peters, 2002).

The paper presents the preliminary results of the study performed on the secondary channel. It aims to understand the sedimentological mechanisms that govern the morphological evolution of the secondary channel and to provide new elements intended for a better management of the river bed. From data and observations collected during and after floods, we will try to explain the morphological response of the bifurcation to flood events of different magnitudes, as well as to the river works done on the main channel.

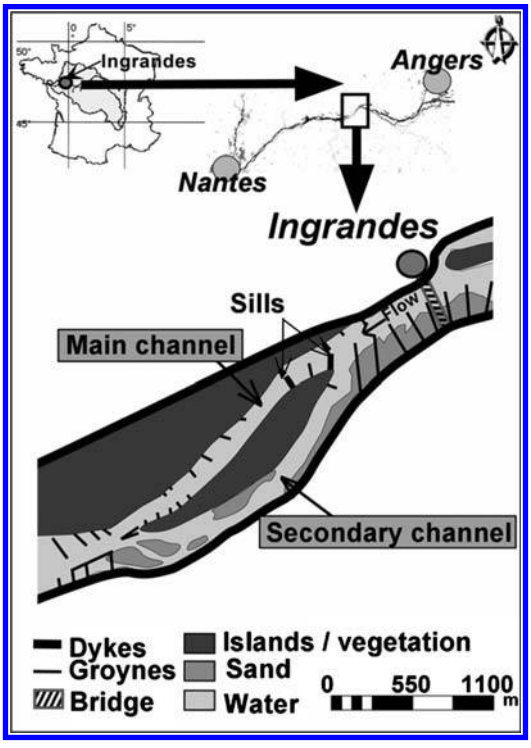

Figure 1. Location of the study site of Ingrandes.

2 STUDY AREA

2.1 *Location and morphological configuration*

The study site of Ingrandes is located approximately 30 km downstream of Angers. In this area the bedrock consists in Devonian and Carbonifereous rocks. At Ingrandes, the presence of resistant conglomerates on the right bank strongly deflects the river course. In this area, the river bed is restricted between dykes and groynes (Fig. 1). Their presence reinforces the asymmetrical configuration of the bed by deflecting the flow towards the deep main channel during low water levels. Close to the village of Ingrandes, the stream bed is characterized by an inflexion and by an average slope of *ca* 0.00025 m/m. The bedload of the river consists in a mixture of sands and gravels. At the gauging station of Montjean (located 6 km more upstream), the discharge is 850 m^3s^{-1} in average and approximately 3200 m^3s^{-1} for the 1-in 2-year flood.

At the upstream part of the study site, the river bed restricted between dykes is 570 m wide and most of the flow is drained by the main channel located on the right bank. Groynes along the left bank determine a higher sandy flat zone that is flooded only during high water levels. Further downstream, the bed divides into two anabranches separated by a vegetated island. The northern branch (main channel) is narrower and deeper than the secondary channel located on the left bank. This can be explained by the effect of the groynes. The secondary channel is 3070 m long and its average width is 300 m. Relics of groynes present in the upstream and downstream parts of this channel affects its morphology: *e.g*. the pool located at the entrance of this branch (on the right bank) is due to the presence of an ancient groyne. A second pool is present in the median part of the channel (left bank). The angle of the downstream connection between the main and the secondary channel is approximately 45°; in this area there is a significant slope discontinuity between the two channels.

2.2 *Works performed for raising the water level at the bifurcation to change the flow distribution*

During summers 2002 and 2003, two artificial sills were constructed in the main channel in order to increase the water level during low flows. These sills are located downstream of the bifurcation (where ancient groynes were present) in order to enhance the inflow into the disconnected secondary channel, mainly during low flows. The sills are connected to the banks of the main channel and are oriented upstream; they are indented in their middle part. The structure consists in boulders (for the foundations) covered with geotextile fenders filled of sand and gravels.

2.3 *Influence of sills on flow distribution and morphological evolution*

As expected, the presence of the sills has induced a raising of the water surface of 0.5 m at Ingrandes during low flows. Concurrently, the duration of inundation of the secondary channel has increased as well as the discharges, restoring the flow balance between the two channels. For a total discharge ranging between 700 and 1200 m^3s^{-1}, discharges recorded in the main channel after the works are 100 m^3s^{-1} lower than those measured before the construction of the sills. Concerning the morphology, the presence of the sills has contributed to a deep scouring just downstream of each sill. Another unwanted effect was the destabilization of the sills close to the banks as a result of the collapse of the bank of the island located between the two channels.

3 METHODS

In order to explain changes of the stream bed morphology, topo-bathymetric surveys were done on the whole reach since 1999. In both main and secondary channels, surveys consisted in bathymetric measurements done using a single-beam echosounder (ATLAS DESO 22). Transverse transect sounding lines were

Copyright © 2006 Taylor & Francis Group plc, London, UK

spaced of 45 m. Longitudinal tracks (almost parallel to the river banks) were also carried out in order to analyse the evolution of the bedforms during flood events (Peters, 1971, Peters, 1978, Ten Brinke et al. 1999, Wilbers & Ten Brinke, 2003). During the bathymetric measurements, the positioning of the vessel was ensured by a differential global positioning system (DGPS Trimble 4700). When the secondary channel was dry, additional topographic measurements were performed in order to detail the morphological evolution of this branch of the river. These measurements were also done using the DGPS.

Digital elevation models (DEMs) were calculated for each topo-bathymetric survey using the TIN (triangular irregular networks) method of Arcgis 9. Afterwards, the TINs were converted into grids and the DEMs were compared in order to obtain sediment budgets for both channels. Comparison between DEMs allowed the mapping of the areas of sediment erosion and deposition between two subsequent surveys.

Scour and fill processes occurring in the secondary channel between two dry periods were assessed using scour chains (Hassan, 1990, Laronne et al. 1994, Hassan et al. 1999). Metal-linked chains were inserted vertically, anchored into the stream bed, and located using a differential global positioning system. After the inundation of the secondary channel, scour chains were relocated and the depth to which movements of bed material occurred was determined by measuring the length of the chain above the elbow (giving the maximum scour depth) and the distance between the elbow and the post flood bed (giving the subsequent sediment deposition).

4 RESULTS

4.1 *Sediment budgets and longitudinal profile*

4.1.1 *Sediment balance between the channels since 1999*

It should be noted that the figures given below do not account for the errors and uncertainties on the bathymetric maps. The balance obtained by comparing measured levels represents an average change in bottom elevation of a few centimetres over the entire area of each channels.

The volumes of sediment eroded and deposited between subsequent surveys are presented in Figure 2. Except for survey 3 (topographic survey of the secondary channel only), all the surveys mentioned here are bathymetric ones. Hence, survey 3 is absent of the comparison done for the main channel (Fig. 2a). The survey 7 is a combination of the two kinds of survey (bathymetry for the main channel and topography for the secondary channel). The comparisons done between surveys 1 and 7 (Fig. 2a) show that the volumes of sediment scoured and filled are higher on the main channel than on the secondary channel (Fig. 2a). The negative sediment budget computed between surveys 5 and 6 for the main channel is strongly linked to the development of the pools located close to the sills: for this same period the secondary channel was subject to sedimentation. Except between surveys 6 and 7, the sediment budgets calculated on the main channel for this period are negative and the volumes of scoured material are at a constant level (*ca.* $-300000\,m^3$). Globally, the main channel is subject to sediment erosion.

In the secondary channel, the scoured volumes are variable according to the period considered and are smaller than on the main channel. The maximum value of scoured volumes ($242350\,m^3$) was recorded between surveys 1 and 2. Low values of scoured or deposited volumes calculated between the surveys 2 and 3 are explained by the low discharges recorded during this period (Fig. 2a). Volumes calculated between surveys 3–4 and between surveys 4–5 are not relevant because some data are lacking for the survey 4 (upstream part of the anabranch, see Figure 4). On the basis of the other set of sediment budgets (1–2, 2–3, 5–6, 6–7), it seems that the secondary channel is quite stable. However, the comparison of survey 7 with a topographic survey done in 2002 (not mentioned in Fig. 2) have shown that the secondary channel was subjected to a scouring of $230000\,m^3$ between 2002 and 2005 (the inundated areas were excluded of this calculation).

In order to analyse sedimentation processes during a single flood event, five bathymetric campaigns were performed on the study reach during the flood of April/May 2001. Scoured and deposited volumes computed for different phases of the flood event (Fig. 2b) show similar trends in both main and secondary channel. Nevertheless, in both cases the volumes are higher in the main channel than in the anabranch.

During the rising limb of the hydrograph (between surveys a and c), the morphological response of the channels was different between surveys a and b than between b and c (Fig. 2b). Between a and b (falling level of the previous hydrograph and beginning of the rising of the studied flood), sediment deposition was the dominant process while scouring prevailed in both channels between campaigns b and c ($-33000\,m^3$ for the main channel and $-19000\,m^3$ for the side channel). During the falling limb of the hydrograph, the sediment budgets were positive between surveys c and d and near equilibrium between d and e. For this time lapse, volumes of sediments deposited in the main channel are two times those deposited in the secondary channel.

4.1.2 *Evolution of the longitudinal profile*

Longitudinal bathymetric profiles were compared in order to determine the influence of the sills on the

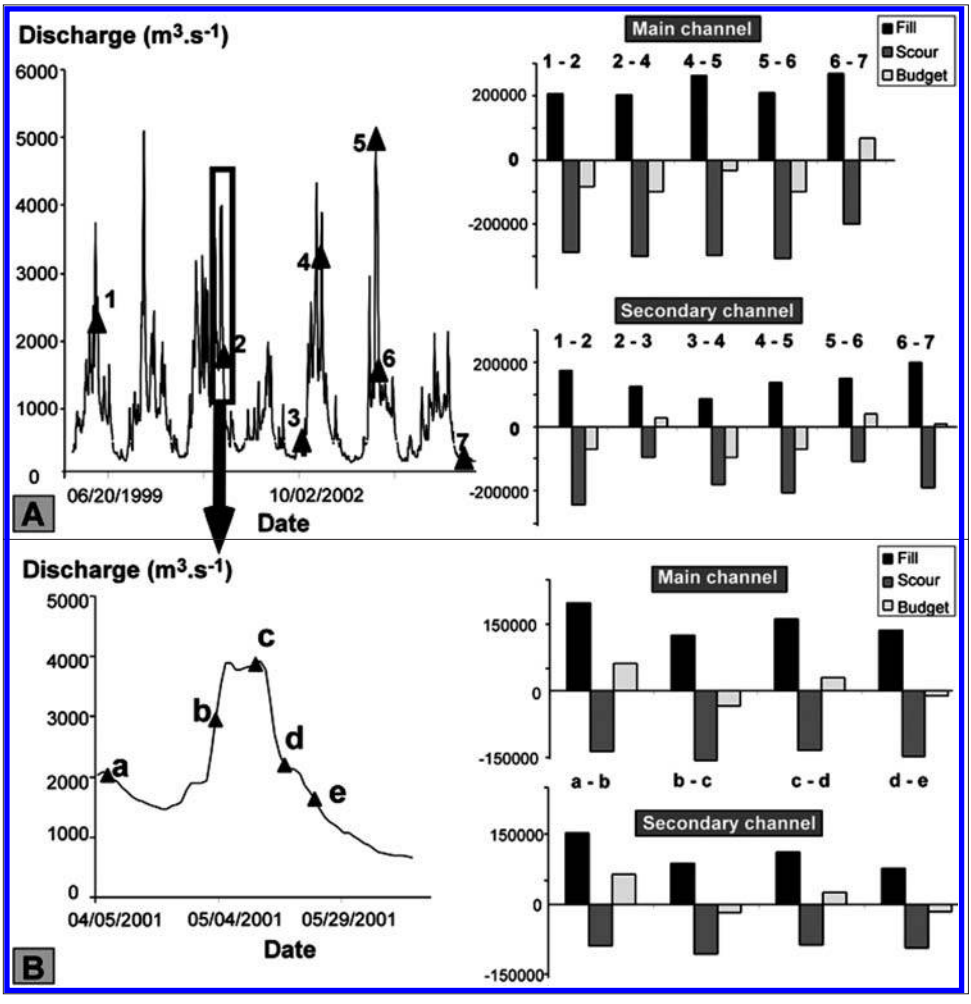

Figure 2. (a) discharge at the gauging station of Montjean (6 km upstream) and sediment budgets computed from digital elevation models (DEM) constructed for the main channel (area located between the upstream sill and the downstream end of the island) and for the secondary channel. Triangles correspond to topographic or bathymetric surveys. Data are lacking for survey 4 (see Fig. 5). (b) sediment budgets calculated for both main and secondary channel during the flood of May 2001; triangles correspond to bathymetric surveys.

sediment dynamics of both main and secondary channels (Fig. 3a, c). In the main channel, an incision – corresponding to the development of scour holes – was noted close to the sills (Fig. 3a, distance 1160 m). This phenomenon is explained by the acceleration of flow, by the chute of the water level and by the presence of significant turbulences. Figure 3a also show the presence of large bedforms in the reach located between the bridge of Ingrandes and the sills (see Fig. 3b for detail).

In the secondary channel (Fig. 3c), the profiles suggest the migration of large sandwaves (distance 1500 m to 2200 m) with superimposed small dunes. Measurements done during the flood of April/May 2001 (Fig. 3b, d) have shown that dunes present in the main channel are characterized by an average height of 2 m while most of the dunes present in the anabranch have a lower height values.

As shown by Figure 3, dunes were less developed in the secondary channel during the rising limb of the hydrograph whereas they were always present in the main channel. The profiles presented in Figure 3 also show that the characteristics of dunes are different according to the stage of the flood, namely rising and falling limbs of the hydrograph. The average height of dunes recorded during survey 2e was lower than during survey 2d.

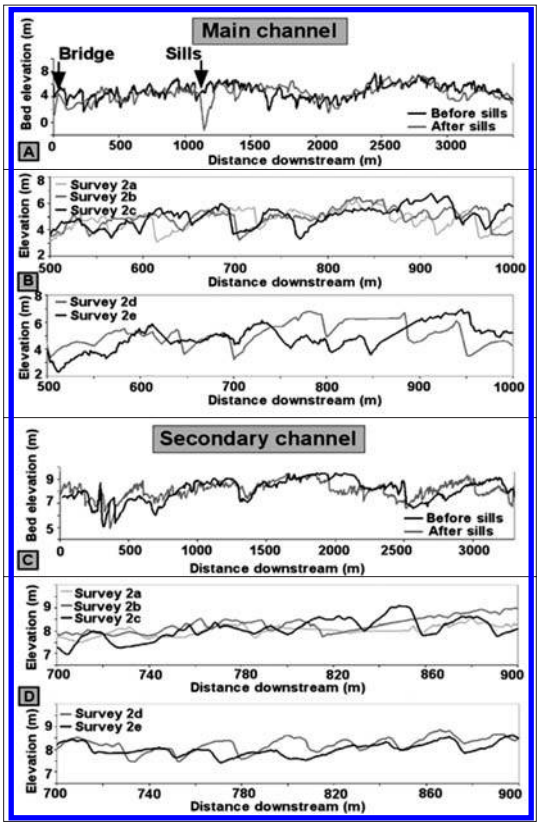

Figure 3. Longitudinal bathymetric profiles measured in the channels of the site of Ingrandes. For discharges, see Figure 2a.

4.2 *Sedimentary behaviour of the secondary channel*

4.2.1 *Morphological evolution of the channel*

The analysis of the DEMs highlighted the presence of relatively stable morphological units such as riffles, pools and a chute. Although these units do not migrate downstream, their morphological evolution is clearly dependent of the migration of 2D sandwaves (Allen, 1984, Ashley, 1990, Miall, 1996), which can partially fill the topographical depressions. The larger of these sandwaves are characterized by a height of 1.5 m, by a wavelength of roughly 500 m, and by an average migration rate of 5 m/day (according to their location in the channel). The slope breaks reported on Figure 4a correspond to lee sides of these bedforms. It seems that large sandwaves growth and extent is linked with the morphological configuration of the secondary channel (*e.g.* migration of sandwave D2 is dependent of the presence of the chute channel). In the downstream part of the channel, sandwaves D5 and D6 amalgamated between March 1999 and April 2001. This coalescence may be due to, in one hand, the confluence with the main channel and on the other hand, to the presence of oblique groynes at the downstream end of the anabranch (see Fig. 1).

The migration of the large sandwaves during flood events influences the variation in position of the thalweg of the secondary channel (Fig. 4b).

The movement of the thalweg is particularly perceptible in the downstream end of the secondary channel (Fig. 4b).

Longitudinal bathymetric profiles measured in order to track dune migration have shown the presence of small dunes (average height of *ca.* 0.35 m) located on the stoss side of the aforementioned sandwaves. The height and length parameters of the small dunes are variable according to the discharge (Fig. 4c). This phenomenon is an evidence of bedload pulses and indicates that large dunes can be reworked during low water levels (Ten Brinke et al. 1999, Carling et al. 2000, Wilbers & Ten Brinke, 2003). This may illustrate changes in hydrodynamics and/or sediment supply during floods. Further investigations will be carried out on this topic in order to understand the sandwaves migration in the secondary channel and to compare these bedforms with those located in the main channel. The maps presented in Figure 4 indicate that sandwaves migration in the anabranch was quite similar before and after the construction of the sills. This observation must be verified with data from the continued monitoring.

4.2.2 *Scour/fill processes*

In order to account for the morphological evolution of the channel bed, topographic differential maps were constructed for this branch of the river (Fig. 5). The comparisons of the DEMs have shown that substantial sediment reworking, linked with sandwaves migration, has occurred between two successive surveys.

The distribution pattern of areas of sediment erosion or deposition is variable according to the period considered: most of the comparisons presented in Figure 5 show that areas of scour and fill are not fixed but tend to migrate downstream. For example, most of the areas scoured between 1997 and 1999 are different from those observed between 1999 and 2001. Moreover, except for comparisons done on a monthly basis (April–May 2001 or January–February 2004), areas of sediment deposition or erosion are clearly separated. Between surveys 1 and 2a (March 1999–April 2001), the migration of sandwave D2 contributed to the filling of pool P2 and the bedform created by the coalescence of sandwaves D5 and D6 was subjected to erosion. The filling of the pool P2 continued until survey 3 (October 2002). Between May 2001 and October 2002 (2e–3), a significant scour of the sandwaves D5 and D6 occurred in spite of a reduced hydraulic activity. During this period, the sandwaves D2 and D3 extended

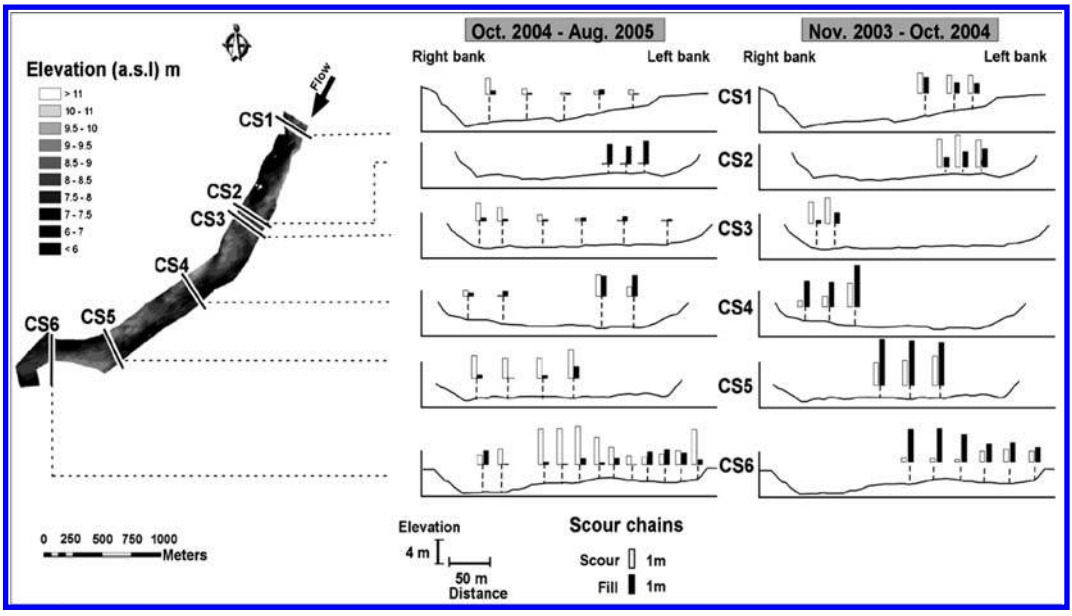

Figure 6. Scour and fill processes in the secondary channel determined from scour chains inserted between November 2003 and August 2005.

laterally. Comparisons done between surveys 3–4 and between surveys 4–5 evidence the migration of large sandwaves in the downstream part of the channel: the old thalweg being buried by one of these bedforms.

Scour chains inserted in the bed of the anabranch (when this channel was dry) completed the topo-bathymetric data (Fig. 6). Two sets of scour chains data acquired according to six cross sections are compared in Figure 6 for the periods November 2003–October 2004 and October 2004–August 2005. Between November 2003 and October 2004, the Loire River experienced a high magnitude flood (peak discharge of 4700 $m^3 s^{-1}$ at Montjean gauging station), while hydrology was reduced between October 2004 and November 2005 (maximum discharge of 2000 $m^3 s^{-1}$). On cross section 1, the thickness of scoured sediments was reduced between October 2004 and August 2005; the values of scour recorded by the chains decrease from the right bank to the left bank. On the left bank of cross section 2, erosion was dominant between November 2003 and October 2004 while sediment deposition occurred between October 2004 and August 2005. During this latter period, significant sediment deposition occurred. This phenomenon evidences the migration of a large sandwave in this area: the migration front of this bedform stopped between cross sections 2 and 3. Downstream of this lee side, on cross section 3, erosion was reduced (except on the right bank). On cross section 6, the morphological changes measured by the scour chains are significant. Thickness of sediment deposited in this area between November 2003 and October 2004 have reached 1.4 m in the central part of the section while scour depths were low: this highlight the deposition of a large sandwave. The significant scour noted on this section between October 2004 and August 2005 may be linked to the shifting of the thalweg in this area.

Except for the lee side of the large sandwaves, scour and fill processes observed in the secondary channel show that sedimentation is not univocal because scour often occurs before sedimentation.

5 CONCLUSION

This paper presents the first results obtained from the survey of the Loire River's bed at the site of Ingrandes where two artificial sills were built. The data from sediment budgets calculated using the DEMs seem to indicate higher reworking in the main channel than in the secondary channel (even if this latter has a larger area than the main branch). In the main channel, the sediment budgets are strongly influenced by the development of scour holes produced by the sills. However, their expected effect on the morphological evolution of the secondary channel seems to be quite limited: no significant changes were noted on the sediment budgets computed for this channel.

The topo-bathymetric survey in the secondary branch allowed observing morphological units (pools/riffles) and large sandwaves. Nucleation and migration of the latter, which are strongly linked to

Copyright © 2006 Taylor & Francis Group plc, London, UK

the morphological configuration, induce a shift of the thalweg and the temporary significant sediment accumulation at the downstream end of the channel, before the confluence. The formation of this bar seems to be linked to the presence of groynes located at the downstream end of the channel. This bar appears to be easily altered, even during low flows.

As the data presented here constitute one part of the measurements done on the site of Ingrandes, further investigations will be done in order to detail the results presented here. Particularly, the evolution of the bedform configuration of the main channel will be analysed and compared to the secondary channel. For example, the variation of the height and length parameters of dunes and sandwaves according to the discharge (Ten Brinke et al. 1999, Carling et al. 2000) will be detailed. Such an analysis, as well as numerical simulations (De Linares, pers. comm.), will support the definition a model of evolution for the bifurcating and asymmetrical reach of the river at the site of Ingrandes.

From the results presented here, the environmental survey performed on the site of Ingrandes will be refined in the future.

ACKNOWLEDGEMENTS

Research presented here was developed under the governmental masterplan *Plan Loire grandeur nature*. The authors wish to thank the *Agence de l'eau Loire-Bretagne* for financial support. The *GIP Estuaire* (S. Aumenier) and *VNF/SMN* are acknowledged for the bathymetric data. *ADESVV* (P. Jugé) provided valuable field assistance for the scour chains. The authors are grateful to P. Man-induced morphological processes in Warta river (Poland), and their impact on the evolution of hydrological conditions

T. Dysarz, J. Wicher-Dysarz & B. Przedwojski
Department of Hydraulic Engineering, Agricultural University of Poznan, Poland

ABSTRACT: In the paper the overview of morphological processes occurring in the selected Warta river reach is given. The processes were induced by the performance of the Jeziorsko dam, which was built in 1986. The main purpose of the presented research is the assessment of these processes impact on the hydrologic conditions in the river system. The historical data and hydrodynamic simulation model are used for the assessment of the hydrologic changes. The data consists of field measurements of the river morphology and hydrologic data from the selected river gages. The hydrodynamic model was used to reconstruct the flow conditions in particular states of the river system evolution. The statistical analysis of the obtained results enabled the assessment of the hydrologic characteristics transformation in the selected Warta river reach. The results are presented as relative and cumulative curves related to the estimated stages of the river system. The presented analyses shows significant changes of the hydrologic regime in the considered area.

1 INTRODUCTION

Our main interest is an impact of the anthropogenic changes on the evolution of hydrologic regime. The presented studies focus on Jeziorsko dam built in the Warta river, Poland, and intensive water management in the reservoir. These actions changed the velocity patterns in the Warta river and induced several sediment transport related processes. The transported material was deposited in inlet part of the reservoir and taken from the reach downstream of the dam. In the presented study we focus on the upper part of the reservoir. The sediment accumulation in the river channel induced one more process affecting hydrologic regime. Due to the increase of floodplain inundation frequency, the luxuriant vegetation start to grow there. These two processes, sediment accumulation and vegetation growth, cause additional increase of floodplain inundation. The processes induced by the dam built and performance seems to be self-driven cycle causing irreversible alterations of hydrologic regime.

The problems studied here are intensively investigated during last decades. The main reason for such interest is their importance for the water management, regional economy and people safety. Example linking hydrological regime and riparian vegetation dynamics was given by Keeland et al. (1997). The Authors linked the annual average depth in the river floodplains and tree diameter. Other example is paper written by Surtevant (1998) who analyzed the riparian wetland vegetation dynamics related to the flow changes and sediment accumulation. The relations between hydrologic regime and riparian vegetation were studied by Stromberg (2001). Similar research done by Nilsson and Svedmark (2002) resulted in formulation of basic principles and consequences of water regime changes.

The changes of the hydrologic regime may be induced by many different factors, anthropogenic as well as natural. However, one of the most important anthropogenic impacts on the hydrologic regime is damming of the river as it is well shown in Petts and Gurnell (2005). The studies on the hydrologic changes and degradation of ecosystems located along the river reaches below the dams were presented by several researches. The examples may be found in Maingi and Marsh (2002), Magilligan and Nislow (2005), Marston et al. (2005) and many others. The dam impact on the upstream condition is also intensively investigated. Interesting examples were given by Mumba and Thompson (2005) and Pinter and Heine (2005). In the first paper the changes in the floodplains located along the Kafue river (Zambia) reach between two dams, Itezhi-tezhi (upstream) and Kafue Gorge (downstream) are analyzed. The Authors proved that dams totally changed the hydrological and ecological conditions in the region due to the almost permanent inundation. Such conditions were imposed by parallel influences of releases from upper dam and high water levels in the lower reservoir. In the second paper, the flood magnitude changes are analyzed in relation to dam, river engineering and climate change impacts.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The methodology used for assessment of hydrologic regime changes ranges from simple approach as equal discharge studies (Pinter and Heine 2005) to complex analysis including discharges and water table frequency (e.g. King et al. 1998, Maingi and Marsh 2002, Magilligan and Nislow 2005, Wellmeyer et al. 2005). This also quite common to simulate the behavior of the water system by means of mathematical model (e.g. Kite 2001, Maingi and Marsh 2002). In each case the methodology applied should match the specific features of the system, processes occurring there as well as data availability.

The main goal of the our paper is to present the hydrological regime evolution in the selected study area. The changes of the hydrologic conditions are caused by three factors. The primary cause is annual scheme of water management in the reservoir. Two next elements are the direct effect of this anthropogenic impact. These are sediment accumulation in the river and vegetation growth. The field measurement data and hydrodynamic simulation model are used for the purpose of our studies. The choice of the methodology is determined by the data availability, the geometrical characteristics of the system and the goal of the research. The final results are presented as relative and cumulative frequency functions related to the particular stages of river evolution.

The paper is divided into six sections. In the first section brief introduction to the investigated problem is given. In the second and third sections the study area and processes occurring there are described. Then the basic elements of the applied methodology are presented. The obtained results are presented and discussed in the fifth section. Finally, last section includes summary and conclusions.

2 CHOSEN STUDY SITE

Jeziorsko reservoir was built in 1986 in central part of Poland. It is located in the Warta river, between the Sieradz (upstream) and Uniejów (downstream) gauge stations. The reservoir inlet with Warta river reach are shown in the attached photo map (fig. 1). The Jeziorsko reservoir is relatively new object. First time it was filled up to the admissible maximum water level (121,50 m a.s.l.) in 1991. The hydropower plant was put into operation in 1995. The schematic view of the reservoir is presented in fig. 2. The main dam is located in the old river stream. The lateral and backwater dams prevent from inundation of adjacent areas. Pichna river is lateral inflow, where Teleszyna is lateral outflow of the reservoir. The total admissible minimum and maximum water levels in the reservoir are 116 m a.s.l. and 121.5 m a.s.l., respectively. The inundation areas related to these levels are shown in the fig. 2.

The Warta catchment area in the inlet of the reservoir is 8450 km^2. The average discharge in the nearest

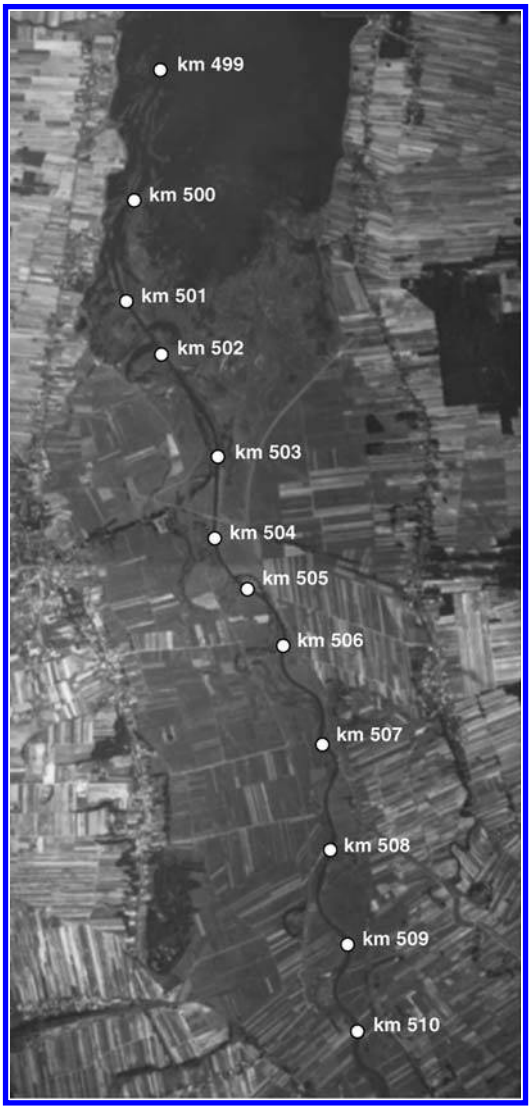

Figure 1. Photo-map of Jeziorsko reservoir inlet part and Warta river.

Sieradz gauge station is about 45 m^3/s, but the discharges variability ranges from 10 m^3/s to 397.5 m^3/s. The wet season during the year is January–May. The lowest discharges are observed during the summer and autumn time, from September to December.

The Jeziorsko reservoir is multipurpose reservoir performing in the annual working scheme (fig. 3). The main purpose of its performance is the flood protection in wet seasons. The reservoir is also the source of water for the big cities in Great-Poland province: Poznan, Kolo, Srem and Konin. The water stored is also used for irrigation purposes and to preserve biological

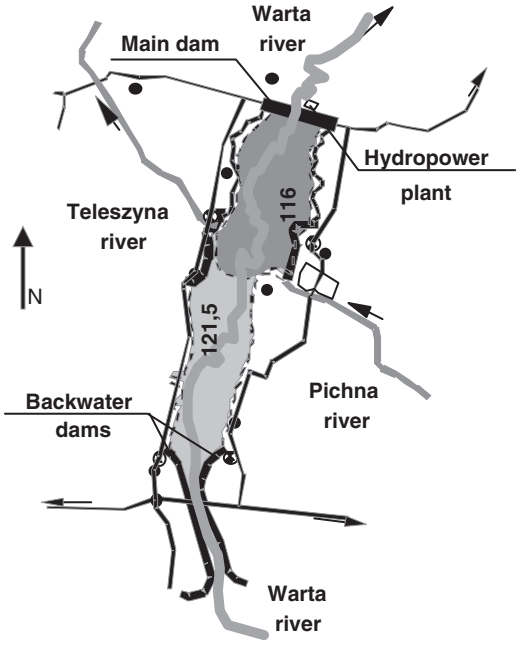

Figure 2. Schematic view of the Jeziorsko reservoir and its main elements.

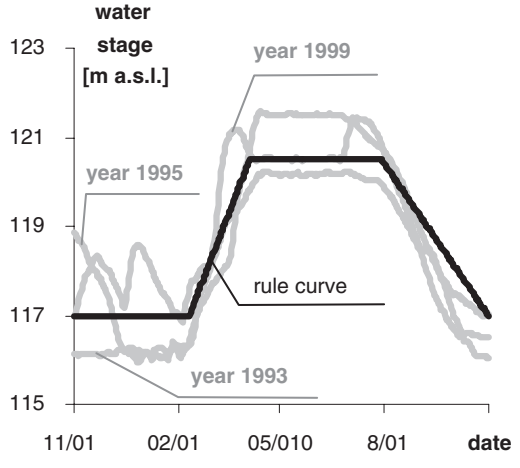

Figure 3. Typical scheme of reservoir performance during a year.

life below the dam. The Pątnów-Konin and Adamów power plants used the water from the reservoir for cooling. Other goal of the Jeziorsko performance is production of hydro-power, though, this is not significant due to the small difference between upper and lower water levels in the dam (about 10 m). The reservoir is also used for recreation and inland fishery.

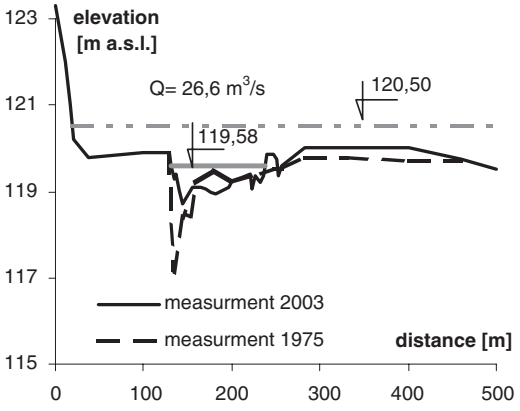

Figure 4. The changes of single cross-section of the Warta river in Km 500 + 510 during period of reservoir performance.

Figure 5. The vegetation growth in the inlet part of the Jeziorsko reservoir.

3 ELEMENTS OF THE INVESTIGATION

Since the very beginning of the reservoir performance the changes of the Warta river bed and floodplains are observed in the inlet part of the Jeziorsko. Due to decrease of flow velocities there the capacity of sediment transport is lower and material is deposited. The most important processes occur in the river reach below the bridge in Warta town, between Km 503 and Km 500 (see fig. 1). The example of the cross-section changes caused by the sediment is shown in fig. 4. This is the cross-section located at Km 500 + 510. It is clearly visible that accumulation of the sediment during the period of reservoir performance totally transformed the river channel causing additional increase of water levels.

The annual scheme of reservoir performance foster the vegetation growth in this area (fig. 5). It enabled

Copyright © 2006 Taylor & Francis Group plc, London, UK

to establish a nature reserve for birds in the upper part of the reservoir in 1998. Since this time the important reservoir performance purpose is conservation of water conditions sufficient for biological life in this area. Due to the existence of the nature reserve and Environmental Protection Ministry act from 1998 the river engineering actions are not allowed in the reservoir. The purpose of this regulation was the protection of birds habitats and biological life in the upper part of the considered object.

The regulation causes also some problems. (Wicher 2004, Wicher-Dysarz and Przedwojski 2005). The water levels in the backwater part are gradually increasing. Long-term results of these processes may cause degradation of the river in the inlet part of the reservoir as well as the reservoir capacity decreasing. Second risk is related to destruction of flood protecting and backwater dikes by overtopping. The losses occurring in such case are difficult to overestimate but the probability of this danger seems to increase.

However, the Ministry act enabled the presented research in some sense. In other conditions the authorities responsible for the reservoir effective and save use should take steps preventing from these processes. Now, it is possible to observe the hydrologic regime evolution in the pure form. The only influences are reservoir performance, sediment accumulation and vegetation growth. Hence, the chosen study area properly fits the research purposes.

4 BASIC METHODOLOGY

The methodology applied for the assessment consists of three main elements. These are: (1) field measurements and data collection, (2) hydrodynamic model simulations and (3) statistical analysis of the results. The listed elements are discussed below.

4.1 *Field measurements and data collection*

The set of available data consists of (a) system geometry, (b) discharges and water stages in the system, (c) state of the vegetation cover.

The channel and floodplain elevations are observed for long period of time in the area under consideration. The most basic set of data consists of the river regulation design prepared in 1975 (Matan 1975). The regulated river seemed to be stable and was not subject to any changes until the reservoir started to perform in 1991. Hence, this set of data may be considered as the original terrain and river bottom without any significant influence of the analyzed processes. The another sets of applied data consists of measurements done in 1997 and in 2004. After a few years of reservoirs performance the Warta river changes were checked and assessed by the team from Department of Hydraulic Engineering, Agricultural University of Poznan (DHE AUP) (Wicher 2004, Wicher-Dysarz and Przedwojski 2005). Hence, the system geometry data consists of three sets of river bottom and floodplain measurements in 37 cross-sections covering the river reach from Sieradz gauge station (Km 520 + 850) to Jeziorsko dam (Km 486 + 500). These data were enabled to describe three stages of the river bottom and floodplain evolution.

Other data used in our analyses are discharges and water stages observed in Sieradz gauge station and water levels measured at the Jeziorsko dam headwater. The set of data from Sieradz gauge station consists of daily measurements done in periods 1963–1970, 1973–1983, 1993–1995 and 1997–2001. These are 27 years of hydrological data. Some of the data were measured and published by Institute of Meteorology and Water Management (IMWM) (1963–1970, 1973–1983). Others were collected by Regional Board for Water Management (RBWM) in Poznan. The later data are made available under the circumstances of cooperation between RBWM and DHE AUP. The data collected from Sieradz gauge station are used to describe the not-affected hydrologic condition in the inlet of the analyzed river reach. The water stages at Jeziorsko headwater were observed during the period of reservoir performance, from 1992 to 2001. This set of data was collected by RWMB which takes care about the reservoir. The data were used to design the average scenario of reservoir performance during the year (see fig. 3).

The impact of vegetation on the roughness coefficients was assessed on the basis of measurements including plants localization and vegetation cover density. The stalk thickness was estimated in the same way. The necessary measurements were done by DHE AUP team in years 2004–05.

4.2 *Hydrodynamic model simulations*

For the simulation of river flow in the study site the HEC-RAS package including hydrodynamic flow model is used. The basis of this methodology is well known set of St. Venant equations approximated numerically. The basic principles and procedures were described in the past by many researchers. Examples may be found in Ligget and Cunge (1975), Abbott (1979) and Cunge et al. (1980). This methodology was developed by Barkau (1982) in order to simulate the flow in meandering river with broad floodplains. Finally, the complete description of the approaches and methods applied in the HEC-RAS package was presented by Brunner (2002).

The main basis of the model is the set of two balance equations. The set of equations is written separately for the main channel and for the floodplains. Typically this procedure provides three sets of equations,

Copyright © 2006 Taylor & Francis Group plc, London, UK

for left and right floodplain and main channel. The floodplain equations are averaged and then added to main channel equations. The summing of equations reduces the source terms describing the exchange of mass and momentum between subsections. Two additional assumptions are necessary: (1) the distribution of discharge in subsections is the same as the distribution of conveyance, (2) water surface elevation is the same in each subsection.

The methodology applied in HEC-RAS package is one of the most developed physically-based models describing 1D free surface flow. The complexity of the complex natural geometries is properly included in 1D model equations. HEC-RAS package was tested and successfully applied in many cases (e.g. Maingi and Marsh 2002). Hence, the model may be applied to solve the described problem. The close relation of the model structure to the physical conservation laws enables proper validation of simulation results done on the basis of accurate field measurement data.

The HEC-RAS model was prepared in such a way, that the system geometry correspond to four stages of river bottom evolution. First analyzed state of the system is the primary bottom described in Matan (1975). This geometry was considered as pre-dam conditions. The second geometry was prepared on the basis of measurements done in 1997 (Wicher 2004). This stage of the system correspond to the system state a few years after the beginning of reservoir performance. The roughness in the particular cross-sections is the same as in the 1975. It does not describe the slight changes of vegetation cover in this period. Hence, the impact of pure sediment deposition may be assessed. The third and fourth geometry of the system was prepared on the basis of measurements done in 2004 and corresponds to current conditions. However, the third scheme does not reflex to the roughness changes due to the vegetation growth. This element is included in the fourth system geometry. Hence, the current state of the system may be assessed in two ways: with and without vegetation growth.

The riparian vegetation impact on the flow conditions may be modeled as the changes of Manning roughness coefficients. However, these coefficients depends on the vegetation characteristics as well as water depth. Klopstra et al. (1997) presented the formula describing velocity changes in the channel with non-submerged vegetation in steady flow conditions.

$$u = \sqrt{\frac{2gi_0}{C_w md}} \tag{1}$$

where g is acceleration of gravity and i_0 is bottom slope. The parameters C_w, m and d describe the characteristics of riparian vegetation. C_w is the coefficient reflecting seasonal changes of leaves cover. Its values were taken as $C_w = 1.05$ for winter period and $C_w = 1.40$ for summer (Armanini et al. 2005). m is

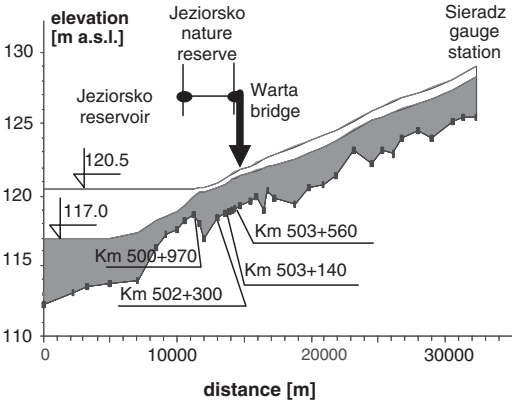

Figure 6. Water profile in the investigated Warta river reach taken from HEC-RAS postprocessor.

average number of plants in one square meter and d is average diameter of bushes stalks.

Following this concept and applying the Manning equation for the wide channel, the formula for the roughness coefficient may be derived

$$n = h^{\frac{2}{3}} \sqrt{C_w \frac{md}{2g}} \tag{2}$$

where n is Manning roughness coefficient, h – the depth.

The presented approach was used to describe the changes of roughness in the floodplain. Parameters m and d were determined on the basis of measurements done in 2004 and 2005.

In the fig. 6 the water profile copied from the HEC-RAS post-processor in shown. The maximum and minimum water stages during the simulations are presented. The area under consideration, Jeziorsko nature reserve is also denoted. In the fig. 6 there are marked the cross-sections for which the results are presented in part five of the paper. The study area is located below the bridge in Warta town which is also marked in fig. 6.

Hydro-morphological stages of the system evolution are presented as five potential river states:

(1) initial bottom reflecting pre-dam conditions (1975) with free outflow in the outlet;
(2) initial bottom reflecting pre-dam conditions (1975) with outflow corresponding to the average annual scheme of reservoir performance (see fig. 3);
(3) bottom measured in 1997, but with the initial roughness and outflow as above;
(4) bottom measured in 2004, but with the initial roughness and outflow as above;
(5) bottom measured in 2004 with roughness reflecting current state of vegetation and its seasonal variation, outflow corresponding to the average annual scheme of reservoir performance.

4.3 *Statistical analysis of the results*

The collected flow data from the Sieradz gauge station are treated as potential scenarios of inputs for the simulation of flow throughout the river. 27 simulations for each of five stages of the hydro-morphological conditions in the river are performed. The computational time step is chosen as 15 minutes to preserve stability of computations. Despite of this only the results produced for each day at 7 a.m. are analyzed. This approach correspond to the procedures of river stages observations in Poland, what should preserve the data homogeneity requirements in any comparative studies.

The obtained results were processed by means of frequency analysis. The basic relative and cumulative frequency curves for the cross-sections in the considered area were prepared. The definitions of relative and cumulative frequencies are adopted from Chow et. al. (1988). The relative frequency $f_s(H)$ of water stages is as follow

$$f_s(H_i) = \frac{n_i}{N} \tag{3}$$

where N is the total number of analyzed results and n_i is the number of such results that

$$H_i - \Delta H < H \le H_i \tag{4}$$

The length ΔH is selected for each analyzed cross-section in such a way that the total interval of water stages variability is divided into 50 sub-intervals. The relative frequency function is linked with the probability density function $f(H)$ according to the formula

$$f(H) = \lim_{\substack{N\to\infty \\ \Delta H\to 0}} \frac{f_s(H)}{\Delta H} \tag{5}$$

The cumulative frequency function $F_s(H)$ is defined as follows

$$F_s(H_i) = \sum_{j=1}^{i} f_s(H_j) = \sum_{j=1}^{i} \frac{n_j}{N} \tag{6}$$

The cumulative frequency function is approximation of probability distribution function $F(H)$ according to the following relationship

$$F(H) = \lim_{\substack{N\to\infty \\ \Delta H\to 0}} F_s(H) \tag{7}$$

For the more clear illustration the probability density curve is fitted to each set of results obtained in each analyzed cross-section. The Pearson type III probability density function is chosen for that purpose. The applied probability density function is defined as follows

$$f(x) = \frac{\alpha^{\lambda}}{\Gamma(\lambda)}(x-\varepsilon)^{\lambda-1}\exp\left[-\alpha(x-\varepsilon)\right] \tag{8}$$

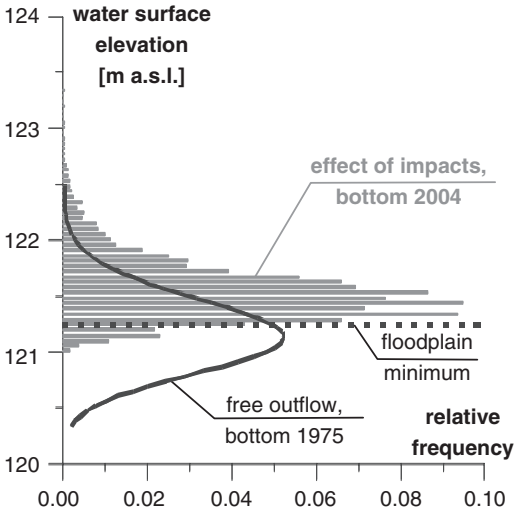

Figure 7. The relative frequency function corresponding to the initial and current state of the hydrological regime in cross section located at Km 503 + 560.

where α, λ and ε are the parameters linked with the sample statistics according to the formulae

$$\lambda = \left(\frac{2}{C_s}\right)^2 \qquad \alpha = \frac{2}{sC_s} \qquad \varepsilon = x_a - \frac{2s}{C_s} \tag{9}$$

In the above equations x_a is the sample data average, s is standard deviation and C_s is the coefficient of skewness. The method of moments is used to fit the distribution to the obtained results.

5 RESULTS

The described analyses are done for the all cross-sections in the river reach between the bridge in Warta town (fig. 6) and the Jeziorsko reservoir. These are sections located at Km 503 + 560, 503 + 380, 503 + 140, 502 + 800, 502 + 300, 501 + 270, 500 + 970, 500 + 510 and 499 + 890. The examples of obtained results are shown in figs 7–15. In the figures presenting relative frequency functions (figs 7, 9, 11, 13) the estimated initial stage is compared with the estimated current hydrologic conditions. The initial stage is represented by Pearson type III probability density function fitted to the results of simulation. In these figures the minimum floodplain elevations are denoted as dashed line. The figs 8, 10, 12 and 14 shows the gradual changes of cumulative frequency functions related to analyzed stages of the hydro-morphological conditions in the river.

Presented results shows two common trends in cross-sections located between Km 503 and 501. The most frequent stages become higher and their relative

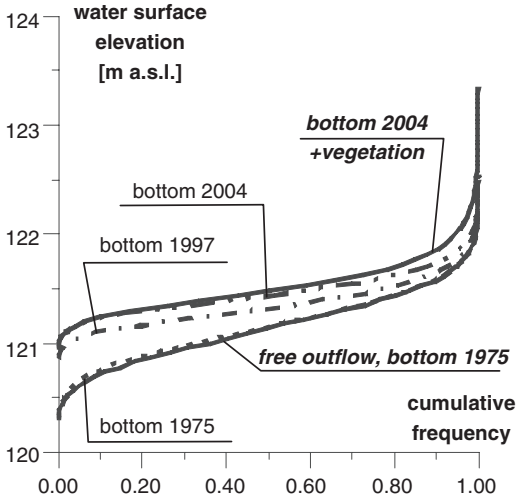

Figure 8. The cumulative frequency function corresponding to the analyzed states of the hydrological regime in cross section located at Km 503 + 560.

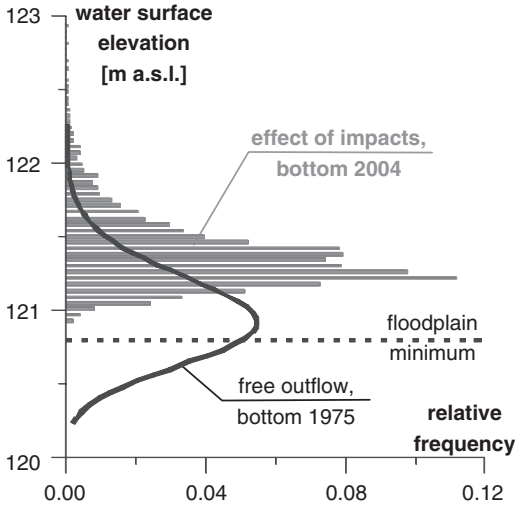

Figure 9. The relative frequency function corresponding to the initial and current state of the hydrological regime in cross section located at Km 503 + 140.

frequency is greater. This means greater frequency of floodplain inundation, what favors the riparian vegetation growth. The same trend is visible in fig. 15, when the most frequent stages and the maximum frequency are presented. More complex changes of hydrological regime may be observed in the cross-sections located near the reservoir, as section in Km 500 + 970 (fig. 13 and 14). The influence of the downstream water stages imposed in the reservoir is clearly visible in fig. 13.

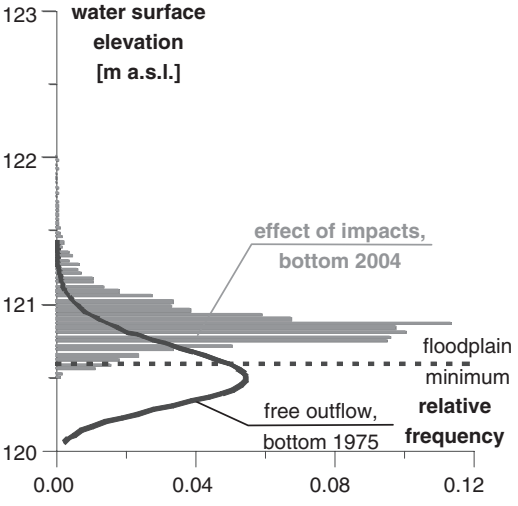

Figure 11. The relative frequency function corresponding to the initial and current state of the hydrological regime in cross section located at Km 502 + 300.

In addition one may notice the shift of lower water stages probably caused by the higher flow resistance upstream.

6 SUMMARY

In the paper the impact of several anthropogenic factor on the evolution of hydrologic regime is presented. The area chosen for investigations is the Warta river in the inlet part of the Jeziorsko reservoir. The

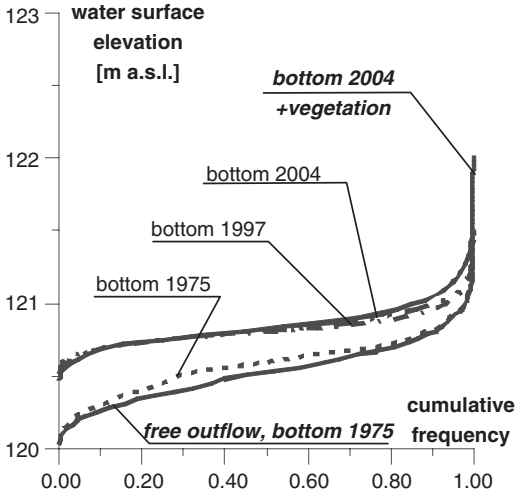

Figure 12. The cumulative frequency function corresponding to the analyzed states of the hydrological regime in cross section located at Km 502 + 300.

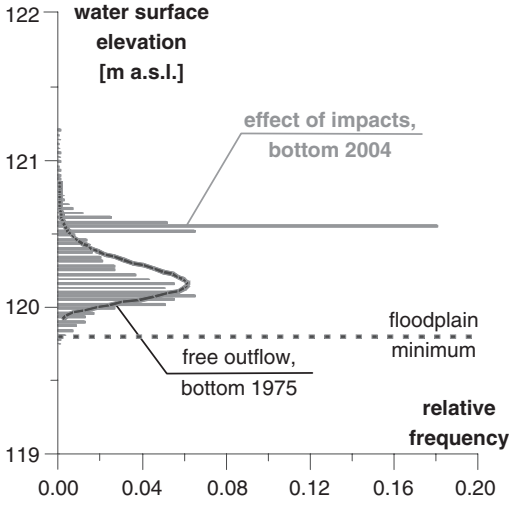

Figure 13. The relative frequency function corresponding to the initial and current state of the hydrological regime in cross section located at Km 500 + 970.

hydro-morphological processes occurring there enable the studies presented in the paper. Our main focus is the effect of aggregated influences on the hydrologic regime changes induced by man-made activity namely the Jeziorsko dam built and performance. The processes analyzed consist of reservoir management and related sediment accumulation with vegetation growth.

For our studies the hydrodynamic flow model is used. Such kind of model supplied with high-accuracy

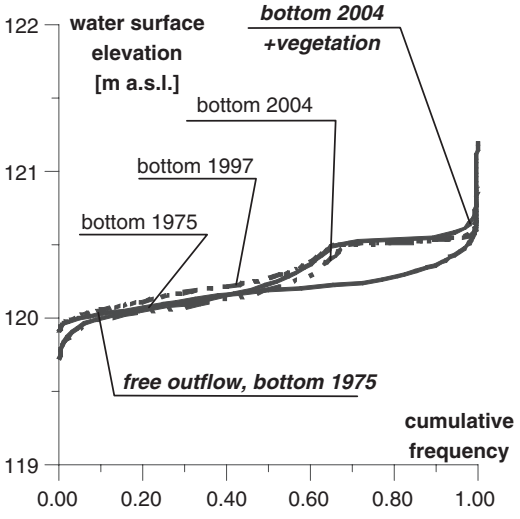

Figure 14. The cumulative frequency function corresponding to the analyzed states of the hydrological regime in cross section located at Km 500 + 970.

field measurement data preserves the appropriateness of simulations. The potential hydrologic conditions in the system were determined on the basis of simulations. The main basis for the computations are as follows: (a) 27 yearly scenarios of inflows to the system observed in the Sieradz gauge station, (b) five stages of the river channel determined on the basis of past and current measurements. Each inflows scenario was tested with each estimated stage of river channel, what gives the total number of simulations equal to 135. The obtained results were processed with the help of statistical analysis preserving the data homogeneity requirements. The relative and cumulative frequency functions related to each river channel state were elaborated in the 9 cross-sections in the analyzed area.

The obtained results shows significant changes of the hydrologic regime along the considered river reach. The impact of reservoir performance may be noticed by comparison of the pre-dam conditions (year 1975, free outflow) and the conditions imposed by reservoir (year 1975, reservoir). This elements are presented in figs 8, 10, 12, 14 and fig. 15. The impact of sediment accumulation after a few years of reservoir performance and now is visible if results obtained for the year 1997 (reservoir) and 2004 (reservoir) are compared. These results are also presented in figs 8, 10, 12, 14 and fig. 15. The total effect of all processes including vegetation growth (year 2004, reservoir + vegetation) is presented in fig. 7–15.

The obtained results shows that potential hydrologic regime in the analyzed area is significantly changed.

Copyright © 2006 Taylor & Francis Group plc, London, UK

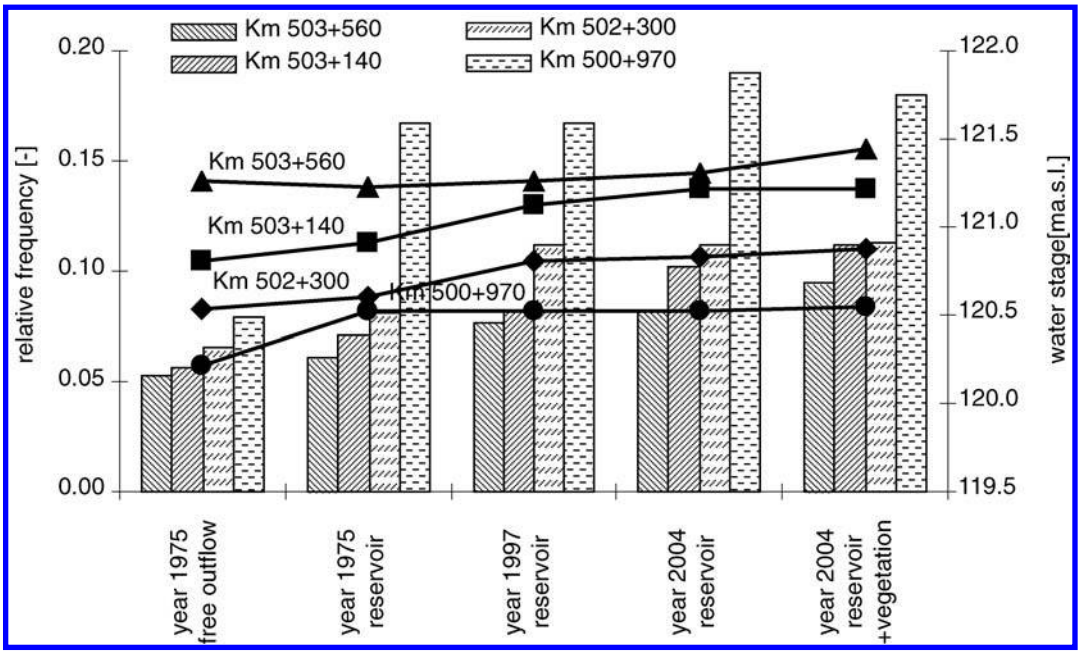

Figure 15. The most frequent water stages and related relative frequency in the selected cross-sections.

The impact of each single process as well as the cumulated impact of all processes have one common trend. The higher water stages become more frequent and their frequency is greater. This is well visible in fig. 15 and figs 7, 9, 11 and 13. The changes are crucial even in the cross-section located in the longest distance from reservoir (Km 503 + 560). The areas located along river reach were not flooded frequently there (fig. 7). Now, the inundation is almost permanent.

Man-made action as dam built induced gradual changes in the natural in environment. This self-driven cycle imposes permanent and probably irreversible change of hydrologic regime. The advantage is luxuriant vegetation growth. However, the changes causes also the increase of risk related to floods occurring in this area every year. Further increase of water stages may cause the dike break by overtopping. The presented results shows that the probability of such an event dramatically increases.

Morphological description of river bifurcations in gravel-bed braided networks

Walter Bertoldi, Stefano Miori, Martino Salvaro, Luca Zanoni & Marco Tubino
Department of Civil and Environmental Engineering, University of Trento, Italy

ABSTRACT: In this work we provide a detailed description of the morphology of Y-shaped bifurcations in gravel-bed braided networks, focussing the attention on their planimetric configuration and on sediment transport processes within different branches. We discuss the results of a series of experimental runs performed in a wide laboratory flume, with a movable bed. The experiments have been designed in order to trace the evolution of a braided network subject to constant liquid and solid discharges. Sequences of time lapsed images have been acquired, through which the width and the orientation of single branches have been measured. The bifurcations have been classified depending on the occurrence of bed load transport in the branches. On the average only 20% of the bifurcations displayed three morphologically active channels (type AAA), while one of the distributaries was not active in 50% of the monitored bifurcations (type AAN). In the latter case, the asymmetrical behaviour of the node is also reflected by the unequal width of downstream branches and by their orientation with respect to the incoming flux. Moreover, the relative distribution of AAA and AAN bifurcations within the entire network was found to evolve toward an asymptotic state, depending upon the stream power of the total flow. A relationship of the active braiding intensity (defined as the number of active branches for each cross section) and the total braiding intensity can be inferred by the abov analysis.

1 INTRODUCTION

Bifurcation is one of the main recurring elements of a braided stream (Figure 1). Recently various investigations have been focussed on this unit process, analyzing both its occurrence (Ashworth 1996; Richardson and Thorne 2001; Bertoldi and Tubino 2005) and the equilibrium configurations and stability (see Bolla Pittaluga et al. 2001; Tubbino and Bertoldi 2006).

According to the theoretical analysis of Bolla Pittaluga et al. (2003) a Y-shaped bifurcation is likely to assume an asymmetrical configuration, characterized by uneven water discharge and sediment rate distributions within the downstream branches, as well as by a different bed elevation at the node. The theory has been recently improved by Miori et al. (2006) including the effect of channel width adjustment. Analyzing the stability of the above configuration it comes out that the unbalance is enhanced at low values of the bed shear stress and for relatively high values of the aspect ratio of the upstream channel.

The above results have been confirmed by various experimental studies (Federici and Paola 2003; Hirose et al. 2003). Bertoldi et al. (2005) have shown that the timescale of a bifurcation evolving to an equilibrium state is typically much smaller than the morphological timescale which characterizes the long term adaptation of the channel bed to boundary conditions. This result

Figure 1. Bifurcations in a braided river (Sunwapta River, Canada).

suggests that node dynamics is mainly affected by local effects. Moreover asymmetry of the configuration is fostered by the migration of alternate bars in the upstream tributary, an effect which was not included in the theoretical analysis of Bolla Pittaluga et al. (2003).

The uneven discharge partition at the node has been also widely documented by field observations (see for example Ferguson et al. 1992 and Zolezzi et al. 2006). In particular they suggest that node dynamics can affect strongly the sediment transport rate in

Copyright © 2006 Taylor & Francis Group plc, London, UK

downstream distributaries and that the asymmetry is more pronounced for values of the discharge lower than those corresponding to formative conditions.

The above analyses mainly refer to single bifurcation units. On the other hand, it is interesting to explore the dynamics of nodes embedded in a braided network. The aim of this work is to provide a detailed description on the spatial distribution of bifurcations and on their influence on the planimetric evolution of the system. A series of experimental runs has been performed in a wide flume, with a well-sorted sand bed, reproducing a braided stream. We have monitored in detail the morphology of Y-shaped bifurcations forming in the flume, focussing the attention on their planimetric shape and on sediment transport processes. Moreover, we have tried to establish a relationship between the degree of asymmetry of the nodes and their planimetric configuration.

Through the analysis of planimetric data that can be more easily measured in such dynamic system, we have obtained qualitative and quantitative information on discharge distribution and sediment transport. In particular we have found that the number of active bifurcations can be related to the active braided index, as defined by Ashmore (2001).

In the following we describe the experimental setup and the measurements techniques; we then introduce a classification of the bifurcations based on the sediment transport occurrence within the branches joining at the nodes. Finally, we performed a statistical analysis of measured values of the channel width and alignment with respect to the upstream flow and to the mean valley slope.

2 LABORATORY FLUME AND EXPERIMENTAL PROCEDURE

The experiments have been carried out in the Hydraulic Laboratory of the University of Trento in a large concrete flume, 25 m long and 3.14 m wide, called "π-flume". The flume was filled with well-sorted quartz sand characterized by a mean diameter d_s of 0.63 mm, forming a 24 m long and 2.90 m wide floodplain.

The water was recirculated by a submerged pump controlled by a software that managed an inverter and an electromagnetic flow-meter. The sediment was not recycled, but the sand was supplied by a dry-sand feeder at the upstream end of the channel by a rotating screw that could be also automatically controlled.

The slope of the sand bed could be modified levelling the sediment with a wood panel supported by a carriage and mounted on a specific rail system.

During each run the sediment transport rate and the planimetric and altimetric configurations of the network have been monitored. In particular, the bed elevation has been surveyed by a laser profiler with grid spacing equal to 10 cm in the longitudinal direction and 1 cm in the transverse direction. A third carriage supported a digital reflex camera located 4 m above the sand floodplain that has been used to acquire vertical images of the flume. The camera has been kept at fixed positions in order to take frequent time-lapse images of the same reach. In this way the evolutionary process of various bifurcations within the network has been followed, with time interval equal to 1 minute. A further set of data has been collected moving the camera along the rails, in order to obtain mosaic images of the whole channel at specific times.

Further details on the experimental setup can be found in Bertoldi et al. (2006).

In each run the braided pattern has been set starting from an initial straight channel cut into the sand floodplain levelled at a prescribed initial slope. We have performed 13 experiments, keeping the same average slope S and varying the water discharge Q (which has been kept constant during each run). The experimental conditions are summarized in Table 1, where Q_s^{IN} is the sediment discharge supplied at the upstream end,

Table 1. Experimental conditions.

$\Omega = \gamma QS$ is the stream power, where γ is the specific weight of water, and b_0 and D_0 denote the width and the flow depth of the initial straight channel, respectively. The latter values have been selected in order to ensure bank-full conditions, with initial values of the width to depth ratio ranging between 10–12.5.

According to the linear criterion for alternate bars occurrence (Colombini et al. 1987), the above range corresponds to stable plane bed. Hence, in each experiment a similar inception process has been observed, with an initial channel widening followed by the formation of migrating bars and by the consequent establishment of bifurcation points due to chute cut-off processes (Ashmore 1991; Bertoldi and Tubino 2005). Afterwards, a braided pattern started to develop. After few hours a sort of dynamical equilibrium condition was reached, in which the average values of the bulk properties of the network (braiding index, number of bifurcations, outgoing sediment discharge, ...) were no longer observed to change appreciably in time. The total duration of experimental runs varied between 30 and 110 hours, depending upon the speed of morphological processes occurring within the network.

In each run the bifurcation units have been monitored in detail. In particular, both the overall pattern of bifurcation points (number, density, distribution, ...) and the morphological characteristics of individual Y-shaped bifurcations (width of branches, alignment, angle, ...) have been measured. In the former case, subsequent surveys have been carried out with a time step greater than the timescale of bifurcation evolution (see also Bertoldi et al. 2006), in order to keep the data uncorrelated.

Moreover, some diffluence units have been monitored in time, starting from their occurrence, until sediment transport ceased in one of the downstream branches. In the present work bifurcations have been characterized in terms of sediment transport activity. Hence, qualitative direct observations have been continuously repeated during each run in order to detect the occurrence of sediment transport in each branch.

3 BIFURCATIONS CLASSIFICATION

As mentioned before, in this chapter we propos a classification of bifurcations based on bed load activity in their constitutive branches. Data discussed herein mostly refer to the conditions of quasi dynamic equilibrium, which has been reached after few hours of experimental run. Incidentally we notice that such condition was typically characterized by values of the mean ratio between the active channels and the total number of channels ranging between 0.35 and 0.5.

Taking into account the most commonly observed configuration, namely a single Y-shaped bifurcation composed by an upstream channel and two downstream distributaries, four different configurations have been observed (see Figure 2). We denote by 'A' the active channels and by 'N' the non active channels, in terms of sediment transport. Consequently we call AAA the bifurcations composed by three active streams, AAN those with one inactive downstream branch and NNN the bifurcations with no transport both in the incoming channel and in the downstream branches. The fourth configuration (ANN) has been rarely observed to occur within the network, since it has been found to be strongly unstable and to invariably evolve into one of the former three classes.

The NNN bifurcations represent diffluence units that have been abandoned by the main stream, because of a change in the water distribution at an upstream node; therefore at the time of the survey they were not involved in the actual dynamics of the network. On the contrary, the first two classes of bifurcations

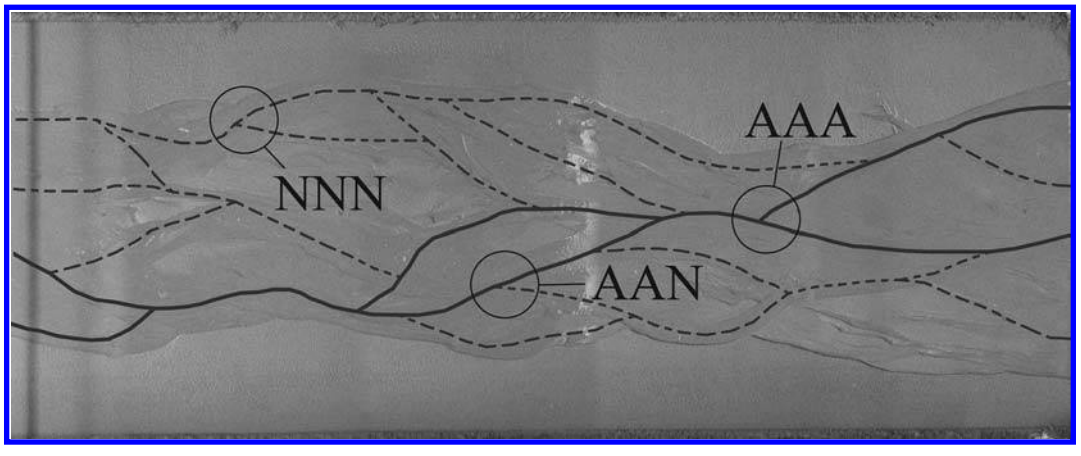

Figure 2. Example of a planimetric configuration in which the active branches and the bifurcations are highlighted.

Copyright © 2006 Taylor & Francis Group plc, London, UK

essentially represent the active part of the network at the time of the survey.

The relative distribution among the above classes of bifurcations observed in run P8 at different time steps is plotted in Figure 3. The first two measures refer to the initial developing stage, when the network is still under construction. In the further steps the network seems to have reached a quasi equilibrium state, though the occurrence of fluctuations testifies the strongly dynamical character of such state. When the above equilibrium is reached, nearly fifty percent of the bifurcations belongs to the class AAN: this finding agrees with previous experimental and theoretical observations on single Y-shaped bifurcations (Bertoldi et al. 2005; Miori et al. 2006), according to which unbalanced equilibrium configurations are more likely to occur, in which one of the downstream distributaries carries a larger part of the water and almost all the sediments. Figure 3 also shows that the network development from one single straight channel toward a dynamic equilibrium is always accompanied by a decreasing percentage of fully active nodes (AAA) and consequently by an increasing number of fully non active bifurcations (NNN).

A similar behaviour has been detected in all the experimental runs, as shown in Figure 4. The Figure suggests that in the early stage of the experiments the percentage of the four classes varies significantly, as the total number of branches in the network increases. At larger values of the braiding index the fraction of active channels decreases; consequently some AAA bifurcations turn to the AAN and NNN typology. After few hours the network reaches an equilibrium configuration in which the relative percentage of bifurcations keeps almost constant.

Moreover Figure 5 shows that the percentages of the three main classes change as a function of the total stream power. In particular, the relative percentage of AAA and NNN bifurcations strongly depends on the stream power, while the frequency of occurrence of AAN keeps almost constant with a value approximately equal to 0.5. The higher sediment mobility is therefore linked to a higher number of AAA units compared to the NNN class.

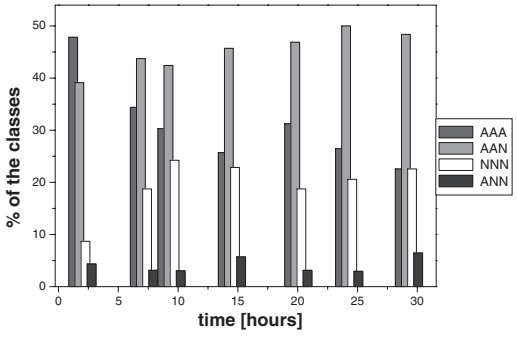

Figure 3. Temporal evolution of distribution of observed bifurcations (run P8).

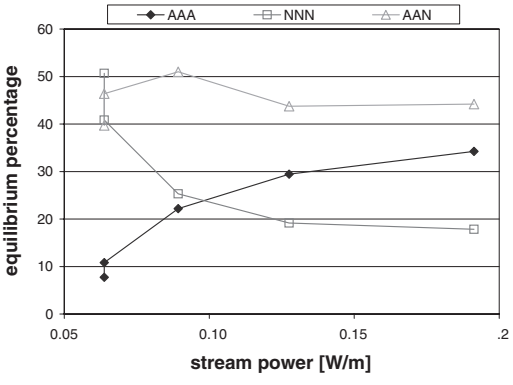

Figure 5. Equilibrium value of the percentage of classes AAA, AAN and NNN as a function of the stream power.

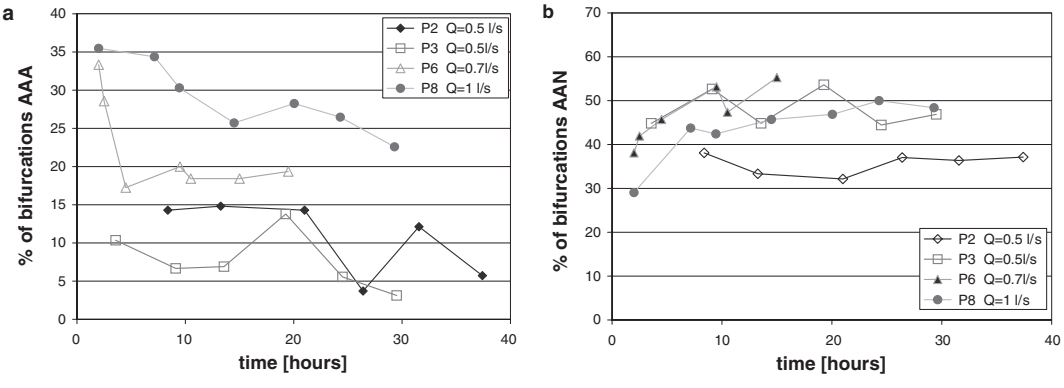

Figure 4. Percentage of AAA (a) and AAN (b) bifurcations as a function of time.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The above distinction in classes based on the sediment load activity suggests an alternative approach to define the "degree" of activity of the network. At first we have measured for each experimental run the value of the braiding index as it is commonly computed (Ashmore 2001), both considering the total number of branches (TBI) and the active fraction (ABI). Figure 6 shows that the ratio between the above parameters reached a well defined value in our experiments, that was found to depend on the stream power. Similar values have been also reported by Egozi and Ashmore (2005). This ratio can be also evaluated considering that active downstream branches are present only in the AAA and in the AAN cases; furthermore only one of the two branches are active in the AAN bifurcations. Hence, we propose the following equation that relates the "degree" of activity of the network (ABI/TBI) to the relative number of bifurcation classes:

$$\frac{ABI}{TBI} = \%AAA + \frac{1}{2}\,\%AAN\,. \qquad (1)$$

Such relationship provides a suitable estimate of the above ratio, taking from direct measurements; it also reflects the increasing degree of activity of the network for increasing values of the stream power. Therefore, Equation (1) can be a useful tool in order to link the information on the number of active channels and the probability of occurrence of fully active bifurcations. It is worth noticing that the morphologic evolution of the AAA nodes is one of the peculiar mechanisms of braiding dynamics, which is responsible for the fluctuations of water and sediment distribution within the network.

4 PLANIMETRIC CONFIGURATION OF BIFURCATIONS

The large number of digital images acquired in the experiments has allowed us to measure in detail and to describe some of the relevant parameters characterizing the planimetric configuration of a bifurcation. The geometrical pattern of individual nodes has been then related to the degree of asymmetry, taking into account both the discharge and the sediment transport distribution.

First of all we have analyzed the number of bifurcations occurring in the network, measuring their spatial density, defined as the total number of bifurcations per unit area. We have found that this parameter does not show a large variability and does not display a specific dependence on the total stream power. As reported in Figure 7, during each run the number of bifurcations increased in the first stage, when the network was evolving from a single straight channel. After this phase, the bifurcation density kept almost constant, reaching a sort of asymptotic value, which was nearly equal in all the runs.

We have then explored the possibility of linking the degree of activity of a bifurcation, namely its typology as defined in the preceding section, with its geometrical properties. In fact, in a braided network laboratory model water discharge measurements in the single branches are quite difficult, as the flow depths are generally very shallow and bed and banks evolution is quite sensible to the disturbances caused by the intrusion of instrumental devices.

Present experimental observations show that the difference between the widths of the downstream distributaries is a suitable parameter which embodies the degree of asymmetry of the diffluence units. We have then introduced a width asymmetry parameter as the ratio between the width difference and the total width:

$$\delta_b = \frac{(b_{rigth} - b_{left})}{(b_{rigth} + b_{left})}\,, \qquad (2)$$

where b_{rigth} and b_{left} are defined in Figure 10. Measured values of δ_b for some AAA and AAN bifurcations are reported in Figure 8. We can observe that fully

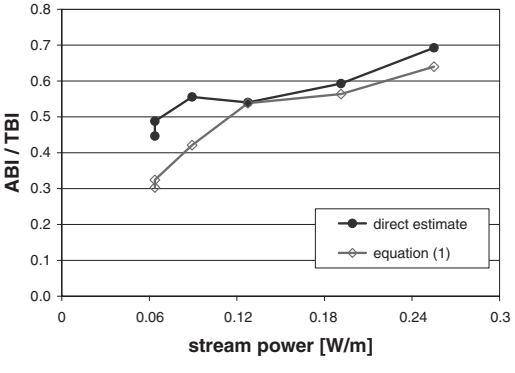

Figure 6. The ratio between the active and the total braiding index as directly measured and evaluated through equation 1 as a function of the total stream power.

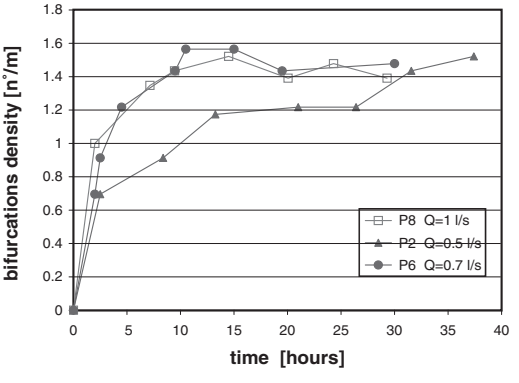

Figure 7. Spatial density of bifurcations as a function of time, for each experimental run.

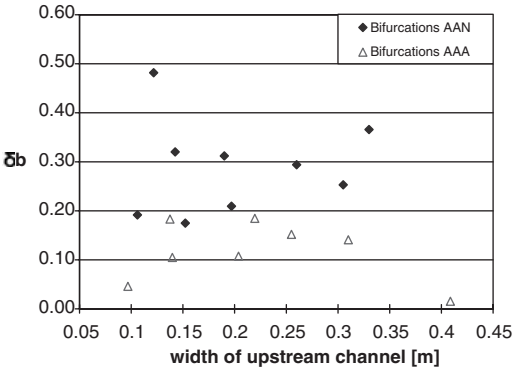

Figure 8. Width asymmetry of the AAA and the AAN bifurcations, as a function of the width of the upstream channel.

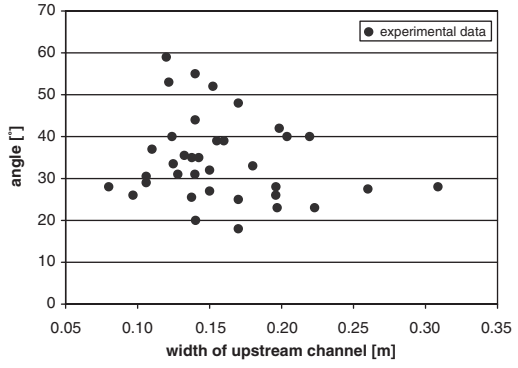

Figure 9. Angles between the downstream branches.

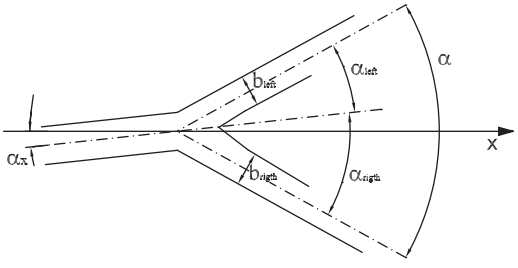

Figure 10. Sketch of the measured angles in a Y-shaped bifurcation.

active nodes show a more balanced pattern, characterized by relatively smaller values of δ_b (note that $\delta_b = 0$ represents a symmetrical configuration). On the contrary, in the AAN bifurcations the downstream branches display fairly different widths, such as δ_b can even reach a value equal to 0.5. Moreover, in this case the width asymmetry exhibits a fairly large variability

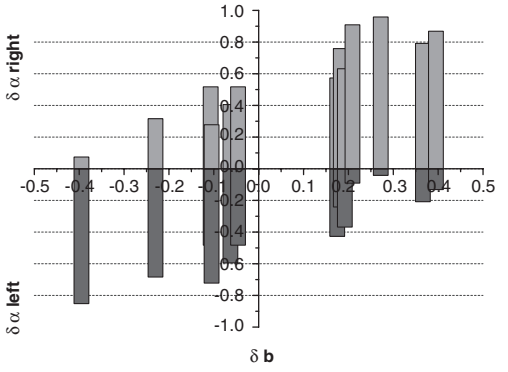

Figure 11. Angle asymmetry as a function of the width asymmetry of the downstream branches.

as the unbalanced character of the AAN class is able to determine a wide range of discharge distributions.

Another relevant parameter is the angle between the downstream branches, defined as the angle formed by the axes of the distributaries. We have found that its value may range from 20 to 55 degrees, with an average value of 35 degrees. These figures are in good agreement with those documented in previous field and laboratory observations (Federici abd Paola 2003; Bertoldi and Tubino 2005).

As a further index of the planimetric asymmetry of the node configuration, we have measured the deviation of the downstream branches with respect to the direction of the incoming flow. Figure 10 summarizes the notation adopted herein: α is the total angle between the distributaries, α_{rigth} and α_{left} are the deviations from the upstream channel direction and α_x is the angle between the longitudinal axis and the upstream branch axis.

We have defined the angle asymmetry as the ratio between the deviation of one branch and the total angle, as reported in the following Equation:

$$\delta\alpha_{rigth} = \frac{\alpha_{rigth}}{(\alpha_{rigth} + \alpha_{left})}, \qquad \delta\alpha_{left} = \frac{\alpha_{left}}{(\alpha_{rigth} + \alpha_{left})}. \tag{3}$$

Present experimental findings show that an asymmetric bifurcation, which is characterized by a large value of the width asymmetry δ_b, generally displays a larger difference in the deviations of the downstream branches. Such relationship suggests that the planimetric configuration of the node is strongly affected by the discharge distribution. In particular AAA bifurcations typically exhibit an almost symmetrical geometry, while in the AAN case the main downstream branch is likely to be oriented as the incoming flow. In this case, the smaller downstream channel behaves as a

Copyright © 2006 Taylor & Francis Group plc, London, UK

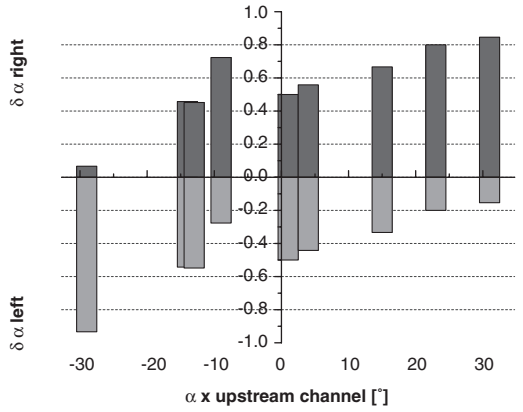

Figure 12. Angle asymmetry as a function of the orientation of the upstream branch, for the AAA bifurcations.

lateral avulsion, draining only a little fraction of the total discharge.

Finally, we analyzed the relationship between the deviation of the distributaries and the orientation of the upstream branch. We have observed that the AAA bifurcations keep more symmetrical when the α_x attains low values. Some examples are given in Figure 12. We may notice that when the upstream channel largely deviates from the main longitudinal direction, one of the downstream branches is almost aligned with the incoming flow, while the second branch generally takes the steeper direction. In this case, the further controlling parameter is the position of the bifurcation inside the network, since we have observed that nodes close to the lateral bank of the floodplain generally display higher values of α_x.

5 CONCLUSIONS

The paper reports on a series of systematic measurements on single bifurcations in a braided network, focussing the attention mainly on the occurrence of sediment transport in the branches and on their planimetric configuration. A classification has been proposed, based on the activity (in terms of bed load transport) of the channels forming the Y-shaped units. Four possible classes have been identified:

- the AAA bifurcations, with all the branches active;
- the AAN, characterized by a strong asymmetry of the water distribution, that implies the inactivity of one of the downstream branches. This class has been found to be the most frequent, nearly corresponding to the 50% of observed bifurcations;
- the NNN type, that represents abandoned bifurcations, that were not involved in the network evolution at the time of the survey;
- the ANN type, a rare and highly unstable configuration, that rapidly evolves into the AAN or the NNN class.

The relative percentage of these classes has been found to provide a suitable parameter in order to define the degree of activity of the network, that is quantified by the ratio between the number of active branches and the total number of wet branches per cross section.

The asymmetry of the planimetric configuration of bifurcations has been described in terms of the width asymmetry of the downstream branches and of the deviations of the axes of branches with respect to the orientation of the incoming flow and to the direction of the main longitudinal direction.

Present experimental results may open the path to the establishment of suitable rules which can be used in order to accurately describe the bifurcation process in a braided stream. In particular they may allow to predict the discharge asymmetry from the planimetric configuration or, in a complementary way, to infer the orientation of the branches joining at the node, when the flow partition is known.

Study on river change and sediment transportation of Tan Chau reach in lower Mekong river

X.L. Luu & S. Egashira
Ritsumeikan University, Kusatsu, Shiga, Japan

H. Takebayashi
University of Tokushima, Tokushima, Japan

ABSTRACT: This study presents field data of topography change, bed material, water surface elevation and hydrograph at Tan Chau reach in Vietnam to understand mechanism of the river change. The results of field survey show that bank shifting tends to occur toward anti-clock wise and sand bars migrate downstream, resulting in a much larger bar, which is influenced by co-presence of non-cohesive and cohesive sediment and artificial works. In addition, bed material loads are originated by bank erosion. A two dimensional numerical model is proposed to simulate flow pattern and associated river change. In this model, erosion rate formula for cohesive material and formula for estimating the thickness of sediment transport layer as a function of bed shear stress are introduced into the standard layer model which was firstly proposed by Hirano (1971). The proposed model can estimate the sediment transport rate on the bed composed of non-cohesive and cohesive material and predict the topography change of study reach.

1 INTRODUCTION

The Mekong River is ranked twelfth in length and sixth in mean annual discharge, globally. It drains the area of 795,500 km^2 from Himalayas, through Southwestern of China, Laos, Thailand, Cambodia and Vietnam. The Mekong Delta which is located in Vietnam plays an important role in society and economic development, supporting 16 million inhabitants and contributing to over 27% of national GDP. Therefore, river change and associated bank erosion cause serious socio-economic problems.

The study reach is about 18 km long, a part of the Mekong River, which is located at Tan Chau near the national border with Cambodia and 190 km away from coast as shown in Fig. 1. Left bank of the reach in Thuong Phuoc has received strongest and fastest erosion which takes place frequently not only in flood season but also in dry season. Annual averaged erosion rate is estimated at about 30–50 m/year. Such bank erosion causes damages of more than 100 houses a year. The bank erosion at northwest side of Tan Chau City is estimated at about 6 m per year, which is not so large comparing to other places. However, Tan Chau is populated densely and urbanized much more than others. Therefore, damages due to the bank erosion are serious. As above circumstances, it is emphasized that bank protections and preferable counter measures should be conducted.

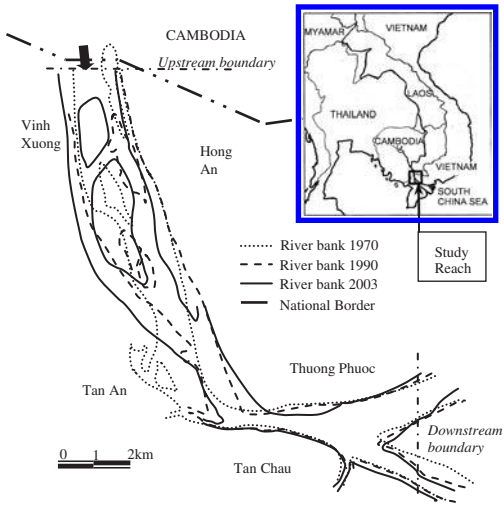

Figure 1. Bank lines measured in 1970, 1990 and 2003.

In 2001, Southern Institute of Water Resource Research – River Training Center conducted a research

Copyright © 2006 Taylor & Francis Group plc, London, UK

about erosion problems at several places. But unfortunately, no reasonable methods have been proposed except temporary bank protections.

Present study described circumstances of bank erosion and associated problems based on field data focusing on Tan Chau reach, 18 km long, and proposed a numerical method to treat such river changes. In the numerical method, new formulas treating with sediment exchange layer as well as with channel erosion rate for sediment composed of non-cohesive and cohesive material, are introduced into the two dimensional numerical models which were proposed by Nagata et al(2000) and Liu(1991).

2 CHARACTERISTICS OF STUDY REACH

Data of hydrograph and water surface elevation were provided by Mekong River Commission. Figure 2 shows water discharge at Neak Luong gauge station, located at about 80 km upstream from Tan Chau reach. The maximum discharge is 31799 m^3/s in September and minimum one is 3050 m^3/s in April, respectively. Flood duration is about 7 months in which water level is rising during 3 to 4 months and lowering during 3 months. Therefore, flow velocity in flood season at some river reach exceeds the specific critical velocity for long time. The specific critical velocity that is a criterion causing active erosion are shown for bed and bank regions in Table 1 (Le, 1997).

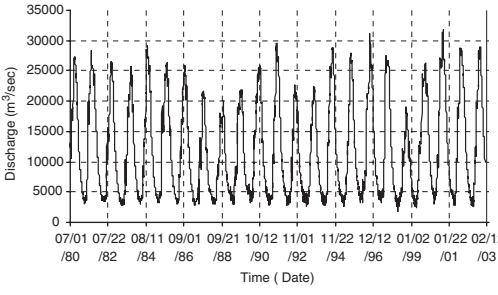

Figure 2. Water discharge of the Mekong River at Neak Luong gauge station (about 80 km upstream from Tan Chau reach).

Table 1. Cross-sectional average flow velocity and specific critical velocity for threshold of active erosion.

Velocity (m/s)	Tan Chau (Mekong)	Long Xuyen (Bassac)
Flow velocity	2.7	1.86
Specific critical velocity of bed erosion	0.5	0.43
Specific critical velocity of bank erosion	0.58	0.78

On the other hand, the Mekong Delta was formed in the duration from Old-Tertiary Period of Cenozoic (ten million years ago) to Pleistocene when the Himalaya Mountains appeared. Thereafter, in the Quaternary Period, Indochina region was affected by sea expanding and 80% of the present Mekong Delta was submerged (Pham et al., 1991). Since then, the Mekong Delta may have been influenced by seasonal and daily changes of hydrological quantities as well as by associated sediment transportation.

3 FIELD SURVEY

Field survey were performed in 2003 and 2005 to measure topography of river and to collect bank and bed material. Cross sections of river reach were measured by Echo Sounder system attaching with GPS, as shown in Figure 4. Specially bed sediment was collected by diver along a deepest line at every 1 km spacing.

3.1 *Size of bed and bank materials*

Figures 5, 6 and 7 show the size distribution curves at left bank, right bank and river bed, respectively. As

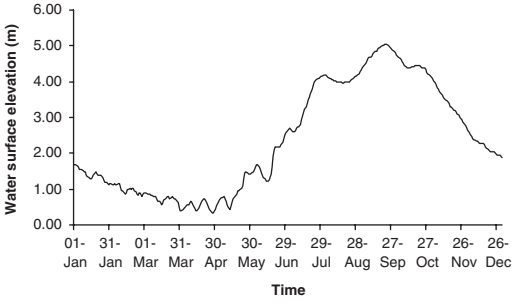

Figure 3. Water surface elevation at Tan Chau gauge station in 2000.

Figure 4. Echo Sounder and GPS system.

Copyright © 2006 Taylor & Francis Group plc, London, UK

shown in these figures, the bank's sediment is composed of wide range of particle size from clay to fine sands, and the medium size is almost smaller than 0.1 mm. Whereas the bed sediment is much coarser than the bank's one, and the medium size ranges 0.15 mm to 0.3 mm. These differences can be seen clearly in Figure 8 in which distributions of mean diameter measured along study reach. Such differences in sediment size between banks and river bed suggests that fine sediment included in side banks , i.e. finer than 0.1 mm in diameter, is released once into flow, and thus transported far as wash load and that the sediment coarser than 0.1 mm deposits onto bed and is transported as bed loads and suspended loads. In addition, bank materials was investigated by core sampling as shown in Figure 9. It suggests that sediment at side banks are effected much by erosion, deposition and channel shifting. Coarse sediment included in side banks, which can be seen partly in Figures 5 and 6, are may deposited by flow recently.

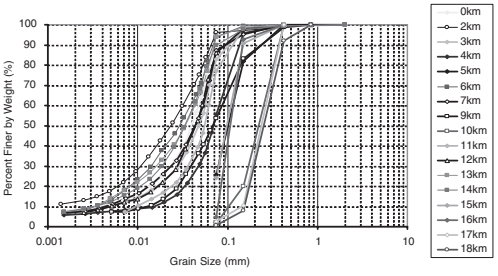

Figure 5. Grain size distribution of left bank material (surveyed on February in 2005).

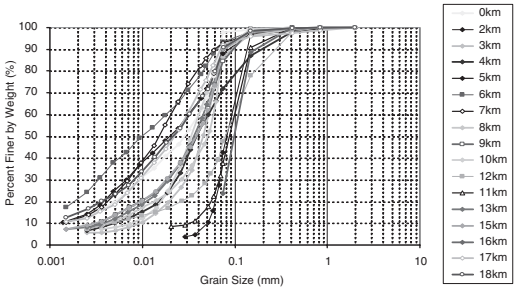

Figure 6. Grain size distribution of right bank material(surveyed on February in 2005).

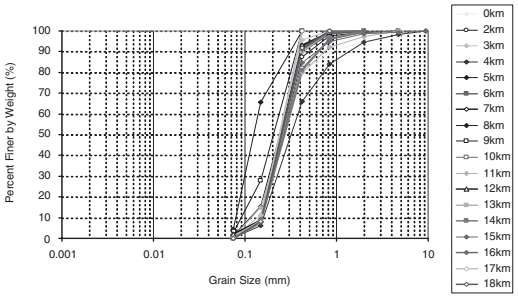

Figure 7. Grain size distribution of bed material (surveyed on February in 2005).

3.2 *Channel deformation*

Figure 1 shows shore lines of study reach. The lines in 1970 and 1990 are obtained by maps which are provided by National Institute of Survey in Vietnam. The line in 2003 is obtained by our measurement. According to Figure 1, two representative characteristics can be distinguished on channel shifting as follows. The bank lines in upstream reach with large islands (submerged bars during flood season) have been shifting to west. Furthermore, the curved reach near Tan Chau City shows a dramatic change that is caused by curved flow. The left bank at the upstream and the downstream of the curvature shift to east and north, respectively. In fact, a stationary point was formed between Tan Chau and Thuong Phuoc. The downstream migration of islands, the rapid development of sand bar at Tan An and the narrow channel at Tan Chau significantly influence to flow pattern as well as direction of hydrodynamic force. These factors may be main reasons of river changes. On the other hand, the right bank at the

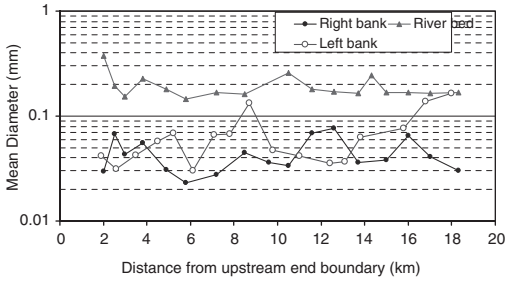

Figure 8. Longitudinal distribution of mean diameter of the materials.

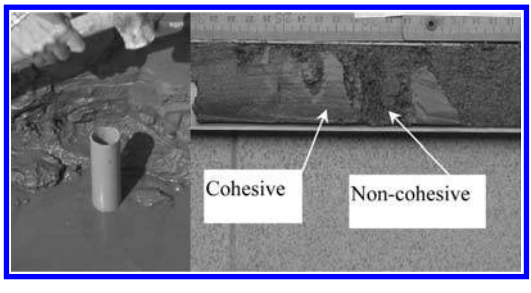

Figure 9. A core sample at river bank. In the deposited layers cohesive and non-cohesive sediment is formed alternatively.

Copyright © 2006 Taylor & Francis Group plc, London, UK

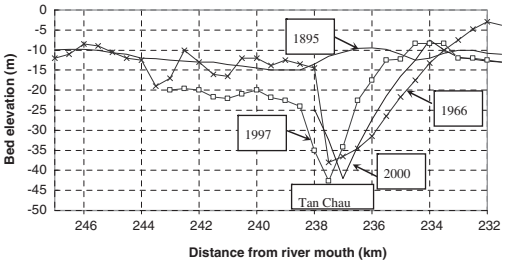

Figure 10. Longitudinal profile of deepest channel bed.

Tan Chau City is consolidated by urbanizing performance, and protected by bank protection works which was constructed from 2000. Hence, the bank erosion along Tan Chau City is almost invisible.

In addition, river bed is expected to be scoured deeply along the right bank at Tan Chau because of curved flow as well as of narrow reach, and its deepest position tends to move to downstream which can be seen in Figure 1 and 10.

4 NUMERICAL CALCULATION

4.1 *Governing equations*

Depth integrated two dimensional form of mass and momentum conservation equations for flow, in addition to these, mass conservation equations of sediment for bed layer as well as for flowing water and sediment transport equations are employed.

Referring to the results on bed and bank material shown in Figures 5, 6, 7, 8 and 9, sediment is transported as bed loads and suspended loads including wash loads. In addition, cohesive sediment exists alternately with non-cohesive sediment, and plays an important role on sediment transport and associated river change. In order to treat such problems, several new relations are introduced into the layer model firstly proposed by Hirano (1971) and bed elevation equation. Specially, in this method, bed surface is clearly defined as the boundary between bed load layer and stationary layer, which is shown in Figure 11. Thickness of bed load layer changes with bed shear stress; i.e. Egashira & Ashida 1992. In addition, as show in chapter 3, some treatments of cohesive material are needed for evaluating sediment transportation and river change.

In Figure 11, bed layer model including bed load layer is shown, in which some parts of bed layer are composed of cohesive sediment.

Supposing that the first layer is composed of non-cohesive material, mass conservation equation of sediment for bed layer (sediment continuity equation/equation for bed elevation) can be given as

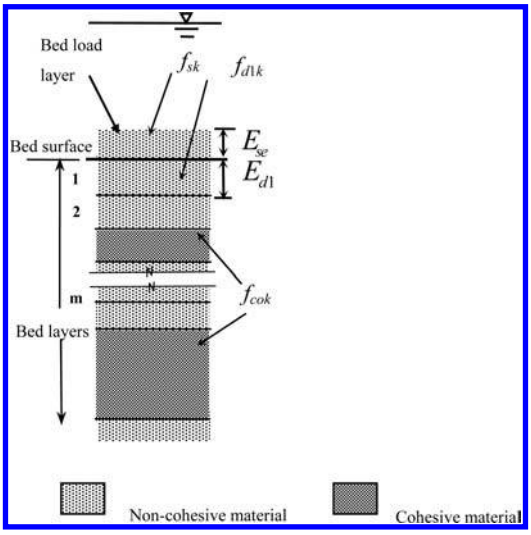

Figure 11. Schematization of sediment exchange process between bed load layer and layers under bed surface.

follows, introducing a new term into a well known formula in order to evaluate the mass change of sediment due to change of thickness of bed load layer.

$$\left(1-\lambda\right)\frac{\partial}{\partial t}\left(\frac{z_b}{J}\right)+\overline{c_s}\frac{\partial}{\partial t}\left(\frac{E_s}{J}\right)+\sum_{k=1}^{n}\left[\frac{\partial}{\partial \xi}\left(\frac{q_{b\xi k}}{J}\right)+\frac{\partial}{\partial \eta}\left(\frac{q_{b\eta k}}{J}\right)+\frac{1}{J}w_k\left(c_{bek}-c_{bk}\right)\right]=0 \quad (1)$$

$$,\left(E_{sd}\geq E_{se}\right)$$

Otherwise, if first layer is composed of cohesive material, and if bed layer is thinner than the equilibrium thickness E_{se}, Equation (1) will be:

$$\frac{\partial}{\partial t}\left(\frac{z_b}{J}\right)+\frac{V_e}{J}=0, \quad \left(E_{sd}\leq E_{se}\right) \quad (2)$$

Continuum equation of each grain size for bed load layer is written as follows.

$$\overline{c_s}\frac{\partial}{\partial t}\left(\frac{f_{sk}E_s}{J}\right)+\left(1-\lambda\right)F_{sk}\frac{\partial}{\partial t}\left(\frac{z_b}{J}\right)+\left\{\frac{\partial}{\partial \xi}\left(\frac{q_{b\xi k}}{J}\right)+\frac{\partial}{\partial \eta}\left(\frac{q_{b\eta k}}{J}\right)\right\}+\frac{1}{J}w_k\left(c_{bek}-c_{bk}\right)=0 \quad (3)$$

in which:

$$F_{sk}=f_{d1k},\ \left(\partial z_b/\partial t\leq 0, E_{sd}\geq E_{se}\right);$$

$$F_{sk}=f_{cok},\ \left(\partial z_b/\partial t\leq 0, E_{sd}\leq E_{se}\right);$$

$$F_{sk}=f_{sk},\ \left(\partial z_b/\partial t\geq 0\right)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

Continuum equation of each grain size for first is evaluated as follows.

$$E_{d1}\frac{\partial}{\partial t}\left(\frac{f_{d1k}}{J}\right)+\left(f_{d1k}-F_{dk}\right)\frac{\partial}{\partial t}\left(\frac{E_{d1}}{J}\right)=0 \tag{4}$$

in which:

$$F_{dk}=f_{d1k},\quad (\partial z_b/\partial t\le 0);$$

$$F_{dk}=f_{sk},\quad (\partial z_b/\partial t\ge 0)$$

In these equations J = Jacobian; λ = porosity; $q_{b\xi k}$ and $q_{b\eta k}$ = sediment transport rate for size class k in ξ and η directions, respectively; f_{sk} = fraction of size class k in the bed load layer; f_{cok} = sediment fraction of size class k in the cohesive sediment layer; E_{dm} and f_{dmk} = thickness and fraction of size class k in the *m-th* bed layer composed of non-cohesive sediment, respectively (m = 1,2..); $\bar{c}_s$ = sediment concentration of bed load layer ((1-λ)/2 is used as $\bar{c}_s$ for simplicity); V_e = erosion rate of cohesive sediment; E_s = bed load layer thickness; E_{sd} = thickness of non-cohesive sediment over cohesive sediment; E_{se} = thickness of equilibrium or saturated bed load layer estimated by the following equation (Egashira et al.,1992).

$$\frac{E_{se}}{d_m}=\frac{1}{\bar{c}_s\cos\theta\left(\tan\phi-\tan\theta\right)}\tau_{*m} \tag{5}$$

in which d_m = the mean sediment size of bed load; θ = local bed slope; ϕ = the angle of repose; τ_{*m} = non-dimensional bed shear stress specified by d_m. Relations among E_s, E_{se} and E_{sd} are as follows.

$$\begin{aligned} &E_s=E_{se},\quad (E_{sd}\ge E_{se});\\ &E_s=E_{sd},\quad (E_{sd}\le E_{se}) \end{aligned} \tag{6}$$

Sediment transport rates of size class k of non-cohesive material are estimated by following equations.

$$q_{b\xi k}=\xi_x q_{bxk}+\xi_y q_{byk} \tag{7}$$

$$q_{b\eta k}=\eta_x q_{bxk}+\eta_y q_{byk} \tag{8}$$

Herein bed load rate q_{bk} for size class-k is defined as $q_{bk}=\sqrt{q_{bxk}^2+q_{byk}^2}$ and is estimated by the following relation (Liu, 1991; Kovacs and Parker, 1994).

$$q_{bk}=17\frac{\rho u_{*e}^3}{(\rho_s-\rho)g}\left(1-\sqrt{K_c}\frac{u_{*ck}}{u_*}\right)\left(1-K_c\frac{u_{*ck}^2}{u_*^2}\right)f_{sk}r_s \tag{9}$$

In Eq. (9), ρ = water density; ρ_s = sediment density; u_{*e} = effective shear velocity; u_* = shear velocity; u_{*ck} = critical shear velocity of size class k;

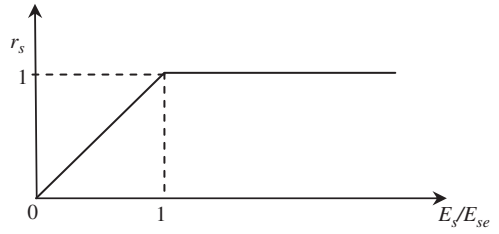

Figure 12. Relation between r_s and E_s/E_{se}.

K_c = correction factor related to bed inclination (Liu, 1991; Kovacs and Parker, 1994). r_s is introduced to describe the unsaturated bed load rate and is a function of relative depth E_s/E_{se} as shown in Figure 12.

The deviation angle β_k of mean path of size class k to the x direction, which depends on the flow near bed and inclination of bed, is calculated by following formulas (Liu, 1991; Kovacs and Parker, 1994).

$$\tan\beta_k=\frac{\sin\alpha-\Pi\Theta_y\left(\frac{u_{*ck}^2}{u_*^2}\right)\tan\theta_y}{\cos\alpha-\Pi\Theta_x\left(\frac{u_{*ck}^2}{u_*^2}\right)\tan\theta_x} \tag{10}$$

$$\Pi=K_{ld}+1/\mu_s \tag{11}$$

$$\Theta_y=\frac{1}{1+\tan^2\theta_x+\tan^2\theta_y} \tag{12}$$

$$\Theta_x=\Theta_y+\frac{\rho}{\rho_s-\rho}\cos^2\theta_x \tag{13}$$

where K_{ld} = the ratio of the lift force to drag force; θ_x and θ_y = the bed inclinations in x and y direction, respectively; α = angle of deviation of flow near bed from x direction; μ_s = coefficient of static friction.

The above mentioned sediment transport rate of size class k in x and y directions are $q_{bxk}=q_{bk}\cos\beta_k$ and $q_{bxk}=q_{bk}\sin\beta_k$, respectively.

The erosion rate of cohesive sediment, V_e, is estimated in terms of Sekine et al.'s formula (Sekine et al., 2003).

$$V_e=\alpha R_{wc}^{2.5}u_*^3(1-r_s) \tag{14}$$

in which α is the empirical coefficient and R_{wc} is the water content ratio of cohesive sediment.

Velocities near the bed are evaluated using curvature radius of streamlines:

$$u_b=8.5u_*,\ v_b=-N_*(h/r)u_b \tag{15}$$

in which N_* = 7.0 (Engelund, 1974); r = the curvature radius of stream lines obtained by depth integrated velocity field.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Settling velocity of suspended sediment of size class-k, w_k, is estimated in terms of Rubey's formula (Rubey, 1933) and quasi-equilibrium suspended concentration, c_{bek}, for size class-k at reference level is evaluated as follows (Lane et al.,1941).

$$c_{bek} = 5.55 f_{sk} \left\{ \frac{1}{2} \frac{u_*}{w_k} \exp\left[-\left(\frac{w_k}{u_*} \right)^2 \right] \right\}^{1.61} r_s \quad \text{[ppm]} \quad (16)$$

in which r_s is the same as the factor in equation (9). It is considered that equilibrium sediment concentration is formed at reference level when bed load layer is saturated, whereas it decreases with the decrease of relative thickness r_s, as shown in Figure 12, because sediment can not be supplied fully through bed load layer for suspension. Therefore, the sediment concentration determined by equation (16) is called "quasi-equilibrium"; c_{bk} = suspended sediment concentration of size class k at reference level. When the vertical distribution of suspended sediment concentration is supposed to be the exponential distribution, the relationship between c_{bk} and the depth-averaged value; c_k is expressed as follows.

$$c_k = \frac{c_{bk}}{w_k h / D_h} \left(1 - e^{-w_k h / D_h} \right) \quad (17)$$

Suspended sediment transport is evaluated using the following continuum equation.

$$\begin{aligned} &\frac{1}{J}\frac{\partial}{\partial t}(c_k h) + \frac{\partial}{\partial \xi}\left(\frac{c_k}{J} Q^{\xi} \right) + \frac{\partial}{\partial \eta}\left(\frac{c_k}{J} Q^{\eta} \right) = \frac{1}{J} w_k (c_{bek} - c_{bk}) \\ &+ \frac{\partial}{\partial \xi} h \left(\frac{D_x \xi_x^2 + D_y \xi_y^2}{J} \frac{\partial c_k}{\partial \xi} + \frac{D_x \xi_x \eta_x + D_y \xi_y \eta_y}{J} \frac{\partial c_k}{\partial \eta} \right) \\ &+ \frac{\partial}{\partial \eta} h \left(\frac{D_x \xi_x \eta_x + D_y \xi_y \eta_y}{J} \frac{\partial c_k}{\partial \xi} + \frac{D_x \eta_x^2 + D_y \eta_y^2}{J} \frac{\partial c_k}{\partial \eta} \right) \end{aligned} \quad (18)$$

in which h is water depth, ξ_t, η_t, ξ_x, η_x, ξ_y, η_y are metrics, D_x and D_y are the dispersion coefficient in x and y directions, respectively ($D_x = D_y = D_h$ as a diffusion coefficient for simplicity).

Bank erosion with non-cohesive material is evaluated using the model of Nagase et al.(1996). This is based on the stability condition by angle of repose of material. In case of cohesive material, equation (2) is applied for this method.

4.2 *Numerical method and computational conditions*

Numerical computations were conducted for two cases. Sediment transport of Case 1 is only bed load. Nevertheless, bed load and suspended load were considered in Case 2. TVD MacCormack numerical scheme is used only for advection terms of momentum conservation equations. Staggered grid system is used and shown in Figure 13, where U, V, Q^{ξ} and Q^{η} are ξ and η components of velocity vectors and discharge fluxes, respectively. In the equations associated with sediment, the first order up-wind scheme is employed for the terms of first-order spatial derivatives, and the central difference approximation is used for the terms of second-order spatial derivatives.

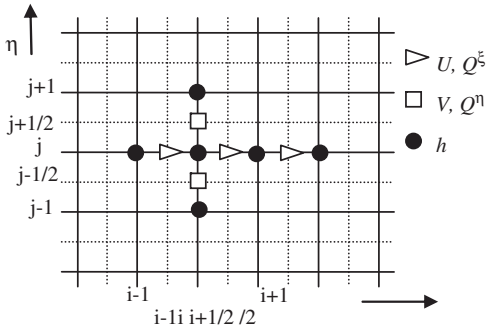

Figure 13. Defined location of variables.

Computational conditions which are employed in this study are summarized as follows. Computation domain, which is shown in Figure 1, is 18 km long. The initial bed geometry is specified based on the data obtained from the field survey in 2003. Flood plain is assumed to be expanded laterally about one kilometer from the both banks and its elevation is assumed to be equal to the bank elevation. The data of the year 2000 in hydrograph which is shown in Figure 2 and water surface elevation which is shown in Figure 3 are used for upstream and downstream boundary condition, respectively. The value of f_{sk} and c_k at the upstream boundary are estimated by use of collected bed material distribution and equilibrium hydraulic conditions. It is supposed that side bank, which is steeper than the angle of repose of non-cohesive sediment, is composed of cohesive sediment. Furthermore, bed is assumed to be covered one meter deep by non-cohesive sediment.

5 RESULTS AND DISCUSSION

The computational domain and its grid system are shown in Figure 14. Figure 15 shows computed results on flow patterns of depth mean. Figures 16 and 17 show contour lines of topography changes and cross-sectional shapes as well as its bed load transport rate in ξ and η direction in flood season (September), respectively. The results shown in Figure 15 suggest that the flow pattern is influenced very much as a whole by initial condition such as a presence of large sand bar and by the narrow channel shape at downstream of

section 46. In addition, stream currents were strengthened along the right bank from section 27 and change to left bank before going to right bank again at section 46. Such complex change of flow pattern will cause a channel shift toward anti-clock wise, and also will be affected by the caused channel change.

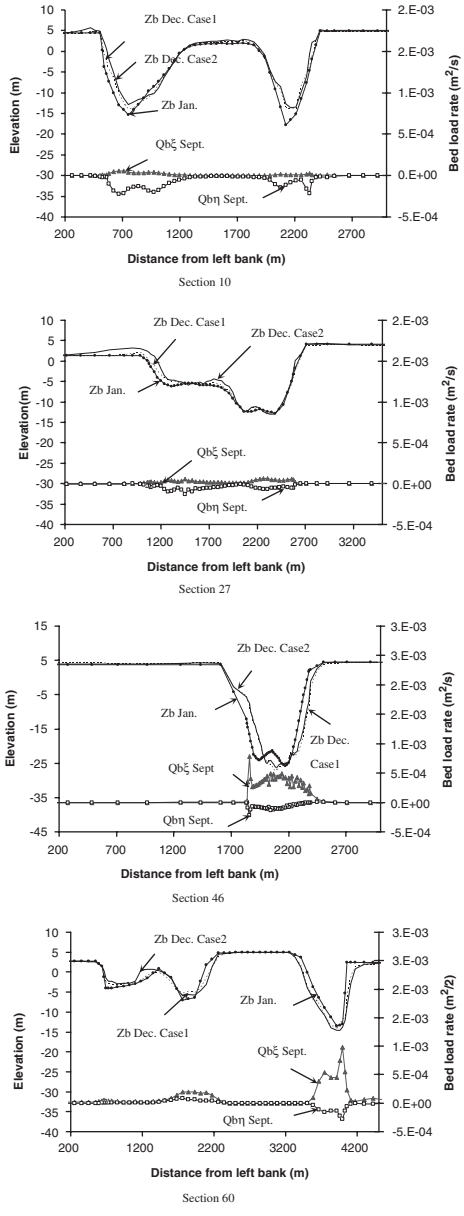

Figure 17. Channel deformation and bed load transported rate of section 10, 27, 46 and 60, respectively.

The Figures 16 and 17 show computed results on topography changes. The influence of suspended load can be easily seen in different results between Case1 and Case2 in Fig 16. This suggests that suspended load deposited much on flood plain where roughness coefficient is high, or deposited at downstream part of sand bar. These cause sand bar develop and migrate to downstream, i.e. development of large sand bar at upstream and sand bar at downstream which located along the left river bank as partly shown in section 60 of Fig 17. In addition, left bank from section 10 to section 27 tend to deposit. This phenomenon agrees with the real situation. However, right bank side at upstream part is not predicted well. This may be caused by upstream boundary conditions, i.e. equilibrium concentration of suspended sediment. The numerical results in section 46 show that right bank is much eroded whereas sediment deposits along left bank. On the other hand, in actual situation, right bank side is covered by protection works, therefore the data which shown in Fig 1 seems to be different with computed results.

As shown in the results of Figure 15, 16 and 17, the computed channel changes correspond qualitatively with the tendency described in Figure 1. However, because of lack of topography data in 1970, 1990, authors must use the topography data of 2005 to predict the river change as the initial condition. Therefore, there is no exact data to verify the results of computation. In addition, actual conditions such as more exactable initial channel shape, sediment characteristics of material which is located under bed surface associated with channel erosion, and artificial works should be introduced into computational conditions.

6 CONCLUSIONS

Channel change in part of Mekong River was investigated using field data and the numerical method to develop a tool treating channel shifting in which the presence of cohesive sediment plays important roles in sediment transport phenomena. Results and further problems are summarized as follows.

Data analysis suggests that bed material can be produced due to bank erosions. River sediment is composed by cohesive and non-cohesive materials. Data of bed and bank material are provided to study the river change which is probably influenced by the co-presence of non- and cohesive sediments.

Bank erosion and associated channel shifting have been controlled by moving of large bar, channel plane form and several artificial performances in addition to the sediment characteristics and hydrological data variations.

A 2-D numerical analysis describing bed deformation and bank shifting was proposed by introducing erosion rate formula for cohesive material and formula for estimating the thickness of bed load layer, and it was used to predict channel morphological process. The simulated results can explain a tendency of the channel shifting, and emphasize that the presence of fine sediment as well as cohesive material influences the channel change.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Further studies are desired for: study of historical formation process on Mekong Delta to evaluate present sediment phenomena, further refinement of numerical model and long time computations of various hydrological conditions to test validity of present model, etc..

Morphodynamics of mountain rivers following repeated sediment release from reservoirs

Giacomo Fasolato, Paolo Ronco, & Matteo Tregnaghi
Hydraulic, Maritime, Environmental and Geotechical Engineering Department, University of Padova, Italy

ABSTRACT: In the paper an appropriate morphodynamic model has been developed and applied to simulate flushing operations repeatedly performed from an alpine reservoir in the last decade and to optimize flushing operations in the future. The morphodynamic model is based on a relatively simple hydrodynamic component, while much attention is devoted to the non-uniform distribution of sediment grainsize ranging over four or five order-of-magnitudes (from boulders to silt) which is typical of alpine rivers.

The experimental conditions of the selected river reach are especially favourable to investigate flushing effects, as the release operations from the reservoir can reasonably be controlled, together with their morphological consequences downstream. The chronological sequences of strong deposition and subsequent erosionphases have been simulated with the model. An improvement of the sediment management criteria may be investigated with the same model.

1 INTRODUCTION

1.1 *Impacts of dams on the river morphology*

In numerous catchments throughout the world human intervention has altered natural river dynamics. Among others, dams and reservoirs constructed in the last century for hydroelectric power generation, flood attenuation, storage for irrigation, navigation, etc., are causing substantial changes to the flow and sediment regimes, with significant impacts on the river morphology, upstream and downstream of the dam. A more evident alteration of the river system caused by dams is the trapping of solids conveyed by the river, which in turn causes the reduction of sediment load in the reach downstream (Morris & Fan, 1997). Moreover, reservoirs significantly reduce flood peaks and flood durations, and consequently lower the sediment transport capacity. As years go, natural consequences of these changes are, upstream, the progressive reduction of the reservoir water storage capacity and river overaggradation; downstream, the change of the natural morphological features, general bottom erosion and many other negative consequences with serious economic, sociological and environmental implications (Basson & Rooseboom, 1997).

1.2 *Strategies to control and mitigate negative impacts*

Several procedures and techniques for preventing, reducing or mitigating reservoir sedimentation and its negative consequences have been devised and experimented as described in scientific and technical literature. One of the more efficient and economic intervention is probably the regular releases of sediments from the reservoir to the river (either by flushing or by mechanical means) especially if sufficient water discharge is allowed to convey the sediments along the fluvial system (Di Silvio & Scagnetto, 2001).

Releasing large quantities of sediments concentrated in time and space, on the other hand, may bring about complications. Obviously, release procedures have to be carefully planned, tested and preventively simulated to guarantee full control and safety of the operation.

The purpose of this work is to describe and reproduce with simplified morphodynamic model (Di Silvio & Peviani, 1989) the consequences of sediment management at basin scale and eventually advise for a possible future improvements. The model is intended to reproduce the flushing operations from an alpine reservoirs repeatedly performed in the last decade and their effects along the river. The results are compared with some measurements and data field collected in the last year by the authors and by the reservoirs manager Enel/GEM (Generation Energy Management).

2 THE PIAVE RIVER

2.1 *An example of substantial human impacts*

The Piave River rises in the Eastern Alps at an elevation of 2,037 m a.s.l. and its mouth, in the Adriatic Sea, is

Copyright © 2006 Taylor & Francis Group plc, London, UK

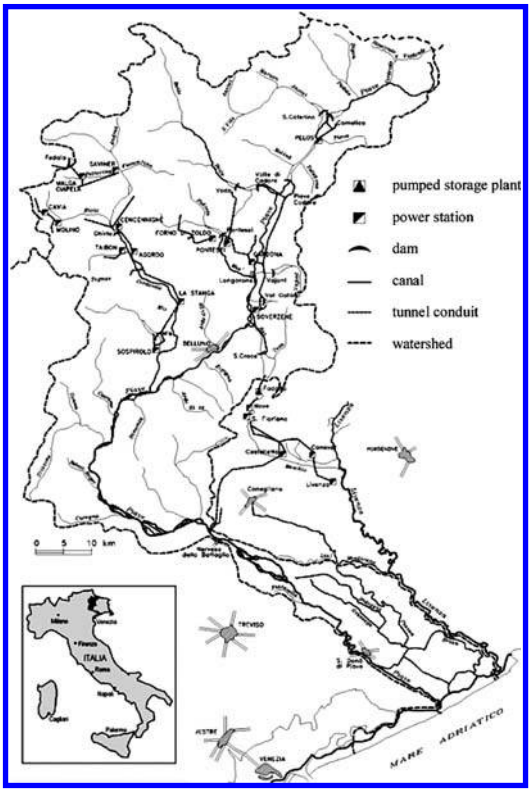

Figure 1. Water resource development in the Piave River Basin (Eastern Alps, Italy).

located about 30 km northeast of Venice. It has a length of 222 km and its watershed has an area of 3,899 km^2 (Figure 1).

During the last 70 years many hydraulic constructions were built for 24 hydroelectric power plants (managed by many different members) with more than 50 dams and 200 km of pipes and channels for irrigation that carry flow and divert water along its course (Enel, 1993).

The present regime of water regulation and diversion has altered both the flow duration and the volume of annual runoff, with consequent reduction of sediment transport capacity. Although it is not possible evaluating with precision the sediment delivery, several dams, along the river and its tributaries, trap sediment yield from an area corresponding to more than 50 per cent of the drainage basin (Surian, 1999, Surian, 2003). Reductions in sediment supply is also due to intense gravel mining. Since 1960s, in fact, in the Piave river and its tributaries a huge volume of sediment was excavated, which was estimated to be in the order of 10^6 m^3 per year (D'Alpaos & Dal Prà, 1996), but no records are available to validate those quantities.

Finally, stream bank protection structures, like groynes and levees, have canalized the river in a single, fixed channel, and reduced in many places bank erosion and consequent sediment load (Surian, 2000).

2.2 *Recent morphodynamic evolution of the river*

As for the evaluation of human impact on the recent dynamics of the Piave River, the research carried out by Surian (1999) is worthy of comment. Historical evolution has been documented using maps, aerial photographs and field data. Morphological features that were examined included channel width, planform configuration, braiding index, bed elevation and grain-size variation. The results indicate that as consequence of decreases in water flow and sediment supply, the river channel has undergone in its main reach a general narrowing to 35 per cent of its initial width. Besides, the planform pattern in several reaches has changed from braided to wandering, with corresponding deepening of the bed and a degradation rate of 20 to 70 mm/per year during this century. As expected, the highest rates were found immediately downstream of the main barrages.

Also the bed material shows a clear evolution. As expected, a general increase of grain size is evident downstream of the structures and describes, very likely, the evolution towards an armored bed (Surian, 2000).

2.3 *Research programs for sediment management*

Many studies are presently being carried on about sediment management of Piave's dams and its consequences, by several agencies and local administrations. The present work, is in part sponsored by the Watershed Agency "Autorità di Bacino dell'Alto Adriatico" in collaboration with the Italian Ministry of Research and University "MIUR" as a part of a national project on reservoir sedimentation (PRIN 2004). ALPRESERV, an European Project dealing with the same problems in many Alpine watersheds, is also involved in the Piave River investigations.

3 MODEL DESCRIPTION

3.1 *Simplified morphological model*

In this work, a simplified morphological model has been selected to reproduce both the quick chronological sequences of strong deposition (hours) due to flushing activities (and probably due also to largest flood) from the reservoir and subsequent slow erosion-phases (months) with moderate flow and relatively small flow (the so-called "vital minimum discharge"). In fact, the same model should be able to describe short time-scale events (e.g. overaggradation phenomena

Copyright © 2006 Taylor & Francis Group plc, London, UK

due to catastrophic floods or flushing operations on dams) as well as long time-scale general aggradation or degradation of the river bottom. In particular, the long term model may be obtained by averaging the unsteady equations over a period of time long enough to eliminate the fluctuations of the hydrological cycle.

Mountain rivers, like Piave, are characterized by geometric irregularities and by frequent alternations of subcritical and supercritical water flow. As the model is intended for a relative coarse space-resolution (about few hundreds meters), the average energy gradient for a sufficiently long reach can be assimilated to the average gradient of the bottom. Therefore the hypothesis of locally quasi-uniform flow (Marin & Di Silvio, 1996) can be generally made. The validity limits of the hypothesis of local uniform flow has been thoroughly analyzed in a recent work (Madeo, 2002) for mountain river.

The hypothesis assumed by the simplified model are described below. A known numerical code (Di Silvio & Peviani, 1989) was used for computation, with some modifications during different simulations.

3.2 *Theoretical assumptions*

The following assumptions have been made to derive the differential equations that describe the physical phenomena:

(I) The celerity of flood waves in mountain rivers is much higher than the celerity of the bottom changes. This leads to assume instantaneous adaptation in time of the water discharge in each branch of the network (a quasi-steady flow condition are assumed).

(II) It is assumed that the motion equation for each sediment fraction, both as bedload and in suspension, is completely governed by the average local parameters, such as discharge, bottom slope, channel width, grain size, etc. (it means, instantaneous adaptation of the vertical sediment concentration in the water stream).

(III) The flow pattern in a mountain river is a sequence of subcritical and supercritical regime, passing through subsequent critical conditions and hydraulic jumps, with a Froude number near to one. The local energy losses at the weak hydraulic jumps as well as the variation of kinetic energy are negligible comparing with the friction losses of the flow itself. This leads to assume that the average flow regime is quite well represented by a quasi-uniform flow, even for relatively short waves of sediment input.

3.3 *Water flow*

Water discharge along the hydrographic network is supposed to be a known function of space and time,

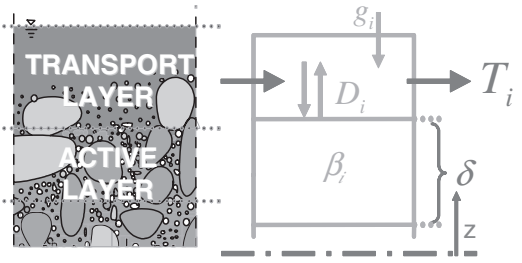

Figure 2. Definition sketch for the sediment balance in the transport- and in the active-layer.

assuming a kinematic wave propagation downstream. Each reach (50–500 m long) is schematized as a rectangular channel with uniform flow condition; width, slope and hydraulic roughness are given.

Water depth is calculated with following Gauckler-Strickler equation (Equation 1):

$$Q = K_s A R^{2/3} S_f^{1/2} \tag{1}$$

where the Strickler coefficient K_s, calculated with Equation 2, may change in time and space.

$$K_s = 26/d_{90}^{1/6} \tag{2}$$

3.4 *Sediment transport*

Modelling erosion and deposition processes in mountain rivers (sediment grainsizes vary over several orders of magnitude from boulders to silt) requires in principles a careful reproduction of a number of phenomena related to the non uniformity of a sediment mixture.

In the present work a simple model based on the "active layer" concept has been selected . The model considers two layers (Armanini and Di Silvio, 1988): the transport layer, containing the particles transported in suspension and as bedload, and the active (or mixing) layer (Hirano, 1971) containing the particles that are not in movement, but are liable to vertical movements to and from the upper transport layer (Figure 2).

The balance in the transport layer between transport T_i and net deposition D_i, is written as Equation 3, where B is the active channel width (m) (different from B_s stream width) and g_i is lateral specific solid discharge (m^2/s).

$$BD_i + \frac{\partial T_i}{\partial x} = g_i \tag{3}$$

Equation 4 expresses the balance in the active layer and it leads to the computation of bedcomposition

Copyright © 2006 Taylor & Francis Group plc, London, UK

changes. In this equation β_i^* is the composition of the undisturbed material below the mixing layer if $D_i < 0$ (erosion), while β_i^* is the mixing layer material composition if $D_i > 0$ (deposition).

$$\frac{\partial(\delta\beta_i)}{\partial t} = D_i - \beta_i^* \cdot \frac{\partial z}{\partial t} \tag{4}$$

Bottom level change is expressed by Equation 5 and the mixing layer thickness is assumed to be twice the representative diameters of the coarsest particles d_{90}, as expressed by Equation 6.

$$\frac{\partial z}{\partial t} = \sum_{i=1}^{4} D_i - \frac{\partial \delta}{\partial t} \tag{5}$$

$$\delta = 2d_{90} \tag{6}$$

The transport equation (Equation 7) for each fraction includes an exposure-correction coefficient ζ_i which accounts for the "hiding and exposure" effect for the non-uniform material:

$$T_i = \alpha \frac{Q^m I^n}{B_s{}^p d_i^q} \beta_i \zeta_i \tag{7}$$

where Q is the water discharge, B_s is the stream width (different from active channel width B, Equation 3), $\zeta_i = (d_i/d_m)^s$ and d_m *is* the mean diameter. The coefficient α and the exponents m, n, p, q and s were empirically evaluated from data in other Alpine rivers (Di Silvio, 1991). In the present formulation of the model the stream width has been evaluated as a function of Q where $B_s = K_p Q^{0,5}$ ($K_p = 3,5$ is assumed as a constant).

3.5 *Numerical solution*

The set of equations is solved numerically using a finite difference approximation. A predictor-corrector method is chosen for the numerical solution of the sediment equations. The predictor step is carried out with a FTBS (Forward Time Backward Space) scheme while the Four-point scheme of Preismann is used for the corrector step (Peviani, 2002).

4 STUDY REACH IN UPPER PIAVE

4.1 *Description of the case study*

An appropriate 8 km reach of the Piave river was selected for a first application and development of the model. It is located in upper area of the Piave basin (Figure 3), between Pieve di Cadore artificial lake (reservoir capacity of $64.3 \cdot 10^6$ m^3) and Santa Caterina dam (reservoir capacity of $6.7 \cdot 10^6$ m^3) and Comelico dam (reservoir capacity of $1.4 \cdot 10^6$ m^3).

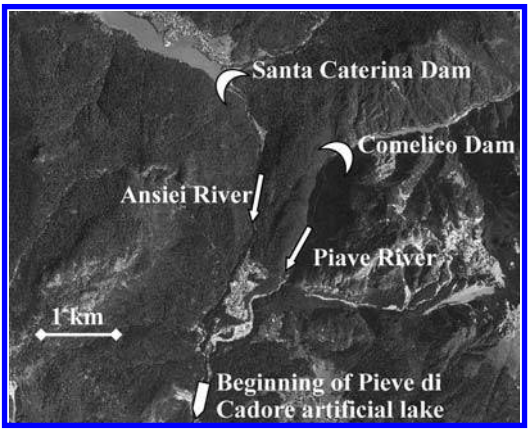

Figure 3. Location of the study site in the upper course of Piave river.

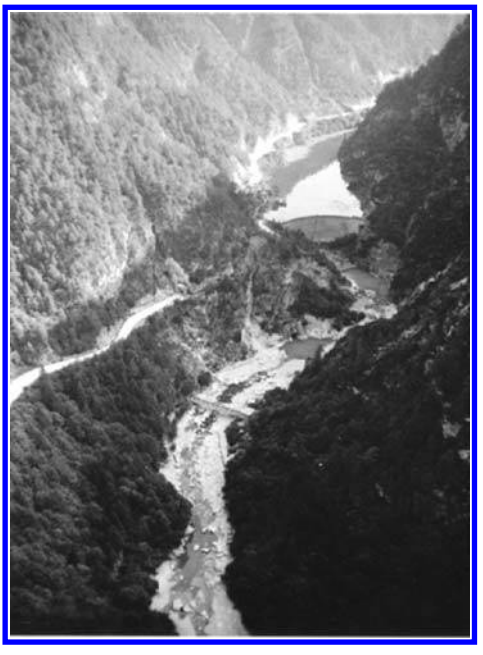

Figure 4. Comelico reservoir and Piave river downstream.

This choice was in part suggested because the boundary conditions are known and, in part, artificially controlled (water and sediment discharge is controlled by reservoirs manager). All the released sediments, moreover, are intercepted by the Pieve di Cadore artificial lake, at the end downstream. It's also a relatively limited area (few hundreds km^2) and easy to be reached for measurements and sampling.

One of the two reservoirs upstream (Comelico, Figure 4) is quite small compared to the catchment area of 372 km^2 and requires frequent removal of sediments

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 1. Flushing operations from Comelico reservoir during the last 12 years.

Year	Period	Sediment removed mc	Mean water discharge mc/s
1994	23/5–27/5	90,000	13.7
1995	15/5–19/5	80,000	9.9
1996	25/5–31/5	70,000	9.4
1997	26/5–30/5	70,000	7.3
2000	22/5–01/6	120,000	8.6
2002	22/5–31/5	80,000	12.7
2004	24/5–06/6	80,000	11.9

Data was furnished by Enel/GEM (Generation Energy Management).

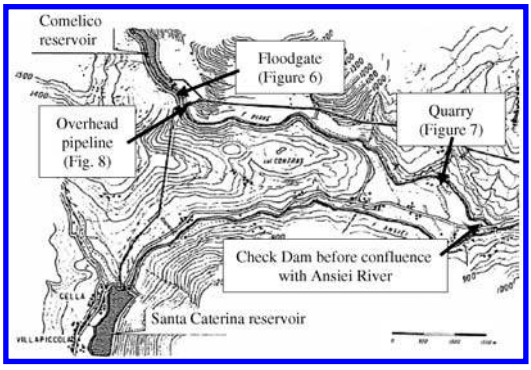

Figure 5. Piave reach between the Comelico Dam and the confluence with Ansiei River.

Figure 6. Floodgate section after flood event registered between 03 and 13 October 2005 (photo taken on 24 November 2005). Thick layer of stratified deposition, created by short period (mainly flushing period but probably also some flood periods) was partially eroded by subsequent long period of water discharged (during low and moderate flow).

by flushing. The water discharge released from the dam is usually on the order-of-magnitude of 1–2 m^3/s, except during the moderate and large floods (during largest flood it can peak also 100–200 m^3/s).

The other reservoir upstream (Santa Caterina) intercepts a tributary of Piave (Ansiei river); it is bigger than Comelico but with a smaller watershed and it is not concerned by flushing operations. The released water discharge, except during moderate flow and large flood, is almost always limited to the "minimum vital flow" prescribed by environmental regulations.

During the autumn of 2005 some samplings have been made by authors in both water courses to characterize the respective granulometry of the bed. As expected, the reach of the tributary Ansiei (where virtually flows only clear water) presents an armoured bed with definitely coarse material. The Piave reach below the Comelico dam, by contrast, presents a more complex pattern, with layers of different material caused by the chronological sequence of strong deposition and subsequent slow erosionphases.

4.2 *Water discharged and flushing operations*

Alternate operations of flushing and flood have continued probably for 70 years (the Comelico dam was built in 1931), but only in the last decades have been quantitatively recorded. The available data covers the period from 1994 to present date. By analysing the water discharges released from Comelico dam (from 1994 to 2005), it was possible to identify three distinct regimes: (i) flushing periods reported on Table 1, (ii) very long minimum flow periods and (iii) moderate flow (from April to June, every year) and flood periods (with a mean of two flood events per year). From autumn 2003, however, the water flow management of Comelico dam has changed because of a new Italian regulations, prescribe a "vital minimum discharge" to be released downstream.

In this paper, particular attention is given to the last flushing operation (May 2004), to the subsequent low flow period and to the last remarkable flood event (October 2005).

By a photographic survey, a qualitative evaluation of morphology can be made along the upper reach of Piave River (Figure 5). The distinctive feature of this riverbed is a thick layer of stratified deposition (created during short flushing period and probably also some flood periods), partially eroded by the subsequent low, moderate water flow and largest flood periods.

Following the flushing operations, in the upper end of the reach (near the flood gate, about 200 m the river downstream, Figures 6, 8a and 8b), bed elevation increased more than 4 m, but this variation rapidly lessened with distance from dam. In the proximity to "quarry zone", located about 3.5–4.0 km downstream, bed deposition is limited to the order of 50 cm (Figure 7).

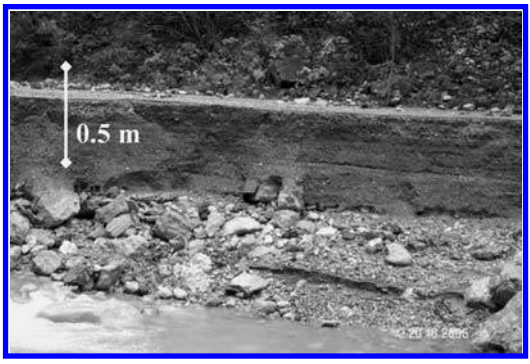

Figure 7. "Quarry zone" section after flood event registered between 03 and 13 October 2005 (photo taken on 20 October 2005). The deposition layer appear less thick at the "Quarry zone".

Figure 8. Cross-section evolution at the "overhead pipeline" respectively before (photo a, taken on 27 July 2005) and after (photo b, taken on 04 November 2005) the flood event registered between 03 and 13 October 2005.

Also granulometry of bed material presents a clear distinction between the sediments transported and the coarser bottom material left after the moderate flow and large flood periods (Figures 6 and 7). Sediment size swings about one or two order-of-magnitude along cross-section. Bed material size was measured

in different sections using the grid-by-number method (Surian, 2000) but a more deep sampling will start from spring 2006.

5 PRELIMINARY MODEL SIMULATIONS

5.1 *Flushing operations (May 2004)*

A first series of model simulations has been made to reproduce the last flushing operation (May 2004) and consequent evolution of bed elevation and grainsize.

Flushing simulation was performed by considering a given amount of sediments inside the reservoir, to be eroded and released though the floodgate by a mean daily water discharge (Figure 9). Problems rise because the daily water discharge (recorded only once a day) present peaks (during few hours) that, also if they are of the daily water order-ofmagnitude, affect significantly results.

In Figure 10 are reported bottom increase and bed material changes. While the bottom elevation increase seems to be correct, bed material size growth is probably more affected by the initial condition within the

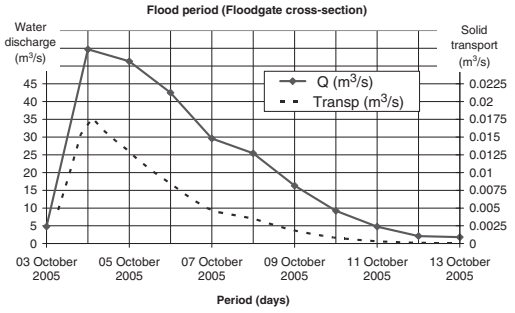

Figure 13. Boundary conditions of flood event (October 2005) (model simulations at "Floodgate" cross-section).

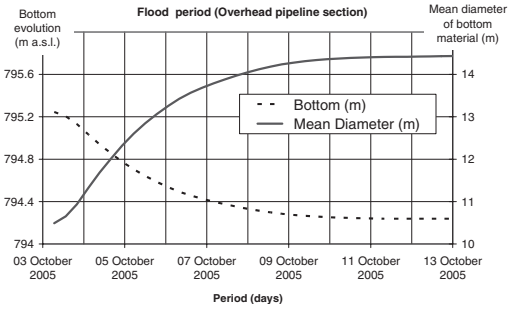

Figure 14. Decrease of bottom elevation and increase of mean diameter following during flood period (October 2005) (model simulations at "Overhead pipeline" cross-section).

reservoir and by the assumed operations of the water and sediment release.

5.2 *Minimum vital flow (from May 2004 to October 2005)*

For the simulation of "Minimum vital discharge" (Figure 11), boundary conditions prescribed at the "floodgate" cross-section show how solid transport discharge decreases during one year. The corresponding bottom erosion and increase of bottom material size is given in Figure 12.

The results show that the bed elevation decreases about 1 m, while the mean diameter size increases more than 1.5 times (Figure 12).

5.3 *Flood event (October 2005)*

An analogous evolution was obtained by modeling the subsequent flood event of October 2005. Again the flood period was reproduced with the available values of discharge recorded once every 24 hours (Figure 13). Also in this case, bottom evolution and gravel size seem to show a realistic trend in different cross sections. For instance, at the "overhead pipeline" cross-section, photographs shot before (Figure 8a) and after (Figure 8b) flood event of 2005 show a general bottom erosion of some meters and a much corser material, that the model correctly reproduces.

On the other hand, comparing the erosion due to 11 days of flood events (with peak discharge bigger than 55 m^3/s) with erosion due to "vital minimum discharge" (order-of-magnitude of 1–2 m^3/s for a period of about 16 months), the order-of-magnitude of change provided by the model appears to be the same (Figure 14). This result seems to indicate an undervalued effect of flood erosion, as indicated from photos of Figure 8.

The final longitudinal profile of the bottom (analyzing globally the three phases) seems to give a realistic trend in several sections analyzed. For instance (Figure 15), the results give a significant overaggradation of the bottom along the Quarry Zone, also during the flood event (this trend can explain the reason of the choice to install in that place a Quarry Zone). Moreover, these modes give a realistic trend of the bottom material size changes along the reach.

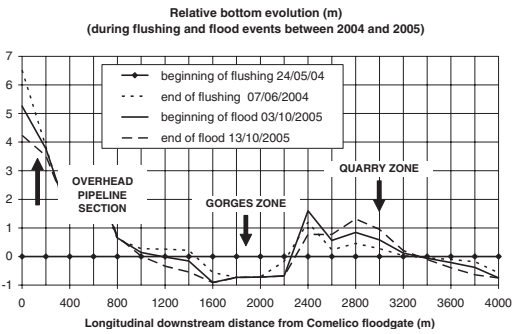

Figure 15. Time and space evolution of relative bottom variation from beginning flushing period until end of flood (initial value of bottom elevation is void).

6 CONCLUSIONS

A preliminary application of a morphological model to a short river-reach downstream a dam has been carried on during the flushing operations (14 days), and the following periods of low flow (483 days) and flood flow (11 days).

Boundary condition presently available are not very detailed (only daily water flows). This probably affects the quantitative results of the model. From the qualitative point of view, however, the deposition/erosion processes in terms of bottom elevation and bottom grainsize composition along the river reach are correctly reproduced, both at the short and the long time scales.

More detailed data regarding the boundary conditions (hourly water discharge, transport composition, modes of flushing operations etc.) will soon be available. These data, together with new measurements along the river reach (bed elevation and grain compositions) will allow a better assessment of the model performance. Improvements of the model (especially as for a the planimetric dynamics of the river width is concerned) will also be carried out, as soon as the experimental data will be available.

ACKNOWLEDGEMENTS

This research has been carried on in the framework of research projects (PRIN 2004) by MIUR (Ministry of Research and University) and Autorità di Bacino Alto Adriatico (River Authority of Northern Adriatic Sea).

Analysis of sediment transport during floods in a large river

J.S. Rocha & J.N. Fernandes
Portuguese National Laboratory for Civil Engineering (LNEC), Lisbon, Portugal

ABSTRACT: The River Tagus is the largest alluvial river bed in Portugal. Studies developed since 1970 give a relatively good opportunity to know the sediment transport behaviour. Three hydrometric gauge stations provided more than four hundred cross sections, surveyed during the velocity measurements for discharge-water level curve determination.

The collected data are highly relevant for calibrating the numerical modelling of hydromorphologic changes, sediment transport and degradation/aggradation phenomena in the river bed.

It is known that the erosion of River Tagus bed during an average flood can reach three meters in a short time. With the restoration of average flow, the river bed will recover its original values during following months.

The paper proposes a simple theoretical interpretation of the sediment transport mechanism of a large alluvial river during the floods, using the data collected in the work to obtain the depth-discharge curves in the gauging stations.

1 INTRODUCTION

The river regime in a movable bed controls in a very complex way its morphology. The river discharge variation implies correspondent bed variations, with significant differences in the behaviour of river bed in low flow and high flow situations.

It is well known that the phenomenon of sediment transport is strongly non-linear. This characteristic made it very hard to determine the right theoretical formulation to be used in a robust way in every case study. The corollary is the long list of available equations to quantify the sediment transport or to quantify the bed movements.

The major part of equations used in professional activity was deduced in experimental facilities, taking into account one of the major theoretical rationales developed during the last century. This may present a scale factor because each experimental facility is a reduced model of the natural system. When the case study is a large river the scale effects may be more significant.

However, the large river case study presents the advantage to be more easily monitored, taking into consideration that all phenomena have longer time periods, making the monitoring work more suitable to the human activities. In large rivers the variations of the main parameters of sediment phenomena are of the order of days or weeks, which may be recorded easily on a large time scale. On the contrary, in small rivers, these variations occur during short time periods, such as hours or minutes, which can only be recorded in automatic devices, not always enough robust to resist the floods.

In the River Tagus, there are enough recorded data to be used in the analysis of sediment transport, and correspondent bed movements.

This paper briefly describes the data collected in River Tagus, from which a case study during a flood was chosen. It also describes the theoretical analysis applied to the numerical simulation of the observed behaviour of bed movements imposed by the flood propagation, the comparison with available methods, as well as the conclusions.

2 THE COLLECTED DATA

The River Tagus basin is one of the largest in the Iberic Peninsula. It cuts longitudinally the Peninsula with a dominant East-West orientation. It covers an area of 80,629 km^2, 69% being in Spain and 31% in Portugal.

The main source is in Albarracin Mountain, at about 1,600 m altitude, falling fast to a 600 m altitude in the confluence of the first tributary, the Guadiela.

The slope is mild in the plain of Castilla-a-Nova, passing in the towns of Toledo (441 m), Talavera de la Reina (392 m) and Alcântara (98 m) in Spain. The 827 km length in Spain is followed by a reach of 43 km at the border of Spain with Portugal and 230 km in Portugal.

Before entering Portugal a large reservoir is formed by Alcântara dam, with maximum water level at 220 m and a volume of 3,333 10^6 m^3.

Table 1. Number of cross sections surveyed in the River Tagus gauging stations.

Station name	Total number	Maximum per year
Tramagal	174	23
Almourol	172	23
Ómnias	109	21

After Cedillo dam, in the border, the River Tagus enters a strong rock reach, with a minimum width in Vila Velha de Ródão (61 m altitude). Afterwards it reaches a movable river bed with rocky banks, passing the urban settlements of Abrantes (21 m), Constância (17 m), Tancos (14.3 m), and finally, in the last 100 km, it enters a large alluvial valley, where it passes urban settlements of Chamusca (9.5 m), Santarém (3 m) and Valada (2.7 m), where the 70 km estuary begins, and finally reaching the Atlantic Ocean downstream the city of Lisbon.

The construction of dams to control the river discharges changed the river regime after 1943, being stabilized after 1983. Presently, there are higher low flow discharges and lower high flow discharges than the natural regime. The annual discharge module is about 360 m^3/s, but it may vary between about 1000 m^3/s in wet years and 90 m^3/s in dry years.

Since 1970 three gauging stations were installed along the alluvial plain. The stations are as follows:

1. Tramagal (100 km from the downstream reference, Vila Franca de Xira),
2. Almourol (85 km),
3. Ómnias (45 km).

The 2 year return flood discharge is approximately 2,300 m^3/s and the maximum observed flood was about 15,000 m^3/s, considered as a 100 year return period flood discharge.

In order to determine the depth-discharge curves the river beds were surveyed when velocity measurements were done. Consequently, relatively long series of data are available to be used in different sediment transport studies, on a large alluvial river.

The available date may be divided in the following three types:

– Instantaneous discharges during the river bed survey,
– Daily discharges in the Water National Information System (SNIRH, www.inag.pt),
– Hydrometric water level in the automatic network in the SNIRH.

The collected data are longer than the analysed ones. It is expectable that, in the future, it will be possible to analyse the older data.

The analysed data are presented in the Table 1.

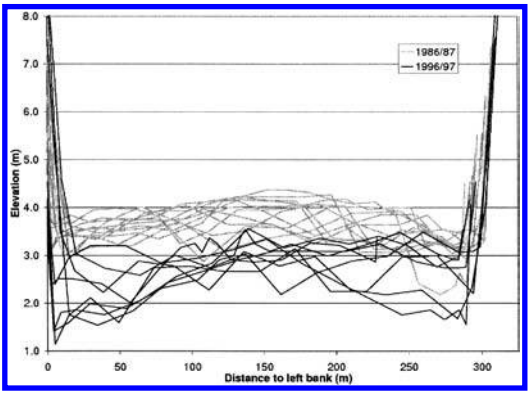

Figure 1. Cross sections at Ómnias station at 1986/87 and 1996/97 hydrological years.

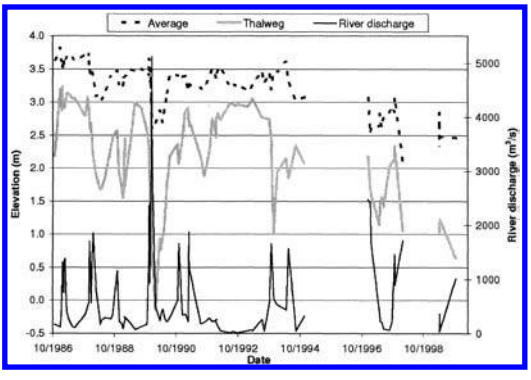

Figure 2. Changes in the river bed elevation at Ómnias station between 1986 and 1998.

In the first two stations, the analysed data were collected between the hydrological years 1990/1991 and 2004/2005, i.e., a total of 15 years. In the Ómnias station, the analysed data were collected between the hydrological years 1986/1987 and 1998/199, i.e., a total of 12 years.

Of note is the fact that the hydrological year in Portugal begins on 1 October and ends on 30 September.

Figure 1 shows a sample of the surveyed cross sections at one of the three gauging stations, Ómnias. The sample shows the natural variation in the cross section along two hydrological years, 1986/87 being in a higher position when compared with 1996/97. In general, the upper and lower position may vary within a 2 m range.

Beside the yearly variations it was also possible to observe a trend to a mild degradation in two of the three stations.

Figure 2 shows the behaviour of the river bed at Ómnias station during 12 years.

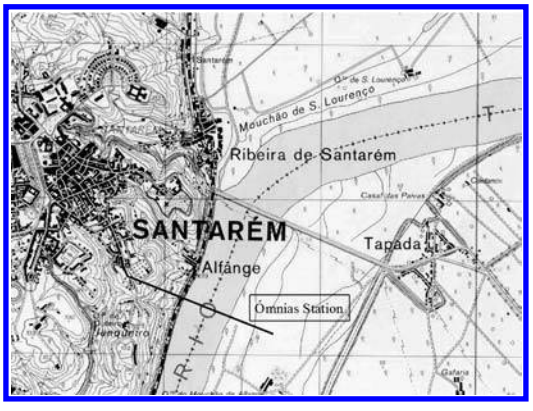

Figure 4. Ómnias gauge station and upstream reach.

3 THE CASE STUDY

Among the hundreds of surveys done in the three gauging stations, one flood event was chosen to analyse in detail the dynamics of the river bed morphology. The time period in which the bed variation related to flood wave was evident begins on 18 December 1989 and ends on 5 February 1990. Figure 3 shows the flood and river bed variations in the chosen time period.

The average river discharge in the period was 1,900 m^3/s. The river bed lowered 1.97 m during the flood passage. Afterwards, since 5 February 1990 until 28 July 1990, the average river discharge being 320 m^3/s, the river bed recovered its initial position going up to a total of 2.33 m, during five months.

This sample of natural river bed behaviour was considered a good case study to analyse in detail the relations between the flood wave and bed variations. There is a simple flood wave with a 5,200 m^3/s peak discharge and discharge decay to a minimum 200 m^3/s. The minimum talweg level occurred during the decay of flow at 1,200 m^3/s discharge.

It is important to note that the Ómnias gauge station is situated in a cross section with width smaller than the upstream reach, Figure 4. The decrease in width is about 30% when comparing with the largest width situated in a bend upstream the bridge.

In Figure 1 it is possible to observe that the cross section is approximately symmetric.

4 THE THEORETICAL ANALYSIS

The analysis of river bed variations in alluvial rivers is concentrated in the prediction of natural scour during floods. It is commonly admitted that during flood water surface rises and river bed decreases.

It is true the scour during floods is more important for practical point of view, in design of structures founded in river beds. The scour is more dangerous to the stability of structures compared with sedimentation.

Also in major situations the structures are built in the encroached cross sections, decreasing the length of river passage, and consequently the construction costs. Consequently, the number of case studies situated in the less than average river width is larger than other cases.

In a strict theoretical reasoning, the hypothesis that, when flood discharge increases the river bed lowers, is not universal.

It is well known the equations to compute the sediment transport in rivers are to be used to estimate the capacity of sediment transport, and they have been deduced in steady conditions. The real sediment transport is one of the two following situations:

- Capacity of sediment transport if the feeding sediment is equal or larger then capacity;
- Feeding sediment if the capacity of sediment transport is larger then feeding.

It is also current to analyse only the behaviour of river bed in the cross section, taken into consideration the equilibrium between actual mean velocity and the competent velocity for the inception of sediment transport. In this analysis the cross sectional area increases which diminishes the flow velocity and then the sediment transport capacity until the erosion process is stopped (Raudkivi, 1990 and Henderson, 1986). In general, the theory admits only the erosion.

It is difficult to find in the nature enough data to confirm different behaviour because the gauging stations are preferable situated in small width cross sections. In laboratory most of experimental tests are done in prismatic flumes with constant width.

Luckily in River Tagus, there is a site upstream all three gauging stations, where data collected can support a more general vision of the river bed behaviour during floods, when there is a substantial increase of river discharge followed by decay.

Copyright © 2006 Taylor & Francis Group plc, London, UK

In that site was done a study, using a mobile river bed model, and two surveys were collected, in a cross section of an enlarged river width compared to a much more smaller width upstream,. In Figure 5 it is presented the plan view of the two surveys done in different dates, upstream to cross section of Figure 6 on low flow conditions, and left to the cross section few months after a flood event (Cardoso, 1991). It was found there was a sedimentation process caused by flood, followed by a recover to the low flow conditions some time afterwards.

The process was reproduced on the mobile river bed model, in tests using unsteady flow conditions.

The Figure 6 shows better the two situations, before and after the flood event. Actually, in this case, the survey is not just after the flood, but some time afterwards. Consequently, the survey after flood shows a transition situation, with a well-defined recovering of talweg, but maintaining sedimentation on the remaining part of cross section.

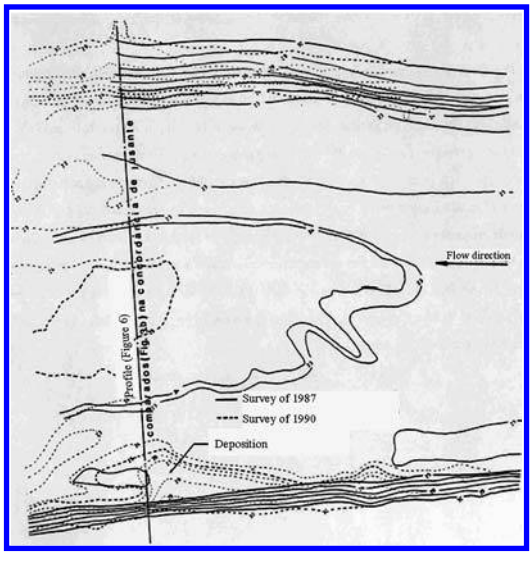

Figure 5. Plan view of the sedimentation after a flood event, in river Tagus.

The river bed variations, scour or sedimentation, shall be explained by the unbalance in sediment transport upstream and downstream, and not by the equilibrium in a cross-section. The experimental tests are mostly done in equilibrium conditions, giving formulations that are good estimators of the sediment transport in mobile river beds. However, an equilibrium condition hardly can be a good way to estimate a process dominated by a non-equilibrium process such as the river bed variation during and after flood wave propagation.

Consequently, a general method is proposed to compute in a simple way the river bed variations. The river bed variation may be computed by the general expression, the sediment continuity equation applied to two cross equations, in general one larger than other

$$\Delta z = (Q_{su} - Q_{sl})\, \Delta t / B_l \qquad (1)$$

where Δz is the river bed variation in a unitary length river reach and in the time period of analysis Δt, and is a function of the difference of sediment discharge, Q_{su}, upstream, and Q_{sl}, local, in a cross section width B_l.

The equations like (1) are very sensitive because the difference is usually a quantity of one or two orders less than the quantity of each sediment discharge value. However, the equation (1) gives directly the type of river bed variation, scour or sedimentation.

The unbalance in sediment transport is considered directly in the computation with mathematical models, such as HEC-6, MOBED, HEC2SR, or similar. However, the application of these models requires heavy work. The analysis presented has only the scope of a quick estimation of river bed variation in a particular site.

The large amount of data available in River Tagus may be used to verify the possibility to use equation (1) to estimate the river bed variation.

Also, it will be convenient to use experimental facilities to confirm the possibility of a general use of equation (1).

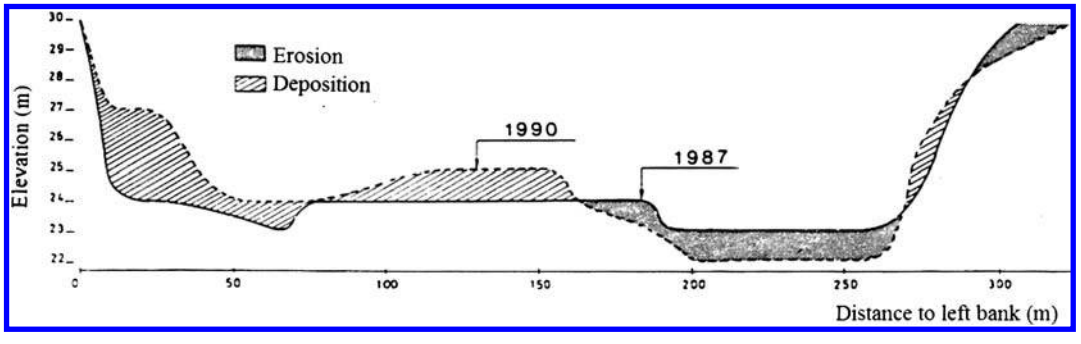

Figure 6. Cross section view comparing before and after a flood event, in river Tagus.

5 THE NUMERICAL ANALISYS

The case study of River Tagus can indicate the order of magnitude of the differences in the sediment transport capacity.

From the data presented in Figure 2 and using a set of the available sediment transport equations, like Meyer-Peter and Muller, Van Rijn, Einstein-Brown, Ackers and White, it is possible to present the Figure 7.

In this Figure it was changed the river discharge, presented in Figure 2, to sediment discharge.

The variations in the river bed are known in enough instants to have a relatively well defined evolution of the river bed. Examples of three positions of the cross section in Ómnias are presented in Figure 8.

Knowing the Δz and Δt, and the B_l, it is possible to obtain the evolutions of the volumes of erosion or sedimentation, that is, the unbalanced sediment discharge, Δq_s, equivalent to $(Q_{su} - Q_{sl})/B_l$. As Q_{sl}, or q_{sl} are also known, the difference can also be compared with the sediment transport in the analysed cross section.

Table 2 presents some computations according to equation (1). It is easy to noticed that the rows on the lower part of the Table are mostly negatives, as expected, because there is erosion in the first phase of the flood wave, and on the upper part of Table 2 the positive values are in accordance with the sedimentation process of recovering the initial position.

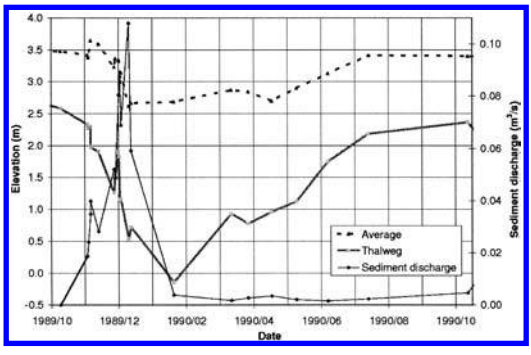

Figure 7. Changes in the river bed elevation at Ómnias station and sediment discharge during and after flood.

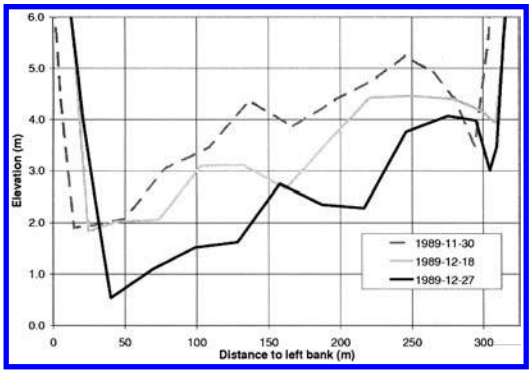

Figure 8. Cross sections in Ómnias station during the flood.

During rise stage of flood, the sediment discharge in the local is higher than the incoming one, consequently, the bed lowers. During the recovering phase, when the river and sediment discharges are lower the trend is for a higher incoming sediment than local capacity. In both cases, the unbalanced values are, in general, one order of magnitude less than the sediment discharge. Table 2 also shows that the values are not always like the described behaviour, and that they correspond to transition phases.

There are not enough data in the sections upstream the Ómnias gauging station to confirm totally the data presented in Table 2. In the future, surveys will be prepared surveys before, during and afterwards a significant flood event, in order to verify equation (1).

6 COMPARISON WITH AVAILABLE METHODS

Most of available analytical approaches for predicting scour during floods (disregarding the possibility of sedimentation) are based on the hypothesis of equilibrium between the actual mean flow velocity and the competent velocity for the inception of sediment transport, corresponding to the time in which scour is stopped (Williman 1970, Neill 1973, Neill 1987, Harris 1988). During floods and after floods, it is common to observe velocities much higher than the inception of sediment transport. The end of scour is not equivalent to the end of sediment transport.

Additionally, there is another fundamental hypothesis of the methods applied to a unique cross section, the equality between the mean velocity and the equilibrium velocity necessary for maintaining a generalized sediment transport over the bed, with a sustained material supply from upstream that compensates the eroded sediment (Maza Alvarez & Echavarria Alfaro 1973). The issue is that the erosion (or sedimentation) is originated by a non-compensation of sediment transport.

Other available methods are also based on regime-type formulas. Those formulas represent, to some extent, a statistical approach to natural alluvial bed configuration, and by consequence, they have an intrinsic guaranty to obtain plausible results in the application on the case studies (Melville & Coleman 2000).

The application of two of the available methods to analysed the present case study gives the values presented in Table 3.

In the River Tagus case study there is the same order of magnitude of estimated and observed scour,

the maximum deviation being about 50%. This is an admissible value for deviations in river hydraulic estimations.

7 CONCLUSIONS

For professional practice, in the first phases of viability studies, in small size projects, before performing computations with a numerical model, where the data collection to build a model can be quite cumbersome, both simple equations and fast estimations of river bed variations during flood passage, may be used. The quantity of data to apply simple equations is much less than that for numerical models.

Most available procedures to estimate river bed variation during floods consider the erosion. There are some cases in which sedimentation might even occur.

Equation (1) deals automatically with the erosion or sedimentation case.

The main difference of the proposed procedure, compared with available procedures, is to consider at least two cross sections to obtain a better estimation of river bed variations.

The case of the quantification of the average river bed was presented, but it can be adapted to other type of analysis, for instance, for the talweg variation.

The simple computation can use also directly the outputs of the fixed bed numerical models like HEC-RAS.

The case of the Zambezi River in Mozambique: Some investigations on solid transport phenomena downstream Cahora Bassa Dam

Paolo Ronco, Giacomo Fasolato & Giampaolo Di Silvio
Hydraulic, Maritime, Environmental and Geotechnical Engineering Department, University of Padua, Italy

ABSTRACT: The Zambezi River is the fourth largest river in Africa (after Congo, Nile and Niger) and it is the largest river flowing into the Indian Ocean. The Lower Zambezi in Mozambique is strongly influenced by the presence of two very large reservoirs (Kariba Dam and Cahora Bassa Dam) that have modified the natural seasonal flows, as well as the sediment balance and morphology of the river. In particular, the downstream of the Cahora Bassa Reservoir non negligible effects are taking place, such as local scour, bank collapse and shore-line progressive erosion, together with economic and ecologic consequences on shrimp production and biodiversity alteration. In order to assess and possibly mitigate those effects, a quantitative and qualitative analysis of the erosion/sedimentation/sediment transport phenomena along the Zambezi seems to be urgently needed. The main constraint is represented by the scanty and unreliable data available: the Mozambican hydrometric monitoring network is very scarce and no long-historical and systematic measures of flow, sediment transport and reservoir sedimentation are available. The objective of the present study is trying to integrate the disposable data with a simplified model of sediment transport applied to the reach downstream of Cahora Bassa Dam.

1 THE ZAMBEZI RIVER BASIN: AN OVERVIEW

1.1 *Characteristics of the River basin*

The catchment area of the Zambezi River basin is 1,385,300 km^2, and is the fourth largest in Africa after the Congo, the Nile and the Niger. Of this area, about 12% (137,000 km^2) lies within Mozambique. The Zambezi River is approximately 2500 km long. The Basin drains from altitudes around 1600 m in northern Zambia and eastern Angola. The upper catchment lies on a vast plateau, the river being contained within a well-defined channel except for two major flood plains known as the Barotse and Chobe swamps. Its descent from this central plateau commences at Victoria Falls (1078 Km from sources) where its altitude drops from 978 to 870 m a.s.l. In its natural state the mid course of the river from Victoria Falls to Lupata consisted of narrow rapids and falls in mountainous areas and pen plains, with fall of 800 m overall. The major reservoirs at Kariba and Cahora Bassa have modified this section of river to a considerable extent. The river crosses the border into Mozambique near the township of Zumbo at an altitude of 330 m above datum and flows into Cahora Bassa reservoir (1630 Km from sources). At the dam site the gorge in very steep sided with a depth of about 600 meters. From the dam, with an altitude of 220 m a.s.l., the river continues in this gorge for a further 60 km before entering the pen plains. The course of the river is only slightly meandering to Lupata flowing in a well defined channel between 800 and 1000 m wide. After passing a gorge at Lupata at 95 m above datum, the river enter the major flood plain. The final 380 km to the Indian Ocean are characterized by a course of 1–4 km wide with heavily braided with ill-defined banks. The delta can be considered to start at Mopeia, 150 km from the Ocean and tidal influence is evident over the last 80 m (SCC Brokonsult, 2001). Major cities within the Zambezi River basin include Lusaka and Harare, the capitals of Zambia and Zimbabwe, respectively. The river basin is depicted in Figure 1. Table 1 provides a summary of the basin area within the numerous nations that share the river basin (SMEC, 2004).

1.2 *The climate*

The climate of the Zambezi Basin is typically subtropical. The year can be divided in four season:

1. hot season from late August or early September to the beginning of the main rains in October or November;
2. rainy season from October/November to March/April;

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 1. Zambezi River basin area within nations.

Nation	Area (km^2)	Percentage (%)
Angola	254,600	18.4
Zambia	576,900	41.6
Dem. Rep. of Congo	1100	0.1
Namibia	17,200	1.2
Botswana	1900	1.4
Zimbabwe	215,500	15.6
Tanzania	27,200	2.0
Malawi	110,400	8.0
Mozambique	137,000	12.2
Total:	1,385,300	

Southern African Regional Development Corporation. website: www.sardc.net/imercsa

3. post rainy season in April and May;
4. cool season from June to early August.

Annual rainfall varies from approximately 1500 mm in the northern part of the catchment to approximately 850 mm in the southern part with the lowest rainfall in the order of 600 to 700 mm occurring in the central Zambezi Valley. Maximum rainfall months are December and January with peak discharges at Victoria Falls occurring between the beginning of March and the end of May. The winter rainfall usually account for about 3% of the annual total. With warm sunny conditions prevailing for much of the time in the Zambezi Basin (in the lowest areas of the Zambezi Valley temperatures can exceed 35°C) insulation is high causing mean annual potential evaporation to be high throughout the area. Class A pan evaporation is typically of the order of 1800 to 2200 mm per annum, with a significant seasonal variation from approximately 200 mm per month between October and March to around 125 mm per month in June and July.(Lahmeyer et al., 2001).

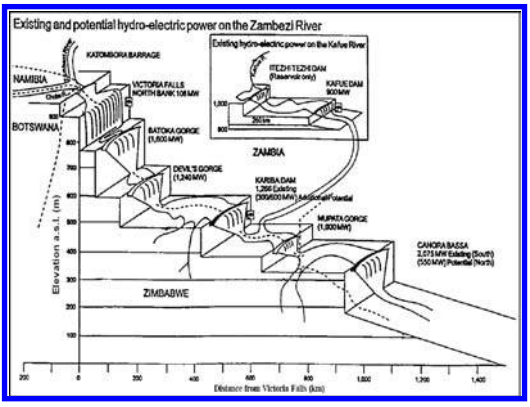

Figure 2. Schematic diagram of reservoirs and potential hydro power production of the Zambezi Basin (after Chounguiça, 1997).

1.3 *Major structures*

Completed in 1959 and situated at Kariba Gorge between Zambia and Zimbabwe (that obtain most of the electricity), the Kariba Dam consists of a double curvature concrete arch dam with a maximum height of about 130 m and a crest length of about 600 m. Six floodgates permit a discharge of 9500 m^3/s. The reservoir has a storage capacity of 180 km^3 and although the live storage is much less, it is the second largest in Africa and one of the largest of the world. Several other impoundment were established within the Zambezi River catchment in Zimbabwe between which are McIlwaine (reservoir capacity 38.8 km^3) and Ngesi (reservoir capacity 26 km^3). For hydroelectric power purpose, in 1972 a dam was built on the Kafue River and a second dam was built upstream, near Itesitesi. With all the construction executed (see Figure 2) in Zambezi River, when entering the territory of Mozambique it can be considered as a regulated river that lost its natural pattern of flow variations in time and in quantity. (Suschka & Napica 1990).

2 THE LOWER ZAMBEZI

2.1 *The Cahora Bassa Dam and Reservoir*

Commissioned in the 1959 by the Portuguese Government in Mozambique for promoting the economic development of the Lower Zambezi Valley through the exploitation of the hydropower potential of the river, the Cahora Bassa (witch means "the work is finish" in Sena idiom and stems from workers who ferries goods and people the nearly 600 Km to Cahora Bassa rapids from the Indian Ocean (Davies et al. 2000)) Dam is one of the most important river impoundment

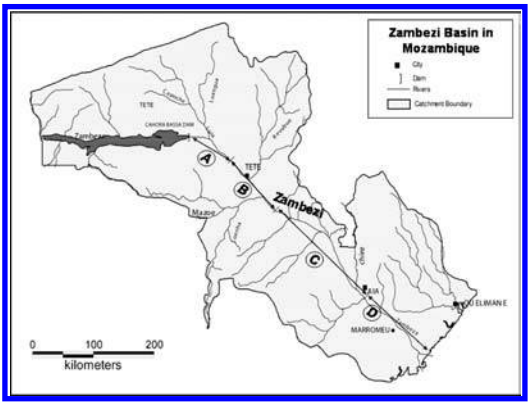

Figure 4. The Zambezi River basin in Mozambique, with the four macro-scale river zones. A: gorges zone; B: transitional zone; C: braided zone; D: distributary zone.

in the Austral Africa. With a maximum height of 164 m, a crest length of 303 m, a total discharge capacity of 13,939 m^3/s through five turbines (2260 m^3/s) and eight sluice gates, it has a power installed of 2075 MW that is mostly sell to South Africa Republic (80%) and Zimbabwe (15%) (HCB, 2004). The 270 Km long and 30 km width reservoir commenced to fill on 5 December 1974 and completed in approximately six months. The created lake has a reference level of 326 m a.s.l. and a surface area of 2660 km^2; the western extremely of the reservoir reaches the junction of the Mozambique, Zambia and Zimbabwe frontiers (see Figure 4).

2.2 *The lower Zambezi Valley*

The Lower Zambezi could be described as a complex physical system with four macro-scale river zones (Davies et al. 2000), comprising narrow gorges, a transitional zone , braided reaches, and a coastal distributary zone (Figure 4.) The complexity is due to the regional geomorphology producing a series of distinct valley-floor-trough, river-floodplain associations. In the uplifted mountainous areas below Cahora Bassa the channel is confined in a narrow wide valley with relatively high gradients. Boulder and bedrock outcrops and high stream energies dominate the instream environment of the gorge zone. Downstream of this zone the valley-floor-trough broadens to several kilometres. With further increases in the width of the valley-floor-trough and a decrease in river channels energies, large floodplains are constructed and a braided sand-river bed dominates. With progressive reduction in bed gradients, the braided give way to a typically coastal distributary channel network where floodplain widths can reach several hundred kilometres (Davies et al. 2000). In Table 2 a summary of the morphological characteristics of the four macro-scale river zones.

Table 2. Morphological parameters (average on the space) of the four macro-scale river zones.

Zone	Area [km^2]	Length [km]	Slope	Width [m]
A	38,587	62	$9.26 \cdot 10^{-4}$	191
B	63,132	158	$5 \cdot 10^{-4}$	1090
C	191,159*	225	$1.83 \cdot 10^{-4}$	1301
D	16,273	155	$1.05 \cdot 10^{-4}$	1021

* 78,215 km^2 after Lake Niassa.

There are many tributaries joining the Zambezi in Mozambique. The largest is the Chire, the catchment of witch is mainly in Tanzania and Malawi, and includes the massive Lake Niassa. Others on the left or northern bank include the Luia River and the Revubue River, and on the right or southern bank are the Luenha River which drains from the north-eastern Zimbabwe (SMEC, 2004).

Average annual rainfall in Mozambique part of the basin varies less than 600 mm around Tete, to over 1400 mm along the northern border with Malawi. In Mozambique most of the basin area is very sparse populated, however the population along the river is significant. The provincial capital of Tete is on the south bank of the Zambezi. Many thousands also live in or rely on the lands of Inhamgoma triangle along the Chire River to east of Mutarara. The delta is very sparsely populated and access is difficult. A large commercial sugar cane operation is located in Marromeu in the upper delta (SMEC, 2004).

2.3 *Principals effects of the Cahora Bassa Impoundment*

2.3.1 *Siltation of the Reservoir*

No quantitative estimate of the rate of sediment accumulation was published in the numerous reports which

Copyright © 2006 Taylor & Francis Group plc, London, UK

formed the basis for the design of the project (Bolton, 1984) and after, during the operational period of the reservoir, no monitoring silt accumulation programme has been developed. This aspects seems to be important in the light of two factor. The first is that 15% of the Cahora Bassa's water comes from the undammed River Luangwa, witch is know to carry a high silt load (the turbidity was measured in 36 ppm at the confluence with Zambezi, close to the CB Reservoir (Hayashi, 2005)), and a further 25% comes from other undammed rivers mainly off the Zimbabwean plateau (Bolton, 1978) The second factor is the relative small "dead" capacity of Cahora Bassa Reservoir: 13 km^3 (HCB, 2004). Due to the lack of systematic quantitative studies of sediment transport rates, bathymetry measurement and monitoring sampling programme, is very hard to evaluate this phenomena. Making assumption on the sediment yield of the basin, the trapping capacity of the upstream Kariba Reservoir and the sediment concentration of the tributaries in Cahora Bassa, Bolton (1984) estimate the total rate of sediment input to Lake Cahora Bassa in the range 20 to 200 $\times$ 10^6 m^3/year.

2.3.2 *Changes in flow pattern*

It is not in the objectives of the present study to produce an extensive quantitative evaluation of the modifications in the flow pattern after the construction of Cahora Bassa Dam. In any case, it is unquestionable fact that the damming of the Cahora Bassa Gorge has considerably changed the hydrological cycle of high and low flow. As evidence data collected at Tete measuring station E320 135 Km downstream of the dam from 1951 to 2004, the presence of the hydropower impoundment regulates the pattern of the monthly runoff in augmenting the minimum value and strongly decreasing the maximum value. As consequence the monthly runoff variation has a much lower amplitude and the discharges are more distributed all along the year changing the normal seasonal flow pattern (the rainfall season starts from January till March) (Figure 5 and Table 3).

2.3.3 *Morphological changes*

Very little information and measurement is available on sediment transport and river bed characteristics, but some considerations are possible. Both Suschka & Napica (1990) Davies et al. (2000) try to evaluate the morphological changes of the Lower Zambezi river after the conclusion of Cahora Bassa Dam but without getting at the same outcome. In fact, since Suschka & Napica in 1990 (ten years after the conclusion of the dam) affirm that "no evident changes in river bed configuration through aggradation or degradation have been measured and a much larger period will be necessary to find noticeable effects", Davies et al. in 2000 emphasize "the dramatic changes in the morphology

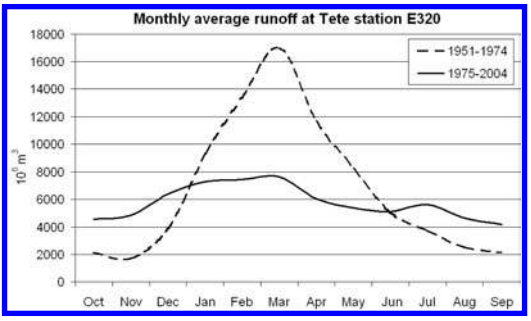

Figure 5. Monthly average runoff at Tete measuring station E320.

Data derived from DNA – National Directorate of Water – Maputo, Mozambique.

of the river floodplain system". In his opinion, the constancy of flow imposed by Cahora Bassa Dam (..) has transformed a flood-pulse driven river ecosystem, floodplain and coastal zone, into a series of confined channels. In fact, both the reduction of the sediment load, caused by the trapping of the reservoir, and the flow curtailment produce the removal of the sediment stores in the gorge zone (erosion), the incision of main flow channel with the stabilization of braid and bars in the transitional zone, the dominance of a single main channel that incises and conveys the majority of flow in the braided zone, and the reduction of the Zambezi Delta wetland mangrove swamp area and increase the salt-water intrusion (Chenje, 2000). Unfortunately, at the moment no quantitative evaluations of the morphological changes on the Lower Zambezi due to the impact of the Cahora Bassa Dam and no accurate explications of the sediment dynamics all along the waterflow has been done; some others impacts are still to be discovered and evaluated in the next future. On the basis of the foregoing considerations, a quantitative approach to these phenomena seems to be absolutely necessary.

3 MORPHOLOGICAL MODELS

Conventional morphological models, even if just one-dimensional, are too cumbersome for very long simulations (years, decades, centuries) at basin scale, especially if the river watershed is very large as in the case of the Zambezi River. Acceptable simplifications can be introduced in the one-dimensional equations that describe the waterflow (De St.Venant equations) along the hydrographic network. By contrast, the sediment movement at the erosion/deposition process, should accurately be described by considering a non-uniform material. At the basin scale, in fact, the sediment grainsize may vary over various orders of magnitude (from fine silt to boulders), while the transport in a given cross section presents a quite extended composition (including the so-called "washload", coming in suspension from distant slopes of the watershed). The simple model (Di Silvio & Peviani, 1989) applied in this paper to the Zambezi River is based on the "local uniform-flow" hypothesis. The model includes a module for the evolution of the bottom composition and allows for the change of the river's active width with the water flow in presence of braiding. The model is described more in detail in a paper presented in this meeting (see *Morphodynamics of mountain river following repeated sediment release from reservoirs*. Fasolato et al., 2006) witch reports an application to the Upper Piave River in Italy.

It is to be stressed that the local-uniform flow hypothesis is definitely correct when the slope of the river is relatively high (as in the case of the Upper Piave River). When the river slope is rather small (as in the case of the Lower Zambezi River), the hypothesis is still acceptable for sufficiently large space-steps and time-steps.

A thorough analysis of the validity limits of the model is giving in Madeo (2002). As far as the Zambezi River is concerned, the selected space-step ($\Delta x = 60$ Km) and time-step ($\Delta t = 1$ year) guarantee that the average values of bottom elevation and bottom composition are correctly reproduced. This means, of course, that a number of oscillations with different frequency can be expected within each space- and time-step. In other words, the local uniform-flow hypothesis allows for a general description of the river morphology over the entire length of the river (about 600 km) and over the considered period (several decades), but does not give any information of the morphological changes within each reach and within each year.

4 MODEL APPLICATION

The morphological model based on the local uniform-flow hypothesis has been applied to the Zambezi River between the Cahora Bassa Dam and the Indian Ocean, to investigate the long-term morphological evolution in the present condition (*with dam*) and by assuming that the dam was not built (*without dam*). The initial conditions, in principle, should be given in both cases as the river's morphological and sedimentological configuration of 1974 (closure of the Cahora Bassa Dam). For the model simulation, in fact, the initial grainsize distribution has been selected as the one measured by the Portuguese administration in 1964 (Brigada de Engenharia Hidráulica). As for the initial topography of the Zambezi, by contrast, it has been chosen the actual one (see Figure 6: LANDSAT 7, 2002/08/03), as no precise information is available for the topography in 1974. It is believed, however, that for sake of comparison (with dam and without dam) it is enough that the initial conditions would be the same.

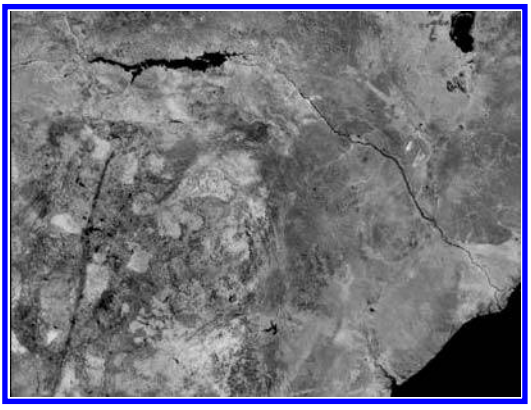

Figure 6. Satellite image of the Zambezi River basin in Mozambique (LANDSAT 7, 2002/08/03).

4.1 *Data processing*

The main constraint for a reliable and realistic hydrological and morphological description of the river, is represented by the scanty and unreliable data available on this matter. In fact, due to a 17 years long civil war and to poor socio-economical conditions, the hydrometric monitoring network of the Mozambican part of the basin is very scarce and, apart from very few specific cases, no long-historical and systematic measures of flow, sediment transport and reservoir sedimentation measurements are available. The Zambezi River Basin is furthermore extended in eight different countries and no single authority has a complete database for all the catchment.

4.1.1 *Hydrological data*

From the data catalogue provided by DNA (National Directorate of Water in Maputo), that list several gauging station all along the Zambezi Basin, only one station is still operating and could provide historical

Copyright © 2006 Taylor & Francis Group plc, London, UK

reliable discharge data. Tete gauging station E320, located next to the only bridge on the entire Lower Zambezi some 135 Km downstream the dam, after the confluence of Luia River and just before the one with Revubue River, provide daily average discharge data from 1951. Cahora Bassa monthly average inflow data, from 1907 to 1997, were provided by HCB (Hidroeléctrica de Cahora Bassa, the owner of the Cahora Bassa Impoundment) and Ara Zambeze (the Lower Zambezi Mozambican Authority) provide dam's daily discharge data from 1999. For the scope of this study, namely the preliminary application of the morphological model at one-year time-step, only an *equivalent* year's average value of the river discharge for the computation of the solid transport is required. In fact, the solid transport Q_s[m^3/s], is computed as:

$$Q_s = M \cdot Q^m \tag{1}$$

where M is a global term that resume the morphological characteristics of the river (see Fasolato et al. 2006) The *equivalent* year's average water discharge Q_{eq} is therefore the value of the water discharge that annually (T) produce the same sediment transport yield V_s, computed by the model, and is calculated as:

$$Q_{eq} = \left(\frac{Q_s}{M}\right)^{1/m} = \left(\frac{V_s}{M \cdot T}\right)^{1/m} \tag{2}$$

where the V_s is:

$$V_s = \int_T Q_s = M \cdot \frac{1}{m} \cdot Q_0^{m-1} \cdot V \tag{3}$$

with Q_0 maximum annual peak discharge and V total annual runoff.

The combination of Eq. 2 and Eq. 3 gives the *equivalent* year's average water discharge as:

$$Q_{eq} = \left(\frac{Q_0^{m-1} \cdot Q_{med}}{m}\right)^{1/m} \tag{4}$$

where Q_{med} is the annual average water discharge. For the application of the morphological model in the configuration *with no dam*, Cahora Bassa Reservoir Inflow data has been used, while in the *with dam* configuration, discharge data from the dam has been used for the computation of the Q_{eq}.

As regard the main tributaries of Zambezi (namely: Luia, Revubue, Luenha and Chire) downstream of the dam, no water discharge measurement are available, but only 10- to 1000-years maximum floods values derived from statistical analysis by some studies and reports (SMEC, 2004; Lahmeyer et al., 2001; SCC Brokonsult, 2001; and Denconsult, 1998). Only the

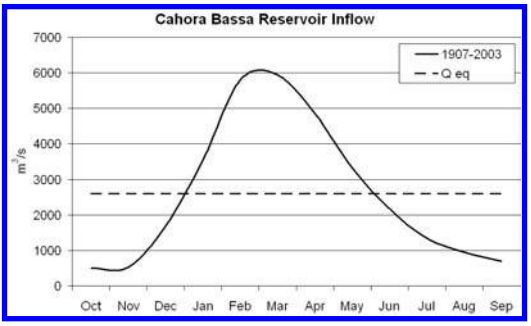

Figure 7. The comparison between the monthly average inflow and the respective Q_{eq} in Cahora Bassa Reservoir from 1907 to 2003. (data from HCB, 2005).

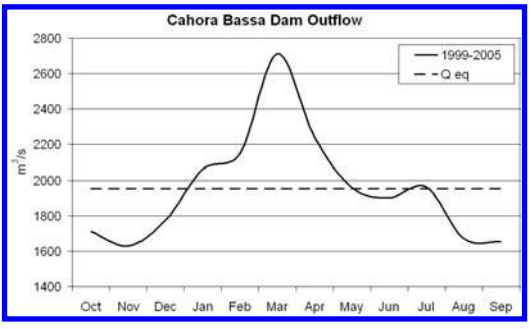

Figure 8. The comparison between the monthly average outflow and the respective Q_{eq}, from Cahora Bassa Dam from 1999 to 2005. (data from Ara Zambeze, 2005).

water discharge from Luia River can be estimated by the difference between the outflow of the Cahora Bassa Dam and the measured flow in Tete E320 (with a certain percentage reduction due to the presence of other minor tributaries between CB and Tete). In this way, using the Q_{eq} values both for Cahora Bassa outflow and for the discharge in Tete, a Q_{eq} value for the Luia River is derived. The ratio between this value and the estimated 10-years maximum flood (estimated by Lahmeyer Int et al., 2001) for the same river, has been applied also to the others three tributaries, obtaining the respective Q_{eq} values.

4.1.2 *Morphological data*

As already anticipate, the grainsize composition of the bottom of the Zambezi and its tributaries, has been extrapolated from the measurement done in the '60 ies by the Hydraulic Engineering Brigade of the Portuguese administration, before the construction of the dam. The samples have been taken from Zumbo (close the Zambian-Zimbabwean border) to the Ocean, about every 15 km, including a large part of the delta coastal profile and the final stretch of the tributaries. As the morphological model requires, the grainsize

Chire	546

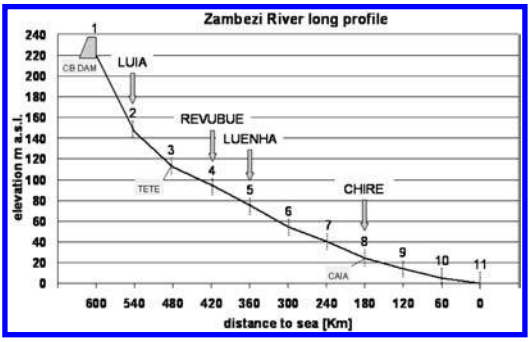

Figure 9. Lower Zambezi simplified configuration for model application.

extension has been splitted in four classes, each one represented by the medium diameter.

The river basin geometrical configuration (width and slopes of the main channels) has been derived from the LANDASAT 7 images, Hydro1K Africa Database (2000) provided by the USGS and "corrected" with the original cartography provided by the local authorities (Cenacarta, 2006).

As far as solid transport is concerned, the two different configurations considered (*with dam* and *without dam*) substantially differed because of the upstream boundary conditions of the model. In fact, the *with dam*-configuration means no solid transport downstream of the dam (hypolimnetic water), while the *with no dam*-configuration considers that an average initial value of 20×10^6 m^3/year of sediment runoff (estimated by Bolton, 1984, as the inflow sediment volume to the reservoir) provides to the sediment transport dynamic downstream of the dam.

4.2 *River's schematization*

With the selected space-step ($\Delta x = 60$ Km), the Lower Zambezi has been divided in 11 cross-sections (see Figure 9) that correspond at the grid calculation of the model. Each cross-sections has been characterized by a series of morphological parameter calculated in the downstream stretch (Table 5). The model's schematization imposed also that tributaries have to be introduced in a specific cross section.

5 PRELIMINARY MODEL SIMULATIONS

A first series of model simulations has been made for a period of 30 years, corresponding to the age of the dam impoundment, to investigate the long-term morphological evolution of the river through the variance of specific indicators, such as the bottom elevation, the total solid transport (bed load plus suspended sediment transport) and the grainsize composition medium diameter in the four macro-scale river zones (section 1: gorge zone; section 3: transitional zone; section 8: braided zone; section 10: coastal distributary zone).

Table 5. Morphological parameters of the selected cross-sections, including tributaries.

From the results obtained with the simulations, it seems that:

(1) Before the construction of the dam, the river appears to be aggrading everywhere downstream the Cahora Bassa Dam (13 cm/year at the transitional zone), especially in the vicinity of the major sediment input (say downstream the tributary Luia, which seems to be the most important source of sediment in the lower reach of the Zambezi). The aggradation seems practically to ends in correspondence of the braided zone, where it is virtually imperceptible (see Figure 11a at section n°8 and Figure 13a at section n°10). The model, however, indicates that, over the centuries, the upgrading profile tends to propagating slowly downstream.

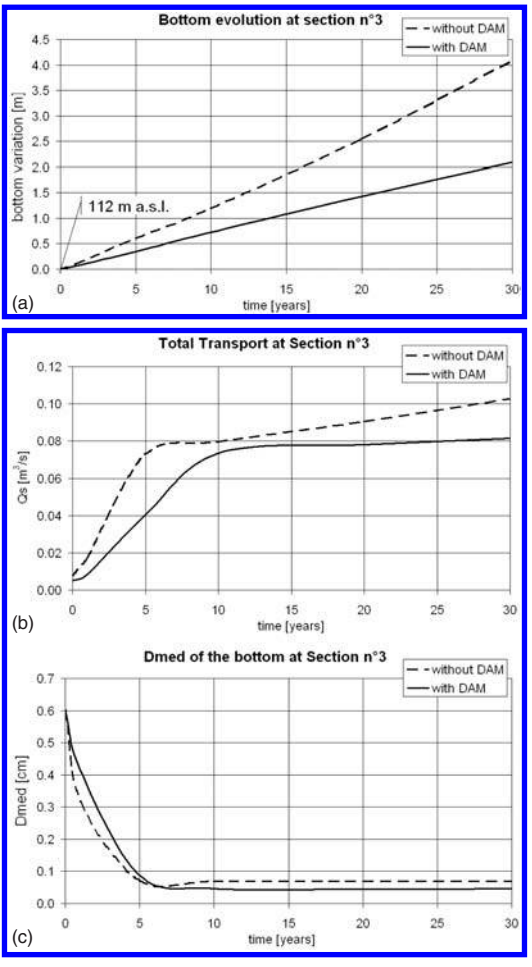

Figure 11(a-c). Bottom evolution, total solid transport and grainsize composition medium diameter in the transitional zone, downstream of cross-section n°3 (city of Tete).

Together with aggradation, the model indicates a corresponding fining of the bottom composition.

(2) The presence of the dam causes, in the first gorge zone, a strong bed erosion, yet limited by the presence of a stony bottom. The model also indicates a consequent thickening of the grainsize bottom composition (armouring), as well as a decrease on solid transport.

6 CONCLUSIONS

A simplified long-term morphodynamic model has been applied to the 600 km lower reach of the Zambezi River, between the Cahora Bassa Dam and the Indian Ocean.

This preliminary application of the model indicates that the present Zambezi River is not in equilibrium but it is slowly aggrading, especially in its upper part closer to the sediment sources.

The presence of the dam since 1974 has given place to a strongly reduction to the sediment input to the river reach and to a less variable waterflow during the year. As a consequence, the "natural" aggradation process has been slowed down, but it is still going on. The aggradation process is limited, at the present, to the upper part of the river, but it is possibly bound to affect the lower part.

It is to be stressed, however, that the conclusions above are definitely provisional. Many more tests, in fact, are necessary (sensitivity analysis) to confirm the results of the model and to check the long-term

tendency of the Zambezi and its delta. Moreover, the present version of the model will be modified to check the limits of the simplified hypothesis of locally uniform flow. Another aspect to be checked is the effect of a more refined grainsize distribution of the material.

AKNOWLEDGEMENTS

ABSTRACT: At river bifurcations, water and sediment are divided over two branches. The dynamics of the division determine the long-term evolution of the downstream branches, which can be studied by 1D models. For such models, a relation describing the sediment division is necessary, but this is poorly understood. We study the division of sediment and the morphodynamics on a time scale of decades by idealised 2D and 3D modelling of bifurcations with upstream meanders and dominantly bed load transport. Initially, migrating alternating bars in the models caused damped quasi-periodic fluctuations in bed levels, water and sediment division until the bars are near equilibrium. Varying the radius of upstream meanders and the slope of one of the downstream channels led to subtle changes in the sediment transport direction and the location of bars and pools. This caused large differences in which branch becomes dominant and in the rate of change in discharge asymmetry. The effects of wider downstream branches or of an overall narrower or wider river are dramatic, again demonstrating the importance of bars. The resulting division of sediment, on the other hand, is similar to the division of flow discharge in all runs after the initial fluctuations have damped out and until the discharge division becomes very asymmetrical. We conclude that bifurcations are extremely sensitive to local conditions affecting the secondary currents and the sediment transport direction, and to the downstream boundary conditions. Although most combinations of parameters lead to the development of an asymmetrical discharge division, some combinations lead to a quasi-stable symmetrical division. Finally we discuss the limitations of the models and the applicability to natural meandering rivers.

1 INTRODUCTION

Bifurcations distribute water, sediment and, indirectly, flooding risks over the downstream river branches. Over a much longer time, fluvial plains and river deltas are built up by avulsing and (temporarily) bifurcating rivers. In order to understand these phenomena, the local water and sediment transport division must be understood. Such understanding can be obtained by combining observations and geological reconstructions with models. However, 2D and 3D models are computationally too expensive for such long-term morphological predictions. A 1D model has to be extended with a 'nodal point relation' for dividing the sediment at the bifurcation, which is not well understood.

The objectives are to understand the causes of bifurcation (in)stability in meandering rivers and to predict the division of sediment to aid future 1D modelling. Accurate measurements of bed level evolution and sediment transport rates at meandering river bifurcations are rare for single events and non-existent for periods long enough to cover significant changes in morphology and discharge division. We therefore focus on systematic idealised modelling with 2D and 3D models to study the effect of specific factors such as the radius of a meander bend upstream of the bifurcation, and the slope of the downstream branches. The input parameters of the model are loosely based on the river Rhine in the Netherlands, which had more than 80 bifurcations in the past 8000 years, some of which were destabilised within a few decades after their creation, whereas some others were stable for many centuries (Stouthamer and Berendsen, 2000).

First we compare two state-of-the-art relations for sediment division that are used in 1D models, and

Copyright © 2006 Taylor & Francis Group plc, London, UK

whether these result in stable or unstable bifurcations. Next we describe the 2D and 3D model setup. After presenting the main results, a number of extra tests are presented to assess the effect of various channel widths and other parameters. Finally, the shortcomings of the models are discussed as well as the applicability of the results to real meandering rivers, and general conclusions are drawn.

2 RESULTS OF A 1D MODEL

A 1D model of a river with a bifurcation consists of three branches connected by a node. At the node, discharge and sediment supply from the upstream branch (1) is divided over the two downstream branches (2,3). The division of flow discharge Q_1 into Q_2, Q_3 at the nodal point follows from mass conservation, the condition that the water levels in the three branches are equal at the nodal point and the other specifications. The depth-width-integrated sediment transport S_1 is divided as S_2, S_3 according to the nodal point relation, in this case by Wang et al. (1995) or Bolla Pittaluga et al. (2002). The Bolla Pittaluga et al. relation divides the sediment based on the bed level differences of the downstream channels, assuming that the influence of this difference extends to the area upstream of the bifurcation and ignoring meander bend effects from upstream. The Wang et al. relation is empirical:

$$\frac{S_2}{S_3} = \left(\frac{Q_2}{Q_3}\right)^k \left(\frac{W_2}{W_3}\right)^{1-k} \quad (1)$$

where $k =$ an empirical power. Wang et al. found from a nonlinear stability (phase-plane) analysis that bifurcations are stable for $k > n/3$ and unstable for $k < n/3$, where $n =$ effective power on flow velocity to calculate the sediment transport. For Engelund and Hansen (1967) $n = 5$; for Meyer-Peter and Mueller (1948) $n > 3$ depending on the ratio of actual to critical shear stress.

An intuitive understanding of the Wang et al. model is offered as follows. Suppose the discharge of a branch decreases. The effect of a large k would be a much larger decrease of the sediment input than the decrease of the sediment transport capacity. Consequently, the bed of the closing branch is scoured to some extent, which increases the flow discharge capacity of this channel. So a large k stabilises the bifurcation.

Each branch has a length of 6 km with a step size of 150 m. The model is run for 50 years with a time step of 0.05 year. The flow in the 1D model is based on the Bélanger equation (backwater curve) and the Manning-Strickler roughness predictor. The specified model parameters are upstream discharge ($Q = 2500\,\mathrm{m^3/s}$), width ($W_1 = 532$ m, $W_2 = W_3 = W_1/2$), Nikuradse roughness length ($k_s =$ 0.19 m), calibrated so that the water depth is about equal to that in the 2D model, initial bed and water surface slope ($i_1 = i_2 = 1 \times 10^{-4}$ m/m, $i_3 = 1.1 i_1$) and downstream water levels of the two downstream channels which were chosen such that the flow is uniform initially. The morphology is computed from an initial bed, a sediment transport predictor (Meyer-Peter and Mueller (1948) or Engelund and Hansen (1967)) and the Exner sediment conservation law. The grain size is specified as $D_{50} = 2$ mm.

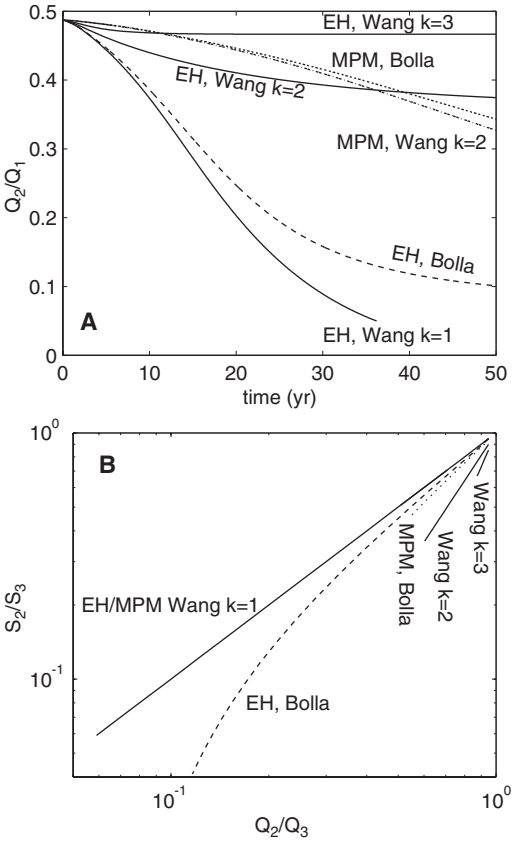

Figure 1. Results of 1D model. A. Time-series of discharge for the less steep branch. B. Sediment and discharge division over the downstream branches.

The 1D model predicts a decrease of discharge through the downstream branch with the smallest slope as expected (Fig. 1). Using the Bolla Pittaluga et al. nodal point relation, the discharge division always becomes very asymmetrical, or, in other words, a dominance of one of the channels. The rate of closure depends on the sediment transport rate, which in the present setting is larger using Engelund and Hansen (1967) than for Meyer-Peter and Mueller (1948). For the Wang et al. nodal point relation the bifurcation

Copyright © 2006 Taylor & Francis Group plc, London, UK

is increasingly asymmetrical for $k = 1$ but stable for $k = 2, 3$. The sediment division by the Bolla Pittaluga et al. relation is initially similar to that of Wang et al. with $k \approx 1$ and gradually changes to $k \approx 2$ for increasing asymmetry.

For both the 1D and 2D/3D model cases we study the range of model conditions from initial plane bed and symmetrical discharge division to (nearly) fully developed bar morphology with highly asymmetrical discharge divisions. For numerical reasons and due to model simplifications it is not possible yet to draw conclusions on the final branch closure process if a branch closes fully at all but this will be addressed in the discussion and in ongoing studies.

3 SETUP OF THE 2DH AND 3D MODELS

The Delft3D-FLOW morphodynamic model system was used (version 3.50.05.00BJ03). The parameters for the 2D and 3D models were very similar to that of the 1D model. The flow and morphology are calculated according to Lesser et al. (2004). The roughness formulation is Darcy-Weissbach with $k_s = 0.15$ m. The initial bed was plane and had a slope of $i = 1 \times 10^{-4}$ m/m, except where the slope of one downstream channel was deliberately increased. The downstream water levels were equal (for cases with $i_2 = i_3$) and chosen such that the flow was uniform initially (± 2 cm). The sediment transport predictor, unless mentioned, is Engelund and Hansen (1967). The bed slope effect on sediment transport is calculated according to Talmon et al. (1995) (see also Struiksma et al., 1985; Lesser et al., 2004). The spiral flow is schematised in the 2D model according to Struiksma et al. (1985), Lesser et al. (2004). The time step of the flow was 30 seconds to ensure numerical stability, and an initial period without morphological updating was allowed to stabilise the flow. Assuming that the flow is not appreciably affected by erosion and sedimentation during a time step, the morphological change in each time step can be multiplied by a large factor to predict the morphological evolution. The chosen factor was 100 which gave no significant differences with larger and much smaller factors.

The grids were curvilinear, and were automatically generated to ensure repeatability. The grids were orthogonalised as much as possible in an automated procedure. The average length of the grid cells was 150 m as in the 1D model. The width of the cells was 28 m for the standard models, 35 m for the wider, and 21 m and 16 m for narrower models. For the 3D models the flow was divided vertically in 10 layers of equal thickness, which was adapted to water depth changes (Lesser et al., 2004).

To split one channel into two, one row of cells had to disappear downstream of the bifurcation for numerical reasons. To ensure that $W_2 + W_3 \geq W_1$, the width of the cells downstream of the bifurcation was increased. The transition to this increased width was done gradually in the five cells upstream of the bifurcation. All three branches had the same lengths and consisted of 40 cells each.

The grids were generated with varying upstream bend radii, where the bend was 17 cells long downstream of a straight stretch. Downstream of the bifurcation a constant bend radius of $R = 20\,W$ was specified.

Avulsions commonly take place because of a slope advantage of the new flow direction over the old channel. To test the effect of an increased slope in one downstream branch, this slope increase was specified in the initial bed levels and the downstream water levels were again adjusted to ensure initial uniform flow.

New downstream branches often are less wide than the old branches, and usually $W_2 + W_3 \geq W_1$. Also, there is an effect of width-depth ratio on the bar dynamics. Three effects of width were tested: an equal increase or decrease of the width of all branches, an equal increase of the width of the downstream branches, and a change in the width ratio of the downstream branches. These were specified as factors on the cell width.

4 RESULTS

4.1 *Bar dynamics*

The 3D model initially predicted a rather complex morphological evolution (Fig. 2). In the first few model years alternating bars developed from the plane bed and migrate downstream. After some time, a fixed bar developed in the inner bend upstream of the bifurcation. Meanwhile, a bar and pool migrated side-to-side into the bifurcated branches and become fixed in position as well. Since more water is discharged into the channel with the pool than into the channel with the bar, the balance of the bifurcation was tipped and one channel became dominant. The rate of bar development and migration depended on the bend radius: the sharpest bends had the fastest development of a fixed bar. Bolla Pittaluga et al. (2002) assumed that the influence of bed level difference of the downstream channels extends to the area upstream of the bifurcation, which is confirmed here (Fig. 2, lowest panel).

4.2 *Effect of bend radius*

The 2D and 3D models always predict a development to a stable, highly asymmetrical discharge division. As expected, the outer-bend branch becomes dominant when the downstream conditions in the two branches are equal (Fig. 3A).

Since the effective secondary flow intensity in the 3D model is slightly smaller than in the 2D model, the bars and pools are slightly less pronounced in the 3D

Copyright © 2006 Taylor & Francis Group plc, London, UK

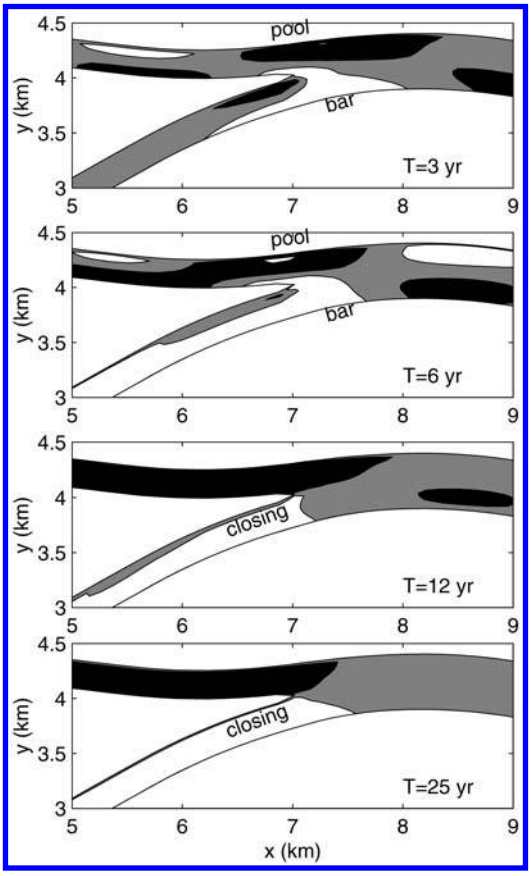

Figure 2. Classified bed levels at 3, 6, 12 and 25 years minus the initial bed level, illustrating the bar and pool evolution. At $T = 25$ years, the bed elevation difference between the downstream branches becomes so large that the inner-bend bar in the upstream bar is no longer visible due to the larger color interval spacing for larger T.

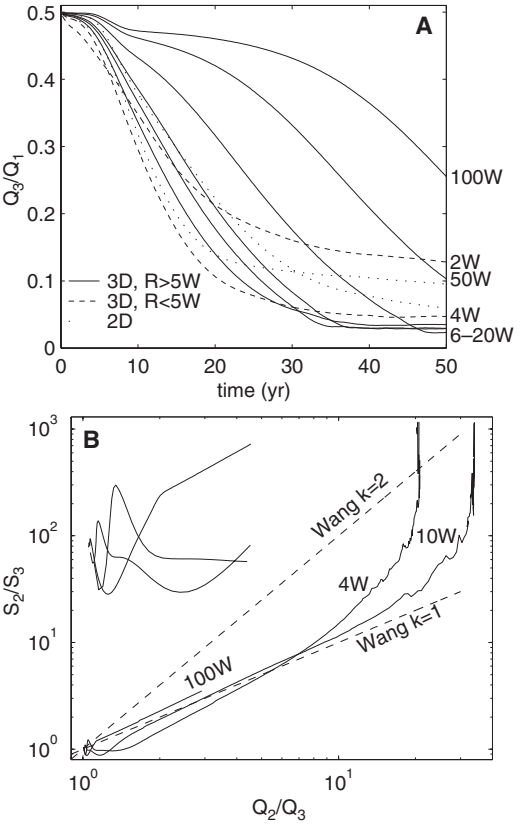

Figure 3. Results of 3D model. A. Time-series of discharge for the inner-bend branch. Labels indicate the bend radius as a multiple of the channel width. B. Sediment and discharge division over the downstream branches compared to the Wang et al. model. Initial quasi-periodic behaviour is magnified in upper left corner.

model and consequently migrate slightly faster. Unexpectedly, the present 2D runs for gentle bends predict dominant *inner*-bend branches although the results are similar to the 3D models for sharper bends ($R > 10W$) (Fig. 3A). This unexpected result might be caused by differences in the submodels for bed-slope and spiral flow effects. In addition, an older version of Delft3D (also in 2DH mode) with which much experience and good results were obtained in the past predicts dominant outer-bend branches. The 2D model results for sharp bends will therefore be interpreted with care and the gentle bends will not be used. Preliminary runs with the latest 2D version demonstrated that this numerical problem has already been solved and that the conclusions in this paper are still valid.

Intriguingly, a plot of S_2/S_3 against Q_2/Q_3 shows a considerable nearly-linear range with $k \approx 1$ (Fig. 3B). This means that the division of sediment transport is fairly similar to that of the flow. Initially the flow and sediment division fluctuates in a damped, quasi-periodic manner. This is caused by the development and migration of the bars from an initially plane bed. Once the bars are nearly in equilibrium and the balance is tipped, the flow and sediment are increasingly discharged into one branch.

In the final stages ($Q_2/Q_3 > 10$) the decline in sediment transport starts to outweigh the decrease in discharge, thereby apparently increasing k from a value below to a value above the stability threshold. The discharge in the closing branch then stabilises at a small but non-zero value in all cases.

4.3 *Effect of asymmetric downstream slopes*

The effect of the upstream bend on the choice which branch becomes dominant can be counteracted

Copyright © 2006 Taylor & Francis Group plc, London, UK

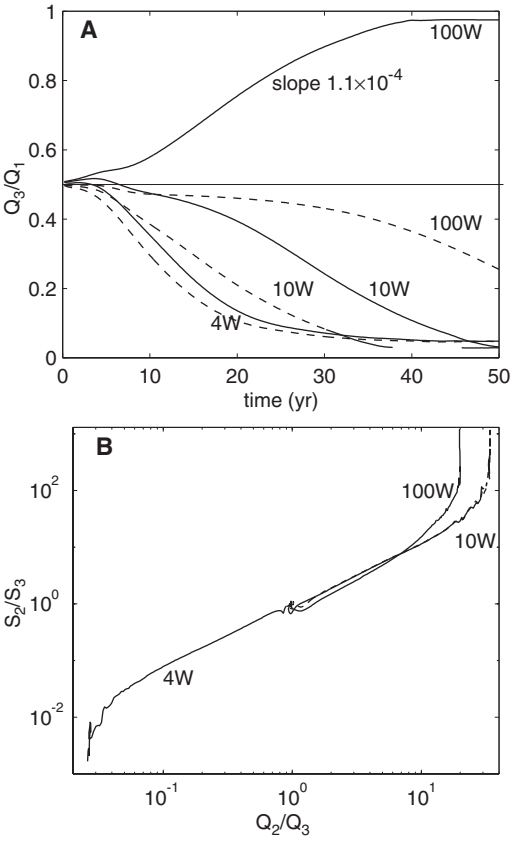

Figure 4. A. Effect of increased slope of the inner-bend branch (–) compared to cases with equal slopes (– –). Time-series of discharge for the inner-bend branch. B. Sediment and discharge division over the downstream branches with asymmetric slopes. The case with $R = 10\,W$ and equal slopes (:) lies on top of the asymmetric case.

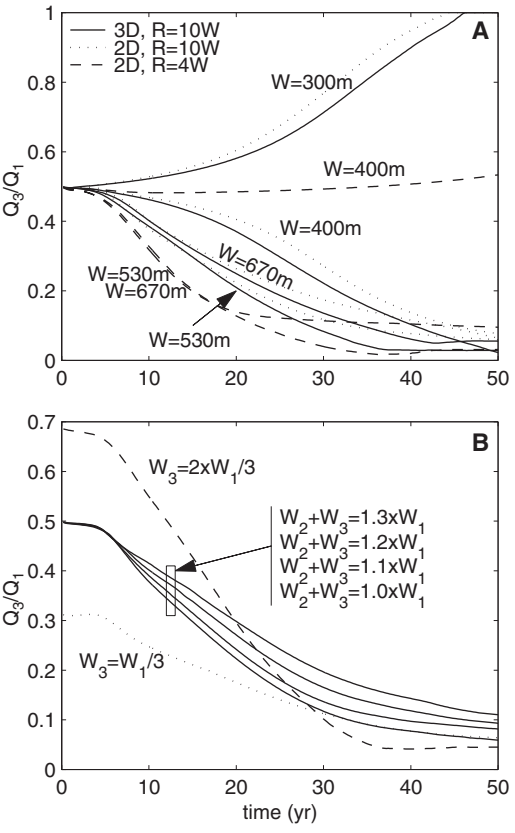

Figure 5. Time-series of discharge for the inner-bend branch. A. Effect of changing the overall channel width. Results with sharper bends are shown for the 2D model. B. Effect of changing the channel width ($W_2 + W_3$, W_2/W_3) downstream of the bifurcation.

by increasing the slope of the inner-bend branch (Fig. 4A). For a slope increase of 30% the inner-bend branch always dominates. For a slope increase of only 10% ($i_3 = 1.1 \times 10^{-4}$ as in the 1D model) the inner-bend branch dominates for gentle bends whereas the outer-bend branch dominates for sharper bends. The nodal point relation remains similar to that in other runs (Fig. 4B). In other words, a larger slope (0–20%) in one branch can be counteracted by upstream meander bend flow depending on the position of the steeper branch along the meander. Thus, there exist combinations of bend radius and downstream slopes for which the bifurcation remains quasi-balanced for a longer time. Such meander effects are not yet included in the existing nodal point relations for 1D models.

4.4 *Effect of different channel widths*

The effect of an equal increase or decrease of the width of all branches is dramatic (Fig. 5A). For narrower channels, all with $R = 10\,W$, the main flow switches from the inner-bend branch to the outer-bend branch in 3D runs. The 2D runs give very similar results. Additional 2D runs show that a sharp bend ($R = 4\,W$) switches the flow for even less narrow channels. This indicates that there also exist combinations of bend radius and channel width for which the bifurcations are quasi-stable, e.g. for $R = 4\,W$ and $W \approx 400$ m.

An equal increase of the width of the downstream branches only, on the other hand, has only a limited effect on the bifurcation stability (Fig. 5B). The closure of the inner-bend branch is slower for increasing downstream widths.

The effect of a change in the width ratio of the downstream branches is limited (Fig. 5B). If either the inner-bend or outer-bend branch is made narrower,

Copyright © 2006 Taylor & Francis Group plc, London, UK

the discharge division eventually approaches that of the symmetrical case. Clearly, an increase of the width of the closing channel does not increase the duration to attain the highly asymmetrical division.

Again, all the runs wherein the widths were varied gave similar nodal point relations with $k \approx 1$ as the other runs.

4.5 *Sensitivity analysis with the 2D model*

The effect of the length of the upstream bend was assessed by increasing this length to 5250 m; almost the whole upstream model domain. The bar pattern changed and the phase of increasing asymmetry took more time. The nodal point relation remained unaffected.

Additional runs with the Van Rijn (1984a,b) sediment transport predictor also gave very similar results for the nodal point relation. In the 2D runs with gentle bends only the outer-bend branches became dominant, contrary to the similar 2D runs with the Engelund and Hansen (1967) predictor. In all these model runs the nodal point relation remained unaffected.

Some model runs in which the downstream water level was varied with discharge ('QH-relation') showed that the outer-bend branch became dominant more slowly compared to runs with a constant downstream boundary, but with the same dependence on upstream bend radius. Runs with a constant Chézy roughness value rather than a constant Nikuradse roughness length gave similar results. In all these model runs the nodal point relation remained – again – unaffected, although the effect of these parameters must be investigated in more detail.

5 DISCUSSION

5.1 *Limitations of the modelling*

Which branch closes off is dramatically sensitive to the model setup. Different setups cause subtle differences in the sediment transport vector field, which decide which branch closes and the rate of closure. Small errors in the numerical scheme, in bed slope effects and in sediment transport predictors therefore have large effects on the outcome at bifurcations, even if the effects on the morphology in single channels are not that sensitive.

Some runs with the 2D model indicate that the results are sensitive to small perturbations of the grid at the bifurcation in cases where both downstream channels tend to be equally dominant initially (for certain combinations of bend radii and downstream slopes). Therefore, they are probably also sensitive to the precise schematisation of the bifurcation. In a curvilinear grid the bifurcation has to be a bluff, whereas in reality it is often a sharp-pointed bar. Further work is planned with a different type of bifurcation with a thin wall in the middle of a simple bend. It is perhaps better to model bifurcations with an unstructured grid, but this option is not yet available in Delft3D.

The models suggest that the bifurcations stabilise in a highly asymmetrical condition. However, the final closure process of one of the branches cannot be understood from the present model runs and has to be studied in more detail. It is possible that several assumptions and numerical aspects affect the value of k in the highly asymmetrical stages. Notably, we assume a constant roughness length and constant downstream water levels, and convert cells to permanently dry cells for water depths <0.1 m.

5.2 *Implications*

The value of $k \approx 1$ for the nearly-linear range in the nodal point relation of Wang et al. is a robust outcome of all given model setups. It means that the division of sediment is close to that of the flow discharge. The implication is that bifurcations are always unstable, or become highly asymmetrical, in partial agreement with Wang et al. (1995). For rivers with parameters similar to the modelled ones, the time scale of reaching the highly asymmetrical condition is of the order of decades to perhaps a few hundreds of years. This is a surprising result, because a number of bifurcations in similar rivers (Red River, Volga) are known to be stable in a more symmetrical condition on much longer time scales of observation, although other bifurcations, such as the historical Rhine bifurcation, were notoriously unstable. In addition, some data sets suggest larger values of k.

Preliminary results of runs with much longer downstream branches suggest that the location of the downstream constant water level (or, the distance from the bifurcation to the lake or sea) is important. For branch lengths approaching the backwater length (which can be estimated as $h/3i$), the discharge distribution becomes asymmetrical much more slowly. Moreover, they stabilise at more symmetrical discharge distributions when they are located at a long distance from the downstream boundary, or have a downstream water depending on the discharge (QH-relation). This is also reflected in the sediment division which follows $k \approx 2$. Runs with tidal water level fluctuations on the other hand de-stabilise more rapidly.

The initial quasi-periodic fluctuations damp out when the bars are nearly in equilibrium with the flow. These bars developed from the initially plane bed in the model. Given a natural river bed that is contingent on earlier conditions, such an initial effect does probably not occur in reality, so that the sediment is divided according to $k \approx 1$ immediately. The initial delay due to the fluctuations is therefore also unlikely to occur in reality.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The duration of the increasing asymmetry phase calculated in the models is probably an underestimate for natural rivers. During an avulsion, a new channel is created. The closure of the old branch commonly happens through sedimentation near the channel entrance rather than narrowing of the channel by sedimentation on the banks. The old channel downstream of the temporary bifurcation may narrow somewhat during the diversion of discharge, but is probably still nearly as wide as the channel upstream of the bifurcation. The models with a larger downstream width show that the closure is slower. Given the right combination of overall width, bend radius and downstream slope asymmetry, the closure may take up to a few centuries based on the present runs, especially for large distances between the bifurcation and the downstream constant water level.

The present model study focussed on dominant bed-load transport conditions. If the suspended bed sediment transport were dominant, then the division of sediment transport would be even closer to that of the discharge because it is less affected by near-bed secondary flow patterns and local bed slopes. According to the analysis of Wang et al. this implies that bifurcations with higher sediment mobilities are even more unstable than low-mobility bifurcations. Preliminary runs with $D_{50} = 0.5$ mm and the Van Rijn (1984b) transport model indeed show that the outer-bend branch becomes dominant even faster. This is highly relevant for many meandering rivers and opposed to the finding of Bolla Pittaluga et al. (2002) that bifurcations are stable for Shields parameters above 0.15.

5.3 *Future directions*

The reality is more complex than the model in some, perhaps crucial, points:

- The discharge is highly variable, affecting the bar development at the bifurcation. The timing of a large discharge peak may tip the balance in the opposite direction.
- In natural rivers, the banks are erodible depending on the bank sediment composition, vegetation, etc. Meander migration changes the boundary conditions at the bifurcation, and the opening downstream branch may widen through bank erosion. Changes in downstream channel width due to deposition also affect the rate of changing asymmetry. Moreover, the bifurcation may migrate downstream with the eroding bends. This may lead to an increase of the angle between the dominant and the subordinate branch, increasing the rate of changing asymmetry.
- The closure of river branches in nature is affected by changing hydraulic roughness and downstream water levels, as well as by large wood deposited after floods, pioneering vegetation and, further downstream, peat development.
- The bed sediment may be sorted in the bend, leading to preferred feeding of coarse sediment to one branch and fine sediment to the other. Moreover, bed surface armouring may stabilise bars.

Since the work of Wang et al. (1995) the common wisdom is that bifurcation stability can be explained from a stability threshold for parameters of the nodal point relation. The present study suggests, however, that bifurcations may develop to become very asymmetrical, which can be interpreted as closure, while persistent bifurcations are related to quasi-equilibria that result from a proper combination of upstream bend radius, channel widths or downstream slopes. Model runs will be done in the future with schematised discharge waves, changing grids, initial bars, other roughness formulations, downstream water levels that depend on discharge and erodible banks to assess their effects on the nodal point relation. Moreover, historical maps and the soil auger archive of the Rhine delta at Utrecht University will be studied (see, e.g., Stouthamer and Berendsen, 2000), as well as satellite images of the Ganges-Brahmaputra delta (see, e.g., Klaassen and Van Zanten, 1989) to test various hypotheses based on the model outcomes.

6 CONCLUSIONS

Based on more than 100 idealised 2D and 3D morphodynamic models we conclude that bifurcations always attain a highly asymmetrical division of discharge and sediment, except for a few specific combinations of parameters that give quasi-stable symmetrical divisions for a much longer period. The division of sediment at the bifurcations is similar to the division of flow discharge during the phase of increasing asymmetry in all models. This is the case for both bed-load and suspended-load transport-dominated conditions.

The models were loosely based on the River Rhine in the Netherlands, and became stably asymmetrical in periods of the order of a decade to perhaps a few centuries for special quasi-balanced cases. The rate of change of symmetry and the choice which branch becomes dominant is extremely sensitive to a number of competitive factors:

1. a slope advantage of one downstream branch increases the discharge through this channel,
2. a bend upstream of the bifurcation can counteract downstream slope advantages of 0–20% for decreasing bend radii,
3. the width of all channels strongly determines the bar pattern and dynamics, which may cause the flow to switch to the other downstream branch compared to cases with other widths,
4. the results are sensitive to the submodels for bed slope effects and sediment transport.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The subordinate branch was never entirely closed in the model runs, but this is perhaps an effect of model assumptions and numerical aspects. The closure process has to be studied further.

Bed load management at the River Lech – A physical model

U. Stephan & K. Wibmer
Institute for Hydraulic Engineering and Calibration of Hydrometrical Current-Meters, Vienna, Austria

ABSTRACT: The Tyrolean river Lech is one of the last near-natural Alpine riverine ecosystems of Austria. The flood event in August 2005 led to large flooding in the Reutte area caused by the extreme discharge and a river bed aggradation due to the high bed load from the upstream catchment. The reason for the latter is mainly a reduced bed slope of the Lech resulting in a halved bed load transport capacity despite a canalised river reach upstream of Reutte. A sustainable solution both ecologically and hydraulically satisfying was developed using a physical model test. The physically modelled river was divided into two channels approaching to the natural, braided river morphology. One channel worked as a bed load entrapment only for high discharges. The second channel forwarded the bed load according to the sediment transport capacity of the downstream river reach and remains untouched by the dredging.

1 INTRODUCTION

The Tyrolean Lech Valley with the river Lech and its tributaries is one of the last near-natural Alpine riverine ecosystems of Austria and because of its size and character one of the most important for whole Central Europe. The valley is mostly untouched by flood protection measures which was the reason for defining the whole Tyrolean Lech Valley as a Natura 2000 reserve (Birds Directive 1979, Habitats Directive 1992). This resulted in a particular protection of the whole area. Usually, a Natura 2000 reserve entails a limited anthropogenic utilisation within the concerned area due to the fact that any ecological deterioration is prohibited. Any technical engagement must always be seen in this context and is permitted only in cases of jeopardy of life. Thus, each river training measure has to consider this specific situation.

The flood event in August 2005 in Western Austria led to large flooding in the Reutte area caused, on the one hand, obviously by the extreme discharge with a return period of at least 200 years, and on the other hand, by a river bed aggradation due to the high bed load from the upstream catchment. The reason for the latter is mainly a reduced bed slope of the Lech resulting in a halved bed load transport capacity despite a canalised river reach upstream of Reutte. In the past years, this aggradation tendency regularly entailed large, ecologically disputed bed load dredgings. Since each bed load dredging also means unfavourable effects on the river ecosystem, notably in an ecologically valuable area, a sustainable solution both ecologically and hydraulically satisfying was needed.

2 BASIC CONCEPT

The bed load transport capacity in the Reutte area and downstream of it amounts to 50,000 m^3/y, while it reaches the double amount in the upstream area. Thus, to achieve a morphological dynamic equilibrium in the downstream river reach an amount of about 50,000 m^3/y on the average could be dredged. To achieve a solution which, on the one hand, minimises human influences on the river ecosystem and does not interrupt the flow continuum, and, on the other hand, also approaches to the natural, braided river morphology, the river is planned to be divided into two channels (Hanisch et al. 2005). One channel works as a bed load entrapment only for high discharges. The second channel, forwarding the bed load according to the sediment transport capacity of the downstream river reach, works like a bypass to the deposition zone and remains untouched by the dredging. Hence, the concept achieves both the morphological dynamic equilibrium of the downstream river reach and reduced human influences on the river ecosystem. The bed load entrapment was planned to be situated upstream of the endangered aggradation area (Fig. 1).

On the upstream and downstream end, the bed load entrapment is bordered by two ramps. The second channel – the diversion channel – starts upstream of the upper ramp and meets the river Lech again downstream of the second ramp (Fig. 2). Thus, the length of the diversion channel arises to almost 1000 m. The upper ramp situated at km 183.397 provides a stable head water level for the inflow into the diversion channel. The lower ramp situated at km 182.775, bordering the bed load entrapment at the downstream end,

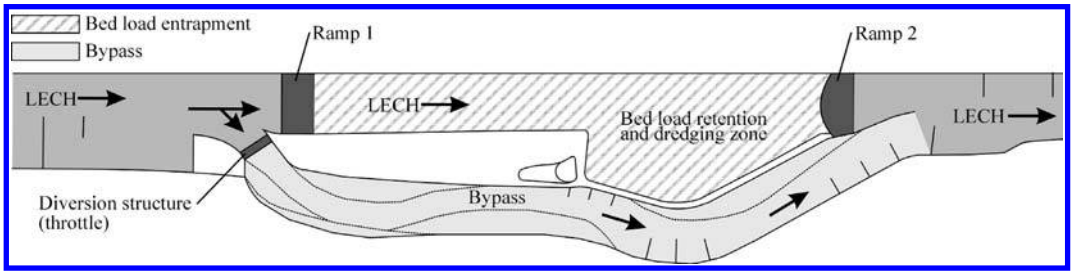

Figure 2. Scheme of the physical model.

reduces the flow velocity inside the entrapment area which leads to a controlled bed load deposition. The river bed widening between the two ramps additionally reduces the flow velocity and the bed shear stress and, thus, increases the retention area.

The inflow into the diversion channel is limited by a discharge throttle (Fig. 2). Discharges lower and equal to the mean flow are forwarded solely to the diversion channel. Discharges higher than the mean flow corresponding to high bed load also flow through the bed load entrapment. Since the bed load entrapment runs dry during low water periods the dredging can be limited to these periods causing only little unfavourable effects on the river ecosystem. These periods mainly occur during the winter, when the whole discharge flows through the diversion channel.

The whole design of the bed load entrapment is based on an optimal discharge and bed load distribution between the two channels. This discharge and bed load distribution mainly depends on the crest height of the upper ramp, on the dimensions of the discharge throttle as well as the position of groynes to direct the flow of water and sediment. Since all these influencing variables were expected to cause highly complex interactions, it was decided to highlight the problem by conducting a physical model test. The model, amongst others, focused on possible control elements such as the discharge throttle or dikes and groynes to influence the discharge and bed load distribution and transport depending on the geomorphologic boundary conditions.

3 PHYSICAL MODEL

The modelled river section had a length of 1573 m and a width of 220 m in nature. According to the available space of the laboratory flume with a length of 25 m and a width of 3 m, the scale factor of the physical model was fixed at 1:80 applying the Froude's law.

The physical model was built with a movable river bed. This scale factor does not allow quantitative but qualitative assessments of morphological results, since the morphological transport processes in nature do

Figure 3. Development of alternate bars in the physical model at the bed-forming discharge.

not exactly correspond to transport processes in the physical model. The reasons are as follows:

– The sieve curve of the bed material could not be reproduced entirely since grain sizes lower than 0.2 mm might agglutinate.
– Bed forms such as dunes, ripples or bars in the physical model differ from natural ones for high scale factors.

To transfer morphological assessments from the physical model to nature it is important to physically reproduce the grain sizes especially between the mean diameter d_m and the d_{90} (Tab. 1). The grain size was scaled down geometrically. In this case, the model sieve curve sufficiently agreed with the natural sieve curve to derive qualitative assessments of the observed morphological processes (Fig. 4).

Model tests investigating the morphological behaviour of the current situation of the river Lech provided a basis for the comparison of current and planned situation. The characteristic morphological behaviour was derived from steady state experiments for different discharges and compared to natural bed forms. Air photographs from the canalised river reach of the Lech show alternate bars with a mean distance of 260 m. In the physical model, similar bars with a mean distance of 225 m could be observed (Fig. 3) which serves as an example for the qualitative agreement of the

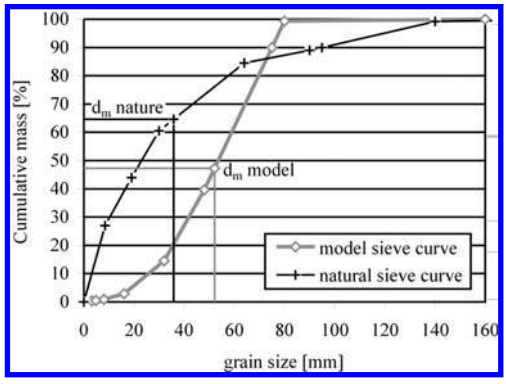

Figure 4. Natural and model sieve curve (both full-scale data).

morphological behaviour in the physical model and in nature. Since bed load transport mainly occurs in terms of alternate bars for the present hydraulic and morphological boundary conditions, an analogous bed load distribution between main and bypass channel can be assumed for both physical model and nature.

In the physical model, the river-adjacent areas were made from concrete and the river bed was a mobile sand bed. The roughness of both the river banks and the river-adjacent areas was simulated by stones of a mean weight of approximately 1000 to 2000 kg per stone which means a stone size of d = 11–14 mm in the physical model (Figs 3, 6). The discharge throttle consisted of a slit PVC-plate which could easily be changed in case of unfavourable results. Thus, different slot sizes could be tested.

The bed load entrapment was optimised within more than 20 experiments varying the crest height of the ramps and ramp heights, the size and height of the slot of the discharge throttle as well as position and layout of different measures to direct the flow and the bed load upstream of the diversion structure.

4 BOUNDARY CONDITIONS

The gauge in Lechaschau was used to define the representative discharges (Tab. 2) for the concerned river reach. The duration curve was calculated from the discharge hydrograph 1996–2001 which serves as a basis

Copyright © 2006 Taylor & Francis Group plc, London, UK

for defining the bed forming discharge BBQ by superposing the duration curve and the sediment transport capacity depending on the discharge (Fig. 5).

The experiments were conducted either as steady state or unsteady state experiments with bed load input into the model inflow. The amount of bed load was calculated according to Meyer-Peter & Müller (1949) using a mean diameter of $d_m = 52$ mm according to the sieve curve of the material used in the physical model (Fig. 4).

5 PROPOSED SYSTEM

The main components of the optimised system (Fig. 6) which yielded the best results concerning the most favourable dividing of flow and bed load between the

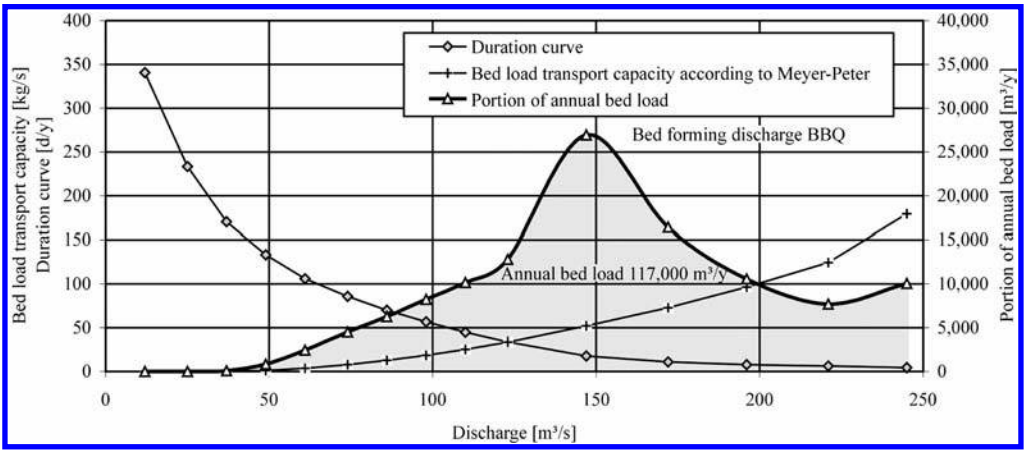

Figure 5. Calculation of bed-forming discharge.

main channel, i.e. the bed load entrapment, and the bypass can be described as follows. The proposed catalogue of measures provided a dynamic equilibrium (Jäggi 1992, Stephan et al. 2003) in the bypass channel, the upstream as well as the downstream river reach and an appropriate bed load supply of the bed load entrapment.

5.1 *Ramps*

The bed load entrapment was situated in the main channel between two ramps. Since the bypass channel started upstream of the upper ramp the crest height of this ramp served as a decisive factor for dividing flow and bed load between the main and the bypass channel. The best results were gained for a crest height being 1.8 m higher than the bed level of the current river bed. Due to the local situation an appropriate flood protection could be guaranteed despite the raised bed level. The crest of the lower ramp had the same height as the base of the upper ramp. The ramp height of the upper ramp was 3.0 m and of the lower ramp 3.4 m. Both ramps had a width of 55 m and a ramp slope of 1:8. Since the upper ramp is expected to be mostly covered with bed load material this ramp was planned as a plane ramp. The lower ramp at the downstream end of the bed load entrapment was planned as a synclinal ramp according to Schauberger (1973). Stone sizes as well as length and size of the bed protection downstream of the ramps were calculated according to Platzer (2000). The stone size of both ramps was fixed to $l_m = 1.5$ m as a mean stone length which means a mean stone weight of approximately 1500 kg.

5.2 *Bed load entrapment (BLE)*

The river section between the two ramps, which served as a bed load entrapment, had a total length of 600 m (Fig. 2). The river width of the upper half of the section being 55 m remained unchanged. The width of the other half of the section was widened up to 130 m which resulted in a reduced flow velocity and, thus, in a favoured bed load deposition within this area. No additional measures to direct flow and bed load between the ramps such as groynes were needed.

5.3 *Discharge throttle*

The slot size of the discharge throttle as shown in Figure 7 was fixed to 15.0 × 1.5 m. To direct flows lower or equal to the mean flow into the bypass channel the bottom line of the throttle had to be 1.7 m below the crest height of the upper ramp. For high discharges the water flowed not only through but also over the discharge throttle. Thus, the river bed had to be protected by a riprap section in front of and behind the throttle to avoid scouring.

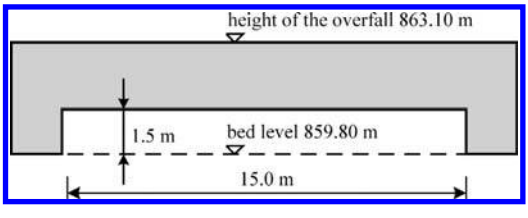

Figure 7. Discharge throttle.

5.4 *Bypass*

The bypass channel showed a slightly curved course with a width ranging from 30 m to 40 m. Alternately situated fields of groynes reduced the channel width by 50% to approximately 15 m for discharges equal and lower than the mean discharge which resulted in the formation of an additional narrower, secondary channel inside the bypass (Fig. 8). It was important to keep the throttle free from deposited bed load material and free flow through the throttle had to be available for every discharge especially for low discharges. Thus, no aggradations should occur in the bypass channel. Best results were obtained for a channel width of 15 m and a bed slope of 0.3%. At discharges larger than 50 m^3/s the groynes were overflowed and, thus, the whole bypass width was available for higher flows decreasing also the sediment transport capacity.

River training structures as well as alternate fields of groynes supported a morphological diversity which strongly enhances also an ecological diversity.

5.5 *Upstream river reach*

Due to the crest height of 861.5 m of the upper ramp, the bed level of the upstream river section was increased by an amount of 1.8 m. This measure was needed to direct low discharges into the bypass, but had also be combined with measures to regulate the bed load input into the bypass channel. Experiments without control measures such as groynes entailed high bed load transport into the bypass resulting in bed load

Figure 8. Bypass channel (view in downstream direction).

Run 8	HQ1, unsteady state	245	5952	2522	3430	57.6
Sum			167,148	49,700	117,448	70.3

deposition close to the discharge throttle and in the bypass. Groynes on the left hand side of the main channel had the same effect on the bed load input into the bypass causing an unfavourable aggradation. The best results were gained by placing two groynes 198 m and 243 m, respectively, upstream of the discharge throttle on the right hand side of the main channel. Thus, especially for high discharges the major part of the bed load material was forwarded into the bed load entrapment avoiding depositions close to the throttle. The groynes being 15 m long were situated right angled to the river bank and were overflowed at a discharge with a return period of one year. In case of changes of the bed load supply from the upstream catchment, design and location of the groynes can easily be adapted to the actual situation. This means a great advantage in meeting changed boundary conditions.

5.6 *Downstream river reach*

The river section downstream of the confluence of bypass and main channel turned out to be endangered by aggradation due to the sudden river widening which, for some cases, proceeded in upstream direction. Hence, to avoid unfavourable bed load depositions behind the confluence the river width had to be reduced locally which was realised by a spur dike and by a single groyne on the right hand side of the river directing the bed load coming through the bypass into the main channel (Fig. 2). Alternately situated fields of groynes in the main channel additionally reduced the river width and, thus, increased the shear stress. They also supported an increased structural variety of the currently canalised river reach since the slightly curved course of the river entailed sequences of bends and fords in longitudinal direction. These measures resulted in a mean bed level 0.3 m lower than the current bed level which still lays within acceptable limits.

6 RESULTS

The optimised solution was investigated by means of a detailed test programme (Tab. 3) with different scenarios and representative flood events from the discharge hydrograph 1996–2001. By comparing bed level measurements of the bypass and the main channel before and after each experiment, bed level changes could be summarised to a cumulative volume describing bed load transport through bypass and main channel, respectively. Table 3 shows eight steady and unsteady state experiments with varying discharges. Five experiments simulating characteristic or extreme scenarios are described more in detail to highlight tendencies of erosion and/or aggradation in bypass and main channel.

The upper chart of the following figures shows the hydrograph of the experimental run (a) and the lower chart presents the deposited area as well as the cumulative volume for both the main (BLE) and the bypass channel (b). All data are converted into full-scale data.

6.1 *Run 1*

The hydrograph of Run 1 consisted of four small flood events approximately corresponding to a discharge with a return period of one year, to the bed-forming discharge and the mean discharge, respectively (Fig. 9). The duration of the first three events was calculated from the duration curve, the fourth curve corresponded to a real flood event of September 2000.

As it can be seen from the deposition curve of the main channel, i.e. the bed load entrapment, adding up the bed level changes of all four flood events, the bed load material was mainly deposited in the widened river section upstream of ramp 2. The bed load material was partly transported to but not over ramp 2.

Copyright © 2006 Taylor & Francis Group plc, London, UK

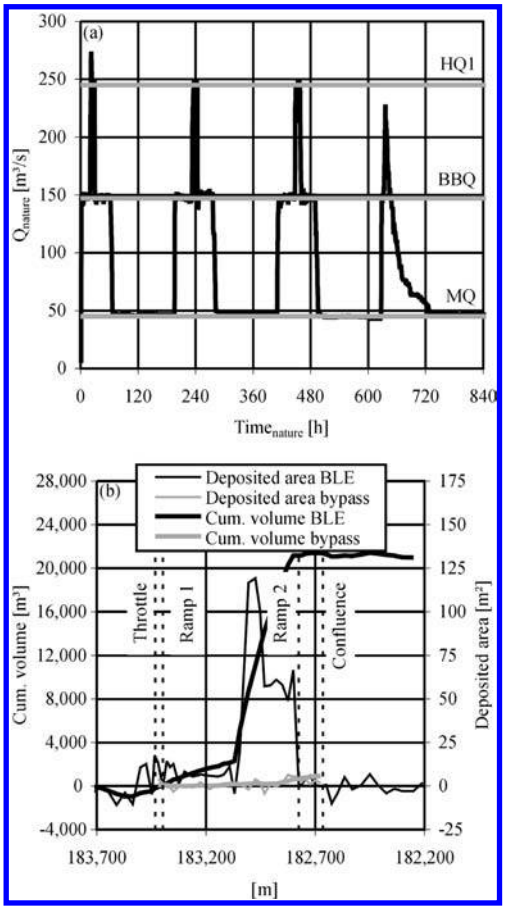

Figure 9. Run 1 – hydrograph (a), deposited area and cumulative volume (b).

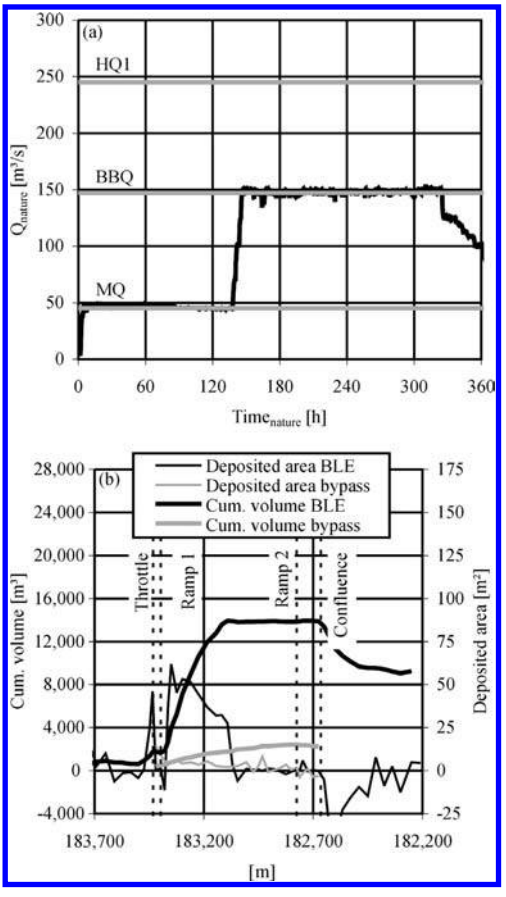

Figure 10. Run 3 – hydrograph (a), deposited area and cumulative volume (b).

Behind the confluence of bypass and main channel neither aggradation nor erosion could be observed which points out a dynamic equilibrium of the downstream river reach. Upstream of ramp 1 the curve reveals a slight tendency of erosion.

The bypass bed levels showed only minor aggradations upstream of the confluence which resulted from alternate fields of groynes. As mentioned above, the groynes reduced the width of the bypass to 15 m for discharges lower than 50 m^3/s and, thus, increased the transport capacity which, finally, resulted in the development of an additional narrower, secondary channel inside the bypass. This secondary, slightly deeper channel enabled discharging of low flows through the bypass whereby the bed load entrapment ran dry. The bed load material deposited near the confluence in the bypass channel was removed again by higher discharges. Thus, the results demonstrate continuous bed load transport into the downstream river reach.

6.2 *Run 3*

The hydrograph of the river Lech in Figure 10 simulated a rather typical scenario during spring time – the snowmelt. Usually, the low flow period during the winter time passes into a long period of higher discharges typically in the range of the bed-forming discharge. For this case, approximately half of the discharge flowed through each of the channels.

Depositions could be observed in front of the discharge throttle and behind the upper ramp 1. The latter seems to be astonishing since the deposition in the main channel did not appear in the widened part of the bed load entrapment but in the narrow part with higher transport capacity. This indicates that the transport capacity related to the remaining discharge in the main channel was too low for the high amount of bed load forwarded over ramp 1 even in the narrow part of the bed load entrapment.

Copyright © 2006 Taylor & Francis Group plc, London, UK

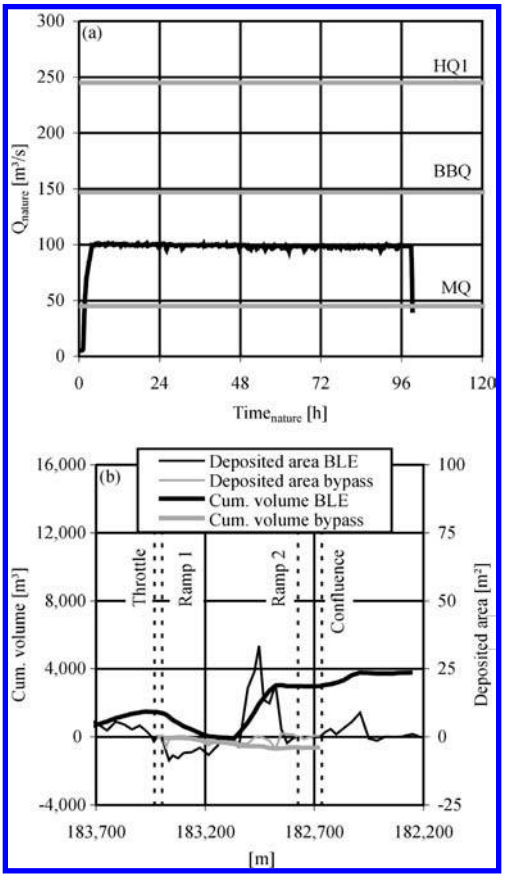

Figure 11. Run 5 – hydrograph (a), deposited area and cumulative volume (b).

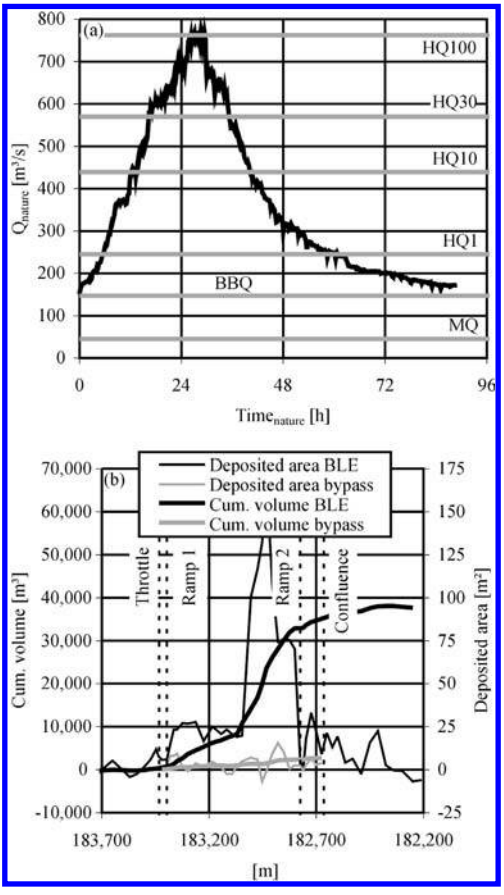

Figure 12. Run 6 – hydrograph (a), deposited area and cumulative volume (b).

Depositions also appeared in the bypass channel, but can be explained by the comparatively high discharge at the end of the experiment. The discharge was not low enough to enable the formation of the additional secondary channel which would accelerate the re-mobilisation of deposited material.

The downstream river reach showed an erosion tendency which resulted from aggradation in both the bypass and the main channel which can be explained by the lack of sediment transport from upstream.

6.3 *Run 5*

To investigate a wide range of different discharges one of the experiments was conducted with a steady state discharge of 100 m^3/s being between the mean and the bed-forming discharge.

Figure 11 exhibits that depositions appeared in both the upstream and the downstream river reach despite a comparatively low discharge. During the experiment, no bed load material was transported over ramp 2 and, thus, depositions occurred in the widened section of the bed load entrapment. The depositions in the downstream river reach resulted from bed load transport through the bypass which indicated minor erosions proving the functional ability to forward the bed load into the downstream river reach especially for low discharges.

6.4 *Run 6*

Figure 12 shows the simulation of a 100 years flood event beginning and ending with the bed-forming discharge.

The river reach upstream of the upper ramp 1 exhibited neither aggradation nor erosion but remained almost unchanged. As also shown in Figure 9, the bed load material was mainly deposited in the widened river section upstream of ramp 2. But aggradation also appeared between ramp 1 and the widened river

Copyright © 2006 Taylor & Francis Group plc, London, UK

section and, to some extent, also in the river reach downstream of ramp 2. This can be explained by the high amount of bed load material mobilised by the high discharge which was also transported over ramp 2. Added up to the bed load material coming from the bypass channel, the total amount of bed load exceeded the transport capacity of the downstream river reach and, thus, caused depositions behind the confluence of main and bypass channel.

The bypass channel also showed a slight tendency of aggradation. This can easily be traced back to the experiment ending with a discharge not lower than the bed-forming discharge. Again, the discharge was not low enough to enable the formation of the additional secondary channel which would enhance the re-mobilisation of deposited material caused by a higher discharge.

6.5 *Run 7*

To investigate the function of the bypass channel during the falling limb of a hydrograph, Run 7 continued Run 6 simulating the falling limb of a flood event beginning with the bed-forming and finishing with the mean discharge (Fig. 13). This scenario led to depositions behind ramp 2 and behind the confluence of bypass and main channel, but not in the bedload entrapment or in the bypass. The bypass even showed an erosion tendency which proofed the re-mobilisation of deposited bed load material after a flood event due to the development of a secondary channel with a higher transport capacity.

6.6 *Summary*

Figure 14, finally, summarizes the bed level changes of all experiments done (see also Tab. 3). The graph demonstrates major depositions of bed load material in the bed load entrapment, especially in the widened section upstream of ramp 2. Only minor depositions can be observed in the bypass channel. But a re-mobilization of this material is to be expected for low flow periods. Both, the upstream and the downstream river reach remain unchanged which is important especially for the downstream river reach. The capacity of the bed load entrapment proved to match very well with the reduced transport capacity of the downstream river reach.

The percentage of deposited material in the bed load entrapment related to all investigated discharges is shown in Figure 15. The linear regression exhibits that the sediment retention in the bed load entrapment increased with higher discharges. For an average year the deposited material amounted to approximately 55% of the total bed load. For extreme flood events even 75% of the total bed load were entrapped in the dredging zone.

7 CONCLUSIONS

The Tyrolean river Lech is one of the last near-natural Alpine riverine ecosystems of Austria. The valley is mostly untouched by flood protection measures which was the reason for defining the whole Tyrolean Lech Valley as a Natura 2000 reserve. Thus, each river training measure has to consider this special situation. In the Reutte area, a reduced bed slope of the Lech resulting in a halved bed load transport capacity despite a canalised river reach often causes unfavourable aggradations increasing the danger of flooding. A sustainable solution both ecologically and hydraulically satisfying was developed using a physical model test. The physically modelled river was divided into two channels approaching to the natural, braided river morphology. One channel – the main channel – worked as a bed load entrapment only for high discharges and ran dry for discharges lower than the mean discharge. This channel section was bordered by two ramps at the upstream and downstream end. The width of half of the section was enlarged to concentrate the depositions within this channel section by reducing the sediment transport capacity. The second channel – the bypass – forwarded the bed load according to the transport capacity of the downstream river reach. The model results indicated that the deposited material amounted to approximately 55% of the total bed load for an average year. This means that 45% of the total bed load material satisfied the transport capacity of the downstream river reach since the model results adding up all experiments exhibited bed levels being in a morphological dynamic equilibrium. However, the experimental runs provided valuable findings concerning the interplay of deposition and erosion of bed material in both the main and the bypass channel varying with discharge.

The physical model "Lech – Bed Load Entrapment Hornberg-Ehenbichl" was essential for assessing the interaction of the different components and for testing the reliability of the complex site layout in the most efficient way. The model furthermore proved its value in optimizing the design and evaluation of operation and maintenance guidelines. However, stochastic factors like discharge regime or saturation level of the sediment transport capacity affect bed load transport and deposition processes.

Hence the permit planning is complemented by a complex river bed stability and bed load monitoring program, the results of which will be presented in the near future.

Intermittency of rheological regimes in uniform liquid-granular flows

A. Armanini, M. Larcher, L. Fraccarollo
CUDAM – Dipartimento di Ingegneria Civile e Ambientale – Università degli Studi di Trento,Trento, Italy

ABSTRACT: To investigate the vertical structure of free-surface liquid-granular flows, it is of particular interest to materialize steady flow conditions. In this contribution, we present a detailed analysis of the rheological stratification of the flow, focusing on the mechanisms governing the transition from the frictional to the collisional regime, on the stress transmission inside the flow and on particles kinematics. In particular, it is observed that in opportune conditions high-concentration flows show locally a typical intermittency of the flow regime, switching alternatively from frictional to collisional. In the experiments a mixture of water and perfectly spherical, identical particles, with a diameter equal to 6 mm and with a density of 2210 kg/m^3, was introduced steadily in the upstream part of the flume and filmed through the sidewall of the channel utilizing a high-speed CCD camera. The reconstruction of detailed particle kinematics and of the effect of the intermittence of the flow regime was obtained utilizing imaging techniques based on the Voronoï polygons.

1 INTRODUCTION

Steady granular flows have been widely studied in literature. Most investigations treat cases where air plays the role of interstitial fluid, while just a few ones consider granular flows in water.

The rheology of granular flows was originally tackled by Bagnold (1954), who analyzed the behavior of a gravity-free dispersion of large solid spheres in a Newtonian fluid under shear. Bagnold distinguished two flow regimes on the base of a non-dimensional parameter, subsequently called the *Bagnold number*, representing the ratio between stresses due to inertia and stresses due to viscosity. Bagnold called *macroviscous* the linear regime characterized by small Bagnold numbers, where the shear stresses behave like in a Newtonian fluid with a corrected viscosity, and *grain-inertia* the one, characterized by large Bagnold numbers, where the stresses were independent of the fluid viscosity but dependent on the square of the shear rate and on the square of the granular-phase concentration.

Recent findings leaded to a better understanding of particle interactions. In particular, a granular material subjected to deformation can determine different types of interactions among grains and, therefore, generate stresses by different mechanisms. Individual particles may interact with the others in form of clusters, generating a network of contact forces through sustained rolling or sliding contacts, or by nearly instantaneous collisions, during which momentum is exchanged and energy is dissipated because of inelasticity and friction. The relative importance of these mechanisms may be used as the characteristic defining the various flow regimes (Savage 1984).

The velocity of each particle may be decomposed into the sum of a mean velocity and of a random component, taking into account the relative motion of the particle compared with the mean value. The concept of *granular temperature* can be introduced to refer to the mean square value of the instantaneous deviation from the mean velocity. The granular temperature plays a fundamental role in generating pressures and governing the internal transport rates of mass, momentum and energy.

The physical similarity between rapid granular flows and dense gases has led to a great deal of work on applying kinetic theories to granular materials, pursuing the idea of deriving a set of continuum equations (typically mass, momentum and energy conservation) entirely from microscopic models of individual particle interactions. All models are based on the assumption that particles interact by instantaneous collisions, implying that only binary or two-particle collisions need to be considered. Particles are usually modeled in a simple way, ignoring surface friction or any other particle interactions tangential to the contact-point, and considering a constant coefficient of restitution to represent the energy dissipated by the impact normal to the point of contact between the particles. Furthermore, molecular chaos is generally assumed, implying that the random velocities of particles are independently distributed.

Coherently to the considerations reported above, two different rheological regimes are observed in

Copyright © 2006 Taylor & Francis Group plc, London, UK

granular flows: a *collisional regime* and a *frictional regime*. The collisional regime is typical of rapid granular flows, and particles interact by means of quasi-instantaneous contacts. This regime was studied widely by many authors, among the others Jenkins & Hanes (1998), and Armanini et al. (2005) showed it to be in strict analogy with the grain-inertia regime identified by Bagnold. The frictional regime, on the contrary, is typical of slow, dense flows of cohesionless granular materials, where the grains move with sustained contacts (Savage 1998).

2 THEORETICAL FRAMEWORK

2.1 *Liquid-granular flows in equilibrium*

In opportune experimental conditions liquid granular flows can take place in equilibrium conditions, in the sense that a moving layer flows over a static loose bed of water-saturated grains. In this case the bottom does not represent an interface where vertical profiles of physical quantities, such as velocity and concentration, change abruptly or present cusps. Therefore velocity, concentration and granular temperature are all continuously varying throughout the flow depth from the top free-surface down to the bottom. This condition importantly influences flow dynamics, which are remarkably different from those that develop over a fixed bed (Larcher 2004, Armanini et al. 2005).

Armanini et al. (2005) showed the experimental evidence of the existence, over the depth of flows in equilibrium, of different rheological mechanisms. In fact, near to the erodeable bed, the frictional (or quasi-static) regime prevails, while near to the free surface any mechanism, including also frictional, pure collisional and turbulent ones, could be present. The distribution of the rheological characterization over the flow depth is responsible of the global flow condition. The flowing layer adjusts its own depth through erosion or accretion of the static deposit. It should be noted that this deposit forms spontaneously.

2.2 *Kinetic theories*

To relate the collisional particle pressure σ_p and shear stress τ_p to the local granular temperature, the following relations, originally derived from kinetic theories in the context of dry granular flows, can be applied to liquid-granular systems:

$$\sigma_p = c\rho_p\left(1+r\frac{\rho_w}{\rho_p}\right)(1+4cg_o)T \tag{1}$$

$$\tau_p = -\frac{8D(1+r\rho_w/\rho_p)\rho_p c^2 g_0 T^{1/2}}{5\pi^{1/2}}\left(1+\frac{\pi}{12}\left(1+\frac{5}{8cg_0}\right)^2\right)\frac{du}{dy} \tag{2}$$

where:

$$g_0(c) = \frac{(2-c)}{2(1-c)^3} \tag{3}$$

describes the variation of the rate of collisions between particles with particles-concentration c (Carnahan & Starling 1969), and where

$$r = \frac{1+2c}{2(1-c)} \tag{4}$$

is the added mass coefficient that takes into account that the motion of a submerged particle is accompanied by the conjugate motion of a portion of fluid (Armanini et al. 2005). In the equations reported above ρ_p and ρ_w represent the density of the granular material and of the interstitial fluid respectively, D represents the diameter of particles and du/dy the shear rate.

2.3 *Uniform granular channel flow*

If the granular phase is completely saturated by water, the external normal stress σ_e and tangential stress τ_e can be written as:

$$\sigma_e = \int_y^h \rho_w g\Delta c\cos\alpha\, dy \tag{5}$$

$$\tau_e = \int_y^h \rho_w g(1+\Delta c)\sin\alpha\, dy \tag{6}$$

Where c is granular concentration by volume, y is the coordinate normal to the bed, h is the free surface level, ρ_p and ρ_w are the densities of the particles and water, $\Delta = (\rho_p - \rho_w)/\rho_w$ is the relative immerse density of the solid phase, g is the acceleration of gravity, and α is the slope angle of the flow.

In uniform flow condition the external stresses are balanced by internal one. While in the direction normal to the flow the external stresses, given by eq. (5), are balanced by the internal stresses due to particle interaction, (eq. 1), the tangential projection of the entire burden of the flow (water + grains) (eq. 6) is charged over the solid phase only (eq. 2), so assuming that the shear stress in the liquid phase is negligibly small.

Armanini et al. (2005) describe the presence of a stratification of rheological mechanisms inside the flow, with the frictional regime located in the slower regions and the collisional layers where velocity and shear rate are larger. This picture of the flow domain was innovative respect to observations keeping collisional and frictional mechanisms in distinct kinds of experiments. However this was not sufficient to satisfy force balances inside the flow domain. In our experiments we recently observed that not only a stratification of rheological mechanisms is possible, but that in certain positions of the flow domain collisional

Copyright © 2006 Taylor & Francis Group plc, London, UK

and frictional regime can coexist, in the sense that they alternate in time. This alternation of different regimes is similar to what happens in the border of a turbulent boundary layer where the alternation between turbulent flow and external potential flow is identified as the phenomenon of *intermittency* (Hinze 1975).

2.4 *Intermittency and coexistence of collisional and frictional regime*

In the case of granular flow the observation was possible accounting time-evolution of the vertical velocity of particles. In fact in the frictional regime particles roll in relatively ordered layers, one on top of the other, and vertical velocity changes in time according to regular sequences, characterized by some peaks at regular intervals. The observation of vertical velocity history denotes that sometimes vertical velocity can exceed these peak values typical of the frictional regime, denoting that the rheological mechanism has switched to collisional conditions. Coherent blocks of particles have been observed also in numerical simulations of dry particles (Drake 1990), in particular Goldhirsch (2003) stressed the emergence of high-density clusters in granular gasses, as a product of external forces. In the present case the large zones of coherent blocks of sliding particles are doubtless due to the action of gravity.

Referring to each particle, it is possible to define an intermittency factor Ω, representing the ratio between the sum of time intervals t_i^{coll} characterized by an instantaneous vertical velocity exceeding the peak value typical of the frictional regime and total time of observation t^{tot}.

$$\Omega = \frac{\sum_i t_i^{coll}}{t^{tot}} \tag{7}$$

All details necessary to define the threshold value of vertical velocity necessary for the definition of the intermittency function are given in section 4.1.

3 EXPERIMENTAL METHODS

3.1 *Experimental setup*

Experiments were carried out in the special laboratory flume developed at the University of Trento for the study of steady uniform liquid-granular flows (Figure 1). The apparatus is composed of two main components: the first is a glass-walled open channel; the second is an external conveyer belt, connected to the channel by chute guides, which recirculates upslope both water and sediment. The channel can be tilted by a telescopic piston served by a hydraulic power station at angles going from 0 to 22 degrees. It has a length of 6 m and a width of 40 cm, narrowed down to 10 cm for the present study by placement of a glass partition. The opaque channel floor is artificially roughened by glued particles. Imaging measurements are made at a distance of about 2 m upstream of the channel outlet, by filming the flow through the sidewalls. To view the basal flow condition at the centre of the cross-section and check if the flow is in equilibrium with the underlying sediment bed, a small port-hole was also pierced through the channel floor. The external conveyer system has a length of 8.40 m, and is equipped with a 50 cm wide U-shaped flexible belt that can be operated at speeds of up to 5 m/s. The belt is aligned to the flume and tilted slightly more, in order to allow the material to be collected from and returned to the flume. A hopper is placed at the end of the flume, to collect water and solid material. This system permits steady flows up to a volume discharge equal to about 20 l/s, without posing limitations to the sediment concentration of the mixture.

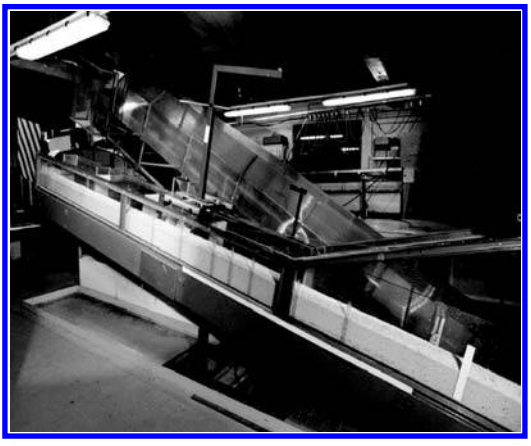

Figure 1. Experimental setup used for the experiments.

During an experimental run, the set-up forms a closed loop, in which a fixed volume of water and granular material circulates. Provided it is sufficiently high, the speed of the conveyer belt does not noticeably influence the flow inside the channel. For the present experiments, fast belt speeds of 5 m/s were adopted. The throughput is then controlled solely by the flow slope, and by the volumes of water and sediment inside the system. When these parameters are kept constant (and aside from certain regimes which exhibit a pulsating behavior that are not object of the present analysis), the recirculating flow settles to a steady state within a matter of minutes. Camera and lighting adjustments can then be made, and video footage acquired. Uniform flow conditions are established in the central reach of the flume, where all measurements can be taken. At the end of a run, the channel outflow is diverted to a trap during a short timed interval

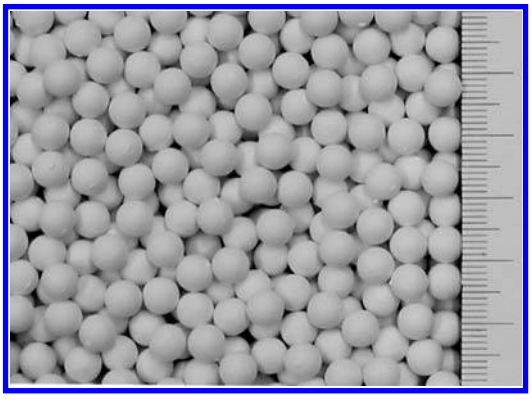

Figure 2. Granular material utilized in the experiments.

(about 10 s), in order to independently measure the water and granular discharges.

3.2 *Characterization of the granular material*

Perfectly identical spherical plastic particles were selected as granular material for the present tests, as shown in Figure 2. They consist in a master composed by barium sulphate and titanium dioxide dispersed on polystyrene.

The particles have a diameter $D = 6.0$ mm and a specific gravity $s = \rho_p/\rho_w = 2.21$. The material is slightly lighter than natural sediment materials ($s \approx 2.65$), hence more readily entrained by water, facilitating observation. Each particle has a volume of 113.04 mm^3 and a weight of 0.25 g. The perfectly white color of the grains contrasts well with darker surrounding fluid, and is ideal for the automated imaging measurements presented in the next section.

3.3 *Imaging methods*

Liquid-granular flows are imaged through the transparent flume sidewall using a gray-scale high-speed digital camera. At the chosen video rate of 500 frames per second, the digital images have a resolution of 1280×1024 pixels. To prevent motion-induced blur, the camera shutter is set at 1/2000 s or 1/4000 s, depending on lighting conditions.

To capture the motions and arrangements of visible particles, imaging methods based on the Voronoï polygons developed specifically for granular flows by Capart et al. (2002) were applied.

To highlight particles on images, the digital frames are first convoluted with a Laplacian-of-Gaussian filter with a width set equal to the pixel diameter of the grains. Particles positions are then obtained by pinpointing local brightness maxima to sub-pixel accuracy. Tracking of the particles on successive frames is performed using a pattern-based matching principle: Voronoï diagrams are constructed on the sets of particle positions identified on separate frames; particles on one frame and the next are then paired based on the goodness-of-match between the shapes of their Voronoï cells and particle trajectories are reconstructed; velocities and are finally derived from the corresponding displacements using the straightforward approximation.

The 2D images are also used to estimate the 3D volumetric granular concentration c (also called solid fraction) near the wall. The point density of visible particles per unit image surface is a poor indicator of 3D concentration, due to the prevalence of occlusion effects. Instead, characteristics of the local particle arrangement can be exploited using the Voronoï diagram built on the particle centers. As the solid fraction rises, excluded volume effects tend to organize a dispersion of identical particles into an increasingly ordered assembly. A measure of this ordering is furnished by the *roundness* of the Voronoï polygons. However the estimation of granular concentration on the base of the analysis of a single 2D image for each instant of time, as it was carried out in the runs presented in the present paper, is still affected by some errors. In fact close to the free surface, where concentration is low and particles in the background may be wrongly recognized by the imaging technique as being near the sidewall, granular concentration can be overestimated. To avoid this kind of error and improve the quality of concentration estimation, future experiments will be carried out filming the flow domain from two different view-points, and applying the concentration estimation based on the stereoscopic Voronoï technique developed by Spinewine et al. (2003).

The typical data set for a single experimental run includes on the order of 100000 velocity vectors and Voronoï cell roundness measurements. This is one order of magnitude higher than the 10000 measurements identified by Louge & Jenkins (1997) as the minimum size needed to obtain statistically meaningful vertical profiles of granular temperature. Such large sample sizes are similar to those generated by computer simulations, and the same statistical techniques are needed to extract useful information. These include methods to characterize velocity correlations in time and space, as well as basic tools to derive average vertical profiles which we sketch in the next paragraphs.

4 EXPERIMENTAL RESULTS

4.1 *Determination of the intermittency*

In order to define the intermittency, it is necessary to determine a threshold value for the velocity fluctuation below which the regime is to be considered purely frictional and above which the regime is collisional.

Copyright © 2006 Taylor & Francis Group plc, London, UK

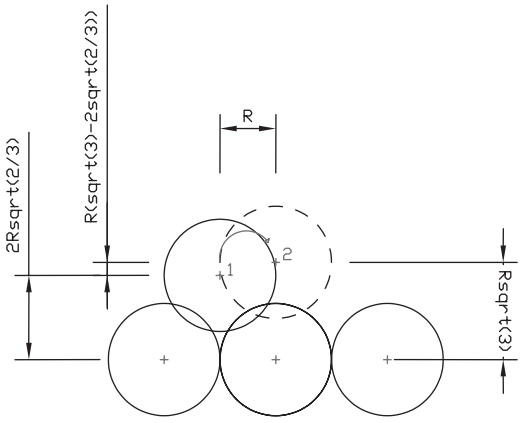

Figure 3. Sketch of the displacement of the center of a spherical particle rolling over an array of spheres of the same diameter.

A precise definition of such a value is very difficult, but a rough estimation of such threshold can be obtained considering a spherical particle rolling over a surface composed by spheres of the same diameter, along a line connecting the more depressed points.

In this case the vertical component of the fluctuating velocity is:

$$u'_y = \left(\sqrt{2} - \frac{4}{3}\right) D \frac{\partial u_x}{\partial y} \cong 0.081 D \frac{\partial u_x}{\partial y} \qquad (8)$$

The threshold value given by eq. (8) could be used to calculate the intermittency: the part of the signal where the fluctuation of velocity is lower than the value given by eq. (8) is considered to belong to the frictional regime, while on the contrary the part of the signal where the fluctuation of velocity is higher that the value given by eq. (8) is considered collisional. In this way it is possible to determine the intermittency function elaborating the signals according to eq. (7). The different functions (T, c, σ_p, τ_p) corresponding to the collisional regime have been calculated as mean values averaged only during the collisional times.

The value given by eq. (8) appeared to be too small to predict correctly the results. This is due to the fact that the particles are not perfectly ordered as it is shown in Figure 3. For example if the center of the particle is constrained to roll remaining in a vertical plane, as it reasonably occurs near the lateral wall of the flume, the coefficient in eq. (8) becomes $(\sqrt{3} - 3/2) \approx 0.232$.

A reasonable agreement between external stresses (equations 5 and 6) and the internal one (equations 1 and 2) calculated on the base of kinetic theories is obtained assuming the following threshold value for the fluctuating component of the velocity:

$$u'_y = 0.8 D \frac{\partial u_x}{\partial y} \qquad (9)$$

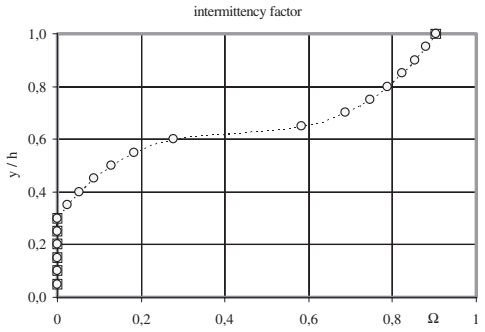

Figure 4. Profile of the intermittency function.

Equation (9) cannot be used when the collisional regime is fully developed, that is when $St = (1/18)\,\rho_p T^{1/2} D/\mu > 5 \div 10$, where St is the Stokes number (Larcher 2004; Armanini et al 2005).

In the next figure the profile of the intermittency function obtained in such a way is reported:

Figure 4 shows that the flow is dominated by the frictional regime in the lower part of the flow, while toward the free surface the collisional regime tends to prevail.

4.2 *Normal and tangential stresses*

As stated in paragraph 2.3, in uniform channel flow conditions external and internal stresses perfectly balance all along the depth. However due to the presence of the collisional regime just part of the flow is susceptible to be described by the kinetic theory: this portion is balanced by the external stresses reduced by the intermittency function:

$$c\rho_p \left(1 + r\frac{\rho_w}{\rho_p}\right)(1 + 4cg_o)T = \Omega \int_0^h \rho_w g \Delta c \cos\alpha \, dy + \sigma_o \qquad (10)$$

In eq. (10) a normal stress σ_o has been added on the free surface, because, otherwise, one should expect that the granular temperature vanishes on the free surface. However it is easy to argue that the free surface acts as a reflective surface for the temperature when the particle concentration in the layer near to the free surface is sufficiently high (*mature debris flow* regime according to Armanini et al. 2005). In this situation the particles reaching the free surface tend, due to inertia, to emerge. When the emersion starts, in fact, a new force appears (due to the reduction in the buoyancy force), which progressively pushes the particle in the downward direction. This effect, hydrodynamic resistance apart, gives to the free surface a reflective behavior.

Copyright © 2006 Taylor & Francis Group plc, London, UK

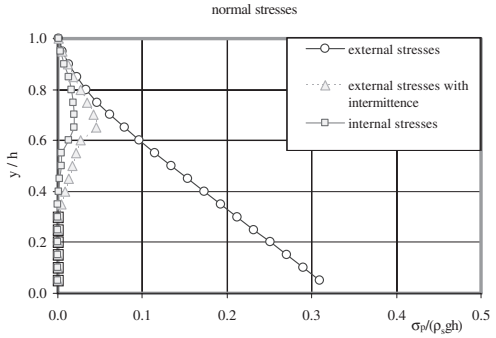

Figure 5. Distribution of normal stresses: internal, external and external reduced according to the collisional intermittency. The stresses are rendered dimensionless respect to $\rho_p gh$.

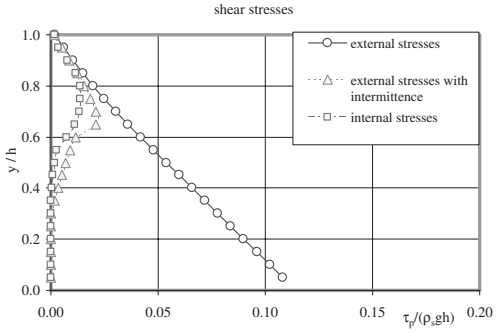

Figure 6. Distribution of tangential stresses: internal, external and external reduced according to the collisional intermittency. The stresses are rendered dimensionless respect to $\rho_p gh$.

In the next figure the distribution of external and internal normal stresses is reported, together with the external stresses reduced according to the intermittency.

From the figure it is first possible to appreciate the unbalance between the external stresses and the internal one, calculated according to the kinetic theory.

The distribution of the external stresses, reduced according to the collisional intermittency, is definitely in better agreement with the kinetic interparticles stress.

The same procedure has been repeated for the shear stresses.

Finally the distribution of particles concentration, granular temperature and particles longitudinal velocity has been calculated. The distributions are reported respectively in the next figures.

It is to be noted that the concentration tends to become smaller and smaller in the vicinity of the free

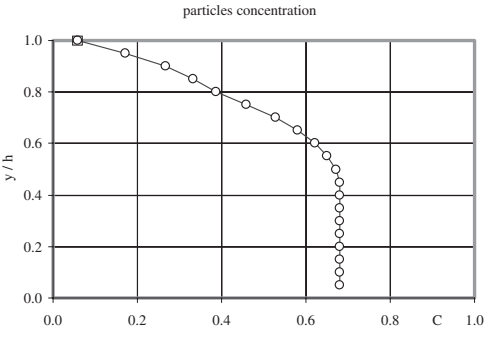

Figure 7. Distribution of the particles concentration.

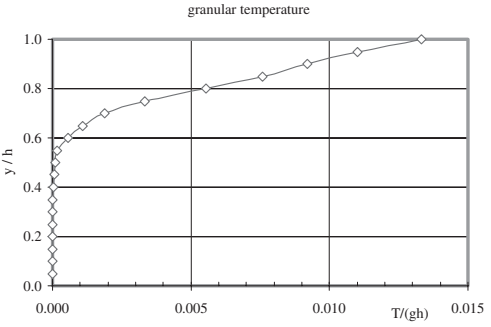

Figure 8. Distribution of the granular temperature dimensionless respect to gh.

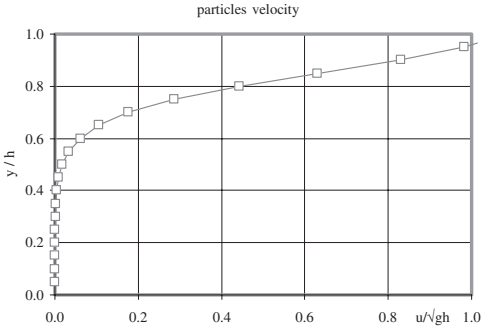

Figure 9. Distribution of the particles longitudinal velocity dimensionless respect to $\sqrt{gh}$.

surface, but apparently it remains finite on the surface (*mature debris flow* regime according to Armanini et al. 2005). However the precision of the measure of this parameter is relatively not high and the method here adopted is not precise especially in this position due to the reflective properties of the free surface.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Future experiments will overcome the limits in concentration estimation thanks to the application of a stereoscopic imaging technique. In the tests with a smaller depth averaged concentration the concentration profile tends to zero at the free surface (*immature debris flow* regime according to Armanini et al. 2005).

On the contrary the granular temperature increases when approaching the free surface.

5 CONCLUSION

The experimental analysis of uniform liquid-granular channel flows in equilibrium gave evidence of the alternate presence of the frictional and of the collisional regime.

The problem was approached introducing an intermittency function based on geometric assumptions, able to take into account the alternation of the two rheological regimes.

The experimental analysis showed that the intermittency parameter, if appropriately calibrated, explains dynamics of granular particles as defined by kinetic theories.

Future developments of the investigation will benefit by a more accurate estimation of granular concentration thanks to the application of a stereoscopic imaging technique.

ACKNOWLEDGMENT

This research has been done thanks to the initial financial support of the center of excellence CUDAM (COFINLAB 2001) and within the activities promoted by the European Projects IMPACT (contract EVG1-CT-2001-00037) and IRASMOS (Specific Targeted Research Project No. 018412). The experimental analysis is part of the master thesis of Mrs. Anna Dalfollo and Mrs. Martina Piccoli, with them the authors are indebt for their help.

Morphological modelling of hyperconcentrated floods in the Yellow River

D.S. van Maren[a], J.C. Winterwerp[a], B.S. Wu[b] & J.J. Zhou[b]
[a]*Delft University of Technology, Faculty of Civil Engineering and Geosciences, The Netherlands and WL | delft hydraulics, MH Delft, The Netherlands*
[b]*Tsinghua University, Faculty of Hydraulic Engineering, Beijng, China*

ABSTRACT: A large amount of the total sediment load in the Chinese Yellow River is transported during hyperconcentrated floods. These floods are characterized by very high suspended sediment concentrations and rapid morphological changes with alternating sedimentation and erosion in the main channel, and persistent sedimentation on the floodplain. However, the physical mechanisms driving these hyperconcentrated foods are still poorly understood. Numerical modelling experiments of these floods reveal that sedimentation is largely caused by a collapse of the turbulence structure by sediment-induced density gradients, whereas erosion prevails when this sediment is largely held in suspension due to hindered settling. Observed patterns of erosion and sedimentation during these floods can be well reproduced using a numerical model in which sediment-induced density effects and hindered settling are included. Based on these results a refined definition of hyperconcentrated flow is proposed.

1 INTRODUCTION

The rivers that originate from the Chinese Loess Plateau carry huge amounts of suspended sediment, especially during hyperconcentrated floods when sediment concentrations exceed 100's kg m^{-3}. A large part of the sediment load carried by these rivers is deposited in their downstream reaches. As a result, the bed level of the downstream reaches of these rivers rises rapidly, and because they are confined by training works the height of river bed exceeds the surrounding land. The best known example is the Yellow River, where the river bed is up to 10 m higher than the adjacent areas. Most of this sediment is deposited during hyperconcentrated floods. However, some stages of these floods are characterized by severe erosion instead of deposition. When these floods are well understood and controlled (through water and sediment releasing reservoirs), siltation may be significantly reduced. The Sanmenxia reservoir, operational since 1961, has shown that water and sediment discharge can indeed be regulated to such an extent that it significantly affects downstream channel morphology. Recently, a new reservoir was completed 100 km downstream of the Sanmenxia reservoir to manage siltation and flooding in the lower Yellow River. However, prediction of the effect of different water- and sediment release strategies from this reservoir is limited because no sediment transport model exists today which can accurately simulate hyperconcentrated floods. Therefore a research project was initiated within the Programme of Scientific Alliances between China and the Netherlands, which aims to predictively model sediment transport and morphology in the Lower Yellow River. The purpose of the research presented in this paper is to analyze the morphologic behaviour of hyperconcentrated floods in the Yellow River using numerical model experiments.

2 HYPERCONCENTRATED FLOW

The high concentrations typical for the Yellow River influence both fluid and sediment dynamics significantly. Therefore a brief summary of sediment-fluid interactions is given first (see Winterwerp and van Kesteren (2004) for more details), followed by an overview of hyperconcentrated floods in the Yellow River.

2.1 *Sediment-fluid interactions in highly concentrated flow*

Even moderate concentrations of several g/l increase the density of the water-sediment mixture to such an extent that turbulence can be significantly damped by

Copyright © 2006 Taylor & Francis Group plc, London, UK

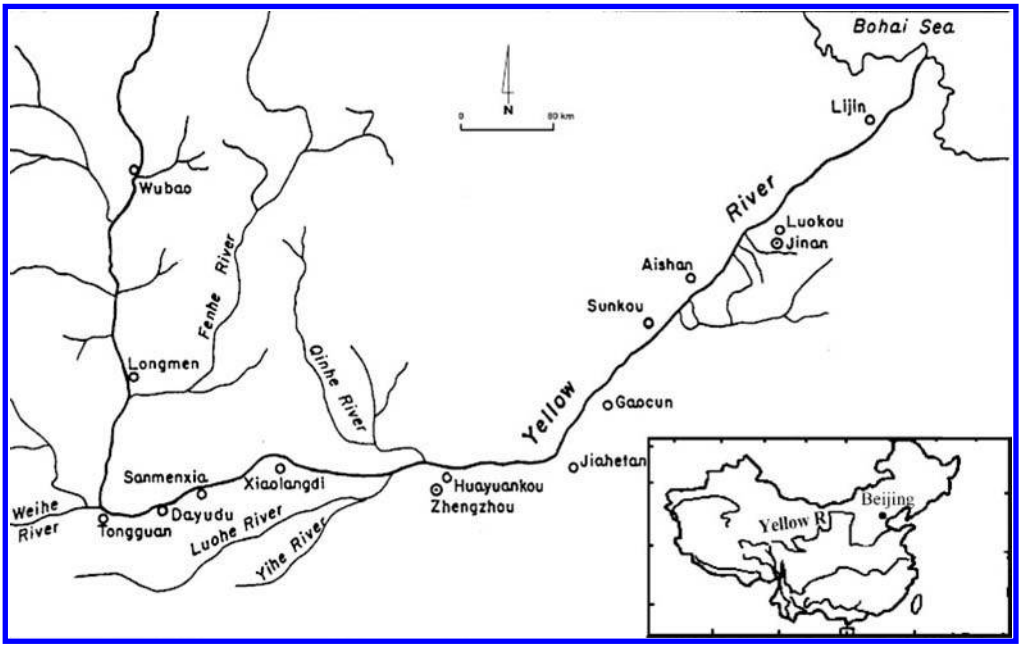

Figure 1. Middle and lower reaches of the Yellow River, China.

the vertical density gradients (Winterwerp 2001). This has two major consequences. The first is a reduced capacity of the flow to keep particles in suspension which, in turn, further increases the vertical density gradients. When the flow is close to saturation, this positive feedback mechanism results in a total collapse of the turbulence and concentration vertical. Secondly, suppression of turbulence leads to a decreasing vertical velocity gradient near-bottom. The velocity profile consequently changes from an almost logarithmic into a more linear profile.

In addition to these turbulence related effects, high sediment concentrations also (1) increase the fluid viscosity and introduce yield strength, (2) decrease the sediment settling velocity and erosion rate (hindered settling and hindered erosion, resp.), and (3) introduce soil mechanical effects such as liquefaction and undrained erosion.

2.2 *Hyperconcentrated floods in the Yellow River*

The Yellow River (Fig. 1) has a length of 5400 km and a basin area of 795,000 km^2. From 1940 to 1969, the average discharge Q in the lower Yellow River was 1630 m^3 s^{-1} transporting 1560 million ton annually. Although most of the water drained by the Yellow River originates in its upper reaches, 90% of the total sediment load is supplied by the highly erodible loess plateau. After flowing through the Sanmenxia gorge the river enters the flat North China Plain where massive amounts of sediment are deposited.

Hyperconcentrated floods are generated on the Loess Plateau by intense rainstorms of short duration (with peaks of 1400 mm in 9 hours; August 1977) which generally occur from half July to half August. For simplicity, floods are called hyperconcentrated here when the sediment concentration C exceeds a critical value around 200–300 kg m^{-3}. The grain size of loess varies between 15 μm in the south to 50 μm in the north, and contains 10–20% clay particles (Wan and Wang 1994). These sediments are easily eroded from the steep slopes resulting in extremely high concentrations, in the order of hundreds of kgm^{-3}. About 40 hyperconcentrated floods occurred between 1960 and 1992 at Longmen station (see Fig. 1), with an average duration of 8–12 days (Zhao et al. 1995). Approximately 1/3 to 1/4 of the annual sediment load of the Yellow River is transported during these hyperconcentrated floods (Wan and Wang 1994). Large floods may transport up to 900 million ton of sediment, which is close to the average annual sediment load.

During normal discharge conditions sedimentation occurs mainly in the river channel, but sedimentation during hyperconcentrated floods is more complicated. According to Li and Zhang (1994), sedimentation during a hyperconcentrated flood can be divided into three stages (see also Fig. 2):

1. The first stage of hyperconcentrated floods between Sanmenxia and Huayuankou is characterized by massive deposition up to several m in the main channel, especially in areas where the river channel

Copyright © 2006 Taylor & Francis Group plc, London, UK

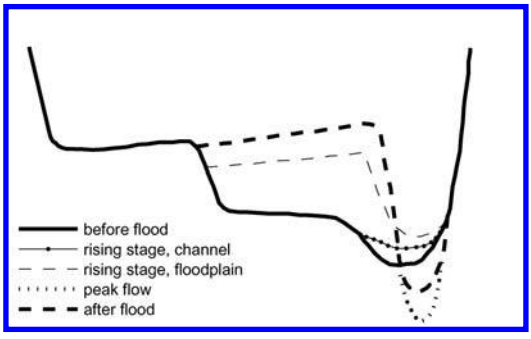

Figure 2. Schematized cross-sectional development during a hyperconcentrated flood.

is shallow and wide. Therefore the discharge capacity decreases, which results in (1) overflowing flood plains, and (2) a very rapid rise of water levels.

2. After the floodplain is flooded, most sediment is deposited on the floodplain, while channel deposition changes into erosion. The main channel erodes, narrows, and becomes more sinusoidal. Consequently, the flow velocity and discharge capacity increase, which in turn results in further channel erosion: the discharge capacity of a channel may double during the passage of a hyperconcentrated flood. Due to this increase in discharge capacity, the water level drops rapidly.
3. The longitudinal water level gradient decreases at the waning stage of the flood, flow velocities decrease, and sediment can no longer be held in suspension. This results in cataclysmic settling from suspension, and rapid deposition. The previously scoured channel is partly filled again, but scouring during stage 2 is larger than sedimentation during stage 3 resulting in net channel erosion during a hyperconcentrated flood.

2.3 *Observations*

Observations of hyperconcentrated floods are logistically complicated because of the high velocities and sediment concentrations. It is very difficult to take samples at these velocities, and most electronic devices are disturbed by the high concentrations. As a result, there is very few data available with a high spatial (both vertically and cross-sectionally) and temporal resolution. The most extensive data collection campaigns in the Yellow River have been carried out in the late 1950's and early 1960's, in order to asses the impact of an upstream dam which was completed in 1961. An example of measured flow velocity, sediment concentration, and grain size D_{50} during a highly concentrated flood in 1959 is shown in Fig. 3. This data shows that at flow velocities over 3 m/s, at a water

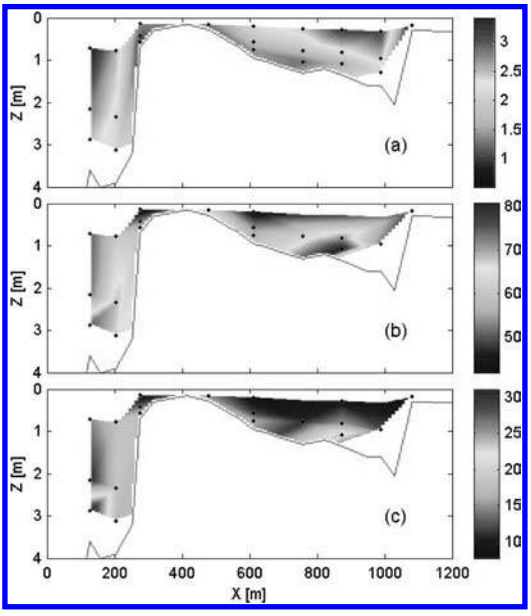

Figure 3. Flow velocity (a) sediment concentration (b, in kg/m^3) and D_{50} (c, in μm) measured at Laitongzai hydrological station (close to Huayuankou) on 15 August 1959.

depth of 1.5 to 3 m, the vertical concentration gradient is still very large. Considering the small grain size (10–25 μm), one would expect a better mixed sediment concentration profile. This is a strong indication that sediment-induced density effects play an important role, which will be analyzed in more detail using a numerical model.

3 MODELLING

3.1 *Model description*

In this study we use the state-of-the-art 'sediment online' version of the Delft3D model to simulate planform morphology development. Delft3D solves the unsteady shallow water equations in 2 or 3 dimensions under the hydrostatic pressure assumption and computes sediment transport and morphological update simultaneously with the flow; see Lesser et al. (2004) for a description and validation. This model simulates the most relevant sediment-fluid interactions described in section 2.1 such as hindered settling and sediment-induced density effects (Winterwerp and van Kessel 2003). This model has been applied previously to reproduce the effect of high sediment concentrations on channel patterns of sediment-laden rivers (van Maren et al. 2005).

Hindered settling is modelled as $w_s = w_0(1-\phi)^5$ (where w_0 is the particle fall velocity in clear water and

Copyright © 2006 Taylor & Francis Group plc, London, UK

w_s the fall velocity reduced by the volumetric sediment concentration ϕ which is given by $\phi = C/C_g$). The gelling concentration C_g is estimated to be 900 kg m^{-3} (see van Maren et al. (2005) for more details). The vertical sediment fluxes are determined by the uplift of sediment by turbulence, and by the downward motion of sediment through the sediment fall velocity w_s. Turbulence is approximately proportional to the cubed depth-averaged velocity. However, sediment-induced density gradients dampen this bed-generated turbulence, leading to a decreasing capacity of the flow to keep sediment in suspension. The turbulent energy k and the turbulent energy dissipation ϵ determine the vertical eddy viscosity ν through $\nu = c_\mu k^2/\epsilon$ (c_μ is a constant equal to 0.09). This eddy viscosity influences the vertical concentration gradients through the eddy diffusivity Γ by $\Gamma = \nu/\sigma_t$, where σ_t is the turbulent Prandtl-Schmidt number. A common assumption is that σ_t equals 0.7. However, Cellino and Graf (1999) observed in laboratory experiments that this value may be valid for clear water flows, but not to flows near sediment saturation when σ_t should be closer to 2 (note that these authors use the β factor common in sand transport studies). Recent numerical experiments by Winterwerp (ress) revealed that sediment-laden flow seems to be described more accurately using $\sigma_t = 2$. A higher Prandtl-Schmidt number reduces the sediment diffusivity Γ ($\Gamma = \nu/\sigma_t$), thereby increasing the vertical concentration gradient and therefore also the sediment-induced density gradients. In order to estimate the effect of σ_t, model runs are done with both 0.7 and 2.0.

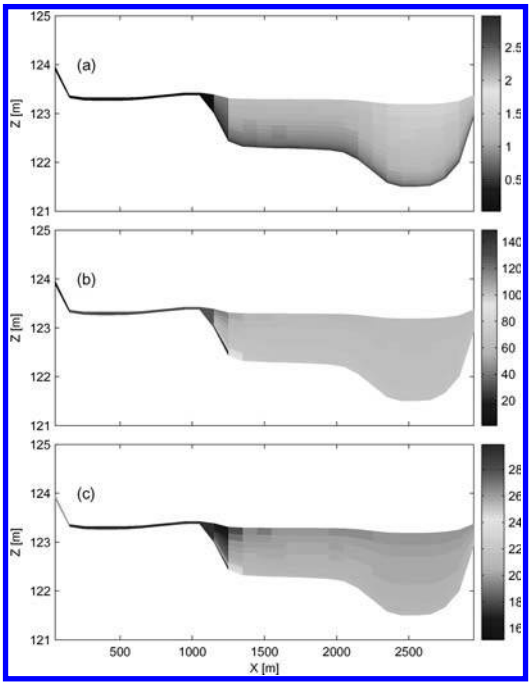

Figure 4. Computed flow velocity (a), sediment concentration (b, in kg/m^3) and D_{50} (c, in μm) during flow conditions similar to those in Fig. 3, using $\sigma_t = 0.7$, 10 km downstream the upper boundary.

3.2 *Model application*

A fundamental problem for modelling hyperconcentrated floods in the Yellow River is the absence of high resolution bathymetric and hydrodynamic data. Even during the extensive measurement campaigns in the late 1950's and early 1960's, there is very little hydrodynamic data required for calibration (such as flow velocity and concentration profiles) available shortly after bathymetric observations. And hydrodynamic data measured several months (or even weeks) after bed level measurements is not suitable for calibration because of the rapid morphologic changes in the Yellow River. As an alternative, we simulate the behaviour of a hyperconcentrated flood using an idealized river stretch. This idealized geometry is used for numerical experiments which should reproduce sediment erosion and deposition patterns similar to those observed in the Yellow River (Fig. 2).

Based on the initial profile in Fig. 2, an artificial river 3 km wide and 40 km long with a constant river cross-section is constructed. The bed level gradient decreases in the downstream direction, and is identical to that near Huayuankou. A time-varying river discharge and sediment concentration per fraction is prescribed at the upstream boundary, with 5 sediment fractions in total (5, 17.5, 37.5, 75, and 150 μm). The discharge and sediment concentration is derived from timeseries measured near Huayuankou in August 1959. The grain size distribution, however, is measured irregularly and therefore a single grain size distribution measured during the flood is used. The river bed is erodible, with an unlimited amount of sediment composed of the same 5 sediment fractions prescribed at the upstream boundary.

Three-dimensional transport of suspended sediment is calculated by solving the three-dimensional advection-diffusion equation for suspended sediment. Exchange of sediment between the bed and the water column is different for the 5 sediment fraction: for the coarse fraction (75 and 150 μm) this is computed with the standard van Rijn formulations (van Rijn 2000) whereas the Partheniades-Krone formulations (Partheniades 1965) are used for the fine sediment fractions (5, 17.5 and 37.5 μm). Critical shear stresses for both erosion and deposition are set to 1 Nm^{-2}, and the erosion rate is set to $5 \cdot 10^{-4}$ kg m^{-2} s^{-1}. The dry bulk density of fresh deposits is estimated at 700 kg m^{-3}.

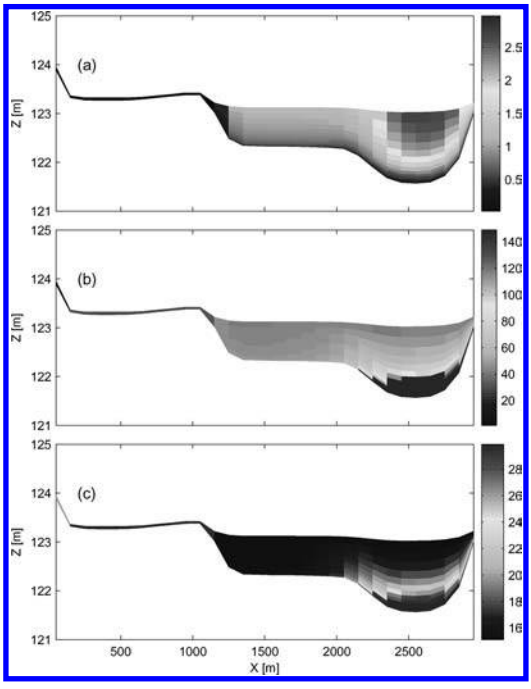

Figure 5. Computed flow velocity (a), sediment concentration (b, in kg/m^3) and D_{50} (c, in μm) during flow conditions similar to those in Fig. 3, using $\sigma_t = 2.0$, 10 km downstream the upper boundary.

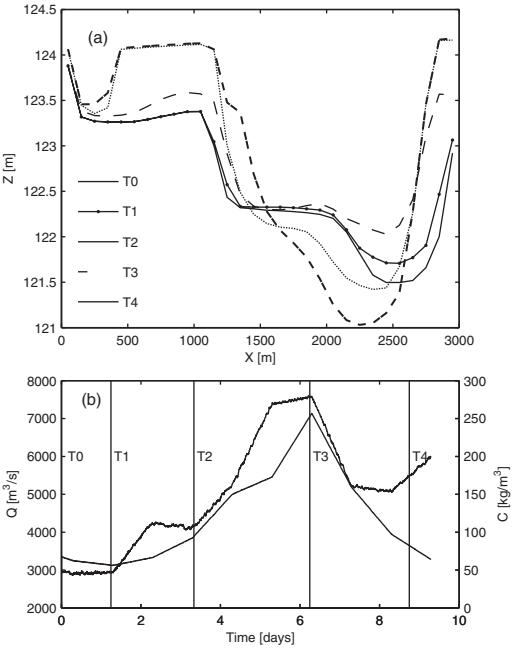

Figure 6. Computed cross-sectional bed level changes using $\sigma_t = 2.0$ and a grain size distribution typical for hyperconcentrated floods, 10 km downstream the upper boundary (a), with prescribed discharge Q (dashed line) and sediment concentration C (solid line) in (b).

3.3 *Model results*

An essential model setting required to simulate the morphodynamic behaviour of the Yellow River seems to be the turbulent Prandtl-Schmidt number σ_t. Using the default setting of 0.7, the sediment concentration profile remains almost vertically uniform (Fig. 4b). In contrast, using $\sigma_t = 2.0$ introduces large vertical gradient in the sediment concentration (Fig. 5b). These model results can be compared qualitatively with the observations in Fig. 3, as the discharge is almost the same. The measured vertical sediment distribution (both concentration C and the grain size D_{50}) is very similar to the computed sediment distribution using a high Prandtl-Schmidt number. Additionally, both measured (Fig. 3) and computed flow velocities using $\sigma_t = 2.0$ (Fig. 5a) have surface flow velocities close to 3 m/s whereas those in the model simulations using $\sigma_t = 0.7$ (Fig. 4a) are only 1.5 m/s. Additionally, sediment deposition rates are unrealistically low using $\sigma_t = 0.7$, while sedimentation rates in the Yellow River are high. We do not have sufficient information to determine the exact value of σ_t, but physical experiments by Cellino and Graf (1999) strongly indicate that σ_t should be closer to 2.0 for flows near saturation. Both Nielsen and Teakle (2004), using mixing length theory, and Nezu and Azuma (2004), using experimental results, conclude that σ_t increases in fine sediment flows with respect to clear water flow but decrease in coarse-grained flow. But although more research is required to determine the exact value (or relationship), $\sigma_t = 2.0$ seems more appropriate than $\sigma_t = 0.7$ for modelling high concentration flows in the Yellow River, and will therefore be used for further analysis.

Large vertical gradients in sediment concentration, such as those in Fig. 5b, damp turbulence and therewith the capacity of the flow to keep sediment in suspension, resulting in further settling (section 2.1). The result is a collapsing turbulence profile, and the effect on the sediment concentration depends on the settling velocity of the sediment in suspension. The sediment concentration profiles of coarse sediment fractions ($D_{50} >= 37.5$ μm) respond rapidly and settle from suspension, whereas the finer grain sizes respond more slowly. The water masses where the turbulence profile has collapsed are advected in the downstream direction, where the turbulence profile re-establishes due to a lower (especially coarse-grained) sediment load. The result is an oscillating sediment concentration, velocity and water level. Such an oscillating water level is occasionally observed in the Yellow River where it is known as clogging (Wan and Wang 1994).

Copyright © 2006 Taylor & Francis Group plc, London, UK

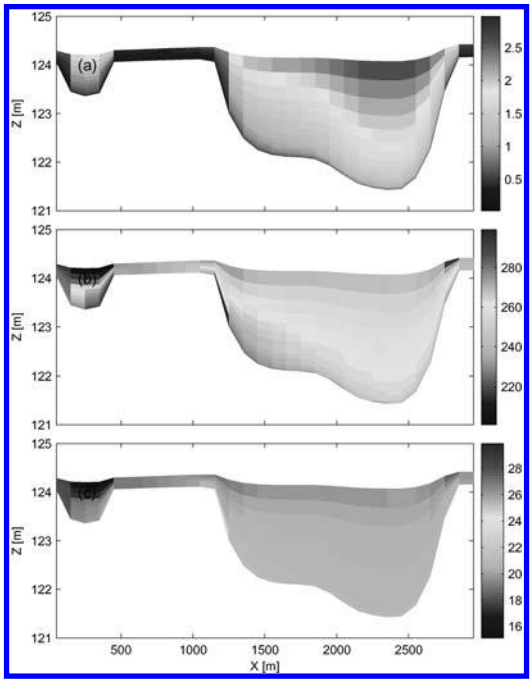

Figure 7. Computed flow velocity (a), sediment concentration (b, in kg/m^3) and D_{50} (c, in μm) during flow conditions T3 in Fig. 6, using $\sigma_t = 2.0$, 10 km downstream the upper boundary.

High near-bed sediment concentrations such as in 5b will probably result in rapid deposition. These conditions coincide with the first phase (T1) in Fig. 6, which do indeed show deposition in the channel. Deposition increases with increasing sediment concentration, which extend onto the floodplain when these are flooded (T2). During the following stage, sedimentation rates are high on the floodplain (nearly one meter in two days), while simultaneously the main channel is eroded. This erosion of the main channel is probably caused by increasing hindered settling with increasing sediment concentration: the sediment concentration profile is more uniform (Fig. 7) and therefore the turbulence does not collapse, thereby preventing the high near-bed sediment concentrations that lead to sediment deposition.

4 DISCUSSION

4.1 *Hyperconcentrated flood simulations*

The most characteristic morphodynamic properties of hyperconcentrated floods in the Yellow River, being channel sedimentation followed by floodplain sedimentation coinciding with channel erosion, are well reproduced. Computed velocity and concentration distributions and morphodynamic behaviour during hyperconcentrated floods show qualitative agreement with observations. During the first stage, collapse of the turbulence profile leads to rapid sedimentation in the main channel. As a result of the increasing river discharge, but also due to the reduced discharge capacity in the main channel, the flood plains are overflown. Sediment deposition rates on these flood plains are high due to the low flow velocities. With increasing upstream discharge and sediment concentration, the fall velocity decreases due to hindered settling effects. Less turbulent energy is therefore required to keep sediment in suspension, and therefore the sediment concentration profile in the main channel is re-established. The result is a deepening of the main channel, in agreement with observations. During the final stage of the flood, it is often observed that the main channel is partly refilled again. This is not reproduced by our model in which the river bed remained stable, even though the discharge conditions during the rising stage (when deposition occurred) and the falling stage of the flood are comparable (e.g. day 4 and day 8 in Fig. 6). To further quantify the exact mechanisms responsible for the transitions described above, and to understand the different morphological response during the rising stage and the falling stage of the flood, we use the stratified flow analogy introduced by Winterwerp (2001) and extended into the hyperconcentrated regime in Winterwerp et al. (2003).

The Ri_f number describes the ratio of potential energy required to keep sediment in suspension to the kinetic energy available to mix sediment, and can be written as:

$$Ri_f = \frac{g\overline{w'\rho'_m}}{\rho_m \overline{u'w'}\partial u/\partial z} \quad (1)$$

where $\overline{w'\rho'_m}$ is the fluctuating part of the vertical velocity w and the density of the water-sediment mixture ρ_m, averaged over the turbulent time scale, $\overline{u'w'}$ is the fluctuating part of w and the horizontal velocity u, averaged over the turbulent time scale, and $\partial u/\partial z$ is the horizontal velocity shear. $\overline{w'\rho'_m}$ can be replaced by $\frac{\rho_s - \rho_w}{\rho_s}\overline{w'c'}$ (with c being the sediment concentration, ρ_s the sediment density, and ρ_w the density of water). Assuming that

(1) the turbulent fluxes are related to the mean velocity gradient (the Boussinesq assumption; $\overline{u'w'} = \nu\frac{\partial u}{\partial z}$),
(2) the velocity profile is logarithmic ($\frac{\partial u}{\partial z} = \frac{u_*}{\kappa z}$ and the viscosity ν is $\nu = \kappa u_* z(1 - \frac{z}{h})$, where κ is the Von Karman constant),
(3) local equilibrium between settling and mixing ($\overline{w'c'} = -w_s C$), and
(4) hindered settling can be simplified as $w_s = w_0(1-\phi)^5$, eq. 1 can be simplified into

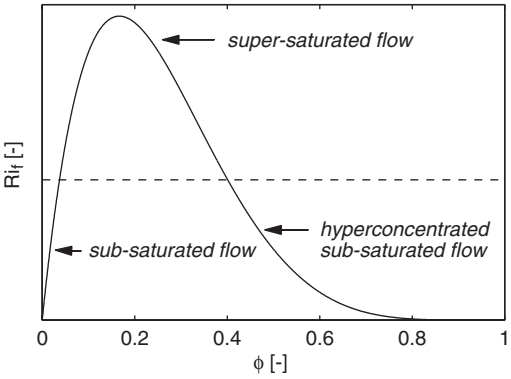

Figure 8. Relation between Ri_f and the volumetric sediment concentration ϕ (solid line); the critical Ri_f is denoted with a dashed line.

$$Ri_f = \alpha \frac{\rho_s - \rho_w}{\rho_m \rho_s} \frac{ghw_0 C\kappa}{u_*^3}(1-\phi)^5 \qquad (2)$$

where α is a coefficient. This expression is valid for sub-saturated conditions, which provides a good starting point to address the problem. For a constant velocity and water depth, Ri_f initially increases with sediment concentration (Fig. 8) At a certain concentration, the turbulent production is damped out by the sediment-induced density gradient. For cohesive sediments, this results in a catastrophic collapse of the turbulence and concentration vertical (Winterwerp 2001), and the sub-saturated flow becomes super-saturated. When the concentration increases further to the point that sediment is held in suspension by hindered settling, a vertical concentration profile is re-established; the supersaturated flow becomes hyperconcentrated sub-saturated (Winterwerp et al. 2003).

Examining Eq. 2, the transition from supersaturated to (hyperconcentrated) sub-saturated flow depends not only on the sediment concentration C, but also on a number of other parameters such as the grain size D_{50} (determining the value of w_0), flow velocity, water depth and gelling concentration C_g. With a decrease in water depth and an increase in flow velocity, the flow becomes hyperconcentrated at lower volumetric sediment concentration ϕ. Similarly, the higher D_{50}, the higher w_0 and therefore Ri_f, and as a result the flow becomes hyperconcentrated at lower ϕ when D_{50} decreases. In addition, the value of ϕ depends not only on the sediment concentration C but also on the gelling concentration C_g (the concentration at which a space-filling network forms). The value for C_g varies between several 10's of kgm^{-3} in cohesive sediment to approximately 1500 kgm^{-3} in sand ($C_g = (1-n)\rho_s$, with the porosity n being approximately 0.45). Therefore ϕ depends on both the sediment concentration, and the amount of cohesive sediment. Based on these considerations, hyperconcentrated flow is therefore a highly concentrated flow where hindered settling effects become so important that sediment can be held in suspension at very low turbulence rates, and occur at a sediment concentration value that exceeds a critical sediment concentration scaling with $1/u^3$, h, D_{50}, and C_g.

The mechanisms described above allow a more physical interpretation of the model results. Sedimentation turned into erosion during the rising stage of the flood because of increasing sediment concentration and flow velocity. The extensive morphologic changes significantly narrowed the main channel, thereby increasing the flow velocities. As a result sedimentation as occurring during the rising stage of the flood, does not occur during the falling stage.

4.2 *Classification of hyperconcentrated flow*

Flows with high sediment concentrations are usually classified according to (1) the triggering mechanism, (2) the sediment concentration, and (3) the rheological and kinematical behaviour (Bradley and McCutcheon 1987). Classifications using the triggering mechanism is mainly limited to lahars, mud flows, debris flows, landslides, debris slides and other type of mass movements. These type of flows occur on steep slopes as a result of excessive rainfall or volcanic eruptions, and are therefore not relevant for channel flow.

Authors that classify sediment-laden flow by sediment concentration usually discern normal flow, hyperconcentrated flow, and mass movements (debris flow, mud flow, and landslides); see e.g. Bradley and McCutcheon (1987) and Costa (1988). Within these classification schemes, the transition between hyperconcentrated flow and higher-concentration flows varies widely. However, since we are concerned with channel flow, our main interest lies in the transition from normal flow to hyperconcentrated flow. Within the commonly applied classification schemes this transition is around $\phi = 0.2$ (Costa (1988) and Bradley and McCutcheon (1987)). Though this classification scheme seems better than the triggering mechanism, it still seems insufficient. Therefore the kinematic behaviour (Newtonian or non-Newtonian flow) has been used, in addition to concentration, as a qualitative measure to distinguish different flow types. The primary mechanism affecting particle support (turbulence, viscosity and buoyancy) may also be important to distinguish different flow types but have only been used very qualitatively. This explains why there is no general consensus on the transitions between normal flow and hyperconcentrated flow. A reason for this may be that here does not seem to be a clear definition of

Copyright © 2006 Taylor & Francis Group plc, London, UK

hyperconcentrated flow. Some authors have defined a hyperconcentrated flow, being:

- 'A highly sediment-laden flow in which the presence of fine sediments materially affects fluid properties and bed material transport compared with the flow without any appreciable quantity of fine sediments' (Julien 1989).
- 'A more or less uniform flow with a high suspended fine-material concentration and a viscosity larger than that of water: coarse sediment may be transported as bed load' (Rickenman 1992).

A description of hyperconcentrated flow without giving a strict definition is more common, some of which can be summarized as:

- A fluid with a logarithmic velocity distribution and a turbulent structure to suspend sediments, a concentration ϕ larger than 0.4, and a certain amount of fine silt and clay (Brush 1989).
- A two-phase turbulent flow that has a sediment concentration C over 300–400 $\mathrm{kgm^{-3}}$, with sediment finer than 0.01 mm being part of the liquid phase, and coarser sediment being the solid phase (Xu 1999).
- A two-phase flow where small-scale turbulence is almost non-existent. When the sediment load is partly cohesive and the sediment concentration high then the fluid is a Bingham fluid, whereas the fluid is non-Newtonian when sediment concentrations are too low or there is no cohesive sediment fraction. The flow can be turbulent, with a logarithmic velocity profile, and laminar, with a uniform velocity profile (Chien and Wan 1998).
- A pseudo-one phase flow of which the fluid properties are considerably affected by sediment carried by the flow. The flow becomes hyperconcentrated at a concentration around 200 $\mathrm{kg\,m^{-3}}$ ($\phi = 0.08$), although this transition is additionally regulated by grain size composition and mineral content (Wan and Wang 1994).

The transition from normal flow to hyperconcentrated flow is associated with a transition from deposition to scouring (Xu 2004). Several attempts have been made to relate the beginning of bed scour (and thus hyperconcentrated flow) to discharge Q or sediment concentration C. Between Aishan and Lijin, for instance, scouring begins when $Q > 1800\,\mathrm{m^3\,s^{-1}}$ whereas sediment is deposited when $Q < 1800\,\mathrm{m^3\,s^{-1}}$ (Wang and Liang 2000). The transition occurs during higher discharges according to Qi (1997): $Q = 3000\,\mathrm{m^3\,s^{-1}}$ in the meandering reach (corresponding to a flow velocity u of 1.9 $\mathrm{ms^{-1}}$) and $Q = 4000\,\mathrm{m^3\,s^{-1}}$ in the braided reach; there is no relation with sediment concentration C. Alternatively, the transition between deposition and erosion in hyperconcentrated floods depends on C and not on Q according to Xu (2004), the concentration C at which the flow becomes hyperconcentrated varies between 200 $\mathrm{kg\,m^{-3}}$ in fine-grained rivers (the Yellow River at Tonguan) and 600 $\mathrm{kg\,m^{-3}}$ in coarser tributaries. If we analyze Eq. 2, however, it is obvious that there cannot be a single discharge, velocity, or sediment concentration at which hyperconcentration, and thereby bed scour, is to be expected.

It can therefore be concluded that there is no clear and widely accepted definition of hyperconcentrated flow. However, numerical modelling experiments using the same basic fluid mechanical theory common for stratified flow produces morphological results in close agreement with observed morphodynamics. We therefore propose that the sub-saturated hyperconcentrated regime (Fig. 8), as defined by the flux Richardson number, can be used to quantify the transition from normal flow to hyperconcentrated flow. This then allows the formulation of a more quantitatively founded definition of hyperconcentrated flow. Hyperconcentrated flow may be defined as a sediment-laden flow in which the vertically homogeneous concentration profile is strongly affected by hindered settling and can be maintained at low turbulence rates, when the sediment concentration exceeds a critical sediment concentration which increases with the water depth, the grain size and gelling concentration and decreases with the cubed flow velocity. Although hyperconcentration therefore preferentially develops in shallow, high-velocity flows carrying fine (partly cohesive) sediments, it may also occur at higher sediment concentrations in deeper channels without a cohesive sediment fraction. When the sediment load is partly cohesive, then the fluid may be non-Newtonian, characterized by increased viscosity, yield strength, and laminar or plug flow. We then have to introduce a second non-dimensional parameter, the effective Reynolds number. This is subject of our further research.

5 CONCLUSIONS

Hyperconcentrated floods, such as those in the Yellow River, are hydrodynamically complex and characterized by rapid morphologic changes. Because of their complex nature, they are still poorly understood. A numerical model based on the standard Delft3D flow model reproduces these complex hydrodynamics and morphodynamics satisfactory. The most important mechanisms are collapse of the turbulence structure due to sediment-induced density gradients leading to deposition, and re-establishment of this profile due to hindered settling, leading to erosion of the bed.

Hyperconcentrated flows have a large spread in grain size, water depth, flow velocity, concentration, and gelling concentration, and may be Newtonian as well as non-Newtonian, turbulent as well as laminar,

Copyright © 2006 Taylor & Francis Group plc, London, UK

two-phase as well as one-phase, and may contain cohesive sediment, but can also be non-cohesive. But despite these differences, they have in common that sediment can be kept in suspension at low turbulence rates due to hindered settling hindered settling. This can be quantified with Ri_f number, and we propose to distinguish hyperconcentrated flow from non-hyperconcentrated flow through Ri_f.

ACKNOWLEDGEMENTS

This work is part of the project 'Predictive Morphological Modelling of the Lower Yellow River', financed by the Dutch Royal Academy of Sciences (KNAW) and the Chinese Ministry of Science and Technology within the framework of the Programme of Scientific Alliances between China and the Netherlands.

Fluctuations in surface granular flow via a PIV-edge detection technique

D. Berzi, L. La Rosa, S. Malavasi & A. Radice
Politecnico di Milano, Department of I.I.A.R., Milano, Italy

ABSTRACT: Some preliminary results of laboratory experiments concerning uniform dry granular flow are presented. Experimental set-up is composed of a rotating drum partially filled with homogeneous granular material. Literature studies showed that two distinctive flow regions develop: an active superficial layer and a plug flow. In this work, the fluctuating behaviour of the slope of the free surface and of the position of the inversion point, localized near the interface between the active layer and the plug flow, is investigated. The time evolution of these quantities is provided by image processing (an edge detection procedure and a Particle Image Velocimetry technique). The analysis of the Probability Density Function of the depth h where the flow changes its direction has allowed for assessing the validity also in the quasi-2D rotating drum configuration of the theories by Jop et al. (2005) and by Berzi & Larcan (2006) on the dense granular flow of cohesionless material. The fluctuating values of h, probably due to the existence of clusters in the flow field, are indeed limited when the theoretical value of the depth of the active layer is close to the mean temporal value of h.

1 INTRODUCTION

Many works in the last years focused on the uniform dry granular flow of cohesionless particles, by making use of both numerical and physical experiments (Pouliquen 1999, Ancey 2001, GDR MiDi 2004). The analysis of such flows is a basic step towards a deeper understanding of the dynamics of the grains and is needed in order to define constitutive models for the normal and the shear stresses relative to the disperse phase of a solid-liquid mixture (e.g., debris flow). Focusing on uniform dry granular flow allows clearly to simplify the problem because it is possible to disregard all the phenomena affecting the dynamics of the granular medium (convective and local accelerations, electrostatic and cohesive effects, influence of the continuous phase on the motion of the grains) except for the particles interaction and, in some cases, the gravity.

Among all the possible experimental configurations which allow to obtain the uniform flow condition, the heap flow and the flow in a partially filled rotating drum have the distinctive feature that a granular flowing layer develops over a mobile bed of the same grains (GDR MiDi 2004). At the bed both the shear rate and the velocity vanish. Thus, no particular boundary condition is needed for taking into account the possibility of slip velocity at the walls like in the case of flow over fixed bed (Jenkins & Richman, 1986).

Previous works (Boateng & Barr 1997, Orpe & Khakhar 2001, Jain et al. 2004) have shown that when a drum partially filled with granular material rotates at constant angular velocity, the flow field can be divided into two basic regions (figure 1). In the upper part of the granular medium there is a semi-lunar active layer where the solid volume fraction is less than the static value and the grains behave like a fluid. In the lower part of the granular medium, instead, there is a plug flow region where the grains move rigidly with the tumbler along circular trajectories. The interface between these two regions is located where the velocity, evaluated in a frame of reference rotating solidly with the apparatus, vanishes. If the frame of reference is not taken rotating solidly with the apparatus, instead, an inversion of the flow can be localized in the proximity of the interface between the active layer and the plug flow and can provide useful information about the fluctuating behaviour of the flow field near to the mobile bed.

The aforementioned literature works showed that there is a diametric cross-section of the flow, perpendicular to the free surface of the granular medium, where the particle trajectories in the active layer are sensibly rectilinear, like in a uniform flow. While the dependence of some time-averaged quantities (i.e., velocity, solid volume fraction, temperature) relative to this section on the experimental control parameters has been discussed in other works (Boateng & Barr 1997, Orpe & Khakhar 2001, GDR MiDi 2004), the time evolution of these variables has received much less attention.

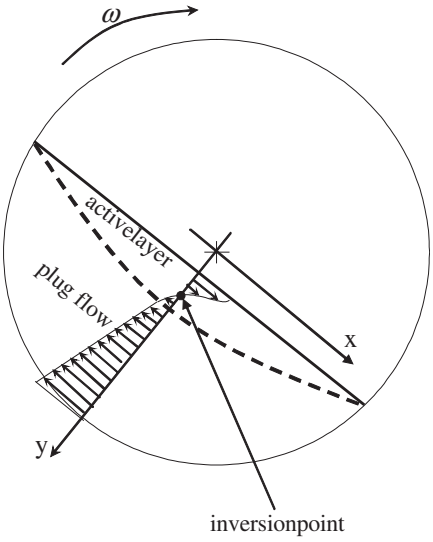

Figure 1. Sketch of the geometry in the rotating drum configuration.

The goal of this paper is to investigate the temporal variations of the position along the y-axis of figure 1 of the free surface and of the inversion point, obtained through two image analysis techniques.

The paper is organized as following. In §2 the experimental set-up is introduced and in §3 a description of the image processing techniques is given. In §4 the experimental results are shown and a possible interpretation is provided on the basis of the theoretical solution of a slow and dense uniform granular flow between smooth sidewalls (Jop et al. 2005, Berzi & Larcan 2006). Finally, some conclusions are given in §5.

2 EXPERIMENTAL SET-UP

The experimental set-up (figure 2) consists of a cylinder (inner diameter $D = 1$ m and axial length $W = 250$ mm), which is mounted on a pair of friction rollers and rotates around its axis at a constant angular velocity ω in the range $3 \div 14$ rpm. One of the endplates of the cylinder is made of a 10 mm thick glass to allow for optical measurements, while the other one is made of steel.

The drum is partially filled with a homogenous cohesionless granular material composed of extruded plastic grains of density $\rho_s = 1164\,\mathrm{kg/m^3}$, median diameter $d_{50} = 2.5$ mm and static friction angle $\phi = 27.6°$. The friction angle between the plastic beads and the glass wall and between the plastic beads and the steel wall has approximately the same value ($\delta = 26°$).

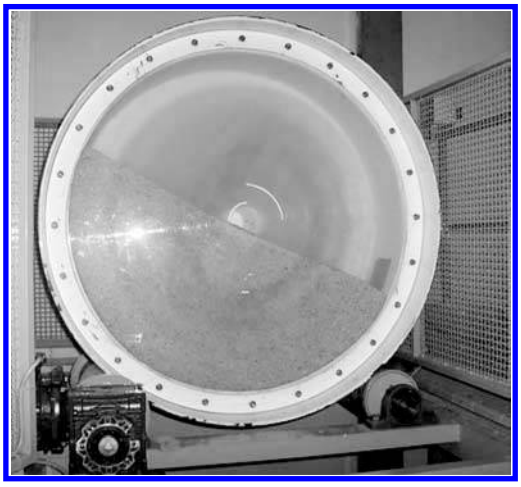

Figure 2. Experimental set-up. Thick rectangle highlights the zone filmed by the CCD.

The results of two experiments, in the following called experiment A and B, characterized by an angular velocity ω respectively equal to 4 rpm and 8 rpm, are presented. Both the experiments have been carried out with the 48% of the volume of the drum filled with the granular material.

A progressive CCD scan-camera was used to record the two-dimensional motion of granular material, with the resulting images stored digitally on processor boards within the camera. The glass wall of the tumbler was illuminated by an halogen lamp to give uniform illumination. In this arrangement monochromatic images with a resolution of 763×576 pixel are grabbed at a frame-rate of 50 Hz for a time interval of 20 s. The shutter time of the video-camera was 1/10000 s. The camera optics zoomed in correspondence with the mid-section of the active layer, where the flow can be considered nearly uniform, to capture a region of about 15×10 cm (figure 2).

3 IMAGE PROCESSING

3.1 *Edge detection*

The free surface of the granular material in the rotating drum was individuated automatically by applying an edge detection procedure to each acquired image. An adequate contrast between the dark background and the light particles was set-up by painting black the rear endplate of the drum.

Typically, edge detection algorithms search for edges in an image as the locations where the intensity gradient is larger than a certain threshold.

Here, the edge detection method proposed by Canny (1986) and implemented in MatLab® is used. As many

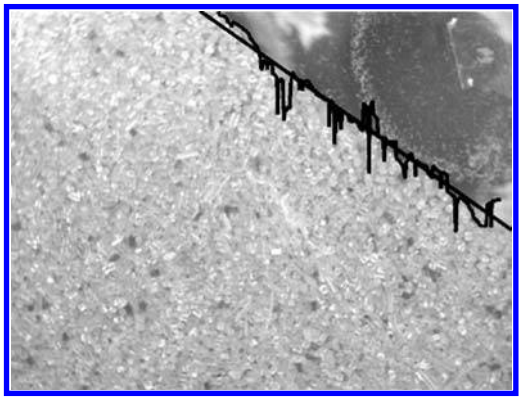

Figure 3. Free surface as evaluated via the edge detection technique. Both edge points and linear interpolation are presented.

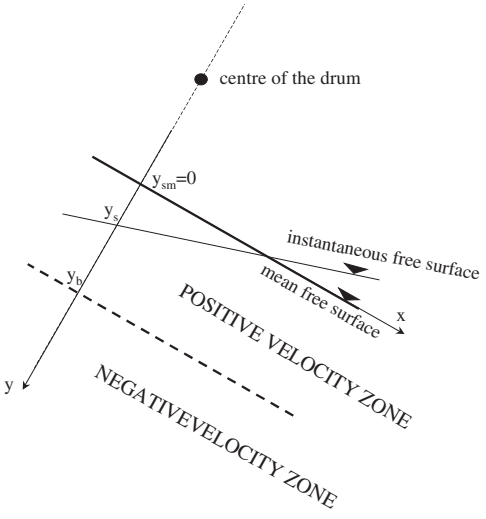

Figure 4. Sketch of the geometry adopted to measure the position of the instantaneous free surface.

other edge detection algorithms, just one calculation parameter has to be set by the operator, i.e. the threshold value of intensity gradient over which a pixel should be considered part of an edge. Given the contrast between the sediments and the black background, the threshold value was set equal to 0.185.

After individuating the edge points in an image, the free surface was determined by linear interpolation. An example of the instantaneous free surface is presented in figure 3.

The x-axis of the fixed frame of reference is taken along the mean free surface, calculated from the sample of the instantaneous ones (figure 4). The y-axis is taken as the orthogonal axis passing for the centre

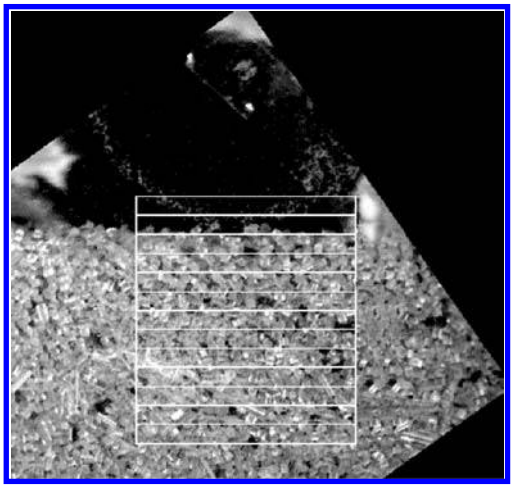

Figure 5. Measuring grid for PIV, experiment A.

of the drum. The coordinate y_{sm} of the average free surface is by definition zero.

In this configuration, the position y_s of the instantaneous free surface was determined as the intersection between the equation of the instantaneous approximately planar free surface and the aforementioned y-axis (see figure 4 for more details).

3.2 *Particle Image Velocimetry*

Velocities in the granular medium were measured by means of a PIV algorithm, derived from that successfully used by Radice et al. (2004) for measurement of sediment velocity in local scour.

An instantaneous velocity field was calculated from two consecutive frames of a movie, namely $F1$ and $F2$. First, the images were rotated in order to make the free surface horizontal; the rotation angle was determined as the mean slope measured by the edge detection technique described above. After contrast enhancing the images were divided into cells of inspection, whose dimensions were 7 cm in the flow direction and 1.8 cm in the orthogonal one. A 30% overlap was used along the y-axis. The upper limit of the measuring grid was located at $y = -0.6$ cm. Figure 5 shows an example of the measuring grid.

On the basis of the expected maximum velocities a limit on the longitudinal and transversal velocities is fixed, before the calculation, respectively equal to 80 cm/s and to 27 cm/s. Then, maximum pixel displacements between two consecutive frames were calculated by knowing the sampling frequency of the CCD and the pixel/cm correspondence C. All the possible pixel displacements within the imposed limits were considered; for each displacement (dx, dy) an interrogation and a target window could be

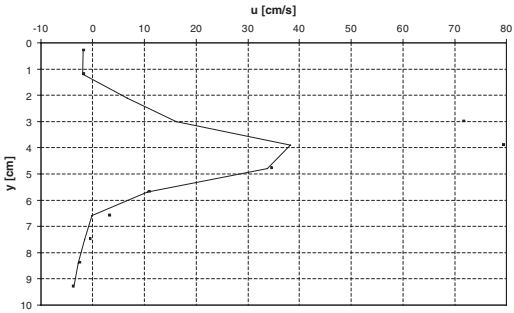

Figure 6. Typical results of PIV measurements. (■, instantaneous velocity profile; —, average velocity profile). Profiles for experiment A are presented.

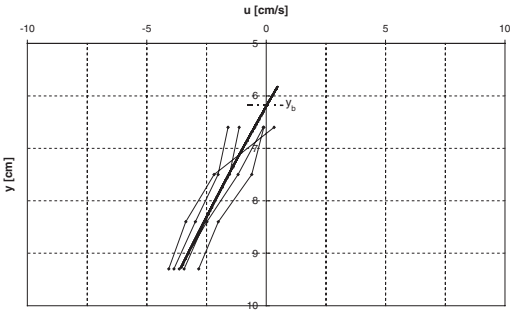

Figure 7. Example of inversion point determination (—, instantaneous velocity profiles; __, parabolic interpolation of the average profile in the plug flow layer). Profiles for experiment A are presented.

fitted within the inspection cell. The most probable movement (dx_m, dy_m) maximizes the parameter:

$$S = \frac{p_x\, p_y}{\sum_{i=1}^{p_x}\sum_{j=1}^{p_y}\left|F_1(i,j) - F_2(i+dx, j+dy)\right|} \quad (1)$$

where p_x and p_y are the pixel dimensions along x and y of the interrogation and target windows, respectively. The velocity components along the x and y directions could then be computed as $u = dx_m/(dt \cdot C)$ and $v = dy_m/(dt \cdot C)$, dt being the inverse of the frame frequency.

Reliability of computed vectors was evaluated by calculating the ratio between the maximum and the average values of S. Vectors were eliminated if this ratio was less than 1.1.

Figure 6 presents the result of a single measurement of the velocity profile in the active layer. Granular velocity in the bottom plug flow is well measured; on the contrary, measurement quality decades as the active layer is considered, probably due to bad reflecting properties of our sediments. In the proximity of the free surface measured velocity is negative, that is physically unsound. Also the time average velocity profile is presented in figure 6.

3.3 *Inversion point determination*

Presented results on velocity measurement showed that was possible to measure velocity in the reverse plug flow, even if velocity determination was still unsatisfactory as the free surface was approached. The negative velocity values in the bottom layer have been used to determine the position of the inversion point, i.e. the coordinate y_b with zero velocity depicted in figure 4.

First, five consecutive instantaneous velocity profiles were averaged; next, a parabolic equation was fitted to the average velocity profile near to the plug flow zone to determine the inversion point. Figure 7 presents the example of one calculation: the five instantaneous velocity profiles are shown in grey, while the parabolic interpolation of the velocity profile is in black; the latter allows determining the value of $y_b = 6.2$ cm.

Repetition of the described procedure for all the instantaneous velocity profiles leaded to the final time series of the inversion point.

4 EXPERIMENTAL RESULTS AND DISCUSSION

Figure 8 shows an example of the time evolution of the surface slope θ concerning both experiment A ($\omega = 4$ rpm) and B ($\omega = 8$ rpm). First of all, it can be noticed that the mean surface slope increases when ω increases, as already found in other works concerning the rotating drum configuration (Boateng & Barr 1997, Orpe & Khakhar 2001, Jain et al. 2004). Averages over a window of 5 data and of 20 data have been performed in order to highlight the presence of two main instabilities in the flow and are depicted in figure 8. It can be seen that there is a low frequency instability affecting both the experiments characterized by a period of about 3 s and by an amplitude of about $2 \div 3°$. The higher frequency instability is instead characterized by a period of about 0.2 s for both the experiments and by an amplitude of about 2° for experiment A and of about 4° for experiment B. Hence, an increase in the angular velocity causes also an increase in the fluctuation amplitude of the surface slope.

Figure 9 shows the time evolution of y_b and y_s for the performed experiments. The mean position of the free surface is taken as reference ($y_{sm} = 0$) for both the experiments (see §3). The mean position y_{bm} of the inversion point increases when ω increases. This result

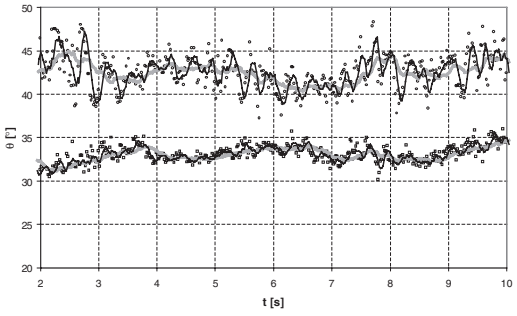

Figure 8. Time evolution of the surface slope θ (□, data from experiment A; ○, data from experiment B; black solid line, average over a window of 5 data; grey solid line, average over a window of 20 data).

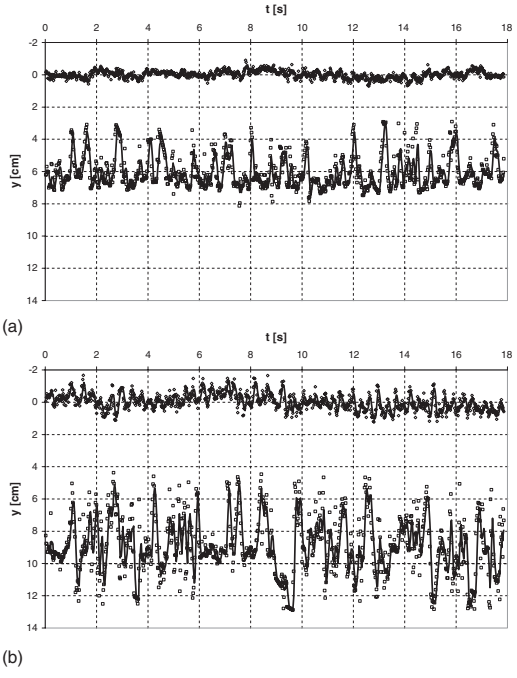

Figure 9. Time evolution of the free surface and of the inversion point (◇, y_s; □, y_b; solid line, average over a window of 5 data) for: (a) experiment A; (b) experiment B.

agrees with the findings of previous works related to the interface between the active layer and the plug flow (Boateng & Barr 1997, Orpe & Khakhar 2001, Jain et al. 2004). Moreover, figure 9 shows that the fluctuations of y_b are stronger than those of y_s. An explanation of this finding can be found if one assumes that the fluctuations of y_s and y_b are connected to the phenomenon of clustering (Bonamy et al. 2002, Goldhirsch 2003) which characterizes the granular flow. In this frame, the fluctuations of y_s and y_b reveal

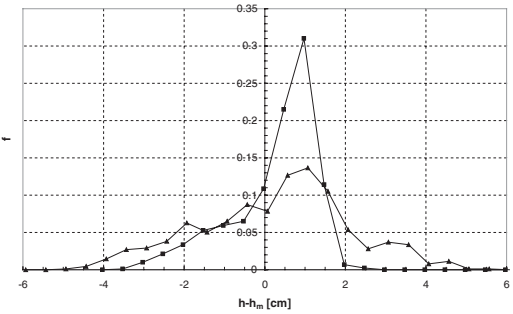

Figure 10. Probability density function of the variable $h - h_m$ (■, experiment A; ▲, experiment B).

the motion of the clusters in the direction of the flow and their amplitude is related to the cluster size.

Experiments performed in a rotating drum by Bonamy et al. (2002) and a recent theoretical analysis by Berzi & Larcan (unpubl.), based on the dimensional theory of Ertas & Halsey (2002), showed that the clusters are multi-scaled in the granular surface flow between sidewalls with their size increasing with the distance from the free surface. The characteristics of the fluctuations of y_b with respect to those of y_s are in agreement with these theories.

Figure 9 shows a further distinctive feature of the behaviour of y_b. For $\omega = 4$ rpm (figure 9a) the fluctuating displacements of y_b seem not symmetrically distributed around the mean value y_{bm} but the low values appear more frequent, as opposed to the case of $\omega = 8$ rpm (figure 9b), where instead y_b values much greater and much smaller than y_{bm} are approximately equally probable. Provided that the displacements of y_b are much greater than the displacements of y_s, the former are representative of the fluctuations of the depth $h = y_b - y_s$ where the flow changes its direction. Figure 10 shows the probability density function (PDF) of the variable $h - h_m$, with h_m the mean temporal value of h. Indeed, it can be noticed that the PDF relative to experiment A is less symmetric than that of experiment B.

Jop et al. (2005) and Berzi & Larcan (2006), even if through different constitutive models for the shear stress, showed that the uniform dense flow of cohesionless solid grains at the surface of a heap between smooth sidewalls is characterized by the following relationship between the depth h_{den} of the flowing layer and the free surface slope θ:

$$\frac{h_{den}}{W} = \frac{\tan\theta - \tan\phi}{\tan\delta} \qquad (2)$$

Here W is the gap between the sidewalls and δ is the friction angle between the grains and the sidewalls.

The non-dimensional mean depth h_m/W against the mean surface slope θ_m for the experiments A and

Copyright © 2006 Taylor & Francis Group plc, London, UK

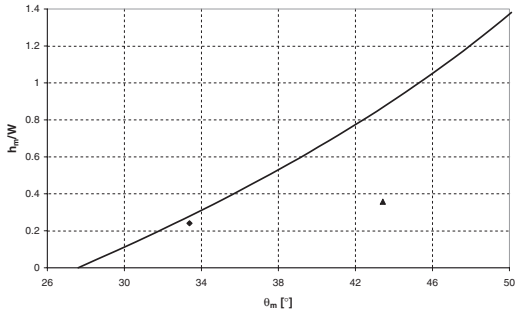

Figure 11. Non-dimensional mean position of the inversion point against the mean surface slope (♦, experiment A; ▲, experiment B; __, equation 2).

B is depicted in figure 11. The curve of equation (2), into which the value $W = 25$ cm and $\delta = 26°$ of our experimental set-up have been substituted, is also shown.

It can be seen in figure 11 that the point related to experiment A is very near to the theoretical curve of equation (2), as opposed to the case of experiment B. If the analysis performed by Jop et al. (2005) and by Berzi & Larcan (2006) on a different flow configuration (heap flow) applied also to the here considered quasi-2D flow in a rotating tumbler, it can be expected that the fluctuations of the depth h could be affected by the presence of this theoretical boundary, i.e., the dimension of the layer in which the granular material can be treated as a fluid.

Figure 12a shows the time evolution of the depth h for the experiment A together with the corresponding value of h_{den}. It can be noticed that the fluctuations of h are indeed limited by h_{den}, originating the asymmetry in the probability density function of h highlighted in figure 10. Hence, this result is a clue of the validity of the theory of Jop et al. (2005) and of Berzi and Larcan (2006) also in the quasi-2D flow in a rotating drum, although more experiments are needed to provide a clear evidence on this argument.

If the mean value of h is instead much lower than h_{den} (experiment B), the fluctuations of the depth h do not suffice at reaching the theoretical limit of equation (2) (Figure 12b). Hence, there is no constraint on the h values and its probability density function is more symmetric (figure 10).

5 CONCLUDING REMARKS

In this paper, the fluctuating displacements of the free surface and of the position where the flow changes its direction concerning the uniform dry granular flow which develops in a rotating drum are investigated. The experimental data have been collected by means

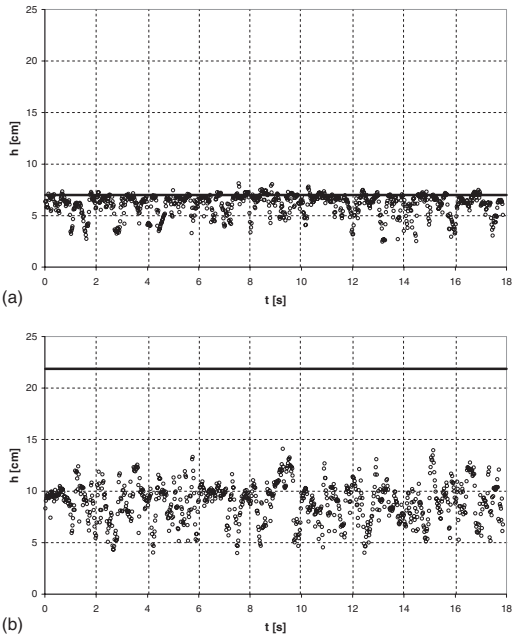

Figure 12. Time evolution of the depth h (○, experimental data; —, theoretical value of h_{den}) for: (a) experiment A; (b) experiment B.

of image processing techniques (edge detection and Particle Image Velocimetry) which allowed to obtain the time series of the variables.

The major conclusions of this work are the following:

(1) it has been possible to measure the fluctuating displacements of the free surface and the grain velocities in the proximity of the interface between the active layer and the plug flow zone which allowed to measure also the fluctuating displacements of the inversion point;
(2) the fluctuations strength is an increasing function of the angular velocity of the rotating drum;
(3) the amplitude of the fluctuations of the free surface is smaller than that of the inversion point. If one assumes that these fluctuations are due to the presence of clusters in the flow field, this result is in agreement with the size distribution of the clusters along the transversal direction observed in the experiments of Bonamy et al. (2002) and with the theoretical analysis of Berzi & Larcan (unpubl.).
(4) The Probability Density Function of the depth h where the flow changes its direction is strongly asymmetric for the experiment A characterized by an angular velocity $\omega = 4$ rpm, as opposed to the case of experiment B ($\omega = 8$ rpm). This asymmetry has been showed to be related to

Copyright © 2006 Taylor & Francis Group plc, London, UK

the constraint on the fluctuations of h posed by the theoretical value of the depth of the flowing layer in dense regime suggested and verified by Jop et al. (2005) and by Berzi & Larcan (2006) in the case of the dry granular flow of cohesionless grains at the surface of a heap between smooth sidewalls. Hence, although a richer experimental campaign is required, the theory by Jop et al. (2005) and by Berzi & Larcan (2006) and in particular the crucial role of the sidewalls in governing the dynamics of the granular flow, seem to apply also to the quasi-2D rotating drum configuration, where the flow cannot be considered quasi-homogeneous even at the centre of the drum (Renouf et al. 2005).

ABSTRACT: Areas devastated by debris flows are frequently reported. Rapid rescue operations, for which the accurate prediction of buried regions are necessary, are required to reduce the number of casualties. In the present study, numerical simulations of the process of covering a house by a debris flow have been performed using a solid-liquid, two-phase flow model. A granular material model, based on the Distinct Element Method is used for the solid phase. The house is made of several pillars, which are connected by passively moving solids, and an elastic collapse model is applied to the joints between the pillars.

1 INTRODUCTION

Instability of the ground due to the heavy rain by typhoon causes landslide or debris flow. Image of the rescue of life from collapsed and buried house due to the landslide and debris flow are often televised. The fundamental mechanism of the landslide or debris flow has been studied from now, and some prediction becomes possible. As a recent example, Moriwaki et al. (2004) studied the failure process in a full-scale landslide experiment. Satofuka, Y. (2004) carried out the numerical simulation for debris flow for the fields. By the way, although the many studies have been made on the mechanism of debris flows or landslide and the deposition process of debris flow or landslide, study that interaction between houses and debris flow or landslide would be indispensable for the reduction of the damage from debris flow or landslide. Furthermore, the accurate judgment of the position of the buried house is necessary for the rapid rescue of the life, so to estimate the position of the buried house due to the debris flow or landslide would be also important. For these reasons, the numerical simulation for covering process of houses by debris flow or landslide have been performed in the present study.

The modeling of the debris flow, the collapse model of the house, interaction model between house and debris flow are necessary to simulate the process of the buried house due to the debris flow. Debris flow is in the condition that water is fully mixed with sand and the stone particles. Hence, the evaluation of the interaction between stone particles (solid-solid phase) and between stones and water (solid-liquid phase) are required for the modeling of the debris flow in the numerical simulation. From such reasons, solid-liquid two-phase flow model, in which motion of solid phase was tracked by using the granular material model based on the Distinct Element Method (DEM) proposed by Cundall, P.A. & Strack, O.D.L. (1979), which can evaluate the motion of each stone particle with interelement collision, was applied and the interaction between stones and water was evaluated by using drag force. The house was formed by connecting several pillars, which was composed of several elements. Each pillars acts as the rigid body by the passively moving solid proposed by Koshizuka et al. (1988) and the joint between pillars obey the simplified elastic collapse model referring to Hakuno, M. & Meguro, K. (1991) and Kawai, T. & Toi, Y. (1977).

2 SIMULATION MODEL

2.1 *Movable bed simulator*

To describe the unsteady process of the debris flow due to the landslide from the occurrence to the end, the discrete model is convenient. In the present study, dynamic motion of the sliding mass and collapsing house composed of the circular elements are evaluated by the one of the discrete model, or the Movable Bed Simulator proposed by the Gotoh, H. and Sakai, T. (1997), which is based on the Distinct Element Method

Copyright © 2006 Taylor & Francis Group plc, London, UK

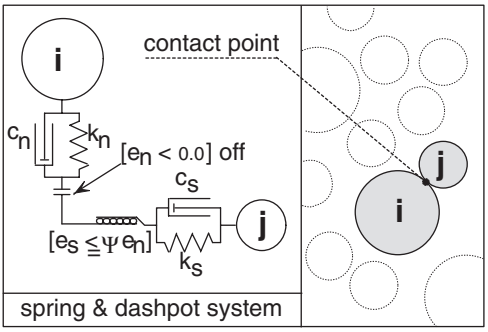

Figure 1. Spring and dashpot system between contacting particles.

proposed by Cundall, P.A. and Strack, O.D.L. (1979). The motion of each circular element in the two dimensional plane is defined by the following translational and rotational equations:

$$m\frac{d\boldsymbol{u}_p}{dt} = -V_p\nabla P + m\boldsymbol{g} + \boldsymbol{F}_P + \boldsymbol{F}_D \tag{1}$$

$$I\frac{d\omega_p}{dt} = \boldsymbol{T}_P \tag{2}$$

$$\boldsymbol{F}_D = C_D\frac{\pi d^2}{4}\cdot\frac{\alpha_l}{2}\rho|\boldsymbol{u}_r|\boldsymbol{u}_r \;;\; \boldsymbol{u}_r = \boldsymbol{u}_f - \boldsymbol{u}_p \tag{3}$$

where ρ = density of fluid; m = mass of the element; d = diameter of the element; $\boldsymbol{u}_f$ = velocity vector of the fluid; $\boldsymbol{u}_p$ = velocity vector of the element; t = time; P = pressure of water; $\boldsymbol{F}_p$ = inter-element force vector; $\boldsymbol{F}_D$ = drag force vector; α_l^p = share of the fluid in the calculated grid; ω_p = angular velocity of the element; $\boldsymbol{T}_p$ = torque acting on the element; $\boldsymbol{g}$ = gravity force vector; C_D = drag coefficient; and V_p = the volume of the element. The judgment of the contact condition is carried out at every calculated time step, and if the element is in the contacting condition, the inter-element force is evaluated by the Voigt system, or the spring and dashpot system shown in Figure 1, which is introduced in both of the tangential and normal direction. In the present simulation, elements are in non-cohesive condition. So the joint, which has no resistance to the tensile force, is assumed in the normal direction. While in the tangential direction, the frictional force works (coefficient of frictional resistance $\psi = 0.577$). To describe these characteristics of inter-element, the joint, which slips at the limit of the shear stress, is assumed in the tangential direction. The detailed model of interaction between elements is mentioned in the paper(Gotoh, H. & Sakai, T. (1997)). The tuning parameters (spring constants in normal and tangential directions (k_n, k_s) and damping constants (c_n, c_s)) used for the debris flow due to the landslide are determined in consideration of the numerical stability by referring the optimization procedure proposed by Gotoh, H. et al. (2001). The tuning parameters are as follows: $k_n = 256.8$ kN/s; $k_s = 98.8$ N/s; $c_n = 0.231$ kNs/m; $c_s = 0.143$ Ns/m. The share of element concentration and the drag force vector in each calculated cell are evaluated from the position of all particles calculated by the governing equations (1) and (2), and these values are used in the solid-liquid coupling.

2.2 *Rigid model*

House is expressed by connecting pillars, which moves as rigid body, with special joint. The pillar is formed with several elements by connecting rigidly. The passively moving solid model proposed by Koshizuka, S. et al. (1998) is applied to the forming of the pillar. At first, the same calculation procedure is applied to both of the element composed of debris flow and house with no distinction, in other words, the conjunction among individual solid elements is not considered in this stage. As a result of this calculation, the components of house deforms, hence the components of house are corrected in the following way.

The translational and rotational velocity vectors $\boldsymbol{T}_k$ and $\boldsymbol{R}_k$ of house is calculated as follows:

$$\boldsymbol{T}_k = \frac{1}{N_k}\sum_{i=1}^{N_k}\boldsymbol{u}_{ki} \tag{4}$$

$$\boldsymbol{R}_k = \frac{1}{I_k}\sum_{i=1}^{N_k}\boldsymbol{u}_{ki}\times\left(\boldsymbol{r}_{ki} - \boldsymbol{r}_{gk}\right) \tag{5}$$

where N_k = number of component of the k-th pillar; $\boldsymbol{r}_{gk}$ = gravity center of the k-th pillar; I_k = momentum of inertia of the k-th pillar; and $\boldsymbol{r}_i$ = position vector of the i-th component. The gravity center and the momentum inertia are given by

$$\boldsymbol{r}_{gk} = \frac{1}{N_K}\sum_{i=1}^{N_k}\boldsymbol{r}_{ki} \tag{6}$$

$$I_k = \sum_{i=1}^{N_k}\left|\boldsymbol{r}_{ki} - \boldsymbol{r}_{gk}\right|^2 \tag{7}$$

Then, the velocity vectors of components of pillar are replaced by

$$\boldsymbol{u}_{ki} = \boldsymbol{T}_k + \left(\boldsymbol{r}_{ki} - \boldsymbol{r}_{gk}\right)\times\boldsymbol{R}_k \tag{8}$$

to satisfy the motion as a rigid body. By applying the above mentioned velocity-vector correction procedure to only components of the pillar, the motion of the pillar as a rigid body can be tracked(refer to Figure 2).

Copyright © 2006 Taylor & Francis Group plc, London, UK

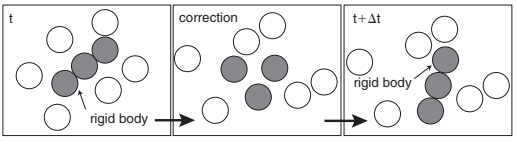

Figure 2. Correction procedure to elements composed of rigid body.

2.3 *Collapse model*

The special joint is applied between pillars. The special joint, which express the elastic failure, is as follows:

$$\left.\begin{aligned} f_n(t) &= e_n(t) \\ f_s(t) &= e_s(t) \end{aligned}\right\} \quad when \quad |f_s(t)| \le f_{limit} \tag{9}$$

where $f_n(t)$, $f_s(t)$ = inter-element force by the spring in the normal and tangential direction respectively. The joint has resistance to the frictional force in the tangential direction till the limitation (f_{limit}), which is parameter for fracture criterion. And after collapse of the house, the interaction between pillar-pillar follows the joint above mentioned 2.1. And also the model parameters applied between pillars are different from using in the 2.1, because the dynamic motion is different between debris flow and pillar. Hence, only the spring constants are used referring to the Kawai, T. and Toi, Y (1977) here. In addition, the similar concept of the collapse model is presented for example Hakuno, M. and Meguro, K. (1991).

2.4 *Model of liquid phase*

The continuity and momentum equations to the local averaged flow in incompressible fluid are described as follows:

$$\frac{\partial u}{\partial t} + \nabla \cdot \alpha_f \boldsymbol{u}_f = 0 \tag{10}$$

$$\begin{aligned} &\frac{\partial \rho \alpha_l u_f}{\partial t} + \nabla \cdot \left(\rho \alpha_l u_f u_f\right) = \\ &-\alpha_l \nabla P + \rho \alpha_l \boldsymbol{g} \\ &+ \nabla \cdot \alpha_l \left(\tau_l + \tau_{Re}\right) - \sum F_D / V \end{aligned} \tag{11}$$

$$\tau_l + \tau_{Re} = \left(\mu + \mu_t\right)\left[\nabla u_f + \left(\nabla u_f\right)^T\right] \tag{12}$$

where V = unit volume of calculation cell in liquid phase; τ_l = stress tensor; τ_{Re} = stress tensor due to turbulent flow; μ = coefficient of viscosity; and μ_t = kinematic eddy viscosity. And the subscript T means the transposed. And the kinematic eddy viscosity was evaluated by the standard k-ε turbulent model in the singlephase flow simply due to the difficulty of the characteristics of the turbulent structure in the sediment laden. The detailed information of the modeling of the liquid phase is in the Harada, E. et al. (2004). And the governing equations are discretized by the finite volume method, or FVM, on the staggered grid, and also upwind difference scheme is applied in the advection term.

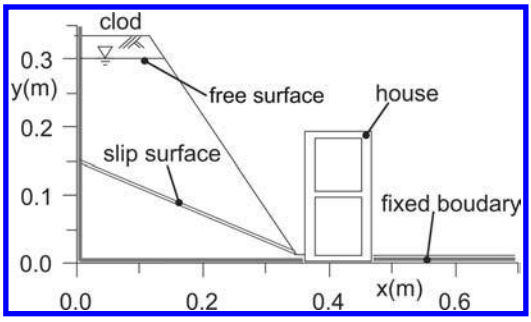

Figure 3. Initial condition and calculated domain as model case.

3 COLLAPSE PROCESS OF HOUSE

3.1 *Calculated condition*

Figure 3 shows the initial condition of the calculation condition. The clod on the slope and the house is formed by using 4721 particles, diameter of which is 0.005 m, 2.65 in specific density. The collapse process of the house located at $x = 3.8$ m due to the landslide of the left side of the clod by the liquefaction over the slip surface is assumed and tracked. The landslide breaks out along with the start of the calculation due to the removing of the sand elements at the bottom of the clod. This operation means the trigger of the landslide due to the liquefaction over the slip surface. And the fully saturated clod is assumed, the Lagrangian mass less marker particles are arranged in the clod shown in Figure 3.

The house is formed by connecting with 7 individual pillars shown in Figure 4. The special joint is applied between same sign elements. The elements of component of the house are made of concrete and wood and so on actually. But in the present simulation, they aren't handled strictly, and the specific density of the element is as same as the clod.

3.2 *Simulation results*

The snapshots of the present simulation are shown in Figure 5. The debris flow due to the landslide starts by the trigger from the time $t = 0.0$ s. Around the time $t = 0.05$ s, the tip of the debris flow reaches to the front of the first floor of the house. The debris flow is

Copyright © 2006 Taylor & Francis Group plc, London, UK

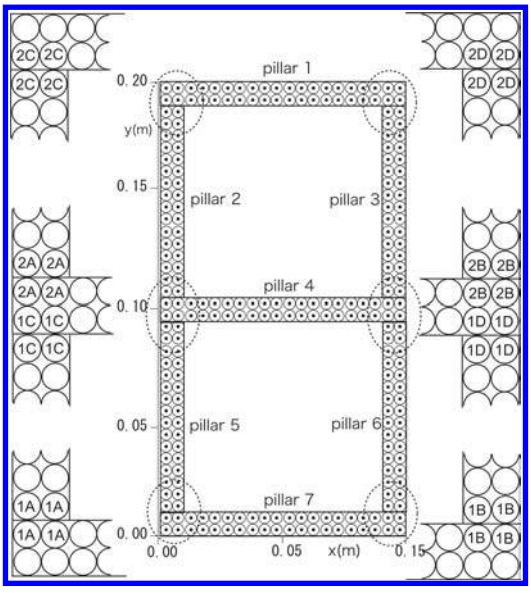

Figure 4. Outline of house composed of 7 pillars and joints between pillars.

blocked by pillar 5 and the separation between water and sand is confirmed. And the water passes through the house, although the increase of the water level due to the resistance of the pillar is shown. The water is actually supposed to be blocked by the pillars, too. However, in this simulation model, the evaluation of the interface between liquid phase and solid phase is imperfect. In other words, the interface between liquid phase and solid phase is estimated by the share of each phase on each calculated cell. Hence, handling of interface between solid phase and liquid phase is obscurity, and the strict evaluation of the interface is impossible. An examination about handling of the interface between different phases is necessary for the strict evaluation. And the slight inclination of the house is confirmed around the same time. The deflection of the house at the part of the first floor keeps increasing around the time $t = 0.35$ s. The significant inclination of the pillars of the first floor is shown, the collapse of the house of the first floor is confirmed from the time $t = 0.45$ s to the time $t = 0.55$ s. While, the slight inclination of the second floor is also confirmed from the time $t = 0.45$ s. After that, around the time $t = 0.65$ s, the conspicuous inclination at the second floor is shown, finally the collapse of the whole of the house is confirmed at the time $t = 0.85$ s.

The path line of the gravity center of the house elements is shown in the Figure 6. The x-axis and the $y$axis indicates the gravity center in the y-direction and the x-direction respectively. The scale of the deflection of the first floor is smaller the that of the second floor, because the the pillar 7 is located as the fundamental part of the house between the fixed boundary elements. And the decrease of the xgc in the first floor is confirmed because of the resistance force at the joints between the first floor and the second floor. It can be confirmed from the snapshot at the time $t = 0.85$ s shown in the Figure 5 as well.

Figure 7 shows the time series of the gravity center of all the components of the house elements in the y direction [upper] and in the x direction [lower] respectively. Around the time $t = 0.25$ s, the significant decrease of the gravity center in the y direction of the first floor is confirmed, which indicates the deflection of the first floor due to the collision of the debris flow. After that, that keeps decreasing by the increasing of the loading of the debris flow till the time $t = 0.46$ s. The decreasing process of the gravity center of the second floor in the y direction along with the decreasing of the gravity center of the first floor is confirmed around the same time, too. Then, although the gravity center of the first floor in the y direction shows calmness, it is confirmed that the gravity center of the second floor in the y direction keeps decreasing due to the pressure of the debris flow. And around the time $t = 0.8$ s, both of the gravity center in both of the x direction and the y direction remain constants, the convergence of the collapse of the house is confirmed. While, these tendencies are also shown in the gravity center of the x direction. In other words, increase of the gravity center in the x direction both of the first floor and the second floor, which indicates the inclination of the pillars, or deflection of the house, due to the increasing of the loading by the debris flow. And after the time $t = 0.46$ s, the stagnation of the gravity center with slight fluctuation of the first floor and the increasing of the gravity center of the second floor are also shown as well as the time series of the gravity center in the y direction.

4 CONCLUSIONS

In the present study, numerical simulation of the collapse process of the house due to the debris flow induced by the land slide has been performed by using the solid-liquid two phase flow model. In the solid model, to track the direct motion of the debris flow and the house, the granular material model(Gotoh, H. & Sakai, T., 1997) based on the Distinct Element Method (Cundall, P.A. & Struck, O.D.L., 1979) was applied. And also, the motion of the house as a rigid body was modeled by introducing the Passively moving solid model (Koshizuka, S. et al., 1998) and the motion of the collapse of the house was modeled by the special joint model, which resists against the tensile force and the shear force till the limitation of the force in the tangential direction.

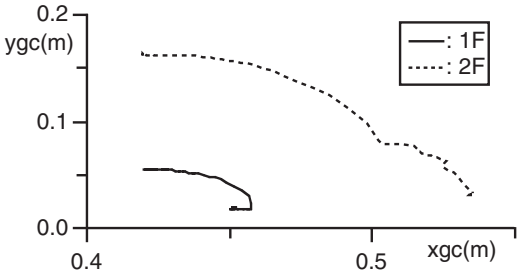

Figure 6. Path line of the gravity center in the *x*-direction and *y*-direction.

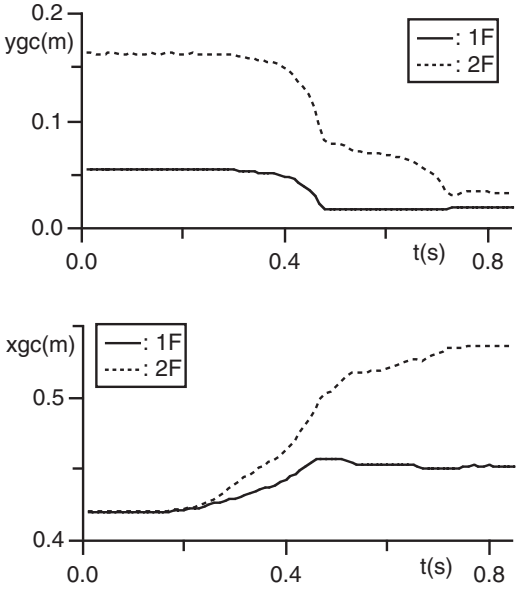

Figure 7. Time series of the gravity center in the *y*-direction [upper] and in the *x*-direction [lower].

Although the simulation of the collapse process of the house due to the debris flow has been performed, the evaluation of the interface between solid phase and liquid phase is imperfect, so the permeation of the water into the pillars was confirmed. In the near future, the investigation of the interface between different phases would be examined. Furthermore, the prompt separation between the clod (solid phase) and the water (liquid phase) is shown in the present simulation. Hence, the development of the liquid phase model in consideration with the surface tension would be necessary for the increase of the accuracy of the simulation model.

Frictional surface flow of a dry granular medium

D. Berzi & E. Larcan
Politecnico di Milano, Department of I.I.A.R., Milano, Italy

ABSTRACT: We focus on the frictional surface flow of dry cohesionless granular material between sidewalls. We use the theoretical model we developed in Berzi & Larcan (unpubl.) for dense granular flow according to which the granular medium is treated as a viscoplastic fluid with a viscosity depending on the normal stress. The model formally includes the influence of the walls in the way suggested by Jop et al. (2005). Our model, as opposed to the empirical two-parameters model of Jop et al.(2005), has the key advantages that (1) there is only one parameter that must be set on the basis of experimental evidences and (2) it is intimately correlated to the type of solid material. We compare the flow properties obtained through the application of the model by Berzi & Larcan (unpubl.) against results of experiments performed by Jop et al. (2005), who analyzed the flow of glass beads on a heap. Although the regime is likely to become collisional near to the free surface (GDR Midi 2004), we obtain a notable agreement between the measurements and what predicted by our theory.

1 INTRODUCTION

The understanding of the dynamics of dry cohesionless granular material in fluid-like condition is a fundamental component for a lot of engineering processes, ranging from industrial to civil applications. Most of the works concerning this topic are devoted to the analysis of the collisional regime, i.e., the regime in which the collisions between the particles are almost instantaneous and the granular medium can be treated as a dense inelastic gas (Jenkins & Savage 1983, Lun et al. 1984, Lun 1991, Goldhirsch 2003).

The frictional regime, sometimes called frictional-collisional (Ancey & Evesque 2000) or dense (GDR MiDi 2004), which is characterized by (a) long-lived interparticle contacts and (b) a major role played by friction in governing the dynamics of the grains, has received much less attention in the literature. This is mainly due to the failure of the kinetic assumptions that makes a mathematical derivation of the closures (shear and normal stress expression, thermal diffusivity) in the balance equations extremely difficult (Zhang & Rauenzahn 1997, Zhang & Rauenzahn 2000). Thus, to our knowledge the study of frictional granular flow has been mainly performed on an empirical basis (Pouliquen & Forterre 2002, GDR MiDi 2004).

In a recent work, Berzi & Larcan (unpubl.) tested an expression for the shear stress in frictional regime in the case of the planar dry flow of cohesionless homogeneous granular material between parallel plates. This expression is characterized by only one fit parameter and is obtained through dimensional analysis, by fully taking into account the main characteristics of the frictional behaviour highlighted in recent theoretical and numerical investigations (Zhang & Rauenzahn 2000, Armanini et al. 2005, Zhang 2005). Here, we test the capability of the aforementioned model of reproducing the properties of a surface granular flow between smooth sidewalls. Experimental runs performed in such a configuration by Jop et al. (2005) are used as a term of comparisons.

2 THEORY

Recent numerical and experimental investigations concerning dense granular flow (GDR MiDi 2004) have shown that the shear stress τ and the normal stress σ are related through a friction law:

$$\left|\frac{\tau}{\sigma}\right| = \mu(I) \tag{1}$$

where the friction coefficient μ only depends on the parameter I, that is the ratio between the time scale given by the confining pressure ($d/\sqrt{\beta_d \sigma/\rho_s}$ with d particle diameter, ρ_s density of the grains and β_d solid volume fraction) and the time scale given by the strain rate ($\dot{\gamma}^{-1}$, $\dot{\gamma}$ being the shear rate). Jop et al. (2005) derived the expression of the friction coefficient in equation (1), as:

$$\mu(I) = \mu_s + \frac{\mu_2 - \mu_s}{I_0/I + 1} \tag{2}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

on the basis of experimental measurements of the basal friction coefficient performed by Pouliquen & Forterre (2002) under an inclined plane flow configuration. In equation (2) $\mu_s = \tan\phi$, ϕ being the static friction angle of the granular medium, while μ_2 and I_0 are fitting parameters. Jop *et al.* (2005) used the local rheology of equation (1) to write the momentum balance for a granular layer flowing on a heap (figure 1) of width W.

They assumed that a semi-infinite granular medium is sandwiched between two vertical smooth plates (sidewalls) and that the flow is uniform along the x-direction with velocity $u(z)$, at an angle θ with horizontal (figure 2). The force balance for the slice of material of length dx, thickness z and width W can be written as:

$$\rho_s \beta_d z dx W g \sin\theta - \rho_s \beta_d z dx W g \cos\theta \mu(I(z)) + \\ -2\rho_s \beta_d dx g \cos\theta \int_0^z \mu_w z' dz' = 0 \quad (3)$$

where β_d is assumed constant over z, and g is gravity.

The first term on the left hand side of equation (3) is the effect of gravitational forces; the second term is the friction force exerted by the bed in accordance with the rheology of equation (1); the last term is a supplementary resistance force which is due to the friction with the sidewalls. Here we assume that a pure solid friction force develops at the sidewalls. This implies that the wall friction coefficient, μ_w, is constant and equal to $\tan\delta$, with δ the (measured) friction angle between the grains and the wall. In equation (3) there is the further assumption of considering the normal stress in the granular medium as isotropic. This is shown to be reasonable by numerical experiments (Gutfraind & Pouliquen 1996). Jop et al. (2005) used equations (1)–(3) and obtained the velocity profile and the variations of the inclination of the surface velocity and of the thickness with the flow rate. They presented comparisons with experiments related to the flow of glass beads on a heap.

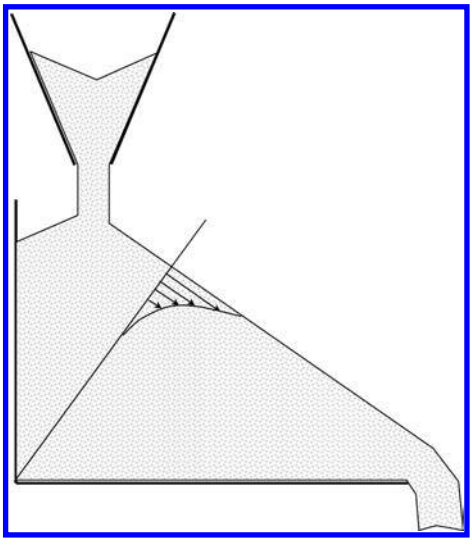

Figure 1. Granular flow on a heap.

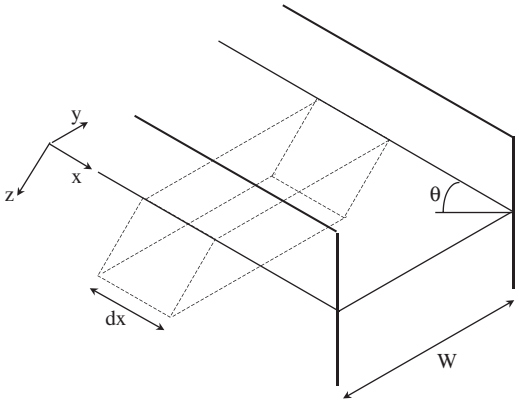

Figure 2. Sketch of the geometry in the force balance of equation (3).

Here, we choose to adopt a constitutive model for the shear stress of a dry granular flow in frictional regime derived by Berzi & Larcan (unpubl.) and successfully tested for reproducing the planar dry flow of cohesionless homogeneous granular material between parallel plates. In the following, the physical arguments behind the constitutive model of Berzi & Larcan (unpubl.) are reported.

Firstly, Zhang & Rauenzahn (2000) showed that in a dense granular flow the shear stress is characterized by an asymptotic finite value when the strain rate goes to zero. However, in order to explain the development of shear zone in the flow domain, also a dependence on the strain rate has to be taken into account. The more simple way for making the shear stress compatible with these statements is to express it as the sum of two components, according to the following expression:

$$\tau = \sigma \tan\phi + \mu_g \dot{\gamma} \quad (4)$$

where the first term on the right hand side of equation (4) is a Coulomb type yield component and μ_g is a granular viscosity coefficient. The last term on the right hand side of equation (4) can be treated in the frame of the kinetic theories (Jenkins & Savage 1983, Lun et al. 1984, Lun 1991) if one assumes that is related to the so called 'weak' population (clusters which are surrounded by network of grains in close contact and mainly experience collisions), as defined by Ancey and

Copyright © 2006 Taylor & Francis Group plc, London, UK

Evesque (2000). Hence the granular viscosity, μ_g, can be expressed as (see, e.g., Lun 1991):

$$\mu_g = \rho_s d T^{\frac{1}{2}} f_1(e, \beta, \beta_d) \tag{5}$$

Here, f_1 is a coefficient, whose expression can be found in the paper of Lun (1991), function of the solid volume fraction β_d, of the restitution coefficient, e, and of the roughness coefficient, β, while T is the granular temperature, defined as one-third the mean squared value of the velocity fluctuations.

Dimensional analysis shows that the constitutive relation for the normal stress has the following general non-dimensional expression:

$$\Im\left(\frac{\sigma}{\rho_s T}, \beta_d, e, \beta\right) = 0 \tag{6}$$

By rendering explicit β_d from equation (6) and substituting into equation (5), one obtains:

$$\mu_g = \rho_s d T^{\frac{1}{2}} f_2\left(e, \beta, \frac{\sigma}{\rho_s T}\right) = \rho_s d T^{\frac{1}{2}} f_3(e, \beta) f_4\left(\frac{\sigma}{\rho_s T}\right) \tag{7}$$

Here, f_2 is a coefficient depending on $\sigma/\rho_s T$, e and β and it is assumed that it can be expressed as a coefficient f_3, which depends on e and β, times a coefficient f_4, which instead depends only on $\sigma/\rho_s T$. In a dense flow the high solid volume fraction causes probably a saturation of the collision rate. Hence, a linear dependence of the shear stress on the strain rate is to be expected (Zhang & Rauenzahn 1997). The μ_g coefficient must be therefore independent on granular temperature and the coefficient f_4 must have the following expression:

$$f_4 = \kappa\left(\frac{\sigma}{\rho_s T}\right)^{\frac{1}{2}} \tag{8}$$

where κ is a dimensionless constant. Using equation (8) into equation (7) leads to:

$$\mu_g = \chi \sigma^{0.5} \tag{9}$$

Here, $\chi = \kappa \rho_s^{0.5} d f_3$ is a coefficient depending only on the grain properties. Finally, the shear stress of equation (4) can be expressed as:

$$\tau = \sigma \tan\phi + \chi\sqrt{\sigma}\dot{\gamma} \tag{10}$$

The coefficient χ appearing in equation (10) is the only parameter of the model. The local rheology of equation (10) is compatible with the analysis of GDR MiDi (2004), provided that a simple manipulation leads to:

$$\frac{\tau}{\sigma} = \tan\phi + \frac{\sqrt{\beta_d}\chi}{\sqrt{\rho_s d}} \frac{\dot{\gamma} d}{\sqrt{\beta_d \sigma/\rho_s}} = \\ = \tan\phi + \frac{\sqrt{\beta_d}\chi}{\sqrt{\rho_s d}} I = \mu(I) \tag{11}$$

Thus, even adopting the constitutive model of equation (10), the friction coefficient μ related to a certain granular material (characterized by a well defined diameter, static friction angle and volume fraction) depends only on the parameter I.

Then, we can use equation (11) and equation (3) to derive the expression of velocity profile of the grains. Equation (3) can be written as:

$$\tan\theta - \tan\phi - \frac{\sqrt{\beta_d}\chi}{\sqrt{\rho_s d}} I - \tan\delta \frac{z}{W} = 0 \tag{12}$$

If we set $I = 0$ in equation (12), we obtain the depth h of the flowing layer over the heap, i.e., the position of the transition between the fluid-like and the solid-like behaviour of the particulate system, where the shear rate vanishes:

$$h = \frac{\tan\theta - \tan\phi}{\tan\delta} W \tag{13}$$

Equation (13) is the same relationship obtained by Jop et al. (2005) and reveals that the depth of the flowing layer is controlled by the sidewalls. Indeed, under the assumption of indefinite planar surface flow ($W \to \infty$), which is mathematically equivalent to considering a negligible effect of the sidewalls ($\tan\delta \to 0$), $h \to \infty$, so that no granular static layer under a granular flowing layer can be observed.

Substitution of the expression of the parameter I and $\dot{\gamma} = du/dz$ into equation (12) leads to:

$$\frac{du^*}{dz^*} = -C_1\left(C_2 z^{*\frac{1}{2}} - C_3 z^{*\frac{3}{2}}\right) \tag{14}$$

where the expressions of the coefficients C_1, C_2 and C_3 are the following:

$$C_1 = \frac{d\sqrt{\rho_s \cos\theta}}{\chi} \\ C_2 = \tan\theta - \tan\phi \\ C_3 = \frac{\tan\delta}{W^*} \tag{15}$$

Here, we have introduced the non-dimensional variables $u^* = u/\sqrt{gd}$, $z^* = z/d$ and $W^* = W/d$.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Integrating equation (14) with the boundary condition $u^* = 0$ for $z^* = h^* = h/d$ leads to:

$$u^* = \frac{2}{3} C_1 C_2 \left(h^{*\frac{3}{2}} - z^{*\frac{3}{2}} \right) - \frac{2}{5} C_1 C_3 \left(h^{*\frac{5}{2}} - z^{*\frac{5}{2}} \right) \qquad (16)$$

Then, integrating equation (16) from the bottom of the flowing layer ($z^* = h^*$) to the free surface leads to:

$$\frac{V^*}{W^{*\frac{3}{2}}} = \frac{4}{35} C_1 C_2 \left(\frac{h^*}{W^*} \right)^{\frac{3}{2}} \qquad (17)$$

where V^* is the non-dimensional mean velocity of the flowing layer. Equation (17) can be written in terms of the non-dimensional flow rate per width unit, $Q^* = V^* h^*$, as:

$$\frac{Q^*}{W^{*\frac{5}{2}}} = \frac{4}{35} C_1 C_2 \left(\frac{h^*}{W^*} \right)^{\frac{5}{2}} \qquad (18)$$

Equations (17)–(18) show the correct scaling for the flow properties already found by Jop et al. (2005).

Equations (13) and (18) show that, once the flow rate is fixed, both the depth of the flowing layer and the inclination of the free surface can be determined. It must be underlined that only one parameter needs to be set, i.e., the coefficient χ relative to the homogeneous granular material used, as opposed to the rheology adopted by Jop et al. (2005) in which there are two fitting parameters. The measurement of the inclination, θ, and of the depth, h^*, for one value of the flow rate Q^* are sufficient to determine the value of the coefficient χ for the granular material used in the experiments. All additional runs, when performed with the same grains, can, therefore, be used for assessing the validity of the equation (11).

3 COMPARISON WITH EXPERIMENTS

Jop *et al.* (2005) performed several tests concerning the surface flow of glass beads (diameter $d = 0.53$ mm, density $\rho_s = 2450$ kg/m^3, static friction angle $\phi = 20.9°$ and $\beta_d = 0.6$) on a heap adjusting the gap W between the smooth lateral glass walls (friction angle $\delta = 10.4°$) from 1 cm up to 30 cm. They were able to set the flow rate and to measure inclination, surface velocity and depth of the flowing layer.

These experimental results can be used as a term of comparison against our theoretical predictions, once the value of the coefficient χ for the glass beads is determined. By substituting equation (13) into equation (18) we obtain a relationship between the non-dimensional flow rate and the inclination of the free surface. Hence, introducing a couple of experimental values of $Q^*/W^{*5/2}$ and $\tan\theta$ in this relation allows for obtaining the coefficient χ. We used the measured values of $Q^*/W^{*5/2} = 0.000384$ and $\tan\theta = 0.443$ and obtained $\chi = 0.03$ (kg/m)$^{1/2}$. We then used this value and solved equations (13)–(18) for different non-dimensional flow rates. The dependence of $\tan\theta$ on the non-dimensional flow rate is depicted in figure 3, together with the experiments performed by Jop et al. (2005) and the results of their model; the arrow indicates the experimental point used for setting the coefficient χ.

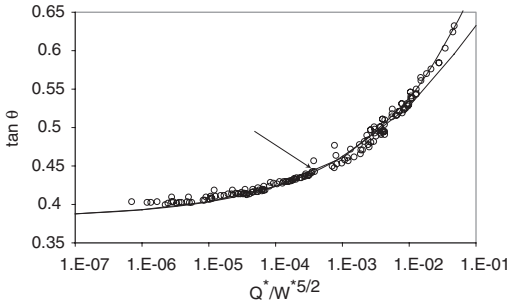

Figure 3. Inclination angle against non-dimensional flow rate (—, present theory; - - -, Jop et al. theory; ○, experiments by Jop et al.).

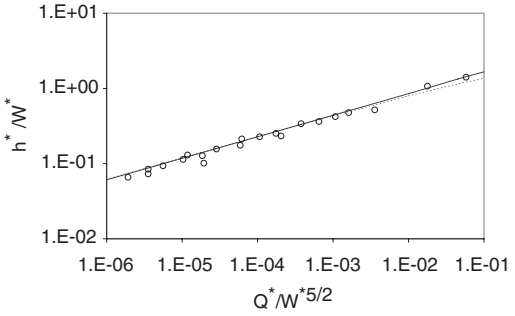

Figure 4. Non-dimensional flow depth against non-dimensional flow rate (—, present theory; - - -, Jop et al. theory; ○, experiments by Jop et al.).

It can be noticed that there is an excellent agreement between the present theory and the experiments, even at the highest values of $Q^*/W^{*5}/2$, where the model proposed by Jop et al. (2005) underestimates the inclination angle.

Figure 4 shows the dependence of the non-dimensional depth of the flowing layer on the non-dimensional flow rate. Once again, the agreement between theory and experiments is excellent. The curve depicted in figure 4 represents the flow rule of

Copyright © 2006 Taylor & Francis Group plc, London, UK

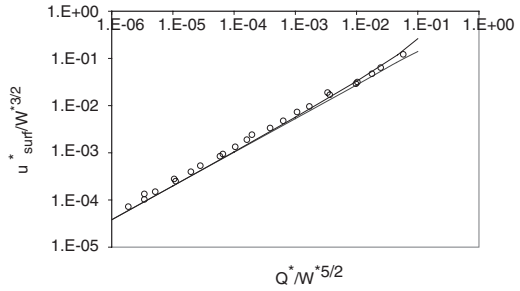

Figure 5. Non-dimensional surface velocity against non-dimensional flow rate (—, present theory; - - -, Jop et al. theory; ○, experiments by Jop et al.).

the granular medium. Thus, it could be used in conjunction with depth-integrated models, such as those based on the Saint Venant equations, to simulate granular avalanche. However, it must be underlined that our model is related to the case of frictional regime, i.e. when most of the flow field is governed by the long-lived interparticle contacts. On the other hand, in a real-scale phenomenon the collisions between the grains could play the major role in governing the dynamics of the granular avalanche.

The agreement between theoretical and experimental results shown in figures 3 and 4 suggests that the flow regime of the granular flows examined was globally frictional. Nevertheless, it is likely that a thin collisional layer develops near to the free surface. The existence of this layer could explain the slight underestimation of the surface velocity $u^*_{surf}/W^{*3/2}$ provided by the curve in figure 5. The theoretical values are obtained by setting $z^* = 0$ in equation (16).

4 CONCLUDING REMARKS

We focused on the frictional surface flow between sidewalls of a dry granular medium over a static layer composed of the same particles of the flux. We tested a constitutive model for the shear stress recently proposed and successfully used in the case of a planar dry granular flow between parallel plates by Berzi & Larcan (unpubl.). This constitutive model allowed to obtain the mathematical relationships between the flow properties and the flow rate and to compare them with the experiments performed by Jop et al. (2005) with glass beads. The notable agreement between theory and experiments confirms the validity of the theoretical model of Berzi & Larcan.

The constitutive models introduced by Berzi & Larcan (unpubl.) and by Jop et al. (2005) suggest that the shear stress is the sum of a rate-independent and a rate-dependent factor. While expressions for the former coincide, the latter factor is different for the two models. The agreement of the present theory with experiments is excellent also at the highest values of the flow rate, i.e., when the rate-dependent part of the shear stress becomes important. Therefore, the constitutive model of Berzi & Larcan (unpubl.) shows a superior capability of predicting the granular flow behaviour under frictional regime and has the additional key advantage of being characterized by only one fitting parameter, which is a function of the type of grains, as opposed to the two-parameters constitutive model of Jop et al. (2005).

ABSTRACT: The purposes of this work are to experimentally analyze the impact of dry and saturated granular flows on obstacles of various shapes and to compare the maximum forces measured in the experiments with the ones predictable with analytical formulae available in the literature.

Effects of interstitial fluid, mixture composition, obstacle size, shape and orientation were examined. Experimental results do not show a particular relevance of grain size composition, whereas obstacle orientation and height clearly affect the maximum force value.

Measurements of the impact process against high dams show that saturated mixtures, like clear water, form vertical jets with instantaneous overshoots one order of magnitude greater than the force corresponding to the hydrostatic front pressure. Immediately after the impulse, measured forces exerted by both dry and saturated mixtures are very similar, accounting for the different mixture densities, and are well approximated by analytical literature equations.

1 INTRODUCTION

Avalanches and debris flows exert enormous impact forces on obstacles in their path, such as bridge piles, defensive walls and buildings. The estimation of these forces is necessary for planning defensive structures (Okuda et al. 1980); researchers developed different automatic devices to measure the debris impact, some of which record only the maximum impact as a pressure mark (Okuda et al. 1980). The Mechanics Institute of the Chinese Academy of Sciences built a specifically designed piezo-electrical sensor: from the more than 70 impact force graphs collected by Zhang (Zhang, 1993) since 1982, fluid dynamic pressures were found as high as 5×10^3 kN/m^2 and impulse forces of individual boulders as great as 3×10^3 kN. Large-scale model tests of flexible barriers by (DeNatale et al. 1997 and 1999) showed that forces in the anchor cables exceeded the loaded cell capacity of 45 kN.

As field monitoring and measurements in mountain areas are generally quite difficult and expensive due to the particular environment and the nature of debris events, experiments are needed to improve the knowledge of debris forces and thus the design of defence works. Until now, physical modeling has been focused on mixture impacts against dams with height equal or higher than flow depth, which are, according to Hungr et al. (1998), the most common case in the field: forces on wall were analyzed by Armanini and Scotton (1993) for water-PolyVinil Chloride (PVC) and anionic-resin mixtures, by Scotton and Deganutti (1997) for granular-water steady surges, by Daido (1993) for sandy mud flows, by Di Paolo et al. (2005) for saturated marble mixtures.

Experiments on granular avalanches motion have been carried out, both for dense and dry snow avalanches, by Naaim-Bouvet et al.(2003), who measured the front velocity variation due to the dam, the dynamic pressures downstream the obstacle and the dependence of run-out shortening on obstacle height.

Objectives of this work are to experimentally analyse debris surge impacts against different type of structures (check-dams, filter-dams, flow-breakers, "houses") in order to find a correct analytical evaluation of impact forces.

The paper is composed of three main parts. The first describes tests carried out with dry and saturated granular mixtures and presents their results: effects on flow energy reduction, deposit extent and shape are investigated accounting for structure's dimensions, shape and orientation with respect to the flow direction.

The second part shows a comparison between some available empirical formulaewhich can be applied to

Copyright © 2006 Taylor & Francis Group plc, London, UK

estimate forces and pressures on the check-dams used in our experiments.

The third part discusses some limitations in the experimental representation of the impact process based on field experience and points out relevant aspects for structural design.

2 EXPERIMENTAL DESIGN

2.1 *Set-up*

Two series of experiments have been carried out, the first, using dry granular mixtures, at the DISTART laboratory (Bologna) while the others, using the same mixtures but in saturated conditions, at the Pavia laboratory.

This section describes first the equipment, which consisted of two chutes, with a reservoir fixed upstream and obstacles fixed downstream. Then, tested materials and measurement devices are presented. Finally, scale effects are discussed.

The DISTART chute is 0.10 m wide and 2.25 m long and is kept at a constant slope of 39° with respect to the horizontal while the Pavia chute is 0.10 m wide and 4.80 m long with a constant slope of 18.5°. The chutes lengths are more than enough to allow the reach of a fully developed flow regime.

The chute bottoms are roughened with 0.3 mm rough sandpaper that was found to properly work under two important aspects, avoiding the material to slide on the bottom as a solid body and avoiding as much as possible the entrapment of finer particles inside the bottom roughness. The different roughness of the bottom and the sides seems to reduce the effects due to chute width and friction at the walls. Chutes sides are transparent to allow optical measurements and video observations.

At the upstream end of the chutes a reservoir with a gate, inclined as the chute, is fixed; a wheel system guarantees a quick opening of the gate and all the material is let rapidly flowing down the chute.

A lever system (the same for both the chutes) is hinged at the downstream end of the chute, see scheme in Figure 1; the obstacle is fixed on the lever system bottom and the impact is transmitted by the upper part of the lever system to the force transducer by means of a screw whose lock has been previously calibrated.

The obstacles are classified into four categories: "houses", flow-breakers, check dams and filter-dams (Figure 2). Houses and flow-breakers are prismatic blocks of square section that differ only for the width; they are positioned in the outlet centre in two ways: perpendicular to the flow (90°, obstacle face orthogonal to the flow) and turned 45° with respect to flow direction. Check dams are prismatic blocks with rectangular section that has the same chute width. Filter dams consist of two teeth with a slope and straight (i.e., perpendicular to the bottom) face and are positioned in two ways: with the straight teeth part facing upstream or downstream the stream.

different grain-size assortment; both mixtures were used dry and saturated.

The mixtures were prepared to represent two typical conditions that frequently occur in the field (Berti et al. 1999). In particular, the first mixture (*mixture 1*) is characterized by widely ranging grain size and its distribution curve was derived following the method by Füller for the perfect distribution curve of the fractions used in the preparation of concrete (Burlamacchi 1994); in fact, in several papers debris are recognised to qualitatively flow "as fresh concrete"; this was pointed out, among the others, by Davies (1985) and Iverson (1997). The second mixture (*mixture 2*) was chosen to be less dispersed (pore not filled in with fine fraction) and biased towards the coarser fraction.

For specific practical reasons, the range of grain sizes used in the laboratory is limited to less than two orders of magnitude: 0.2–8 mm. In fact too fine particles would have produced powders very difficult to be controlled and not much significant for results as they can be retained by chute bottom roughness. On the opposite, too big particles would have got stuck among the teeth of filter dams and could have affected the results.

The properties of the two mixtures were measured without any compaction or vibration and produced similar results: the bulk density in air ρ_b is 1530 kg·m^{-3} for *mixture 1* and 1580 kg·m^{-3} for *mixture 2*; internal friction angle ϕ is 31° for mixture 1 and 33° for mixture 2; porosity is around 0.35 for *mixture 1* and 0.36 for *mixture 2*. Concerning the experiments in saturated conditions a volumetric concentration of 40% in reservoir were used, in agreement with some field data (Iverson, 1997). The granular material in the reservoir was placed behind the gate with a angle equal to internal friction angle and then saturated till the required concentration.

At the end of the tests, some fine material was lost but the amount was always less than few percent and thus not relevant to the outcome of the tests.

2.3 *Measurements*

The force impacting on the obstacles was measured with a load cell fixed with the oscillating lever system to the chute outlet (Fig. 1) with a 118N scale. The acquisition frequency is 25 Hz for the DISTART experiments and 250 Hz for the ones in Pavia. The inertia of the measurement system was found not to be relevant for the measured processes; however, the measure cannot represent the rapidly varying transitory in greater details, i.e., the impulsive force at the impact (Di Paolo et al., 2005).

Two laser level transducers were used to measure flow depth at a frequency of 250 Hz: one was placed at about 0.15 m from the chute outlet, and the other 0.20 m from the first. Front velocity was derived by the front travel time between these two transducers.

Video recordings at the chute side were performed to provide a qualitative description of the flow impacting on the obstacle, with a particular attention to the development of dead zones in presence of houses or flow breakers, to particle saltation in case of filter dams and to the back-waves generating inside the chute in case of sufficiently high check-dams. In the experiments with dry mixtures a standard digital camera was used whereas in the ones with saturated mixtures a high speed digital camera, capable of 240 frames per second with a half VGA resolution, was adopted (Biancardi and Ghilardi, 2003). This camera allowed to automatically measure velocity profiles by means of cross correlation of consecutive frames (Barbolini et al., 2005). The front velocities were in agreement with the ones measured wit laser transducer. In Figure 4 there is an example of a measured velocity profile.

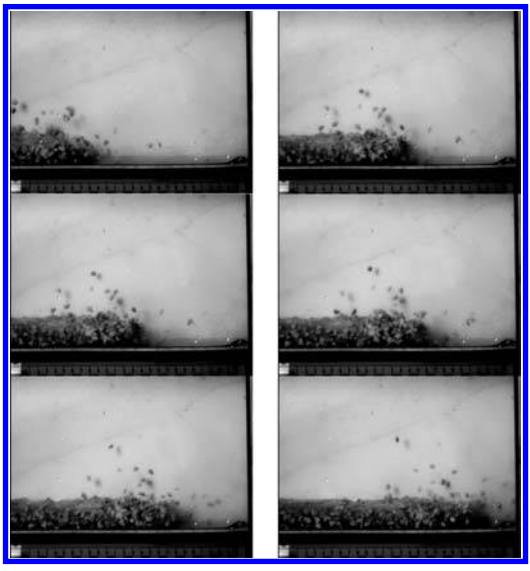

Figure 5. Sequence of images taken with high speed camera of the flow before the impact.

2.4 *Tests*

Several testes were performed, keeping constant for each case (saturated and dry mixtures) channel length, slope and mixture volume whereas mixture composition, obstacle shape and orientation with respect to the flow direction were varied. For each mixture, a preliminary test without any obstacle was carried out in order to evaluate the effects of obstacles on flow and deposition and compare the results with those of the unperturbed case. Tested conditions are summarized in Tab. 1.

At the beginning of each test, the retention gate of the reservoir was instantaneously pulled up, generating at the downstream end of the chute a flow of less than 3 cm peak depth and 3 m/s peak velocity (see results in Tab. 1).

When the front impacts on the obstacle, it produces a force that is transferred by the lever system to the force transducer; the force on the obstacle increases abruptly until a maximum value is achieved, and then decreases with increasing time as flow depth and velocity quickly drop (Figs. 6–7).

All tests were performed more than once in order to check if tested conditions were repeatable and to provide data for possible statistical analysis.

3 RESULTS

The forces on the obstacles develop in time in a way that strictly dependends on the obstacle type: in particular, check-dams retain a certain quantity of material

Table 1. Measured data for experiments carried out. Mx = mixture type (d = dry, s = saturated); Rot = rotation angle respect flow direction, Y_f = front height; U_f = front velocity.

upstream the dam that pushes permanently on the dam itself producing a constant force on the obstacle at the event end, whereas the other obstacles cause only a temporary storage of material that is eventually mobilised at the event tail and therefore no permanent force acts on the obstacle.

3.1 *Mixture saturation*

The presence of water is significant only in the case of wide obstacles with respect to channel section, check-dams and filter dams. Inside a saturated mass, neutral over-pressures are present and persist during the impact process (Iverson 1997; Major et al. 1999); they develop at the impact into vertical accelerations due to the incompressible interstitial fluid. The formation of vertical jets at walls occurs also in case of clear water (Partenscky, 1988; Rams-den 1996), whereas does not show up in case of a dry granular flow, that reflects more or less as a single back-wave. This behaviour is probably due to the compressibility of the dry porous media and thus to its capacity of compressing at the impact and dilating during shearing. Both in water and in saturated mixtures initial overshoots lasting less than 0.1 s were recorded, with peak values one order of magnitude higher than the force corresponding to the hydrostatic front pressure.

3.2 *Obstacle height*

When the whole channel width is crossed by a dam, dam height and slope (if it has) are critical parameters. The higher the dam, the greater the force and the shorter the downstream deposit.

Flow impact on check-dams produces in general a very abrupt arise of the force to the maximum value F_{max} that is strictly related to the ratio of dam height to flow depth. The lowest dam used in the experiments has an height which is less than the peak depth, and it is able to retain only a small amount of material: the force F_{fin} still acting on the dam when the flow stops is very low.

The medium dam and the highest dam, which are more than two times higher than the peak depth, produce an almost complete reflection of the flow inside the chute and a deposit upstream of the obstacle. The force peak values are similar in both cases.

The values of F_{fin} are not negligible and can be compared to those of the soil forces on retaining walls, which can be estimated in the range:

$$F_{fin} = \frac{1}{2}\rho_b g b y_{ob}^2 \frac{1-\sin\varphi}{1+\sin\varphi} \div \frac{1}{2}\rho_b g b y_{ob}^2 \frac{1+\sin\varphi}{1-\sin\varphi} \qquad (1)$$

where y_{ob} is the depth of the material at rest on the obstacle, g is the acceleration due to gravity and b is the chute/dam width. The two expressions in (1) represent, respectively, an active thrust, due to the elastic motion of the soil towards the walls, and a passive thrust, due to the elastic motion of the walls towards the soil. It has to be noted that (1) gives only the range of values for F_{fin}

Copyright © 2006 Taylor & Francis Group plc, London, UK

as it cannot be a priori predicted if the last soil motion will be towards or away from the side walls. In the case of saturated mixture this force slowly decreases because of the water drainage after the stop.

3.3 *Obstacle orientation*

The force exerted on houses and filter dams depends, both in cases of saturated and dry mixtures, on the obstacle orientation. In the first case, the obstacle acts like a spring-board for the coarser particles and the average flow is only decelerated but not retained behind the dam, which generates the lowest value of F_{max} (Tab. 1). In the second case, the flow is decelerated by the dam teeth but continues flowing until the spacing between teeth is partially filled up and then material is retained upstream. In this case, the measured force is larger and is comparable to that exerted on the medium check-dam. In particular, for the filter dams the ratio between F_{max} measured with teeth slope upstream and downstream is about two in the case of saturated mixture and up to five for dry material.

For obstacles such as houses and flow-breakers, a relevant effect on maximum force and deposit extension is the orientation of the obstacle with respect to flow direction. Houses and flow-breakers rotated at 45° are subjected to much greater force, because of the larger surface on which the flow impacts; these obstacles cause wider deposits than all the others because their shape forces the material to divide and flow towards the sides of the deposition plane. The edges of such rotated obstacles appear to be subject to such great forces that may in real cases produce structural damages due to engraving and fatigue effects.

For houses, the rotation from 90° to 45° does not significantly affect the value of impact force except for a small increase due to the wider side of the obstacle exposed to the flow.

3.4 *Mixture composition*

Maximum forces are mainly affected by obstacles design and orientation, but also mixture composition plays an important role since mixtures composed of higher fractions of coarser particles produce higher forces due to greater density and friction angle.

4 EXISTING DESIGN FORMULAE

Formulae for estimation of design debris flow forces per unit width are available only for flows against walls with width equal to channel width and height equal or higher than flow depth. In this case, two 'families' of formulae can be found in the literature.

The first is proper of slow flows and enlightens the pressure term. In the work by Armanini and Scotton (1993), the impact force (per unit width) of water-PVC mixtures F is approximated by:

$$F \approx 9\rho_m g \frac{y_n^2}{2} \tag{2}$$

where y_n can be assumed equal to the obstacle height. Similarly, the recommendations by some European torrent control authorities for designing structures in mountain torrents suggest (1973):

$$F = (7 \div 11)\rho_m g \frac{y_f^2}{2} \tag{3}$$

with y_f defined as the "maximum surge depth".

A similar expression was obtained by Scotton and Deganutti (1997) for the range of pressure increase at a wall with respect to the front hydrostatic pressure:

$$\Delta p = (2.5 \div 7.5)\rho_m g y_f \tag{4}$$

The second type of formulae is proper of rapid flows and enlightens the momentum of the incoming flow. Italian guidelines for mudflows (Commissario di Governo per l'Emergenza Idrogeologica nella regione Campania, 2001) propose to assume the total force as the sum of dynamic pressure and static pressure acting on the obstacle surface:

$$F = \rho_m u_f^2 \cos^2\theta\, y_f + \frac{1}{2}\rho_m g y_f^2 \tag{5}$$

An expression for mud forces against a wall is also given by Daido (1993):

$$F = (5 \div 12)\rho_m y_n u_n^2 \tag{6}$$

where u is the mean flow velocity, or the surge pressure given by Armanini and Scotton (1993):

$$\Delta p = \rho_m u_f (u_f + a) = \alpha_p \rho_m u_f^2 \tag{7}$$

where a is the celerity of the reflected wave and α_p is an impact coefficient that varies from 2.0 for slow and stony debris to 0.7 for rapid and muddy debris.

Equations (2), (3) and (6) propose different coefficients and different parameters, in particular y_n or y_f. In case of multiple surge events, without other specifications, y_f shall be assumed equal to the maximum depth value which can be up to three times y_n and thus the coefficient in (3) results (7 ÷ 11) times greater than the coefficient in (2). It appears thus very dangerous to extend equations like (2), (3) and (6) without taking care of the special conditions for which they were derived and also of the values they adopt (front or

Copyright © 2006 Taylor & Francis Group plc, London, UK

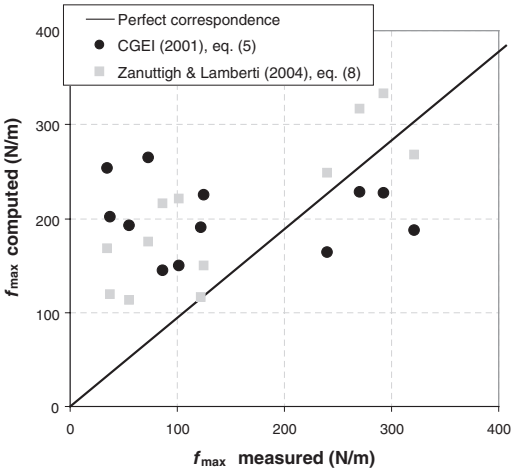

Figure 8. Comparison among measured forces and maximum forces computed with equations (5) and (8).

average or surge depth, front or average or maximum velocity).

Another approach is proposed by Zanuttigh and Lamberti (2006) under the hypothesis of a vertical wall against which a total reflection occurs. It consists of applying the momentum balance to the control volume including the upstream moving hydraulic jump that forms after the impact.

$$F = C_s \frac{(1+\sqrt{2}Fr_f)^2}{2} \rho_m g y_f^2 \qquad (8)$$

where C_s is a safety factor to account for non represented processes in the experiments, as boulders and vertical accelerations at the impact. The values for C_s suggested for calculating F are equal to 1.0 for stony debris and to 1.5 for muddy debris (Zanuttigh and Lamberti, 2006).

4.1 *Comparison with existing formulas*

We tested the capability of some existing formulaeto predict the force values recorded in our laboratories. Since presented formulae do not consider the obstacle shape, in particular the orientation of the obstacles with respect to the flow direction, the data set used for this comparison is made up only of check dam experiments.

Relation proposed by Armanini and Scotton (1993) and Scotton and Deganutti (1997) does not consider the dependence of force from velocity. Calculated forces result higher than those measured in our tests and the behavior of the forces is not well fit.

The Daido (1993) formula overestimates several times the measured forces, probably because the coefficient that multiply dynamic pressure, assumed by the author equal to 5 to 15, is too high and it is more appropriate to calculate impulsive forces due to pore pressure and boulders impact; however, these were not measured by our experimental set-up (Di Paolo et al. 2005).

A good agreement with experimental data is generally given by Italian guidelines (5); however, for the highest values of velocity they underestimate the measured force value. A better result is given from equation (8) with $C_s = 0.3$ for dry granular material and $C_s = 1$ for saturated material (Zanuttigh and Lamberti, 2006). That formula has a good agreement with experimental data, and underestimates measured forces in only one case (Figure 8).

5 CONCLUSIONS

The impact of dry and saturated granular flows on obstacles of various shapes has been experimentally analysed.

The impact process of granular flows on obstacles can be approximated by the impact of an inviscid fluid flow and equation (8) was found to be a good approximation to evaluate debris design force on structures.

Experiments show that the orientation of defence structures with respect to flow direction is strongly relevant on the recorded impact force values, but it is not considered in the existing design formulae.

Dynamic forces in nature are composed by an average and a fluctuant component. Solicitations due to the impacts of single boulders on obstacles and thus the fluctuant force components were not identified in this set of experiments but can be very important in determining fatigue over structures and can be regarded as an aim for a further work to improve the analytical prediction of forces acting on structures during real field events.

Limiting conditions for the existence of permanent periodic roll waves in stony debris flows

S. Longo
Department of Civil Engineering, University of Parma, Parma, Italy

ABSTRACT: This paper is about the free surface instabilities of granular flows, usually called roll waves. A shallow layer of dilatant (shear thickening) fluid is considered to study finite amplitude permanent roll waves down a slope, simplified by Karman's momentum integral approach. The existence of conditions of a periodic discontinuous solution is derived, as smooth profiles with depth increasing monotonically between periodic shocks. Energy dissipation in the body of the stream and in the discontinuity are analysed and discussed. Two conditions are derived. The first is related to the physically acceptable shape of the smooth profiles, and the second is related to positive energy loss across the shock. A minimum-length roll wave (MLRW) is defined as the periodic permanent roll waves with zero energy dissipation in the shock. Some properties of the MLRW are compared with the available results.

1 INTRODUCTION

Free-surface instabilities of flows down inclined channels have been widely observed in Newtonian and non-Newtonian fluids. Natural gravity flows as debris flows are recorded in many areas and are a constant reminder of the need for prediction and control. In most cases, the flow of mud and debris is far from uniform and stationary. It manifests a succession of waves which, given enough space, develop into long waves. This behaviour is common to water and many non-Newtonian fluids. Roll waves can develop in laminar or turbulent flows and are essentially controlled by the Froude number. Several authors in many areas have reported observations of roll waves in mud flows. The widespread formation of free-surface instabilities, independent of the rheological properties of the fluid, is due to the effects of inertia: if the flow field could adjust its characteristics instantaneously, it would respond to a variation of the current depth reducing the local mean velocity, and the wave would simply be a kinematic wave. In real situations, the response is delayed, and an increased current depth enhances a positive mass flux, leading to the growth of the perturbation (Smith 1990; Forterre & Pouliquen 2003). In addition, the presumed structure of the wall boundary layer favours the growth of the perturbations: the adverse gradient pressure acts to destabilise the boundary layer, reducing the wall friction and accelerating the wave crest (Longo 2004). Dressler (1949) also emphasised the need for a friction reduction in the flow direction, from smaller to larger water depths, in order to obtain roll waves. Although the rheological properties of the fluid do not control the instability mechanism, all the characteristics of the development of the wave depend on those properties.

The first study of the phenomenon was based on linear-stability analysis of the basic equations written in the long-wave approximation and applied to the laminar current. In turbulent flow in rectangular channels, assuming a Chézy resistance law with a constant coefficient, Jeffreys (1925), Stoker (1957), and Liggett (1975) found a critical Froude number of 2.

Dressler (1949) developed the finite-amplitude wave theory. In his paper, Dressler described discontinuous periodic solutions obtained joining Bresse profiles with shocks. Dressler's theory, originally developed for fully turbulent flows, was extended to laminar flows for Newtonian fluids by Ishihara et al. (1954) and to power-law fluids by Ng & Mei (1994), who essentially focussed on pseudoplastic fluids (mud). Prasad et al. (2000) applied Dressler's theory to flowing dry grains at moderate-low void concentration (the inter-particles fluid is air). In their analysis, which was based on experiments, the authors assumed that a large increase in the volumetric solid fraction takes place near the front of the wave. They approximate the depth-averaged dispersed flow of the grain in a manner similar to those of shallow fluid flow. Forterre & Pouliquen (2003) carried out experiments on long-surface-wave instability in granular material flows in dense regimes, using a linear-stability analysis to predict many features of the waves.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Most of the results available refer to the limit condition for the existence of roll waves, but no one can infer the determination of roll-wave parameters (wavelength, wave height, celerity) for a given system. There are some experimental indications from Ponce & Maisner (1993), who, using Brock's data (1967), found that the observed periodic roll waves match the maximum growth rate (in linear-stability analysis). Referring to frequency, Kapitza (1948) suggested that all waves are expected to be unstable, and the least unstable are selected by the system. He also suggested that the observed waves have the maximum absolute rate of energy dissipation. A different criterion is developed by Ng & Mei (1994), who infer that the observed roll wave has the lowest amplitude corresponding to no energy loss across the shock.

In this paper, Dressler's theory is extended to granular flows in dense regimes. The friction law for dry, granular materials flowing in a dense regime is a subject for research; our assumptions are a simplification. Some recent results on this topic suggest that a generalised basal-friction law (Pouliquen 1999) can quantitatively predict rather well the long-wave instability of dry, granular material (Forterre & Pouliquen 2003). In the present analysis, it is assumed that grains behave like a power-law fluid, with a fluid index (the exponent of the shear rate in the constitutive equation) of $n = 2$ (dilatant fluid). Dilatant fluids in which $n = 2$ were experimentally described and modelled by Bagnold (1954) for granular mixture at a relatively high shear rate. They also correspond to dry, granular material at large grain-volume concentrations and moderate shear rates. We will assume this value for the fluid index, but we need to mention that Chen & Ling (1996, 1998) and Hunt et al. (2002) revisited Bagnold's data and concluded that the value of the fluid index is ~ 1.5. It is assumed that the fluid is homogeneous and that no segregation occurs.

The roll waves herein described are periodic, discontinuous solutions with a discontinuity (shock) connecting a smooth profile in a shallow-flow approximation. The waves are permanent and move downstream with a celerity higher than the maximum fluid velocity. It is assumed that they are permanent and stable.

The next section is devoted to deriving the basic equations applying Karman's momentum-integral method. In §3, we describe the 'special solution', and in §4 we obtain a first admissibility condition for roll waves in a dilatant fluid. In §5, the discontinuity between two subsequent waves is analysed under some restrictive hypotheses. Section 6 is devoted to energy balance in the discontinuity, with the derivation of a second admissibility condition. In §7 and in §8, the Minimum Length Roll Waves is discussed and the limiting discharge condition is interpreted, using the two admissibility conditions, with comparison between experiments and theory. The energy balance in the unstable stream is treated in §9, and discussion and conclusions are given in §10 and §11.

2 BALANCE AND CONSERVATION EQUATIONS

Let us consider a 2D laminar flow of a fluid down a plane of inclination θ. The coordinate system has the x-axis along the bed and the y-axis normal to it. For long waves, we can assume that variations in the flow occur on lengths larger than the thickness. Applying Karman's momentum integral method to mass conservation and linear-momentum balance, we obtain the following set of equations:

$$\begin{cases} y_{,t} + (uy)_{,x} = 0 \\ u_{,t} + \beta u u_{,x} - (\beta - 1)\dfrac{u}{A}\dfrac{dA}{dy} y_{,t} + \\ rg\cos\theta\, y_{,x} + u^2 \beta_{,x} = g\sin\theta - \dfrac{\tau_b}{\rho R} \end{cases} \tag{1}$$

where u is the depth average velocity of flow function of the longitudinal coordinate x at time t, A is the cross-sectional area of flow, y is the depth of the flow, β is the momentum flux factor (equal to 5/4 for a dilatant fluid in laminar condition in a very wide rectangular section and with $n = 2$), and r is the ratio of the normal stress in the x-direction to the normal stress in the y-direction. g is the acceleration of gravity, τ_b is the average boundary shear stress, ρ is the bulk mass density, R is the hydraulic radius of the flow. The first equation is the mass conservation; the second equation is the momentum-balance equation.

For non-uniform flow, r could depend on the divergence of the flow (Gray et al. 1999) but many numerical simulations have shown that this ratio is equal to ~ 1 for dense granular flows (Ertas et al. 2001).

Introducing a moving reference having celerity c, and assuming that in the moving reference the chosen state variables U and Y are functions of $\xi = x - ct$ only, the two equations (1) for a wide channel ($R \approx Y$) become:

$$\begin{cases} (UY)_{,\xi} - cY_{,\xi} = 0 \\ -cU_{,\xi} + \beta U U_{,\xi} + c(\beta - 1)\dfrac{U}{Y} Y_{,\xi} + \\ rg\cos\theta\, Y_{,\xi} = g\sin\theta - \dfrac{\tau_b}{\rho Y} \end{cases} \tag{2}$$

where the spatial variation of the momentum flux correction term has been dropped, even though this term should always be retained in order to satisfy the principle of frame indifference (Chen 1992).

Copyright © 2006 Taylor & Francis Group plc, London, UK

Rearranging the two equations and integrating results:

$$U = \frac{(cY - K)}{Y} \tag{3}$$

where K is the constant discharge per unit width in the moving frame. It was defined as 'overrun' by Chow (1959) and 'progressive discharge' by Dressler (1949). The discharge in the fixed frame varies with space and time.

For dilatant power-law fluid with $n = 2$, the bottom shear stress in a wide channel is

$$\tau_b = \rho a \frac{U^2}{Y^2} \tag{4}$$

and the energy slope is $j = aU^2/gY^3$, where a is a parameter (depending on the density, size, concentration of grains, and internal friction for a granular mixture) with the dimension of a square length.

On using expressions 3 and 4 and assuming a length scale for both horizontal and vertical directions $l = c^2/g$, equation 2 can be rearranged and written in non-dimensional form as:

$$Y^*_{,\xi^*} = \sin\theta \frac{\left[Y^{*5} - b\left(Y^* - K^*\right)^2\right]}{Y^{*2}\left[\beta Y^{*2} - Y^{*2} + rY^{*3}\cos\theta - \beta K^{*2}\right]} \tag{5}$$

where $b = \frac{a}{\sin\theta}\frac{g^2}{c^4}$, K^* is the non dimensional constant discharge per unit width in the moving frame, ξ^* is the non dimensional abscissa in the moving frame and $Y^*_{...} = Y_{...}g/c^2$.

3 THE 'SPECIAL SOLUTION'

Owing to the kind of functions obtained integrating equation 5 (logarithm, hyperbolic function, polynomials), no periodic solution is forecast for the wave profile. A possible solution is a discontinuous periodic solution, piecing together continuous profiles with shocks. Such a solution was suggested by Dressler (1949) for Newtonian fluid. Dressler named it the 'special solution', and we will follow the same definition. As for a Newtonian fluid, the solution has to admit a region with supercritical mean velocity and a second region with sub-critical mean velocity (in the moving reference). The two regions are separated by a critical section with mean velocity equal to the critical velocity. The flow depth in the critical section is Y_c.

There is experimental evidence that a roll-waves profile in a Newtonian fluid has a finite steepness in the critical section. We assume that this holds true also for roll waves in a granular flow and it is possible to demonstrate that no solution with an inflection point is possible.

As a consequence, the possible periodic solution requires that the critical depth also be a root of the numerator in equation 5 in order to have a finite steepness. The pole in $Y = Y_c$ must be erased. The result is that both numerator and denominator vanish in Y_c.

The apparent discharge is also constrained. Using mass conservation and equation 3 results in:

$$K^{*2} = \frac{Y_c^{*2}(\beta - 1) + rY_c^{*3}\cos\theta}{\beta} \tag{6}$$

Substituting equation 6 in the wave profile (equation 5) and considering that both numerator and denominator vanish in the critical section, results in:

$$Y^*_{,\xi^*} = \sin\theta \left[\frac{Y^{*4} + Y_c^* Y^{*3} + Y_c^{*2} Y^{*2} + \left(Y_c^{*3} - b\right)Y^* + \frac{bY_c^*}{\beta}\left[(\beta - 1) + Y_c^* r\cos\theta\right]}{Y^{*2}\left[(\beta - 1)\left(Y^* + Y_c^*\right) + r\cos\theta\left(Y^{*2} + Y_c^* Y^* + Y_c^{*2}\right)\right]}\right] \times \frac{1}{} \tag{7}$$

4 LIMITING CONDITION FOR A POSITIVE STEEPNESS OF THE PROFILE

In order to construct roll waves from the previous profile, it is necessary that $dY^*/d\xi^*|_{Y^*c} > 0$. The denominator in equation 7 is always positive. In the critical section, we simply have to make the numerator positive also. This condition is satisfied if (Longo 2003):

$$b < b_{crit} = \frac{25}{4}\left(\frac{25 - 16\beta}{25r\cos\theta}\right)^3 \tag{8}$$

The inequality 8 can also be expressed as:

$$c > c_{crit} = \left(\frac{ag^2 r^3}{\tan\theta\left(1 + \tan^2\theta\right)}\frac{4}{25}\left(\frac{25}{25 - 16\beta}\right)^3\right)^{1/4} \tag{9}$$

In this form, our findings indicate that, for a given bottom inclination and a given rheological parameter of the dilatant fluid, only waves with celerity higher than the critical celerity can propagate. Roll waves can exist only if the condition $c > U$ is satisfied. As a consequence, equation 9 can be extended in the form $c > c_{crit} > U$, and using the resistance law, the discharge per unit width q has an upper limit given by the following inequality:

$$\left(\frac{gq^3\sin\theta}{a}\right)^{1/5} < \left(\frac{ag^2 r^3}{\tan\theta\left(1 + \tan^2\theta\right)}\frac{4}{25}\left(\frac{25}{25 - 16\beta}\right)^3\right)^{1/4} \tag{10}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

Equation (10) can be solved in terms of the stream depth for the stable flow with the following result:

$$Y^* < Y^*_{crit} \equiv \left(\frac{4}{25}\right)^{1/6} \sqrt{br\cos\theta\left(\frac{25}{25-16\beta}\right)} \qquad (11)$$

This condition is not necessary, because the condition $c > U > c_{crit}$ also satisfies Whitham's criterion (Whitham 1974) ($c > U$) and inequality (9). However, inequalities 9, 10, and 11, if not satisfied, can prevent the appearance of roll waves or can dump already developed roll waves, depending on the status of the flow. For instance, a well-established pattern of permanent periodic roll waves can be destroyed by increasing the flow discharge, but can appear again downstream, where the celerity of the free-surface perturbations increases over the mean flow velocity. Typically, wave celerity increases with the distance from the inlet of the channel, and we can expect that for sufficiently long channels, the section of first appearance of the permanent roll waves is moved downstream. Obviously, if the permanent roll waves already developed are much faster than the critical value reported in equation 9, they continue to exist also in the presence of an increased discharge with $U > c_{crit}$, given that the condition $c > U$ is satisfied.

This behaviour is consistent with some experimental results (Forterre & Pouliquen 2003; hereafter FP), who described the long-surface-wave instability in dense granular flows of sand and glass beads and, for the former, visually observed that waves develop in the domain between the no-flow state (sediments at rest) and a stable flow at higher discharge. In their description, summarised in a qualitative diagram, if the thickness of the layer at a fixed inclination is increased, then the waves form further and further downstream and eventually disappear. In the present analysis, a finite-amplitude analysis of the roll waves can predict a limiting condition for the existence of permanent periodic roll waves. Later, we shall verify that a second limit on the existence of roll waves is related to the energy balance in the shock. Both limits shall be discussed in §8.

5 SHOCK CONDITION

The shock condition is obtained from the mass-conservation and momentum-balance equations for a control volume across the shock:

$$\begin{cases} c\left[Y\right]_f^b = \left[UY\right]_f^b \\ c\left[UY\right]_f^b = \left[\beta U^2 Y + \frac{1}{2} g Y^2 r\cos\theta\right]_f^b \end{cases} \qquad (12)$$

where the square brackets are the operator $[<.>]_f^b = <.>|_b - <.>|_f$ and b and f stand for the two control sections, back and front.

The weight of the roller and bottom friction have been neglected. In extended form, the details are reported in Longo (2003).

Neglecting the trivial solution $Y_b = Y_f$ (no shock), equation 12 can be solved, obtaining the relation between back and front stream depth. The minimum wavelength $\lambda^* \to 0$ corresponds to $Y \to Y_c$. The maximum wavelength $\lambda^* \to \infty$ corresponds to the maximum depth in front of the shock (and the maximum wave height). The height of the shock is given by $H^* = Y_b^* - Y_f^*$ and it tends to asymptotic values slightly dependent on bottom inclination and strongly influenced by the value of β. The wave steepness also tends to asymptotic values, with faster adjustment towards the limit for larger bottom inclination.

6 ENERGY DISSIPATION IN THE SHOCK

The rate of change of mechanical energy across the jump is equal to the following

$$\begin{aligned} \Delta P^* = &-\frac{1}{2}\left(1-\frac{K^*}{Y_b^*}\right)^2 Y_b^*\left(\alpha_b - \alpha_b\frac{K^*}{Y_b^*} - \beta_b\right) + \\ &\frac{1}{2}\left(1-\frac{K^*}{Y_f^*}\right)^2 Y_f^*\left(\alpha_f - \alpha_f\frac{K^*}{Y_f^*} - \beta_f\right) - \\ &\cos\theta\left[\frac{Y_b^{*2}}{2}\left(r-\frac{K^*}{Y_b^*}(1+r)\right) - \frac{Y_f^{*2}}{2}\left(r-\frac{K^*}{Y_f^*}(1+r)\right)\right] \end{aligned} \qquad (13)$$

Substituting the expression for discharge in the moving frame and dividing by the discharge per unit width in the moving frame, for $\alpha = \beta = 1$ and for $r = 1$, equation 13 has the classical expression:

$$\Delta E_j^* = -\cos\theta\frac{\left(Y_b^* - Y_f^*\right)^3}{4Y_b^* Y_f^*} \qquad (14)$$

Having neglected the thermal energy contribution, a necessary condition for a physically based shock is $\Delta E_j^* < 0$, that is, the shock dissipates mechanical energy. The (mechanical) energy dissipation condition in the shock limits the admissible values of Y_f^* and Y_b^*. Some results are shown in Figure 1. The physically admissible area is the region $Y_f^* < Y_b^*$, also contoured by a curve $f_{crit}(Y_f^*, Y_b^*) = 0$ in which $\Delta E_j^* > 0$. Note that if $\alpha = \beta = 1$ and $r = 1$, the critical curve has equation $Y_f^* = Y_b^*$, and the finitude amplitude shocks always dissipate energy, whereas for different values of the flux factors and of the parameter r, finite amplitude shock without energy dissipation is possible.

A sensitivity analysis indicates that increasing the bottom inclination moves the critical curve towards higher values of front/back stream depth. A reduction of the ratio r enlarges the closed-hatched area, corresponding to energy production in the jump (physically

Copyright © 2006 Taylor & Francis Group plc, London, UK

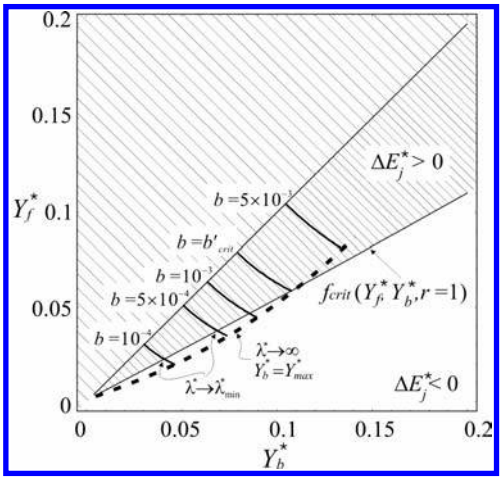

Figure 1. Energy and momentum balance in the jump. The hatched area is unacceptable, because $Y_f^* > Y_b^*$. The closed-hatched area corresponds to energy production in the jump, physically impossible. The thick curves satisfy the momentum balance across the shock, for different values of the parameter b. The dashed-tick curve represents the maximum layer thickness, in front of the shock, for different values of the parameter b, and corresponds to an infinite wavelength. $\beta = 1.25$, $\alpha = 1.705$, $\theta = 30°$, $r = 1$, $b'_{crit} = 0.00216$.

impossible). A reduction in the two factors α and β moves the critical curve towards modest values of the front/back stream depth.

The limitation due to energy dissipation condition in the shock corresponds to a limitation in wave height $(Y_f^* - Y_b^*)$ and is equivalent to imposing a minimum wavelength, since wavelength increases with the wave height.

A double-band structure is observed for $r \to 1$ (not shown), with finite amplitude shock heights corresponding to zero energy dissipation confined to two separated wave-number bands. The intermediate wave band corresponds to a stable state (no shock) and fixes a cut-off frequency. More correctly, the shock acts as a band-rejection filter.

A second limitation on the maximum value of the parameter b is obtained by observing the energy balance in the hydraulic jump and the function $Y_b(Y_f)$, describing the possible back-front heights compatible with the mass and momentum balance for a control volume across the shock. The curves are reported for different values of the parameter b in Figure 1. The starting point of the thick curves corresponds to $Y_b^* \equiv Y_f^* \equiv Y_c^*$ and to $\lambda^* \to 0$. The end point corresponds to $Y_b^* \equiv Y_{max}^*$, $\lambda^* \to \infty$.

A critical value of the parameter b exists which corresponds with a maximum flow depth in front of the shock coincident with the zero energy dissipation in the jump. The critical value b'_{crit} is obtained numerically solving a strongly non-linear system of equations representing energy dissipation and momentum balance in the shock, with the further condition that the wavelength tends to infinity.

For $b < b'_{crit}$, only wavelengths greater than λ_{min} are allowed. The critical value of the parameter b fixed by the existence condition of the wave profile (see §4) is generally larger than b'_{crit}.

The condition $b < b'_{crit}$ is equivalent to

$$c > c'_{crit} = \left(\frac{ag^2}{b'_{crit}\sin\theta}\right)^{1/4} \tag{15}$$

which in non-dimensional form reads

$$Y^* < Y^*_{crit} \equiv \left(\frac{b^3}{b'_{crit}}\right)^{1/6} \tag{16}$$

Similar results were obtained by Ng & Mei (1994) for mud flows. On using the dissipation energy criterion in the shock, they obtained a minimum discharge in the moving frame (equivalent to a maximum discharge in the fixed frame), a minimum celerity of the roll waves and a maximum wave number (corresponding to a minimum wavelength). As for the limit described in §4, this is not a necessary condition for roll waves, because the condition $c > U > c'_{crit}$ also satisfies the Whitham criterion. In §8, there is a discussion of the limiting discharge as computed using the limits 9 and 15.

7 THE MINIMUM-LENGTH ROLL WAVE (MLRW)

The requirement of a minimum energy dissipation in the shock is met by the waves with a wavelength equal to λ_{min}. Herein, these waves are called MLRW. The computation of the relevant characteristics of the MLRW is carried out as follows:

(i) for given b ($<b'_{crit}$), θ, α, β, r, evaluate $\lambda^*_{\min}$, Y_b^* and Y_f^*;

(ii) evaluate Y_c^* and K^* and solve for the average depth and the average discharge in the fixed frame

(iii) on using the velocity law

$$\frac{U}{\sqrt{gY}} = Y\sqrt{\frac{\sin\theta}{a}} \tag{17}$$

as obtained from equations 2 and 4, evaluate the normal velocity Y_n^* and the Froude number as

$$Y_n^* = b^{1/5}\langle q^*\rangle^{2/5}, \quad F = \frac{Y_n^*}{\sqrt{b\cos\theta}} \tag{18}$$

$\langle q^*\rangle$ is the non dimensional average discharge in the fixed frame. The non-dimensional wave celerity is obtained as

$$\frac{c}{U_n} = \sqrt{\frac{b}{Y_n^{*3}}} \tag{19}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

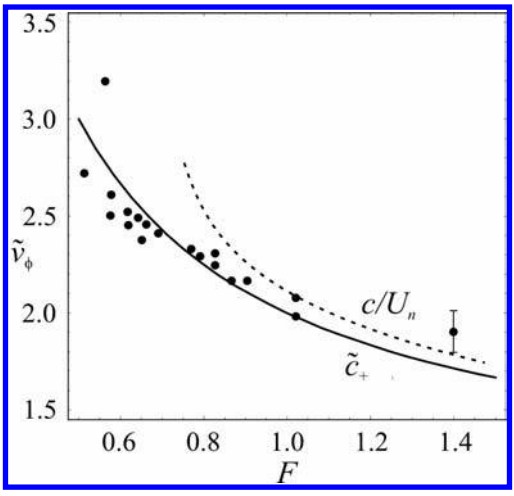

Figure 2. Phase velocity as a function of the Froude number. • experiments by FP; solid line, velocity of the gravity waves as computed by FP (linear model), $\tilde{c}_+ = 1 + 1/\mathrm{F}$; dashed line, MLRW celerity, present model. $\beta = 1.03$, $\alpha = 1.02$, $r = 1$.

In Figure 2, the experimental phase velocity of granular roll waves as a function of the Froude number as reported in FP is compared with the MLRW celerity as obtained in the present model. For $F < 1$, the MLRW systematically has a celerity in excess of the experiments and the linear-model prediction. For $F > 1$, the experiments are few and no firm conclusion can be drawn.

A sensitivity analysis was carried out in order to discover the possible causes of the discrepancy between experiments and the results of the present model. As expected, reducing the two flux factors towards unity improve the overall results, with the MLRW celerity collapsing with the linear model prediction. In fact, for $\alpha \to 1$ and $\beta \to 1$, the MLRW shock height tends to become rather small and the non-linearity is weak.

8 LIMITING DISCHARGE

In FP's experiments (2003), it was observed that granular flows of sand 0.8 mm in diameter down an inclined rough plane develop in roll waves as long as the thickness layer is close to the threshold of the flow. But when one increases the thickness of the layer at a fixed inclination, increasing the discharge, the roll waves disappear and the flow recovers its stability. For granular waves of glass beads 0.5 mm in diameter, the flow is stable and then becomes unstable at a larger flow rate. For sand flows, there must be a mechanism to recover stability, e.g., a drainage of energy which prevents roll waves from growing and which is related to the characteristics of rapid flows. In the present model, two possible mechanisms are detected. The first is related to the physical evidence of a positive steepness of the roll waves in the critical section. The second is related to the energy balance in the shock. Both mechanisms limit the value of the parameter b; these limits can be converted into a limiting thickness of the (normal) flow, even though they do not represent a necessary condition for the existence of roll waves.

8.1 *Results for sand*

In their analysis, FP adopt an experimental velocity law for sand flows expressed as

$$\frac{U}{\sqrt{gY}} = -0.77 + 0.65\frac{Y}{Y_{stop}(\theta)} \tag{20}$$

The function Y_{stop} represents the thickness of the deposit left by a steady uniform flow at the inclination θ. For sand, this function is expressed as

$$Y_{stop}(\theta) = 2.03d\left(\frac{\tan\delta_2 - \tan\delta_1}{\tan\theta - \tan\delta_2} - 1\right) \tag{21}$$

with $d = 0.8$ mm, $\delta_1 = 27.0°$, $\delta_2 = 43.4°$. δ_1 and δ_2 are two parameters of the material.

In the present model, the assumed velocity law is reported in equation 17.

With a different velocity law having been used, a comparison between the present model and the experimental results by FP requires the computation of the equivalent value of the parameter a. It is also realistic to assume a is not constant but is a function of the flow conditions. The equivalent value of a can be evaluated in two ways: (i) imposing an equal velocity computed using equation 17 and equation 20; (ii) imposing the equality only of the quadratic contribution (i.e., equalising the velocity law in equation 17 with the second contribution in equation 20).

In both cases, the equivalence is imposed in the limit stability points (Y_{lim}, θ) reported in Table 1, as obtained from the qualitative diagram sketched by FP.

In keeping with the analysis of Bagnold (1954) and Takahashi (1991), the computed parameter a decreases for decreasing void concentration of the sediments, which is expected for fast flows at increased values of θ. The second criterion for evaluating the equivalent value of the parameter a gives results (last column in Table 1) in fairly good agreement with the experiments (see Figure 3).

These results have been obtained assuming fixed values for the two factors $\alpha = 1.03$ and $\beta = 1.02$. Measurements of velocity profiles in a granular flow on an erodible bottom (Longo & Lamberti 2001) reveal that α and β can assume values much larger than unity, but it is expected that nearly uniform velocity profiles can develop for fast flows down an inclined plane. It is also expected that bottom stress in unsteady flow differs considerably from the corresponding value in

Table 1. Limiting conditions for the existence of roll waves in granular sand flows. The values for b'_{crit} refer to the turbulent profile ($\beta = 1.02, \alpha = 1.03$), with $r = 1$. Y_{lim}, experimental values by FP (2003); b_{crit}, Y_{crit}, computed values using equations 4.9 and 4.13; b'_{crit}, computed value for the limiting condition discussed in §7; $a_{(1)}$, $Y'_{crit-comp1}$, computed values using criterion (1); $a_{(2)}$, $Y'_{crit-comp2}$, computed values using criterion (2).

θ °	Y_{lim} (mm)	(b_{crit})	Y_{crit} (mm)	b'_{crit}	$a_{(1)}$ $\times 10^{-5}$ (m^2)	$Y'_{crit-comp1}$ (mm)	$a_{(2)}$ $\times 10^{-6}$ (m^2)	$Y'_{crit-comp2}$ (mm)
33	6.5	0.4434	6.1	0.1505	11.0	19.4	15.0	7.3
34	5.5	0.4590	4.7	0.1561	5.2	13.2	9.4	5.6
35	4.7	0.4759	3.7	0.1619	2.6	9.1	5.9	4.4
36	4	0.4940	2.8	0.1680	1.4	6.6	3.7	3.4
37	3	0.5135	2.2	0.1745	0.9	5.3	2.3	2.6

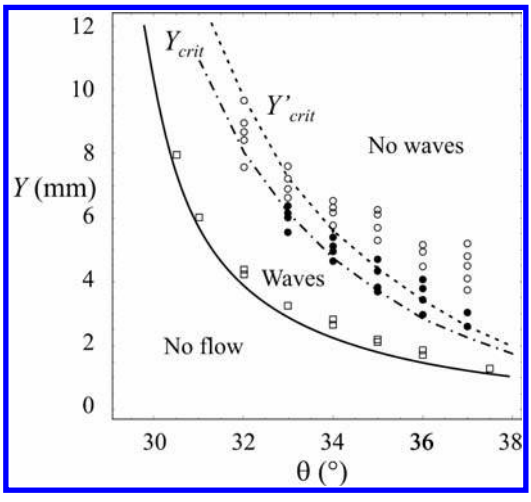

Figure 3. Stability diagram, as sketched by FP (2003) for sand flows, and computed upper limit of existence of roll waves. •, Waves; ○, no waves; □, flow threshold; dashed line, present model, results due to b'_{crit}; dash-dot line, present model, results due to b_{crit}.

steady flow, with a consequent spatial variation of both flux factors. The lack of experimental data to evaluate α and β suggests that it would be better to consider these two factors calibration parameters (see also FP (2003) on this point).

If we express the Froude number corresponding to the limit in equation 11 (first critical Froude number), we obtain

$$F_{crit} = \frac{U_{crit}}{\sqrt{gY_{crit}\cos\theta}} \equiv Y_{crit}\sqrt{\frac{\tan\theta}{a}} \equiv \frac{1}{\left(b_{crit}\right)^{1/6}\sqrt{\cos\theta}} \equiv \frac{1}{\left(\frac{25}{4}\right)^{1/6}\sqrt{\frac{25-16\beta}{25r}}} \qquad (22)$$

The first critical Froude number $F_{crit} = F_{crit}(\beta, r)$ is independent of the bottom inclination and the rheological parameters of the granular medium. For $r = 1$ and $\beta = 1.02$ assume the value $F_{crit} = 1.25$.

If we express the Froude number corresponding to the limit in equation 16 (the second critical Froude number), we obtain

$$F'_{crit} = \frac{U'_{crit}}{\sqrt{gY'_{crit}\cos\theta}} \equiv Y'_{crit}\sqrt{\frac{\tan\theta}{a}} \equiv \frac{1}{\left(b'_{crit}\right)^{1/6}\sqrt{\cos\theta}} \qquad (23)$$

The computed value of F'_{crit} does not depend on the criterion used to evaluate the equivalent a; using the computed values of b'_{crit}, it does not depend on bottom inclination and is constant for given values of α, β and r, i.e., $F'_{crit} = F'_{crit}(\alpha, \beta, r)$ and $b'_{crit} \propto (\cos\theta)^{-3}$. For $\alpha = 1.03$, $\beta = 1.02$ (turbulent flow) and $r = 1$, results $F'_{crit} = 1.496 \pm 0.001$; for $\alpha = 1.704$, $\beta = 1.25$ (laminar flow) and $r = 1$, results $F'_{crit} = 2.99 \pm 0.01$, while for $r = 0.9$ in laminar flow results $F'_{crit} = 3.04 \pm 0.01$.

8.2 *Results for glass beads*

The approach used for sand (§8.1) can also be applied to glass beads, the second material used in the granular flows analysed by FP. In the experiments of the writers, flows of glass beads did not experience natural roll waves; it was necessary to impose a disturbance at the entrance of the flow. The forced instability is convective, and a region of linear instability is present. The experimental velocity law for flows of glass beads is expressed as

$$\frac{U}{\sqrt{gY}} = 0.136\frac{Y}{Y_{stop}(\theta)} \qquad (24)$$

As for sand flows, the function Y_{stop} represents the thickness of the deposit left by a steady uniform flow at the inclination θ, and is expressed as

$$Y_{stop}(\theta) = 1.65d\left(\frac{\tan\delta_2 - \tan\delta_1}{\tan\theta - \tan\delta_2} - 1\right) \qquad (25)$$

with $d = 0.5$ mm, $\delta_1 = 20.9°$, $\delta_2 = 32.76°$.

In order to compare the results of the present model with the experiments, for glass beads we can assume, without further hypothesis, that

$$a = \sin\theta\left[\frac{Y_{stop}(\theta)}{0.136}\right]^2 \qquad (26)$$

The two critical Froude numbers are independent of the specific granular material flowing. The stability diagram for glass beads is reported in Figure 4.

The dot-dashed and the dashed curves in Figure 4 correspond to $F_{crit} = 1.25$ and to $F'_{crit} = 1.496 \pm 0.001$.

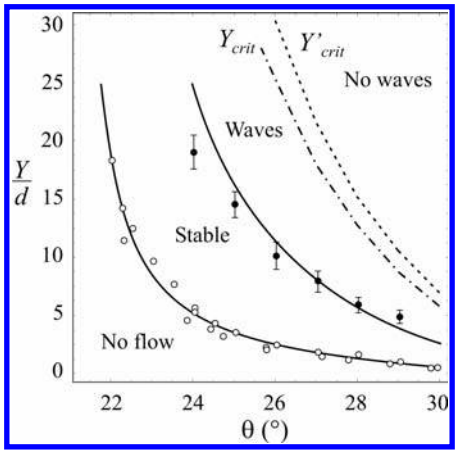

Figure 4. Stability diagram, as sketched by FP (2003) for glass beads ($d = 0.5$ mm), and computed upper limit of existence of roll waves. ○, Flow threshold; ●, waves; continuous line, theoretical predictions by FP; dashed line, present model, results due to b'_{crit}; dash-dot line, present model, results for b_{crit}.

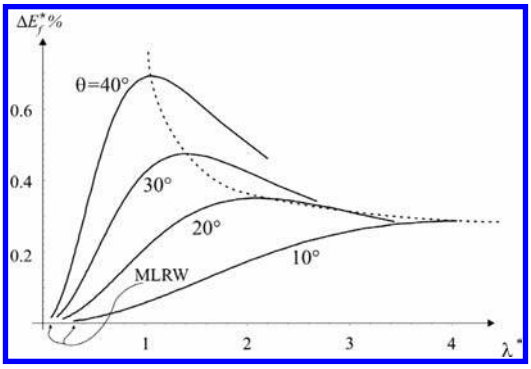

Figure 5. Extra dissipation due to friction. $\beta = 1.25$, $b = 0.01$, $r = 1$.

Unfortunately, the measurements by FP could not be extended to Froude numbers higher than ~1.4 for the maximum bottom inclination ($\theta = 29°$ for glass beads) due to the limited length of the channel, and to Froude numbers higher than ~0.85 for the minimum bottom inclination ($\theta = 24°$ for glass beads) due to the limited discharge rate of the feeding silo. Apparently, observing the published data, a single test is available beyond the first threshold but below the second threshold, and it indicates an unstable flow, whereas a stable flow is expected. No firm conclusions can be drawn about the experimental verification of the present model for flows of glass beads.

9 ENERGY DISSIPATION IN THE UNSTABLE STREAM

The mean energy dissipated for friction in a wavelength is computed in non-dimensional form as

$$\Delta E_f^* = -b \sin\theta \int_{Y_f^*}^{Y_b^*} \frac{U^{*2}}{Y^{*3}} \frac{1}{Y_{crit}^*} dY^* \qquad (27)$$

A stream in steady, uniform motion obviously results in $\Delta E_f^* + \lambda^* \sin\theta = 0$ for any value of the wavelength λ^*. In the presence of roll waves, including the energy dissipated in the jump, the energy balance over a wavelength results in

$$\Delta E^* = \Delta E_f^* + \Delta E_j^* + \lambda^* \sin\theta \qquad (28)$$

Assuming a friction law in non-uniform, unsteady motion equal to the friction law in steady, uniform motion, the energy budget is generally a negative function. That is, the system dissipates more energy than the energy gained from gravity.

The results of numerical integration are shown in Figure 5. In the vertical, the percentage of extra energy dissipation with respect to the stable uniform stream is reported. The starting point corresponds to the MLRW, and all the curves have a maximum value decreasing for lower bottom inclination. The jump enhances dissipation, and the stream in unstable motion dissipates more than the equivalent stream in stable, steady, uniform motion (*equivalent* means having the same average discharge with identical channel characteristics). All the computations have neglected the finite size of the moving shock, the contribution of the weight of the grains in the shock, and the curvature of the trajectories. It has been demonstrated that for roll waves in water streams, inclusion of the weight of the fluid in the jump in linear momentum balance across the shock tends to reduce the ratio Y_b^*/Y_f^* (Brock 1967) and favours smaller wavelengths. Surface tension contrasts the growth of instabilities and rounds the wave crest (Hwang et al. 1994) and the energy balance is very sensitive to small variations in the parameters. Also, the assumption of a different friction law gives different results. In a dry, granular stream, surface tension is not present, but all the other mentioned factors are present. According to Kapitza (1948) and Ng & Mei (1994), the observed roll wave has the smallest mean energy averaged over the wavelength. Such a roll wave clearly meets the condition of finite amplitude shock with zero dissipation across it and has back/front depth on the critical curve, but still dissipates more energy than the energy gained. Dressler's hypothesis (that a roll wave with a minimum of dissipated energy could be present and hence could be the stable solution) unfortunately, is not borne out, at least for granular flows. Unless a different friction law is included, to manage

Copyright © 2006 Taylor & Francis Group plc, London, UK

the boundary layer structure in the presence of adverse gradient pressure, the energy budget is negative. Also, computing the energy budget of the MLRW for varying b (and hence for varying wave celerity c at a given bottom inclination θ) results in a monotonic function, with extra dissipation increasing with decreasing b. This result is not of much help in determining the stable permanent roll wave.

10 DISCUSSION

One of the most striking aspects of granular roll waves is the stabilising effect of an increased discharge. Roll waves appear at the onset of motion and eventually disappear, increasing the discharge or bottom inclination. It seems that the present model gives an answer to the phenomenon, even though more experiments are necessary to better quantify the effects and to extend the validity of the approach to other granular media. Some doubts still remain about the stability of the permanent periodic roll waves. We need to mention that reports on experiments on roll waves in water (Brock 1967) make a substantial difference between natural and periodic roll waves. The former spontaneously appear in a channel as a result of amplification of natural (non-imposed) disturbances and are generally not periodic; the latter are periodic and are usually obtained by forcing the inlet with a paddle and by adjusting the amplitude and period of the paddle motion. This result indicates that roll waves (in water) are not necessarily periodic, and if periodic roll waves are stable, they need a minimum length of the channel to become permanent. This minimum length of the channel is of the order of thousands wavelengths and imposes severe restrictions on its feasibility in the laboratory. If the results for roll waves in water hold true also for granular roll waves, a typical length scale for the channel should be of the order of $\sim$200 m (the typical distance between surges, as observed by FP, is $\sim$20 cm). We can infer that roll waves in a 2 m long channel are presumably not 'mature', in the sense that they have not acquired stable characteristics (if any). It is also difficult to verify that they are strictly periodic.

The hypothesis that the measured granular roll waves are not mature can also explain the apparent overestimation of the wave celerity by the theoretical MLRW model and the good fitting of the linear model by FP. In fact, typical results on natural roll waves in water indicate that the average wave celerity increases downstream, presumably reaching a maximum when a stable, permanent shape is obtained. If it holds true also for granular roll waves, the experimental points in a downstream section of the channel should move up in the diagram reported in Figure 2.

On the basis of the results obtained in §9, two main indications arise. The first is that the resistance law adopted cannot be fully correct in the unsteady motion analysed and the boundary layer structure should be included in order to explain a reduced friction and dissipation; the second is that we can infer that permanent roll waves, as described in the present analysis, cannot completely fill the flow system. They have to coexist with other waves which dissipate less than the energy gained from gravity, leaving the excess for satisfying the energy balance. Otherwise, all the experimentally observed roll waves are unstable (Kapitza 1948), and would disappear if enough space were given (not necessarily recovering a uniform stream). Experimental investigations of roll waves in granular flows may be of considerable help to further analysis. The new experiments should be designed also with the aim of increasing the height of the roll wave and the general vertical scale of the flow, in order to eliminate some concerns that naturally arise modelling with a continuum model a phenomenon where the flow depth is on the order of 10 grain diameters.

In general, we can add that it may be questionable to use an empirical model for rheology (as we did in the present analysis), because, especially for granular flows, the experiments reveal many special characteristics. We have also to add that most, if not all, the stability analysis on roll waves are based on empirical friction laws that, strictly speaking, nothing have to do with constitutive equations, because they do not respect one or more than one of the general rules for constitutive equations. Nevertheless the agreement of theory with the experiments is often surprising.

It is also a subject of discussion that the MLRW herein described and obtained using energy criteria, can be found in real system. We share the idea that a combination of criteria based on energy consideration and linearized instability can be a reasonable approach for studying roll waves in their general form, including irregular, non periodic trains (see Ng & Mei 1994). In the Newtonian limit the properties of the minimum roll waves (shortest wavelength and lowest amplitude without energy loss in the shock) appear to be consistent with the experimental data (Ng & Mei 1994).

11 CONCLUSIONS

The proposed solution for finite amplitude roll waves in a dilatant fluid shares many similarities with the solution proposed by Dressler (1949) for a Newtonian fluid and by Ng & Mei (1994) for mud. The solution is expressed as a discontinuous function obtained by connecting two continuous profiles with a shock. The continuous profiles are obtained in the shallow equations approximation.

In order to construct the profile between two shocks, it is necessary that the steepness of the wave be

Copyright © 2006 Taylor & Francis Group plc, London, UK

finite and positive in the section where critical condition is reached. It results in the inequality $b < b_{crit}$, b being a non-dimensional group based on rheological characteristics of the fluid, wave celerity, and bottom inclination. The inequality can be converted into a limiting minimum wave celerity for given rheological parameters and bottom inclination and in a maximum (mean) flow rate in the fixed frame. It can also be converted into a maximum stream depth or a maximum Froude number, which fixes an upper threshold to the permanent periodic wave existence observed in some experiments on sand flows. This critical threshold is expressed as $F_{crit} = F_{crit}(\beta, r)$.

The energy-balance analysis in the shock reveals that, assuming uniform flux factors (energy and momentum), in the back and in the front of the shock, finite amplitude shocks without (mechanical) energy dissipation are allowed within a single band of wavelength. If different factors are assumed, namely increasing the value of factors from the back (minimum depth) to the front (maximum depth), a double band of wavelength with finite amplitude shocks without energy loss is allowed. These limiting conditions are highly sensitive to r, the ratio of the normal stress in the horizontal direction to the normal stress in the vertical direction. The physical consideration of a non-positive (mechanical) energy balance in the shock requires that a second inequality ($b < b'_{crit}$) be satisfied. This inequality, expressed in a similar fashion by Ng & Mei (1994) for mud flows, leads to the evaluation of a second threshold expressed as $F'_{crit} = F'_{crit}(\alpha, \beta, r)$.

The comparison with experimental results reported by FP (2003) reveals that the prediction of a limiting curve for the existence of permanent periodic roll waves in the plane (Y, θ) is rather good for sand flows. For flows of glass beads, the set-up of the experiments did not allow flows at a Froude number higher than the computed thresholds, and the comparison is not possible. We need to mention that the experimental results are qualitative in respect to stability limit.

The computed wave celerity of the MLRW is in excess respect to the linear model prediction and to the experiments; a correction of the shock dynamics introducing the weight of the roller increases the discrepancies between experiments and the present model. Perhaps a longer channel could lead to measurements with improvement in the overlap of the theoretical and the experimental results. Also, a complete description of the roll waves, introducing different back/front correction flux factors could improve the predictive strength of the model.

Integration of the energy dissipation in the stream reveals that the energy budget is a negative function, also in condition of no dissipation in the shock, i.e., the system with permanent waves dissipates more energy than the energy gained from gravity, with a minimum for the MLRW.

Instability and kinematic for sand-water mixture or dry sand flowing past a circular cylinder

S. Longo
Department of Civil Engineering, University of Parma, Parma, Italy

A. Valiani & L. Lanza
Department of Civil Engineering, University of Ferrara, Ferrara, Italy

ABSTRACT: The present analysis refers on experiments with a mixture of grains and water and dry grains around a circular cylinder. The flow is driven by the internal cylinder of a Taylor-Couette cell. Velocity measurements of the mixture at the external surface are carried out using a commercial PIV and a new microPIV. The flow field is quite similar to the flow field generated by a Newtonian fluid around a circular cylinder, with a wake and a re-circulation zone. Near the body, the velocity scale of the wake decays linearly if the asymptotic velocity is high, decays logarithmically for low asymptotic velocity. The transverse length scale increases as x'^n (x' is measured along the axis of symmetry with the origin at the boundary of the body) with $n < 0.5$ (or nearly zero in some flow conditions). For dry grains flow, microPIV reveals strong instabilities, with a fast movement en-block of the grains.

1 INTRODUCTION

The analysis of granular flow in presence of on obstacle is of interest from a theoretical point of view, because allows the study of the complex rheology of the fluid, but also for applications. Many defence structures against debris flow are steel sheeting cylinder piles filled with local materials and capped with concrete. They act dissipating the flow energy, stopping the boulders and favouring water filtration. Other defence structures against snow avalanches have a triangular shape with pyramidal elevation, with a corner in the expected flow direction, and are able to protect the buildings in the wake. There are also many applications in food manufacturing, chemical and pharmacy. Nevertheless experiments and theoretical models are quite few.

Granular flow is often characterized by variations of bulk density. Some experiments by Gray et al., (2003), show that a granular stream impacting an obstacle or being deviated by a wall shows different zones of compression and expansion, with shocks and discontinuities. In these experiments it is very difficult to measure fluid velocity in the body stream. It is possible to use Laser Doppler Anemometry (LDA) (Longo & Lamberti, 2002) and Particle Image Velocimetry (PIV) (Deng & Wang, 2003) for measuring velocities near a transparent wall. Results usually underestimates real velocity due to the wall boundary layer, but fortunately the error is limited due to slip of granular flows at the boundary.

In literature there are several references on Newtonian fluid flows around a circular cylinder (see Zdravkovich 1997), and most of the theory of wings uses conformal mapping of flow round a circular cylinder of infinite extension. In comparison, the studies on non-Newtonian fluid flows are scarce. Sarpkaya et al. (1973) present a detailed analysis on flow of water and polymers additive around a circular cylinder. The most evident effect of the additives is an instability of the separation curve of the stream, due exclusively to the rheology of the fluid.

Nedderman et al. (1980) analyze the gravity driven flow of mustard seeds around a cylinder, adopting a kinematic description based on a stochastic model. Other more detailed analysis refer to the kinematic of complex fluids around bodies (Pilate & Crochet, 1977).

In the present study we report on experiments with a stream of water or air plus sediment at high void concentration around a circular cylinder. In Section 2 there is a description of the experimental set-up, of the measurement technique and of the tests carried out with a mixture of sediments and water.

In Section 3 there is the description of the flow field using the experimental data, with the analysis of the wake, the vorticity field and the divergence of the flow. Section 4 is devoted to the analysis of dry

Copyright © 2006 Taylor & Francis Group plc, London, UK

granular stream (air is the inter-particle fluid), with a short description of a micro-PIV used for the velocity measurements. Conclusions are reported in the last Section.

2 EXPERIMENTAL SET-UP

The flow field is generated in a Taylor-Couette cell (Fig.1), with an internal rotating vertical cylinder in stainless steel $D_{int} = 167$ mm, and an external fixed cylinder in PMMA $D_{ext} = 190$ mm, having a wall thick $s = 5$ mm. The gap between cylinders is equal to $\delta = 11.5$ mm and represents the shear section. The internal cylinder is in motion and, in order to transfer momentum to the granular mixture, its wall is roughed by gluing sand-paper on it. The internal surface of the PMMA cylinder is smooth and allows an almost free-slip of the grains. The rotation of the stainless-steel cylinder is due to a stepper with a resolution of 1000 steps per root, connected to a mechanical gear 1:6 in order to increase the torque. The stepper has a vertical axis, is not fixed and the counter balance torque is obtained using an iron beam, instrumented with strain-gages in order to estimate the torque. In principle the measurement of the torque allows the evaluation of the mean wall stress. Unfortunately, due to mechanical imperfections in the gear system, the S/N ratio is too low, especially in presence of sand-water mixture.

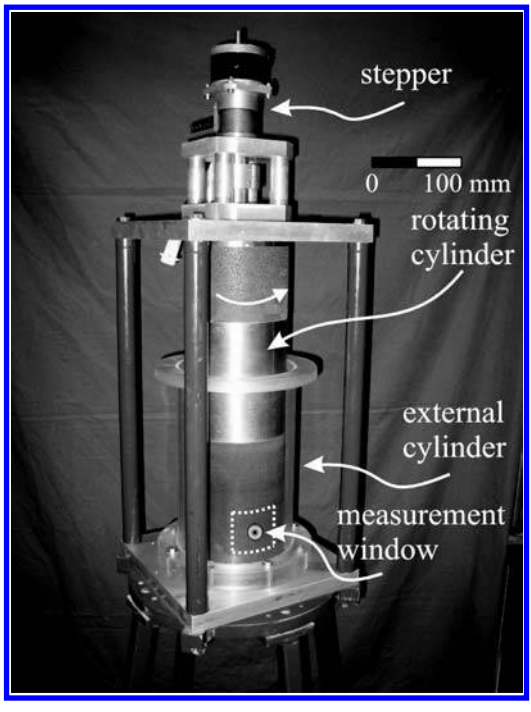

Figure 1. Taylor-Couette cell.

The tests were carried out with a mixture of water and artificial grains used for thermal insulation purposes (Leca is the commercial name), made of clay. The grains where sorted in order to have a diameter in the range $d = 0.25$–0.50 mm. They have an almost spherical shape and a specific weight in water nearly equal to 1.0. Sorting for the specific weight was obtained, eliminating the floating particles. The choice of almost neutrally buoyant particles was forced by the need of reducing at a minimum the normal effective stress increment due to gravity, which would reduce grains mobility.

Measurements were carried out in the Laboratory of Civil Engineering "Paolo Lamberti" of the University of Ferrara, using a commercial TSI PIV with a 2048×2048 pixel video camera, fitted with a 50 mm/f lens. More details on the PIV system are reported in Lanza et al. (2004).

The light source is a laser Ar^+, water cooled and mounted on the same side of the video camera. Usually, the laser has a cylindrical lens for the generation of a light sheet; for the present purposes, the lenses were removed and polarized lens were added to the video camera in order to eliminate reflections. The acquisition frequency of the couple of images is 3.75 Hz, with a time interval between the two images ranging from 600 μs to 1000 μs.

In the tested condition, PIV measures the grain particles velocity. The curvature of the PMMA cylinder and the refraction generate image distortion; an additional distortion is due to the lenses of the video camera. A numerical correction to the acquired data was performed using an algorithm with experimental parameters. The algorithm elaborates the transformation of the pixel position on the CCD of the camera onto metric position in the plane space equivalent to the enrolled cylinder.

The transformation is in terms of quadratic polynomials:

$$\begin{aligned} x_{corr} / x_{meas} &= L_x\left(x_{meas}, y_{meas}\right) \equiv \\ a_1 x_{meas}^2 + b_1 y_{meas}^2 + c_1 x_{meas} + d_1 y_{meas} + e_1 & \\ y_{corr} / y_{meas} &= L_y\left(x_{meas}, y_{meas}\right) \equiv \\ a_2 x_{meas}^2 + b_2 y_{meas}^2 + c_2 x_{meas} + d_2 y_{meas} + e_2 & \end{aligned} \quad (1)$$

used to correct both coordinates. The coefficients of the polynomials are estimated using the maximum likelihood criterion.

Calibration requires the following steps: (1) acquisition with the video camera of a regular grid of 1.0 cm squares, stuck on the external surface of the PMMA cylinder. It is necessary to fix the position of the video camera, in order to keep the same point of view during tests. (2) Estimation of the coordinate (in pixel) of the

Copyright © 2006 Taylor & Francis Group plc, London, UK

knots of the grid, using the acquired image. (3) Minimization of the following residuals, parametric in the coefficient of the interpolating polynomials;

$$\chi_x^2 = \sum \left(L_x(x_i, y_i) - x^*_{i\,real} / x_i \right)^2$$
$$\chi_y^2 = \sum \left(L_y(x_i, y_i) - y^*_{i\,real} / y_i \right)^2 \quad (2)$$

Summation is extended to all knots of the grid. Considering that the grid, for practical purposes, is stuck on the external surface of the PMMA cylinder, (whereas the observed grain particles move near the internal surface), the algorithm does not correct for refraction. This is one of the reasons of the reduced validation rate near the lateral boundaries of the frame, where refraction is more evident.

The correction function could also be evaluated using the criteria of geometrical optics, but it is more complicated and there are not real advantages with respect to the adopted polynomials. The estimated coefficients have an uncertainty of 2% at 95% confidence level. The maximum correction (near the lateral boundaries) is about 20%. Image elaboration was carried out using an interrogation window 32 × 32 pixel (∼8 × 8 d) with 50% overlap. The result is a matrix of vectors in the knots of a square grid, 16 pixel length, corresponding to 1.25 mm (∼4 d).

The output files contain the coordinates (in pixel) of the interrogation window, and the two components of the space vector at time t (first frame) and $t + \mathrm{d}t$ (subsequent frame). Applying the transformation, a matrix containing the velocity vector in the knots of an irregular grid is obtained. For easy use, the matrix is interpolated by a regular grid, with square length equal to 1.3 mm. For each test 100 couples of frame were acquired, correspondent to ∼27 s.

2.1 *The tests*

In a first series f tests, there is a circular cylinder having a diameter $D = 15$ mm and a height of a few millimeters. The cylinder is glued to the internal surface of the PMMA cylinder and has the axis in the radial direction, at ∼50 mm over the bottom of the Taylor-Couette cell. The free surface of water at rest is at ∼150 mm, while grains bottom is at 20 mm below the free surface. At the maximum rotation rate of the internal cylinder, the mixture looks almost homogeneous, with a void concentration reduced to 87% of the void concentration at rest.

The variation in the void concentration is greater near the free surface than near the obstacles. Measurements were carried out imposing a rotation rate ranging from 50 to 200 rpm, corresponding to a peripheral velocity of the internal cylinder from 440 to 1760 mm/s. The undisturbed flow field (without the obstacle), is quite regular, with shear in the radial direction and in the horizontal plane. The mean value of the shear rate in the radial direction and the mean velocity near the external (transparent) wall are shown in Table 1.

It has been verified that the shear in the radial direction is not uniform, with higher values near the driving wall. In most of the flow field, the shear rate is much smaller than the average shear rate. Note that at 200 rpm the measured velocity of the grains near the external cylinder is smaller than the measured velocity at 150 rpm, presumably as a consequence of emerging instabilities in the flow field.

3 DESCRIPTION OF THE FLOW FIELD

The presence of the obstacle modifies the flow patterns, with a low velocity zone upstream, a stagnation or dead zone (sediments at rest) downstream, a boundary layer at the interfaces with the dead zone and the obstacle, a wake, and a re-circulating zone at the beginning of the wake. In Figure 2 the average flow field (100 couples of frames, ∼27 s) is shown. In the

Table 1. Imposed velocity scales.

Imposed rotation rate (rpm)	Lateral velocity of the driving wall (mm/s)	Asymptotic velocity of the flow U_o (mm/s)	Radial shear rate (s^{-1})
50	440	305	11.7
100	880	615	23.0
150	1320	920	34.8
200	**1760**	**760**	**87.0**

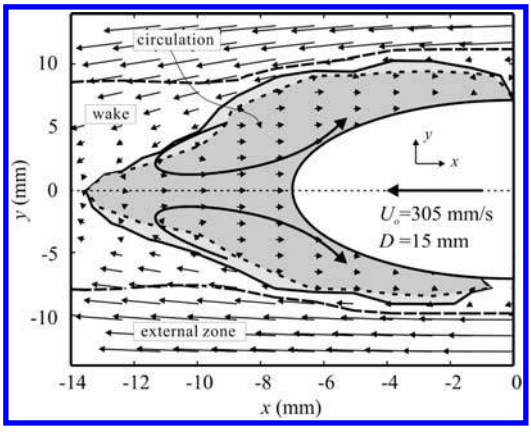

Figure 2. Mean flow past the circular body. Thick line represents the re-circulating zone. The internal dashed line limits the zero velocity, the external dashed line limits the wake boundary. The picture is distorted for an easier visualization.

Table 2. Extension of the re-circulating zone.

Rotation rate (rpm)	Length of the re-circulating zone (measured from the boundary of the cylinder body) x' (mm)
50	6
100	10.7
150	10.3
200	**7.6**

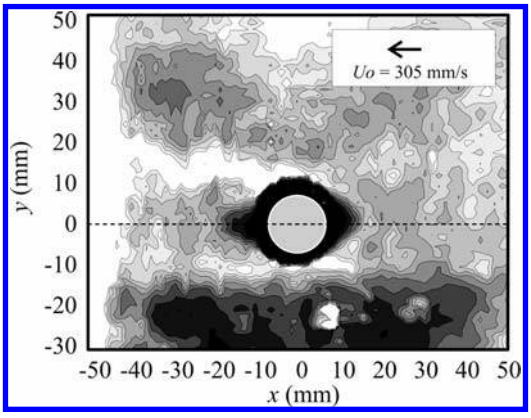

Figure 3. Mean granular temperature. The 'cold' zones are dark.

re-circulating zone (thick line) there are two counter-rotating vortices, while the average velocity is of a few mm-s. The size and the shape of the re-circulating zone are almost not dependent of the asymptotic velocity. In all tests, the length downstream (Tab. 2) is a fraction of the diameter of the obstacle, except for the 200 rpm rotation rate test, presumably characterized by instabilities of the flow. In Figure 3 the mean variance of the grains velocity (defined as 'granular temperature', even though a proportional coefficient is missing in the expression) is shown:

$$T = \overline{\left(U_x - \bar{U}_x\right)^2} + \overline{\left(U_y - \bar{U}_y\right)^2} \qquad (3)$$

The over-bar means time average.

The granular temperature is the trace of the kinetic stress tensor (equivalent to Reynolds' stress tensor); it represents a measure of the grains fluctuations and usually, neglecting mean transport, it is larger in the source areas. The source is essentially due to shear rate. In the present tests, the minimum values of the granular temperature is reached in the dead zones upstream and downstream, near the boundaries of the obstacle, where friction is dominant.

The hot zones define the wake, are due to high shear rate and aid momentum flux from the external zone

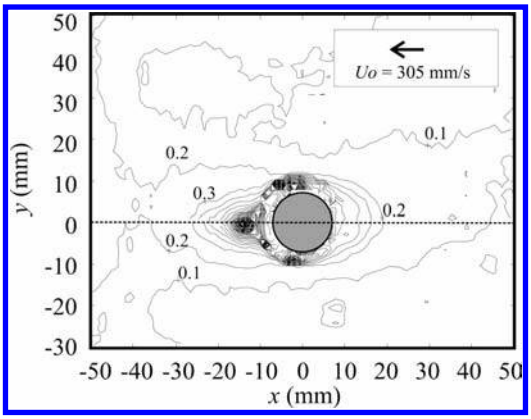

Figure 4. Index of turbulence. Average value on 100 frames (~27 s).

toward the wake, reducing progressively the defect of velocity. The granular temperature distribution is quite similar for all tests, and presents a little asymmetry. The asymmetry is due to the increasing grain volume concentration toward the bottom of the cell, for the combined effects of gravity and for the boundary effects imposed by the rigid wall; in fact, at higher grain volume concentration, collisional and frictional stresses are dominant. The average turbulence index, defined as:

$$\gamma = \left[\frac{\overline{\left(U_x - \bar{U}_x\right)^2} + \overline{\left(U_y - \bar{U}_y\right)^2}}{\bar{U}_x^2 + \bar{U}_y^2}\right]^{1/2} \qquad (4)$$

is shown in Figure 4. The maxima are in the dead zone, where the average velocity is almost zero and fluctuations due to grains in motion and to stick-slip phenomena are dominant.

Note that the data rate of the frames, equal to 3.75 Hz, and the spatial resolution of 8 d, filter most of the high frequency fluctuations related to micro-mechanic collisions, even though the presence of water as inter-particle fluid, favours the dampening of these fluctuations.

3.1 *The wake past the obstacle*

Downstream the obstacle, there is the wake, with a mean velocity lower than the external velocity and a velocity profile almost symmetric and similar to the velocity profile in the wake of a Newtonian fluid.

In Figure 5 the wake is represented as limited by velocity equal to 50% of the axial defect velocity *Us(x)* (with respect to the asymptotic velocity, i.e. the velocity in the external region in the same section). This definition slightly differs from the classical defect

Copyright © 2006 Taylor & Francis Group plc, London, UK

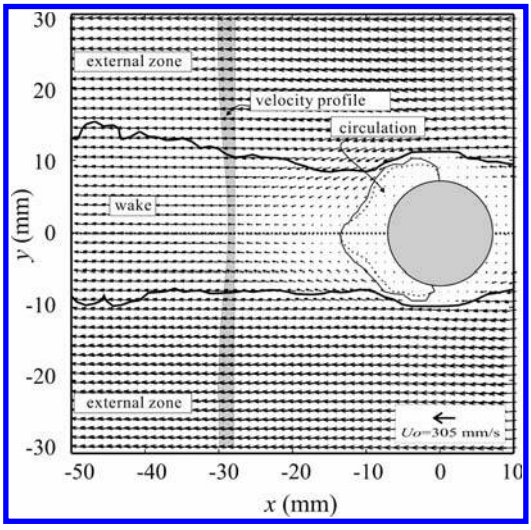

Figure 5. Wake past the obstacle. Average of 100 frames (~27 s).

velocity definition, which refers to the undisturbed velocity. The local width of the wake is often assumed as the geometrical transverse scale, whereas the defect velocity is assumed as transverse velocity scale.

For turbulent wakes of Newtonian fluids in a 2-D flow field at high Reynolds number, the velocity profile becomes self-similar at distance $>80\ D$, with $l \propto x^{1/2}$ and $Us \propto x^{-1/2}$ (Tennekes & Lumley, 1972).

The spatial characteristics of the wake for the present tests is shown in Figure 6. For the test at 50 rpm, the velocity scale has a logarithmic decay, according to the following expression:

$$\frac{U_s}{U_0} = \ln\left[\alpha\left(\frac{x'-D/2}{D}\right)^{\beta}\right] \qquad (5)$$
$$D < x' < 4D$$

with $\alpha = 1.57 \pm 0.8\%$; $\beta = -0.33 \pm 3.2\%$

The parameters were computed using the least squares method, with $R^2 = 0.989$ at a confidence level of 95%.

In all the other tests the velocity scale decays linearly, according to the following expression:

$$\frac{U_s}{U_0} = a - b\left(\frac{x'-D/2}{D}\right) \qquad (6)$$
$$D < x' < 4D$$

The value of the estimated parameters are shown in Table 3.

In Figure 7 the spatial evolution, downstream and upstream, of the transversal length scale is shown.

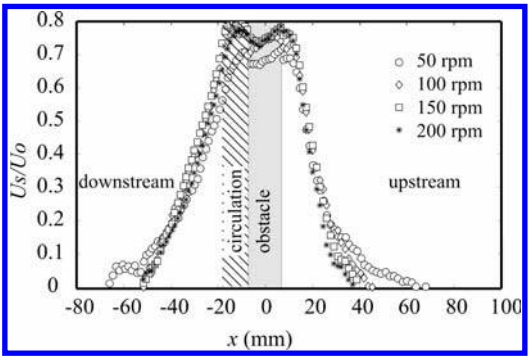

Figure 6. Upstream and downstream variation of the velocity scale *Us*.

Table 3. Parameters of the function in eq.6. The uncertainty is at 95% confidence level.

Test (rpm)	a	b	R^2
100	$0.88 \pm 1.4\%$	$0.31 \pm 4.3\%$	0.988
150	$0.93 \pm 2.8\%$	$0.33 \pm 4.2\%$	0.987
200	$0.81 \pm 4.7\%$	$0.29 \pm 6.4\%$	0.972

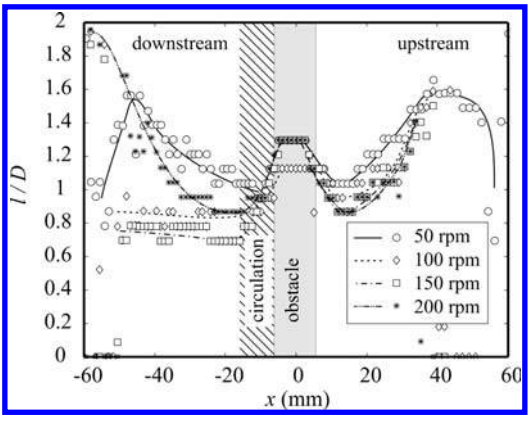

Figure 7. Downstream and upstream transversal length scale.

The data are less coherent than for the velocity scale. For the tests at 100 rpm and 150 rpm the length scale is almost constant or slightly increasing downstream.

The interpolating functions have the following expression:

$$\frac{l}{D} = c\left(\frac{x'-D/2}{D}\right)^{n}, \quad D < x' < 3D \qquad (7)$$

and the least square method estimated parameters are shown in Table 4.

Test (rpm)	c	n	R^2
50	$1.13 \pm 4.6\%$	$0.22 \pm 27\%$	0.67
100	$0.76 \pm 4.0\%$	$0.1 \pm 65\%$	0.26
150	$0.72 \pm 2.7\%$	$0.06 \pm 73\%$	0.23
200	$0.91 \pm 5.1\%$	$0.37 \pm 22\%$	0.75

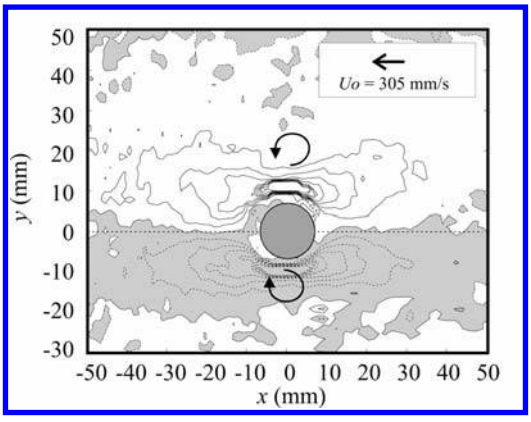

Figure 8. Mean vorticity.

3.2 *Vorticity and divergence*

The average vorticity is shown in Figure 8. Two macro vortices are evident near the upper and lower separation points, two smaller macro vortices appear in the re-circulating zone. Near the bottom and near the free surfaces there are some footprints of local generated vorticity. The variance of vorticity (not shown) is almost uniform, with small values in all the domain. That means that, at least in the analyzed set-up condition, no Von Karman vortices develop.

In Figure 9 the divergence field is shown. In stationary conditions, mass conservation equation for the granular phase can be written as:

$$\mathbf{U} \cdot grad(\ln \rho) = -div\ \mathbf{U} \tag{8}$$

ρ is the bulk density of the grains. Along the symmetry axis the spanwise velocity *Uy* is almost negligible with respect to the streamwise velocity (it should be rigorously zero), and eq. (8) can be integrated to obtain the grain volume concentration:

$$\frac{\rho}{\rho_0} \equiv \frac{C}{C_0} = \exp\left(\int_{x_0}^{x} \frac{-div\ \mathbf{U}}{U_x} dx \right) \tag{9}$$

ρ_0 is the bulk density of the grains in the section x_0; C and C_0 are the corresponding volume concentration of

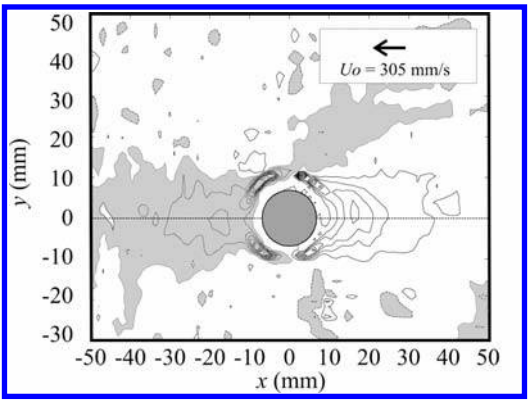

Figure 9. Mean divergence. Dark zones represent positive divergence.

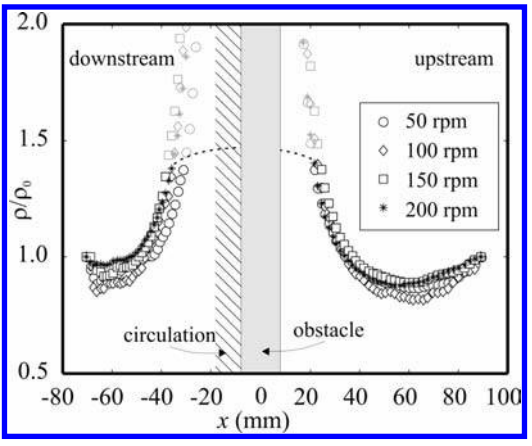

Figure 10. Bulk density variation along the axis of symmetry.

the grains. The results of the integration, carried out separately for the downstream and the upstream areas, are shown in Figure 10.

The uncertainties are high if the velocity is low, i.e. in the zones nearby the dead zones. The results represent only an estimation, because three dimensional effects play an important role, especially in these zones. The indicative limit value of bulk density is shown by the dashed line, but it is affected by a high degree of uncertainty considering that even a small increment in bulk density implies an almost immediate stop of the grains.

4 MEASUREMENTS FOR DRY GRANULAR STREAM

In a second series of tests we analyzed a dry granular stream (air is the inter particle fluid) of almost

Copyright © 2006 Taylor & Francis Group plc, London, UK

spherical particles similar to those used in the first series, $d = 0.25$–0.50 mm. Measurements were carried out using a new instrument able to measure the tangential velocity (two components) of a continuous or discrete surface (Longo, 2004).

The instrument uses PIV technique with an image analysis performed via hardware.

4.1 *Description of the instrument*

The instrument adopts (a) a commercially available opto-electronic chip (Agilent Technologies), (b) a processor by Cypressus, (c) an original interface based on a Microcontroller Microchip PIC. The opto-electronic processor has a micro-CCD which, with a lens, captures the image of the surface, whose velocity has to be measured. A cross-correlation algorithm, applied onto sub-sequent images, allows the estimation of the velocity vector of the patterns contained in the captured images.

The processor by Cypressus codes the output according to a PS/2 protocol. The two processors are available wired and in use on optical mouses, whereas the interface and the software are original. The software, written in Assembly, transforms the binary data from the commercial tool in two analog signals (one for each velocity component), for acquisition by a DAQ board. It is also converted for acquisition through a serial port. It is possible to control the start and the stop of data acquisition. Some tests show that the device can measure the velocity of a continuous surface or of a granular stream apparent surface, with the only limitation that recognizable patterns during motion must exist. The static calibration of the device was carried out measuring the peripheral velocity of a rotating cylinder controlled by a stepper, with an uncertainty equal to 0.6%.

A calibration diagram is shown in Figure 11. The calibration shows an excellent linearity in the range 0–70 mm/s ($R^2 = 0.9986$), a limited STD and an excellent repeatability. According to Agilent, the optical processor can measure up to 300 mm/s (the last generation processors up to 450 mm/s), but a higher velocity also means higher non-linearity and high drop-out rate. The size of the measuring window depends on lenses. With standard lenses in optical mouses it is equal to $2 \times 2\,\text{mm}^2$, with the focal plane at 5 mm from the external surface of the lens and with a focal depth equal to 0.5 mm. The resolution is equal to 2 mm/s and the frequency of acquisition is nearly equal to 200 Hz (the duty cycle lasts for 6 ms) and is limited by software, because the data rate of the optical processor is equal to 1500 frames/s.

It is possible to modify the lens in order to adapt the velocity range and the measuring plane to different needs. We also verified the possibility to use fiber glasses.

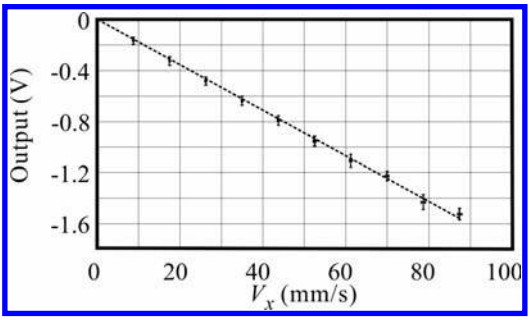

Figure 11. Calibration line of the micro PIV. Single velocity component.

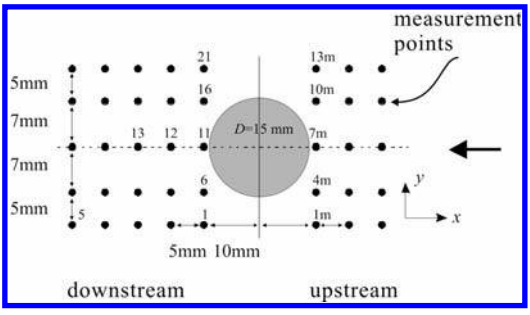

Figure 12. Scheme of the measurement points.

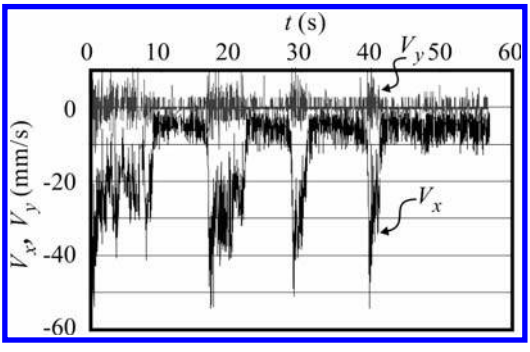

Figure 13. Time series of the two velocity components in point 13. Test at 100 rpm.

4.2 *Application*

The measurements were carried out in a series of points according to the scheme shown in Figure 12, acquiring the velocity signal at 100 Hz for 60 s.

The pattern of velocity field is similar to those obtained using PIV for granular stream in water, even though apparently there is no re-circulation (it could also be the result of a limited resolution of the device). In Figure 13 the two components of the velocity measured along the axis of symmetry, at 20 mm past the axis of the obstacle (point 13, at 12.5 mm past the

Copyright © 2006 Taylor & Francis Group plc, London, UK

boundary of the obstacle) are shown. The rotation rate is equal to 100 rpm and a strong instability is recorded, with stick-slip of the grains at time intervals of few seconds.

The period is of about 10 s. Near the obstacle, the period is the same but the amplitude is smaller. At higher rotation rates the instability disappears.

Upstream the cylinder, the measurements are much more regular and do not show instabilities. Presumably the phenomenon is characterized by large fluctuations of the force exerted by the granular stream on the obstacle. We suppose that the instability is due to the mechanical behavior of the granular stream in static or quasi-static regime. The grains tend to stop for internal friction effects and tend to increase the size of the dead zone. A larger dead zone means a larger force, up to a limiting value, controlled by internal friction. Over this threshold, there is a dilatancy of the grains with a fast and abrupt motion of the grains in the dead zone.

5 CONCLUSIONS

The flow field of a mixture of grains and water round a cylinder is similar to the flow field of a Newtonian fluid.

- Past the obstacle there is a re-circulation zone, a wake zone and an external zone.
- The velocity scale of the wake decays linearly downstream (except for low mean velocity of the stream), the transversal length scale weakly increases. It is still necessary to verify if self-similarity is present, or can be found adopting available rheological models.
- In the range of the present measurements, no Von Karman vortices develop; at high velocity three-dimensional effects, presumably due to flow instabilities, control the flow field.
- Measurements of a dry granular stream were carried out using an innovative PIV and reveal periodic instabilities past the obstacle. The in-stability generates abrupt motion of the grains at rest in the dead zone.

A new approach to solving boundary conditions in shallow water equations using a Riemann solver

V.C. Medina Iglesias, A. Bateman Pinzon & D. Velasco Montes
Hydraulic, Maritime and Environmental Engineering Department, Technical University of Catalonia (GITS-UPC), D1 ETSECCPB, Barcelona, Spain

ABSTRACT: In recent years, the finite volume method has been improved by the Godunov method and Riemann solvers, but the method of characteristics (MOC) is generally used to introduce boundary conditions. This paper proposes a new approach to introducing boundary conditions in a way that is consistent with the Riemann problem solution. The same Riemann solver can be used for the entire domain, including the boundaries. This approach allows shocks and waves of any other type to be introduced as boundary conditions in a way that it is compatible with the Riemann problem solution.

1 INTRODUCTION

The use of the finite volume method in shallow water problems has become more widespread. The Godunov method and Riemann solvers have been combined to obtain high-resolution methods capable of solving transcritical regimes. To test the new advances, researchers usually work with typical standard problems such as dam breaks or bottom topography with a bump.

Problems of this type have boundary conditions that make mathematical sense, such as reflecting or non-reflecting boundary conditions. Under these conditions, the values of the dependent variables of the boundaries can be found immediately. Different boundary conditions are found in real computations applied to rivers and channels. In general (subcritical regimes), the boundary conditions are the upstream discharge value and the downstream water level. To apply boundary conditions, two upstream and two downstream dependent variables are needed. Therefore, the values of two free variables (upstream water level and downstream discharge) need to be interpolated.

This task is usually performed using the method of characteristics (MOC), but this involves using two different numerical schemes to solve the problem: a finite volume method inside the domain and the MOC at the boundaries. This solution is subject to the same problem as the MOC – it cannot be used to solve transcritical regimes. Thus, inside the domain we have a method that can deal with transcritical regimes, and at the boundaries we have a method that cannot deal with discontinuities.

This paper proposes a new approach to introducing normal hydraulic boundary conditions in a way that is consistent with a Riemann solver, making it unnecessary to use the MOC for the boundaries. With this method, boundary conditions with shocks and rarefactions can be used. This method determines which boundary conditions imply a well-posed hydraulic problem and which do not.

In a similar work (Bateman, 1993), the transcritical boundary conditions problem was solved using a modified MOC.

2 GODUNOV METHOD AND THE RIEMANN SOLVER IN SHALLOW WATER

The method proposed in this paper can be applied to any hyperbolic problem. To keep the solution scheme consistent, the same method must be used to solve the domain and the boundaries. This method was specially designed to work with a Godunov method (Godunov, 1959). It uses the Riemann problem solution structure, which is described next.

The Riemann problem solution has two different waves, one from the weak form and one from the quasi-linear form. These two forms and their solutions are defined in the next section. The theory introduced in this chapter is discussed in many different publications (LeVeque, 2002), so we describe it only briefly.

Hyperbolic systems usually take the differential form, and we find differentials in the property and the flux.

$$\frac{\partial q(x,t)}{\partial t} + \frac{\partial f(q(x,t))}{\partial x} = 0 \qquad (1)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

Flux is $f(q(x,t))$, $q(x,t)$ is a state in the state space, x and t are the independent variables, space and time. The rest of this paper deals with shallow water equations, which are systems of two hyperbolic equations that express mass and momentum conservation. There are two conservative dependent variables, depth h(m) and unit discharge hu (m^2/s):

$$q = \begin{pmatrix} h \\ hu \end{pmatrix}$$
$$\begin{cases} \dfrac{\partial h}{\partial t} + \dfrac{\partial hu}{\partial x} = 0 \\ \dfrac{\partial hu}{\partial t} + \dfrac{\partial \left(u^2 h + g \dfrac{h^2}{2} \right)}{\partial x} = 0 \end{cases} \quad (2)$$

Gravity is g, u is the velocity (m/s) defined as hu/h. These equations reproduce the behavior of a rectangular cross section of a channel without friction or slope.

2.1 *Flux computing and discretization*

The relationship between the Godunov method and the Riemann problem is due to the computation of the flux in (1). We have one flux at x_1, upstream of the control volume $[x_1, x_2]$, and the other at x_2, downstream of the control volume. The Godunov method computes these fluxes by solving a Riemann problem. A Riemann problem is a differential problem that has a discontinuity with dependent variable values on either side of it. We can define the average flux between two control volumes at this time as $F^n_{1+1/2}$, and use the self similarity of the hyperbolic equations to compute it.

$$F^n_{i+1/2} = \frac{1}{\Delta t} \int_{t^n}^{t^{n+1}} f\left(q(x_{i+1/2}, t)\right) dt$$
$$F^n_{i+1/2} = f\left(q(x_{i+1/2}, t)\right) \frac{1}{\Delta t} \int_{t^n}^{t^{n+1}} dt \quad (3)$$
$$F^n_{i+1/2} = f\left(q(x_{i+1/2}, t)\right)$$
$$F^n_{i+1/2} = f(q^{\perp}(Q^n_i, Q^n_{i+1}))$$
$$F^n_{i+1/2} = f(q^{\perp}(q_l, q_r))$$

Finally, the Riemann problem solves the hyperbolic equation system between states q_l, q_r, to find the flux solution state $q^{\perp}(q_l, q_r)$. The boundary conditions are an exception because the dependent variables on either side of the Riemann problem are unknown. For example, in the downstream boundary, the right state q_r is known and the left state q_l has one unknown dependent variable (subcritical regime).

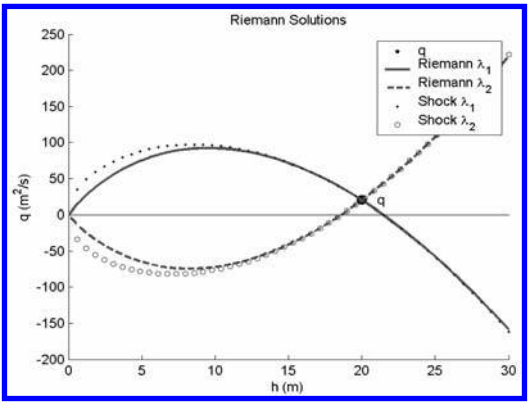

Figure 1. 4 Avaible curves in the state space associated with one state q and solution to a Riemann problem.

2.2 *Riemann solver*

In the SWE Riemann problem there are two families of solution waves, the Rankine Hugoniot waves and the Riemann invariant waves, the first ones are a discontinous waves, namely shocks and the second one are continous waves, namely rarefactions. The solution consists of two states q_l, q_r connected to a third state q_m by waves. Thus, a wave connects q_l, q_m and a wave connects q_m, q_r. Every wave must belong to a family of curves. Each family of solutions has two waves, thus, in every state in the state space, we find four different waves: *Shock* λ_1, *Shock* λ_2, *Riemann* λ_1, *Riemann* λ_1 and *Riemann* λ_2. However, only some parts of these waves are valid. This condition is imposed by entropy (Lax, 1972).

Using the valid solutions from Lax (1972), we constructed a solver by combining the different valid waves to obtain a state q_m, which is connected to a 1-wave in the left state of the Riemann problem q_l and a 2-wave in the right state of the Riemann problem q_r. The valid waves that connect q_l to q_m are:

$$u_m = \begin{cases} u_l + 2\left(\sqrt{gh_l} - \sqrt{gh_m}\right) & h_m < h_l \\ u_l - \left(h_m - h_l\right)\sqrt{\dfrac{g}{2}\left(\dfrac{1}{h_m} + \dfrac{1}{h_l}\right)} & h_m > h_l \end{cases} \quad (4)$$

The valid waves that connect q_r to q_m are:

$$u_m = \begin{cases} u_r - 2\left(\sqrt{gh_r} - \sqrt{gh_m}\right) & h_m < h_r \\ u_r - \left(h_m - h_r\right)\sqrt{\dfrac{g}{2}\left(\dfrac{1}{h_m} + \dfrac{1}{h_r}\right)} & h_m > h_r \end{cases} \quad (5)$$

It's important to note the difference between q_m and $q^{\perp}$, the first one is the Riemann solution and the second

Copyright © 2006 Taylor & Francis Group plc, London, UK

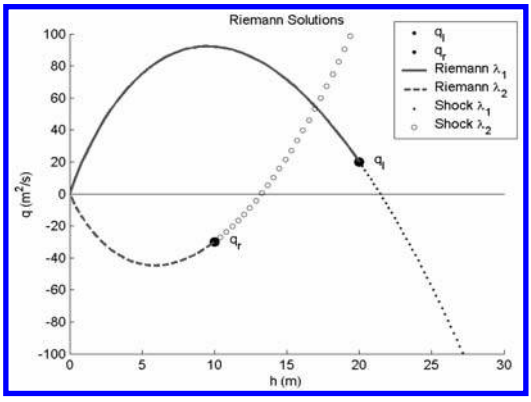

Figure 2. Valid solutions connecting with the two Riemann problem states q_l, q_r.

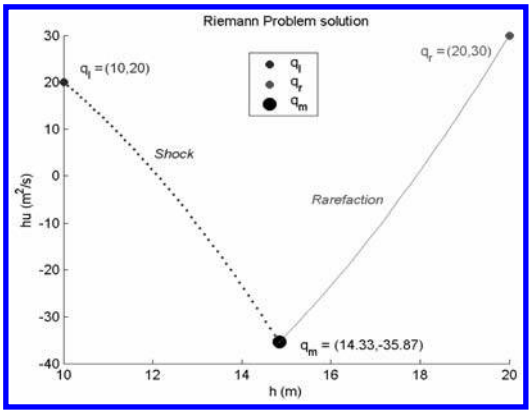

Figure 3. Example of a Riemann problem solution, the left state q_l is connected to the solution state q_m by a *Shock* λ_1 and the solution state is connected to the right state q_r by a *Riemann* λ_2 wave.

one is the flux solution. This difference is essential for the proposed algorithm to solving boundary conditions.

Thus, the algorithm of the Godunov method is:

$$\begin{aligned} &\textit{Dependent Variables} \begin{cases} q_l = Q_i^n \\ q_r = Q_{i+1}^n \end{cases} \\ &\downarrow \\ &q_m = \textit{Riemann Solver}\,(q_l, q_r) \\ &\downarrow \\ &q^{\perp} = q^{\perp}(q_l, q_r, q_m) \\ &\downarrow \\ &F_{i+1/2}^n = f(q^{\perp}) \end{aligned} \tag{6}$$

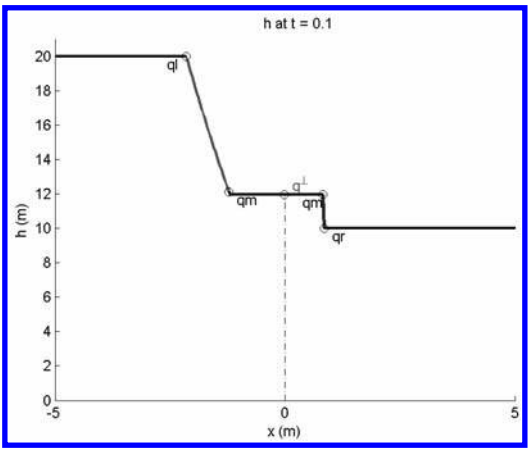

Figure 4. Example of the Riemann problem between q_l, q_r solution q_m and flux computation $q^{\perp}$.

3 BOUNDARY CONDITIONS

With hyperbolic problems, the definition of boundary conditions is not trivial. The number and application points of the conditions determine whether the problem is well posed. The shallow water equation system has two dependent variables and two equations. The system is first-order, so two boundary conditions and an initial state must be imposed. In the domain, there are two different boundaries $x_{1-1/2}, x_{n+1/2}$, and each boundary condition must be imposed on the right boundary.

3.1 *Description of the problem*

In hyperbolic problems, conditions should be imposed on the upwind side, which is defined by the eigenvalues of the hyperbolic system. They can be both positive, both negative, or one negative and one positive. These three cases are the supercritical regime, inverse regime and subcritical regime. In a supercritical regime, the boundary conditions should be defined on the upstream boundary. In an inverse regime, they should be imposed on the downstream boundary. In the subcritical regime, one condition should be imposed on the upstream boundary and the other on the downstream boundary.

As mentioned above, to solve a Riemann problem we need to know the values of the dependent variables on both sides of the Riemann problem. In the supercritical and subcritical regimes, all of the Riemann dependent variables of one boundary are defined and, on the other side, one dependent variable is defined and the other one is unknown. In these regimes, a complete boundary conditions method should test whether the Riemann problem solutions on the boundaries depend on the right dependent variables. On the boundary with

Copyright © 2006 Taylor & Francis Group plc, London, UK

all of the conditions imposed, the solution should be the conditions imposed. On the side without boundary conditions, the Riemann problem solution should not depend on the unknown outside dependent variables. This defines the well-posed problem condition.

The subcritical regime is different. In order to solve the Riemann problem, we have one boundary condition on each side, so the other one must be interpolated. A complete boundary conditions method should find the unknown dependent variable. It should be consistent with the imposed boundary condition and the domain dependent variables. The well-posed problem conditions used for the other regimes should also be applied.

First, the method should test the well-posed condition. Second, the method should interpolate the values of the incomplete dependent variables. These problems have traditionally been solved with the MOC, but this is not consistent with a Godunov method capable of dealing with transcritical regimes.

3.2 *General description of the solution*

This method uses the Riemann problem solution structure to introduce the boundary conditions in the domain. We will use the Riemann solution structure to test whether the boundaries are well posed, and we will use this structure to compute the values of the incomplete boundary conditions (subcritical).

For supercritical and inverse regimes, we need the complete boundary with two imposed conditions (h_{cc}, hu_{cc}) to belong to the supercritical or inverse zone of the state space. We also need the Riemann problem solution state q_m to fulfill another condition, depending on the regime, in order to obtain $q^{\perp} = (h_{cc}, hu_{cc})$.

For subcritical regimes, one dependent variable is imposed on each side of the domain and the other needs to be interpolated. To find this unknown variable, we will impose that it belong to the states connected by valid waves to the inside domain state. Figure 5 shows an example of a subcritical regime with a unit discharge hu_{cc} imposed in the upstream and the other dependent variable h_{cc} interpolated. The state (h_c, hu_{cc}) is connected to the inside state q_r by a *Riemann* λ_2 rarefaction.

$$q_r = Q_1^n \qquad q_l = \begin{pmatrix} h? \\ hu_{cc} \end{pmatrix} \tag{7}$$

Conceptually, this method finds q_m, but for the Godunov method we need $q^{\perp}$. However, as we will see:

In a subcritical regime, boundary conditions are only well posed if $q^{\perp} = q_m$ is fulfilled.

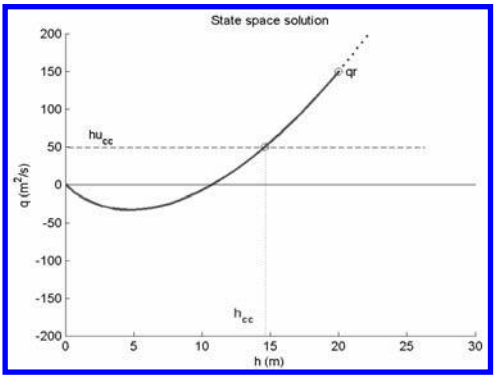

Figure 5. Deduction of the boundary condition h_{cc} from the inside state q_r and the imposed boundary condition hu_{cc}

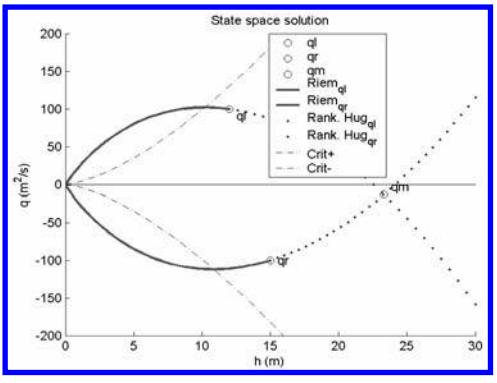

Figure 6. State space figure with the Riemann problem states, the solution state, the waves and the supercritical and inverse zones boundaries.

The demonstration is simple. If we impose a unique boundary condition $(h_{cc} or hu_{cc})$, the resulting flux should depend on the inside state $(q_l or q_r)$ and on the boundary condition itself. The states that depend on the inside state $(q_l or q_r)$ have one degree of freedom, so by imposing the boundary conditions $(h_{cc} or hu_{cc})$, the value of the solution state q_m is defined exactly.

In some cases the solution is undefined, but these cases are not mathematically well posed. The flux solution $q^{\perp}$ should therefore fulfill $q^{\perp} \in [q_m, q_l]$ or $q^{\perp} \in [q_m, q_r]$, depending on the case (downstream or upstream conditions). In some cases, we will find $q^{\perp} = q_m$. However, other cases fulfill $q^{\perp} \in (q_m, q_l]$ or $q^{\perp} \in (q_m, q_r]$, such as transcritical rarefactions. In these cases, the problem is not well posed because $q^{\perp} \neq (h_{cc}, hu_{cc})$, so the boundary condition is not imposed.

3.3 *Figures used to describe the cases*

To illustrate different situations in which this method can be applied, we will use two different figures: one

Copyright © 2006 Taylor & Francis Group plc, London, UK

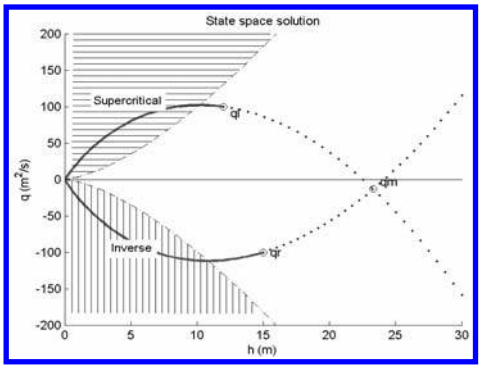

Figure 7. Inverse regime zone and supercritical zone. The remaining zone is for the subcritical regime.

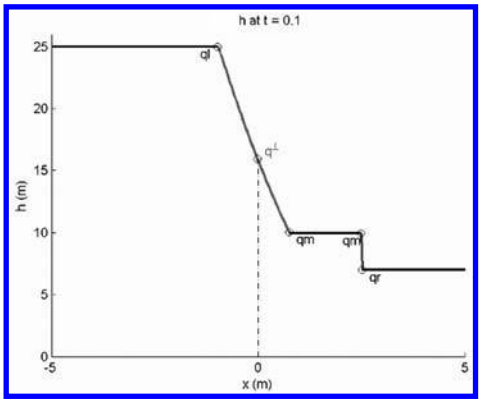

Figure 8. Dependent variable h in the space domain associated with the states $q_l, q_r, q_m, q^{\perp}$. The waves were developed for 0.1 s Possible cases.

with the state space (Figure 7) and another with a dependent variable (h) in the space domain (Figure 8). The latter will reproduce the waves produced in the state space.

The state space graphs will contain the Riemann problem states q_l, q_r, the solution state q_m and the flux state $q^{\perp}$. The valid waves connected to these states will also be drawn. The continuous waves represent the rarefactions; q_l connects to *Riemann* λ_1 and q_r connects to *Riemann* λ_2. The discontinuous lines represent the shocks; q_l connects to *Shock* λ_1 and q_r connects to *Shock* λ_2. We will also find two curves, Crit+ and Crit−, which define the boundaries of the supercritical and inverse regime zones respectively, λ_1, λ_2 are the eigenvalues of the hyperbolic system.

Supercritical regime Crit +

$$\lambda_1 = 0 \Rightarrow u - \sqrt{gh} = 0 \Rightarrow \quad (8)$$

$$u = \sqrt{gh} \Rightarrow \frac{u}{\sqrt{gh}} = 1 = \textit{Froude number}$$

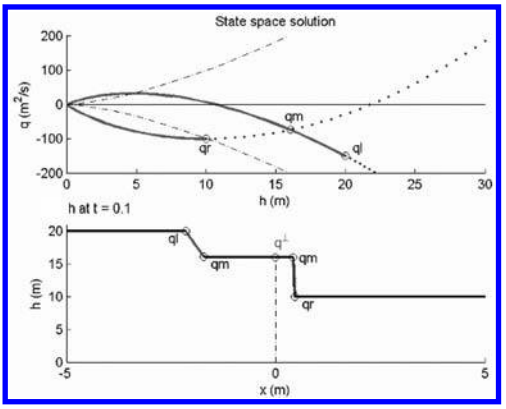

Figure 9. State space and waves.

Inverse regime Crit –

$$\lambda_2 = 0 \Rightarrow u + \sqrt{gh} = 0 \Rightarrow \quad (9)$$

$$u = -\sqrt{gh} \Rightarrow \frac{-u}{\sqrt{gh}} = -1 = \textit{Froude number}$$

3.4 *Possible cases*

This section analyzes various cases and interprets them as boundary conditions. Each case has two interpretations: one as an upstream condition $(q_l, q_m, q^{\perp})$, only one wave connecting q_l, q_m, and the other as a downstream condition $(q_r, q_m, q^{\perp})$, only a wave connecting q_r, q_m. The name of the case depends on q_m.

3.4.1 *Subcritical regime*

In this case, we have $q^{\perp} = q_m$, so the state q_m imposed as a boundary condition for a subcritical regime is valid. If we tried to impose q_l as a supercritical condition on the upstream boundary, it would be wrong because $q^{\perp} \neq q_l$. Likewise, if we tried to impose q_r as an inverse regime boundary condition, it would be wrong because $q^{\perp} \neq q_r$.

In the state space, a *Shock* λ_2 wave connects q_r to q_m and a *Riemann* λ_1 wave connects q_l to q_m.

3.4.2 *Subcritical regime*

In this case, we have $q^{\perp} = q_m$, so the state q_m imposed as a boundary condition for a subcritical regime is valid.

If we tried to impose q_l as a supercritical condition on the upstream boundary, it would be wrong because $q^{\perp} \neq q_l$. Likewise, if we tried to impose q_r as an inverse regime boundary condition, it would be wrong because $q^{\perp} \neq q_r$. In the state space, a *Shock* λ_2 wave connects q_r to q_m and a *Shock* λ_1 wave connects q_l to q_m.

3.4.3 *Subcritical regime*

In this case, we have $q^{\perp} = q_m$, so the state q_m imposed as a boundary condition for a subcritical regime is

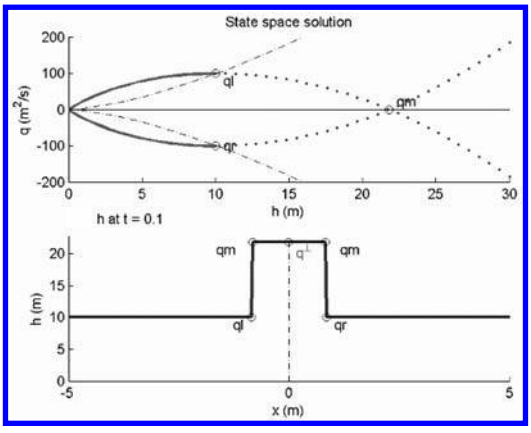

Figure 10. State space and waves.

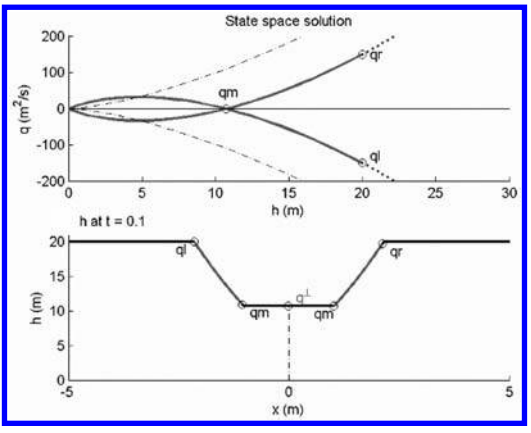

Figure 12. State space and waves.

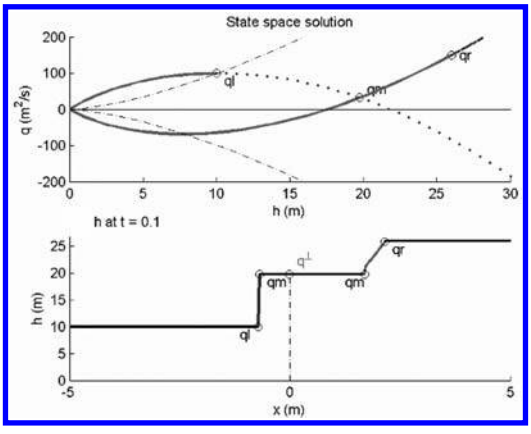

Figure 11. State space and waves.

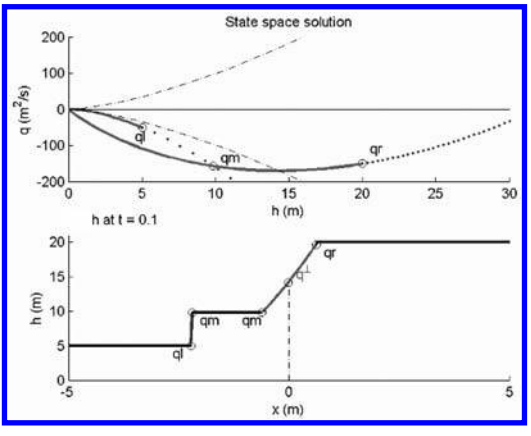

Figure 13. State space and waves.

valid. If we tried to impose q_l as a supercritical condition on the upstream boundary, it would be wrong because$q^{\perp} \neq q_l$. Likewise, if we tried to impose q_r as an inverse regime boundary condition, it would be wrong because $q^{\perp} \neq q_r$.

In the state space, a *Shock* λ_1 wave connects q_r to q_m and a *Riemann* λ_2 wave connects q_l to q_m.

3.4.4 *Subcritical regime*

In this case, we have $q^{\perp} = q_m$, so the state q_m imposed as a boundary condition for a subcritical regime is valid.

If we tried to impose q_l as a supercritical condition on the upstream boundary, it would be wrong because $q^{\perp} \neq q_l$. Likewise, if we tried to impose q_r as an inverse regime boundary condition, it would be wrong because $q^{\perp} \neq q_r$.

In the state space, a *Riemann* λ_1 wave connects q_r to q_m and a *Riemann* λ_2 wave connects q_l to q_m.

3.4.5 *Inverse regime*

As a downstream condition in a subcritical regime (q_r does not exist), q_m would be valid because $q^{\perp} = q_m$. As a downstream inverse regime boundary condition ($q_r = (h_{cc}, hu_{cc})$), q_r would not be valid because $q^{\perp} \neq q_r$.

As an upstream boundary condition (supercritical or subcritical), it would be wrong because $q^{\perp} \neq q_l$ in supercritical ($q_l = (h_{cc}, hu_{cc})$) and $q^{\perp} \neq q_m$ in subcritical.

3.4.6 *Inverse regime*

As a downstream condition in a subcritical regime (q_r does not exist), q_m would be valid because $q^{\perp} = q_m$. As a downstream inverse regime boundary condition ($q_r = (h_{cc}, hu_{cc})$), it would be valid because $q^{\perp} = q_r$.

As an upstream boundary condition (supercritical or subcritical), it would be wrong because $q^{\perp} \neq q_l$ in supercritical ($q_l = (h_{cc}, hu_{cc})$) and $q^{\perp} \neq q_m$ in subcritical.

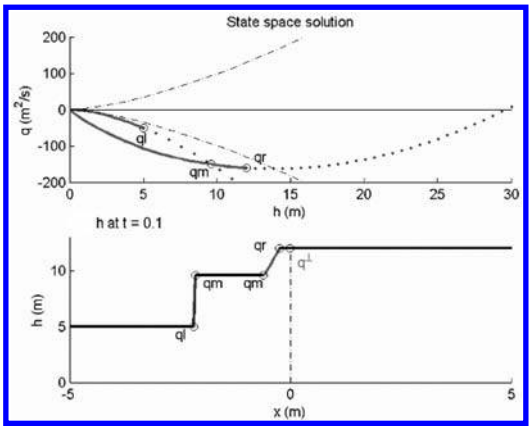

Figure 14. State space and waves.

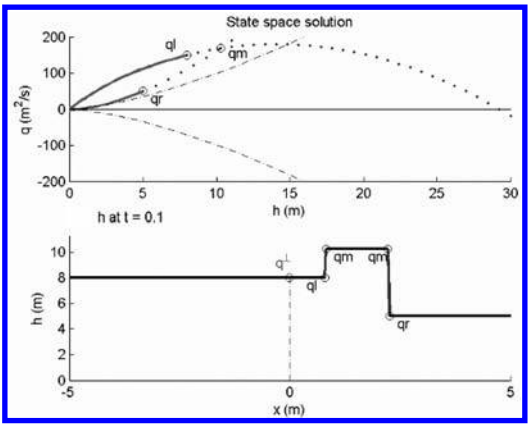

Figure 16. State space and waves.

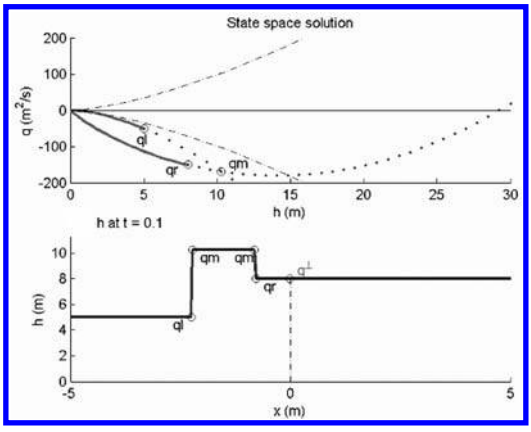

Figure 15. State space and waves.

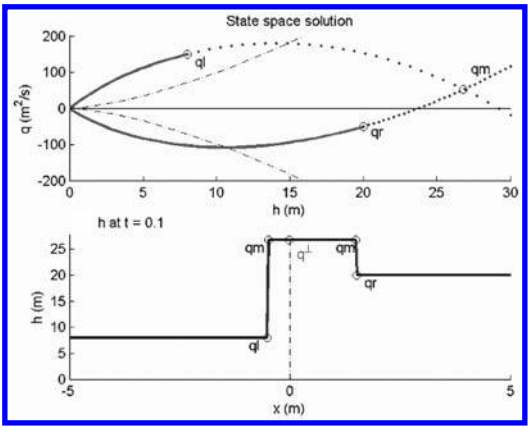

Figure 17. State space and waves.

3.4.7 *Inverse regime*

This case is interpreted like the previous one but has two shocks.

3.4.8 *Supercritical regime*

As an upstream condition in subcritical regime (q_l does not exist), it would be valid because $q^{\perp} = q_m$. As an upstream supercritical regime boundary condition ($q_l = (h_{cc}, hu_{cc})$), it would be valid because $q^{\perp} = q_l$.

As a downstream boundary condition (inverse or subcritical), it would be wrong because $q^{\perp} \neq q_r$ in supercritical ($q_r = (h_{cc}, hu_{cc})$) and $q^{\perp} \neq q_m$ in subcritical.

3.4.9 *Subcritical regime*

This case is important because, if we use $q_l = (h_{cc}, hu_{cc})$ as an upstream supercritical boundary condition, we find that $q^{\perp} \neq q_l$, although q_l is inside the supercritical zone. Thus, it is not a valid upstream supercritical condition.

The condition that must be valid is $s > 0$(Rankine-Hugoniot speed) in this case, the slope of the imaginary line joining q_l and q_m must be positive:

$$\frac{hu_l - hu_m}{h_l - h_m} > 0 \tag{10}$$

A similar condition must be imposed on the inverse regimes. In this case, the slope of the imaginary line joining q_r and q_m must be negative:

$$\frac{hu_r - hu_m}{h_r - h_m} < 0 \tag{11}$$

3.4.10 *Supercritical regime*

This case is the symmetric of 3.4.5, so the interpretation of the boundary conditions is symmetric.

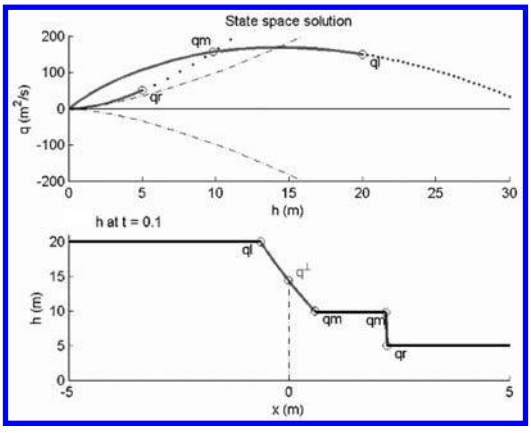

Figure 18. State space and waves.

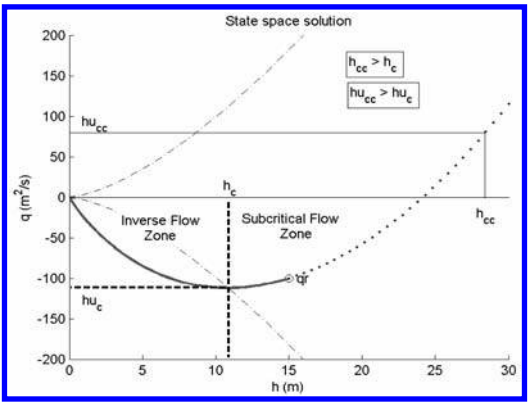

Figure 19. State limit that must be applied to the upstream boundary conditions of subcritical regimes.

3.5 *Solution algorithm*

The type of algorithm depends on the type of boundary condition to be imposed. It does not depend on the regime inside the domain.

3.5.1 *Supercritical regime:*

(a) Check the imposed values of the dependent variables are included in the supercritical regime zone in the state space.
(b) Solve the Riemann problem (q_l, q_r) and find q_m.
(c) Check condition (10) to define $q^{\perp} = q_l$.

3.5.2 *Inverse regime:*

(a) Check the imposed values of the dependent variables are included in the inverse regime zone in the state space.
(b) Solve the Riemann problem (q_l, q_r) and find q_m.
(c) Check condition (11) to define $q^{\perp} = q_t$.

3.5.3 *Subcritical regime:*

To define the subcritical regime algorithm, previous steps must be carried out. In this regime, we impose one boundary condition with a dependent variable (h_{cc} or hu_{cc}) and we interpolate the other dependent variable (hu_{cc} or h_{cc}). To interpolate the unknown dependent variables, we use the waves that connect the known state. In these waves, we find the state that has the imposed boundary condition value (Figure 5). However, the curves are not injective (the shapes are parabolic).

However, there is another limitation. The interpolated state must not be inside the supercritical or inverse regime zones, because if it were it would not be a subcritical condition. Excluding the zones that correspond to supercritical or inverse regimes, the remaining part of the curves is injective. Thus, the mathematical and hydraulic problems are coupled. The limit state is the intersection between the curves and the Crit+ and Crit− curves. This intersection defines the state (h_c, hu_{cc}). For an upstream condition, our boundary condition dependent variables must fulfill:

$$\begin{aligned} h_{cc} &> h_c \\ hu_{cc} &> hu_c \end{aligned} \tag{12}$$

The state is therefore outside of the inverse regime zone.

If we impose a downstream boundary condition, the dependent variables must fulfill:

$$\begin{aligned} h_{cc} &> h_c \\ hu_{cc} &< hu_c \end{aligned} \tag{13}$$

This limitation imposes a maximum for the negative discharges for upstream and downstream boundary conditions. The algorithm is as follows:

(a) Determine the values of h_c and hu_c as interpolation limits.
(b) Considering these limitations, find the unknown dependent variable that corresponds to the known dependent variable imposed as a boundary condition. The result of this step is q_m.
(c) Check that state q_m is not in the supercritical or subcritical zone, because that would indicate a compatible but complete boundary condition (which is only valid for supercritical and inverse regimes).
(d) At this point, we know that $q^{\perp} \in [q_m, q_r]$ or $q^{\perp} \in [q_m, q_l]$. We only need to check that $q_m = q^{\perp}$.

A sufficient condition to fulfill d) is that the inside state (q_l or q_r) is outside of the inverse and supercritical regime zones.

Figure 21 shows an example of this situation. If we impose a subcritical upstream boundary condition (q_m, q_r), q_m fulfills c) but the inside state q_r does not fulfill d). Finally, $q_l \neq q_m$, so it is an invalid upstream boundary condition.

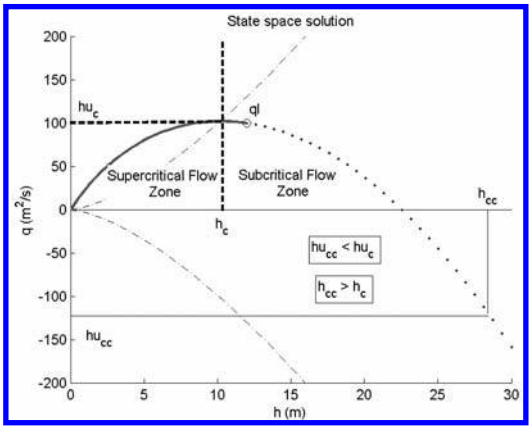

Figure 20. State limit that must be applied to the downstream boundary conditions of subcritical regimes.

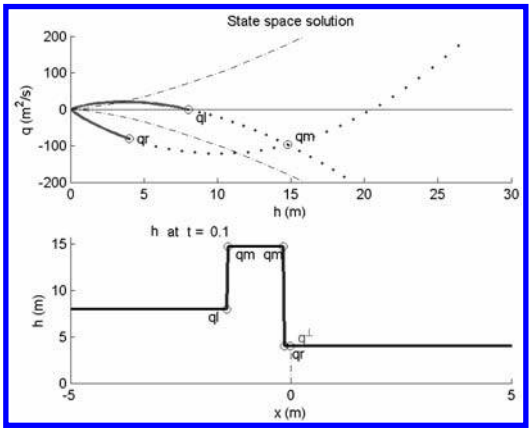

Figure 21. Example of a violation of subcritical boundary conditions.

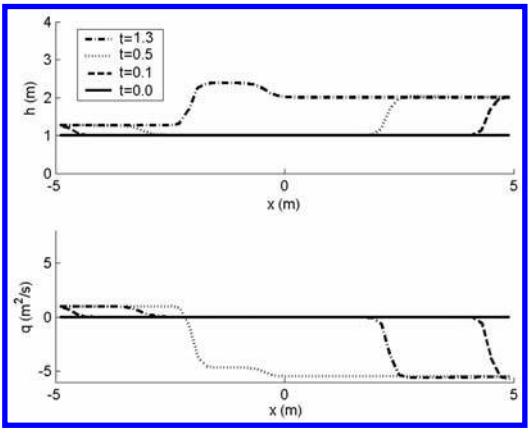

Figure 22. Four states of the channel in the first seconds.

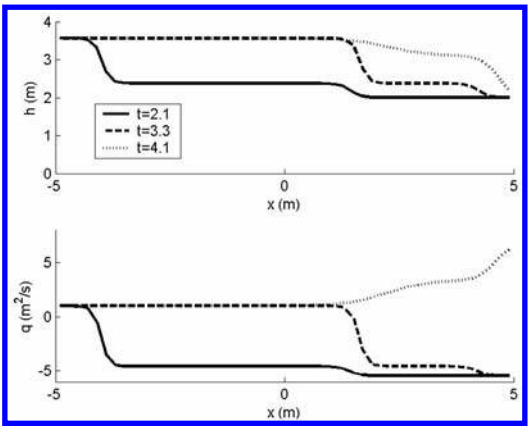

Figure 23. Three states of the channel in the first seconds.

Let us conceptually interpret these limitations. Condition a) imposes that the boundary conditions at least have an influence inside the domain (upwind). Condition c) imposes that the condition may not be complete, because that would imply imposing two values for dependent variables, which is not valid for subcritical regimes.

In hydraulic terms, this condition means that neither the upstream nor downstream discharge may exceed the critical discharge in a channel.

4 RESULTS

This section presents results obtained in a simulation involving a channel 10 meters long and 1 meter wide. The initial conditions are rest, 1 meter depth. The boundary conditions are an upstream discharge of 1 cubic meter per second and a downstream water level of 2 meters.

Figure 22 and Figure 23 show different time results.

When the boundary conditions are imposed, shocks come from the boundaries, and keep unaltered until the wave traveling from the opposite node arrives. Figure 24 shows the changes over time in the depth and discharge in the upstream boundary and in the inside domain node next to the upstream boundary.

Figure 25 shows the changes over time in the state space in the upstream. The boundary curve is always at 1 cubic meter per second because it is imposed, and it changes the depth to adapt to the inside domain situation. The inside node line changes over time until it reaches a steady state, as does the whole channel, in the imposed boundary conditions, discharge 1 m^3/s and depth 2 m. Could happen that the imposed boundary conditions are wrong, in this situation the computation should stop or use spetial condition like critical depth.

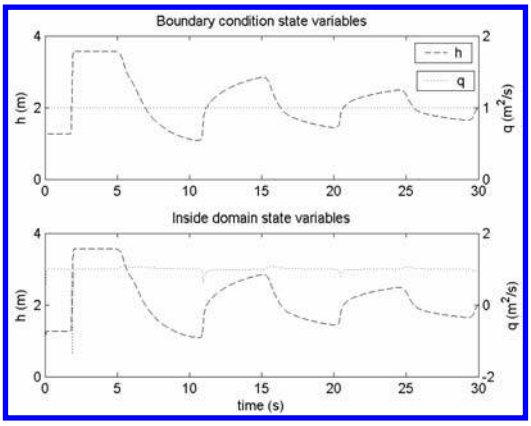

Figure 24. The dependent variables in the upstream boundary and in the inside domain node next to the upstream boundary.

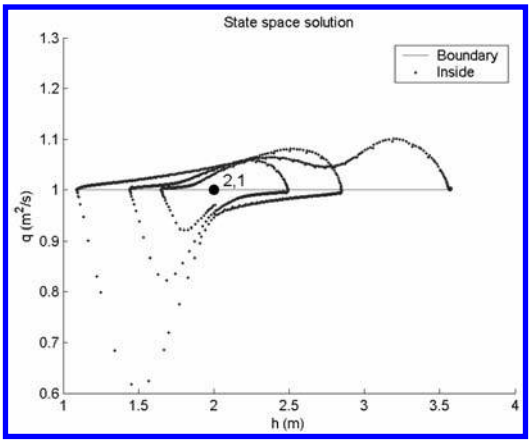

Figure 25. State space variables evolution in the upstream boundary condition and in the inside domain node, both are converging to boundary conditions, $h = 2\,m$, $q = 1\,m^3/s$.

5 CONCLUSIONS

The proposed method combines a filter, which ensures that only well-posed problems are defined, and a method for interpolating the unknown dependent variables in partial boundary conditions (subcritical regimes).

The method is based on the Riemann problem solution and is optimal for the Godunov method.

It allows discontinuities such as boundary conditions to be introduced.

The method can immediately be extended to one-dimensional Euler equations, but more research is required before it can be extended to multidimensional problems.

The method is computed using an exact Riemann solver because is not computationally expensive, so the combination with approximate Riemann solvers should be researched.

The role of quasi-conservative form for morphodynamic modelling in river flow computations

Annunziato Siviglia, Giampiero Nobile & Marco Colombini
DIAM University of Genova

ABSTRACT: Coupling the De Saint-Venant equations with the Exner equation yields to a model for the morphohydrodynamics that can be used to describe flow in rivers the shape of which is determined by the flow itself. Modern numerical models of natural rivers are built upon synchronous solution of the above system, accounting for the strong coupling between water flow, sediment transport, and morphological evolution. Such models are described by a system of hyperbolic equations expressed in primitive (non-conservative) form, thus requiring the use of non-conservative numerical methods for its numerical solution. Methods based on the primitive formulation are known to wrongly compute both the strength and the celerity of shock waves (bores), with consequent loss of mass. Such a problem may affect the numerical solution making it completely useless, in particular for long term morphodynamic simulations. In the present contribution it is shown how a quasiconservative formulation of the governing equations may help to reduce these errors. In particular, numerical solutions are obtained using a quasi-conservative formulation of the well-known MacCormack method. To test the proposed formulation, the model is first applied to idealized benchmark problems. The robustness of the model is then tested routing severe floods through a complex river system and comparing numerical results with the measurements obtained on a physical model of the Vara River in Northern Italy.

1 INTRODUCTION

The relevance of hydro-morphodynamic models (HMM) is essentially based on a simple consideration: water flows in a container which determines the characteristics of the flow but at the same time is amenable of modification by the flow itself. To date, HMM are becoming one of the basic tools for engineering planning, design and assessment. The most widespread class of HMM in literature is the one which uses the De Saint-Venant equations for hydrodynamic flow routing, while bed evolution is described by the Exner equation (Krishnappan 1985; Holly and Rahuel 1990; Cui et al. 1996; Wu et al. 2004).

The majority of the above models are uncoupled (i.e. bed and flow solutions proceed separately) while only few of them solve simultaneously the governing equations. As discussed by Lanzoni et al. (2006), near critical conditions a decoupled approach does predict morphodynamic influence (i.e. propagation of information on bed variations) either upstream or downstream, while only a coupled approach is able to propagate bed information in both directions.

Coupled solutions should then be used for the study of long term evolutions of natural rivers (Cao et al. 2002; Correia et al. 1992; Singh et al. 2004), or, in general, when it is not possible to assume that the flow adapts instantaneously to changes in bed elevation (Colombini and Stocchino 2005).

A second important issue urging for the adoption of a coupled strategy in morphodynamic models is related to the boundary conditions. Lyn (1987) investigated the coupling between flow and sediment dynamics in situations where both the fluid and the sediment discharge are rapidly changing, showing that decoupled models are not capable of satisfying either a general boundary condition or an arbitrary initial condition.

Therefore, adopting a coupled approach for solving the governing equations is a stringent requirement in order to obtain reliable results when flow is close to critical conditions, a situation that characterizes most mountain rivers and, at least locally, is often encountered in natural rivers due to the presence of bridge piers, sudden variations in bed slope or river width.

In all the aforementioned studies, the coupled system is solved without particular focus on the numerical properties of the mathematical formulation adopted for the solution. However, it is well known that a non-conservative (primitive) formulation of the numerical solution leads to a wrong computation of the discontinuities of the solution with consequent loss of

Copyright © 2006 Taylor & Francis Group plc, London, UK

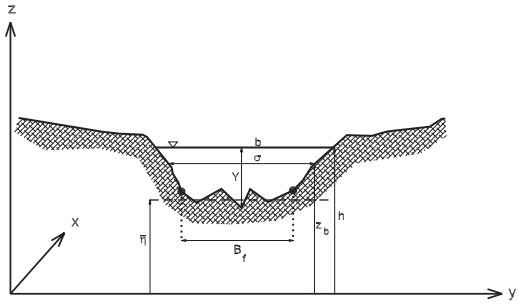

Figure 1. Cross sectional geometry.

mass, thus rendering rapidly meaningless long term morphodynamic simulations.

In his work on the solution of quasilinear hyperbolic system, Lax and Wendroff (1960) proved that conservative numerical methods, if convergent, do converge to correct solutions of the equations. On the contrary, Hou and LeFloch (1994) have shown that non-conservative schemes do not converge to the correct solution if a shock wave is present in the solution, a situation that is often encountered in morphodynamic problems where discontinuities of the solution can appear both in the flow (bores) and on the bed (drop structures, weirs)

To overcome these difficulties a quasi-conservative formulation of the fully coupled De Saint-Venant Exner model, is proposed in the present contribution. An appropriate numerical scheme, based on the well known MacCormack scheme, is also developed to deal with the proposed formulation.

2 PROBLEM FORMULATION

A one dimensional hydro-morphodynamic model which describes the flow over erodible bottom in natural channels is formulated. The riverbed is assumed to be composed of well-graded sediments with the same particle size d_s as those transported by the water flow. The solid transport is characterized by bed-load only, thus ignoring the role of suspension. In such a context, the HMM can be described by a two phase model. The governing equations are obtained imposing mass conservation of the fluid and solid phases and the momentum principle to a dilute suspension of sediment particles flowing in an open channel with a cohesionless bottom. Defining a Cartesian coordinate system (x, y, z) with the x-axis longitudinal, y-axis transversal and the z axis vertical upward (see figure 1), the system of governing equations reads:

Liquid phase continuity equation

$$\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial x} + \lambda_p \frac{\partial B_f \overline{\eta}}{\partial t} = q_l \qquad (1)$$

Solid phase continuity equation

$$(1-\lambda_p)\frac{\partial B_f \overline{\eta}}{\partial t} + \frac{\partial B_f \overline{Q}_s}{\partial x} = q_{sl} \qquad (2)$$

Momentum equation

$$\frac{\partial Q}{\partial t} + \frac{\partial}{\partial x}\left(\beta \frac{Q^2}{A}\right) + gA\frac{\partial h}{\partial x} + gAS_f = \frac{Q}{A} q_l \qquad (3)$$

where A is the cross sectional area, Q and Q_s are the flow rate and the sediment discharge, ql and q_{sl} the liquid and solid discharges per unit length due to lateral inflow/outflow, B_f is the width of the active portion of the bed λ_p is the porosity, η is the bottom elevation, h is the water level, β is the correction coefficient for the momentum, g is the gravitational acceleration and S_f is the friction term. Moreover, in the above equations, an overbar denotes a quantity averaged over the active width B_f.

It is worth noting that the last term on the left hand side of equation (1) accounts for the water that is made available or entrapped through the erosion/ deposition process. The full derivation of equation (1) is given in Lanzoni et al. (2006) (but see also Correia et al. (1992) and Cui et al. (2005)). In the recent literature on the subject of 1-D wave propagation in erodible streams (Cao et al. 2002; Lyn and Altinakar 2002; Cao and Carling 2003) various contributors argued for the significance of the last term which, as clarified by Cui et al. (2005), is likely to be negligible in most natural river and will therefore be ignored in the following.

The above equations can now be written in conservative form. This notion has its roots in the mathematical treatment of the flux and accumulation of physical quantities, e.g., mass, momentum, energy, etc., associated with fluid flow in a control volume. The nature and meaning of conservation-law form have been vastly addressed in the literature (e.g. Cunge et al. (1994), Lai et al. (2002)) and can be traced back to the work of Lax (1957).

Following Cunge et al. (1994), after some algebraic manipulations, the hydrodynamic equations can be rewritten in the following conservative form:

$$\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial x} = q_l \qquad (4)$$

$$\frac{\partial Q}{\partial t} + \frac{\partial}{\partial x}\left(\beta \frac{Q^2}{A} + gI_1\right) = gI_2 + gA(S_0 - S_f) + q_l \frac{Q}{A} \qquad (5)$$

where S_0 is the local bottom slope, I_1 represents a hydrostatic pressure force term

$$I_1 = \int_Y (h - z_b(y))\sigma(x,z)dz \quad , \qquad (6)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

where Y is the water depth, $zb(y)$ is the bed elevation, with

$$\sigma(x,z,t) = \frac{\partial A(x,t)}{\partial z} \quad , \tag{7}$$

and I_2 accounting for the pressure forces in a volume of constant depth due to longitudinal variations,

$$I_2 = \int_Y (h - z_b(y)) \frac{\partial \sigma(x,z)}{\partial x} dz \, . \tag{8}$$

Assuming that the width of the active portion of the bed does not change in time, thus assuming $B_f = B_f(x)$, the 1-D solid phase continuity equation in conservative form reads:

$$(1-\lambda_p)\frac{\partial \overline{\eta}}{\partial t} + \frac{\partial \overline{Q}_s}{\partial x} = \frac{q_{st}}{B_f} - \frac{\overline{Q}_s}{B_f}\frac{\partial B_f}{\partial x} \tag{9}$$

where the last term on the right hand side is treated as a source term similarly to the term I_2 in the momentum equation.

The unknowns in the governing equations (4), (5), (9), are A, Q, $\bar{\eta}$, S_f, and $\bar{Q}_s$, so that a friction resistance law and a sediment-transport formula are required to evaluate S_f and $\bar{Q}_s$. Both are obtained assuming that, locally and instantaneously, the relationships available for steady and uniform flow conditions still hold.

More precisely, the energy loss per unit length of the channel is expressed through a friction coefficient as:

$$S_f = \frac{Q^2}{g(A^2C^2R)} \, , \tag{10}$$

where C is the global conductivity in the cross section and R is the hydraulic radius. Due to the complexity of natural geometries, the calculation of the quantities (A^2C^2R) has been done integrating over the width b (Engelund 1964):

$$A^2C^2R = \left[\int_b c(y)(h - z_b(y))^{3/2} dy\right]^2 \tag{11}$$

where b is the width of the free surface and $c(y)$ is the local conductivity which is a function of the transversal coordinate y. In order to quantify c the Strickler's formula has been adopted:

$$c(y) = \frac{K_s}{\sqrt{g}}(h - z_b(y))^{(1/6)} \tag{12}$$

with K_s being the dimensional Strickler coefficient dependent on the local bed roughness only.

A similar procedure is followed for the sediment transport, leading to

$$\overline{Q}_s = \frac{\sqrt{(s-1)g d_s^3}}{B_f} \int_{B_f} \Phi(\theta(y), \theta_c) dy \tag{13}$$

where s is the relative density, and the local Shields stress is given by

$$\theta(y) = \frac{S_f(h - z(y))}{(s-1)d_s}. \tag{14}$$

Several formulations are available for the sediment discharge function $\Phi(\theta, \theta_c)$. In the following we have considered the one proposed by Meyer-Peter and Müller (1948), where

$$\Phi = 8(\theta - \theta_c)^{3/2}, \qquad \theta_c = 0.047. \tag{15}$$

and the the relationship proposed by Parker (1990), which reads

$$\Phi = 0.00218\, \theta^{3/2} G(\xi), \quad \xi = \frac{\theta}{\theta_r}, \quad \theta_r = 0.0386, \tag{16}$$

with

$$G = \begin{cases} 5474(1 - 0.853/\xi)^{4.5} & \xi \geq 1.65, \\ \exp\left[14.2(\xi - 1) - 9.28(\xi - 1)^2\right] & 1 \leq \xi 1.65, \\ \xi^{14.2} & \xi < 1. \end{cases} \tag{17}$$

The latter, based on field measurements performed on gravel-bed rivers, is characterized by the absence of critical value of the Shields stress for sediment motion even though very low sediment transport rates are predicted for $\xi < 1$.

3 COUPLED VS. DECOUPLED APPROACHES

The choice of the solution strategy for solving the differential problem given by (4), (5) and (9) relies on the relative order of magnitude of the celerities associated with the characteristic curves of the hyperbolic system. The behavior of such curves is well known (De Vries 1965): far from the criticality ($1-F^2 = O(1)$) the celerity of a bed wave is considerably smaller than that of surface waves. The bed interacts only weakly with the water surface, thus justifying an approach in which the equations that govern the dynamics of the liquid phase are solved separately from those governing the solid phase. Near critical conditions exists a transcritical region, $0.8 < F < 1.2$ (Sieben 1999), in which two of the three celerities have the same order of magnitude; in this region the surface waves strongly interact with bed waves provided $1-F^2 = O(\gamma)$, where $\gamma = (Q_s/Q)$ is the solid to liquid discharge ratio (Lyn and Altinakar 2002).

Based on the above considerations, three different solution strategies can be identified (Kassem and Chaudry 1998) according to the method of solution

Copyright © 2006 Taylor & Francis Group plc, London, UK

employed: *decoupled*, *semicoupled* and *fully-coupled*. In the decoupled (asynchronous) approach, the solution is obtained assuming that the change in one variable during a computational time step is small enough that its effect on the other variables can be ignored. Therefore, the hydrodynamic governing equations (4–5) can be solved separately from the morphodynamic equation (9) and can be expressed in the so called conservative form:

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F}}{\partial x} = \mathbf{S}\,. \tag{18}$$

where **U** is the vector of unknowns, **F** is the vector of fluxes and **S** is the vector of source terms. They read, for the liquid phase:

$$\mathbf{U} = \begin{bmatrix} A \\ Q \end{bmatrix} \quad , \quad \mathbf{F} = \begin{bmatrix} Q \\ \beta \frac{Q^2}{A} + gI_1 \end{bmatrix} \tag{19}$$

$$\mathbf{S} = \begin{bmatrix} q_l \\ gI_2 + gA(S_0 - S_f) + q_l \frac{Q}{A} \end{bmatrix} \tag{20}$$

while for the solid phase we have:

$$\mathbf{U} = \left[(1-\lambda_p)\overline{\eta}\right], \qquad \mathbf{F} = \left[\overline{Q}_s\right] \tag{21}$$

$$\mathbf{S} = \left[\frac{q_{sl}}{B_f} - \frac{\overline{Q}_s}{B_f}\frac{\partial B_f}{\partial x}\right]. \tag{22}$$

In the semicoupled approach, the solution proceeds through an iterative procedure. At each time step, the flow solution obtained assuming fixed bed is used to predict the changes in the bed level along the channel. Then, the new bed level is used to adjust the flow variables and the previous steps are iterated until convergence is achieved. As well as in the decoupled approach, the governing equations can be written in conservative form.

In the fully coupled (synchronous) approach all the governing equations are solved simultaneously at each time step. In this case, a problem arises in the evaluation of the term S_0, representing the local slope of the bottom,

$$S_0 = -\frac{\partial \overline{\eta}}{\partial x} \quad . \tag{23}$$

This term can be safely treated as a source term when either a decoupled or a semi-coupled approach is adopted since both solution strategies consider the bed as frozen so that, at each time step, this term is function of the instantaneous geometry of the river. On the contrary, in the coupled formulation the term S_0 represents the first derivative of one of the three independent variables of the complete problem and cannot be considered as a source term anymore. How to incorporate the term gAS_0 in the fluxes is still an open issue, so that primitive versions of the complete set of governing equations are usually adopted for the numerical solution (Cao et al. 2002; Correia et al. 1992; Singh et al. 2004):

$$\frac{\partial \mathbf{U}}{\partial t} + \mathbf{J}\frac{\partial \mathbf{U}}{\partial x} = \mathbf{S}\,. \tag{24}$$

where **J** is the Jacobian matrix corresponding to the fluxes **F** given by

$$\mathbf{J} = \frac{\partial \mathbf{F}}{\partial \mathbf{U}}\,. \tag{25}$$

and

$$\mathbf{U} = \begin{bmatrix} A \\ Q \\ (1-\lambda_p)\overline{\eta} \end{bmatrix} \tag{26}$$

$$\mathbf{J} = \begin{pmatrix} 0 & 1 & 0 \\ \frac{gA}{b} - \frac{\beta Q^2}{A^2} & 2\frac{\beta Q}{A} & \frac{gA}{1-\lambda_p} \\ \frac{\partial \overline{Q}_s}{\partial A}|_Q & \frac{\partial \overline{Q}_s}{\partial Q}|_A & 0 \end{pmatrix} \tag{27}$$

$$\mathbf{S} = \begin{bmatrix} q_l \\ q_l\frac{Q}{A} - gAS_f + g\frac{A}{b}\frac{\partial A}{\partial x}|_Y \\ \frac{1}{B_f}\left(q_{sl} - \frac{\partial B_f \overline{Q}_s}{\partial x}|_{Y,Q} + B_f\frac{\partial \overline{Q}_s}{\partial A}|_{x,Q}\frac{\partial A}{\partial x}|_Y\right) \end{bmatrix} \tag{28}$$

4 PRIMITIVE VS. CONSERVATIVE FORMULATIONS

Once the choice of a fully coupled model for the solution of the morphodynamic system of equations is made, a problem remains in terms of *primitive* versus *conservative* formulations. In purely hydrodynamic problems, both the formulations are available.

It is useful in this context to introduce the concept of *primitivity* of the formulation writing the system of governing equation in the generic form:

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F}}{\partial x} + \mathbf{A}\frac{\partial \mathbf{U}}{\partial x} = \mathbf{S}\,, \tag{29}$$

Setting now **A** to zero produces the conservative form of the equation while setting **F** to zero leads to the primitive form.

Clearly, starting from the conservative form, the primitivity of the equations can be increased moving terms from **F** to **A**, an operation that is always possible while viceversa it can be reduced, when possible, moving terms from **A** to **F**.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The idea behind the *quasi-conservative* formulation presented herein is that the errors related to primitivity can be reduced considerably if all the terms that can be written in a conservative fashion are collected in the fluxes, isolating as much as possible terms that cannot be expressed in conservative form.

The purely hydrodynamic system of equations, which can be written in conservative form, can be of guidance in this procedure leading to the following quasi-conservative formulation of the coupled system

$$\mathbf{U} = \begin{bmatrix} A \\ Q \\ (1-\lambda_p)\overline{\eta} \end{bmatrix} \quad , \quad \mathbf{F} = \begin{bmatrix} Q \\ \beta\frac{Q^2}{A} + gI_1 \\ \overline{Q}_s \end{bmatrix} \tag{30}$$

$$\mathbf{A} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & \frac{gA}{1-\lambda_p} \\ 0 & 0 & 0 \end{pmatrix} \tag{31}$$

$$\mathbf{S} = \begin{bmatrix} q_l \\ gI_2 - gAS_f + q_l\frac{Q}{A} \\ \frac{q_{sl}}{B_f} - \frac{\overline{Q}_s}{B_f}\frac{\partial B_f}{\partial x} \end{bmatrix} \tag{32}$$

Note that the only non vanishing coefficient of the array $\mathbf{A}$ is the one related to the bottom slope S_0 thus reducing primitivity of the system to the minimum.

5 NUMERICAL SOLUTION: THE MACCORMACK METHOD

In this section primitive and quasi-conservative version of the so called MacCormack method are developed to numerically integrate equations (4), (5) and (9) in their different formulations. This classic scheme, developed in the early 1970's (MacCormack 1971), is still widely used for solving open-channel problems, because of its easy implementation for natural river with variable spatial steps and its ability to capture shock waves with second order accuracy both in time and in space.

The MacCormack method is a predictor-corrector two-steps scheme which proceeds in sequence:

$$\mathbf{U}_i^p = \mathbf{U}_i^n - \frac{\Delta t}{\Delta x}\left[\mathbf{F}_{i+1}^n - \mathbf{F}_i^n\right] + \Delta t\mathbf{S}\left(\mathbf{U}^n, x\right) \tag{33}$$

$$\mathbf{U}_i^c = \mathbf{U}_i^n - \frac{\Delta t}{\Delta x}\left[\mathbf{F}_i^p - \mathbf{F}_{i-1}^p\right] + \Delta t\mathbf{S}\left(\mathbf{U}^p, x\right) \tag{34}$$

where the apexes p and c stand for predictor and corrector, respectively.

In both steps, the source terms are evaluated using the pointwise discretisation, but the source term evaluated in the first step is updated of a time step Δt and used for sources evaluation in the second step. It is worth noting that derivatives which are included in the source terms are discretized at each step with backward or forward differences as well as the flux gradient $\delta\mathbf{F}/\delta x$.

In order to formulate a primitive version of the MacCormack scheme the flux gradient (Toro and Siviglia 2003) can be expressed by:

$$\frac{\partial\mathbf{F}}{\partial x} = \frac{\partial\mathbf{F}}{\partial\mathbf{U}}\left(\frac{\partial\mathbf{U}}{\partial x}\right) = \mathbf{J}\left(\frac{\partial\mathbf{U}}{\partial x}\right) . \tag{35}$$

Using (35) the predictor and corrector steps of the MacCormack scheme can be rewritten in primitive form as follows:

$$\mathbf{U}_i^p = \mathbf{U}_i^n - \frac{\Delta t}{\Delta x}\mathbf{J}_{i+\frac{1}{2}}\left[\mathbf{U}_{i+1}^n - \mathbf{U}_i^n\right] + \Delta t\mathbf{S}\left(\mathbf{U}^n, x\right) \tag{36}$$

$$\mathbf{U}_i^c = \mathbf{U}_i^n - \frac{\Delta t}{\Delta x}\mathbf{J}_{i-\frac{1}{2}}\left[\mathbf{U}_i^p - \mathbf{U}_{i-1}^p\right] + \Delta t\mathbf{S}\left(\mathbf{U}^p, x\right) \tag{37}$$

Different options are available for the coefficient matrix $\mathbf{J}_{i+\frac{1}{2}}$ The most promising results are obtained computing this term as a spatial average, namely:

$$\mathbf{J}_{i+\frac{1}{2}} = 0.5\left(\mathbf{J}_i + \mathbf{J}_{i+1}\right) . \tag{38}$$

The quasi-conservative version of the MacCormack scheme is obtained combining the conservative and primitive formulations presented above so that

$$\begin{aligned} \mathbf{U}_i^p &= \mathbf{U}_i^n - \frac{\Delta t}{\Delta x}\left[\mathbf{F}_{i+1}^n - \mathbf{F}_i^n\right] \\ &- \frac{\Delta t}{\Delta x}\mathbf{J}_{i+\frac{1}{2}}\left[\mathbf{U}_{i+1}^n - \mathbf{U}_i^n\right] + \Delta t\mathbf{S}\left(\mathbf{U}^n, x\right) \end{aligned} \tag{39}$$

$$\begin{aligned} \mathbf{U}_i^c &= \mathbf{U}_i^n - \frac{\Delta t}{\Delta x}\left[\mathbf{F}_i^p - \mathbf{F}_{i-1}^p\right] \\ &- \frac{\Delta t}{\Delta x}\mathbf{J}_{i-\frac{1}{2}}\left[\mathbf{U}_i^p - \mathbf{U}_{i-1}^p\right] + \Delta t\mathbf{S}\left(\mathbf{U}^p, x\right) \end{aligned} \tag{40}$$

Finally, the update of the solution to the new time level $n+1$, in all the three schemes presented above, is evaluated as an average between the predictor and corrector steps:

$$\mathbf{U}_i^{n+1} = 0.5\left(\mathbf{U}_i^p + \mathbf{U}_i^c\right) . \tag{41}$$

Another very important issue to address in the numerical solution is related to the generation of spurious oscillations in the vicinity of strong gradients: according to Godunov's theorem these are unavoidable by linear schemes of accuracy grater than

Copyright © 2006 Taylor & Francis Group plc, London, UK

one. Therefore, another step is introduced in order to furnish the scheme with total variation diminishing (TVD) dissipation capable of making the solution oscillation free while retaining second-order accuracy both in space and time almost everywhere (except at extrema points). Following Garcia-Navarro and Alcrudo (1992), the update step now becomes:

$$\mathbf{U}_i^{n+1} = 0.5\left(\mathbf{U}_i^p + \mathbf{U}_i^c\right) + \frac{\Delta t}{\Delta x}\left(\mathbf{D}_{i+\frac{1}{2}} - \mathbf{D}_{i-\frac{1}{2}}\right) \tag{42}$$

where the TVD flux $\mathbf{D}_{i+\frac{1}{2}}$ is a function of the solution at time level n only.

Finally, the CFL stability condition that governs the choice of time step in the numerical solution, can be written as

$$\Delta t \leq CFL\frac{\Delta x}{\max(\lambda_i)} \tag{43}$$

where CFL is the Courant number (≤ 1), Δx is the grid spacing and λ_i is the local eigenvalue (local celerity).

6 BOUNDARY CONDITIONS

Boundary conditions have to be imposed at the upstream and downstream sections of the domain. Studying the mathematical properties of the governing equations it can be shown that the eigenvalues λ_i are always real and distinct. Moreover, they are always two positive and one negative for both subcritical and supercritical flows. Thus, three of the six unknowns at the boundaries (two upstream and one downstream) can always be prescribed by imposing conditions at the boundaries. Information on the remaining unknowns comes out from the interior of the domain and can be found (Garcia-Navarro and Saviron 1992) using the method of the characteristics. This method requires the solution of the so called characteristic equations, which in this case read:

$$\mathbf{a}_i \cdot \frac{d\mathbf{U}}{dt} = \mathbf{a}_i \cdot \mathbf{S} \qquad i = 1,2,3 \tag{44}$$

where

$$\mathbf{a}_i = \begin{bmatrix} -J_{21}J_{33} + J_{23}J_{31} + J_{21}\lambda_i \\ \lambda_i^2 - J_{33}\lambda_i \\ J_{23}\lambda_i \end{bmatrix} \tag{45}$$

In equations (44), d/dt represents the (total) derivative along the characteristic line

$$\frac{dx}{dt} = \lambda_i \tag{46}$$

where λ_i are the eigenvalues of the matrix $\mathbf{J}$.

7 NUMERICAL RESULTS AND DISCUSSION

In this section we firstly assess the performance of the proposed quasi-conservative method using a model hyperbolic system of equations, namely the timedependent non-linear inviscid shallow water equations, written in conservative, primitive, and quasiconservative form. This model system contains nonlinear wave propagation, with smooth and discontinuous solutions. Moreover, for sufficiently simple initial conditions, such as those for a Riemann problem, these equations possess analytical solutions in the form of rarefaction and shock waves.

With reference to equation (29) the model equations written in primitive form read

$$\mathbf{U} = \begin{bmatrix} Y \\ u \end{bmatrix}, \quad \mathbf{F} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \quad \mathbf{A} = \begin{bmatrix} u & Y \\ g & u \end{bmatrix}, \tag{47}$$

while in quasi-conservative form we obtain

$$\mathbf{U} = \begin{bmatrix} Y \\ Yu \end{bmatrix}, \quad \mathbf{F} = \begin{bmatrix} Yu \\ Yu^2 \end{bmatrix}, \quad \mathbf{A} = \begin{bmatrix} 0 & 0 \\ gY & 0 \end{bmatrix}, \tag{48}$$

and in conservative form

$$\mathbf{U} = \begin{bmatrix} Y \\ Yu \end{bmatrix}, \mathbf{F} = \begin{bmatrix} Yu \\ Yu^2 + \frac{1}{2}gY^2 \end{bmatrix}, \mathbf{A} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}. \tag{49}$$

Here $Y = Y(x,t)$ is water depth, $u = u(x,t)$ is particle velocity, and g is the gravitational acceleration. Note that the choice of primitive variables is not unique and that $\mathbf{S} = 0$ for all schemes.

The test solves the model equation in the domain $x\epsilon$ [0, 50] with initial conditions

$$\begin{cases} Y(x,0) = Y_L = 1 & \text{if} \quad x \leq 25 \\ Y(x,0) = Y_R = 0.1 & \text{if} \quad x > 25 \\ u(x,0) = 0 & \forall x \in [0,50] \end{cases} \tag{50}$$

which physically represents a typical dam-break problem in inviscid context.

The analytical solution of this problem contains a left-facing smooth rarefaction wave and a right-facing shock wave, which is associated with the nonlinear fields $u \pm \sqrt{gY}$.

In Figures 2–5 the solutions obtained at time $t = 7s$ with the three different (conservative, primitive and quasi-conservative) formulations are compared with the corresponding analytical solutions. All the results have been obtained with a fine mesh (500 cells) in order to have information on the convergence of the numerical method.

Figure 2 suggests that the conservative formulation of the MacCormack scheme using $CFL = 0.95$ converges to the exact solution. There is good resolution of the smooth part of the flow and high resolution of discontinuities even though spurious oscillations

Copyright © 2006 Taylor & Francis Group plc, London, UK

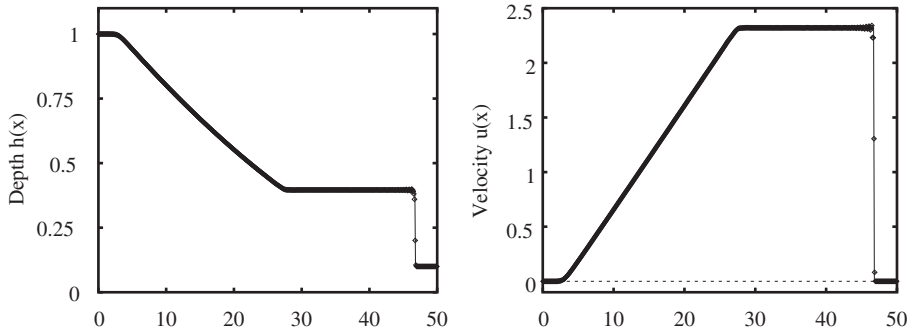

Figure 2. Conservative MacCormack scheme (symbol) and exact solution (line). Results at time $t = 7.0\,s$ for mesh $M = 500$ cells and CFL $= 0.95$.

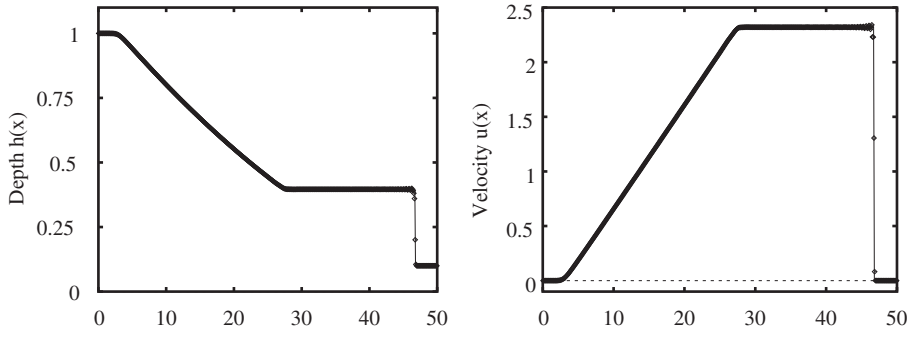

Figure 3. Conservative MacCormack scheme (symbol) and exact solution (line). Results at time $t = 7.0\,s$ for mesh $M = 500$ cells and CFL $= 0.8$.

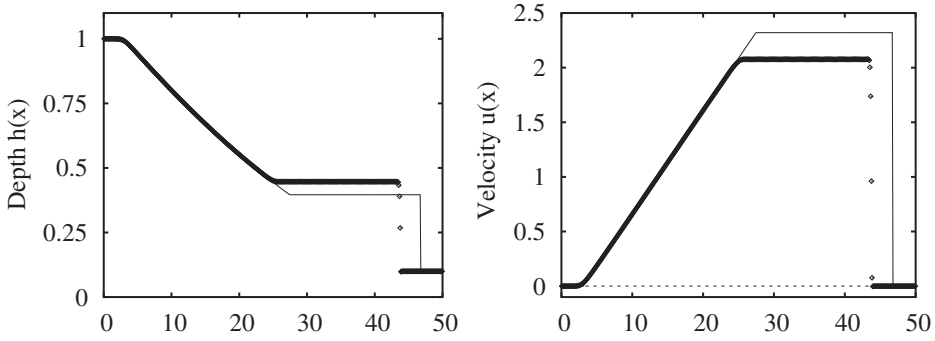

Figure 4. Fully primitive MacCormack scheme (symbol) and exact solution (line). Results at time $t = 7.0\,s$ for mesh $M = 500$ cells and CFL $= 0.8$.

appear in the vicinity of the shock wave. Decreasing *CFL* to 0.8, as shown in Figure 3, makes the oscillations disappear, thus implying that a more stringent stability condition is required by the TVD step. In all the numerical experiments performed, the condition $CFL < 0.85$ was found sufficient to avoid spurious oscillations.

In Figure 4 the results obtained using the fully primitive version of the MacCormack scheme are given. It is clearly shown that both the intensity and the position of the shock are badly predicted, the numerical solution converging to a wrong solution. Note however that the solution is sharply resolved and spurious oscillations are absent in this solution too.

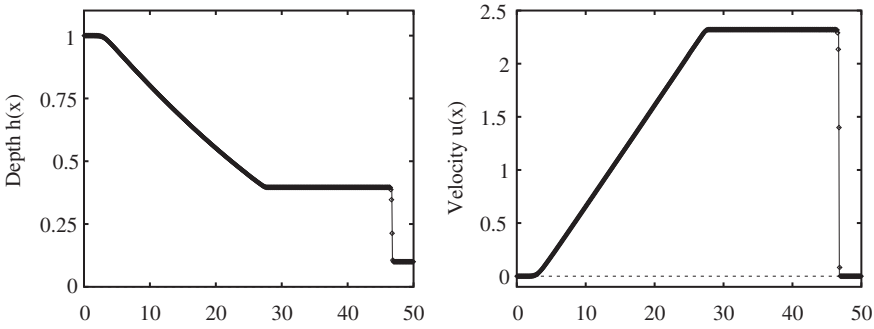

Figure 5. Quasi-conservative MacCormack scheme (symbol) and exact solution (line). Results at time $t = 7.0\,s$ for mesh $M = 500$ cells and CFL $= 0.8$.

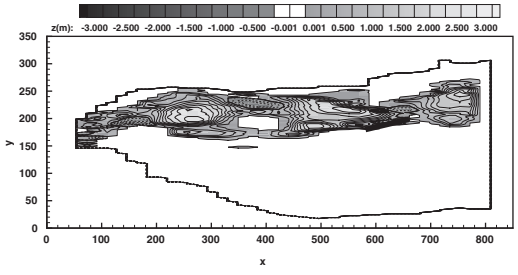

Figure 6. Erosion-deposition contour map at the end of the hydrograph having return period $T = 30$.

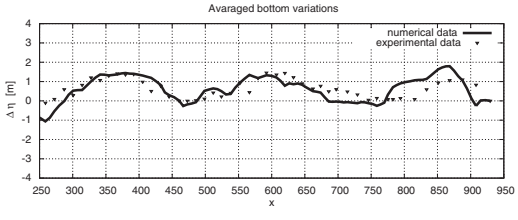

Figure 7. Avaraged bottom variations at the end of the hydrograph having return period $T = 30$.

The above simulations provide an indirect numerical confirmation of the Lax and Wendroff (1960) and Hou and LeFloch (1994) theorems. In fact the conservative numerical method converges to the correct solution of the equations (Lax and Wendroff 1960), while non-conservative (primitive) schemes do not converge to the correct solution if a shock wave is present in the solution (Hou and LeFloch 1994).

The quasi-conservative version of the MacCormack scheme outperforms the fully primitive version of the same scheme. The magnitude of the error related to the primitivity of the mathematical formulation is shown to depend on the relevance of the primitivity itself. Adopting a quasi-conservative formulation, the errors in the computation of the shock speed and strength are sharply reduced to the level that no differences are noticeable comparing Figures 5 and 3.

Once the performances of the proposed model have been numerically tested in a relatively simple configuration, attention has been focused on an application to a natural river. Applications of the present model to the Vara River are part of a more complex river management programme markedly oriented towards the understanding of sediment transport processes. The general aim of the project is to obtain detailed information on some flood defense systems to be constructed along the entire river, with particular emphasis on their interference with the global sediment balance.

At the moment both a physical and a numerical model have been developed In the following some preliminary numerical results are compared with the experimental measurements collected on the physical model.

The Vara River is located in the northern Italy and it drains an area of about 572 Km^2. Reaches morphologically controlled by the massive presence of man-made structures alternates with reaches with either single threaded morphologies with alternate bars or confined meanders. The runoff produced by storm events swiftly exits the watershed, and discharge returns to baseflow levels within 20 h.

In the present study, we focus our attention on a reach of the Vara River which is about 1 Km long and 30 m wide, with an average channel slope of 1% and it is near critical conditions. Along the right side of the main channel, a flood plain is present which is planned to be used as a storage area. At the downstream end of the reach under investigation, a dam with three open gates on the bottom is located to control the flooding of the storage area.

During a flood event, the obstruction created by the dam reduces the velocity of the near critical flow, inducing the formation of an hydraulic jump that in turn increases the water level, progressively flooding the storage area.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The net result in term of peak reduction of the flood is of the order of 20% but, as expected, the dynamics of sediment transport is shown to be strongly affected by the presence of the flood defense system.

The backwater effect induced by the dam implies a decrease of the sediment transport capacity of the flow that ultimately leads to the formation of a significant deposit upstream of the dam. In figure 6 is reported the 2-D erosion-deposition map obtained from the experiments performed on the physical model after one flood having a return period of 30 *years*. The amount of the deposit after just one, even though intense, flood is about 2–3 meters.

The topography shown in the map is obtained scanning the physical model with a laser device and is described, for computational purposes, by a mesh consisting of 140 cross sections. The grain size of the uniform sediment used in the physical model corresponds to an actual diameter d_s of about $9\,cm$. The upstream boundary conditions in both model consists of: i) an hydrograph with a return period of 30 years ($Qmax = 419\,m^3/s$ in the Vara River); ii) equilibrium condition (neither aggradation nor degradation) for the bed. At the downstream end of the reach the rating curve relative to the effect of the dam has been experimentally determined on the physical model.

In order to compare numerical and experimental results, 2D information coming out from the physical model has been transformed in 1D information by means of an averaging procedure over the channel width.

The comparison between numerical and experimental results of the longitudinal distribution of $\bar{\eta}$ after one flood event is given in figure 7 where the difference between the final and initial bed configurations is plotted. Either the intensity or the spatial location of the three regions in which deposition occurs on the physical model are reproduced with a good agreement by the numerical model. No comparisons are made regarding the bed configuration during the flood since it was not possible to stop the simulation on the physical model without altering the bed configuration itself. The numerical simulation shows that deposit just upstream of the dam constantly increases in height during the entire flood, whereas the upstream and middle deposits reach their maximum when the peak of the flood is passing and are slightly eroded during the tail of the hydrograph.

8 CONCLUSIONS

A quasi-conservative formulation of the coupled hydro-morphodynamic model is proposed. New forms of the MacCormack scheme, are also developed and assessed for dealing with the quasi-conservative formulation of the movable-bed model. Comparing numerical results and exact solutions for a test case it is shown that the proposed quasi-conservative formulations outperforms the fully-primitive formulation.

The application of the model to the case of the Vara River, which involves a complex natural geometry and severe flood conditions, reveals its robustness.

A good agreement is found between the numerical results and experimental observations made in laboratory by means of a physical mobile-bed model of the Vara river reach.

Finally, future developments of the present model involve its application to dam break problems over erodible bottom and embankment breaches. Since such phenomena are characterized by rapidly varying flows, the adoption of a quasi-conservative formulation coupled with the quasi-conservative version of the MacCormack numerical scheme proposed in the present contribution, is expected to significantly increase the accuracy of the numerical solutions in these contexts.

Front dynamics of a water surge at high Reynolds number: Similarity solutions to the Saint-Venant equations

C. Ancey, S. Cochard, M. Rentschler & S. Wiederseiner
Ecole Polytechnique Fédérale de Lausanne, Ecublens, Lausanne, Switzerland

ABSTRACT: In this paper, we seek similarity solutions to the shallow-water (Saint-Venant) equations for describing the motion of a gravity-driven surge supplied in fluid by a source placed at the inlet of a horizontal plane. Gratton and Vigo have shown that imposing certain conditions on the inflow rate makes it possible to find similarity solutions to the Saint-Venant equations when a Benjamin-like boundary condition is imposed at the front (i.e., non-zero flow depth). When the flow depth is zero at the front, we show that the solution to the Saint-Venant equations is singular: its curve is the limiting curve of the regular solutions. We also show that the front takes the form of an acute wedge, with a straight free boundary, and is separated from the body by a bore. This singular behavior explains why current numerical models fail in computing the front position and velocity when no *ad hoc* downstream boundary conditions are supplemented.

1 INTRODUCTION

There is a growing number of models inspired from shallow-water (Saint-Venant) equations, which are used to describe time-dependent, free-surface flows involving fluids with various rheologies. Essentially, these models are based on a set of hyperbolic partial differential equations that are obtained by integrating the mass and momentum balance equations across the flow depth. Typical examples include density currents (Rottman and Simpson 1983), particle suspensions (Parker et al. 1986), viscoplastic fluids (Huang and Garcìa 1998), dry granular flows (Savage and Hutter 1989), saturated granular fluids (Iverson and Denlinger 2001), etc.

The models cited above have often been used to compute the collapse of a finite volume of fluid or the spread of a surge emanating from a source with a given inflow rate. The common characteristics of these flows is that they have a front exhibiting a significant curvature of the free surface. For an inertia-dominated regime, an *ad hoc* boundary condition must often be imposed at the front by constraining the value of the Froude number in order to take into account the resisting effect of the ambient fluid (Benjamin 1968). This is tantamount to considering the front as a discontinuity (bore) moving at a prescribed velocity. Using phase-plane formalism, Gratton and Vigo (1994) provided evidence that the front controls the dynamics of the body on some specific circumstances. A few analytical results have also been established without imposing this front condition: Ritter (1892) provided an analytical solution to the shallow-water equations for the dam-break problem. In that case, it was shown that the head was an elongating wave presenting an acute angle at the leading edge. Later, Dressler (1952) and Whitham (1954) demonstrated that hydraulic resistance modified the shape and velocity of the front. In addition to providing more rigorous proofs, Hogg and Pritchard (2004) found that taking shearing effects into account substantially alters the mathematical structure of the solution to the dam-break problem, especially in the tip region.

The objective of this paper is to find similarity solutions to the Saint-Venant equations in the context of rapidly varying surges emanating from a source and spreading along a horizontal plane. Similarity solutions were found in an earlier paper by Gratton and Vigo (1994), where these authors considered a Benjamin-like boundary condition at the front, i.e., the Froude number Fr is constant and the flow depth is nonzero. Gratton and Vigo (1994) claimed that the solution associated with the boundary condition $h = 0$ is found by taking the limit $Fr \to \infty$. In this paper, we will show that the proper solution associated with a zero flow depth at the front is a singular curve, which structurally differs from the solutions related to a Benjamin-like boundary condition. Emphasis will be given to the topological structure of the equations in the tip region. It will be shown that the front dynamics is fully controlled by the critical points of the phase plane, implying that the shape and velocity of the tip

Copyright © 2006 Taylor & Francis Group plc, London, UK

region are imposed independently of the far-field conditions. We will show that the solutions found in this paper are in fairly good agreement with the analytical solutions to the Euler equations (Ancey et al. 2006).

2 GOVERNING EQUATIONS

2.1 *Flow-depth averaged equations*

We consider a shallow layer of fluid flowing over a rigid horizontal impermeable plane. The fluid is inviscid and incompressible; its density is denoted by ρ. The ratio $\epsilon = H_*/L_*$ between the typical vertical and horizontal lengthscales, H_* and L_* respectively, is assumed to be small. $U_* = O(\sqrt{gH_*})$ is the velocity scale.

Integrating the local Euler equations over the flow depth provides the shallow-water equations. Since they are classic, the details of their derivation are not reported here (Stoker 1957). The shallow-water equations take the generic dimensionless form

$$\frac{\partial h}{\partial t} + \frac{\partial h\bar{u}}{\partial x} = 0, \tag{1}$$

$$\frac{\partial h\bar{u}}{\partial t} + \frac{\partial h\overline{u^2}}{\partial x} + h\frac{\partial h}{\partial x} = 0, \tag{2}$$

where the bar refers to flow-depth averaged values. The dimensionless velocity, flow-depth, distance, and time were defined as $\bar{u} = \hat{u}/U_*$, $h = \hat{h}/H_*$, $x = \hat{x}/L_*$, and $t = \hat{t}U_*/L_*$, respectively, where the hat refers to dimensional variables. Introducing the Boussinesq coefficient γ makes it possible to relate the mean square velocity to the square of the mean velocity: $\overline{u^2} = \gamma\bar{u}^2$. In so doing and assuming that γ is known, we obtain a closed set of equations for h and $\bar{u}$

$$\frac{\partial h}{\partial t} + \frac{\partial h\bar{u}}{\partial x} = 0, \tag{3}$$

$$\frac{\partial \bar{u}}{\partial t} + (2\gamma - 1)\bar{u}\frac{\partial \bar{u}}{\partial x} + \bar{u}^2\frac{\partial \gamma}{\partial x} = -\frac{\partial h}{\partial x}\left(1 + \frac{\bar{u}^2}{h}(\gamma - 1)\right). \tag{4}$$

When γ is set equal to unity in the momentum balance equation (4), we retrieve the usual form of the shallow-water equations (Stoker 1957). When γ is constant and in excess of unity, the conservation form of Eqs. (3–4) is identical to the equations used by Hogg and Pritchard (2004) to analyse the effect of shear on front structure. In that case, the structure of the governing equations is slightly altered: the convective acceleration term is weighted by the shape factor $2\gamma - 1$, while a Chézy-like term affects the pressure gradient. These modifications are minor and do not disturb the hyperbolic nature of the equations; they may, however, have significant impact on some occasions, e.g. when computing the nose features in the dam-break problem (Hogg and Pritchard 2004). A pervasive assumption is to ascribe the Boussinesq coefficient to unity by advocating that in the high Reynolds number limit, the velocity profile is blunt, which implies that γ must not differ significantly from unity.

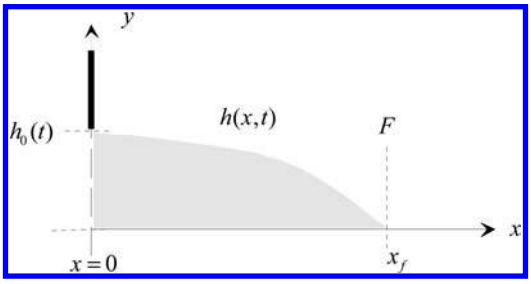

Figure 1. The configuration of the flow.

2.2 *Flow geometry and boundary conditions*

A two-dimensional flow regime is assumed, namely any cross-stream variation is neglected. The depth of the layer is given by $h(x, t)$ (see Figure 1). The flow is generated by a source of fluid: at $t = 0$, the sluice gate at the inlet is raised with a given aperture rate $h_0(t)$. Ahead of the front, there is a dry bed.

At the source $x = 0$, the unleashed volume $\mathcal{V}$ varies with time as follows

$$\mathcal{V} = \int_0^{x_f} h(x, t)dx = At^n, \tag{5}$$

with n a prescribed coefficient; in the forthcoming numerical applications, we will take $n = 5/2$. The boundary condition (5) is equivalent to imposing the flow rate at the inlet: $\bar{u}h = nAt^{n-1}$. To get rid of the initial-value problem, we furthermore assume that the Froude number at the source is imposed: $Fr_0 = \bar{u}/\sqrt{h} = 2a/3$, where a is a constant. The flow depth varies with time: $h = h_0(t) = at^m/d$, where $m = \frac{2}{3}(n - 1)$ ($m = 1$ in the numerical applications here, since $n = 5/2$) and d is a constant. Note that d and a are linked: they both related through the relation $A = \frac{2}{3n}a^{5/2}d^{-3/2}$ (this relation is found by integrating the solution to find the volume).

The other boundary conditions is prescribed at the front. The front position x_f is the point where the flow depth drops to zero: $h(x_f) = 0$; moreover, the front velocity is $\bar{u}(x_f) = \dot{x}_f$.

2.3 *Jump conditions*

The solutions to the system (3–4) may admit discontinuities (shock or hydraulic jump in the hydraulic

Copyright © 2006 Taylor & Francis Group plc, London, UK

literature). The flows either side of these are connected by jump conditions which express conservation of mass and momentum across the moving discontinuity. Denoting the shock speed by σ, these jump conditions associated with conservative form of Eqs. (3–4) are given by (Whitham 1974)

$$[\![h\bar{u}]\!] = \sigma[\![h]\!], \tag{6}$$

$$[\![\gamma h\bar{u}^2 + h^2/2]\!] = \sigma[\![h\bar{u}]\!], \tag{7}$$

where the $[\![\cdot]\!]$ denotes the difference upstream and downstream of the shock.

3 PHASE-PLANE FORMALISM

In order to solve the similarity problem, we will use the 'phase-plane' (or portrait) formalism as earlier authors did for the same kind of problem (Grundy and Rottman 1986; Gratton 1991; Gratton and Vigo 1994). The types and characteristics of the similarity solutions are described in details by Gratton and Vigo in (Gratton and Vigo 1994) when the downstream boundary condition is of the Benjamin type, i.e., at the front, the Froude number is constant and the flow depth is nonzero. Gratton and Vigo claimed that the boundary condition $h(x_f) = 0$ is obtained asymptotically by making the Froude number tend to infinity (Gratton and Vigo 1994), but we will show that in the particular case investigated here, their construction is not possible. Except for this point, the formalism is identical to that used in (Gratton and Vigo 1994) and we will not replicate their results. This notably implies that we will focus on a single particular case $n = 5/2$ in our applications for clarity (the other cases being similar).

Gratton and Vigo (1994) have shown that the governing equations (3–4) admit similarity solutions for a range of conditions at the source $0 \leq n < 4$. This condition on n is needed for the shallowness assumption to be consistent. Following Grundy and Rottman (1986) and Gratton and Vigo (1994), we pose

$$u = \delta\xi t^{\delta-1} V(\xi), \tag{8}$$

$$h = \delta^2 \xi^2 t^{2(\delta-1)} Z(\xi), \tag{9}$$

where ξ is the similarity variable

$$\xi = \frac{x}{t^\delta}, \tag{10}$$

with δ to be determined from the initial conditions (5). The boundary conditions impose

$$Z(\xi_f) = 0 \text{ and } V(\xi_f) = 1, \tag{11}$$

where ξ_f denotes the front position. At the source, we have the asymptotic behaviour

$$Z \propto \frac{a}{d}\frac{1}{\delta^2\xi^2} \text{ and } V \propto \frac{2}{3}\frac{a^{3/2}}{\sqrt{d}}\frac{1}{\delta\xi} \text{ when } \xi \to 0. \tag{12}$$

Since the solution may admit discontinuities, we supplement the following condition derived from Equation (5), which ensures that the mass balance is not violated

$$\int_0^{\xi_P} \xi^2 Z(\xi) d\xi = \delta^{-2}\mathcal{V}, \tag{13}$$

with $\mathcal{V}$ the total volume and ξ_P the front abscissa. When there is not discontinuity, this equation is redundant with Equation (12).

4 SIMILARITY SOLUTIONS

We shall see that ξ is an autonomous variable in the governing equations for Z and V, which means that we can get rid of ξ and directly seek a relation between Z and V by solving a first-order ordinary differential equation in the form

$$\frac{dZ}{dV} = \frac{F(V,Z)}{G(V,Z)}. \tag{14}$$

The behaviour of the solutions to this equation can be qualitatively outlined by working in the $V - Z$ plane and discussing the various possibilities of finding an 'integral' curve passing through a given region.

4.1 *Matrix representation and critical curves*

Substituting the similarity forms into the governing equations (3–4), we obtain two ordinary first-order differential equations for Z and V that can be cast in a matrix form

$$\mathbf{M}(V,Z)\frac{d\mathbf{w}}{d\xi} = \frac{Z}{\delta\xi}\mathbf{S}(V,Z), \tag{15}$$

with $\mathbf{w} = [Z, V]^{\mathrm{T}}$,

$$\mathbf{M} = \begin{bmatrix} V-1 & Z \\ (\gamma-1)V^2 + Z & Z(V(2\gamma-1)-1) \end{bmatrix}, \text{ and} \tag{16}$$

$$\mathbf{S} = \begin{bmatrix} 3V\delta - 2 \\ 2\delta Z + V(V(4\gamma-3)\delta - 1) \end{bmatrix}. \tag{17}$$

The determinant of the matrix $\mathbf{M}$ is

$$\det \mathbf{M} = \delta Z\,(Z - I(V))\,, \tag{18}$$

with $I(V) = 1 + (V-2)V_\gamma$. Along the V-axis ($Z = 0$) and the curve C_I of equation $Z = I(V)$, the solutions

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 1. Properties of the special curves C_A, C_F, C_I, and C_J.

Label	Equation	Properties
C_A	see Eq. (27)	Exceptional solution to Eq. (14)
C_F	$F=0$	Integral path having horizontal tangent when crossing C_I
C_I	$Z=I(V)$	Critical curve separating sub- and super-critical regimes
C_J	$Z=J(V)$	Integral path having vertical tangent when crossing C_J

$V(\xi)$ and $Z(\xi)$ to Equations (15) are not properly defined because $\det \mathbf{M}=0$: these functions are multivalued except when the crossing occurs close to a critical point. A multivalued behaviour is not physically admissible and this issue is fixed by constructing discontinuous solutions (see Section 5).

When $\det \mathbf{M}$ is nonzero, the system of equations (15) can be inverted to provide

$$\xi\frac{dZ(\xi)}{d\xi}=\frac{F(V,Z)}{\delta\,(Z-I(V))}, \tag{19}$$

$$\xi\frac{dV(\xi)}{d\xi}=\frac{G(V,Z)}{\delta\,(Z-I(V))}, \tag{20}$$

with $F(V,Z)=-Z(2Z\delta+V(-2V\delta\gamma+4\gamma+3\delta-3)-2)$ and $G(U,Z)=Z(2-(V+2)\delta)+V(V(2\gamma+((V-4)\gamma+3)\delta-3)+1)$.

Instead of solving this system of differential equations, we form the ratio of the two equations to arrive at a single ordinary differential equation (14) for $Z'(V)$.

When $\det \mathbf{M}$ is zero, the system may have solutions if the determinant of the cofactor matrix

$$\mathbf{N}=\begin{bmatrix} V-1 & 3V\delta-2 \\ (\gamma-1)V^2+Z & 2\delta Z+V(V(4\gamma-3)\delta-1) \end{bmatrix}, \tag{21}$$

is also zero. In the space (V,Z), the locus of the points for which $\det \mathbf{N}=0$ is a continuous curve C_J of the equation

$$Z=J(V)=\frac{V\,(\gamma\delta V^2+(-4\delta\gamma+2\gamma+3\delta-3)V+1)}{(V+2)\delta-2}, \tag{22}$$

Note that $G(V,Z)=Z-J(V)$, which means that C_J is also the locus of points where the integral curves, solutions to Equation (14) have vertical tangents. Except for the case $\gamma=1$ and $n=1$ ($\delta=1$), the curves C_I and C_J do not coincide, but intersect at two points: A_γ with coordinates $(2/(4\gamma-3),(9-8\gamma)/(4\gamma-3)^2)$ and P_* with coordinates $(1,1-\gamma)$. P_* lies inside the first quadrant only when $\gamma\leq 1$. These points play an important role since their existence means that there may be continuous solutions with discontinuous gradients at points A and P_*. They will be useful thereafter in constructing the solutions (see Section 5). When $\gamma=1$ and $n=1$ corresponding to the dam break problem (Whitham 1974), the curves C_I and C_J coincide, which implies that a piece of this curve is a part of the solution sought.

4.2 *Critical points*

In addition to the curves C_I and C_J, there is another specific curve that plays a role in the phase portrait: the curve C_F is the curve along which F vanishes, i.e., at which the integral path has a horizontal tangent; its equation is given by

$$H=\frac{2+U\,(3-3\delta+2\gamma\,(-2+U\,\delta))}{2\delta}. \tag{23}$$

The properties of these curves are summarized in Table 1.

In the first quadrant of the phase plane $V-Z$, there are three critical points resulting from the crossing of the specific curves C_F and C_J. The first one is the origin point O, which is a node. Point A_γ is also a singularity (node). The third one is referred to as point B_γ and has coordinates $(2/(3\delta),(9-8\gamma)/(9\delta^2))$; it is a saddle.

Figure 2 shows a few trajectories, the specific curves (C_I, C_J, and C_F), the critical points (O, A_γ, B_γ), the intersection point P_* between C_I (solid line) and C_J (dashed line), and the front P. Note that at point A_γ, the three curves C_I, C_J, and C_F meet, which implies significant behaviour changes close to point A_γ. A few trajectories (thin curves with arrows) representing solutions to Equation (14) are also reported and illustrate the behaviour of the solutions close to the critical points; not all the paths are physically meaningful since some cross the critical curve C_I (solid line).

5 FLOW DISCONTINUITIES

5.1 *Rankine-Hugoniot condition*

The crossing of the critical curve C_I at a regular point of intersection is not possible, but is possible at a critical point (A_γ here). When the crossing is not permitted, we consider that a shock occurs, which is ruled by the jump conditions (6–7). If we know the flow variables

Copyright © 2006 Taylor & Francis Group plc, London, UK

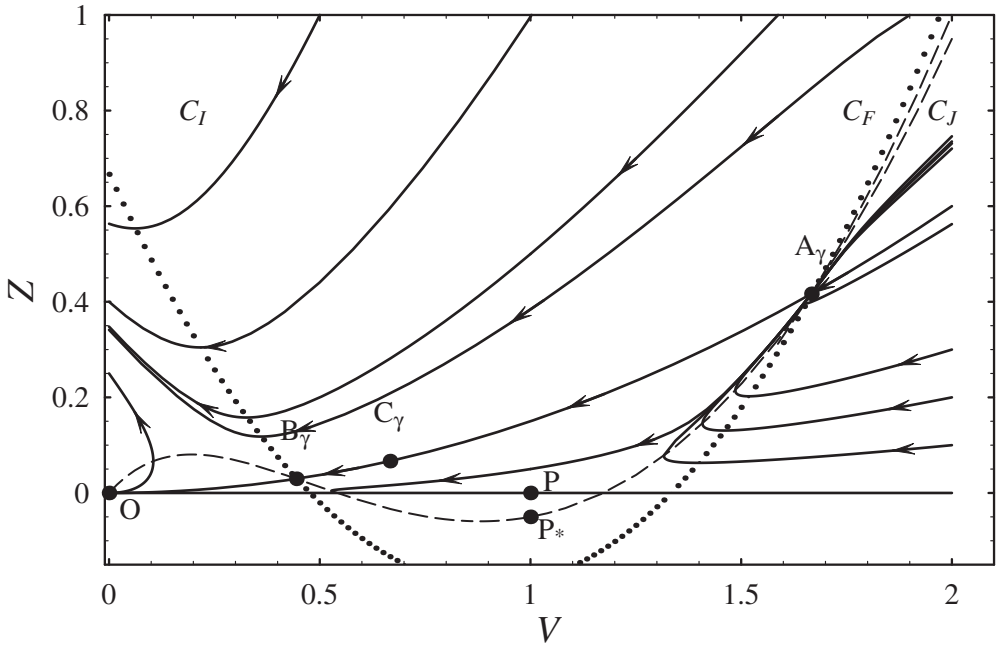

Figure 2. Specific curves C_I (solid line), C_J (dashed line), C_F (dotted line). The thin curves with arrows represent a few trajectories computed numerically. The critical points O, A_γ, B_γ, and C_γ are plotted together with the front (point P). Computations made for $a = 4$, $d = 1$, and $\gamma = 1.05$.

Z_1 and V_1 upstream of the shock, we can solve the shock equations (6–7) to determine the shock velocity σ and a curve referred to as the 'shock curve' $V_2(Z_2|Z_1,\ V_1)$, which is the locus of all the points satisfying the jump conditions (6–7). Solving this system of equations, we derive the shock velocity and the variation in upstream velocity V_2 with upstream flow depth Z_2

$$\sigma = \frac{\gamma}{\chi} V_1 \pm \frac{1}{\chi}\sqrt{\frac{1}{2}\left(\chi(Z_1+Z_2) + 2(\gamma-1)V_1^2\right)\frac{Z_2}{Z_1}}, \tag{24}$$

$$V_2(Z_2|Z_1, V_1) = \frac{V_1}{\chi} \pm \frac{(Z_2 - Z_1)}{\chi}\sqrt{\frac{1}{2}\frac{\chi(Z_1+Z_2) + 2(\gamma-1)V_1^2}{Z_1 Z_2}}, \tag{25}$$

with $\chi = \gamma + (1-\gamma)\frac{Z_2}{Z_1}$. Since there is a quadratic dependence on velocity in Eqs. (6–7), we actually find two shock curves, but a single one is physically admissible by requiring that energy dissipation through the shock be positive. This shock curve is then used to pass from one trajectory to another one that satisfies the boundary conditions downstream. The problem boils down to finding the point (V_1, Z_1) at which the shock occurs. To that end, we use a trial and error procedure: first we select a point (V_1, Z_1) on the integral path emanating from the source S, then we plot the shock curve $V_2(Z_2|Z_1,\ V_1)$, and finally we find the intersection point between the shock curve and the other integral path coming from the front point P. The procedure is iterated until the fluid volume found by numerical integration is consistent by the inflow rate imposed at the plane entrance Equation (13).

5.2 *Weak discontinuities*

It is worth recalling that a particular case of discontinuity includes the functions that are continuous, but whose derivative is not continuous at isolated points. This case is encountered when the curves C_I and C_J coincide (i.e. for $\gamma = 1$ and $n = 1$): when an integral curve crosses the critical curve, we have both $\det \mathbf{M} = 0$ and $\det \mathbf{N} = 0$, which implies that at this point, we can pass from one trajectory to another one and since $\det \mathbf{N} = 0$, the new trajectory is a piece of C_I (Gratton and Vigo 1994).

6 SIMILARITY SOLUTIONS FOR $\gamma > 1$

We first consider the case where the Boussinesq coefficient is prescribed in advance. We are interested in

Copyright © 2006 Taylor & Francis Group plc, London, UK

determining the solutions to Equation (14) evolving in the first quadrant ($V \geq 0$, $Z \geq 0$) and related to $\gamma > 1$ and boundary conditions (11–13).

To simplify presentation, computation and numerical applications were made by taking $n = 5/2$ and $\delta = 3/2$.

6.1 *Special solution*

Note that there is a special analytical solution

$$Z = \frac{1}{4}(9 - 8\gamma)V^2, \tag{26}$$

which is the solution to Equation (14). This curve is a parabola that we call $\mathcal{P}$; the boundary condition (12) implies that the source point S lies at infinity on $\mathcal{P}$. No computation at this stage is needed since the corresponding integral path coincides with the special curve $\mathcal{P}$. As shown in Figure 2, $\mathcal{P}$ crosses the critical curves C_I and the specific curve C_J at point A_γ. Since this point is singular, the crossing is not associated with a hydraulic jump. A bit farther, the parabola once again crosses the curve C_I at point C_γ with coordinates $(2/3, 1 - 9\gamma = 8)$, which is a regular point, implying that the solution should become discontinuous in the neighbourhood of C_γ. The parabola $\mathcal{P}$ does not pass through point $\mathcal{P}$. Since the integral curve crosses the critical curve C_I, discontinuous solutions can be constructed. We then envisage two possibilities.

6.2 *Trajectories in the front neighborhood*

The first possibility occurs that, when reaching point A_γ (for which $\det \mathbf{M} = \det \mathbf{N} = 0$), the integral curves take another path to reach point P. Since A_γ is also a node, all the curves (except for the singular curves) are tangent to a limiting curve C_A, whose equation is given in terms of a Taylor expansion

$$Z = \frac{9 - 8\gamma}{(4\gamma - 3)^2} + \left(V - \frac{2}{4\gamma - 3}\right) \frac{-16\gamma^2 - 4\delta\gamma + 24\gamma + 9\delta - 9}{2(4\gamma - 3)(4\delta\gamma - 4\gamma - 2\delta + 3)} + O(V^2). \tag{27}$$

This equation is obtained by applying L'Hôpital's rule to Equation (14). Note that in numerical applications, we used a power series expansion to order $O(V^6)$ that ensures accuracy to within 10^{-4} in the numerical solution. Except when $\gamma = 1$, this limiting curve does not pass through P. A graphical representation of C_A is given in Figure 3 (dotted line). Since P is a regular point, a single integral curve passes through it: it is

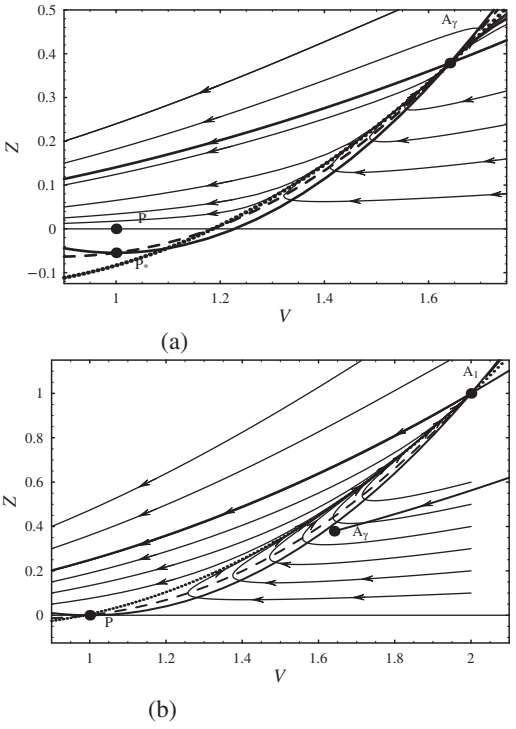

Figure 3. Specific curves C_I (solid line), C_J (dashed line) together with C_A (dotted line). (a) Computations made for $a = 4$, $d = 1$, and $\gamma = 1.05$. (b) Computations made for $\gamma = 1$. The thin curves with arrows represent a few trajectories computed numerically; the arrows indicate increasing ξ. The critical point A_γ (respectively A_1 in subplot b) is plotted together with the front P. The parabola $\mathcal{P}$ is a special trajectory and is plotted in bold; in subplot b, we have also superimposed the parabola $\mathcal{P}$ computed with $\gamma = 1.05$ and ending at A_γ.

the trivial solution $Z = 0$ (the V-axis). The situation is sketched on Figure 3(a): no integral curve except for the trivial solution $Z = 0$ passes through point P representing the front.We conclude that there is no way of joining A_γ and P when $\gamma \neq 1$ by following pieces of integral curves representing regular solutions to Equation (14).

The second possibility occurs when the parabola meets the critical curve C_I at A_γ or C_γ, which would make it possible to use the hydraulic jump conditions (24–25) to find another admissible integral curve. This is not possible because a hydraulic jump cannot form between a dry bed and the current, as mentioned above in solving the Euler equations. Indeed, using the shock conditions (24–25) to relate P to the integral path coming from the source (S) leads to constructing a nonphysical solution since the energy balance equation is violated. Point P can in no way can be located on a shock curve.

Copyright © 2006 Taylor & Francis Group plc, London, UK

6.3 *Construction of the solution within the tip region*

None of these possibilities being effective, we must find another way of constructing the solution. A reasonable assumption is to consider that in the vicinity of the front, the Boussinesq coefficient drops to unity, which ensures that we can find a non-trivial integral path passing through P: the limiting curve C_A, as shown in Figure 3(b) is the only one passing through P except for the trivial solution. We construct the solution as follows. At point A_γ, the flow undergoes a shock: in the phase plane, this implies that there must be a shock curve mapping point A_γ onto another point of the limiting curve C_A that we refer to as point A′. This situation is depicted in Figure 3(b) and Figure 4(a). On Figure 4(a), we have plotted the two shock curves (long-dashed curve) emanating from A_γ using Eqs. (24–25) together with points A_γ and A′; the only physically admissible shock curve is that corresponding to a flow depth increase and a velocity decrease to ensure energy dissipation. Between A′ and P, the integral path follows the limiting curve C_A. We can now compute the solution.

Since the integral path $S \to A_\gamma$ is given by Equation (26), we can analytically compute $V(\xi)$ by integrating Equation (20); we obtain: $\ln \xi^2 = \ln(9V-4) - 3\ln V + e$, where e is a constant of integration. Taking into account the asymptotic behaviour when $\xi \to 0$ given by Equation (12), we deduce

$$\xi_A = \frac{\sqrt{2a^6 - 9a^4 + 27}}{2a^{3/2}\sqrt{3d\delta}}. \tag{28}$$

The path $A' \to P$ must be integrated numerically. For instance, for $a=4$, we find $\xi_A = 1.850$ using the relation just above, $\xi_P - \xi'_A = 1.284$, which leads to $\xi_P = 3.133$. The fluid volume $\mathcal{V}$ is found by numerical integration of $\int_0^{x_p} h(x)dx$ and we find $\mathcal{V} = 8.516t^{5/2}$, which is very close to the exact variation imposed by Equation (13), i.e. $\mathcal{V} = 8.533t^{5/2}$ (relative error of -0.2%). Better agreement can be obtained by considering that the critical transition occurs just upstream of point A_γ; e.g. for $a=4$, the numerical computation (not reported here) showed that the transition occurs at $\xi_A = 1.738$ instead of $\xi_A = 1.850$.

7 SIMILARITY SOLUTION FOR $\gamma = 1$

We are now interested in determining the solution to Equation (14) in the usual case for the Saint-Venant equations, where the Boussinesq coefficient is set equal to unity. The resulting integral path in the phase plane continues to evolve in the first quadrant ($V \geq 0$, $Z \geq 0$) and must satisfy the boundary conditions (11–13). We still take $n = 5/2$ for the computations.

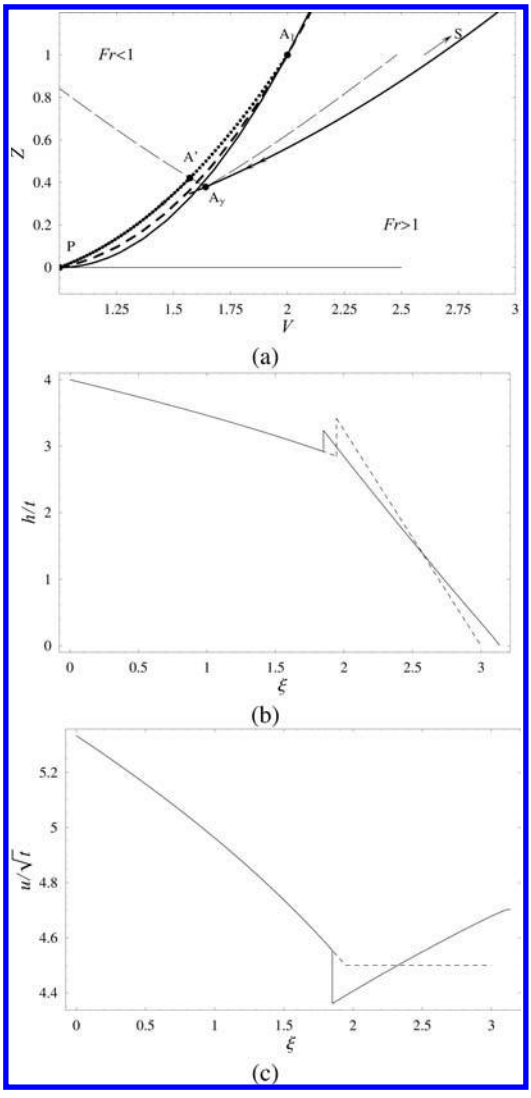

Figure 4. (a) Phase plane in the vicinity of A_γ: the specific curves C_I (solid line), C_J (dashed line), $\mathcal{P}$ (dotted line) are reported. The critical point A_γ is plotted together with the front P. The long dashed lines represent the shock curves emanating from point A_γ. (b) Flow-depth variation with ξ: the solution to the Saint-Venant equations (solid line) is compared with the solution to Euler equations (dashed line). (c) Velocity variation with ξ. All the computations made for $a=4$, $d=1$, and $\gamma = 1.05$.

The general numerical solution of the problem represented by Equation (14) and boundary conditions (11–13) involves computing the solution from the source S to the front P. Given the asymptotic behaviour exhibited by Equation (12), the source is located at infinity on a parabola of equation $Z = (V/\mathcal{F}_0)^2$, where

Copyright © 2006 Taylor & Francis Group plc, London, UK

$\mathcal{F}_0 = \frac{2}{3}a$ denotes the Froude number at the inlet. For numerical purposes, we need to give finite values (V_0, Z_0) to the coordinates of the source point S in the phase plane. Taking large values for the initial value V_0 and posing $Z_0 = (V_0/\mathcal{F}_0)^2$ allows us to reasonably approximate the behaviour close to the source; typically taking $V_0 = 10^4$ is sufficient to obtain solutions accurate to within 10^{-4} close to the inlet. Equation (14) is solved numerically by moving from the source S_0 to the front P. The goal is to find an integral curve reaching point P.

As previously, there is no integral path relating the source point S and the front point P. Moreover, we suspect the occurrence of a jump. Indeed, the topological structure of the phase plane is a bit different compared to the case $\gamma > 1$, since the integral path does not pass through the critical point A1 in the supercritical region and thus crosses the critical curve C_I at a regular point that we refer to as R.

To construct the solution with a discontinuity, we have used the trial and error procedure, as specified in Section 5. As earlier, we note that the only trajectory coming from P is the limiting curve C_A. We then assume that a piece of the path $P \rightarrow A_1$ on this curve is a part of the solution sought; the other part of the solution is a piece of the integral path $S \rightarrow R$. On this latter curve, we guess the position of the point marking the discontinuous transition towards the path $P \rightarrow A_1$; we refer to this point as point E. At regular point E, there is a jump. As a typical example, we have plotted the shock curves (long-dashed line) on Figure 5(a); a single curve crosses the limiting curve emanating from P and we refer to this intersection point as E′.

The path EE′ represents the jump experienced by the surge; the path PE′ is the integral path representing the head while the path ES is the integral curve representing the body. Equations (20) and (14) have been numerically integrated to produce $Z(\xi)$ and $H(\xi)$. For instance, for $a = 4$ and $d = 1$, we found: $\xi_P = 3.077$, $\xi_E = 1.590$ versus $\xi_a = 2.999$ and $\xi_b = 1.945$ for the reference solution given in a companion paper (Ancey et al. 2006), $\xi_P = 3.133$ and $\xi_A = 1.850$ for the Saint-Venant solution related to $\gamma > 1$. The fluid volume $\mathcal{V}$ is found by numerical integration of $\int_0^{xp} \pm h(x)dx$, and we find $\mathcal{V} = 8.533t^{5/2}$, which perfectly matches the fluid volume imposed by Equation (5). It is also worth noting that the solution thus built is sensitive to the numerical estimation of the transition point E: changing the position of the endpoint E by a few percent along the curve SR leads to altering the fluid volume, which shows that there is only one solution for a given set of boundary conditions, at least locally. Similarly to the case $\gamma > 1$, we applied the same shock conditions as used by (Gratton and Vigo 1994) instead of the Rankine-Hugoniot relations (24–25) and again we obtained a solution that differed slightly from the solution given here: indeed, we found $\xi_P = 3.072$, $\xi_A = 1.593$, and $\mathcal{V} = 8.512t^{5/2}$ (i.e. relative deviation of -0.3% with the input volume).

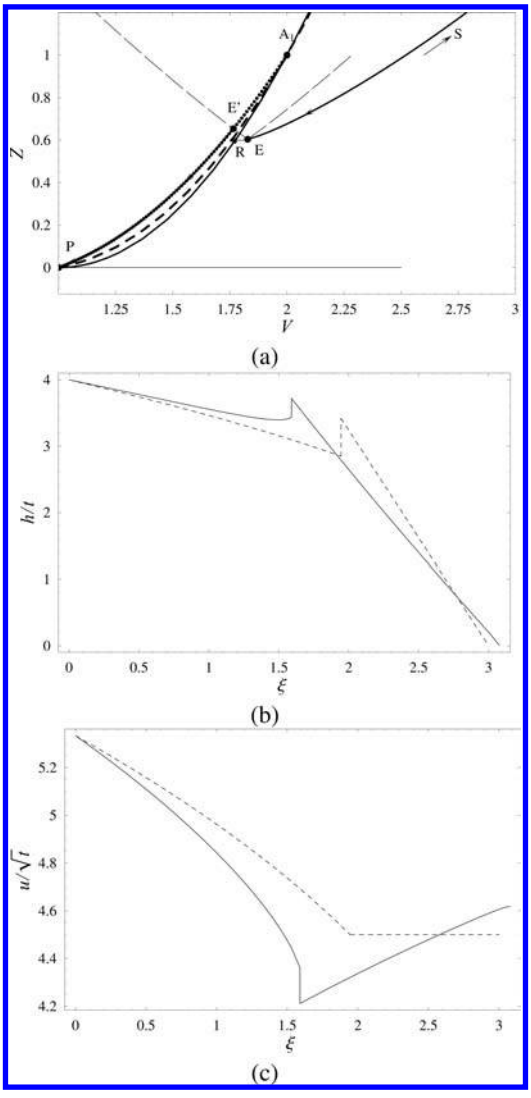

Figure 5. (a) Phase plane in the vicinity of A_1 and construction of the transition point E and its conjugate E'. Same caption as in Figure 4(a). (b) Flow-depth variation with ξ: the solution to the Saint-Venant equations (solid line) is compared with the solution to Euler equations (dashed line). (c) Velocity variation with ξ. All the computations made for $a = 4$, $d = 1$, and $\gamma = 1$.

On Figure 5(b–c), we have reported the flow-depth and velocity variations with the similarity variable ξ (solid lines). We have also reported the reference solution (dashed lines) found in another paper (Ancey et al. 2006). Note the significant difference in the position of the transition point between the solutions, whereas

Copyright © 2006 Taylor & Francis Group plc, London, UK

the front position is properly evaluated to within 5%. In contrast, the departure from the theoretical curve remains moderate since the relative deviation doe not exceed 10% for the velocity and the flow depth.

8 DISCUSSION

A striking feature of our results is that the head of the surge is wedge-shaped with an acute angle. This wedge structure has been observed in experimental realizations of gravity currents in tanks. Different examples drawn from various flow conditions in the laboratory and in nature clearly demonstrate the existence of wedge-like fronts contrasting with the Benjamin assumption. For instance, in the experiments conducted by Simpson (1972), the development of the flow patterns were made visible by using a blend of dense fluid and fine aluminium particles: a stretching vortex occupying the tip region was clearly observed at the leading edge and produced an intense roll-up of fine aluminium particles, which makes it possible to visualize the streamlines and the two vortices; in the upper part of the head, a counter-clockwise rotating vortex occurred. This flow pattern is very close to the one exhibited by the Saint-Venant equations.

In most gravity-current models, the details of the front shape and structure are omitted and the front is replaced by something close to a hydraulic jump and ruled by a Benjamin-like relation according to which the Froude number at the front is a function of the relative submersion of the current and the density ratio between the current and the surrounding fluid. This boundary condition produces currents with a very narrow vertical front, which may appear unrealistic in some circumstances. This is the case of currents with an increasing flow rate, as studied here, where it has been shown that the head occupies one third of the total current length and adopts a wedge shape. The actual shape of the front has drawn little attention so far. In his seminal paper, Benjamin (1968) supplemented the earlier heuristical analysis of von Kármán, demonstrating that a steady front makes an angle of $\pi/3$ with respect to the horizontal: Benjamin provided an approximate analytical solution describing the shape for the lock-exchange problem when the flow depth is half the total depth and again found that the front angle was $\pi/3$. Recently, McElwaine (2005) has extended Benjamin's results by considering steady finite-volume currents down a steep slope, which experience resistance from the surrounding fluid. He also found that the front makes an angle $\pi/3$ with the bottom line. Our result contrasts with the earlier findings: the front angle is not constant, but varies with time. Therefore, there appear to be significant changes in dynamics in the front angle between steady and time-dependent flow conditions. This observation may have a potential impact since until now, most models have used a constant-Froude-number boundary condition even though the flow is not steady.

When compared to analytical solutions to the Euler equations (Ancey et al. 2006), the Saint-Venant equations successfully capture the shape and the dimensions of the front when the Boussinesq coefficient γ is known in advance. In the converse case, when γ is set equal to unity, the front shape is properly predicted, but its dimensions are slightly overestimated. This clearly shows that minute changes in the value of γ markedly affect the solution to the Saint-Venant equations, as shown earlier by Hogg and Pritchard (2004) in the case of a surge induced by a dam break. Surprisingly, whatever the value of γ, the front position is properly evaluated to within 4%. On the whole, despite the potential pitfalls of the problem investigated (strong time dependence, non-hydrostatic pressure, rapid regime transition), we can consider that the Saint-Venant equations provide very satisfactory results, even in the usual case where the Boussinesq coefficient is set equal to unity, since the relative deviation with the solution to the Euler equation usually does not exceed 10%.

9 CONCLUSION

The goal of this paper was to find similarity solutions to the Saint-Venant (shallow-water) equations when the boundary conditions at the front impose a zero flow-depth. The solutions to the Saint-Venant equations were constructed by making use of the phaseplane formalism and seeking similarity forms in a way similar to earlier investigations (Gratton and Vigo 1994).

When the Boussinesq coefficient was in excess of unity, it was not possible to find a physically admissible solution close to the front without providing further information. This conclusion is akin to the observation made by Hogg and Pritchard (2004) in their investigation of drag influence on head shape for the dam-break problem. Instead of using a Benjamin-like condition at the front (imposing a nonzero flow depth), we assumed that the flow-depth averaged velocity was uniform, which implied that the Boussinesq coefficient dropped to unity.

A very important point that did not seem to be noted in the previous investigation was that the only way to construct the solution close to the front was to determine a special curve, referred to as C_A in the phaseplane analysis. Indeed, in the phase plane $V - Z$ (e.g. see Figure 2), the integral path representing the solution must pass through certain points; the front was represented by point P and laid in the neighborhood of a critical point called A, which was a node: all the curves in a given region around A were attracted by A and pass through it tangent to an asymptotic curve

Copyright © 2006 Taylor & Francis Group plc, London, UK

C_A. None of these integral paths passed through A, but the limiting curve C_A did. This curve represented an *exceptional* and local solution to the Saint-Venant equations.

It is worth noticing that this topological structure of the similarity solutions in the front vicinity entails that a specific numerical method must be used to compute accurate solutions to Saint-Venant equations close to the front and explains why the current numerical methods fail to predict the behavior close to the front.

ABSTRACT: The occurrence of river levee breaks due to high return period floods can have catastrophic effects on the environment and human lives. The study of these kinds of problems is of great importance for hydraulic hazard assessment, for the development of civil protection plans and for the organization of corrective and preventative measures to reduce flood damage.

In this context, the paper presents the main results of two case studies concerning two floodable regions located in the middle reach of the Po river (Northern Italy). For the first case, numerical simulations were performed by means of a 2D finite volume MUSCL-Hancock scheme (belonging to the Surface Gradient Methods class) and also by a *quasi*-2D numerical model based on the subdivision of the domain in storage cells linked through weirs.

Even if the flooding dynamics was not correctly described in the first hours after the breaching, the results obtained through the *quasi*-2D approach showed a fairly good agreement with fully-2D ones: flooded areas, maximum water depths and, above all, the discharge flowing through the breach are comparable. The satisfactory results obtained led to the adoption of a hybrid methodology that was applied to the second case study: the discharge flowing through the breach was computed by the *quasi*-2D approach and then adopted as the inflow boundary condition for the fully-2D modeling of the sole area prone to flooding. In this way the flooding dynamics was predicted avoiding the burdensome 2D description of the riverbed; in addition the downstream boundary condition was moved far away from the breach and the computational time significantly reduced.

1 INTRODUCTION

High return period floods are in most cases a severe test for river systems; the levee breaks potentially ensuing from the high stresses induced upon the embankments can have catastrophic effects on the environment, human lives, infrastructures and real estate resting on the flooded areas. Historical information is essential, but sometimes not enough to understand all the potential hazards, as for dam- or levee-breaks that have never occurred before. In these cases the flood hazard evaluation is usually performed with the help of numerical simulations or, only on very rare occasions, by means of physical scale models.

Once a design scenario is identified, the application of a mathematical model can lead to evaluate the main flooding characteristics, such as inundated area, water depths and velocities, arrival times of the wetting front and water stay on the ground (Aureli & Mignosa 2004); nevertheless the mathematical model must allow to take into account the influence of man-made or natural levees (channel embankments, roads, railways, etc.) upon the inundation dynamics. The study of these kinds of problems is of great importance for hydraulic hazard assessment, for the development of civil protection plans and for the organization of corrective and preventative measures to reduce flood damage.

The paper presents the main results of two case studies concerning the floodable regions located in the middle reach of the Po river (Northern Italy) bounded by the river right levee and by the embankments of two couples of consecutive tributaries (Taro-Parma and Parma-Enza). In the Parma-Enza test case fully-2D and *quasi*-2D numerical simulations were compared in terms of flooded areas, flooding dynamics and discharge flowing through the breach.

The satisfactory results obtained led to the adoption of a hybrid methodology applied to the Taro-Parma test case, in which the discharge flowing through the breach was computed by means of a *quasi*-2D

Copyright © 2006 Taylor & Francis Group plc, London, UK

approach and then adopted as the inflow boundary condition for the fully-2D modeling of the sole area prone to flooding.

2 2D NUMERICAL MODEL

The numerical scheme, implemented by the authors themselves, solves the initial and boundary values problem of the 2D shallow water equations in integral form (Toro 2001) by adopting a finite volume approach:

$$\begin{cases} \dfrac{d}{dt}\int_{\Omega}\mathbf{U}\,d\Omega+\int_{C}\mathbf{n}\cdot\mathbf{H}(\mathbf{U})\,dC=\int_{\Omega}\left[\mathbf{S}_0(\mathbf{U})+\mathbf{S}_f(\mathbf{U})\right]d\Omega \\ \text{Initial Condition}: \mathbf{U}(t^0,x,y)=\mathbf{U}_0(x,y),\quad (x,y)\in\Omega \end{cases} \tag{1}$$

In Problem 1 Ω represents the area of the integration cell, C the cell boundary, $\mathbf{n}$ the outward unit vector normal to C, while $\mathbf{H(U)} = [\mathbf{F(U)}, \mathbf{G(U)}]$ is the tensor of fluxes. Moreover:

$$\mathbf{U}(t,x,y)=\begin{pmatrix} h \\ uh \\ vh \end{pmatrix},\quad \mathbf{F}=\begin{pmatrix} uh \\ u^2h+\frac{1}{2}gh^2 \\ uvh \end{pmatrix},$$
$$\mathbf{G}=\begin{pmatrix} vh \\ uvh \\ v^2h+\frac{1}{2}gh^2 \end{pmatrix},\ \mathbf{S}_0=\begin{pmatrix} 0 \\ ghS_{0x} \\ ghS_{0y} \end{pmatrix},\ \mathbf{S}_f=\begin{pmatrix} 0 \\ ghS_{fx} \\ ghS_{fy} \end{pmatrix}. \tag{2}$$

In Equations 1 and 2 the time variable is denoted by t, g is the acceleration due to gravity, h represents the water depth, u and v are the depth averaged velocities in the x and y directions respectively, while S_{0x}, S_{0y}, S_{fx}, and S_{fy} are the bottom and frictional slopes along the same axes. The friction terms are computed according to Manning's equation.

A first order accurate *Godunov splitting* procedure (LeVeque 2002, Toro 2001) of the friction source term replaces Problem 1 by the sequence of the two following de-coupled problems:

$$\left.\begin{aligned} &\frac{d}{dt}\int_{\Omega}\mathbf{U}\,d\Omega+\int_{C}\mathbf{n}\cdot\mathbf{H}\,dC=\int_{\Omega}\mathbf{S}_0\,d\Omega \\ &\text{Initial Condition}: \mathbf{U}=\mathbf{U}(t^n,x,y) \end{aligned}\right\} \xrightarrow{\Delta t^n} \hat{\mathbf{U}}(t^{n+1},x,y), \tag{3}$$

$$\left.\begin{aligned} &\frac{d}{dt}\int_{\Omega}\mathbf{U}\,d\Omega=\int_{\Omega}\mathbf{S}_f\,d\Omega \\ &\text{Initial Condition}: \mathbf{U}=\hat{\mathbf{U}}(t^{n+1},x,y) \end{aligned}\right\} \xrightarrow{\Delta t^n} \mathbf{U}(t^{n+1},x,y) \tag{4}$$

where the superscript n indicates the time level and $\hat{\mathbf{U}}$ is a provisional solution for the vector of the conserved variables $\mathbf{U}$ resulting from the numerical solution of Problem 1 in absence of friction. In (3) and (4) Δt^n represents the current time step and $t^{n+1} = t^n + \Delta t^n$.

The numerical scheme adopted for the discretization of Problem 3 belongs to the *Surface Gradient Methods* class (Zhou et al. 2001) in which the gravitational forcing effect is combined with the propagation algorithm. The scheme is explicit, shock capturing and high resolution. It belongs to the MUSCL-Hancock family and it is second order accurate in space and time (Toro 2001, Hirsch 1990).

For a computational domain divided into Cartesian cells of area $\Delta x \times \Delta y$, the updating conservative *unsplit* algorithm (Toro 2001, Zhou et al. 2001) reads:

$$\hat{\mathbf{U}}_{i,j}^{n+1}=\mathbf{U}_{i,j}^{n}-\frac{\Delta t^n}{\Delta x}\left(\mathbf{f}_{i+\frac{1}{2},j}-\mathbf{f}_{i-\frac{1}{2},j}\right)-\frac{\Delta t^n}{\Delta y}\left(\mathbf{g}_{i,j+\frac{1}{2}}-\mathbf{g}_{i,j-\frac{1}{2}}\right)+ +\Delta t^n\,\overline{\mathbf{S}}_{0_{i,j}}, \tag{5}$$

where the last term represents a suitable local centred estimate (Zhou et al. 2001) of the slope source term, while $\mathbf{f}_{i\pm1/2,\,j}$ and $\mathbf{g}_{i,\,j\pm1/2}$ are the numerical fluxes in the x and y directions respectively (designated by the subscripts i and j). Following Zhou et al. (2001), in order to appropriately predict these numerical fluxes, boundary-extrapolated values (Toro 2001, Hirsch 1990) for the vector of the conserved variables $\mathbf{U}^n = \mathbf{U}(t^n, x, y)$ were achieved, independently in the x and y directions, through a non linear second order accurate reconstruction based on the non conservative vector $\mathbf{Q}^n = \mathbf{Q}(t^n, x, y) = (h + z, uh, vh)^T$ where $z = z(x, y)$ is the bottom surface. In the SGM methodology the water surface, $h + z$, is in fact adopted as the basis for MUSCL data reconstruction at the cell interfaces. Afterwards, in order to achieve second order accuracy in time, a new set of boundary-extrapolated values was obtained through evolution on a half of the current time step Δt^n following the procedure characteristic of MUSCL – Hancock schemes (Toro 2001). Finally the numerical fluxes were computed by the FORCE (*First ORder CEntred*) scheme (Toro 2001, Aureli et al. 2004).

Problem 4 is then solved by a second order implicit trapezoidal method, which allows the numerical code to preserve the explicit structure (Caleffi et al. 2003, Aureli et al. 2004).

The described scheme offers the advantage of accurately predicting the propagation of free surface small perturbations and satisfies the exact C-property (Vázquez-Cendón 1999, Bermúdez & Vázquez, 1994), even on complex topographies. Furthermore, it allows to handle easily (Zhou et al. 2002) unerodible discontinuities in bed topography (embankments, submersible obstacles, etc.). On a flat bed it is absolutely equivalent to a *Depth Gradient Method* (Zhou et al. 2001) and it doesn't entail additional computational costs compared to conventional numerical methods for the homogeneous part of Problem 1. To deal with the evolution in time of wetting and drying fronts, the algorithm was applied at cells in

Copyright © 2006 Taylor & Francis Group plc, London, UK

which $h_{i,j} > \epsilon$ (Toro 2001), where ϵ is a small positive tolerance assumed equal to 10^{-3} m.

From the 2D stability condition $0 < Cr_x + Cr_y \leq 1$ (where $Cr_x$and Cr_y are the Courant numbers in the x and y directions respectively) the following way to compute the time step Δt^n is derived:

$$\Delta t^n = Cr \min\left\{ \frac{\Delta x}{\max\left|u_{i,j} + \sqrt{g h_{i,j}}\right|}, \frac{\Delta y}{\max\left|v_{i,j} + \sqrt{g h_{i,j}}\right|} \right\} \quad (6)$$

where $Cr \leq ½$ (Toro 2001).

The accuracy, robustness and efficiency of the computational code were checked comparing numerical simulations with reference solutions of significant test cases (Maranzoni 2004) with satisfactory results in reproducing steady and rapidly varying flows on complex topographies.

3 *QUASI*–2D APPROACH

The results obtained by means of fully-2D numerical modeling of floodable areas and of part of the adjoining rivers require at first a suitable 2D numerical model and then a significant effort both for data collecting and treatment. Also the numerical elaborations can be demanding from a computational point of view. For these reasons a *quasi*-2D modeling of the system *river-floodable region* was performed in order to verify if comparable results could be obtained with a significantly reduced effort.

The mathematical model adopted is the hydrodynamic module of the software DHI-Mike11 (DHI 2002); the model solves the vertically integrated equations of conservation of mass and momentum under the usual De St. Venant hypotheses.

A model of the river of interest was set up on the basis of cross section surveys; closed flood plains can be described as cells linked to the main channel through broad-crested weirs characterized by the length and elevation of the separation dikes. The topological description of the area prone to flooding can be achieved through the introduction of a number of storage cells, each representing a portion of the domain of interest. Whereas present, elevated roads, railways and minor waterways must be adopted as cell boundaries; sometimes, it is necessary to introduce fictitious borders to limit cell extension (Cunge et al. 1980). Every cell is represented by a computational node and is characterised by a function *water depth-storage volume* derived by the topography of the represented portion of the domain.

Contiguous cells are properly joined by link channels provided with weirs allowing to compute the flow exchange. Each embankment or channel levee is then intended as a broad crested weir between two adjoining cells and its length and width as a function of depth were adopted to define the weir structure.

The structure schematizing the area prone to flooding is linked to the main river at the chainage corresponding to the breach location of the investigated scenario. The link, initially disabled, is activated at the chosen time of breaching to allow the flow exchange across the breach.

4 DESCRIPTION OF THE STUDY AREAS

4.1 *Test case 1: Parma–Enza region*

The first case study concerns a floodable region located in the middle reach of the Po river (Northern Italy), bounded by its right levee and by the embankments of the two tributaries Parma and Enza.

The floodable region and the adjacent Po river reach were described by means of a DTM with a square regular mesh of 50 m, obtained by an interpolation procedure on the available cartographic maps and river cross sections. The dimension of the grid was chosen as a compromise between the estimated computational time and the satisfactory modeling of the region under study. The main constraints were due to the cross extent of the riverbed (somewhere around a few hundred meters), to the assumed breach width (300 m) and to the description of the man-made elements affecting the inundation dynamics (channel embankments, roads, railways, etc.). The modeling of the riverbed is in fact essential to correctly compute the discharge flowing through the breach, especially when the flow is backwatered for the partial filling of the floodable region.

The embankment system of the contouring rivers was considered as a solid and insuperable boundary. This assumption was validated *a posteriori* comparing the maximum computed water stages with the top height of the levees. On the contrary, the interior levees were considered unerodible and potentially overtoppable, since water stages can rise enough to submerge them.

Figure 1 shows a contour map of the whole bathymetry of the considered region, together with the right river embankment of the Po river (in white) and the location of the levee break for the simulated flooding scenario.

In the Po riverbed a Manning's roughness coefficient $n = 0.03\ \mathrm{s \cdot m^{-1/3}}$ was assumed. This value allowed to well reproduce, for a wide range of discharges, the *stage-discharge* relationship observed at a gauged station placed at the downstream boundary of the considered reach. On the contrary, the available documentation on the arrival time of the wetting front in two historical inundations that occurred in 19th and 20th centuries was not enough to calibrate

Copyright © 2006 Taylor & Francis Group plc, London, UK

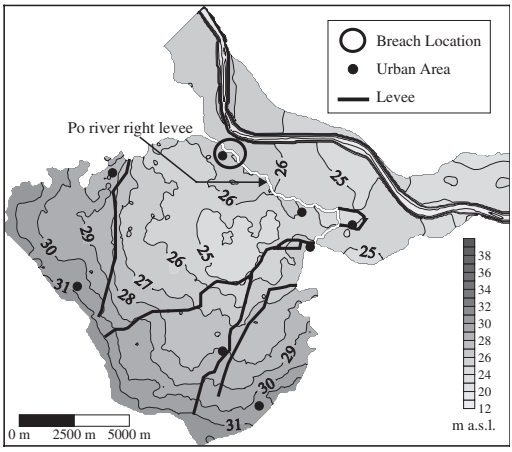

Figure 1. Contour map of the study area for Test case 1.

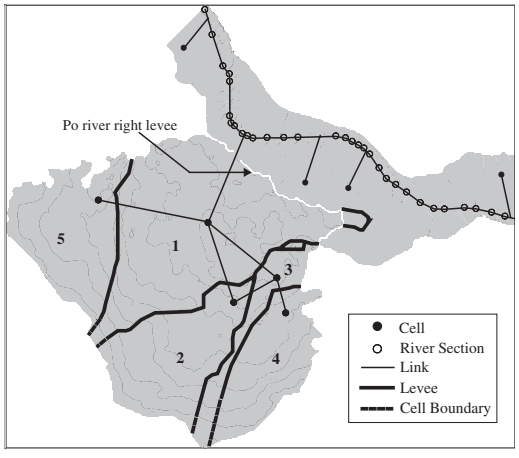

Figure 2. Cell structure describing the study area concerning Test case 1.

a Manning coefficient for the floodable regions. A value of $n = 0.05\,\mathrm{s}\cdot\mathrm{m}^{-1/3}$ was then adopted, based on the results of previous studies on neighbouring areas (Aureli & Mignosa 2004).

For the *quasi*-2D simulation, the floodable domain was divided into five cells bounded by the main interior levees and connected by the net of link channels represented in Figure 2. At this aim fictitious borders were introduced in the south-western region of the domain extending the existing levees.

4.2 *Test case 2: Taro–Parma region*

The second case study considered concerns the floodable region always located in the middle reach of the Po river (Northern Italy) bounded by the river right

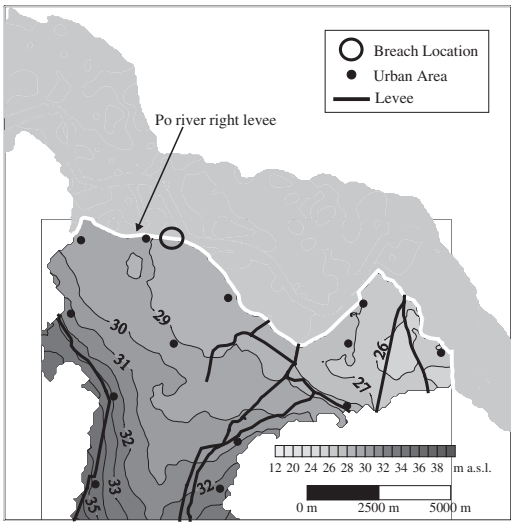

Figure 3. Contour map of the floodable area for Test case 2.

levee and by the embankments of the two tributaries Taro and Parma.

A hybrid approach was adopted for this test case: only the area prone to flooding was described, again by means of a DTM with a square regular mesh of 50 m, obtained by an interpolation procedure on the available terrain data. Particular attention was devoted to the description of the many channel embankments, roads and man-made elements that could affect the inundation dynamics. Once again the interior levees were considered unerodible and potentially overtoppable.

Figure 3 shows a contour map of the bathymetry of the considered floodable region, together with the right river embankment of the Po river (in white) and the location of the levee break for the simulated flooding scenario. As for the previous test case, a value of $n = 0.05\,\mathrm{s}\cdot\mathrm{m}^{-1/3}$ was adopted for the Manning roughness coefficient.

For the *quasi*-2D simulation the floodable domain was divided into thirteen cells bounded by the main interior levees and connected by the net of link channels represented in Figure 4. In order to limit cell extension and at the same time to obtain a better description of flooding evolution, fictitious borders were introduced in the central portion of the floodable region.

5 HYDROLOGICAL INPUT

As a hydrological input, a Synthetic Design Hydrograph of 200 years return period was considered (Maione et al. 2003). The procedure to estimate SDH was based on the statistical analysis of recorded flood waves through the construction of the Flow

Copyright © 2006 Taylor & Francis Group plc, London, UK

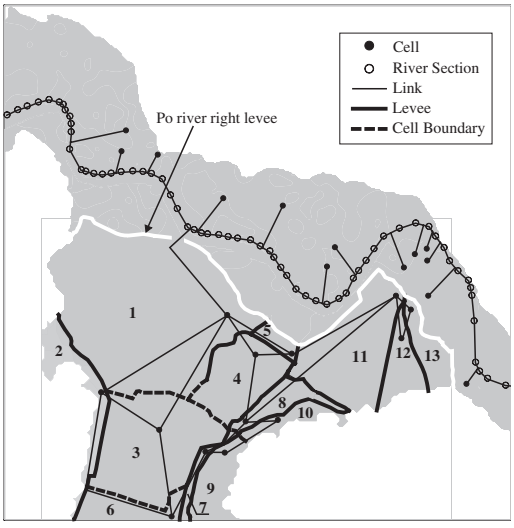

Figure 4. Cell structure describing the study area concerning Test case 2.

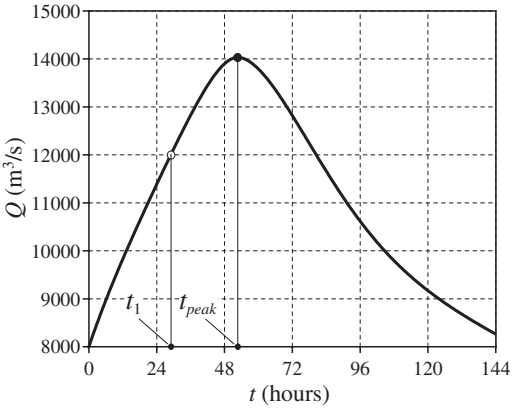

Figure 5. Synthetic Design Hydrograph (SDH) of 200 years return period.

Duration Frequency (FDF) reduction curves and the determination of the peak location (Maione et al. 2000).

Figure 5 shows the adopted SDH together with the chosen time of the levee-break. For both test cases the breach was considered to occur at t_1 on the rising limb of the hydrograph, when the incoming flood wave reached the value of 12000 m^3/s. For this discharge no overtopping occurs in any part of the Po river levee under investigation; however water levels are such to induce high stresses in the earthen embankment, so that erosion or piping phenomena could really develop. A further anticipated time of breaking, albeit more hazardous for the considered area, is impractical and never reported in the historical descriptions.

To point out the more dangerous effects on the flooded areas, the breach was assumed to occur instantaneously: the developing times of the historical breaches were in fact noticeably shorter (order of hours) than the time scale of the floods (order of weeks) in the Po river (Aureli & Mignosa 2004). Hence, to consider the levee-break as instantaneous leads only to a slight overestimation of the water volumes initially flowing through the breach.

6 RESULTS

6.1 *Test case 1: Parma–Enza region*

In the following the results obtained by means of the fully- and *quasi*-2D approaches for the first case study under investigation are presented. A flooding scenario, characterized by a 300 m wide breach (about the mean over 27 historical values, Aureli & Mignosa 2004) occurring in the rising limb of the SDH, was hypothesized; the breach was located in the upstream part of the Po river right levee (Figure 1).

To proceed with the numerical simulations, proper initial and boundary conditions were introduced. The initial conditions in the Po river were obtained by a preliminary simulation with a constant inflow discharge of 8000 m^3/s (the initial value of the SDH) extended in time until steady-state conditions were reached everywhere. Zero water depths and velocities were assumed for all the grid cells in the floodable area outside the riverbed.

At upstream boundary cells (inflow section of the Po river) a time varying discharge derived from the above-mentioned SDH was assigned. The inflow discharge was assumed normal to the boundary string and assigned to each cell proportionally to the 5/3 power of the current water depth.

At solid boundaries representing the river embankments a free-slip (reflective) condition was imposed whereas at the downstream boundary (outflow section of the Po river) a far-field (transmissive) condition was introduced. The assignment of the downstream boundary condition is not straightforward for the scenarios under investigation. The downstream boundary is in fact only a necessary delimitation of the computational domain and it isn't characterized by any particular hydraulic condition; moreover the flooding scenarios are only hypothetical. For these reasons, a constant or time varying water level cannot be applied. At the same time the adoption of a *rating curve* would require a set of assumptions (constant water level across the section, single valued relationship between stage and discharge) that are not easily acceptable in a two dimensional time varying flow. On the basis of several numerical experiments carried out for schematic test cases, the writers found that the transmissive condition imposed at ghost cells provides satisfactory results.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Anyway, the computational domain was extended far away downstream the breach site in order to reduce the disturbances potentially induced by the adopted boundary condition.

The simulations were carried on until the maximum water stages were reached in all the flooded areas and the water started to go back into the riverbed across the breach.

Figure 6 (left column) shows water stage contour maps resulting from the 2D numerical modeling at some significant times. About 7 hours after the break, the flood reached the levees contouring the portion of the domain facing the breach. Eight hours later the eastern levee was overtopped and the flooding spread towards the east. The maximum planar extension of the flooding (66 km^2) was reached 47 hours after the levee break with a water stage of about 30.5 m a.s.l., almost constant everywhere in the flooded area.

The same SDH adopted for the fully-2D simulations was then assigned as upstream boundary condition for the *quasi*-2D simulation. At the downstream boundary a *rating curve* was imposed. In order to minimize the influence of this approximated condition, the river reach was extended far away downstream the breach site.

In Figure 6 (right column) the results for the *quasi*-2D approach are presented. Water stages and flooded areas were initially not well predicted through the *quasi*-2D approach: the reservoir behaviour of the cell structure is in fact not capable of reproducing the rapidly varying flow effects that were predominant in the first hours after the breaching. Afterwards, fully-2D and *quasi*-2D flooded areas and maximum water stages are comparable.

Fairly remarkable is the agreement between the discharges flowing through the breach computed by the fully-2D and *quasi*-2D models (Figure 7).

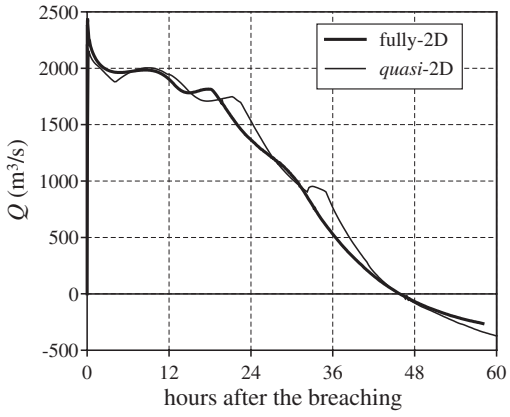

Figure 7. Discharge flowing through the breach for Test case 1: comparison between fully-2D and *quasi*-2D results.

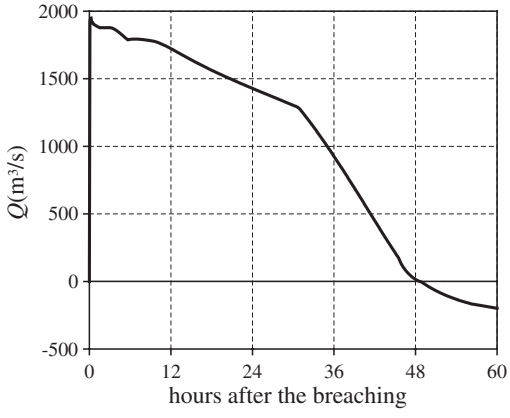

Figure 8. Discharge flowing through the breach for Test case 2.

6.2 *Test case 2: Taro–Parma region*

As previously introduced, for the *quasi*-2D simulation of the Taro-Parma region, the area prone to flooding was described by means of thirteen storage cells (Figure 4) linked to each other through broad-crested weirs characterized by the length and elevation of the separation dikes. Due to the extension of the floodable region investigated and to the absence of natural levees in the central portion of the domain, fictitious boundaries were properly introduced to allow a more realistic description of the flooding. This led to the creation of cells 1, 3, 4 and 6 (Figures 3 and 4). Each cell is represented by a computational node and is characterised by a function *water depth-storage volume* derived by the topography of the represented portion of the domain. This complex structure of cells was linked to the main river stream at the chainage corresponding to the breach location.

Again the link was disabled until t_1 and then activated to allow the flow exchange across the breach.

Taking advantage of the good agreement obtained in the previous test case, the discharge flowing through the breach, computed by means of the *quasi*-2D modeling (Figure 8) was assumed as the inflow boundary condition for the fully-2D simulation of the sole area prone to flooding. This inflow discharge was suitably applied in correspondence to the computational nodes representing the breach location. As for the previous case a 300 m wide breach occurring in the rising limb of the SDH was adopted; the breach was located in the upstream part of the Po river levee (Figure 3). Once again the simulations were carried on until the maximum water stages were reached in all the flooded area and then started to decrease.

Figure 9 shows water stage contour maps resulting from the numerical modeling at 3, 12, 24 and 48 hours

after the beginning of the flooding. About 3 hours after the break the flooding spreads on a region of more then 10 km^2 with mean water stages of 30 m above sea level. The agreement between *quasi*- and fully-2D results is satisfactory. Nine hours later the planar extension of the flooding is almost doubled. Water stages are now above 31 m above sea level and the agreement between the results obtained by means of the two approaches is still satisfactory. Anyway the overtopping of some levees in the eastern portion of the domain once again points out the incapability of the cell structure to correctly reproduce the advancing of the wetting front during transients. Twenty four hours after the breaking, water stages in the portion of the domain facing the breach site are above 31.5 m a.s.l. and the flooding has spread towards the east, reaching the Parma river left levee. The agreement between *quasi*- and fully-2D results is very good apart from the extreme eastern portion of the floodable domain in which the *quasi*-2D model underestimates the filling of a small cell.

The maximum planar extension of the flooding (68 km^2) was reached 48 hours after the levee break. The agreement between the computed planar extension of the flooding and water stages is still very good: this result is fairly obvious since in this case the same total volume flowing out of the breach was imposed for both the models and the flow dynamics is very slow. Anyhow, the good results of the first case study, if confirmed by other numerical tests, encourage this kind of hybrid approach.

7 CONCLUDING REMARKS

The results of the first test case showed that the main characteristics of the flooding due to levee breaking in the Po river (Northern Italy) could be described by following a simple *quasi*-2D methodology. This approach combines a 1D description of the main river with a schematization of the floodable region through a proper number of storage cells, each representing a portion of the domain of interest.

Some of the most significant results useful to evaluate hydraulic hazard, such as total flooding extension and maximum water depths, are comparable with those obtained by a more burdensome fully-2D simulation. Another advantage provided by the *quasi*-2D approach is the possibility to easily extend downstream the description of the main river reach, minimizing the influence of the boundary condition that could be assigned far away from the breach site.

However this approach is not able to describe the flooding dynamics, especially in the first hours after the breaching, due to the incapability of the cell structure to correctly reproduce the advancing of the wetting front during rapid transients.

Velocities and arrival times of the wetting front, other two significant parameters that influence the flood hazard, cannot then be evaluated by means of this simple approach.

Taking advantage of the good agreement between the discharge hydrographs flowing through the breach obtained by *quasi*-2D and fully-2D simulations applied to a first test case, a hybrid approach on a second case study was adopted: the discharge flowing through the breach computed by means of the *quasi*-2D methodology was considered as the inflow boundary condition for a fully-2D simulation of the sole area prone to flooding. In this way the computational effort was significantly reduced since: a) the burdensome 2D description of the river can be avoided, b) the number of computing cells is significantly lowered and c) the numerical stability condition – if requested as for explicit schemes – is less restrictive due to the absence of computational nodes of the riverbed where maximum water depths and high velocities take place. At the same time it was possible to evaluate velocities and time arrival of the wetting front in order to evaluate more complete flood hazard maps.

The good results obtained in the first case, if confirmed by other numerical tests, encourage this kind of hybrid (*quasi*-2D + fully-2D) methodology. This approach requires a reduced effort to perform extensive analyses of flooding events, such as those occurred in the past in the Po River valley where the extension of the areas subject to flooding reached several hundreds of square kilometres.

ACKNOWLEDGMENTS

This work was developed within a research agreement between the Civil Engineering Department of Parma University and the Po River Basin Authority. The Authors thank the mentioned Authority for the consent to publish the main results of the study.

Two-dimensional dam-break simulation over movable beds with an unstructured mesh

José A. Vásquez
Northwest Hydraulic Consultants, North Vancouver, Canada

João G.A.B. Leal
University of Beira Interior, Covilha, Portugal

ABSTRACT: This paper reports the application of a two-dimensional (2D) depth-averaged model to dam break flows over alluvial sand beds with an initial bed step. The model applies the Finite Element Method to discretize the computational domain using an unstructured mesh made of triangular elements. Two downstream boundary conditions were tested: zero (dry) and non-zero (wet) initial water depths. The model successfully reproduced the two types of transient waves observed in the experiments: the hydraulic jump produced with wet downstream condition and the surge moving over an initially dry bed. Since the present sediment transport model applied a single layer for sediment transport, comparison and discussion with results of a previous one-dimensional (1D) two-layer model are also provided.

1 INTRODUCTION

1.1 *Dam-breaks and movable beds*

Dam-break flows can lead to highly unsteady flows with fast-moving wave fronts. Traditionally, dam-break phenomenon has been studied under fixed-bed conditions. However, movable beds can affect the celerity of flood waves propagating in rivers after a dam-break. Even more, the wave celerity is influenced by the sediment mobility (Capart & Young 1998, Leal et al. 2002, Fraccarollo & Capart 2002, Cao et al. 2004, Leal et al. 2006). Therefore, dam-break analysis on rivers requires the inclusion of the effects of alluvial bed on the flow hydraulics.

Dams represent an obstacle to the normal sediment transport in a river, inducing sediment deposition upstream from the dam, as well as bed erosion downstream. For an existing dam in an alluvial river, a bed elevation difference will develop between the riverbed elevations upstream and downstream from the dam. During a real dam-break event, it is very likely that a movable bed step will exist at the location of the dam that will impact how the flood wave propagates downstream.

Leal et al. (2002) conducted experimental dam-break research that incorporated the effects of both sediment mobility and bed steps on wave propagation. These experiments provide high-quality data under more realistic conditions than simpler experiments conducted on flat fixed-beds. Leal et al. (2003a,b) successfully simulated these experimental observations using a one-dimensional (1D) numerical model.

In this paper, the two-dimensional (2D) numerical model developed by Vasquez (2005a) is applied to simulate two of the experimental tests of Leal et al. (2002) of dam-breaks over sand beds with an initial bed step. One distinctive feature of the model is the application of an unstructured (irregular) mesh made of triangular Finite Elements. The main objective of the present work is to verify the applicability of such model to dam-break flows over movable beds. Additionally, some qualitative tests of bed changes in a varying width flume, and a dam-break in a sharp 90° bend over a fixed bed, are presented to show the 2D capabilities of the model.

1.2 *Background information*

Vasquez (2005a) developed a 2D river morphology model by extending the existing fixed-bed hydrodynamic model River2D (Steffler & Blackburn 2002). This new movable-bed version is referred as River2D-MORphology. River2D-MOR has been successfully applied to reproduce experiments of bed aggradation and degradation in straight flumes (Vasquez et al. 2005a, Vasquez et al. 2006a), scour and deposition in laboratory bends (Vasquez et al. 2005b) and meandering rivers (Vasquez et al. 2006b), as well as knickpoint migration under transcritical flow conditions (Vasquez et al. 2005c). Preliminary qualitative tests (Vasquez

Copyright © 2006 Taylor & Francis Group plc, London, UK

2005a) suggested that River2D-MOR could be applied to dyke-breach and dam-break analysis. However, until now, it has not been tested quantitatively to verify if the model is indeed suitable for dam-breaks over movable beds.

The main features of River2D-MOR at the moment are (Vasquez 2005a):

- unstructured Finite Element (FE) mesh;
- simulates bedload sediment transport;
- free or forced upstream sediment inflow;
- transcritical flow capabilities;
- secondary flow correction for flow in bends;
- incorporates the effects of transverse bed slope on bedload direction.

Unstructured meshes have the advantage of being more flexible that structured (regular) meshes. Triangular elements allow to easily accommodate practically any planform river geometry with elements that can dramatically change in size to obtained higher resolution around areas of interest. For example, structured meshes based on quadrilateral elements can be problematic in certain channel geometries with sharp angles (Heer & Mosselman 2004), for which triangular elements are perfectly suitable (Vasquez 2005b). River2D-MOR is a decoupled model, that is, sediment equations are solved after the flow equations.

The remaining of the paper is organized as follows. In section 2, information of the hydrodynamic model is briefly introduced; later a qualitative application to dam-break in a channel with a sharp bend is shown to demonstrate the 2D capabilities of the model. In section 3, the bedload model is introduced along with an example application to an alluvial channel with a continuously changing width. In section 4, a description of the experimental tests of dam-break over movable beds is provided. The results of the model are presented in section 5. The discussion of the paper are presented in Section 6. Finally, summary and conclusions are presented in Section 7.

2 HYDRODYNAMIC MODEL

2.1 *River2D*

River2D is a fixed-bed hydrodynamic model that has been developed at the University of Alberta in Canada (it is freely available at www.River2D.ca). River2D is based on the 2D depth-averaged Saint-Venant equations expressed in conservative form; which form a system of three equations representing the conservation of water mass and the two components of the momentum vector. The model is intended for use on natural streams and rivers and has special features for supercritical/subcritical flow transitions, ice covers, and variable wetted area. River2D handles dry beds by changing the surface flow equations to groundwater flow equations in areas where the water depth drops below a minimum value. A continuous free surface with positive (above ground) and negative (below ground) depths is calculated. This procedure allows calculations to carry on without changing or updating the boundary conditions (Steffler and Blackburn 2002).

For the spatial discretization River2D uses a flexible FE unstructured mesh composed of triangular elements. The Finite Element Method used by River2D is based on the Streamline Upwind Petrov-Galerkin (SUPG) weighted residual formulation (numerical details of the model are shown in Ghanem et al. 1995). In this technique, upstream biased test functions are used to ensure solution stability under the full range of flow conditions, including subcritical, supercritical, and transcritical flow. A fully conservative discretization is implemented which ensures that no fluid mass is lost or gained over the modeled domain. This also allows implementation of boundary conditions as natural flow or forced conditions.

The equations solved by the River2D are (Steffler and Blackburn 2002):

The water continuity equation:

$$\frac{\partial h}{\partial t}+\frac{\partial q_x}{\partial x}+\frac{\partial q_y}{\partial y}=0 \tag{1}$$

The vertically averaged momentum equation in the x-direction:

$$\frac{\partial q_x}{\partial t}+\frac{\partial (uq_x)}{\partial x}+\frac{\partial (vq_x)}{\partial y}+\frac{g}{2}\frac{\partial h^2}{\partial x}= gh\left(S_{ox}-S_{fx}\right)+\frac{1}{\rho}\left(\frac{\partial (h\tau_{xx})}{\partial x}+\frac{\partial (h\tau_{xy})}{\partial y}\right) \tag{2}$$

The vertically averaged momentum equation in the y-direction:

$$\frac{\partial q_y}{\partial t}+\frac{\partial (uq_y)}{\partial x}+\frac{\partial (vq_y)}{\partial y}+\frac{g}{2}\frac{\partial h^2}{\partial y}= gh\left(S_{oy}-S_{fy}\right)+\frac{1}{\rho}\left(\frac{\partial (h\tau_{yx})}{\partial x}+\frac{\partial (h\tau_{yy})}{\partial y}\right) \tag{3}$$

where t = time, h = water depth; (u, v) = depth-averaged velocities in the (x, y) directions; $q_x = uh$ = flow discharge in x-direction per unit width; $q_y = vh$ = flow discharge in the y-direction per unit width; (S_{ox}, S_{oy}) = bed slopes in the (x, y) directions; S_{fx} and S_{fy} = corresponding friction slopes; τ_{xx}, τ_{xy}, τ_{yx}, τ_{yy} = components of the horizontal turbulent stress tensor; ρ = water density; and g = gravitation acceleration.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The basic assumptions in equations (1) through (3) are (Steffler and Blackburn 2002):

- The pressure distribution is hydrostatic, which limits the accuracy in areas of steep slopes and rapid changes in bed slopes.
- The horizontal velocities are constant over the depth. Information on secondary flows and circulations is not available.
- Coriolis and wind forces are assumed negligible.

The friction slope terms depend on the bed shear stresses which are assumed to depend on the magnitude and direction of the vertically averaged velocities. For example, in the x direction:

$$S_{fx} = \frac{\tau_{bx}}{\rho g h} = \frac{\sqrt{u^2 + v^2}}{g h C_*^2} u \tag{4}$$

τ_{bx} is the bed shear stress in the x direction and C_* is the dimensionless Chezy coefficient, which is related to the effective roughness height k_s through

$$C_* = 5.75 \log\left(12 \frac{h}{k_s}\right) \quad ; \frac{h}{k_s} \geq \frac{e^2}{12} \tag{5a}$$

$$C_* = 2.5 + \frac{30}{e^2}\left(\frac{h}{k_s}\right) \quad ; \frac{h}{k_s} < \frac{e^2}{12} \tag{5b}$$

$e = 2.7182$; C_* is related to Chezy's C coefficient through

$$C_* = \frac{C}{\sqrt{g}} \tag{6}$$

The depth-averaged turbulent shear stresses are modeled with a Boussinesq type eddy viscosity. For example:

$$\tau_{xy} = \upsilon_t \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right) \tag{7}$$

where υ_t = eddy viscosity coefficient, which is assumed as composed of three components: a constant, a bed shear generated term, and a transverse shear generated term

$$\upsilon_t = \varepsilon_1 + \varepsilon_2 \frac{h\sqrt{u^2 + v^2}}{C_*} + \ldots$$
$$\varepsilon_3^2 h^2 \sqrt{2\frac{\partial u}{\partial x} + \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right)^2 + 2\frac{\partial v}{\partial y}} \tag{8}$$

The default value for ε_1 is 0. This coefficient can used to stabilize the solution for very shallow flows when the second term in equation (8) may not to adequately describe υ_t for the flow. Reasonable values for ε_1 can be calculated by evaluating the second term in equation (8) using average flow conditions (average flow depth and average velocities) for the modeled site. The default value for ε_2 is 0.5. By analogy with transverse dispersion coefficients in rivers, values of 0.2 to 1.0 are reasonable. Since most river turbulence is generated by bed shear, this term is usually the most important. In deeper lake flows, or flows with high transverse velocity outlets gradients, transverse shear may be the dominant turbulence generation mechanism. Strong recirculation regions are important examples. In these cases, the third term, ε_3, becomes important. It is essentially a 2D (horizontal) mixing length model. The mixing length is assumed to be proportional to the depth of flow. A typical value for ε_1 is 0.1, but this may be adjusted by calibration.

In the present application, assuming that turbulence is bed-generated, the default values of the model $\varepsilon_1 = 0$, $\varepsilon_2 = 0.5$ and $\varepsilon_3 = 0$ were adopted. A qualitative application to a dam-break test case is shown below for illustration purposes.

2.2 *Dam-break in channel with 90° bend*

Soares Frazão et al. (2001) and Soares Frazão & Zech. (2002) performed experiments of dam-break through a sharp 90° bend, which consisted of a 2.44 m by 2.39 m upstream reservoir connected to a 0.495 m wide rectangular channel. The upstream channel reach is about 4 m long while the downstream reach, after the bend, is about 3 m long. The downstream end of the channel is open. The sudden raise of the gate between the upstream reservoir and the channel is used to simulate the dam break.

After dam-break, water flows rapidly into the channel and reflects against the bend wall, where a bore forms that travels back in the upstream direction towards the reservoir. Using a 2D Finite Volume model, Aureli et al. (2004) have recently simulated one of the experiments with an initial water level in the reservoir of 0.20 m above the initially dry channel bed. To simulate the free fall at the downstream end an artificial high slope slide was introduced in the numerical model. The same experiment was used for the present qualitative application.

In River2D a constant roughness $k_s = 5$ mm was set throughout the model. Although it is possible to use a downstream boundary condition similar to that used by Aureli et al. (2004), given the illustrative purposes of this test a simple downstream boundary condition with zero depth was assumed. Therefore, the results presented are only qualitative.

Figure 1 shows snapshots of the computed water surface at different times. At $t = 7$ s the reflection in the bend wall becomes evident. Figure 2 shows the

Copyright © 2006 Taylor & Francis Group plc, London, UK

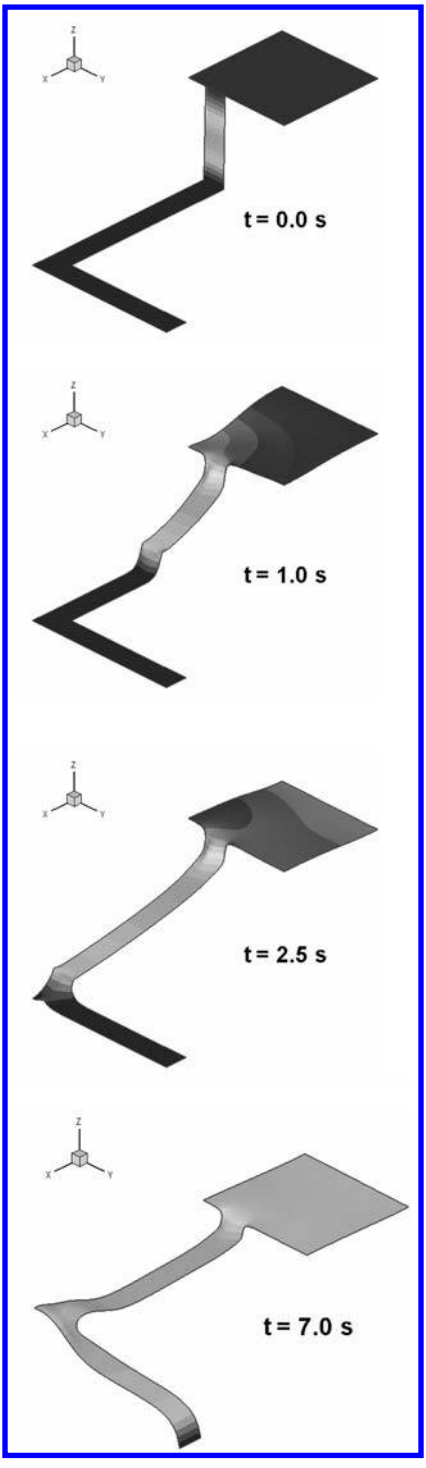

Figure 1. Computed water surfaces for a dam-break in a channel with a 90° sharp bend.

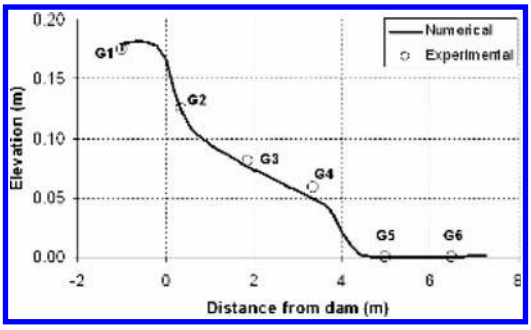

Figure 2. Experimental and numerical results at 2.5 s for dam break through a 90° bend.

comparison between the computed profile and the levels recorded at 6 gauges. Gauge G1 is located at the center of the reservoir, while gauges G2 through G6 at located along the centerline of the channel.

Figure 2 shows that the model produces reasonable results at the beginning of the simulation when the effects of the downstream end are still not important. However, the accuracy of the results deteriorates as time progresses because of the constant downstream water level enforced by the model.

3 BEDLOAD MODEL

River2D was extended by Vasquez (2005a) to incorporate a solver for the bed load sediment continuity (Exner) equation

$$(1-\lambda)\frac{\partial z_b}{\partial t}+\frac{\partial q_{sx}}{\partial x}+\frac{\partial q_{sy}}{\partial y}=0 \tag{9}$$

where z_b = bed elevation; λ = porosity of the bed material (with a default value of 0.4); and (q_{sx}, q_{sy}) = components of the volumetric rate of bedload transport per unit width q_s that depend on the direction α of sediment transport:

$$q_{sx}=q_s\cos\alpha \tag{10a}$$

$$q_{sx}=q_s\sin\alpha \tag{10b}$$

In a straight flume, where the direction of bedload and mean flow coincide, the direction of bedload in equation (10) is simply tan $\alpha = (v/u)$. However, in curved channels the secondary flow produces a deviation between the depth-averaged flow direction and the direction δ of the bed shear stress

$$\delta=\arctan\left(\frac{v}{u}\right)-\arctan\left(A\frac{h}{r_c}\right) \tag{11}$$

The term -arctan(Ah/r_c) is the deviation of the bed shear stress relative to the streamlines, caused by the

Copyright © 2006 Taylor & Francis Group plc, London, UK

secondary flow. A is a parameter of order 10 and r_c is the curvature of the streamlines computed from the flow field as

$$r_c = \frac{(u^2+v^2)^{3/2}}{-uv\frac{\partial u}{\partial x} - v^2\frac{\partial u}{\partial y} + u^2\frac{\partial v}{\partial x} + uv\frac{\partial v}{\partial y}} \quad (12)$$

The direction of bedload is computed taking into account the effects of the bed slopes $\partial z_b/\partial x$ and $\partial z_b/\partial y$ along the x and y coordinates respectively

$$\tan\alpha = \frac{\sin\delta - \frac{1}{f_s\tau^*}\frac{\partial z_b}{\partial y}}{\cos\delta - \frac{1}{f_s\tau^*}\frac{\partial z_b}{\partial x}} \quad (13)$$

τ^* is the dimensionless shear stress or Shield's parameter and f_s is a shape factor of order 1. The applicability of the secondary flow model (equations 11 through 13) has been demonstrated for both curved flumes (Vasquez et al. 2005b) and meandering rivers (Vasquez et al. 2006b).

Equation (9) is discretized using a conventional Galerkin Finite Element Method (GFEM). The time advance is performed using a Runge-Kutta second order scheme. Since GFEM lacks upwinding properties (equivalent to a central difference scheme) it is known to be adequate for diffusive problems, but not for advection-dominated problems (Donea & Huerta 2003, Vasquez 2005a). The model should not be applied to problems where advection is important, such as migrating bedforms or sediment waves. An illustrative application showing the formation of forced bars in a sand-bed channel is presented below.

3.1 *Application to varying width flume*

Tsujimoto (1987) reported experiments of bed level changes in an initially flat alluvial channel with continuous expansions and contractions, produced by changing the channel width $B(x)$ according to a sinusoidal function

$$B(x) = B_o - B_1\sin(2\pi x/L) \quad (14)$$

The only experimental data provided by Tsujimoto (1987) are related to channel plan geometry: $B_o = 0.19$ m, $B_1 = 0.04$ m and $L = 0.40$ m. No more details of the experiment are given such as sediment size, inflow, downstream water level, bed slope, roughness or sediment transport rate, preventing a quantitative comparison with any particular experiment. The measured bed profiles showed very rich bed variability. The transverse concavity of the bed profiles switches from downward across the narrowest section to upward across the widest section. Across the narrow section a central bar develops, while across the wide section two lateral bars are present near the walls. In contrast with free alternate bars in straight channels, which migrate in the downstream direction, the bars formed in the channel with varying width remain fixed in position, similar to the point bars formed in alluvial bends.

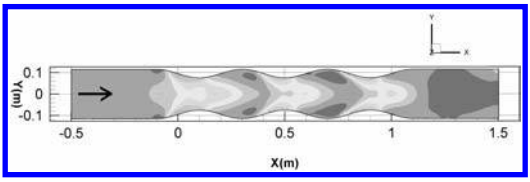

Figure 3. Plan view of computed bed changes in a channel with sinusoidal varying width.

For the numerical simulation, the following values were adopted: discharge 0.0056 m^3/s, depth 0.07 m, bed slope 0.001, roughness $k_s = 0.0014$ m, $A = 2$ and $f_s = 2$. The computational mesh was made of nodes spaced roughly 1 cm apart. Sediment transport was computed using the Engelund-Hansen equation for a 1 mm sand grain. Figure 3 shows the plan view of the computed results after 1000 s using a time step of 1 s. The model correctly predicts the concavity of the bed and the formation of bars. Figure 4 shows the pattern of lateral and central bars computed by the model which agrees, at least qualitatively, with the experimental results.

4 DAM-BREAK OVER MOVABLE BED

Leal et al. (2002) performed dam-break experiments in a rectangular horizontal flume 19.2 m long, 0.5 m wide and 0.7 m high. The dam was simulated by a vertical PVC lift-gate installed at the middle of the flume, which had an opening time between 0.1 and 0.2 s. The wave-front normally took less than 6 s to reach the downstream end of the flume. Three groups of tests were carried out depending on the bed type: fixed-bed, sand-bed and pumice-bed.

Two of the tests performed with an initial bed step of $h_{su} = 0.19$ m over a sand-bed were selected for the numerical simulation. The tests are Ts.25 and Ts.28, their initial conditions are shown in Figure 5 and Table 1. The initial conditions downstream from the dam varied between tests. The bed was dry for Ts.25 ($h_d = 0.0$ m) and wet for test Ts.28 ($h_d = 0.075$ m). The sand had a median grain size $D_{50} = 1.22$ mm, specific gravity $G_s = 2.65$ and settling velocity $w = 9.92$ cm/s.

Leal et al. (2003a) applied the Bagnold sediment transport equation, which can be expressed as a function of the depth-averaged velocity $U = (u^2+v^2)^{1/2}$ as

$$q_s = \frac{\xi\tau_b U}{\rho g(G_s - 1)} \quad (15)$$

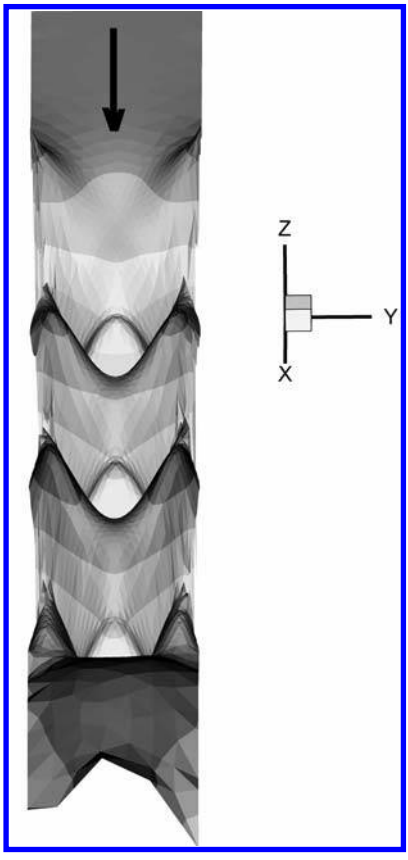

Figure 4. 3D view of computed bed changes in a channel with sinusoidal varying width.

Table 1. Initial conditions of experimental tests.

Test	h_u (m)	h_d (m)	h_{su} (m)	h_{sd} (m)
Ts.25	0.400	0.000	0.190	0.071
Ts.28	0.400	0.075	0.190	0.071

Where ξ is sediment parameter that depends on the sediment transport modes and settling velocity of the sediment and has a value $\xi \approx 0.57$ for the sand used in the experiments. Based on assumptions of sheet (debris) flow and bedload transport under high shear stress, Leal et al. (2003a) transformed (15) into

$$q_s = \frac{8.03\xi\sqrt{g}/C}{(G_s - 1)(C^2 - \xi U^2/h)} U^3 \qquad (16)$$

With a value $C = 31.3\,\mathrm{m}^{1/2}\mathrm{s}$ for the sand-bed experiments.

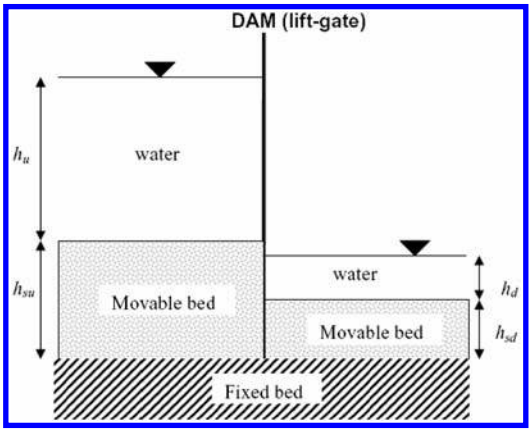

Figure 5. Initial conditions of Leal et al. (2002) experiments of dam-break over movable beds.

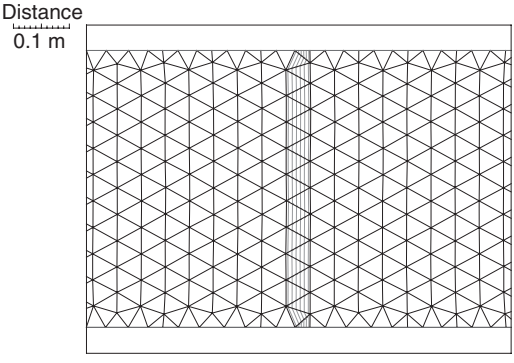

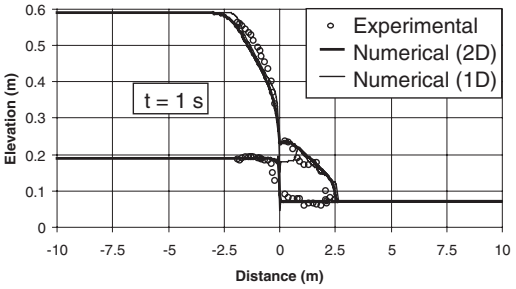

Figure 6. Detail of unstructured mesh near the dam location (dashed lines are bed contours of inclined ramp).

5 RESULTS

Since the vertical bed step at the dam location cannot be reproduced in the model, it was replaced by a steep inclined ramp spanning over a single element. In order to reduce the size of the ramp, the node spacing in the mesh was set to about 5 cm. The computational mesh had roughly 12 nodes in the transverse direction and about 500 nodes in the longitudinal direction, as shown in Figure 6, giving a total of 6076 nodes and 10935 triangular elements. Figure 6 also shows the contour lines of the inclined ramp.

The roughness height adopted was $k_s = 0.0164\,\mathrm{m}$, which gives a Chezy roughness $C = 31.3\,\mathrm{m}^{1/2}\mathrm{s}$ for a water depth $h = 0.075\,\mathrm{m}$. The upstream boundary was set as a no-flow boundary; while the downstream boundary was set to a fixed water level, which changed according to the test simulated. For test Ts.25, the downstream water level was set equal to

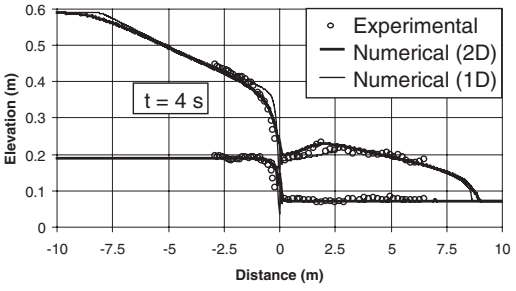

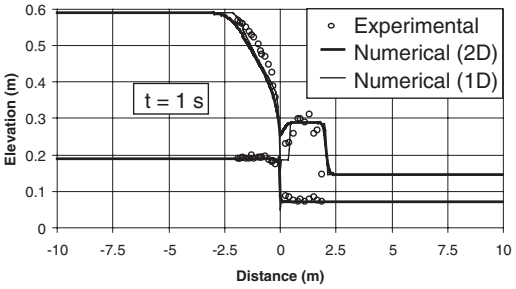

Figure 7. Experimental and numerical results for dam-break experiment Ts.25 at 1and 4 seconds.

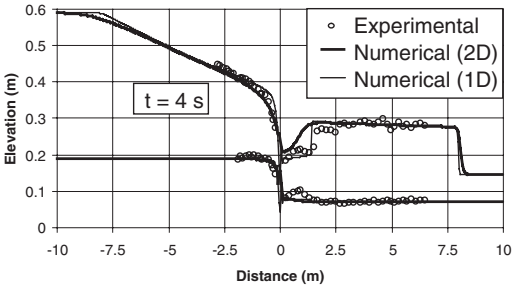

Figure 8. Experimental and numerical results for dam-break experiment Ts.28 at 1and 4 seconds.

the bed elevation, $h_{sd} = 0.071$ m, meaning that all the reach downstream from the dam was initially dry, $h_d = 0.0$ m. For test Ts.28, the downstream water level was set at elevation $h_d + h_{sd} = 0.146$ m. In both cases, the initial water level upstream from the dam was set to elevation $h_u + h_{su} = 0.590$ m.

Similar to the initial bed profile, the initial horizontal water levels upstream and downstream from the dam were connected by an inclined water "ramp" over a single element, to represent the condition immediately after the dam break.

Figure 7 shows the results for test Ts.25, with an initially dry downstream boundary; while Figure 8 shows the results for test Ts.28, with an initial wet downstream boundary. The results for both tests are shown for 1 and 4 seconds after the dam-break. In both Figures are also presented the results of the two-layer 1D model of Leal et al. (2003a).

By looking at the computed water levels upstream from the dam, for both tests the 2D model and the 1D model tend to underpredict the observed levels at 1 s. However, at 4 s, the agreement between the observed and computed water levels upstream from the dam is quite good.

For test Ts.25 (Fig. 7) both models underpredict the bed levels, while the agreement is better for test Ts.28 (Fig. 8). This is in accordance with what was expected, since for the higher initial downstream depth (Ts.28) the sediment transport is less important and the bed changes will be smaller.

6 DISCUSSION

In general, the agreement between measured and computed results is good. Just like the 1D model, the 2D model is able to capture the effects of the downstream water level on the wave fronts, with a weaker hydraulic jump when the bed is initially dry in test Ts.25. At 4 s, the upstream water levels agree very well with the observed data; although at 1 s the agreement is not as good. Probable reasons for the lower prediction accuracy at 1 s could be the assumed initial water profile (not perfectly vertical) and the non-hydrostatic pressure distribution. At the beginning of the experiment, immediately after the dam-break, the water contained upstream rushes down very quickly. The vertical acceleration of the flow is not negligible as assumed in the shallow water equations solved by the depth-averaged model. However, as time progresses, these initial effects tend to vanish (cf. Fraccarollo & Capart 2002) leading to a better agreement with data.

According to Fraccarollo & Capart (2002), the time required for the flow to equilibrate its sediment load is estimated as $20(h_u/g)^{0.5}$. For the experiments presented, this renders a time equal to 4 s. Therefore, for times equal or higher than that value the equilibrium approach assumed in both models is valid and the results show better agreement ($t = 4$ s in Figures 7 and 8).

The 1D model of Leal et al. (2003a,b), when applied to test Ts.25 and Ts.28 generated water surface

profiles with very sharp fronts (wave-front and hydraulic jump), almost square in shape. In contrast, the profiles computed by River2D are smoother with more rounded corners. The 1D model uses a 2nd order MacCormack-TVD scheme that can reproduce better sharp discontinuities.

The discrepancies between the 1D and the 2D numerical results are more pronounced near the dam cross-section. In that section, at 1 s the 1D model imposes small water depths flow due to the initial bed-step, while the 2D model gives higher water depths. Nevertheless, the agreement is still good.

Mention should be made to the fact that the node spacing in both models is equal to 5 cm, therefore the resolution can not explain the differences mentioned before.

The computed bed elevation shows good agreement with the measured data, although some oscillations are visible in the solution, especially on the 1D model. The 2nd order 1D model creates oscillations around discontinuities. The TVD correction minimizes these oscillations. Due to mathematical complexity that correction was not applied to the sediment mass conservation equation, allowing the presence of oscillations in the bed profile. In the 2D model, the oscillations might be the result of applying the conventional Galerkin formulation to solve the sediment continuity equation, which is not suitable for highly convective problems (Donea & Huerta 2003, Katapodes 1984, Vasquez 2005a). Vasquez (2005a) has shown that when migrating bed forms are present in the solution (e.g. free alternate bars, prograding deltas), the bedload model produces spurious oscillations due to its lack of numerical upwinding. The Petrov-Galerkin scheme, which is used by the hydrodynamic model, seems as a good candidate for incorporating upwinding in future versions of the bedload model.

Although the 2D model solves a conventional sediment continuity equation with only one layer of sediment transport, the results are not significantly different to those obtained by the 1D model of Leal et al. (2003a) with a more complex two-layer model. It seems that for the present dam-break application, with relatively heavy bed material ($G_s = 2.65$), the effects of debris flow (sheet flow) are not strong enough to prevent the application of a 1-layer model. A comparative study between 1- and 2-layer models is desirable to gain a better understanding of the real limitations of each approach for dam-break analyses.

7 SUMMARY AND CONCLUSIONS

A 2D river morphology model, originally intended for alluvial meandering rivers, has been tested for dam-break flows over movable sand-beds. The model uses the Finite Element method and unstructured (irregular) meshes made of triangular elements. The model was tested using two experiments with an initial bed step at the dam location, with both dry and wet downstream boundary conditions. The model results were also compared with the results of the 1D model by Leal et al. (2003a). The results show that the 2D model was able to reproduce the observed water levels and the influence of the boundary condition on the wave fronts with reasonable accuracy. Given the other capabilities of the model to simulate bed changes in straight and curved alluvial channels, it seems as a promising tool for practical dam break analysis. However, the model still needs improvements to provide numerical upwinding in the sediment solver for cases of highly convective sediment waves.

ABSTRACT: A relevant example of unsteady processes with strong interaction between hydrodynamics and solid transport, the propagation of dam-break waves over a mobile bed has been the subject of several recent research works. It has thus gained the role of a benchmark for solid transport models. From a physical point of view, the features of the process lead to the rejection of the hypothesis of immediate adaptation of solid transport to hydrodynamics. From the numerical standpoint, the tracking of water and bed wave fronts requires adequate numerical schemes. In the last few years, extensive work has dealt with the idealized scheme of one dimensional dam break over loose bed. More recently, existing models have been applied to study also the asymmetric wave propagation over the floodplain. In previous works the authors have adopted an original two phase non-equilibrium model to simulate one dimensional dam break over mobile bed. Here the model is extended to a two dimensional depth-averaged framework and then applied to simulate a dam break wave propagation over an alluvial floodplain.

1 INTRODUCTION

Risk protection and public safety have been motivating research about dam failure for a very long time. Among the extremely rich variety of applications, the study of the flow induced by the abrupt failure of a rigid dam has played a major role in the field of hydraulics.

Since the seminal papers by Ritter (1892), Stoker (1948) and Dressler (1952), intense work has been done to bridge the gap between the extremely idealized scheme considered by theoretical analysis and real-scale processes.

From this standpoint, one of the most recent improvements was the inclusion into the analysis of the effect of morphological evolution of the floodplain downstream the dam. In fact, apart from being itself an immediate source of hazard, the dam-break wave may also determine intense erosion of floodplain, which – in turn – substantially modifies the flood propagation.

During dam break wave propagation, entrainment, transport and deposition of solid material occur in a way which can be difficulty represented within the classical framework of alluvial flows (e.g. Graf & Altinakar, 1998).

Applied research about dam break wave propagation over loose bed floodplain is rather recent. Both experimental and theoretical analysis of the process have been started less than one decade ago.

A relevant contribution to the understanding of the process has come from the recent IMPACT EU-funded research project: several research groups from all over the Europe had the opportunity to benchmark their models against well assessed experiments, performed in the most accurate conditions ever adopted.

If we except the qualitative observations of Chen & Simons (1979), the first systematic experiments of dam-break wave on an mobile bed were conduced by Capart & Young (1998) and Ferreira & Leal (1998), both referring to the idealized case of horizontal saturated bed with no water height downstream. The same experimental scheme was further investigated by Spinewine & Zech (2002) and Leal et al. (2003).

Copyright © 2006 Taylor & Francis Group plc, London, UK

By the whole, experiments by the aforementioned authors cover a wide range of sediment properties, from synthetic pebbles slightly heavier than water up to common sand.

Within the IMPACT project (Zech et al., 2005), an additional experimental configuration has been investigated: a one-dimensional dam break with initial bed discontinuity (Spinewine, 2005). The same author also reports some results of experiments about dam break in a channel with sudden expansion.

The complexity of the two-phase flow has gathered an impressive number of theoretical contribution, but still the topic is non completely clarified.

One of the main difficulties involved in the process is the strong coupling between liquid and solid phase during the whole duration. The analysis developed by Fraccarollo & Capart (2002) points out that evolution of liquid and granular flow may – at least in a certain time range of the process – follow comparable timescales. More in detail, the authors recognize the existence of three relevant timescales: the first needed for gravity wave to resemble shallow water condition (i.e.: quasi-hydrostatic pressure), the second for bedload to equilibrate the transport capacity, finally the third for the flow to exhibit diffusive rather than inertial character due to frictional momentum losses. Depending on the relative values of the three timescales, an adequate flow model has to be adopted in order to describe the process both from hydraulics and geomorphic point of view.

This complex behavior motivates the special features of the mathematical models which have been applied to simulate dam break flows over mobile bed.

Among the researchers involved into the IMPACT Project, El Kadi et al. (2003, 2004) used a standard morphological model based upon the Meyer-Peter & Muller (1948) formula with the addition of an explicit spatial lag; Ferreira et al. (2003) adopted some relations derived in the context of sheet flows to calculate the instantaneous solid discharge; the approach used by the Researchers of University of Trento (Fraccarollo et al. 2003) considers constant concentration of sediment between bed and transport layer and equal velocity of the two phases; Spinewine & Zech (2002) applied a refined formulation of the two-layer model proposed by Capart & Young (2002).

The numerical study by Cao et al. (2004) again adopts a non-capacity model for dam-break flow, sediment transport, and morphological evolution.

Finally, dam break over mobile bed has been recently simulated by Iervolino et al. (2005), by means of a two-phase formulation of the dynamical model proposed by Di Cristo et al. (2002) and Leopardi et al. (2003). The same model has been previously applied to simulate also dam erosion due to overtopping (Iervolino et al. 2004), giving promising results.

For what concerns two-dimensional processes, it has to be noted that the equal velocity hypothesis between liquid and solid phase has to be rejected when dealing with intensively scoured topographies. In fact, it may be imagined that even when the two phases move with comparable velocity values, their directions may in many cases be significantly different due to unequal inertia of the two phases. Among the aforementioned models, only the one by Spinewine (2005) does not suffer from this limitation.

In this paper a two-dimensional, depth averaged, two phase model for non-equilibrium solid transport is proposed. The model is applied to the case of a dam break over an erodible bed in a channel with sudden enlargement and its capabilities to re-produce the main features of the process are discussed.

2 THEORETICAL FRAMEWORK

Classical morphodynamical models couple sediment continuity equation (the so-called Exner equation) to hydrodynamic equations. This approach implies the choice of a bed load transport formula. Since this formula is usually an uniform flow formula, the hypothesis of instantaneous adaptation of bed load transport to variations in flow conditions is made (de Vries, 1965).

As a consequence, an accelerating stream causes scouring of the bed, while a decelerating one always causes deposition. This constraint would result in a contradiction with some experimental results, like the earth-dam failure experiment by Benoist (1983, 1989) used as a test-case by many authors (e.g. Leopardi et al. 2003).

During the dam break on a mobile bed the hypothesis of immediate adaptation of solid transport to hydrodynamics has to be rejected. In fact, experimental investigations have shown that the scouring wave evolves with timescales close to that of hydrodynamics.

In the present work a two-dimensional extension of the one-dimensional morphodynamical model proposed by Iervolino et al. (2004) will be used. The model uses the dynamical equation obtained by Di Cristo et al. (2002), which is coupled with a bed evolution equation based on the balance between erosion and deposition, as suggested by Iervolino et al. (2004) following Fraccarollo & Capart (2002).

The hydrodynamics is described using the classical Shallow Water theory equations. In order to explicitly account for the effect of sidewalls, a zero-equation turbulence model is employed.

The water mass conservation equation is

$$\frac{\partial h}{\partial t}+\frac{\partial hU}{\partial x}+\frac{\partial hV}{\partial y}=-\frac{\partial z}{\partial t} \qquad (1)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

Note the inclusion of the mobile boundary term in equation (1). Little influence on results shown in present work has been found by including this term, but it may have greater role when dealing with higher erosion/deposition rates.

The water momentum conservation equations read:

$$\frac{\partial hU}{\partial t}+\frac{\partial hU^2}{\partial x}+\frac{\partial hUV}{\partial y}+\frac{g}{2}\frac{\partial h^2}{\partial x}+gh\frac{\partial z}{\partial x}= =-ghS_{fx}+\frac{\partial}{\partial x}\left(h\nu_t\frac{\partial U}{\partial x}\right)+\frac{\partial}{\partial y}\left(h\nu_t\frac{\partial U}{\partial y}\right)$$
$$\frac{\partial hV}{\partial t}+\frac{\partial hUV}{\partial x}+\frac{\partial hV^2}{\partial y}+\frac{g}{2}\frac{\partial h^2}{\partial y}+gh\frac{\partial z}{\partial y}= =-ghS_{fy}+\frac{\partial}{\partial x}\left(h\nu_t\frac{\partial V}{\partial x}\right)+\frac{\partial}{\partial y}\left(h\nu_t\frac{\partial V}{\partial y}\right) \quad (2a,b)$$

in which g is gravity, x, y are the space coordinates in an horizontal plane, t is time, $h = h(x,y,t)$ the water depth, $U = U(x,y,t)$ and $V = V(x,y,t)$ are the depth integrated flow velocity in x and y direction, respectively, $z = z(x,y,t)$ is the bottom elevation, and ν_t is the eddy viscosity; Sf is friction slope (estimated with Chezy formula); its components in x and y direction, namely Sf_x and Sf_y results from:

$$Sf_x = Sf\frac{U}{\sqrt{U^2+V^2}},\ Sf_y = Sf\frac{V}{\sqrt{U^2+V^2}} \quad (3a,b)$$

Finally, vectorial friction velocity is defined according to:

$$\mathbf{u}_* = \left(U^*, V^*\right) = =\left(\sqrt{ghSf}\frac{U}{\sqrt{U^2+V^2}}, \sqrt{ghSf}\frac{V}{\sqrt{U^2+V^2}}\right) \quad (4)$$

and eddy viscosity is computed as $\nu_t = \omega|\mathbf{u}_*|h$ (Elder, 1959), where ω is a coefficient. By assuming a logarithmic velocity profile along the vertical direction, the value of 0.066 can be estimated for ω.

Morphological evolution is computed coupling (1) and (2) with the equations describing the sediment mass and momentum conservation. The sediment mass conservation equation is similar to the classical Exner (1925) equation:

$$(1-e)\frac{\partial z}{\partial t}+\frac{\partial C\delta}{\partial t}+\frac{\partial C\delta U_p}{\partial x}+\frac{\partial C\delta V_p}{\partial y}=0 \quad (5)$$

in which $C = C(x, y, t)$ is the sediment concentration in the transport layer, $\delta = \delta(x, y, t)$ the thickness of the transport layer, $U_p = U_p(x, y, t)$ the sediment transport velocity in x direction, $V_p = V_p(x, y, t)$ the sediment transport velocity in y direction and e the–bed porosity.

The equations representing momentum conservation of a mean particle are the 2D extension of the one reported by Iervolino et al. (2004):

$$\frac{\partial U_p}{\partial t}+U_p\frac{\partial U_p}{\partial x}+V_p\frac{\partial U_p}{\partial y}+ \frac{\Delta g tg\varphi}{\Delta+1}\left[\frac{1}{\sqrt{1+\left[\left(\frac{\partial z}{\partial x}\right)^2+\left(\frac{\partial z}{\partial y}\right)^2\right]}}-\frac{1}{tg\varphi}\frac{\partial z}{\partial x}\right]+ -\frac{c_d}{(\Delta+1)c_s d}\left(\beta U^*-U_p\right)\sqrt{\left(\beta U^*-U_p\right)^2+\left(\beta V^*-V_p\right)^2}+ +\frac{\alpha}{c_s d}U_p\sqrt{U_p^2+V_p^2}=0 \quad (6a)$$

$$\frac{\partial V_p}{\partial t}+U_p\frac{\partial V_p}{\partial x}+V_p\frac{\partial V_p}{\partial y}+ \frac{\Delta g tg\varphi}{\Delta+1}\left[\frac{1}{\sqrt{1+\left[\left(\frac{\partial z}{\partial x}\right)^2+\left(\frac{\partial z}{\partial y}\right)^2\right]}}-\frac{1}{tg\varphi}\frac{\partial z}{\partial y}\right]+ -\frac{c_d}{(\Delta+1)c_s d}\left(\beta V^*-V_p\right)\sqrt{\left(\beta U^*-U_p\right)^2+\left(\beta V^*-V_p\right)^2}+ +\frac{\alpha}{c_s d}V_p\sqrt{U_p^2+V_p^2}=0 \quad (6b)$$

in which Δ is the dimensionless ratio $(\rho_s-\rho)/\rho$, with water density ρ and solid phase density ρ_s; α is the Bagnold coefficient (Bagnold, 1954), β the ratio between fluid velocity in the transport layer and shear velocity, φ the sediment friction angle and c_d the drag coefficient; finally c_s is the shape coefficient of the particles, i.e. the ratio between the volume and the cross section area coefficients. In the present computations, it has been evaluated assuming spherical particles.

The first term in equation (5) represents the erosion deposition rate e_b. Closure of the model requires an

Copyright © 2006 Taylor & Francis Group plc, London, UK

independent relation for it. In present work the one proposed by Fraccarollo & Capart (2002) is used:

$$(1-e)\frac{\partial z}{\partial t} = -e_b$$

$$e_b = \pm\frac{|\tau_s - \tau_b|}{\rho_s |U_p|} = \quad (7)$$

$$= \frac{1}{\sqrt{U_p^2 + V_p^2}} \left(\frac{\alpha}{c_s}\left(U_p^2 + V_p^2\right) + \frac{1}{\sqrt{1+\left[\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2\right]}} g \frac{\Delta}{\Delta+1} C\delta \cdot tg\varphi \right)$$

in which $|\tau_s - \tau_b|$ represents the stress excess at the bottom, producing erosion (if greater than zero) or the deposition (otherwise).

Deposition velocity during an unsteady process is assumed to be bounded by sediment fall velocity in still clear-water, w_s. So, if the term obtained by equation (7) is smaller than $-w_s$ it is assumed equal to $-w_s$. Despite the unsteadiness of the process simulated in the present work, this limiter has been found to have little or none influence on the results; it may have greater significance under different flow conditions.

The model is then composed by seven partial derivative equations with the unknown functions: h, U, V, z, $C\delta$, U_p, V_p. Numerical integration is performed using a finite volume formulation on a structured, non staggered grid. The technique is described in detail in Leopardi (2001) and it is based on a parabolic interpolation at the interfaces among adjacent cells and predictor-corrector explicit time stepping. The method has high accuracy both in space and time, along with fairly good shock capturing capabilities. An *ad hoc* treatment for no flow cells (outblock) is used in order to manage complex geometries.

In order to avoid unphysical results, two further limiters are introduce in the implementation of the model. The first is a slope limiter that bounds the bed slope source term in equations (2a,b) to a maximum value of 0.1. When dealing with relatively mild slopes – as in the present case – this limiter has been verified to act only in the sense of improving model stability, while having no perceivable influence on the solution.

The second limiter is designed in order to avoid that the numerical flux of solid phase flowing out of a cell may be greater than the available mass in it.

3 NUMERICAL SIMULATIONS

3.1 *Fixed-bed simulations*

As a preliminary test, the adequacy of the model to reproduce wave propagation over a floodplain with a sudden expansion has been verified by simulating the experiments described by Soares Frazão et al. (2003). The flow domain is sketched in figure 1: it consists of a narrow fixed bed channel (width b, length l) followed by an idealized floodplain generated by the sudden increase of the width on one side (width B, length L-l). Experiments cover both steady and unsteady conditions of flow, the latter obtained producing a dam-break wave. During the evolution of the two processes, wide regions of recirculation as well as steep fronts (shock waves) occur, thus requiring adequate numerical models to be reproduced.

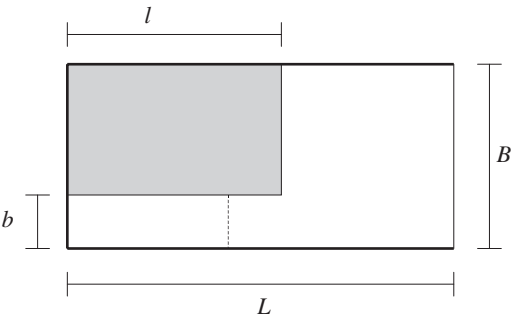

Figure 1. Sketch of the flow domain for dam break with sudden enlargement.

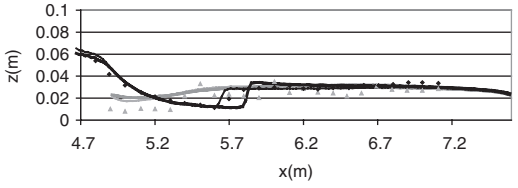

Figure 2. Water profiles along channel sidewalls. Thick lines: without turbulence model. Thin line: with turbulence model.

Simulated tests present $l = 4.82$ m, $L = 7.60$ m, $b = 0.12$, $B = 0.495$ m. Computational grid is made of square cells with $\Delta x = \Delta y = 0.02$ cm, which have been verified to satisfy grid independence.

Non dimensional Chezy coefficient has been calibrated against experimental results, and the classical value of 0.066 has been used for the ω coefficient of the Elder's law.

Results, with reference to steady flow conditions, are summarised by figures 2 and 3. In the first one simulated water profiles along the two sidewalls are compared with corresponding measured ones: black symbols and line are used for the continuous sidewall, gray for the discontinuous. Thick lines correspond to simulation without turbulence model, and thin line to computation performed taking into account sidewall effects. In figure 3, flow trajectories are compared to the one obtained by Frazão et al. (2003) by means of a PIV technique.

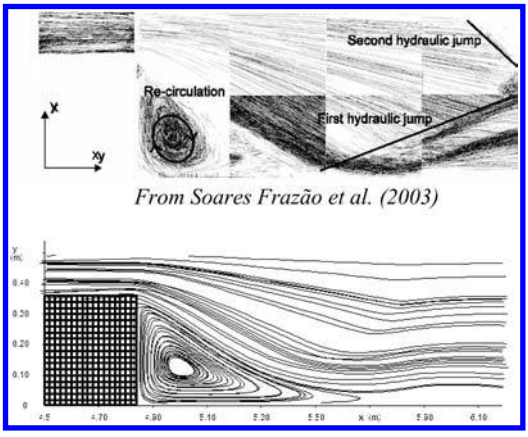

Figure 3. Measured and computed flow trajectories.

A general agreement can be inferred from both figures: water depths are well reproduced, even if with some minor accuracy near the jump (which is sharper in the computation than in the experiments) and in the proximity of the re-circulation zone.

As far as dam-break test is concerned, the unsteady process is triggered by the sudden removal of a dam located at abscissa 4 m with initial depth of 0.2 cm upstream and dry bed downstream. Comparison with experimental and numerical results of Soares Frazão et al. (2003) shows again overall agreement, thus confirming the capabilities of the numerical model to deal with such kind of complex flow.

As an example the instantaneous field of velocity vectors 2.75 s after dam removal is shown in figure 4 and compared with measured velocity magnitude.

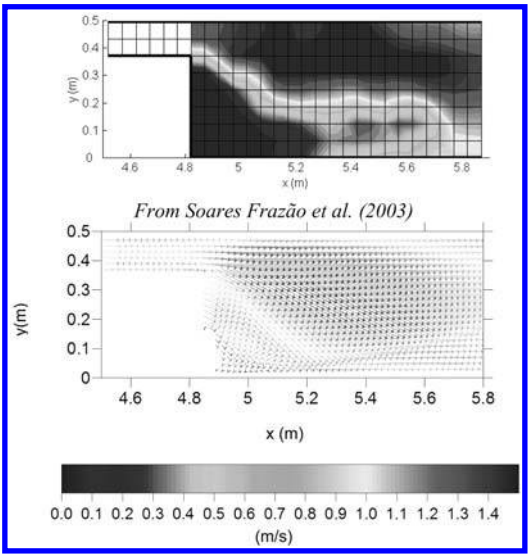

Figure 4. Measured and computed velocity magnitude. t = 2.75 s after dam removal.

3.2 *Mobile-bed simulations*

The scheme considered for two dimensional dam break over mobile bed is the one recently discussed by Spinewine (2005). It is geometrically analogous to the fixed bed case, but with $b = 0.25$ m, $B = 0.50$ m, $L = 6$ m and $l = 4$ m. At $t = 0$, water is stored in the first 3 m of the narrow channel, with saturated granular bed downstream. Experimental installation is designed to guarantee little influence of gate opening on the process.

A computational grid with $\Delta x = 0.05$ m and $\Delta y = 0.025$ m has been used. In order to better reproduce the roughness of the granular bed, Griffiths'law has been adopted to compute the Chezy non dimensional factor

$$C_h = 2.15 + 2.43 \ln\left(\frac{h}{d}\right) \tag{8}$$

whose application range is for h/d between 1 and 200 (Griffiths, 1981).

Sediment parameters have been set to the experimental values, reported by the Author, while β and α have been given the values, respectively, of C_h and 0.114. Results have shown little sensitivity respect to the values two parameters, which have been varied within the same range already used in analogous simulations (Iervolino et al. 2005).

Two computations are shown and discussed in what follows, differing for the inclusion of the turbulence terms by the zero-equation model with $\omega = 0.066$, in order account for sidewall influence hydrodynamics and bed evolution.

For both cases (Figures 5 and 6), gray level maps with simulated bed deformation are shown for t = 1,2,3,5 s after dam removal. The iso-contour relative to initial bed level is superposed as a solid line.

3D-plot for free surface elevation are also reported for same time sequence. Constant-level contours with 1 cm increment are traced on the wireframes to better represent the free surface shape (Figure 7).

Finally, the time evolution of sediment mass discharged out of the domain is reported in figure 8. Again, thick line is used for computations without turbulence, thin one otherwise. Dashed line represents the final measured value of 2.05 kg.

3.3 *Discussion of results*

Experimental observations of Spinewine (2005) are, in the writers' knowledge, the only published data concerning two dimensional dam break wave over mobile bed. This generalised lack of experimental data, even if partially justified by the complex

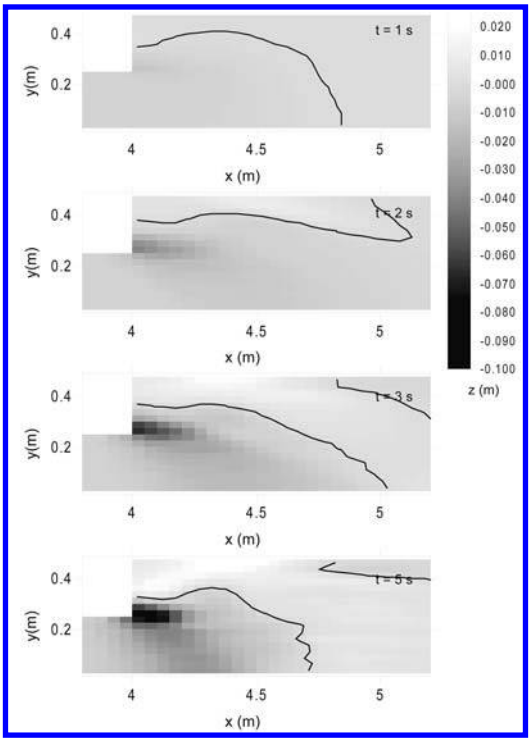

Figure 5. Bed evolution without turbulence model (t = 1,2,3,5 s). The iso-contour relative to initial bed level is superposed as a solid line.

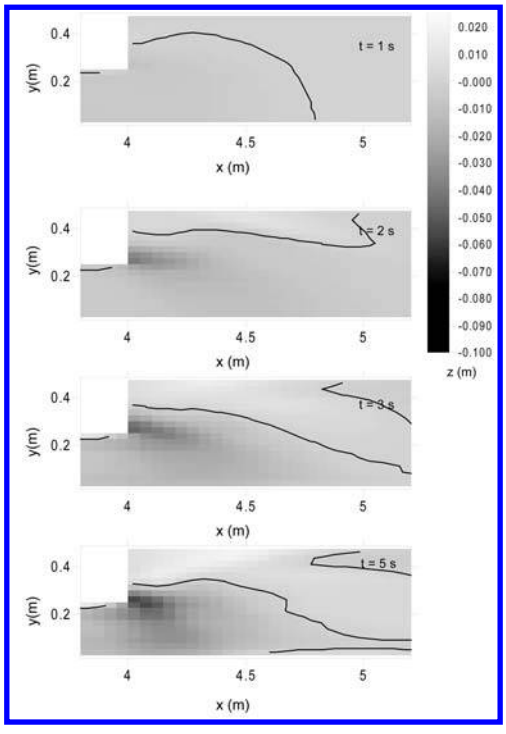

Figure 6. Bed evolution with turbulence model (t = 1, 2, 3, 5 s).The iso-contour relative to initial bed level is superposed as a solid line.

experimental conditions and the strong unsteadiness of the process, should be addressed in the near future, in order to gain insight and provide a fundamental aid to mathematical modelling.

Despite little more than a qualitative comparison can be made with available experiments, present simulation reproduce favourably the overall features of the process:

- Independently on the inclusion of turbulent diffusive terms, the maximum scour depth is located just downstream the inner corner of the floodplain enlargement.
- Its value appears instead to be significantly influenced by the presence of turbulent diffusivity. Maximum scour at $t = 5$ s is, in fact, close to 0.1 m for the former simulation and about 0.06 m for the latter.
- The formation of an oblique hydraulic jump causes a partial re-deposition of the eroded material, up to the appearance of a bar in the floodplain, which is elongated in the longitudinal direction close to the left wall.
- When turbulence is included in the simulation, a second deposition zone can be observed close to the right wall, which spreads in the transversal direction for a length of few centimetres. It is generated by deposition in the low-velocity zones near the wall. So, accounting for the wall effect has a more pronounced positive influence on the reproduction of the process than in the fixed bed case. Due to the depth-to-width ratio of the present laboratory case, this effect can be appreciated also on the free surface configuration, which shows progressively increasing differences between the two simulations.

The total mass discharged from the model in the whole process is 2.56 kg for the simulation without turbulence and 1.97 kg when turbulence is included. Both values are reasonably close to the measured one of 2.05 kg.

Moreover, the comparison of present results with the computations presented by Spinewine (2005), based on a two layer description of the flow of water and sediment, shows that main difference consists in the more pronounced effect of wave reflection against right sidewall.

4 CONCLUSIONS

Dam break on mobile bed is a challenging test for numerical models. Since the scouring wave evolves

Copyright © 2006 Taylor & Francis Group plc, London, UK

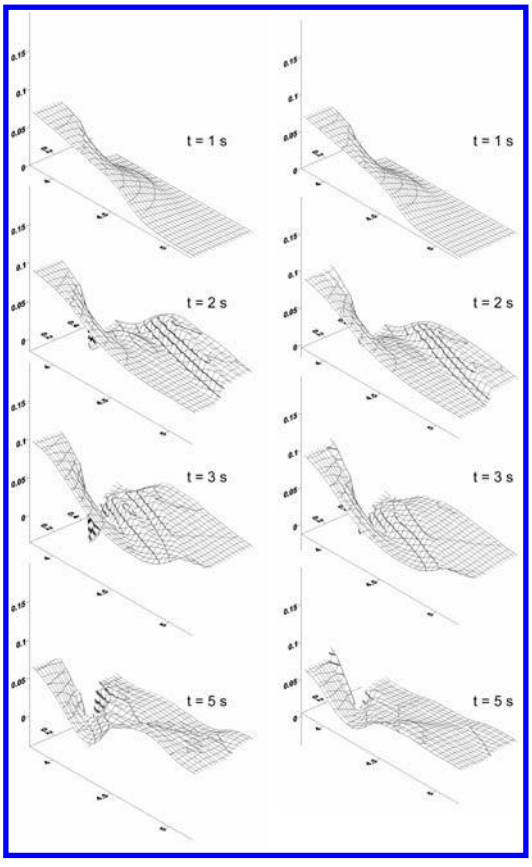

Figure 7. 3D view of computed free-surface at different times. Left: without turbulence model; right: with turbulence model.

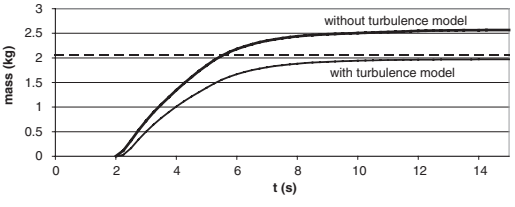

Figure 8. Time evolution of sediment mass discharged out from the experimental plant.

with timescales close to that of hydrodynamics, the hypothesis of immediate adaptation of solid transport to hydrodynamics has to be rejected.

In the present work physical experiments of dam break on mobile bed have been simulated using an original two-phases non-equilibrium model. Moreover, the effect of the inclusion of the sidewall on the results has been investigated. Results show the appearance of a deposition zone close to the sidewalls which is otherwise absent, which in turn contributes to modify the shape of free surface. This suggests that such an effect should be taken into account in some applications, depending on the depth-to-width ratio. Moreover, the estimation of maximum scour depth is sensibly affected by the transversal turbulent diffusivity, and its inclusion leads to predict lower depth.

Model predictions are compared with the experimental documentation of the process, even if little more than a qualitative assessment can be done, and with the computations made with a state-of-the-art model. Both comparisons gave encouraging results.

It has to be stressed that the lack of data about two dimensional dam break over mobile bed claims for future experimental research, a fundamental tool to gain further insight and improve mathematical modelling of the process.

One dimensional modeling of dam break flow over erodible sediment bed

P. Costabile & F. Macchione
University of Calabria, LAMPIT (LAboratorio di Modellistica numerica per la Protezione Idraulica del Territorio), Dipartimento di Difesa del Suolo, Rende, Cosenza Italy

ABSTRACT: This paper deals with the simulation of dam break waves over movable beds. The aim of this work is to analyze the suitability of a model proposed in the simulation of debris flow events. It is based on a shallow water approach and the system of equations includes two mass conservation equations (one for the mixture and another for the solid phase) and a single momentum balance equation. A uniform distribution of velocity is also assumed in the cross section. Moreover, the model takes into account a non equilibrium transport of the sediments based on an auxiliary relationship that introduces an erosion/deposition velocity. The governing equations are solved in coupled way by the implementation of an explicit first-order finite volume method. The model has been tested in a number of experimental cases and has achieved fairly good agreements between the simulation and the measurement.

1 INTRODUCTION

Over the last decade the problems related to the definition of flooding areas due to partial or total dam failure have been a topic of increasing interest in the fields of hydraulic engineering. This is a tricky subject because dam break waves may cause catastrophic damage to the valley downstream and loss of life.

Some of the most famous dam break events are the Malpasset (France) dam failure in 1959, Banqiao (China) dam break in 1975 and the catastrophic event of Lake Ha! Ha! (Quebec) in 1998 (Lapointe et al. 1998). Many models were developed in order to simulate this phenomenon: finite differences, finite elements and finite volume techniques for the numerical integration of shallow water equations have been significantly improved. Most of them refer to ideal or real situations in which the bed profile does not change over time. Indeed this is a very reasonable hypothesis for rock channels but it is questionable in rivers in which significant erosions and depositions phenomena occur.

The propagation of a dam break wave in natural valleys is very complex since it may produce significant morphological changes to the bed with a large amount of conveyed material. This intense sediment transport may dramatically modify the dynamic behaviour of the flow and, in turn, may affect the arrival time and the maximum water levels, very important factors in the evaluation of the risk assessment.

The water depth profile of a dam break wave over a movable bed is significantly different from that over a fixed bed. It is well known in the literature that, for the fix bed case, the flow exhibits a continuous, monotic decrease in free surface. This behaviour is not observed in the movable case because the physical evidence shows the formation of a hydraulic jump near the centre of dam break wave due to interaction with the evolution of the bed (Capart & Young 1998).

The analysis of a dam break over an erodible bed also represents a chance to improve theoretical knowledge of some key processes linked to sediments transport in shallow water. It is quite evident that the singularities in the water depth profile (i.e. hydraulic jump, shock waves) produce hydrodynamic situations in which sediment transport is very far from equilibrium conditions; in turn, the bed evolution is one of the mechanisms that can lead to the formation of shock waves.

All this provoke a highly unsteady phenomenon with intense sediment transport moving as a sheet flow and debris flow. These kinds of situations occurs in various conditions of engineering interest as fast flows, flash floods (Lapointe et al. 1998) and debris flow (Takahashi 1991, Iverson 1997). Moreover, from analysis of recent natural or constructed dam failures, it has been shown (Zech & Spinewine 2001) that the volume of transported material may, in some instances, even be as important as the volume of water itself. Regardless of the total transported volume, it should be noted that these geomorphic consequences may significantly increase the entity of a flood wave due to localised effects as happened in the catastrophic event of Pollalie Creek (Gallino & Pierson 1985): a temporary artificial

Copyright © 2006 Taylor & Francis Group plc, London, UK

dam originated by the deposition of the materials transported by the flow collapsed causing a considerable increase of the flood.

Recently, sediment transport in highly transient non-equilibrium conditions has been a topic of increasing interest to hydraulic scientists leading to extensive field, laboratory, theoretical and numerical studies.

Several experimental works have been carried out in order to understand the peculiarities of the phenomenon (Capart & Young 1998, Fraccarollo & Capart 2002, Leal et al. 2003). In the context of the IMPACT project different tests were performed: the first test ("flat bed case") assumes the same level of sediment at both sides of the dam (Spinewine & Zech 2002) while in the second test ("stepped bed case") the level of the upstream sediments is higher than the downstream one (Spinewine & Zech 2003); the latter test was performed with material of different size and density in order to magnify the sediment transport processes.

These experimental works represent the benchmarks cases which can be used to validate the numerical model developed by the various research groups within the project.

Different models have been proposed to deal with this problem, all based on a shallow water approach; a possible main classification can be made as regards the conceptual vertical flow structure: one-layer flow models and two-layer models.

One-layer models consider a sediment-water mixture everywhere, that is the absence of a clear water layer: the models of Capart & Young (1998), Caleffi & Valiani (2002), Cao et al. (2004), belong to this category; non equilibrium conditions are generally taken into account by means of a spatial-lag relationship or through formulas of entrainment and deposition fluxes. Another model based on the one-layer description, used within IMPACT project, was developed by El Kadi & Paquier (2004).

Two-layer models are more complex; they assume that the flow is subdivided into two non-miscible layers separated by an interface: in the lower layer the flow is represented as a solid-liquid mixture while the upper layer is sediment free (clear water layer).

The models of Fraccarollo & Capart (2002) and Fraccarollo et al. (2003) belong to this family; the above authors assume a uniform velocity profile and a sediment concentration equal to that of the static bed. A similar approach was undertaken by Spinewine & Zech (2003) in which the velocities of the flow in the layers are not equal and the sediment concentration is different from that of the static bed. Leal et al. (2003) developed another conceptual model in which the wave propagation is idealized as a two layer transport model, where flow velocities and sediment concentrations are considered uniform; localized erosion/deposition processes are represented by vertical fluxes.

This paper deals with the simulation of dam break waves over movable beds. The main purpose of the present work is not so much to improve theoretical knowledge of the hydrodynamics of this particular phenomenon, but to analyze the ability of the model presented herein to simulate highly unsteady flow with intense sediment transport that cannot be simulated with a classical equilibrium transport model.

With this in mind, the authors prefer to analyze the suitability of a simple model based on shallow water equations and that considers the effects of evolution of the bed on the flow, so that it can represent the propagation of a liquid-granular mixture. The hyperbolic conservation system includes two mass conservation equations (one for the mixture and another for the solid phase) and a single momentum balance equation.

In other words, the vertical flow structure is defined by two interfaces: the water free-surface and the morphodynamic bottom profile; a constant vertical profile for the velocity is also assumed. Moreover, the model takes into account a non equilibrium transport of the sediments based on an auxiliary relationship that introduces an erosion/deposition velocity.

As showed in the next section, the bed evolution law is the main feature that makes the proposed model different from the other one layer models. So one of the main purposes of this work is to analyze the suitability of this particular relationship within a model that is based on a mathematical formulation of governing equations well-known in the literature (i.e. Cao et al. 2004).

The governing equations are solved in a coupled way through the implementation of an explicit first-order finite volume method. In previous works (Costabile et al. 2004, Costabile & Macchione 2004), this model was already applied to test cases presented in Capart & Young (1998) and in Fraccarollo & Capart (2002) with fairly good agreement with experimental results.

Some applications to experimental cases used within IMPACT project are shown in this paper, in order to understand if there are any significant differences between the results obtained with the conceptually simple one-layer model presented herein and those from the more complex two layer models.

2 MATHEMATICAL MODEL

This paper considers a one-layer model based upon a solid-liquid mixture moving in unsteady flow conditions. In recent years many authors have presented the governing equations for the water-sediment mixture both for the morphological evolution in alluvial rivers (Cao et al. 2002) and for highly unsteady flow with intense sediment transport such as dam break wave over erodible bed or debris flow (Capart & Young

Copyright © 2006 Taylor & Francis Group plc, London, UK

1998, Brufau et al. 2000, Caleffi & Valiani 2002, Cao et al. 2004). The complete governing equations can be derived from the Reynolds transport theorem. So, apart from certain simplifications in the momentum balance and from different relationships for the bed evolution, the above mathematical formulation is well-known in the literature and has been applied to the available experimental test-cases of dam – break over movable bed.

In order to describe the dynamic of the mixture a 1D shallow water approach is used, so the governing equations are related to the mixture and solid phase mass balance and to the complete mixture momentum balance along the main stream direction (the same velocity for the solid fraction and the interstitial fluid is assumed); moreover, the model includes a bed evolution law.

The set of four differential equations is:

$$\frac{\partial A}{\partial t}+\frac{\partial Q}{\partial x}=rb \tag{1}$$

$$\frac{\partial Q}{\partial t}+\frac{\partial\left(\frac{Q^2}{A}+g\frac{A^2}{2b}\cos\theta\right)}{\partial x}=gA\left(S_o-S_f\right)+ -\left[\frac{bur}{\rho}\left(\rho^*-\rho\right)+\frac{g}{\rho}\frac{A^2}{2b}\cos\theta\frac{\partial\rho}{\partial x}\right] \tag{2}$$

$$\frac{\partial(cA)}{\partial t}+\frac{\partial(cQ)}{\partial x}=rbc^* \tag{3}$$

$$\frac{\partial z}{\partial t}\cos\theta+r=0 \tag{4}$$

The system of equations (1), (2) and (3) can be expressed in the following form:

$$\frac{\partial\mathbf{U}}{\partial t}+\frac{\partial\mathbf{F}(\mathbf{U})}{\partial x}=\mathbf{G}(\mathbf{U}) \tag{5}$$

$$\mathbf{U}=\begin{bmatrix}A\\Q\\cA\end{bmatrix}\qquad\mathbf{F}(\mathbf{U})=\begin{bmatrix}Q\\\left(\frac{Q^2}{A}+g\frac{A^2}{2b}\cos\theta\right)\\cQ\end{bmatrix} \tag{6,7}$$

$$\mathbf{G}(\mathbf{U})=\begin{bmatrix}rb\\gA(S_0-S_f)-\left[\frac{bur}{\rho}\left(\rho^*-\rho\right)+\frac{g}{\rho}\frac{A^2}{2b}\cos\theta\frac{\partial\rho}{\partial x}\right]\\rbc^*\end{bmatrix} \tag{8}$$

where x = space coordinate; t = time level; $\mathbf{U}$ = conservative variable vector; $\mathbf{F}$ = flux vector; $\mathbf{G}$ = source term vector; A = mixture cross section area; Q = mixture discharge; c = dimensionless sediment volumetric concentration; g = acceleration due to gravity; b = channel width; θ = angle of bed inclination; S_0 = local bed slope; S_f = slope friction term; u = mean velocity in the cross-section; r = bed erosion/deposition velocity; ρ = mixture density; c^*, ρ^* = parameter related to sediment concentration and density in a static bed; z = bed level.

Mixture density can be computed as follows:

$$\rho=\rho_s c+\rho_w\left(1-c\right) \tag{9}$$

where ρ_s is sediment density and ρ_w is water density. Bottom slope S_0 can be evaluate as:

$$S_o=\sin\theta=-\frac{\partial z}{\partial x} \tag{10}$$

In this work the temporal evolution of the bottom profile is described by means of an erosion-deposition velocity; for this, the relationship first proposed by Egashira & Ashida (1987) and later modified by Brufau et al. (2000) is used. The erosion/deposition model considered herein has the following expression:

$$r=K_f u\tan\left(\theta_f-\theta_e\right) \tag{11}$$

where θ_e is the equilibrium angle, θ_f is the energy line angle, K_f is a calibration parameter. The equilibrium angle depends on mixture concentration, on density ratio s, and on static internal friction angle; it can be computed as follows:

$$\theta_e=\arctan\left[\tan\phi\frac{c(s-1)}{c(s-1)+1}\right] \tag{12}$$

The density ratio s can be defined as:

$$s=\frac{\rho_s}{\rho_w}$$

The structure of equation (12) may be derived from a simplified stability analysis of an incoherent saturated mass upon an inclined plane of constant slope. The energy line angle is computed as:

$$\theta_f=\arctan\left(\frac{S_f}{\cos\theta}\right) \tag{13}$$

Slope friction is computed by means of Manning-Strickler formula where coefficient n_m is estimated from the value of sediment diameter d:

$$n_m=\frac{21.1}{d_{50}^{1/6}} \tag{14}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

So according to equations (4) and (11), a positive value of r means that erosion takes place; clearly this happens when $\theta_f > \theta_e$. Obviously the deposition occurs when $\theta_f \leq \theta_e$.

Finally c^*, ρ^* are defined as:

$$c^* = \begin{cases} \max(c, c_D) & r \leq 0 \\ c_b & r > 0 \end{cases} \tag{15}$$

$$\rho^* = \begin{cases} \rho_D & r \leq 0 \\ \rho_b & r > 0 \end{cases} \tag{16}$$

where c_D, ρ_D = volumetric sediment concentration and density of a static bed just after deposition and c_b, ρ_b = volumetric sediment concentration and density in a static bed.

It should be noted that the bed evolution law considered in this work has been proposed in the context of the mathematical modelling of debris flow (Brufau et al. 2000). It is interesting to observe that the mathematical formulation of the governing equations used in Brufau et al. (2000) is very similar to that of Cao et al. (2004) except for the last two terms on the right-hand side of equation (2) that are considered negligible for debris flow events. This conclusion is commonly accepted for the fluvial sediment transport usually encountered but not under extreme situations, as dam-break flow over an erodible bed, in which the use of complete rather than simplified momentum equation is essential (Cao et al. 2003, Cao et al. 2004).

3 NUMERICAL MODEL

An explicit finite volume method is used for the numerical resolution of system (5) so that the temporal evolution of the solution is computed as follows:

$$\mathbf{U}_j^{n+1} = \mathbf{U}_j^n - \frac{\Delta t}{\Delta x}\left(\mathbf{F}_{j+1/2} - \mathbf{F}_{j-1/2}\right) + \Delta t \mathbf{G}_j^n \tag{17}$$

where Δt is the time step; Δx is the spatial step; j is the spatial node index; n is the time step index; and $\mathbf{F}_{j+1/2}$ is the numerical flux at $x = x_{j+1/2}$.

In the present work HLLC approximate Riemann solver is used for the computation of $\mathbf{F}_{j+1/2}$; HLLC numerical flux can be expressed as follows:

$$\mathbf{F}_{j+1/2}^{HLLC} = \begin{cases} \mathbf{F}_L & \text{if } S_L \geq 0 \\ \mathbf{F}_L^* & \text{if } S_L \leq 0 \leq S^* \\ \mathbf{F}_R^* & \text{if } S^* \leq 0 \leq S_R \\ \mathbf{F}_R & \text{if } S_R \leq 0 \end{cases} \tag{18}$$

where $\mathbf{F}_L$ and $\mathbf{F}_R$ stand for $\mathbf{F}(\mathbf{U}_j^n)$ and $\mathbf{F}(\mathbf{U}_{j+1}^n)$ respectively.

$$\mathbf{F}_L^* = \mathbf{F}_L + S_L\left(\mathbf{U}_L^* - \mathbf{U}_L\right) \qquad \mathbf{F}_R^* = \mathbf{F}_R + S_R\left(\mathbf{U}_R^* - \mathbf{U}_R\right) \tag{19,20}$$

$$S_L = u_L - a_L q_L \qquad S_R = u_R + a_R q_R \tag{21,22}$$

In previous relationships q_K ($K = L, R$) are given by:

$$q_K = \begin{cases} \sqrt{\frac{1}{2}\left[\frac{(h_* + h_K)h_*}{h_K^2}\right]} & \text{if } h_* > h_K \\ 1 & \text{if } h_* \leq h_K \end{cases} \tag{23}$$

$$S^* = \frac{S_L h_R(u_R - S_R) - S_R h_L(u_L - S_L)}{h_R(u_R - S_R) - h_L(u_L - S_L)} \qquad h^* = \frac{1}{g}\left[\frac{1}{2}(a_L + a_R) + \frac{1}{4}(u_L - u_R)\right]^2 \tag{24,25}$$

$$\mathbf{U}_K^* = h_K\left(\frac{S_K - u_K}{S_K - S^*}\right)\begin{bmatrix} 1 \\ S^* \\ C \end{bmatrix} \tag{26}$$

$$a_K = \sqrt{g h_K} \tag{27}$$

One can find further details in Toro (1997), Toro (2001). In this way one achieves first order accuracy.

The problems arising from an incorrect treatment of source terms are well known in the literature. In order to avoid spurious numerical oscillations, for example, Bermudez & Vazquez (1994) presented, for the fixed bed case, an upwind representation of the source terms in order to be consistent with an upwind discretization of numerical flux so that avoiding numerical spurious oscillations.

In this work two algorithms are taken into account. The first uses a pointwise approach; the second is based on a splitting scheme (Toro 2001) which consists in solving, in succession, two initial value problems: one can obtain a predicted solution $\mathbf{U}(p)$ by solving the homogeneous pure advection problem with the initial condition of the full problem; the final solution is given by solving the ordinary differential equation:

$$\frac{\partial \mathbf{U}}{\partial t} = \mathbf{G}(\mathbf{U}) \tag{28}$$

with initial condition $\mathbf{U}(p)$. No significant differences were found in the applications of the two methods.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The bed evolution was computed using the following explicit scheme:

$$z_j^{n+1} = \alpha z_j^n + (1-\alpha)\frac{z_{j+1}^n - z_{j-1}^n}{2} - \frac{r_j^n}{\cos\theta_j^n}\Delta t \qquad (29)$$

where $0 \le \alpha \le 1$. Simulations are performed with a value of α very close to unity (0.99–0.999) in order to minimize numerical diffusion.

4 MODEL VALIDATION

In previous works (Costabile et al. 2004, Costabile & Macchione 2004), this model was already applied to some tests presented in the literature (Capart & Young 1998, Fraccarollo & Capart 2002) with fairly good results. The aforementioned tests both refer to a so called "flat bed case" (Spinewine & Zech 2002) in which the same level of sediment at both sides of the dam was imposed; the density ratios used in the tests were $s = 1.048$ and $s = 1.54$, respectively.

In this work the suitability of the model presented is further analysed through its application to the "stepped bed" test cases (Spinewine & Zech 2003). As mentioned in the introduction, these tests were used as benchmarks to validate the numerical models developed during the IMPACT project by several research groups and so one has the opportunity to compare the results achieved in the present work with those obtained from the more complex models above.

The benchmark test conditions are briefly recalled (for further details see Spinewine & Zech 2003). The experiments were carried out at the laboratory of the Civil and Environmental Engineering Department, Université Catholique de Louvaine (UCL) Belgium. The facility consists in a rectangular flume, 6 m long, 0.25 m wide, 0.7 m high. Same initial conditions were assumed for both tests. An initial discontinuity was provided in the bed profile so that the upstream bed level was initially 0.10 m higher than the downstream level. Total hydraulic head upstream h_0 was equal to 0.35 m. Uniform coarse sand ($s = 2.63$, $d = 0.00182$ m) and light PVC pellets ($s = 1.55$, $d = 0.0036$ m) were used in the experiments. A wide analysis of the numerical prediction of the model developed within IMPACT project can be found in Spinewine & Zech (2004).

In the following sections the results of the model presented in this paper are shown. In both tests a value of $\Delta x = 0.01$ m and for numerical stability a Courant number $C_r = 0.1$ are used; the low value of Courant number is due to significant source terms in the equations (Brufau et al. 2000). Moreover, for the sake of simplicity, it is assumed $c_D = c_b$. The following simulations refer to $K_f = 10$ but a sensitivity analysis to this parameter is also presented. Only the comparison between experimental and numerical results of the model here presented are shown; the numerical results of the other modellers are not shown in this paper in order to avoid a limited readability of the figures. We chose the same scale of the figures used by Spinewine & Zech (2004) to make the comparison with the results obtained within IMPACT project easier.

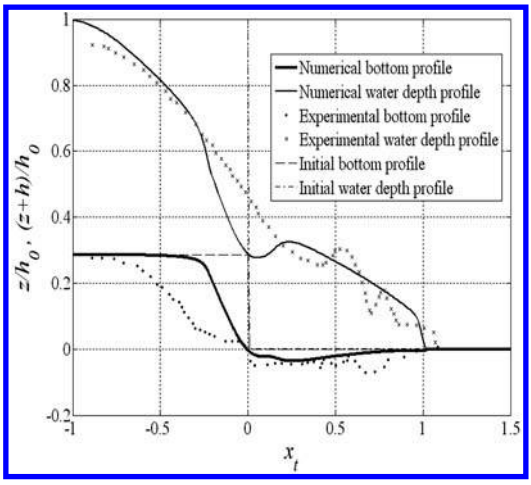

Figure 1. PVC test. Comparison between experimental and numerical results. $t = 0.57$ s.

4.1 *PVC test case*

Figures 1–4 show dimensionless experimental and numerical profiles for different instants of time, where:

$$x_t = \frac{x}{t\sqrt{gh_0}}$$

Figures 1–4 highlight a satisfactory agreement between experimental data and numerical simulations. The model significantly underestimates the bed scour in the early stages of the phenomenon (Fig. 1), but gives good results subsequently (Figs. 3–4). The poor prediction of the bed scour in the early stages was only to be expected. As stated in Spinewine & Zech (2004), strong vertical effects and a plastic mass failure of the soil around the bed step occur just after the initial collapse especially for the PVC test case; it is evident that these processes are not modelled here.

On the other hand all the models failed in this prediction except the UCL models that accounts for the initial mass failure of the bed by means of a liquefaction criterion. Figures 2–3 show that model is able to predict accurately the front wave celerity. In the initial stages, the differences between the experimental

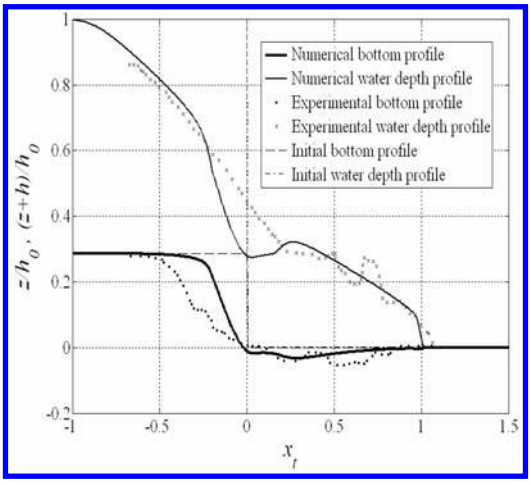

Figure 2. PVC test. Comparison between experimental and numerical results. $t = 0.75$ s.

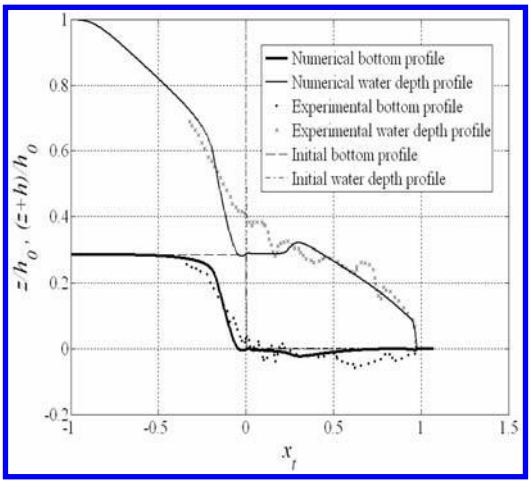

Figure 3. PVC test. Comparison between experimental and numerical results. $t = 1.51$ s.

and numerical water depth profiles are significant but they seem to diminish progressively over time. The re-deposition rate in the first reaches is not reproduced very well as shown in Figure 4; the IMPACT models came up against the same problem (Spinewine & Zech 2004).

The previous considerations are confirmed by the Figure 5 that shows a comparison between numerical and experimental envelopes of maximum water level and minimum bed levels. Despite the clear underestimation in the maximum scour in the early stages, the simulation provides a quite satisfactory result overall.

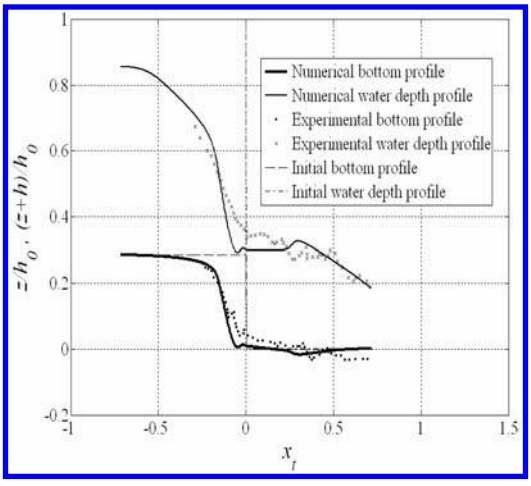

Figure 4. PVC test. Comparison between experimental and numerical results. $t = 2.26$ s.

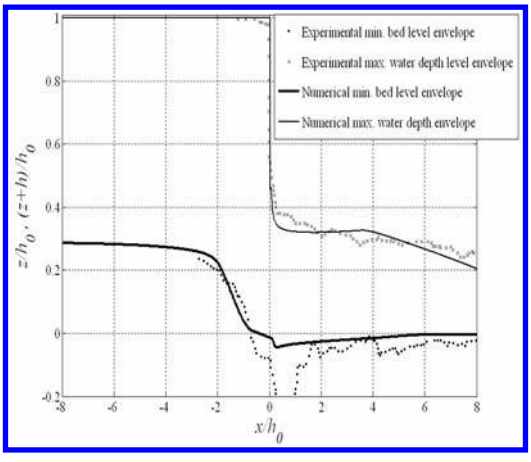

Figure 5. PVC test. Comparison between numerical and experimental envelopes of max. water depth and min. bed level.

4.2 *Sand test case*

Figures 6–9 show dimensionless experimental and numerical profiles for different instants of time. Good results are achieved in the sand case. The computed bed profile shows a good agreement with experimental data even if at the early stages of the process (Fig. 6) the bed scour is underestimated for $x_t > 0.2$. A tendency to slightly overestimate the erosion in the sections just before the initial bed discontinuity may be also noted in Figures 7–9.

Moreover the computed wave has a slower front celerity than the experimental one.

Figure 10 provides a comparison between numerical and experimental envelopes of maximum water

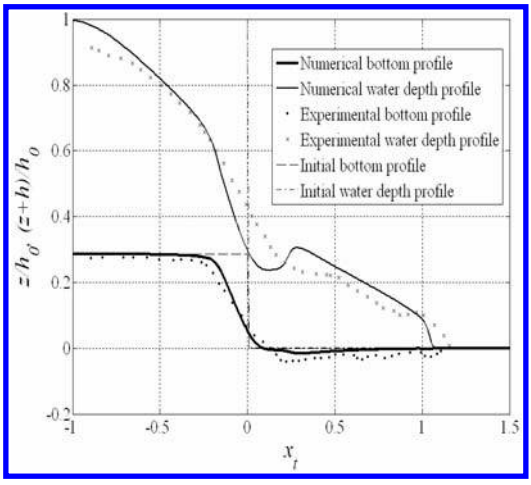

Figure 6. Sand test. Comparison between numerical and experimental results. $t = 0.57$ s.

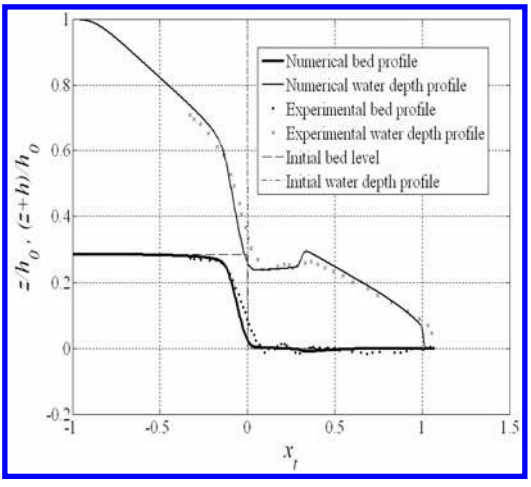

Figure 8. Sand test. Comparison between numerical and experimental results. $t = 1.51$ s.

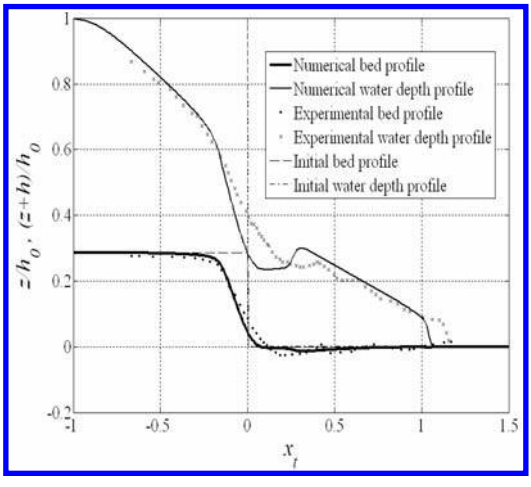

Figure 7. Sand test. Comparison between numerical and experimental results. $t = 0.75$ s.

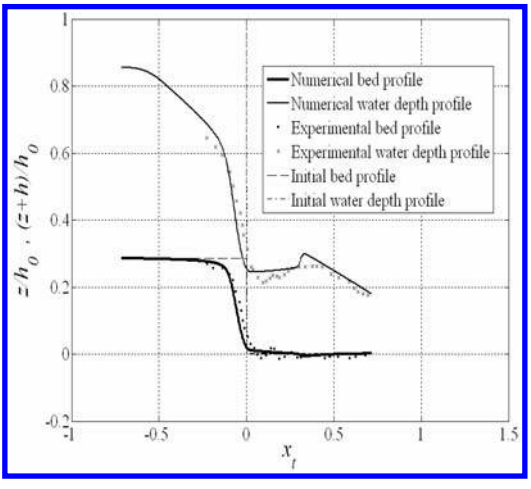

Figure 9. Sand test. Comparison between numerical and experimental results. $t = 2.26$ s.

level and minimum bed level. It confirms the previous considerations on simulated erosion and highlights a slight overestimation on water depth profile.

Nevertheless for the envelope of the minimum bed level the overall result is satisfactory when compared with the predictions of the IMPACT models shown in Spinewine & Zech (2004).

5 SENSITIVITY ANALYSIS

The model has one calibration parameter in the relationship of erosion/deposition velocity. The model sensitivity to above mentioned parameter was performed. In particular, two other values of parameter K_f were taken into account: $K_f = 5$ and $K_f = 20$ that is the half and the double of the reference value.

Figures 11–18 show a zoom near the location of the gate, in order to better analyze the differences among the various simulations.

In Figures 11–14 the sensitivity of the model to K_f for the sand test is shown. It is quite evident that there are no significant differences between the various simulations even at the early stage of the phenomenon; hence one may suggest that parameter K_f does not significantly affect the results for the sand test case in the range of values here examinated.

Copyright © 2006 Taylor & Francis Group plc, London, UK

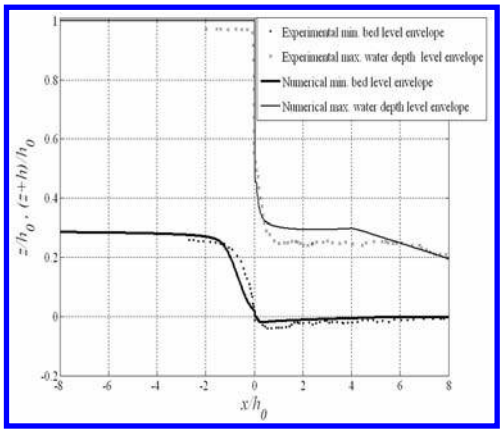

Figure 10. Sand test. Comparison between numerical and experimental envelopes of max. water depth and min. bed level.

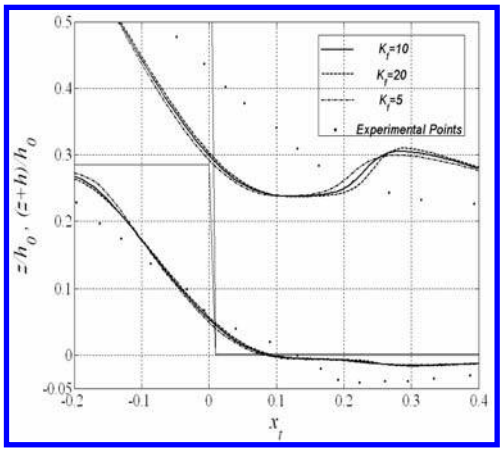

Figure 11. Sand test. Sensitivity to parameter K_f. $t = 0.57$ s.

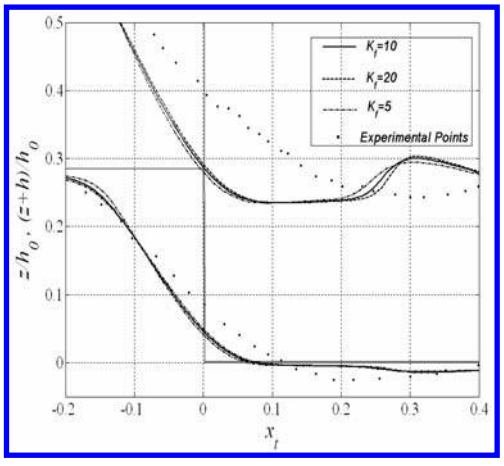

Figure 12. Sand test. Sensitivity to parameter K_f. $t = 0.75$ s.

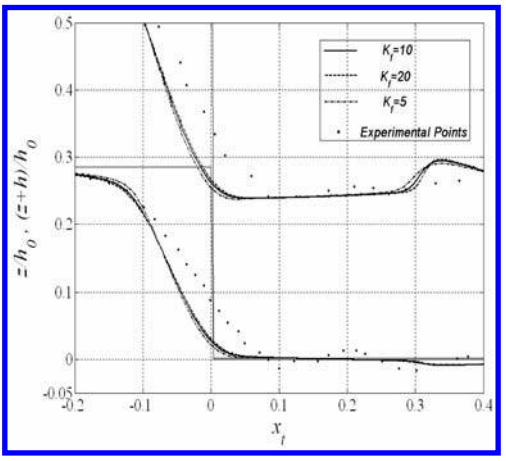

Figure 13. Sand test. Sensitivity to parameter K_f. $t = 1.51$ s.

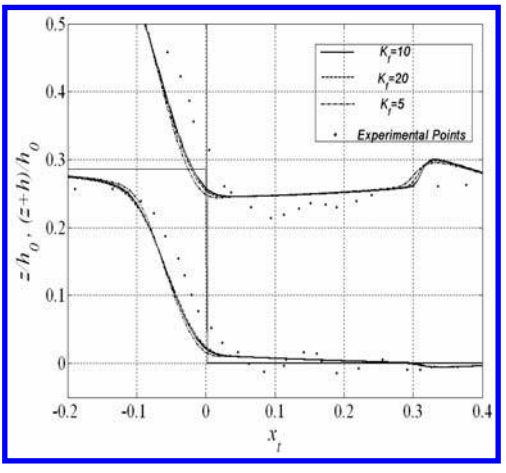

Figure 14. Sand test. Sensitivity to parameter K_f. $t = 2.26$ s.

Different conclusions can be drawn for the PVC test. As shown in Figures 15–18, the solution referring to $K_f = 5$ is different from the reference simulation ($K_f = 10$) while slight discrepancies appear for $K_f = 20$. So it seems that K_f slightly affects the simulation for the PVC test case. In particular, the effect of K_f is more evident in the range of values $0 > x_t > -0.1$ where the erosion/deposition rates are different (Figs. 17–18).

The sensibility analysis highlights that K_f has a little influence on the simulations despite both erosion and deposition rates are proportional to K_f.

Indeed it should be noted that in the early stages of phenomenon the greater K_f the greater both erosion/deposition velocity and local concentration. However in this situation the value of the equilibrium angle θ_e increases (eq. 12) and consequently

Copyright © 2006 Taylor & Francis Group plc, London, UK

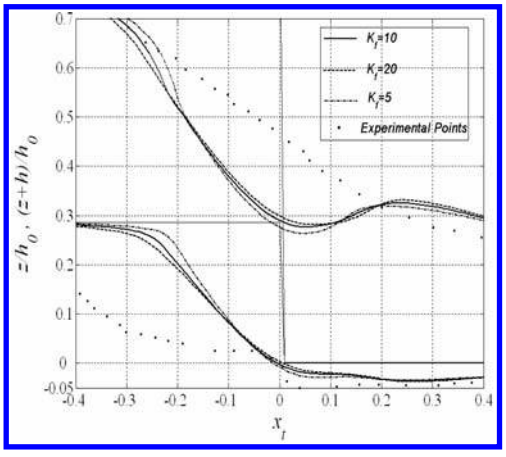

Figure 15. PVC test. Sensitivity to parameter K_f. $t = 0.57$ s.

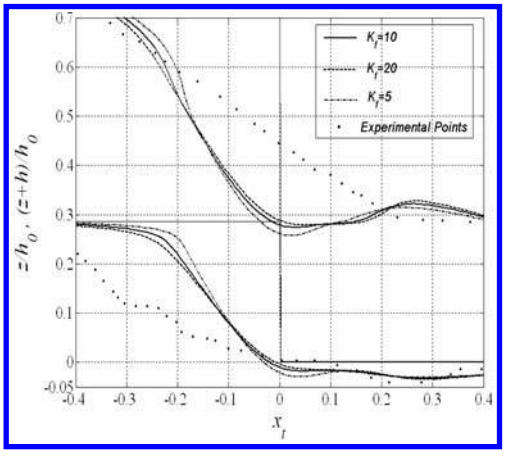

Figure 16. PVC test. Sensitivity to parameter K_f. $t = 0.75$ s.

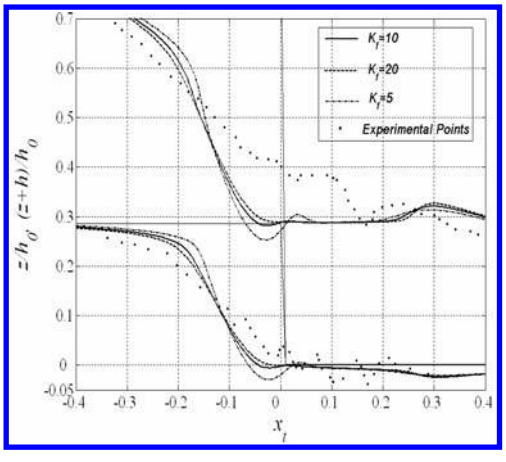

Figure 17. PVC test. Sensitivity to parameter K_f. $t = 1.51$ s.

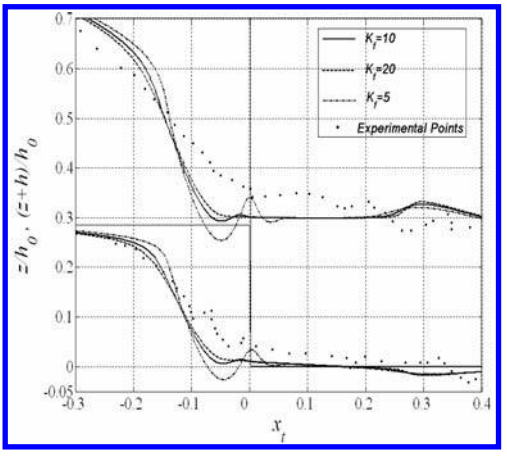

Figure 18. PVC test. Sensitivity to parameter K_f. $t = 2.26$ s.

$\tan(\theta_f - \theta_e)$ diminishes. So the greater K_f the smaller the value of $\tan(\theta_f - \theta_e)$; so this reduction moderates the effects of the increasing values of K_f on the erosion/deposition velocity.

6 CONCLUSIONS

This paper examined the suitability of a one layer model to the computation of dam break waves over movable sediment bed.

The model here presented is based on a shallow water approximation and considers a one layer conceptual idealization of the flow structure; the numerical integration of the governing equations is carried out by means of a first order finite volume method technique.

The simple approach used, both in conceptual and numerical aspects, allowed us to achieve fairly good predictions as regards water depth and bottom profiles. The overall result of the simplified model here presented, especially if compared with those achieved with more complex models within the IMPACT project, seems to highlight a good capability in predicting this phenomenon. In particular the bed evolution law here considered seems to perform well.

The model has just one calibration parameter K_f. A sensitivity analysis was performed to highlight the role of this parameter: it seems that K_f slightly affects the results.

Dike erosion – A preliminary outlook

Willi H. Hager & Jens Unger
VAW, ETH Zurich, Zurich, Switzerland

ABSTRACT: Dike breaching along larger rivers result yearly in a great loss of lives and goods. Although this 'classic problem' of hydraulics has threatened people from the old times, few actions have so far been taken by the hydraulics community. The following presents the results of a preliminary study and the future research to be considered by a Swiss National Science Foundation project aiming to understand the essentials of both plane and spatial dike breachings. It is found that this problem may be attacked only as a combined numerical *and* experimental approach, of which this work relates exclusively to the latter aspect. Some experimental findings are described and the results of selected preliminary test observations are discussed to allow for an appreciation of the technical problems involved in such a research project.

1 INTRODUCTION

According to the Thesaurus Dictionary, a *dike* is an embankment of earth and (or) rock built to prevent floods. Dikes are therefore typically used in river engineering. In contrast, a *dam* corresponds to a barrier across a waterway to control the flow or to raise the water level. Whereas the dike is normally made up of loosely placed sediment, a dam often consists of a surface layer and a dam core made up of different material such as clay, rock and possibly also concrete. Dams are normally much higher than dikes but are significantly shorter in length. To withstand the enormous water pressure of up to several hundreds of meters, dams require a much more involved technology than do dikes. Whereas dikes were erected from ancient times, successful dam engineering initiated only in the first decades of the 20th century. The following refers exclusively to dikes as a more or less homogeneous accumulation of natural sediments consisting of sand or gravel. The components silt and sand below 1 mm are not considered here because of their particular mechanical properties involving effects of viscosity, among others (Ivicsics 1979).

A *simple dike* corresponds to a trapezoidal-shaped accumulation of sand or gravel of which the up- and downstream angles are below the angle of natural repose, i.e. some 33° for natural sand. Besides the materials mentioned, no other material such that a core or a surface layer are added to the simple dike. The erosion process of the simple dike is therefore governed exclusively by surface sediment transport. Any surface strengthening such as grass may be considered as an added safety against dike failure by erosion. A simple dike is also resistant against internal erosion such that the failure mode under consideration may be formulated essentially in terms of sediment surface erosion and sediment deposition.

The erosion process of a simple dike may be either plane or spatial. The latter case normally occurs in applications, due to incipient erosion at a location where the dike crest is slightly lower than in the vicinity, resulting for instance from a local settlement of the dike structure. Spatial dike erosion includes the complicated lateral erosion process, of which the fundamentals are currently not completely understood. The following therefore relates mainly to plane dike erosion as a basic erosion process. Once this phenomenon is understood both from the experimental and the numerical points of view, spatial dike erosion is analyzed as a consequence from the processes observed in nature.

Figure 1 shows a historical photograph of a dike breaching having occurred close to the bridge abutment. Upstream from the breach, the dike has resisted against the flood discharge but it failed at this critical location, possibly because of a slight river contraction due to the abutment. The consequence of such a dike failure may be catastrophic because the backland from the dikes is often unprotected and the waters have no blockage and large plains may be inundated within a comparatively short time. Such scenarios have been and are still typical for large floodplains, causing an enormous financial loss and may be accompanied with fatalities. Hydraulics has so far not solved the problem and it is normally impossible to predict the limits of discharge, rainfall and the dike characteristics under which the next failure occurs. This

Figure 1. Flooding of Alpine Rhine Valley upstream of Lake Constance, with bridge failure caused by dike breaching and lateral flow onto flood plain (Minor & Hager 2005).

research project would like to add to this basic feature of dike hydraulics both by an experimental and a computational approach.

2 PRESENT KNOWLEDGE

The erosion of dikes was only considered once the basics of sediment transport were available, despite the damages that occurred with dike breaches for a long time. Therefore, the history of predictive dike hydraulics starts around 1960. An early work on the washout of erodible fuse plugs was conducted by Tinney & Hsu (1961). Using both a laboratory model and small prototype observations allowed defining some characteristics of the side erosion of a dam. Sandover (1969) determined experimentally the discharge coefficients of a dike made up by uniform incohesive sediment during dike erosion. Das (1973) investigated the end scour phenomena downstream of a dike due to dike overtopping without indication of the temporal scour progress. Martins (1981) analyzed the stability of overflow rockfill dams with a model study, thereby concentrating to its downstream face. Note that his dams included an impervious core separating the upstream from the downstream sections. Powledge et al. (1989 a, b) conducted a large study on the overflow erosion of embankments. Part I related to the various protection systems in preventing overflow erosion, whereas Part II accounted for hydraulic observations during dam overtopping and to a number of case stories. Despite this research applies to dams of limited width, it may be considered the most complete study until 1990.

Abt & Johnson (1991) determined the riprap dimensions required for overtopping flow of sloped surfaces. Their result is a diagram in which the riprap diameter is plotted against the unit discharge for various dam surface slopes. Bechteler & Broich (1991) aimed at the mathematical modelling of dike breaching. The sediment transport was described with the standard Meyer-Peter-Müller MPM and the Engelund-Hansen equations. The main purpose of their study was to define the dike outflow hydrograph, resulting in large differences between the computational approaches used. Coleman et al. (2002) considered the overtopping of homogeneous incohesive dikes in a laboratory flume. The breach advance profiles in both the streamwise and the transverse directions were observed using digital potentiometers. Each experiment was repeated several times and stopped at a certain instant to furnish the momentary breach geometry. This approach uses a significant laboratory effort, therefore, and may be applied only to a limited number of experiments. The results of this excellent study include some information on the breach advance geometry, the erosion rate and the breach discharge.

A further study was conducted by Rozov (2003) thereby assuming a rectangular breach geometry. A closed-form solution of the breach width as a function of time may be obtained with a simplified computational approach. Leopardi et al. (2003) presented a computational approach to dike breaching using the shallow-water equations, the Exner equation and the Meyer-Peter-Müller MPM equation for sediment transport. This model was applied to a typical case study resulting in a reasonable overall agreement. Höeg, et al. (2004) conducted a unique series of field experiments in Norway to study the stability of embankment dams constructed of various materials. Up to six meter high dams were investigated in terms of failure characteristics; so far, no final report is available. Cao et al. (2004) presented a computational model to the hydraulics of erodible dikes. Their model was stated to be one of the first so far available; it is based on sediment transport and the morphological evolution of the breach characteristics. The *Landesamt für Umweltschutz* (LfU 2004) proposed means to protect dikes from erosion during overtopping. Finally, an uncertainty analysis of the prediction of the embankment dam breach parameters was conducted by Wahl (2004), thereby involving historical data that may be important for testing novel laboratory observations and predictions using improved computational approaches. A general account on this topic was also presented by Singh (1996).

3 VAW OBSERVATIONS

Figure 2 shows a definition sketch of the experimental set-up for simulating the erosion pattern of a

Copyright © 2006 Taylor & Francis Group plc, London, UK

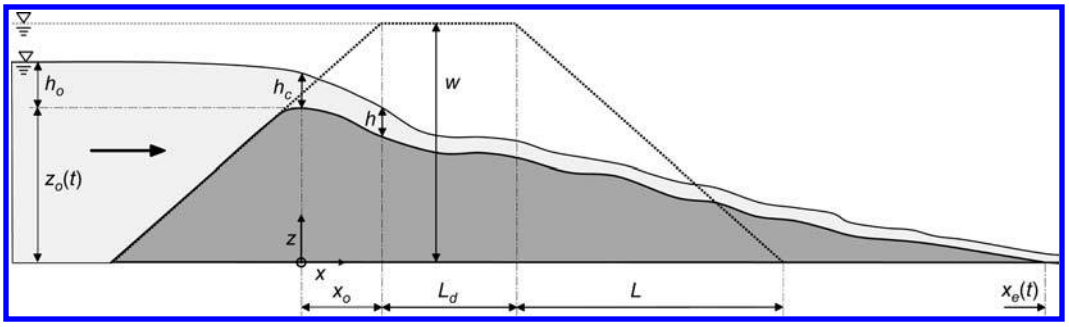

Figure 2. Sectional view of dike for plane erosion tests (Lüthi 2005).

simple dike as used at *Versuchsanstalt für Wasserbau, Hydrologie und Glaziologie* VAW, of ETH Zurich. Following a preliminary test phase, the erosion process of a dike was observed to be almost plane if both the dike width and the sediment size are small. A dike width of only $B = 0.10$ m was adopted for these preliminary tests, therefore. Depending on the sediment size, a meandering flow pattern resulted with only a portion of the dike width eroded for wider dikes consisting of larger sediment sizes. In all tests, a steady discharge scenario was considered.

The main parameters investigated in this project were:

- Critical flow depth $h_c = [Q^2/(gB^2)]^{1/3}$ as discharge load, between discharges $Q = 1$ to 10 l/s,
- Height of dike w, from 0.05 to 0.30 m,
- Slope of dike from 1:2 to 1:5, normally 1:3 both at the up- and downstream dike faces,
- Crest width of original dike $L_d = 0.10$ m, and
- Sediment median size $d_{50} = 1.15$, 2.3 and 5.0 mm for uniform sand, and a sand mixture.

Here h is the local flow depth, z the instantaneous height of dike from the origin and t is time. The origin of the coordinate system $(x;z)$ is located at the bed beneath the instantaneous upstream crest of the dike. The reservoir filling was relatively fast, typically within 1 minute. The dike core was initially dry such that the overflow process started prior to the phreatic surface had reached the dike toe. The approach flow velocity was usually so small that the upstream overflow depth h_u was equal to the overflow energy head. In all tests, no tailwater submergence was applied such that the overflow was free at all times. The deposition pattern was not further investigated in these tests. The data relating to the free surface water profiles were also recorded.

The temporal progress of both the water surface $h(x,t)$ *and* the sediment surface $z(x,t)$ was determined for a total of 40 tests with a CCD camera across the glass wall of the channel. This technique allowed for a simple determination of the two profiles from the test data. Both the free surface and the erosion profiles were further treated to allow for a general insight into the mechanics of plane dike erosion. The following relates to some particular results obtained during this research.

Figure 3 shows the temporal progress of a typical test. Initially, the constant discharge Q was added resulting in dike overtopping at time $t = 0$. Shortly later, at $t = 12$ s, the overflow front reaches the original dike bed elevation; it may be noted that the small overflow discharge at this time results in a step-pool formation down the dike face associated with a retreat of the hydraulic control towards the upstream crest point. At time $t = 7$ s almost half of the dike is eroded with a further retreat of the hydraulic control. A wavy pattern of the erosion surface may be observed without any transition to locally subcritical flow. At time $t = 160$ s, the dike is eroded almost completely leaving an undular erosion surface.

Figure 4 shows the results of two typical runs relative to the temporal progress of the sediment surface $z(x,t)$. Both figures show an important feature that was generally observed: The hydraulic control point separating the reaches of subcritical and supercritical flows moves along the original upstream dike surface. Because both the discharge and the sediment size were small in the tests of figure 4 (a) and large in figure 4 (b), an similar erosion pattern may be observed from the two plots.

It was also stated that the downstream eroded dike face remains almost linear at a certain time during the initial erosion phase, such that two particular points were considered: (1) The hydraulic control point $(x_o;z_o)$, where $x_o(t)$ is approximately known for a certain elevation $z_o(t)$ as previously observed, and (2) the dike end point $(x_e;0)$, where the straight from the hydraulic control point cuts the origin $z = 0$. A simplified analysis of the large data set was therefore conducted using a one-dimensional approach. This research allows to predict the two functions $z_o(t)$ and $x_e(t)$. The details of this analysis are not discussed here. The future application of

Copyright © 2006 Taylor & Francis Group plc, London, UK

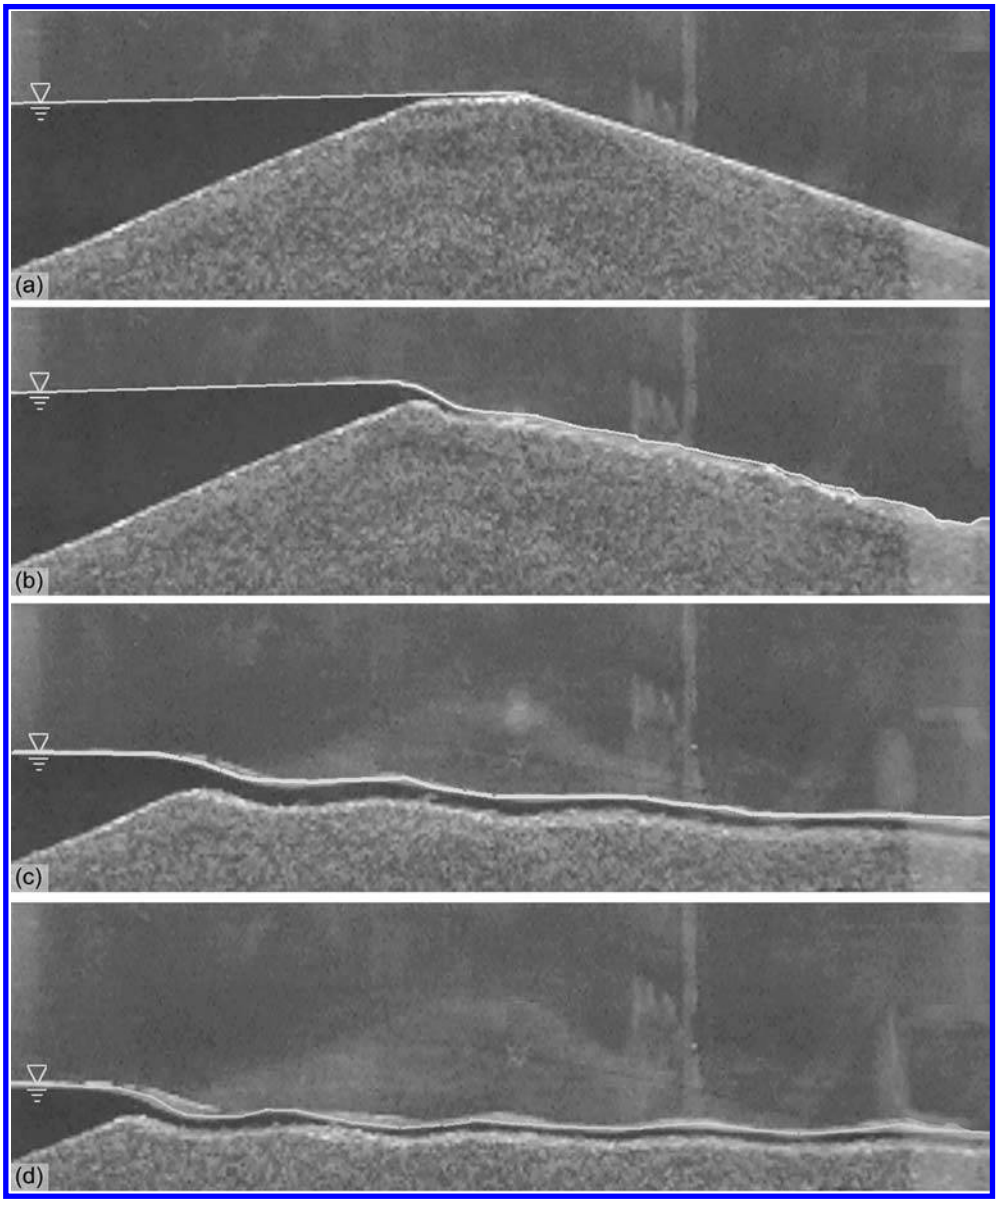

Figure 3. Temporal progress of dike erosion for slope 1:3, $w = 0.20$ m, $d_{50} = 5$ mm at times $t =$ (a) 0, (b) 12 s, (c) 70 s and (d) 160 s.

these results for the present project shall be described below.

4 OUTLOOK

The erosion of dikes modelled both experimentally *and* numerically poses extraordinary problems to both instrumentation and to computational performance. Three items must, therefore, receive a particular attention:

- Transition from subcritical to supercritical flow reaches, and vice versa,
- Changes from wetted to dry, and from dry to wetted surfaces, and
- Erosion and deposition both in the streamwise and in the transverse directions.

Copyright © 2006 Taylor & Francis Group plc, London, UK

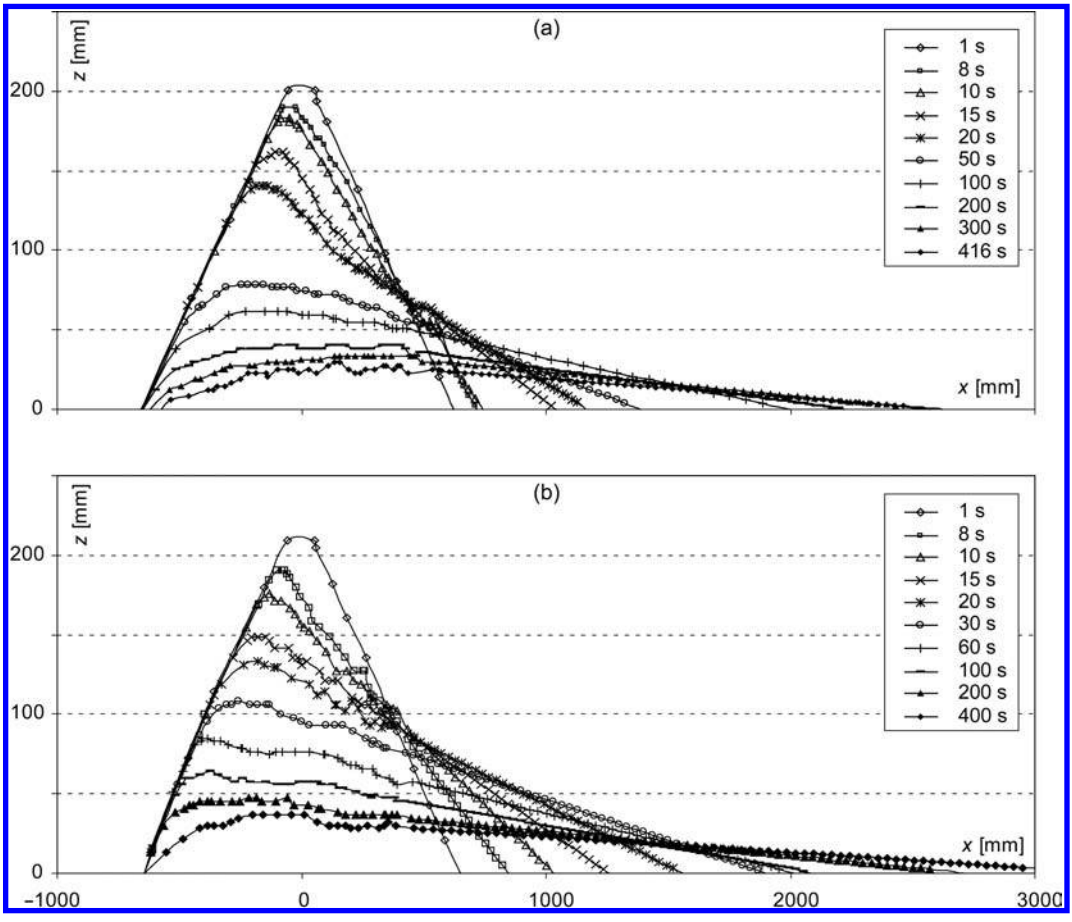

Figure 4. Streamwise erosion progress $z(x,t)$ for (a) $Q = 5$ l/s and $d_{50} = 1.1$ mm, (b) $Q = 11.5$ l/s and $d_{50} = 5.0$ mm (Lüthi 2005).

Item 1 is not only linked to the dike crest zone because of the step-pool pattern of the flow down a dike for a small flow depth and a relatively large sediment size. It was found in the preliminary experimentation that these flows develop particularly during the initial phase for dikes made up of large sediment (Lüthi 2005). Further, this problem also occurs on the downstream flood plain, where the supercritical dike overflow may undergo a change to subcritical flow along with undular or direct hydraulic jumps. Undular jumps are often complex because of local Froude numbers slightly above 1. Handling such flows may ask for the inclusion of the effect of streamline curvature, resulting in complex equations of the Boussinesq type for the free surface.

Item 2 relates to the phase boundaries between the water and the sediment. It applies therefore to the breach region, but also to larger deposition zones in the flood plain. The effect of surface tension is irrelevant in prototype dikes but may be important under laboratory conditions. So far, the existing VAW computational code is able to model these zones relatively well (Faeh 1996, 2000). The results will have to be checked with the hydraulic test data to assess the computational accuracy.

Item 3 is particularly complex because a novel type of sediment transport equation should be developed. The current transport formulae apply essentially for uniform flow conditions in an almost horizontal sediment bed. Dikes have a slope that is of the order 1:5 (V:H) and steeper, such that the slope effect may not be neglected. An even more complex problem involves the side erosion: Currently, no general models are available by which this effect can be accounted for in a thorough approach for incohesive sediment. This latter information is of course essential from the very beginning of a dike breaching because the breach geometry and therefore the breach discharge depend

Copyright © 2006 Taylor & Francis Group plc, London, UK

significantly on it. Model observations allow for a development of the current mathematical formulation, therefore.

It may be clear from the previous discussion that this research is directed to the hydrodynamics of dike breaching. The details of a dike are therefore simplified, resulting in the 'simple dike' model as previously introduced. It was mentioned that a dike made up of incohesive sediment corresponds to the simplest arrangement of which the safety against failure is the smallest for a certain scenario. This 'simple dike' structure retains the basics of the erosion and the deposition problems, relating both to the numerical and the experimental aspects.

5 SPATIAL DIKE BREACHING

Figure 5 shows the temporal advance of a spatial dike breaching, in which the main breaching features may be appreciated. Figure 5 (a) relates to the starting condition, with the upstream water elevation practically at the dike crest level. Note that the dike remained stable at its toe under a slight tailwater submersion. In prototypes, a dry flood plain may be more realistic, a condition that could also be considered in the tests. In Figure 5 (b) the central portion of the dike is overtopped resulting in a central breach geometry which is indicated in the photo with white lines. In the case considered, the dike sediment was relatively small such that there was a smooth overtopping in contrast to conditions involved with larger sediment and a smaller discharge. In Figure 5 (c), the dike is almost eroded to half of the original height: The side erosion progressing along the left dike side is a particular feature. In this test, the right dike side was completely eroded due to the slightly asymmetric dike crest geometry. In prototypes, side erosion is the important mechanism in predicting the temporal advance of the flood plain discharge, dike erosion rate and sediment deposition. The almost final erosion stage is seen from Figure 5 (d), with the remaining left dike abutment. Figure 5 (e) relates to a streamwise look from the glass wall. Note the 'white water' due to suspended silt, preventing any observation of the internal flow patterns because of invisibility.

Figure 6 relates to the end stage of the dike erosion test after the water was almost completely drained from the test section. It is noted from Figures 6 (a) and (b) that the right tailwater portion was eroded during the test, whereas the other side underwent a sediment deposition associated with an undular surface structure at the interface of the two reaches. Figure 6 (c) relates to the remnants of the 'abutment' showing an almost vertical dike flank. This part is complex in the computational approach and needs a particular attention.

6 SIGNIFICANCE OF PROJECT

When initiating the dike breaching project proposed as a general topic of risk mitigation and the assessment of natural hazards, the authors were shocked by the relatively small actions undertaken by the hydraulics community so far. As was evidenced in the state-of-the-art review, a modest amount of works is currently available: What are the reasons for this deficit in knowledge? The authors are of the opinion that the complexity of the overall problem is high, e.g. to investigate a spatial flow field in two-phase flow where erosion and deposition of the granular phase is a key issue. Nevertheless, based on the past achievements in the experimental and the computational analysis of sediment-water flows, this problem can be advanced essentially if adequate instrumentation is available.

The complexity of the dike breaching problem in prototypes stems from the relatively large surface involved allowing exclusively for a refined numerical treatment. However, because a number of processes are currently poorly understood, as previously outlined, additional laboratory observations on particular features are required for an adequate numerical simulation. These relate to the sediment erosion and deposition patterns, and to the side erosion of incohesive granulate. To further these processes from a scientific background, a combined experimental *and* numerical approach to the dike breaching problem is considered essential.

A key issue of the experimental approach is the recording of the flow fields due to a dike breaching. An adequate instrumentation involving e.g. stereo and underwater photography based on advanced videometry to retrace the main features of erosion, and Particle Tracking Velocimetry system to define the velocity fields at any time along the breach surface are required (Godding et al. 2003, Unger 2006). In the computational field, the findings from hydraulic experimentation will have to be implemented thereby advancing several subroutines regarding the sediment transport algorithms. Both the plane *and* a spatial breach development have to be considered because scenarios in the nature may include particularly the latter type of flow. Yet, to advance current knowledge, the simpler plane dike breach has to be understood before the more complex case is considered.

As demonstrated previously, there are currently a number of cases that may result in large damages due to dike overtopping. To predict their essence and to take measures in terms of evacuation and damage reduction, only numerical approaches allow for the proper planning of the major actions that have to be organized prior to an event. These include:

– Evacuation scenarios for the population and protection measures for the infrastructure concerned,

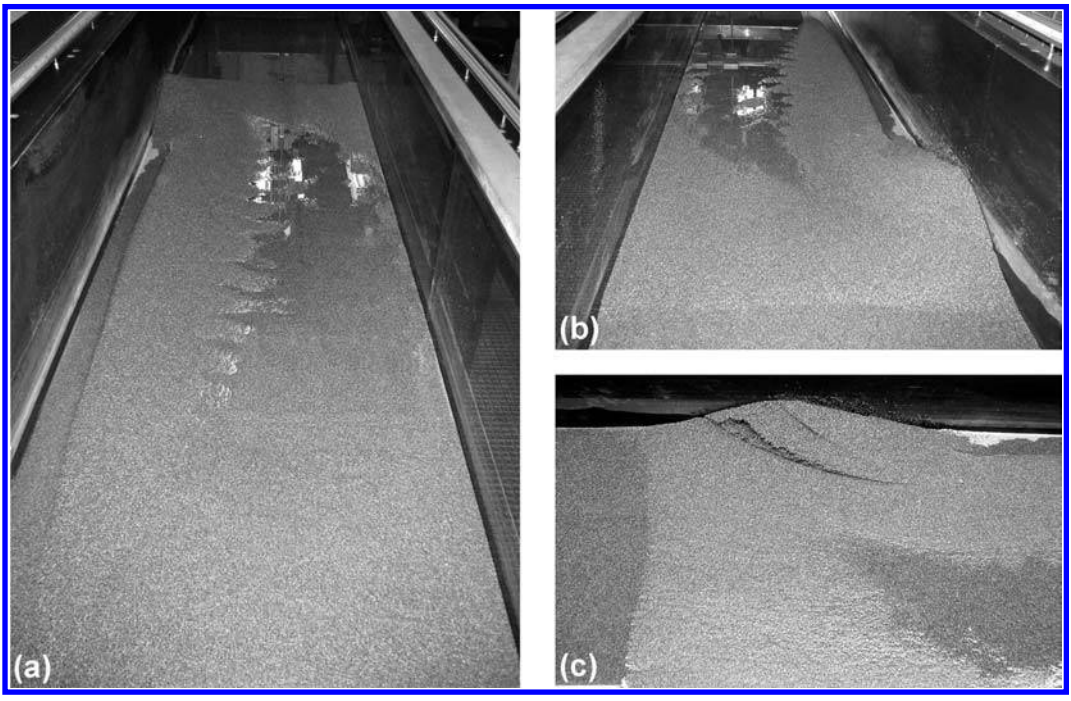

Figure 6. End stage of dike eroded by overtopping (a) from tailwater, (b) from upstream and (c) side view of lateral dike erosion.

– Safety structures to be erected directing the main flood discharge to less critical zones,
– Optimizing tasks to study actions to be undertaken before a dike is about to break, and
– Interactions of hydraulic engineers and the authorities as an important tool in the decision support.

The dike breaching project is considered a great chance to demonstrate the capabilities of modern hydraulic engineers in advancing an exiting hydraulic problem for the safety and the risk reduction from natural hazards.

7 CONCLUSIONS

Dikes are made up mainly of sediment placed along a river to protect the flood plains from inundations. To explore the hydraulics of the dike breaching process, the so-called 'simple dike' was introduced. This structure is made up by an almost homogeneous and practically straight dike subject to erosion exclusively due to overtopping. The experimentation proposed herein points to the definition of the relevant sediment transport equation, to the handling of flow transitions from sub- to supercritical flow, and vice versa, and to the understanding of the wetting and the drying fronts of the dike and the flood plain during the erosion process. These three key issues along with the temporal evolution of the water and the sediment surfaces, and the velocity field both on the dike surface and the tailwater were identified as the parameters of note that have to be known for further predictions. These include flooding maps and the design of flood mitigation structures to effectively protect a certain flood plain from large and unexpected inundations. The major actions to be taken in a future dike breaching project are presented and their relevance for the modern society is described.

Discontinuities in geomorphic dam-break flows

Rui M.L. Ferreira & Sílvia Amaral

ABSTRACT: Geomorphic dam-break flows have been shown to feature discontinuities other than the downstream progressing wavefront. Of particular importance is the jump that forms, for some combinations of initial conditions and bed materials, near the location of the dam. No attempts to characterize this jump were undertaken until recently. In this text, the discontinuities occurring in geomorphic dam-break flows are investigated in the framework of a shallow-flow theory. The main objective is to understand whether they are susceptible to be described by Riemann waves or if they are flow features aroused by momentum sources, namely friction, or by phenomena beyond the shallow-flow theory. For that purpose, experimental results are presented and compared with a theoretical solution of the governing equations given initial discontinuous data. The classification of the discontinuities follows the comparison between the observed and calculated flow features for the same initial conditions. No attempt is made to address the phenomenological aspects of the formation and evolution of the discontinuities. Nevertheless, the observed behavior is discussed in conjunction with the weak solution of the governing equations.

1 INTRODUCTION

Geomorphic dam-break flows arise from the rapid release of stored water into a mobile bed channel and provoke important morphological changes in the downstream valley. Such flows propagate in the form of a bore, a type of wavefront, often laden with sediment, which, given the involved length scales, can be considered a discontinuity. The speed of this discontinuity, along with the maximum water depth associated to the dam-break flow, have been studied at length, as they constitute important elements for downstream risk assessment (Zech et al. 2004).

The wavefront may not be the only discontinuity in geomorphic dam-break flows. A hydraulic jump occurring near the location of the dam was reported in the early mobile-bed experiments of Chen and Simons (1979). More recently, Capart and Young (1998) drew attention to an upstream-progressing jump seen to form at early times at the dam location. For some combinations of initial conditions and bed material, the experimental results of Leal et al. (2002) also exhibit discontinuities forming at the vicinity of the dam and traveling at much smaller velocities than the wavefront. The experiments performed in these works do not provide a coherent body of data, since the shape and the dimensions of the flumes are too distinct to make the results commensurable. On safe grounds, only one observational result can be uttered: on prismatic rectangular mobile-bed channels, geomorphic dam-break flows resulting from the instantaneous removal of a vertical dam exhibit, for some combinations of initial conditions and bed material, a jump that forms near the location of the dam at early times and whose velocity is slower than that of the wave-front. This discontinuity will be henceforth called a *2-jump*.

The characterization of the wavefront benefits from more than one hundred years of theoretical and experimental studies (for the review of early results, *cf.* Stoker 1958, pp. 22–22). Quite on the contrary, the amount of empirical results concerning the 2-jump is virtually limited to the works cited in the preceding paragraph and the theoretical results are almost inexistent (see Ferreira 2005, pp. 303–305, for a review).

In this text, the discontinuities occurring in geomorphic dam-break flows are investigated. Special emphasis is placed on the quantification of the variables that

Copyright © 2006 Taylor & Francis Group plc, London, UK

describe the 2-jump. It should be made clear that the thorough phenomenological characterization of these discontinuities will not be attempted. The main objective is to understand whether they are susceptible to be described by Riemann waves of the weak solution of the homogeneous part of the governing shallow-water equations or if they are flow features whose mathematical description requires a different formal treatment.

Empirical evidence, the experimental results described in Amaral (2004), §5, and Spinewine (2005) is compared with the solution of the governing equations, as presented by Ferreira (2005), pp. 396–430. The classification of the discontinuities follows the comparison between observed and calculated flow features for the same initial conditions. If the solution of the homogeneous shallow-water equations does not seem to describe occurring flow discontinuities, it is concluded that phenomena not included in the inertial and flux terms of the governing one-dimensional equations is responsible for the 2-jump.

The above methodology requires previous acquaintance with the conceptual model for the description of the geomorphic dam-break flows. It also requires some knowledge on the weak solution of the shallowwater equations given the dam-break Riemann problem. Both are addressed in the second section of the text. The third section is dedicated to the presentation of the experimental procedures and results. A comparison between the observed flow profiles and theoretical solution is carried out in the fourth section. The nature of the discontinuities is discussed in the fifth section. Finally, the text is ended by a number of concluding remarks.

2 CONCEPTUAL MODEL AND THEORETICAL SOLUTION

Written in vector notation, the first order, nonhomogeneous, hyperbolic system of conservation laws that describe geomorphic dam-break flows is

$$\partial_t (\mathbf{V}(\mathbf{U})) + \partial_x (\mathbf{F}(\mathbf{U})) = \mathbf{G}(\mathbf{U}) \tag{1}$$

where $\mathbf{V}$: $\mathbb{R} \times]0, +\infty[\rightarrow \mathbb{R}^3$ is the vector of dependent primitive variables, $\mathbf{U}$: $\mathbb{R}^3 \rightarrow \mathbb{R}^3$ is the vector of conservative variables, $\mathbf{F}$: $\mathbb{R}^3 \rightarrow \mathbb{R}^3$ is the flux vector, $\mathbf{G}$: $\mathbb{R}^3 \rightarrow \mathbb{R}^3$ is the vector of the source terms and x and t are the space and time co-ordinates, respectively.

Should the collapse of a dam be idealized as an instantaneous removal of a vertical barrier initially separating two constant states that extend indefinitely on both up- and downstream directions, as seen in figure 1, the mathematical expression of the dambreak problem is a Riemann problem. The conceptual model employed in this study to describe geomorphic dambreak flows is that developed by Ferreira 2005, §3. It

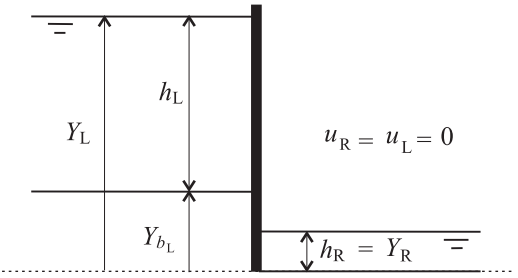

Figure 1. Initial conditions of the dam-break problem. The involved variables are: Y, the water elevation, h the water depth, Y_b the bed elevation and u, the depth-averaged flow velocity. The subscripts L and R stand for the initial left and right states, respectively.

features unsteady flow hydro- and sediment dynamics and channel morphology. In what concerns sediment dynamics, the dense limit approximation of the granular flow theory, rooted in Enskog's kinetic theory of dense gases (Chapman and Cowling 1970, §16), provided the theoretical background for the core of the model.

The one-dimensional conceptual model results from the integration of two-dimensional governing equations in an idealized layered domain. Multiple-layer shallow-water models were introduced by Capart (2000) and further developed by Fraccarollo and Capart (2002) and Spinewine (2005). Ferreira et al. (2003) followed a different approach. They considered that the total shear and normal stresses are continuous across the flow depth and into the bed and that the layers are mathematical idealizations based on the predominant type of stress.

Thus, the conceptual model employed in this study features i) a lowermost layer, the bed, composed of grains with no appreciable vertical or horizontal mean motion, ii) the contact load layer, where collisional stresses are dominant and iii) the suspended sediment layer, where turbulent stresses dominate (details in Ferreira 2005, pp. 229–231).

There is no result guarantying the existence and unicity of the solution to the Cauchy problem represented by governing equations of the conceptual model and any complete set of initial conditions. Furthermore, the theoretical attempts to prove the existence of the a weak solution for the Riemann problem fail because of the source terms, namely friction and non-equilibrium sediment transport. Fraccarollo and Capart (2002) attempted to show that there is a time window where the effects of flow friction are negligible and were local equilibrium is a valid hypothesis for the sediment transport. Although the results of Fraccarollo and Capart (2002) are strictly valid for erosional flows and for a particular conception of a frictional time scale, it will be assumed that

Copyright © 2006 Taylor & Francis Group plc, London, UK

there is indeed a time window for which geomorphic dam-break flows feature equilibrium sediment transport and are marginally affected by the bed shear stress. The conservation equations become homogeneous and are susceptible to be written in the following quasi-conservative form

$$\partial_t (h + Y_b) + \partial_x (hu) = 0 \tag{2}$$

$$\partial_t (a_m hu) + \partial_x \left(a_c u_c^2 h_c + u_s^2 h_s + g\left(\tfrac{1}{2}h_s^2 + \tfrac{1}{2}a_c h_c^2 + h_s h_c\right)\right) + g(a_c h_c + h_s)\,\partial_x (Y_b) = 0 \tag{3}$$

$$\partial_t ((1-p)Y_b + C_c h_c) + \partial_x (Chu) = 0 \tag{4}$$

where h is the water depth, u is the depth averaged flow velocity, Y_b is the bed elevation, h_c, u_c and C_c are, respectively, the thickness, the depthaveraged velocity and the flux-averaged concentration of the contact load layer, h_s and u_s are, respectively, the thickness and the depth-averaged velocity of the suspended sediment layer, $a_m = 1 + (s-1)C$, $a_c = 1 + (s-1)C_c$, s is the specific gravity of the sediments, C is the flow-averaged sediment concentration and g is the acceleration of gravity. The concentration C_s was eliminated since its value is generally much lower than C_c.

Equations (2) to (4) can be solved for the total flow depth, h, the layer-averaged flow velocity, u, and the bed elevation, Y_b. Closure equations for C_c and h_c are derived from the dynamics of the contact load layer (details *in* Ferreira 2005, pp. 277–289). They read

$$C_c = \frac{\theta d_s}{tan(\varphi_b) h_c} \tag{5}$$

$$h_c = m_1 \theta + m_2 \tag{6}$$

The variables and parameters in equations (5) and (6) are θ, the Shields parameter, defined as $\theta = C_f u^2/(g(s-1)d_s)$, d_s the particle diameter, $tan(\varphi_b)$, the ratio of shear to normal stresses near the bed and m_1 and m_2, parameters that should depend on the mechanical properties of the sediment particles, on its diameter and density and on the viscosity of the fluid. Ferreira (2005), pp. 283–285, hypothesized that, for a given fluid, m_1 and m_2 may show little variation with the particle properties and can be considered constants. In this work, it is considered that $m_1 = 6.5$ and $m_2 = 1.5$. The depth-averaged velocity in the contact layer is obtained assuming that $u(y)/u_* \propto (y/h_c)^{\frac{1}{6}}$ where $u_*^2 = C_f u^2$ is the friction velocity. Depth-averaging over the layer thickness, it is obtained

$$u_c = u\left(\frac{h_c}{h}\right)^{\frac{1}{6}} \tag{7}$$

Although equations (2) to (4) express the conservation of fundamental flow quantities and despite being homogeneous equations, Glimm's theorem Glimm (1965) for the existence and unicity of weak solutions of the Riemann problem can not be directly applied. This is so because equations (2) to (4) cannot be written in pure conservative form. Indeed, term $g(a_c h_c + h_s)\partial_x(Y_b)$ represents a source of momentum and is not reducible to a conservative flux.

Ferreira (2005), pp. 361–363, using Glimm's theorem, attempted to prove the existence of weak solutions for the Riemann problem

$$\partial_t (\mathbf{V}(\mathbf{U})) + \partial_x (\mathbf{F}(\mathbf{U})) + \mathsf{A}\partial_x (\mathbf{V}(\mathbf{U})) = \mathbf{G}(\mathbf{U}) \tag{8}$$

$$\mathbf{U}_0 \equiv \mathbf{U}(x, t=0) = \begin{cases} \mathbf{U}_\mathrm{L} & \text{if } x < 0 \\ \mathbf{U}_\mathrm{R} & \text{if } x \geq 0 \end{cases} \tag{9}$$

where equation (8) condenses equations (2) to (4) and where A is a matrix such that $\mathsf{A}_{23} = g(a_c h_c + h_s)$ and $\mathsf{A}_{ij} = 0, (i,j) \neq (2,3)$. Weak solutions were shown to exist but they are not unique. In fact, existence can only be asserted if A is linearized across discontinuities. Thus, the solution depends on the specific linearization carried out. The Rankine-Hugoniot jump conditions derived from the integral form of equation (8) become

$$(\mathbf{U}_\mathrm{d} - \mathbf{U}_\mathrm{u})\, S_j = (\mathbf{F}_\mathrm{d} - \mathbf{F}_\mathrm{u}) + \mathsf{A}^* (\mathbf{U}_\mathrm{d} - \mathbf{U}_\mathrm{u}) \tag{10}$$

where S_j is the velocity of the shock associated to the $\lambda^{(j)}$-characteristic field, A^* is the linearized matrix A and d and the subscripts u stand for "downstream" and "upstream", respectively. A consistent linearization can be obtained by averaging the terms across the discontinuity.

Ferreira (2005), pp. 363–366, showed that the weak solution of system (8) subjected to (9), in which $\mathbf{U}_0$ expresses the geometry seen in Figure 1, admits two types of self-similar solutions, depending on the values of h_L, Y_{b_L} and h_R. If the eigenvalues associated to the eigenvectors of system (8) are such that $\lambda^{(1)} > \lambda^{(2)} > \lambda^{(3)}$, the solution of type A comprises one expansion wave associated to the $\lambda^{(3)}$-characteristic field initial and two shock waves, associated to the $\lambda^{(2)}$- and the $\lambda^{(1)}$-characteristic fields. The wave structure of each of these solutions, represented in the x–t plane, can be seen in Figure 2. The corresponding flow profiles are shown in Figure 3. Solution of type B, first studied by Fraccarollo and Capart (2002) in the wake of Fraccarollo and Armanini (1999), does not admit 2-jumps. On the contrary, in the solution of type A, the shock associated to $\lambda^{(2)}$ is a flow feature that may be associated to the 2-jump.

It is noted that the $\lambda^{(2)}$-shock features a negative jump in the flow depth and a positive, aggradational, jump in the bed elevation. The direction of propagation and the type of morphological impacts featured by the observed jump provide the fundamental criteria to decide whether it is a flow structure describable by a

Left: solution of type A; right: solution of type B. The flow regions are: w – clear water/suspended sediment layer; c – contact load layer and b – bed.

Riemann shock or one that requires different conceptualization. Thus, 2-jumps that migrate upstream and that are associated to scour in the bed are clearly not described by the flow and sediment dynamics included in equations (2) to (4).

3 EXPERIMENTAL PROCEDURES AND RESULTS

The experimental work took place in the laboratory of hydraulics of the Department of Civil and Environmental Engineering of the Université catholique de Louvain, Louvain-la-Neuve, Belgium. The experimental tests were performed in 6 m long and 25.1 cm wide horizontal channel. The dam was simulated by a vertical gate, placed at 3 m from the extremities, whose movement is directed downwards (Spinewine 2005, p. 56). A manually activated trigger releases the pressure of 7 bar, generated in a compressor, required to open the gate at a speed of about 5 m s^{-1}. The maximum non-dimensional time necessary to open the gate is $t_0^* = t_0\sqrt{\frac{9.8}{max(h_L)}} = 0.4$ where to is the maximum time necessary to open the gate and $max(h_L)$ is the maximum initial water depth behind the gate.

The experimental texts were recorded in digital video by a CCD camera acquiring 200 fps with the resolution of 512 × 1024. The flow was fully recorded in the downstream reach of the channel. Upstream the gate, only the first 0.8 m were recorded. Since the recording area is about 0.8 m wide per 0.5 m height, each test had to be repeated five times. In order to synchronise the runs, a TTL flash light visible by the camera in each of its positions is triggered by the gate release. It should be mentioned that the repeatability of the tests was found to be highly satisfactory provided that the sameness of the initial conditions was ensured with some zeal. A mote detailed description of the experimental set-up and of the tests, along with additional tests performed for other initial conditions and bed material, may be found in Spinewine (2005).

The sediment particles used in scale laboratory models seldom abide to the global geometric scale. As a result, the mobility of the sediment is generally underestimated. In order to increase sediment mobility, the tests were performed with PVC pellets with $s = 1.56\,\mathrm{kg\,m^{-3}}$. The equivalent diameter of a PVC particle – the diameter of a sphere with the same volume – is 3.9 mm. The dimensions of the particles exhibited little variability.

All tests featured a piecewise horizontal bed. In accordance with figure 1, the datum was set to the level of the downstream bed. It is important to note that the downstream bed was saturated in all tests, even if $h_R = 0$.

The fundamental non-dimensional parameters that describe the initial conditions illustrated in figure 1 must take into account the flow depth downstream the dam and the jump in the bed elevation across the dam. The particular choice of parameters employed in this text are

$$\alpha \equiv \frac{h_R + |min\,(0, Y_{b_L})|}{h_L + max\,(0, Y_{b_L})} \tag{11}$$

and

$$\delta \equiv \frac{Y_{b_L}}{h_L + max\,(0, Y_{b_L})} \tag{12}$$

The length scale implicit in (11) and (12) is

$$L_* = h_L + max\,(0, Y_{b_L})$$

From this length scale, time and velocity scales can be derived. It is obtained $T_* = \sqrt{\frac{L_*}{g}}$ and $U_* = \sqrt{gL_*}$, respectively.

The initial conditions for the nine experimental tests shown here, described with the variables presented in figure 1, are shown in Table 1.

The raw data obtained from the tests is composed of video footages taken in the five locations along the channel. This data was treated to render flow profiles (details in Amaral 2004). In this profiles three surfaces were identified: a) the free surface, b) the boundary between the transport layer and the clear water layer

and c) the boundary between the bed and the transport layer. The profile of the water depth was computed as the difference between the the free surface and the bed. From the water depth profiles, it was possible to estimate the location and the strength of the observed discontinuities at each instant.

4 COMPARISON BETWEEN EXPERIMENTAL AND THEORETICAL RESULTS

The observed flow profiles are shown in figure 4 – solution of type B – and 5 – solution of type A. The theoretical profiles, calculated from the weak solution of system (8) given the initial conditions discriminated in table 1, are also shown in these figures, superimposed to the flow profiles.

The values of the friction coefficient employed in the closure equations (5) and (6) are shown in Table 2. They were chosen so to achieve best agreement between the experimental and the theoretical profiles. Sediment concentrations are controlled by the value of $tan(\varphi_b)$. Lacking universally acknowledged estimates for this parameter, it was imposed $tan(\varphi_b) = 0.45$, a value chosen so that the maximum concentration in the contact load layer would be around 0.3 in all tests whose solution is of type B.

Both the experimental profiles and the theoretical solutions are shown in self-similar co-ordinates. It is observed that the thickness of the contact load layer and the minimum bed elevation are correctly estimated in almost all tests. Naturally, phenomena pertaining to soil mechanics, namely slope stability and *en masse* bed movement, could not have been reproduced by the theoretical solution since the governing equations do not incorporate formulations for those phenomena. Hence, the the steep slopes featured by the weak solutions at the end of the expansion wave associated to the $\lambda^{(3)}$– characteristic field in figures 4e, f and g are in clear contrast with the much gentler slopes featured by the observed profiles. This gentle slope was essentially formed at the beginning of the times when the gate was lowered: the sharp bed step could not be maintained by the cohesionless bed material; a fracture surface was formed at the toe of the step with the inclination of the rest angle of the particles; finally the sediment above this fracture surface entered the contact load layer and was eventually deposited further downstream. A simple mechanism accounting for this mass failure was proposed and tested by Spinewine and Zech (2005).

In the tests with a negative bed step (4a and b) the theoretical solution captures the bed profile reasonably well. It is observed that a steep positive slope results from the initial discontinuity. Presumably, it is the flow that provides the extra shear force tomaintain the bed slope larger than the submerged rest slope.

The instability of the initial bed step in the experimental texts shown in figure 5 obeyed same same mechanisms already explained for the tests depicted in figures 4e, f and g. However, because of the presence of a layer of water downstream, the transport capacity is much lower and the flow does not evolve into a debris-flow-like wave front. Hence, the bed material resulting from the initial bed step failure is deposited almost instantaneously at the toe of the step and, as the flow looses memory of the gatemovement, becomes a bed discontinuity progressing downstream along with the jump in water surface. As a result, the bed profile calculated along the expansion wave associated to the $\lambda^{(3)}$-characteristic field is, in these tests, a better description of the observed profile.

The effect of flow resistance is perceived in the observed profiles inasmuch they are not truly selfsimilar. This is particularly true for the flows depicted in figures 4. Furthermore, it is noticed that Froude similarity does not completely determine the flow profiles. If that was the case, parameters α and δ would suffice to determine the profiles. Instead, it is observed in figures 4c and d, whose profiles are both characterized by $\alpha = 0$ and $\delta = 0$, that neither the velocity of the wave front nor the overall shape of the profile is the same for both flows. Ferreira et al. (2006) propose that the shape of the self-similar profile of any flow variable U_i can, under certain simplifying conditions, be determined by

$$\Gamma_i = \Pi_i \left(\alpha, \delta, s, tan(\varphi_b), \frac{d_s}{L_*} \right) \tag{13}$$

In the present case, s and $tan(\varphi_b)$ are constants. Thus, the relative submersion of the particles, d_s/L_*, must be accounted for the differences in the observed profiles. The only way to introduce this effect in the theoretical solution is by varying the friction coefficient. This justifies the values of C_f seen in table 2.

Evidently, all flows exhibit a discontinuous wave front. As for the 2-jumps, their existence and the variables that characterize them were determined in accordance to the principles explained in section 3. It is clear that tests 25_-05_00, 35_-05_00 and 35_00_00

(figure 4a, b and d) develop 2-jumps that progress upstream. Tests 25_05_05 and 35_10_10 (figures 5a and b) develop 2-jumps that move downstream. The properties of these discontinuities will be discussed in the next section.

5 DISCUSSION

In both solutions, the shock associated to the $\lambda^{(1)}$-characteristic field is physically identifiable with the wave-front (see figures 4 and 5). On the contrary, the 2-jump may not always be identifiable by the shock associated to the $\lambda^{(2)}$-characteristic field in the solution of type A. Indeed, it is clear from figures 2 (left) and 5 that this is a downstream progressing shock, while the observed 2-jumps often migrate upstream.

The dynamics and the kinematics of the wave-front are sufficiently well described by the Rankine-Hugoniot jump conditions, equations (10) with $j = 1$. Indeed, the strength of the wavefront, defined as $h_R - h_1$, remains approximately constant throughout the duration of the experimental test (see figure **??**) which enables a meaningful comparison between the weak solutions and the experimental profiles.

The velocity of the wavefront, however, decreases over time, as seen in figure 6, especially for the tests for which $h_R = 0$ (figures 6a to f). This fact prompted Leal et al. (2006) to describe the path of the wavefront in the x_t plane as a 2nd order equation. There is no appreciable decrease in the velocity of the wavefront in the experiments for which $h_R > 0$. This suggests that bottom friction is the main responsible for the delay of the wavefront.

Since bottom friction is not included in the weak solution of 8, in order to delay the velocity of the wavefront in the theoretical solution it is necessary to increase the factors that affect S_1 in 10. Such factors are related to the inertia of the contact load layer and are expressed by its thickness and the sediment concentration. Given that $tan(\varphi_b)$, m_1 and m_2 are constants, a good agreement of the observed and the calculated wavefront velocity requires a good estimate for the friction coefficient C_f.

The influence of d_s/L_* can only be addressed in the theoretical solution with adjustments of the friction factor. Thus, the correct modeling of the velocity of the wavefronts of tests 25_00_00 ($d_s/L_* = 0.0180$) and 35_00_00 ($d_s/L_* = 0.0129$), both characterized by $\alpha = 0$ and $\delta = 0$ can only be attained if the friction factor relative to 25_00_00 is increased. Indeed, as seen in figure 6c, the non-dimensional velocity of the wavefront of the test characterized by $d_s/L_* = 0.0180$ is smaller than that of the test for which $d_s/L_* = 0.0129$. As expected, the friction coefficient is larger for the flow with the smaller relative submersion.

An undesirable consequence of the increase of C_f is the increase of the flow depth in the first constant state (the state upstream the $\lambda^{(2)}$-shock). As seen in figure 7, the theoretical shock strength is consistently overestimated, for the same initial conditions.

Fraccarollo and Capart (2002) noticed that the wavefront propagates as an erosional shock. Since it is associated to the $\lambda^{(1)}$-characteristic field, it is fundamentally a hydrodynamically-driven shock: the bed jump is comparatively small. On the contrary, Ferreira 2005, §5.2.2, showed that the $\lambda^{(2)}$-shock is always an aggradational shock in which morphodynamics is of

Calculated and measured non-dimensional shock paths. a) $\alpha = 0.167$, $\delta = -0.167$; b) $\alpha = 0.125$, $\delta = -0.125$; c) $\alpha = 0.0$, $\delta = 0.0$ (features tests with $d_s/L_* = 0.0129$ and $d_s/L_* = 0.0180$); d) $\alpha = 0.0$, $\delta = 0.143$; e) $\alpha = 0.0$, $\delta = 0.200$; f) $\alpha = 0.0$, $\delta = 0.286$; g) $\alpha = 0.200$, $\delta = 0.200$; h) $\alpha = 0.286$, $\delta = 0.286$. Solid lines (——) stand for the calculated path of the $\lambda^{(1)}$-and the $\lambda^{(2)}$-shocks; open circles (○) stand for the measured path of wavefront; solid circles (●) stand for the measured path of the 2-jump. In figure c), the convention is maintained for the test with $d_s/L_* = 0.0129$; for the test with $d_s/L_* = 0.0180$, the dashed line (- - - -) stands for the calculated path of the $\lambda^{(1)}$-shock and the open squares (□) stand for the measured path of the wavefront.

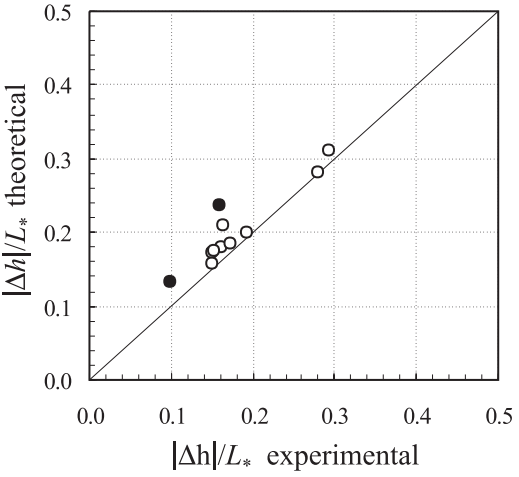

Figure 7. Calculated and measured non-dimensional shock strengths in terms of flow depths. Open circles (○) stand for the wavefront; solid circles (●) stand for the 2-jump.

paramount importance. Since the influence of the variables that describe sediment dynamics is strong in the $\lambda^{(2)}$-characteristic field, the dynamics of the associated shock are fundamentally determined by the solid phase: the $\lambda^{(2)}$-shock progresses with the velocity of propagation of the jump in the bed, much slower than the wavefront.

The experimental work revealed that only the tests depicted in figure 5 featured 2-jumps susceptible to be identified with the $\lambda^{(2)}$-shock. These downstream-progressing discontinuities are driven by the dunelike advancement of a sharp-edged bed wave. The strong coupling between hydrodynamic and morphodynamic variables in the $\lambda^{(2)}$-characteristic field is revealed by the fact that the strength of the shock is of the same magnitude in both types of variables.

Because of the correct coupling between hydrodynamic and morphodynamic variables, the results of the weak solution are a good reproduction of the observed behavior, especially in what concerns the shock velocity (see 6g and h). The shock strength is less well reproduced. As seen in figure 7, the shock strength is overestimated by the theoretical solution. This is mainly due to the fact that the weak solution overestimates the bed elevation in the 2nd constant state.

It is proposed that 2-jumps that occur in geomorphic dam-break flows whose mathematical description is a weak solution of type A are well described by the $\lambda^{(2)}$-shock. Its dynamics traduce the equilibrium of the flux and inertial terms across the shock, being the gravity-related term included in the flux terms, once linearized in accordance with equation 10.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Other types of 2-jump were found in the experimental tests whose profiles are depicted in figures 4. The mathematical description of these tests is a weak solution of type B. Ferreira et al. (2006) determined the locus, in the α–δ plane, of the boundary between solutions of types A and B. When $\alpha = 0$ the solution is necessarily of type B. If $\alpha > 0$ and $\delta < 0$, the solution is also of type B. It follows from the fact that type B solutions exhibit a continuous wave associated to the $\lambda^{(2)}$-characteristic field, that any 2-jump developing from such initial conditions can not be described by the jump conditions (10).

Alcrudo and Benkhaldoun (2001) developed a theoretical solution for the dam-break flow over fixed bed with a discontinuity in the dam location. Their solution features an extra discontinuity, a jump born in the source term that describes the force of gravity. Such discontinuity is impossible in mobile bed problems, as the derivative of the bed elevation, $\partial_x(Y_b)$, ceases to be treated as a source. Thus, the origin of these 2-jumps must be searched in interaction between the bed and the flow in the first instants.

It is observed that these 2-jumps are associated with important scour at the vicinity of the dam. Capart and Young (1998), working with almost neutrally buoyant particles ($s = 1.05$), observed a 2-jump with these properties and whose upstream velocity is comparable to those shown in figures 6a, b and d. They proposed that bottom friction could be a cause of the jump, by slowing down the wavefront.Mathematically, the characteristics in the $\lambda^{(2)}$-characteristic field would fold backwards in the x–t plane until converging into a compressive shock. Capart and Young (1998) backed these model with the early studies of Dressler (1954) on the influence of bottom friction. Numerical experiments carried out for fixed and mobile beds Ferreira et al. (2006) have shown that it is always possible to find continuous solutions even in the presence of very large bottom friction. It is thus unlikely that this 2-jump is mainly originated by the compressing of the $\lambda^{(2)}$-characteristic field under the effect of friction.

Chen and Simons (1979) report an upstream progressing 2-jump in a bed featuring an initial positive bed step. Chen and Simons (1979) believe that the jump is originated by the increased flow velocity over the bed discontinuity, as it would occur in a weir. Although their initial conditions are difficult to interpret, their results may be used to state the case for the influence of two-dimensional effects in the first stages of the flow. A highly accelerated parcel of flow directed downwards would originate an scour hole, not explainable by the shallow water theory. Once formed, this accelerated flow region would progress upstream, a process similar to the knickpoint migration. This would explain the 2-jump observed in test 35_00_00 (figure 4d).

The jumps seen in the tests featuring an initial negative bed step, 25_-05_00 and 35_-05_00 (figures 4a and b) may also owe to two-dimensional flow effects. An accelerated parcel of flow directed upwards would be susceptible to slow down the flow in the vicinity of the bed jump, thus provoking the free surface elevation seen in figures 4a and b. The hydrodynamic response to compatibilize the supercritical and subcritical flow regimes thus created would be forming a jump. It would progress upstream in an antidune-like movement.

6 CONCLUSION

The present study attempted to contribute to the characterization of the discontinuities observed in geomorphic dam-break flows. Special attention was conceded to the often observed 2-jump that forms at early times at the location of the dam.

A comparison between experimental flow profiles and the weak solution of the dam-break Riemann revealed that there is a class of 2-jumps whose mechanics are susceptible to be described by the Rankine-Hugoniot conditions of the shock associated to the $\lambda^{(2)}$-characteristic field. The distinctive traits of these 2-jumps are its positive velocity of propagation and, in what concerns bed morphology, its aggradational nature.

When the weak solution features an expansion wave in the $\lambda^{(2)}$-characteristic field, the causes of the 2-jump must be searched outside the realm of phenomena described by the homogeneous onedimensional governing equations. It is observed that these 2-jumps migrate upstream and are associated to scour holes. Possible explanations comprise: i) frictional effects combined with non-equilibrium sediment transport and; ii) two-dimensional flow effects. More likely, a combination of the preceding effects may be the cause of these 2-jumps. Hence, this flow features certainly call for more effort in their empirical characterization.

Experimental study of landslide-induced flooding in open channels

Jun Yan, Zhixian Cao & Li Chen
State Key Laboratory of Water Resources and Hydropower Engineering Science, Wuhan University, Wuhan, China

ABSTRACT: There are an increasing number of high dams constructed on valley rivers with steep bank slopes in Southwest China. An appropriate combination of hydroclimatic and geotechnical conditions and reservoir operation may favor the occurrence of large-scales landslides. Large-scale landslides produce landslide dams in rivers, which may block the stream flow and cause inundation upstream, and subsequently fail and lead to devastating flooding downstream. The need for accurate assessment of the potential threat to the society and the safety of hydraulic constructions has been well recognized. However, current understanding of the physical processes of landslide-induced flooding continues to be poor due to the complicated nature of the phenomenon, and inevitably reliable methods and tools for evaluation of possible consequences of river-blocking landslides are still missing. This paper presents an experimental study of landslide-induced flooding in open channels. A flume of 80 m × 1.2 m × 0.8 m is deployed, along with an array of ten automatic water-level probes. Tests are carried out over initially fixed beds. For each of a set of constant incoming clear-water flow discharges, a massive body of loose sediments of a variety of sizes is instantly added to the flow through a sediment-feeder at the middle of the flume, simulating a landslide. Water levels are recorded every half a second at ten cross-sections along the channel. The failure of the landslide body is visually observed. The experiments provide useful data resources for understanding landslide-induced flooding and for testing mathematical river models.

1 INTRODUCTION

High and even unconventionally high dams are being constructed or planned on valley rivers with steep bank slopes in Southwest China. An appropriate combination of hydroclimatic and geotechnical conditions and reservoir operation may trigger the occurrence of large-scale landslides that can induce devastating disasters. When landslides take place, initial waves are first generated, which may threaten the safety of dams and other hydraulic constructions. Subsequently, landslides may block the river channel and form landslide dams. Then inundation upstream of the landslide dams is inevitable. When a landslide dam fails, the devastating floods with large surges or debris flows may lead to catastrophic disasters in the downstream. Landslide dams break down mostly due to the overflowing of water after the landslide dam lakes are fully filled with water.

To date, there have been reports on landslide-induced floods. On June 1, 1786, an earthquake triggered a large landslide that fell into the Dadu River and blocked it. After ten days, the landslide dam failed (Dai *et al*. 2005). In 1967, a landslide blocked the Yalong River, a tributary of the Yangtze River. The height of landslide dam was more than 300 m, and nine days later, the landslide dam failed (Li *et al*. 1986, Chen *et al*. 1992). In Tibet, a super-large landslide occurred along Zhamu Creek and blocked the Yigong River on April 9, 2000. After two months, a catastrophic flood resulted from the landslide dam failure (Shang *et al*. 2003). Large-scale landslide-induced flood events have occurred not only in China, but elsewhere over the world (e.g. Costa & Schuster 1988, Ohmori 1992, Cruden *et al*. 1993, Cruden *et al*. 1997, Bovis & Jakob 2000, Miller & Cruden 2002, Nicoletti & Parise 2002, Abril & Knight 2004). However, existing studies have only reported the occurrences and disasters due to landslide. Current understanding of the physical processes of landslide-induced flooding continues to be poor, and reliable methods for evaluation of possible consequences of river-blocking landslides are still missing. Mathematical modelling and experimental studies for landslide-generated initial waves have been carried out mainly for reservoir and ocean waters (Heinrich 1991, Jiang & Leblond 1992, 1993, Rzadkiewicz *et al*. 1997, Guo *et al*. 2000, Lynett & Liu 2002, Rabinovich *et al*. 2003, Hu *et al*. 2003, Zhou *et al*. 2003, Li *et al*. 2004). Yet, the mathematical models and the experiments are case specific and are not generally applicable to landslide-induced flooding in open channels. Also it is noted that large-scale landslides-induced floods relate to highly unsteady flow, non-equilibrium sediment transport and

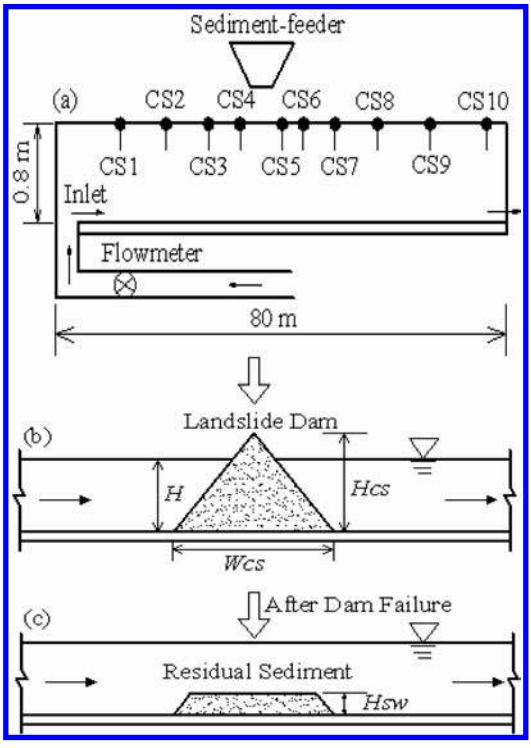

Figure 1. (a) Experimental setup (not scaled); (b) Sketch of landslide dam; and (c) Sketch of residual sediment blocks.

rapid riverbed deformation. Intense interaction exists between flow, sediment, and morphological evolution. To evaluate the flooding induced by landslides, a fully coupled model is normally required.

This paper presents an experimental study of landslide-induced flooding in open channels. Particular attention is paid to the variation of water levels in response to the initial waves, the inundation upstream the landslide dam, and also its failure. The experiments provide useful data resources for understanding landslide-induced flooding and for testing mathematical river models.

2 EXPERIMENTS

2.1 *Experimental setup*

The experimental setup is illustrated in Figure 1a. A flume of 80 m × 1.2 m × 0.8 m, with an array of ten automatic water-level probes, is deployed and a sediment-feeder supplies dry sediments to simulate landslide occurrence. The flume is made of glass with a bottom slope of 1/1000 and the Manning roughness is equal to 0.012. The sediment feeder is located 30 m from the flume inlet. The ten automatic water-level

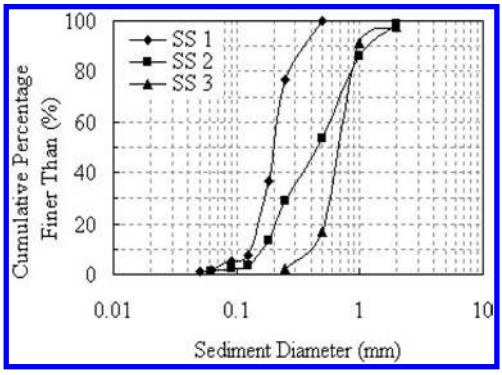

Figure 2. Gradation curve of sediment samples.

Table 1. Flow discharge and landslide volume.

	Q (m^3/s)	V (m^3)		
Case A	0.012	0.135	0.076	0.0375
Case B	0.036	0.218	0.160	0.113

probes are located at the center of the flume, respectively at 15 m, 21 m, 25 m, 28 m, 32 m, 34 m, 37 m, 41 m, 46 m and 60 m from the inlet. The tracking speed of the water level probes is set at 100 mm/s, the corresponding measurement error is within ±0.5 mm, and the sampling frequency is set at 2 Hz. A computer is deployed to process the data transmitted from the water level probes.

2.2 *Experimental procedures*

Experiments are carried out for different landslide volumes, sediment sizes and flow discharges. Three sediment samples are chosen to produce the landslides, and their gradation curves are plotted in Figure 2. The flow discharge (Q) and landslide volume (V) are given in Table 1. Corresponding to a specific discharge, a steady flow is first achieved by regulating the tailgate opening at the outlet of the flume. Then, the sediments uniformly pre-placed in the sediment-feeder are added instantly into the channel to simulate landslide occurrence. The variations of water level at ten cross sections are recorded with the automatic probes.

3 RESULTS AND ANALYSIS

3.1 *Summary of experiments*

In total, 20 cases of experiments are carried out, as summarized in Table 2. In Table 2, *SS* denotes sediment sample; H is water depth at the landslide site; H_u and H_d denote, respectively, the maximum heights of

initial waves in the upstream and downstream of landslide dam; H_{cs} and W_{cs} denote the height and bottom length of the landslide dam (Figure 1b); T_b denotes time of river-blockage before dam failure; T_f denotes time of dam failure; and H_{sw} denotes the height of the residual sediment at the landslide site after dam failure (Figure 1c).

3.2 *Analysis*

Typical variation of water levels is illustrated in Figures 3 to 6 for four different landslide volumes of Sediment Sample 2 in two different flow discharges.

3.2.1 *Initial waves*

Initial waves are generated immediately after landslide occurrence, in both the upstream and downstream of the landslide site. The maximum heights of the initial waves are shown in Table 2. The experiments indicate that landslide volume and the initial steady flow depth at the landslide site play important roles in dictating the maximum heights of the initial waves. For a specific case, the maximum heights of the initial waves are higher in the upstream than in the downstream (i.e., $H_u > H_d$), as can be seen in Table 2. Also, comparing Figure 3 with Figure 4, and Figure 5 with Figure 6, one finds that the maximum heights of the initial waves induced by a small landslide are lower than those of a large landslide, as expected. For different cases, the heights of the initial waves for every cross section are illustrated in Figures 7 and 8. It seems difficult to properly explain the complicated nature of the initial waves with currently available knowledge.

When the initial waves propagate to the inlet and the outlet of the flume, the gates prevent them from further progressing. The initial waves are reflected, which propagate towards the location of the landslide dam. For large landslides or large water depths at the landslide site, the reflected waves can overtop the landslide dams and accelerate dam failure through the experimental observation.

3.2.2 *River-blockage and dam failure*

After landslide occurrence in the flume, landslide dams are formed immediately, uniformly covering the entire width of the flume. Subsequently, the channel is blocked and the inundation upstream begins to occur. Water level variations during river-blockage are illustrated in Figures 3 to 6. The rising and falling of water levels, respectively in the upstream and downstream of the landslide dam are demonstrated.

As the upstream water level approaches the height of the landslide dam, overtopping occurs as the water flow gradually erodes the sediment of the top of the dam. In a later time, the landslide dams begin to fail. Water level variations during dam failure are also shown in Figures 3 to 6. For large landslides, surges are generated in the downstream, and for large landslide volumes, hydraulic jumps are also observed in the downstream of the landslide dam. When the water level difference between the upstream and downstream decreases to a certain value, the water flow becomes insufficient to further erode the dam body, and the course of dam failure is completed.

The times of river-blockage and dam failure are summarized in Table 2. Comparing T_b with T_f, the

time of river-blockage is longer than that of the dam failure. Especially, for large landslides, the time difference between them is much more pronounced. According to the volume of landslide, and also H_{cs} and W_{cs}, the underwater repose angle of sediments can be estimated for the three sediment samples. The repose angle normally ranges between 29 degrees and 35 degrees.

3.2.3 *Estimating peak discharge*

There have been empirical relationships for estimating the peak discharge of flood due to dam failure. Chanson (2005) presented a relationship based on the continuity equation and Bernoulli principle. In Chanson's relationship, the total head remains constant throughout the breach. Yet, in the present experiments, there is always inflow from the upstream, which may affect the total head. However, in a quantitative sense, the inflow is unimportant as its quantity is negligible compared to the initial water quantity prior to dam failure. Thus, Chanson's relationship is introduced to evaluate the discharge of the present experiments. The time of dam failure (T_f) are listed in Table 2. Of the total 20 cases of experiments, only Case 4, Case 12, and Case 18 satisfy the applicability conditions of Chanson's (2005) relationship for peak discharge. These three cases assume the same experimental conditions except the different sizes of sediment forming the landslides. The calculated discharge is shown in Figure 9. Apparently, the discharge hydrographs for the three cases show inappreciable differences between each other. Alternatively, the role of sediment size in dictating the breach process is rather weak under the specific conditions.

By revising Costa's (1985) regression relationships, Walder and O'Connor (1997) proposed four predictive methods to estimate the peak discharge of flood due to dam failure, which involve a series of parameters such as dam height and reservoir storage volume.

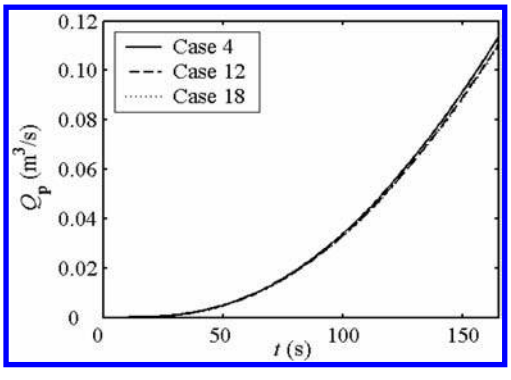

Figure 9. Discharge hydrograph due to Chanson's (2005) relationship.

Figure 10 shows the peak discharges calculated using the four methods due to Walder and O'Connor (1997). Obviously, the four methods deviate from each other significantly, even by an order of magnitude for the same case. This observation characterizes the significant uncertainty of the empirical methods of Walder and O'Connor (1997).

Large-scale landslide-induced floods relate to highly unsteady flow, non-equilibrium sediment transport and rapid riverbed deformation. Dam-break flood flow, sediment and bottom boundary interact with each other strongly. It is difficult to reliably estimate the peak discharges of floods due to landslide dam failure using empirical relationships (e.g., Walder & O'Connor 1997, Chanson 2005). To evaluate the floods more accurately, a fully coupled mathematical modeling methodology will have to be used. Development of such a model is underway by extending the model of Cao *et al*. (2004) to a 2D framework.

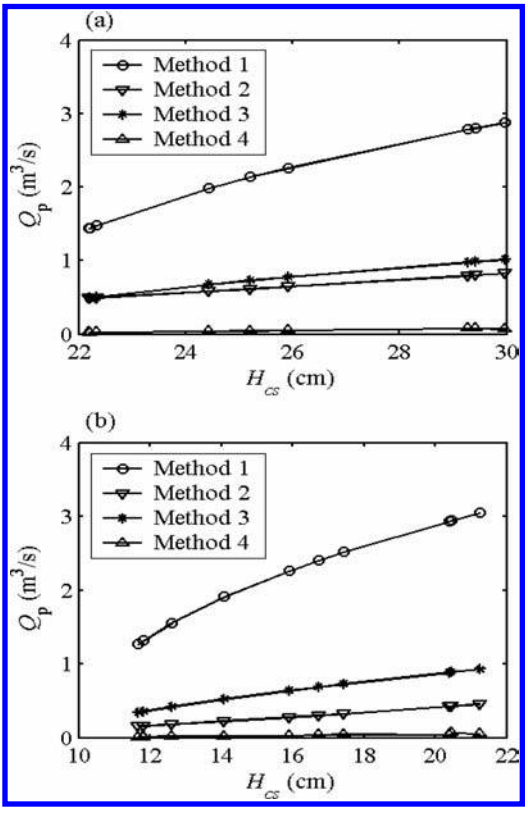

Figure 10. Peak discharge Q_p versus landslide dam height, calculated using the four empirical methods of Walder and O'Connor (1997), under (a) large inflow discharge ($Q = 0.036\,\mathrm{m^3/s}$); and (b) small inflow discharge ($Q = 0.012\,\mathrm{m^3/s}$).

3.2.4 *Sediment transport*

The sediment transport processes differ for different sediment samples and landslide volumes. For Sediment Sample 1 with the finest sediment size (Figure 2), turbidity currents are observed immediately following landslide occurrence at both the upstream and downstream. While propagating upstream and downstream, the turbidity currents gradually die out as the sediments deposit on the bottom of the flume. The maximum distance that the turbidity currents could move is found to increase with the landslide volume.

For large landslides of Sediment Sample 3 of the most coarse sediment size (Figure 2), piping of the landslide dam is observed before dam failure by overtopping. Along with the piping effect, the downstream side slope is eroded gradually and some sediment particles are entrained by seepage flow. However, for small landslides of Sediment Sample 3, piping is not so apparent, and overtopping seems to occur very slowly.

In general, when the upstream water level approaches the top of the landslide dam, overtopping occurs and breaches develop. Then, the breaches are cut deeply by flow and both sides of the breaches collapse gradually. The eroded sediments are carried to the downstream by the energetic dam-break flow, and in this course some particles are seen to deposit on the flume bottom.

It is noted that during the experiments, not all the sediments of the landslide dams can always be eroded and carried away by the flow, depending on the inflow discharge, landslide volume and sediment size. Generally, most sediment particles are eroded during the dam failure, and after that process the steady flow is not competent to carry the residual sediments to the downstream. Alternatively, after dam failure, there are residual sediments that stand at landslide location and form sediment blocks (Figure 1c). The heights of sediment blocks are given in Table 2. For a specific discharge, the residual sediment blocks of small landslides are higher than those of large landslides. The residual sediment blocks can considerably affect the flow, even long after the landslide dam fails. Figure 4 shows such effect for Case 11 of small landslide volume and inflow discharge (Table 2), as the difference in water levels in the upstream and downstream of the landslide site is by far greater than its counterpart before landslide occurs.

4 CONCLUSIONS

A series of flume experiments are carried out to enhance the understanding of flooding due to simulated landslide. The flooding comprises the initial waves generated immediately following the occurrence of landslide, the inundation upstream the landslide dam, and subsequently surge waves in the downstream due to landslide dam failure.

As a landslide slides into the channel, initial waves are generated (Figures 3 to 6). Both landslide volume and initial water depth at the landslide site play important roles in dictating the maximum height of the initial waves. Yet the variation of the maximum height of the initial waves along the channel exhibits a rather complicated picture, which current knowledge seems insufficient to properly explain. This would have to be reserved for future studies by resorting to physically based numerical models.

As a landslide dam blocks the channel, inundation occurs in the upstream as evidenced by the rising of the water levels, irrespective of piping in the landslide dam of coarse sediments. When the upstream water level approaches the top of the landslide dam, overtopping is observed, which cause the landslide dam to fail. For large landslides, hydraulic jumps are observed in the downstream during the process of dam failure.

The sediment transport processes differ for different sediment samples and landslide volumes. For landslides of finer sediments, turbidity currents are observed immediately following the occurrence of a landslide. For large landslides of coarse sediments, piping of the landslide dams is observed before dam fails by overtopping. As the landslide dam fails, the eroded sediments are carried to the downstream and may later deposit on the bed, and the residual sediments may stand at the landslide site.

An attempt is made to estimate the peak discharge of flood due to landslide dam failure as of the present experiments, using the empirical methods by Walder & O'Connor (1997) and Chanson (2005). Significant deviations between the four methods of Walder & O'Connor (1997) are found, and the applicability of Chanson's (2005) relationship is rather limited. This seems to call for the development and application of advanced numerical models.

The data and understanding presented herein are pertinent to landslides of non-cohesive dry sediment on fixed channel bed. The experimental data can be used to test mathematical river models that aim to quantify the phenomenon of landslide induced flooding in open channels.

It is noted that the landslides are simulated in the experiments through the sediment feeder in a very idealized manner. Further studies need to develop a landslide simulator that can better simulate real landslides in nature.

Dam-break propagation over a movable bed in a non-prismatic channel

João G.A.B. Leal
University of Beira Interior, Covilha, Portugal

Pedro Silva
Engidro Estudos de Engenharia, Lisbon, Portugal

Rui M.L. Ferreira
Instituto Superior Técnico, Lisbon, Portugal

ABSTRACT: This paper reports an experimental and numerical study of the 2D dam-break flow propagation. The experiments were carried out in a horizontal flume with a sudden enlargement. The bed was movable (natural sand) up- and downstream of the lift-gate that simulates the dam. The tests were recorded with video cameras. A 2D numerical model by Leal et al. (2005), incorporating two transport layers, was used to simulate the experimental results. The computational domain was discretized with an equally sized square mesh. The numerical results show good agreement with the experimental ones. Some discrepancies were found in the wave-front location. The model successfully reproduced the flow features. Namely the hydraulic jump that result from the reflection of the wave in the enlarged wall. The numerical model reproduces generally well the bed topography observed in the experiments. Nevertheless, some discrepancies can be pointed out. Namely, the numerical scour hole is less pronounced than the experimental one, and is accompanied by a small deposition bar near the non enlarged wall.

1 INTRODUCTION

Dam-break flows are catastrophic events that result from the total or partial failure of a dam. In the last century, some important accidents and failures occurred at, among other places, Vajont, Malpasset, Teton e Machhu II. These accidents have increased society's awareness towards these hazards and have helped devising strategies for risk assessment.

Since Ritter's initial study in 1892, dam-break waves have been studied by many authors. Due to the complexity of the involved phenomena, most of them considered only one-dimensional propagation (1D). Yet, it is clear that dam-break waves have a two-dimensional (2D) behaviour, affecting all flood plain.

The dynamic behaviour of 2D flows features, in general, a decrease of the free-surface level and a diminution of the wave-front celerity relatively to 1D flows. Therefore, the consideration and study of 2D dam-break flows is a necessary evolution of the existing 1D studies.

Two-dimensional dam-break studies are scarce. Dam-break flows in flumes with a sudden enlargement were studied within the framework of CADAM EU project (Frazão et al., 2000).

In the IMPACT EU project efforts were made to upgrade the models developed in CADAM in order to allow the simulation of movable beds. This upgrade is justified by field observations that show the capacity of dam-break flows on changing significantly the bed morphology. A recent example was the dyke failure in Ha! Ha! River (Lapointe et al., 1998), where morphologic impacts included strong erosion of the bottom and margins in convex reaches and generalized deposition at low slope reaches. The interaction between the flow and the bed changes the dynamic behaviour of the flow, inducing intense sediment transport and affecting flow resistance which, generally, provokes the rise of the free-surface and the delay of the wave-front propagation. Furthermore, flow features such as hydraulic jumps or critical flow points can be created or destroyed as the bed morphology evolves (cf. Ferreira et al. 2005). This constitutes a challenge to present-day modelling capabilities. Therefore, accounting for sediment transport emerges as an important step in the evolution of hydrodynamic studies towards a better simulation of flow events.

A conceptual 2D model composed by two transport layers was developed by Leal et al. (2005), based on a 1D conceptual model previously developed by Leal et al. (2003a,b). Those authors compared their

Copyright © 2006 Taylor & Francis Group plc, London, UK

2D numerical results with experiments made with a bed that was movable only in the upstream reach of the flume.

In the present study, new experiments were made with a movable bed in the entire flume, thus allowing for a better evaluation of the morphological capabilities of the numerical model.

The paper is organized as follows. In section 2, a description of the experimental set-up and a characterization of the tests is provided. In section 3.1, a brief review of the conceptual model is presented, highlighting the main hypotheses subjacent to the model. In section 3.2, the most important details of the numerical scheme used are described. The experimental and numerical results are presented and discussed in section 4. The main conclusions of the study are summarized in section 5.

2 EXPERIMENTAL SET-UP

The experimental tests were carried out at the Hydraulics Laboratory of the University catholique de Louvain, in a non-prismatic 6 m long horizontal flume with 0.48 m high rectangular cross sections. The flume is composed of two reaches, the first is 4.0 m long and 0.25 m wide, the second is 2.0 m long and 0.50 m wide (Figure 1 top).

A gate is installed 3.0 m from the upstream end of the flume. The gate is opened downwards, with a opening velocity of approximately 500 cm/s. This allows the simulation of a total and instantaneous dam-break.

The flume walls are transparent permitting flow visualization. For this purpose, two video cameras were used. One was placed laterally (C1), capturing the flow propagation along the enlarged wall, and the other (C2) was placed above the flume, capturing the wave-front location and configuration (Figure 1 bottom).

Each test had to be repeated twice, changing the position of the cameras (R1 to R2, in Figure 1 top), in order film the entire enlarged reach.

Natural uniform sand (mean diameter, $d = 1.82$ mm, and specific gravity, $s = 2.65$) was used as bed material.

The initial conditions (Figure 2) consisted in coincident bed levels up- and downstream ($z_u = z_d = 0.125$ m), i.e., horizontal movable bed, and in dry saturated bed downstream ($h_d = 0$ m). Two initial upstream water levels were tested, $h_u = 0.15$ m and $h_u = 0.25$ m, resulting in two distinct tests (T1 and T2, see Table 1).

The experimental procedure comprised the following steps: i) gate lifting; ii) movable bed smoothing to a height of $z_u = z_d = 0.125$ m, compacting it; iii) turning on the lights and the capturing software; iv) filling the upstream reach with water to a height of $h_u = 0.15$ m or $h_u = 0.25$ m and the downstream reach to saturation of the bed; v) starting the capture.

T.2	0.15	0.00	0.125	0.125

3 MODEL DESCRIPTION

3.1 *Conceptual model*

The model used in the present paper is a 2D generalization of the 1D model with two transport layers of Leal et al. (2003a). The details of the 2D model can be consulted in Leal et al. (2005). The model assumes the existence of two layers, the upper with clean water and the lower with high sediment concentration (sheet-flow). In each layer, velocities and

Copyright © 2006 Taylor & Francis Group plc, London, UK

sediment concentrations are considered to be uniform and the hydrostatic pressure distribution is assumed valid. Mention should be made to the fact that the sheet-flow is modelled as to have smaller velocities than the clear water and as to have smaller sediment concentrations than the immobile bed.

The 2D conservation equations can be written in vector form as (Leal et al. 2005):

$$\frac{\partial \mathbf{U}}{\partial t}+\frac{\partial \mathbf{F}(\mathbf{U})}{\partial x}+\frac{\partial \mathbf{G}(\mathbf{U})}{\partial y}=\mathbf{S} \tag{1}$$

with

$$\mathbf{U}=\begin{bmatrix} z_s \\ \rho u_{(x)} h \\ \rho u_{(y)} h \\ z_e \end{bmatrix}, \tag{2}$$

$$\mathbf{F}(\mathbf{U})=\begin{bmatrix} hu_{(x)} \\ \rho_w u_{w(x)}{}^2 h_w+\rho_c u_{c(x)}{}^2 h_c+\varphi \\ \rho_w u_{w(x)} u_{w(y)} h_w+\rho_c u_{c(x)} u_{c(y)} h_c \\ Chu_{(x)} \end{bmatrix}, \tag{3}$$

$$\mathbf{G}(\mathbf{U})=\begin{bmatrix} hu_{(y)} \\ \rho_w u_{w(x)} u_{w(y)} h_w+\rho_c u_{c(x)} u_{c(y)} h_c \\ \rho_w u_{w(y)}{}^2 h_w+\rho_c u_{c(y)}{}^2 h_c+\varphi \\ Chu_{(y)} \end{bmatrix}, \tag{4}$$

$$\mathbf{S}=\begin{bmatrix} 0 \\ -g(\rho_w h_w+\rho_c h_c)\dfrac{\partial z_b}{\partial x}-\tau_{bc(x)} \\ -g(\rho_w h_w+\rho_c h_c)\dfrac{\partial z_b}{\partial y}-\tau_{bc(y)} \\ 0 \end{bmatrix}, \tag{5}$$

$$\varphi=g\left(\rho_w h_w{}^2+2\rho_w h_w h_c+\rho_c h_c{}^2\right)/2 \tag{6}$$

In the previous equations $z_s=h+z_b$ is the free-surface elevation; $\rho\mathbf{u}\mathbf{h}$ is the density flow rate per unit width; $z_e=(1-p)z_b+C_c h_c$ is an equivalent bed elevation that takes into account the sediment stored in the water column; $p=$ porosity; $g=$ gravitational acceleration (taken equal to 9.8 m/s^2); h, u, C and ρ stand for, respectively, depth, velocity, sediment concentration and density; and τ_{bc} is the bottom shear stress. The subscripts w, c and b represent, respectively, the clear water, the sheet-flow and the immobile bed. The subscripts (x) and (y) stand for, respectively, the components in the longitudinal and in the transversal direction.

The depth-average variables are all considered in terms of the entire flow depth $h=h_w+h_c$, being the depth-average flow velocity, sediment concentration and fluid density given by

$$\mathbf{u}=\left(\mathbf{u}_c h_c+\mathbf{u}_w h_w\right)/h \tag{7}$$

$$C=\left(C_c h_c\sqrt{u_{c(x)}{}^2+u_{c(y)}{}^2}\right)\Big/\left(h\sqrt{u_{(x)}{}^2+u_{(y)}{}^2}\right) \tag{8}$$

$$\rho=\rho_w\left(1+(s-1)C\right) \tag{9}$$

Assuming that the velocity profile for each direction depends only on the flow variables in the direction considered and based on the velocity distribution proposed by Sumer et al. (1996), Leal et al. (2005) obtained the depth-average velocity of the transported sediments in the sheet-flow layer

$$\mathbf{u}_c=\frac{\mathbf{u}}{u}u_c=\frac{10}{7}\beta^{3/4}\sqrt{g(s-1)d\theta}\,\frac{\mathbf{u}}{u} \tag{10}$$

Where the friction velocity and the Shields parameter are, respectively, given by

$$u_*=\sqrt{R}u \tag{11}$$

$$\theta=u_*{}^2\big/\left(g(s-1)d\right) \tag{12}$$

where $R=$ dimensionless friction coefficient that can be quantified on the basis of the sheet-flow experiments of Sumer et al. (1996), by making use of the sediment transport parameter

$$w_*=w\big/\sqrt{g(s-1)d} \tag{13}$$

being $w=$ sediment fall velocity. A value of $R=0.013$ was obtained for sand.

By analysing the sheet-flow data of Sumer et al. (1996) and Pugh & Wilson (1999), Leal et al. (2003b) observed the following linear relation for the sheet-flow height

$$h_c/d=\beta\theta \tag{14}$$

where $\beta=$ constant that depends on the type of sediment, namely on the sediment parameter w_*. The value estimated by Leal et al. (2003b) for the sand is $\beta=7.0$.

Leal et al. (2003a) using Bagnold's sediment transport formula obtain the total volumetric concentration of transported material expressed as

$$C=\frac{8.03\xi\sqrt{gR}}{(s-1)\left(1/R-\xi u^2/h\right)}\frac{u^2}{h} \tag{15}$$

where ξ is a parameter equal to 0.57, for sand.

A Chézy-type friction law can be used if the main dissipation mechanism is born in the granular phase and is proportioned by frequent binary inelastic collisions of the transported grains. In this case the shear stress, τ, is proportional to $(\partial u/\partial z)^2$ (cf.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Bagnold, 1956), being z the elevation, and following Fraccarollo & Capart (2002), the bed shear stress is expressed by

$$\boldsymbol{\tau}_{bc} = \rho_w R \mathbf{u} u \tag{16}$$

3.2 *Numerical model*

The numerical scheme used to solve Equation 1 is a TVD version of MacCormack's scheme. A brief description of the scheme is presented. For a more detailed 1D version, refer to Ferreira & Leal (1998). Two viscosity terms, aroused by the TVD algorithm, are added to the classical MacCormack scheme, thus redefining the update step, which becomes:

$$\mathbf{U}_{i,j}^{n+1} = \mathbf{U}_{i,j\ MacCormack}^{n+1} + \frac{\Delta t}{\Delta x}\left(\mathbf{D}_{i+1/2,j}^{n} - \mathbf{D}_{i-1/2,j}^{n}\right) + \frac{\Delta t}{\Delta y}\left(\mathbf{D}_{i,j+1/2}^{n} - \mathbf{D}_{i,j-1/2}^{n}\right) \tag{17}$$

where vector $\mathbf{D}$ is the TVD correction given by

$$\mathbf{D}_{i+1/2,j}^{n} = \frac{1}{2}\sum_{k=1}^{3}\left[\left(1-\phi\left(\left(r_{i+1/2,j}\right)_k\right)\right)\left(\Psi\left(\tilde{\lambda}_{i+1/2,j}\right)\right)_k \times \left(1-\left|\left(\tilde{C}r_{i+1/2,j}\right)_k\right|\right)\left(\tilde{\alpha}_{i+1/2,j}\right)_k\left(\tilde{\mathbf{e}}_{i+1/2,j}\right)_k\right] \tag{18}$$

Here, ψ is the entropy correction proposed by Harten and Hymen in 1983, $\phi(r)$ is the flux limiter function proposed by Van Leer in 1974 (see Hirsch, 1990), $\tilde{\lambda}$, and $\tilde{\mathbf{e}}$ are, respectively, the Roe's approximate eigenvalues and eigenvectors of the approximate Jacobian matrixes, $\tilde{C}r$ is the approximate Courant number; $\tilde{\alpha}$ represents the projections in the approximated eigenspace of the any jump in the values of $\mathbf{U}$ (cf. Ferreira & Leal, 1998). For the shallow-water equations, Roe's approximations for the depth-averaged flow velocity and the shallow-water propagation speed can be written, respectively, in the x and y directions, as

$$\tilde{\mathbf{u}}_{i+1/2,j} = \frac{\mathbf{u}_{i+1,j}\sqrt{h_{i+1,j}} + \mathbf{u}_{i,j}\sqrt{h_{i,j}}}{\sqrt{h_{i+1,j}} + \sqrt{h_{i,j}}} \qquad \tilde{c}_{i+1/2,j} = \sqrt{g\left(h_{i+1,j} + h_{i,j}\right)/2} \tag{19}$$

$$\tilde{\mathbf{u}}_{i,j+1/2} = \frac{\mathbf{u}_{i,j+1}\sqrt{h_{i,j+1}} + \mathbf{u}_{i,j}\sqrt{h_{i,j}}}{\sqrt{h_{i,j+1}} + \sqrt{h_{i,j}}} \qquad \tilde{c}_{i,j+1/2} = \sqrt{g\left(h_{i,j+1} + h_{i,j}\right)/2} \tag{20}$$

Equation 1 does not allow a simple determination of the approximation vector $\tilde{\mathbf{U}}$. Therefore, and because the use of the TVD algorithm is required for avoiding spurious oscillations in the solution, Leal et al. (2005) proposed the adoption of the following procedure:

- 1st: at time level $n+1$ the dependent variables $\mathbf{U}$ were computed by the classical MacCormack scheme using the information of the previous time level n.
- 2nd: the variables h, $\mathbf{u}$, ρ, C and z_b were determined by applying Newton's method.
- 3rd: the TVD term $\mathbf{D}$ was computed using Roe's approximations (Equations 19 and 20).
- 4th: Jameson's artificial viscosity was applied to z_b (see Hirsch, 1990).
- 5th: the corrected values of variables h, $\mathbf{u}$, ρ, C and z_b were used to determine the final values of $\mathbf{U}$ used in the next time level (return to 1st step).

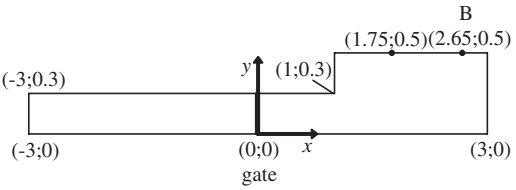

Figure 3. Location of the points where the time evolution was measured.

All physical boundaries were modelled with a free-slip condition, being totally reflective. The downstream end of the flume was modelled with a weir law, where the bed level was computed based on the two previous cells

$$z_{bi_{end},j} = 2z_{bi_{end}-1,j} - z_{bi_{end}-2,j} \tag{21}$$

where i_{end} refers to the computational x coordinate of the flume end section. The spatial domain was discretized using a 0.05 m length size square mesh.

4 RESULTS AND DISCUSSION

The time evolution of the free-surface level, z_s, and the sheet-flow elevation, z_c, were measured at two points (Figure 3). Point A is located in the region where a hydraulic jump occurs, and point B is situated in a region downstream of the hydraulic jump.

In Figures 4 and 5 is presented the time evolution of the free-surface and sheet-flow elevations, measured and computed, at points A and B (Figure 3).

The numerical results are in good agreement with the experimental measurements. The major discrepancies can be identified for the wave-front arrival in the point nearest to the gate (point A). This may be the consequence of a misestimation of the friction coefficient. Indeed, Leal et al. (2005) mentioned that the use of a constant friction coefficient is not sufficient to simulate adequately the wave-front position throughout the entire flood plain.

As for the flow depth, the differences are more evident for the higher upstream initial water depth ($h_u = 0.25$ m). Comparing the experimental results presented in Figures 4 and 5, one can conclude that in

Copyright © 2006 Taylor & Francis Group plc, London, UK

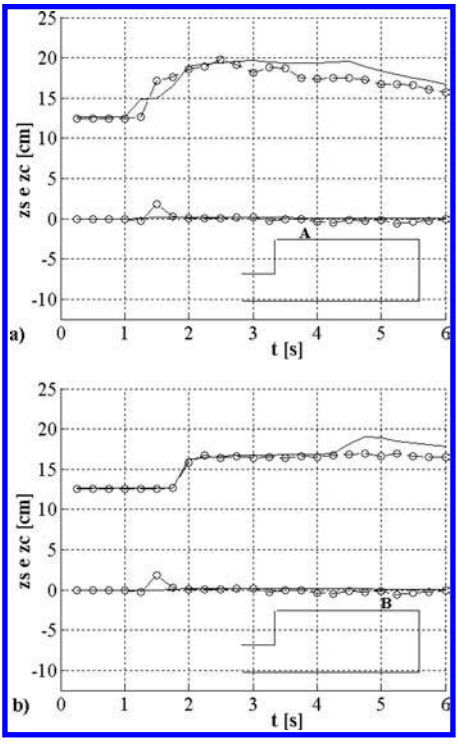

Figure 4. Time evolution of the free-surface and sheet-flow elevations for test T1 ($h_u = 0.25$ m) at: a) point A; b) point B.

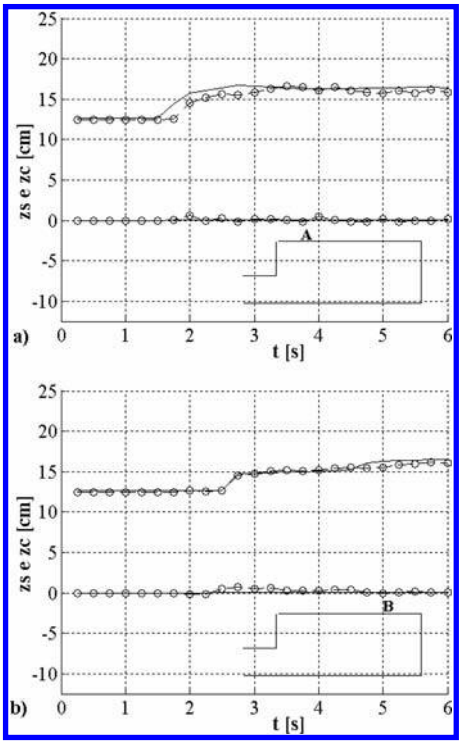

Figure 5. Time evolution of the free-surface and sheet-flow elevations for test T2 ($h_u = 0.15$ m) at: a) point A; b) point B.

the region of the hydraulic jump (point A), where the flow is reflected on the enlarged wall, there is a stronger interaction between the flow and the boundaries in the test for which h_u is larger. As a result, the free-surface is much more irregular in the test depicted in Figure 4.

Reference should be made to the fact that the bed material used, natural sand, does not allow for checking the ability of the model to simulate the sheet-flow layer. For that purpose please refer to Leal et al. (2005), where the model results were compared with lighter bed material tests.

The morphological capabilities of the model can be highlighted by looking at the measured and the computed final bed topography (Figure 6).

The experimental final bed topography (Figure 6a) is composed by a scour hole near the enlargement and a deposition region near the enlarged wall ($y = 0.5$ m). This configuration suggests that the bed material is eroded underneath the accelerated flow caused by the sharp corner of the enlargement located at $(x,y) = (1.0,0.25)$, being deposited in the recirculation zone near the enlarged wall.

The numerical bed topography (Figure 6b) shows the same configuration as the one observed in the experiments. Nevertheless, some discrepancies can be pointed out. Namely, the numerical scour hole is less pronounced than the experimental one, and is accompanied by a small deposition bar near the non enlarged wall. The deposition region near the enlarged wall is reproduced by the model, but shows higher dimensions than the experimental one.

At the downstream end of the measured region, the numerical results present a deposition region in the middle of the flume that was not observed on the experiments. This discrepancy can be caused by the strong interaction between the flow and the boundaries referred previously. As a result, the experimental and numerical wave reflection will, consequently, give raise to different bed topographies.

5 SUMMARY AND CONCLUSIONS

According to the analysis presented above and within the range of tests carried out, the following conclusions can be drawn:

– The numerical free-surface profiles are in good agreement with the experimental measurements. The major discrepancies can be identified for the wave-front location.

Copyright © 2006 Taylor & Francis Group plc, London, UK

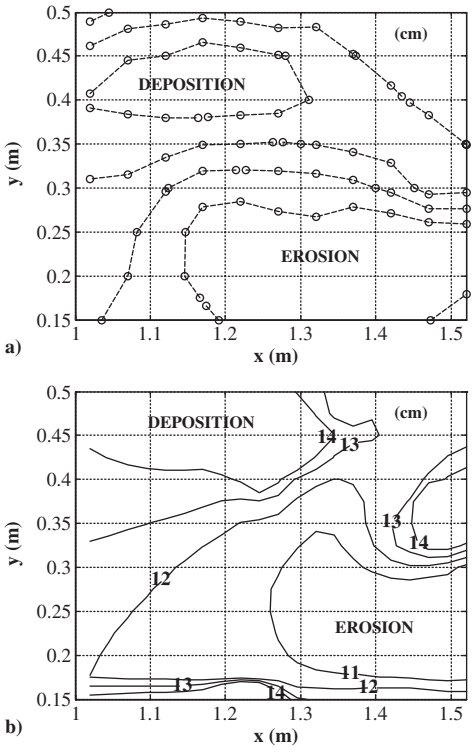

Figure 6. Final bed topography for test T1 ($h_u = 0.25$ m): a) experimental; b) numerical.

- The difference between numerical and experimental flow depths are more evident for the higher upstream initial water depth ($h_u = 0.25$ m). The increase of h_u induces a stronger interaction between the flow and the boundaries, being the free-surface much more irregular.
- The experimental final bed topography is composed by a scour hole near the enlargement and a deposition region near the enlarged wall.
- The numerical model reproduces generally well the bed topography. Nevertheless, the numerical results underestimate the experimental ones. The reason for this underestimation should be investigated in future studies.

ACKNOWLEDGEMENTS

The authors wish to acknowledge Prof. Yves Zech and Dr. Benoit Spinewine for making possible the realization of the experimental study at the University catholique of Louvain (UCL). The contribution of Prof. António Cardoso was also important, allowing the stay of the second author in the UCL. This study was financed by the European Commission through the IMPACT project under the fifth framework programme (1998–2002), Environment and Sustainable Development thematic programme, for which Karen Fabbri was the EC Project Officer.

ABSTRACT: In Japan, most of population and property concentrate to floodplain, and the main facility against flood is continuous flood levee, thus, the river administers have constructed flood levees with arranging flood control dams to suppress the disaster against flood. However, due to heavy rainfalls that exceed the design or equipped facility level, inundation due to breach of flood levee have often caused serious disasters. We are aware that it is necessary to prepare evacuation system against contingency, and in this purpose it is necessary to know how the breach develops as time process. In this paper, we explain how it is important to clarify the evolution process of levee breach, and develop a numerical simulation of the breach process that can evaluate the toughness of levee and floodplain against flood.

1 INTRODUCTION

The flood disasters in Japan are characterized by peculiar climate and geographical conditions and human activities under them. The Japan islands are on the route of Typhoons in July–October, and Bai-u front is active there in June–July, which bring a day or few days heavy rainfall events. The Japan islands are narrow and higher mountains form the backbone, and thus the watersheds are small and rivers are short and steep. These bring rapid runoff process.

On the other hand, the most of human activities (rice paddy fields and urbanization) concentrate on the floodplains of these rivers and they are exposed to risk of inundation during floods.

As the countermeasure against flood disasters, the river administrators have made effort to construct continuous flood levees and flood-control dams. It resulted that the risk of inundation have been reduced from a few years in the basis of the return period to 5–10 years, and the mortality have decreased from the order of 10^3 to that of 10 during this half of the century. This was caused not only by the effect of flood-protection facilities but also by a few decades with mild climate. In these few years, however, heavy rainfalls occurred frequently to cause serious disasters. Heavy rainfalls are particularly concentrated locally and temporally. They might be caused by the global warming and/or by the heat-island phenomena. In addition, the safety level in the master plan has not completed and the increase of the effect in higher safety level might be difficult to be recognized compared with investment. The public works are saturated in these years with lower growth of economy, and have been exposed to opposite opinion from the viewpoint of environment particularly for dam projects. Furthermore, the society has been changed to aged and less communicated neither assisted each other. As a result, peoples are not good at fleeing from inundation.

For examples, in 2000, heavy rainfall attacked Nagoya metropolitan area, and the city perfectly lost the functions and we recognized the fragile structure of urban area against flood. The flood-levee breach brought us particularly serious damage. In 2004, 10 typhoons hitting the Japan islands and heavy rainfalls due to front activities caused levee breaches at many rivers to bring catastrophic disasters, when more than 200 peoples were killed. It was a shock when we considered the recent tendency of decrease of flood damage as mentioned above. We have realized that serious disasters of inundation are brought by breach of flood levee as well as inundations caused by worse drainage.

Against inundations as contingencies when the external force (rainfall or flood discharge) exceeds the present safety level, which are inevitable because of present lower safety level and probabilistic feature of rainfall, residence of the dangerous area would

Copyright © 2006 Taylor & Francis Group plc, London, UK

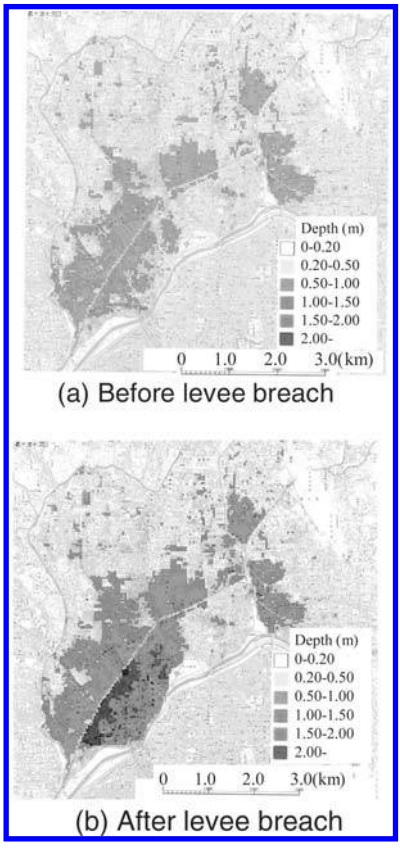

Figure 1. Simulation of inundation in the Shinkawa river basin (Aichi Pref.) on the Tokai heavy rainfall 2000.

flee safely or should be safely evacuated by proper guidance.

Figure 1 shows the example of the results of inundation simulation to reproduce the event of the Tokai heavy rainfall in 2000. Figure 1(a) shows just before levee breach and the wide area is already inundated. When we look at Figure 1(b) showing after the levee breach, we realize how serious what the levee breach brings about. Figure 2 shows another example of the levee breach (Kariyata river in Niigata Pref., 2004), where some houses including a temple were perfectly destroyed and a few peoples were killed.

For safe evacuation, the "hazard map" is prepared by community and distributed to residence, which is a kind of guide map for safe evacuation. The hazard map is made by consulting with a hypothetical map of inundation, that is a map of the inundation depth when the design flood attacks the river with present flood protection facilities. Because the facilities have not completed, there remain several critical points where the water stage exceeds a safety level (a kind of guarantee of the safety of the levee: the level lower free

Figure 2. Levee breach along the Kariyata river in Niigata Pref., 2004.

board below the top of the levee). The inundation flow is calculated often by employing 2D hydraulic model, where the levee breach is assumed at a breach point, and the calculated results of inundation depth for several breaching points are overlaid to obtain the maximum inundation at any points in floodplain. The hazard map is made by consulting such an inundation map, and it might be useful for making evacuation plan at pre-event, for example, designation of refuge and evacuation route, and evacuation-order needed area.

However, a contingency that may happen is quite different from the hazard map. In general, once the breach occurs at one location, the river discharge decreases rapidly which outflows to the floodplain, and the rest of the levee is saved from breach. It is important where the breach occurs, how the breaching evolutes and where becomes seriously dangerous. We have not been familiar yet to the breaching process, and in the manual prepared by the ministry is merely hypothetical based on limited numbers of experiences. Hence, we cannot evaluate the efforts to make the levee and the floodplain tough and to make the inundation propagation retarded. Such efforts are just what are required in order to mitigate the disaster when the external force exceeds the present facility level.

2 LEVEE BREACH

Though the manual recommend a proper mixture of sand (from the river) and clay (from mountain area) as the levee material on design of flood levee, most of levee have been constructed since early days when the riverbed materials have been damped up step by step in its history.

After the survey of the breached levee, the causes of levee breach are categorized into the following three: (1) overtopping of river flow; (2) slope-failure (sliding) and piping by seepage; and (3) bank erosion and/or scouring at the foot of a levee.

Copyright © 2006 Taylor & Francis Group plc, London, UK

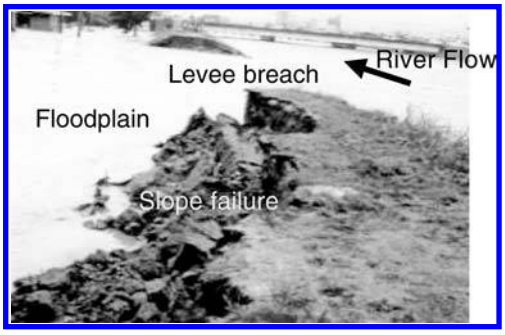

Figure 3. Levee breach in Shinkawa river in 2000 (Aichi Pref.).

In 2004 disasters in Japan, we experienced many levee breaches by overtopping. At the Shinkawa levee breach shown in Figure 3, the overflow eroded the body of the levee and it governed the evolution process of levee breach though the trigger of the breach was slope failure. And, the propagation of inundation was subjected to this evolution process. It determined the water discharge pouring to the floodplain, and it caused the initial rapid and dangerous flow near the levee.

3 MODEL TO DESCRIBE EVOLUTING PROCESS OF LEVEE BREACH

Considering the situations mentioned in Chapter 2, we have conducted to simulate the levee breaching process by applying the 2D horizontal flow model and a model coupling the bed-load transport and morphological change, where the area for simulation includes river, flood levee and floodplain. Previously, the flood in rivers has been treated in longitudinally 1D scheme, the flow over the levee in laterally 1D scheme, and inundation in floodplain in horizontally 2D scheme, separately. Figure 4 shows one of the model fields for simulation, which approximates the levee breaching area of the Sninkawa.

The numerical simulation was conducted in the framework of NHSED2D developed by Nagoya Hydraulic Laboratory (Goto *et al*., 2001). As for the flow, depth-averaged 2D hydraulic model was employed, where the boundary resistance was expressed by the friction factor. Meanwhile, the sediment transport and morphological process were described by Ashida-Michiue bed-load transport formula (1972) and the 2D equation of continuity for sediment transport. The transport fluxes of bed load were distributed to the directional components by considering the direction of bed-load motion subjected to both the bed undulation (gravity effect) and the deflection of bottom flow direction (Nakagawa *et al*., 1986). The difference in flow direction between depth-averaged flow and the near-bed flow were taken into

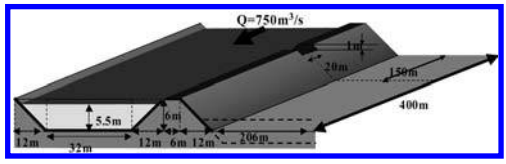

Figure 4. Model area for simulation.

account after Engelund equation (1974) for velocity profile at a river bend. In addition, the collapse was taken into account when the calculated morphology exceeds the angle of repose in the numerical simulation.

The governing equations were discretized by finite volume method, and collocated grid and fractional step method were employed in the numerical simulation. Rhie & Chow (1984) method is employed in interpolating between cells. And, the fractional step method (Ferziger & Peirc, 1997) was applied in time development in calculation.

4 SIMULATED EVOLUTION PROCESS OF LEVEE BREACH

For the first case of the simulation, which is regarded as the reference when we discuss the effect of the site characteristics on levee breach, the followings are set: The bed slope = 1/3690; the levee slope = 1:2; the channel width at the bottom: $B = 32$ m; the levee height = 6 m from the floodplain (the same level as the river bed); friction factor = 0.0167; and size of bed material of river bed, material of levee and floodplain: $d = 0.375$ mm. The discharge Q of the river before the breach is 750 m^3/s that corresponds to the flow depth $h = 5.5$ m, and the overflow starts from a hypothetical notch on the top of the levee (20 m wide and 1 m deep) as a trigger of breach. Though the river discharge has a hydrograph in general, a steady discharge corresponding to the peak is assumed here. These values are roughly set as similar as the flood in the Shinkawa river on the Tokai heavy rainfall in 2000. The domain for calculation is 400 m long in the longitudinal direction, and the floodplain is 400 m × 206 m.

By numerical calculation, the flow behavior around the breach can be described with morphological change (see Figure 5), and we can realized the spatial characteristics of the phenomena as well as the temporal evolution.

From the results of the simulation, it is characterized that the evolution process is divided into the following stages:

(i) the initial stage;
(ii) the second stage when the vertical erosion of bank proceeds dominantly, and the overflow notch is widen towards downstream of the river;

Copyright © 2006 Taylor & Francis Group plc, London, UK

(iii) the third stage when the local scour at the attaching point of the flow along the levee slope to the floodplain becomes remarkable and the width of over flow (breach width) increases dominantly toward downstream of the river. Subsequently, the discharge from the river to the floodplain rapidly increases; and

(iv) the fourth stage when the discharge supplied by the river totally outflows from the breach to the floodplain and the breach width continues to increase even toward upstream of the river.

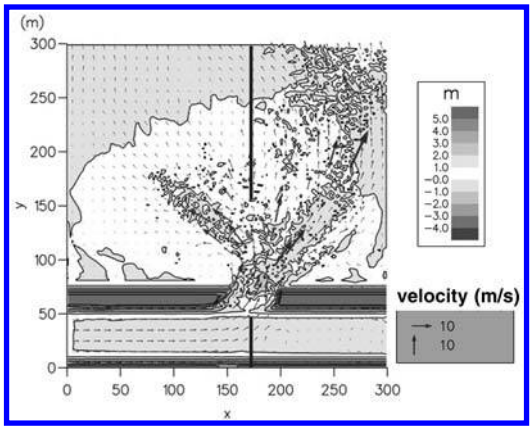

Figure 5. Spatial characteristics of flow and morphological change at levee breach ($t = 55$ min) in case of erodible floodplain.

The initial stage is subjected to the trigger of levee breach (either of overflow, slope failure, piping or bank erosion), of which type may be various, while the fourth stage might be influenced by the hydrograph pattern for each flood. Hence the discussion here should be focused on the second and the third stages mainly.

The above feature coincides the phenomena observed at the real levee breach of the Shinkawa river in 2000.

5 EFFECTS OF FEATURES OF RIVER, LEVEE AND FLOODPLAIN ON LEVEE-BREACHING PROCESS

5.1 *Effects of relative height of levee to floodplain*

In Japan, most of fluvial fan areas have been cultivated as rice paddy field and then often have been urbanized. Resultantly, the river is surrounded by flood levees

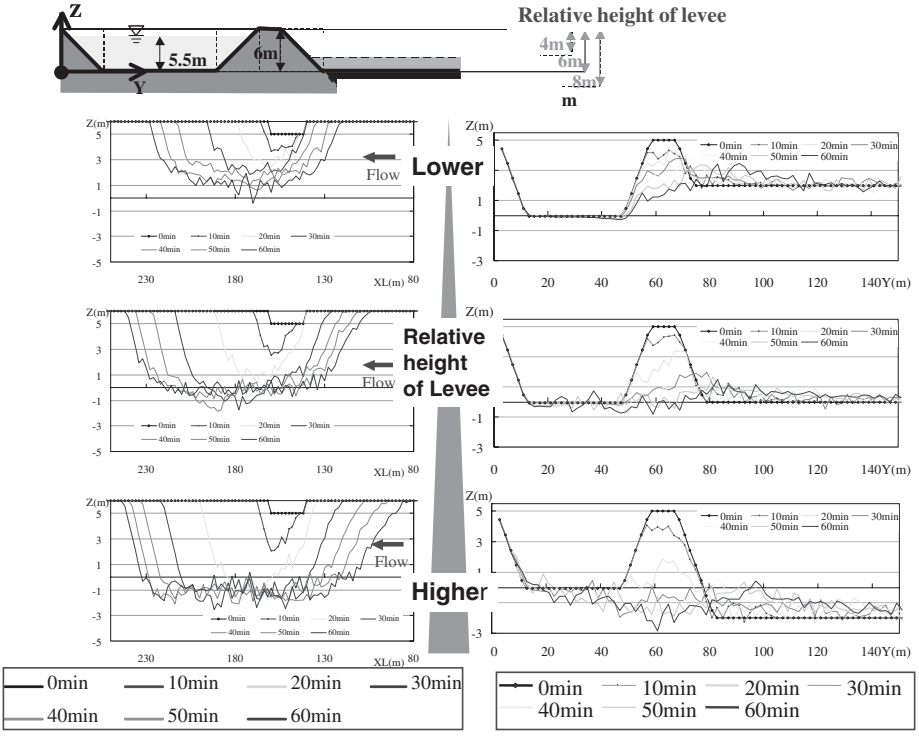

Figure 6. Difference of evolution process of levee reach due to different relative height of levee.

Copyright © 2006 Taylor & Francis Group plc, London, UK

both sides. A rivers in a fluvial fan often flows the highest crest of the fluvial fan, and the river bed is higher than the floodplain. Such a river is often called "Tenjo" river ("Tenjo" means a ceiling in Japanese), which requires higher levees, and it has high risk of disaster on levee breach during flood.

Considering the above, the evolution process are compared with among the levee with different relative height of river bed in order to recognize how high is the risk of a "Tenjo" river. For the time being, the information for the levee breach, that is utilized on preparing a hazard map, is based on the experiences independently the height of levee. When the capacity for flood is the same, a higher-bed river implies a river with higher levee looking at from the floodplain. In this section, the evolution process of levee breach for the three cases are compared each other as shown in Figure 6. In this figure, the breach evolution is expressed as the temporal growth of breaching section (front view) and the temporal loss of levee cross section (side view). Obviously, the breaching section for higher levee is larger, and it results that the large amount of discharge causes serious inundation. In addition, not only the materials but also river-bed materials outflow to the floodplain, and deposition of these debris is another aspect of a disaster.

5.2 *Effect of paved floodplain*

It is interesting that the development of the local scour caused by attacking flow along the levee slope contributes the evolution of the breach and the increase of inundation discharge as already mentioned in Chapter 4. Is the evolution of levee breach possibly suppressed if the area where the overflow along the levee slope attacks is paved? The retardation of breach development of levee must be helpful from the viewpoint of evacuation.

In this section, the evolution process of levee breach is compared between erodible floodplain and paved floodplain.

Figure 7 shows the calculated result of the velocity vector and the morphology after 50 min for paved floodplain that would be compared with Figure 5 (in the same river with the same discharge but with non-paved floodplain). By comparing them each other, it is concluded that the pavement of the floodplain, particularly the place to be attacked by the overflow along the levee slope, considerably retards the evolution process, and subsequently to suppress the rapid increase of discharge of inundation.

5.3 *Effect of river-course shape*

The geometry of river-course, particularly, river bend or meandering, is often paid attention to when we discuss the weak points for levee breach. Some of the

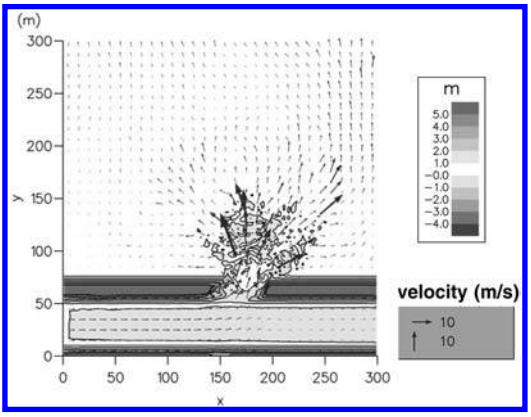

Figure 7. Spatial characteristics of flow and morphological change at levee breach ($t = 55$ min) in case of paved floodplain.

Figure 8. Levee breach at the Ikarashi river, Niigata Pref. in 2004.

historical levee breaches happened in a straight course (for example, at the Shinkawa river in 2000), some at the outer bank (for example, at the Kariyata river), the other at the inner bank (for example, at the Ikarashi river in Niigata Pref., see Figure 8) of river bends. The water stage at the outer bank rises up due to the centrifugal force effect, and if the levee heights are the same in the both sides, the outer has higher risk of overflow. However, some rivers have different height for the each levee historically or with some strategy of flood protection.

When we discuss the risk of levee breach, the hydraulics of flow along a river would be a tool, but once the levee breach starts for example by overtopping, the governing flow is not the flow along the river but the levee-crossing flow. In this sense, 1D model lateral to the river might be employed, and then the evolution process might be same independently of the river-course geometry. However, actual flow is supplied from the river not from a kind of reservoir, and it might affect the evolution process as well as a trigger phenomenon. Hence, 2D-scheme simulation model

Copyright © 2006 Taylor & Francis Group plc, London, UK

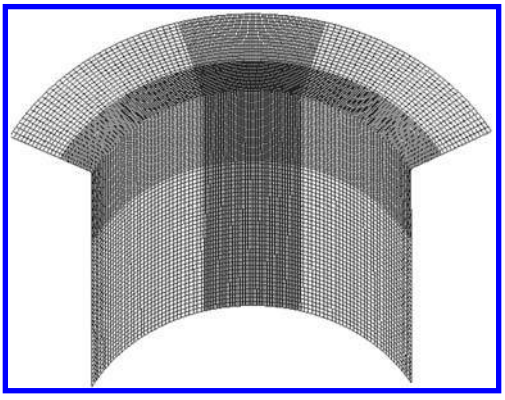

Figure 9. Grids prepared for simulation of levee breach at the inner bank.

has been developed, and it is employed to investigate the difference of evolution process of levee breach due to the river-course geometry.

In this section, river bends of a model river and levees with the same dimension with those investigated in Chapter 4 (bed-slope = 1/3690; size of materials of river bed, levee and floodplain: $d = 0.375$ mm; width of the river at the bottom: $B = 50$ m) are focused on as model courses. The courses with two different values of curvature radius R of river bend (at the centerline) are compared each other respectively for breach at inner and outer bank: (i) $R = 3B$ and (ii) $R = 6B$. The friction factor was adjusted so that the water stage for the given discharge ($Q = 750\ \mathrm{m}^3/\mathrm{s}$) is 0.5 m above the initial notch bottom as a trigger of the levee breach. Figure 9 shows the grids for a model of river course, levee and flood plain when the breach at the inner bank is discussed.

Figure 10 shows the calculated results by the present simulation demonstrated by the temporal development of breach section. Comparing the case of breach at the inner bank with that at the outer bank, the breach section develops almost only toward the downstream of the river for the former case, while it widens both downstream and upstream and it becomes bigger for the latter case. Such characteristics could not be estimated by uni-directional analysis lateral to the river.

As shown in Figure 11, the inundation flow behavior and the subsequent morphological change show some differences between the breach at inner bank and that in the outer bank.

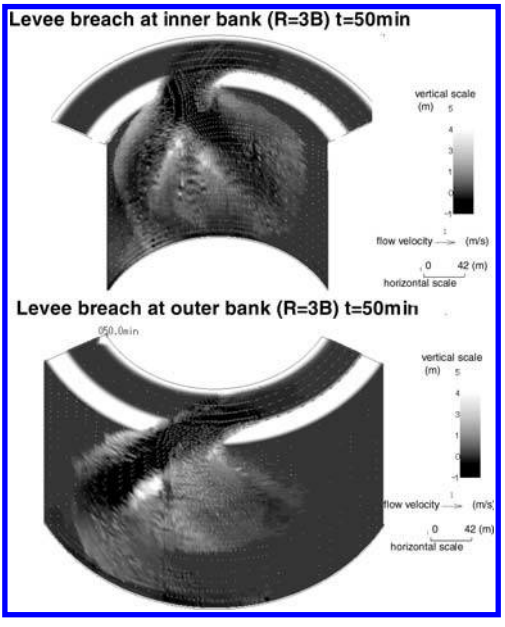

Figure 11. Comparison of flow and morphological change at levee breach between inner-bank case and outer-bank case.

6 DISCUSSION ON ACTUAL LEVEE BREACH EXAMPLES BASED ON SIMULATION

6.1 *Levee breach in Kariyata river in 2004*

The Kariyata river is a tributary of the Shinano River. In July 2004, because of heavy rainfall exceeding 200 mm a day due to an active front, the Kariyata river was suffered levee breaches at several locations. Among them, the levee reach at Nakanoshima district (at the outer bank) brought a serious disaster

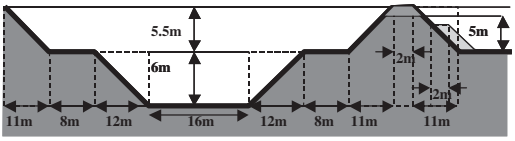

Figure 12. Modeled cross section of river with levee in the levee-breach simulation for the Kariyata river.

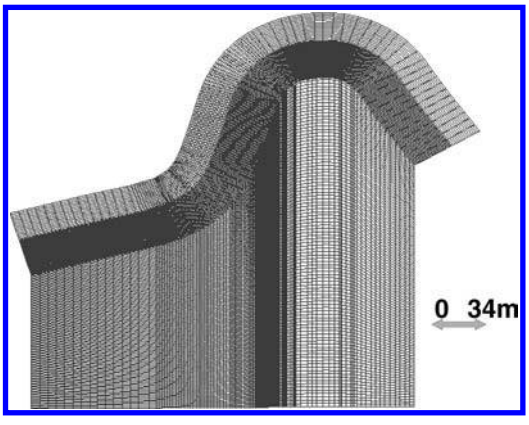

Figure 13. River-course geometry and grids for simulation of levee reach in the Kariyata river.

(see Figure 2). Though the levee height was slightly higher than the other side levee, the overtopping happened at both side. Disadvantage of this side was that the top of the levee was not paved, while the top of the levee was paved in the other side levee. A torrent from the breach destroyed several buildings completely, and rapid rising inundation killed a few peoples. In this chapter, by making use of the simulation developed in this study, it was investigated how the evolution of levee breach caused such a catastrophic situation.

The simulation was conducted under the following condition that roughly approximated the actual event: bed slope = 1/1000; Manning's $n = 0.03$, the size of river-bed, levee and floodplain: $d = 0.375$ mm; and the cross section of the river with the levee is shown in Figure 12. The discharge was set 1850 m^3/s, when the overflow appears 0.5 m deep from the initial notch bottom. The river-course geometry is shown in Figure 13 with the calculation domain and grids.

When the river is managed by a local government, the details of the cross sections of the river with the levees are often unclear. For this site in 2004, various ambiguous information for levee spread, and thus the following three situations were tested: (i) simple cross section; (ii) most of the levee has revetment over the floodplain-side slope except around 50 m segment near the; (iii) there was an additional step slope on the floodplain-side slope.

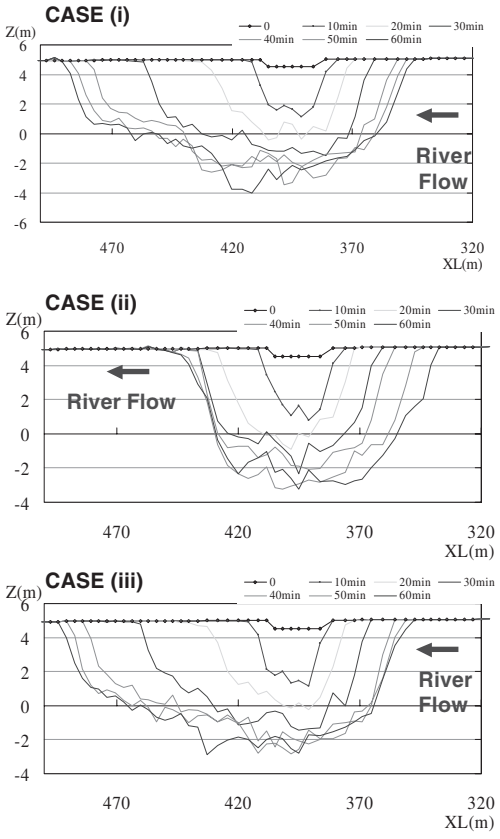

Figure 14. Evolution process of levee breach at Nakanoshima site of the Kariyata river (three scenarios).

In Figure 14, the calculated results were shown as temporal growth of breach section. Independently of the detailed differences (i)–(iii), most of breaching process proceeded within 30 min, and the inundation within such a short time made the disaster extremely serious. Limited opening of the backside revetment suppressed the widening of the breach section, but the flow from the river to the floodplain was limited to this width. And because of the vertical development of the breach, the concentrated intensive flow attacked the locally limited area. The added side step on the backside of the levee retarded the evolution of the levee breach, but its effect was slight.

Figure 15 shows the spatial flow behavior and morphological change in the floodplain for the above three scenarios and the scenario with continuous revetment covering the backside of the levee. As aforementioned, the backside revetment prevents the breach, but if it has an opening, the concentrated flow is intensive and causes severe morphological change though the

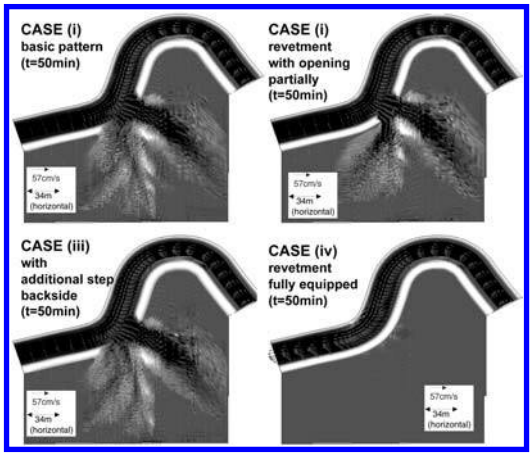

Figure 15. Spatial flow behavior and morphological change at levee breach in the Kariyata river (four scenarios).

evolution of breach section is suppressed in the width of breach.

6.2 *Levee breach in Ikarashi river in 2004*

The Ikarashi river is another tributary of the Shinano River. In July 2004, the heavy rainfall due to active front caused a big flood, and the river flow overtoped the levee several places. At Suwa district, the levee breach occurred at the inner bank (see Figure 8), and the inundation widely propagated down to Sanjo city, where several peoples died because of rapid rising of inundation depth.

Just downstream of the levee breach was utilized as a paddy field, and direct attack of flow due to levee breach never killed persons but rapid propagation of the inundation flow to the residential area caused serious mortality. Deposition of sediment on the paddy field caused the damage for crops. The simulation developed in this study can describe not only the erosion but also deposition, and it can be used for farmland damage estimation.

At the breaching point, the river flow was overtopping, and we estimated that the trigger of levee breach was overflow. Some persons insisted that a piping might have become the trigger of the levee breach and they considered that dispersed gravels remaining in the farmland was a ruin of quick sand. However, such gravels were observed inside the levee as a gravel layer, which were used as levee materials in early days. Thus, we investigated that how the gravels inside the levee were transported on the levee breach to spread in the floodplain.

As seen in Figure 8, the Ikarashi river is meandering and Suwa district faces to the inner bank of the bend. Thus, the river-course geometry adopted as the calculation domain was expressed as similar as Figure 9,

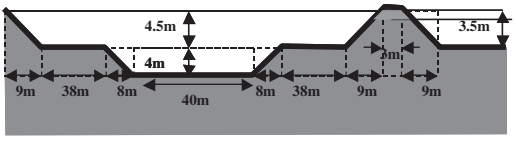

Figure 16. Modeled cross section of river with levee in the levee-breach simulation for the Ikarashi river.

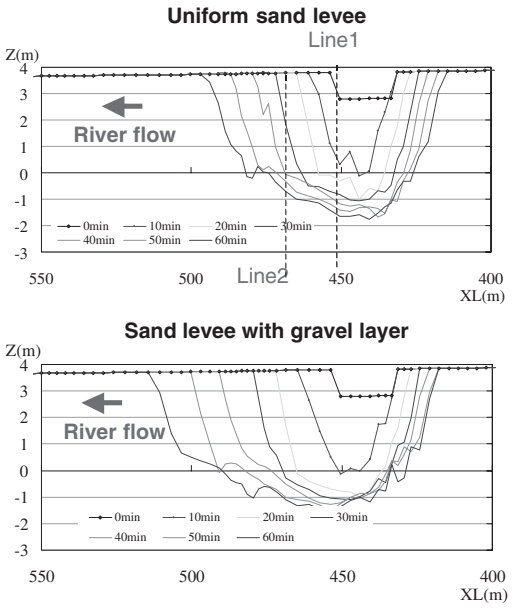

Figure 17. Temporal growth of breach section. Comparison between (i) uniform sand levee and (ii) sand levee with gravel layer (gravel size = 10 cm).

where the bed slope = 1/800, the material size of riverbed, levee and floodplain: $d = 0.375$ mm. Manning's $n = 0.03$, and the cross section of the river was as shown in Figure 16. The discharge was 1580 m^3/s, when the overflow was 0.5 m deep from the initial notch bottom. According to the boring data, the gravel layer was assumed to be 1.0 m thick with the lower boundary 0.5 m above the floodplain level, and the diameter of the gravels was $d_G = 100$ mm.

Figure 17 shows the temporal growth of breach section, where the uniform sand levee and the sand levee with a gravel layer. According to the calculated results, the levee breaching flow can transport gravels as large as 10 cm, and the breach section became larger than the case of uniform sand made levee.

Figure 18 shows the spatial distribution of flow behavior by velocity vector, morphological change by contour lines, and the change of average material size due to dispersion of gravels by grey-scale gradation. The dark zone implies deposition of dispersed gravels

Copyright © 2006 Taylor & Francis Group plc, London, UK

Figure 18. Arrows indicate the flow behavior; contour lines indicate the morphological change; and the dark area in gradation indicate gravels dispersion from the inside of levee.

from the gravel layer inside the levee, and it is recognized that gravels as large as $d_G = 10$ cm inside the sand levee could be transported to the floodplain and form recognizable deposits in the floodplain somehow far from the levee on the occasion of levee breach by flood.

7 CONCLUSION

In this paper, the authors have insisted that the understanding of evolution process of levee breach is important for disaster mitigation on contingency such as evacuation as well as the trigger of levee breach is important for designing and maintenance of the flood levee.

Though the complexities exist on real phenol-mena, 2D depth-averaged flow analysis with model describing morphological change by using the bed-load transport formula and sediment continuity equation have been applied not only to the river course but also levee and floodplain simultaneously, and a simulation model has been developed.

Firstly, the applicability of the model has been verified by discussing the levee breach event in the Shinkawa river (a straight channel) in 2000. Then, the effects of the characteristics of river course have been investigated through the simulation: the effect of the relative height of the river course and the river bend (the difference in levee breach between at the outer bank and at the inner bank). The higher position of a river course with higher levee has higher risk of large breach that causes larger amount of inundation discharge. It suggests higher risk in flood levees in fluvial fan area. At river bend, the water stage at the outer bank is higher, but the breach depends on the overtopping depth. If the overtopping occurs, a levee is possibly breached irrespectively outer or inner bank, and the final breach section has less difference. But, the breach at the inner bank widens only downstream of a river, while the breach at the outer bank widens towards both directions. In addition, it has been clarified that the local scour at the overflow attacks in the floodplain attached to the levee promotes the breach evolution, and the simulation has demonstrated that the paved floodplain delays the evolution of levee breach, which is advantage for proper evacuation.

Furthermore, the present simulations have been roughly applied to the two examples of levee breaches in the Kariyata and the Ikarashi rivers where severe disasters occurred in 2004. For these incidents, several aspects related to the levee breach were disputed, and some of them have been discussed rather objectively by applying the present simulation model: the effect of the condition of revetment cover on the floodplain-side slope of the levee; and the reason why gravels dispersed and spatially distributed in the floodplain near the breaching point. These examples suggest how to use the present model in the survey of the happened disasters with levee breach and in making evacuation strategies.

A 3-D numerical investigation of the development of density driven finite-channel lock-release currents at high Grashof numbers

Seng Keat Ooi, George Constantinescu & Larry Weber
Civil & Environmental Engineering, IIHR-Hydroscience & Engineering, The University of Iowa, Stanley Hydraulics Laboratory, Iowa City

ABSTRACT: Lock-exchange gravity current flows produced by the instantaneous release of a heavy fluid are investigated using 3D high-resolution Large Eddy Simulation (LES) simulations at Grashof numbers between 9.6×10^8 and 8×10^9. It is found that the finely resolved 3D simulations on meshes containing around 35 million cells correctly predict a constant front velocity over the initial slumping phase and a front speed decrease proportional to $t^{-1/3}$ (the time t is measured from the release) over the inviscid phase, in agreement with theory and experimental observations. It is found that the KH billows do not preserve their structure across the width of the channel and break rapidly into smaller 3D structures. In the near-wall region beneath the upstream part of the current, it is found the intensity of the turbulence is large enough to induce the formation of low and high streamwise velocity streaks, similar to the ones observed in channel flows.

1 INTRODUCTION

Gravity currents form when a heavier fluid propagates into a lighter one (Simpson, 1997). In the case of lock-release gravity currents in channels (see sketch in Figure 1), a lateral wall is present at one of the ends of the channel and the heavier lock fluid occupies initially a finite volume between the lateral wall and the lock gate. When the lock-gate wall is removed a gravity current (GC) will start forming and propagate near the bottom wall. This case is the main focus of the present paper. Also we limit our investigation to compositional currents when the density differences are produced by a difference in a property of the fluid (e.g., temperature, salinity, etc.) and we study only the case when the initial height of the heavier lock fluid is equal to the channel height. Especially because of the possible negative effects on the environment, predicting and understanding the evolution of gravity currents is of considerable interest to both the engineering and geophysical communities (e.g., Simpson, 1997).

For practical applications, accurate prediction of the speed of the current front and the spatio-temporal distribution of the bed shear stress is of great interest. This is because in the case in which these compositional currents propagate over loose beds they can entrain sediment and significantly alter the deposition/entrainment patterns in the region. Also in many applications (e.g., submerged dams) it is important to be able to predict the forces induced by the gravity current on an obstacle situated in the way of the current. Obtaining the bed shear-stress distribution, the pressure distributions on obstacles, the spatio-temporal distribution of the velocity and concentration fields or information on the global energy balance at different stages of the evolution of the GC is quite difficult and very expensive to achieve experimentally. To be able to numerically predict these more complex phenomena in a range of representative flow conditions (high enough Reynolds and Grashof numbers when the flow inside part of the GC is highly turbulent) for practical applications, one has first to validate the method for cases for which experimental data is available and to compare the prediction of some of the global flow features of the current (e.g., speed of propagation) with theory. Our approach is to use highly-resolved fully 3D LES simulations at Grashof numbers around 10^9 and above where highly-resolved Direct Numerical Simulation (DNS) using non-dissipative methods is too expensive computationally.

2 BACKGROUND

For finite-volume lock-exchange GC the flow physics is more complex compared to the classical case of a gravity current that forms in an infinite channel in which the volumes of the heavier and of the lighter fluids are infinite and the current propagates with practically constant speed some short time after the gate release. For finite-volume lock-exchange GC, several phases can be identified in the evolution of the current.

Copyright © 2006 Taylor & Francis Group plc, London, UK

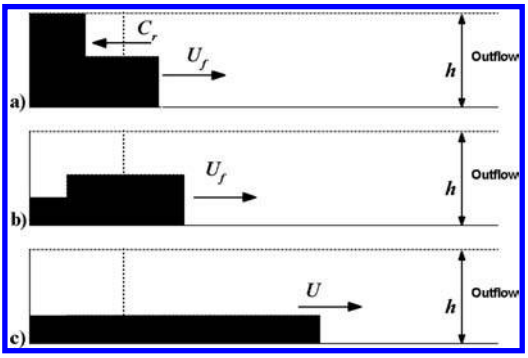

Figure 1. Sketch of lock-exchange flow in a channel limited by an end wall (a) Gravity current immediately after the gate is removed with associated front velocity of denser fluid and bore velocity of lighter fluid; (b) Gravity current in the slumping phase after the bore has been reflected; (c) Gravity current in the self-similar phase after the bore has caught up the front.

Initially, immediately after the gate release, a bore of lighter fluid is observed to form concomitantly with the main GC containing heavier fluid in the lower part of the channel. The speed of propagation of the bore and front of the GC are relatively close to each other initially. Once the bore propagating backwards (Figure 1a) has reflected from the end wall (Figure 1b), a flow of lighter fluid than the one inside the GC starts propagating toward the front of the GC with a velocity (U_{bore}) slightly higher than the front velocity (U_f). The current is in the slumping phase. Rottman and Simpson (1983) have shown that for the case when the initial depth of the lock fluid is close or equal (our case) to the depth of the channel, the bore advancing toward the front has the form of an internal hydraulic jump. During the slumping phase the flow is not self similar. However, the front propagates with practically constant depth and constant velocity (U_f). The ratio between the front velocity and the buoyancy velocity $u_b = (g'h)^{0.5}$ (g' is the reduced gravity and h is the channel depth) is in fact a parameter depending on the ratio between the initial depth of the denser fluid in the lock area and the total depth of the channel.

The inviscid self-similar phase starts once the forward propagating bore has overtaken the front of the GC (Figure 1c). From this moment the front advances with a velocity which decays in time proportional to $t^{-1/3}$. The flow is self-similar (a self-similar solution of the shallow water equations that describes this phase exists) and determined by the balance between the inertial force of the current and the buoyancy force (horizontal density gradient). If the channel is sufficiently long, a third phase, known as the viscous phase, may occur when viscous effects become dominant.

The lock-exchange flow corresponding to a bottom compositional current in a channel with a lateral wall was studied experimentally and analytically by Rottman and Simpson (1983) and by Hacker et al. (1996). Numerous numerical Reynolds Averaged Navier Stokes (RANS) based models and integral models were used by various researchers to predict the main features of compositional currents. A good review is given in Choi and Garcia (2002). The case of the propagation of the lock fluid into a linearly stratified fluid was studied experimentally and numerically by Maxworthy et al. (2002). Their 2-D DNS simulations employed meshes with around 106 grid points for Grashof numbers in the range of 108-4 $\times$ 108 to obtain stable solutions without adding numerical dissipation.

Regarding, 3D simulations using eddy resolving techniques, the first highly-resolved DNS simulations were performed by Hartel et al. (2000a, 2000b) for the case of an infinite-volume lock-exchange compositional GC at a Grashof number (Gr) around 1.2 $\times$ 106 (the corresponding Reynolds number was Re $\sim$ 710). The case of a particle-driven finite-volume lock-exchange GC at Gr = 5 $\times$ 106 was studied using 3D DNS by Necker et al. (2002). These studies were the first to numerically capture the presence of the lobe and cleft instability at the head of the current. Subsequently, the same group (Necker et al., 2005) performed a detailed analysis of the energy budgets, dissipative losses, influence of initial level of turbulence inside the lock fluid and of the mixing between interstitial and ambient fluid for particle-driven GC for the same range of Grashof numbers.

3 DESCRIPTION OF NUMERICAL MODEL AND COMPUTATIONAL TEST CASES

The numerical solver is a finite-volume non-dissipative DNS/LES code (Pierce and Moin, 2001) that solves the conservative form of the Navier-Stokes equations on non-uniform Cartesian meshes. A semi-implicit iterative method that employs a staggered space-time discretization is used to advance the equations in time while ensuring second order accuracy in both space and time. A Poisson equation is solved for the pressure. The algorithm discretely conserves energy which ensures robustness at relatively high Reynolds numbers in the LES regime. All operators are discretized using central discretizations except the convective terms in the scalar transport equations for which the QUICK scheme is used. The code is parallelized using MPI.

In the applications considered in the present study the density variations between the lock fluid and the channel fluid are sufficiently small such that the Boussinesq approximation can be applied to account for buoyancy effects (we assume the fluid density varies linearly with the non-dimensional concentration C). If the terms in the Navier-Stokes and transport

Copyright © 2006 Taylor & Francis Group plc, London, UK

equations for the salinity, temperature, etc., are made dimensionless using the channel depth, h, and the buoyancy velocity, $u_b = (g'h)^{0.5}$, $g' = g(\overline{C}_{max} - \overline{C}_{min})/\overline{C}_{min}$, where g' is the reduced gravitational acceleration, $\overline{C}_{max}$, $\overline{C}_{min}$ are the maximum and minimum concentrations (densities) in the domain, g is the gravitational acceleration, and one defines the non-dimensional concentration $C = (\overline{C} - \overline{C}_{min})/(\overline{C}_{max} - \overline{C}_{min})$, then one can rewrite the governing momentum ($i = 2$, vertical) and concentration transport equations using two dimensionless parameters, the Grashof number, $Gr = (u_b h/\nu)^2$, which is the ratio of the buoyancy forces to the viscous forces in the fluid and the Schmidt number, $Sc = \nu/\kappa$, which is the ratio of the molecular viscosity, ν, to the molecular diffusivity, κ: In the case of LES, due to filtering one has to add the extra sub-grid terms.

$$\frac{\partial u_i}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial u_i}{\partial t} + \frac{\partial (u_i u_k)}{\partial x_k} = -\frac{\partial p}{\partial x_k} + \frac{\partial}{\partial x_k}\left(\frac{1}{\sqrt{Gr}} + \nu_{SGS}\right)\left(\frac{\partial u_i}{\partial x_k} + \frac{\partial u_k}{\partial x_i}\right) - C\delta_{i2} \tag{2}$$

$$\frac{\partial C}{\partial t} + \frac{\partial (C u_k)}{\partial x_k} = \frac{\partial}{\partial x_k}\left(\left(\frac{1}{\sqrt{Gr}Sc} + \alpha_{SGS}\right)\frac{\partial C}{\partial x_k}\right) \tag{3}$$

where p is the dimensionless pressure. The last term in equation (2) is the non-dimensional gravitational term through which the stratification effects are felt in the momentum equations. This term is active only in the vertical direction ($i = 2$).

As the sub-grid scale (SGS) viscosity and diffusivity in the corresponding terms in equations (2) and (3) are calculated dynamically (Pierce and Moin, 2001) no model constants are needed. All simulations are performed with Sc = 600 (this increases proportionally the equivalent Reynolds number $\sqrt{Gr}Sc$ of the concentration equation compared to the momentum equations) which corresponds to saline diffusion in water.

The lock exchange cases (A, B and C) corresponding to the laboratory experiments carried out by Hacker et al. (1996) are simulated in the present study. In all these cases, the bottom-propagating denser lock fluid extends up to the free surface, initially. The main difference among these three cases in the initial aspect ratio of the denser lock fluid, $R = h/x_o$ (x_o is the initial lock length) which is equal to 0.67, 1.00 and 1.78, respectively. We concentrate most of our analysis on cases B and C, but discuss validation results for all three cases.

The Reynolds numbers defined with the front velocity and the channel half depth ($Re = U_f(h/2)/\nu$) are in the range of 7,000 to 20,000 during the slumping phase (see Table 1), so the flow inside the GC is turbulent, at least in the region behind the front. In agreement with the experimental setup of Hacker et al. (1996), no-slip boundaries were specified on the bottom wall and on the lateral wall, while the top was treated as a slip boundary (zero shear). A convective outflow boundary condition was used at the right extremity of the computational domain. This allows coherent structures to exit the domain in a time accurate way. The size of the grid was $3072 \times 160 \times 72$ in all simulations. The length of the computational domain varied between 8.7 h and 17.4 h. The domain size in the spanwise direction varied between 0.768 h and 1.025 h over which the computational points were distributed uniformly. The typical size of a cell was 0.0045 h in streamwise direction, 0.018 h in the vertical direction and 0.012 h in the spanwise direction. Near the right boundary the streamwise cell size was increased to 0.025 h. Near the end and bottom walls, the cell size in the wall-normal direction decreases to $\Delta n = 0.001$ h. Assuming conservatively $u_\tau/U_f \sim 0.04$ this translates into $\Delta n^+ \sim 1$ wall unit for case B which had the highest Grashof number. The grid spacing in the spanwise direction is close to 10 wall units. The other two cases should be slightly better resolved. The mesh size, especially near the walls in the normal direction, is fine enough for the code to be able to resolve the dynamically important turbulent structures without resorting to wall functions. The flow field for all the simulations was initialized with the fluid at rest, i.e., $u_i = 0$ everywhere. The non-dimensional concentration field was initialized with a constant value of 1 in the lock region and a constant value of 0 in the channel. Additionally, a disturbance was applied on the concentration interface (lock gate region) to accelerate the growth of 3D instabilities and transition to turbulence in the head region of the GC. The simulations were run on 16 or 24 processors of a Xeon PC cluster with Myrinet.

Table 1. Details of the lock-exchange 3D simulations. The Reynolds number $Re = U_f(h/2)/\nu$ and Froude number of the front $Fr = U_f/(g'h)^{0.5}$ correspond to the slumping phase when the front velocity is constant.

Case	Gr	L/h	Aspect ratio, $R = h/x_0$

4 RESULTS

As observed by Hacker et al. (1996), the dynamics of the GC is strongly dependent on the value of the initial aspect ratio R of the lock fluid. Table 1 summarizes the parameters of the simulations along with the predicted and measured values of the Reynolds and Froude numbers during the slumping phase when the front velocity U_f is practically constant. Figures 2 and 3 visualize the evolution of the GC using spanwise averaged concentration isocontours as predicted by the simulations (cases B and C) along with the corresponding experimental visualizations from Hacker et al. (1996). The position of the reflected bore is denoted x_b in these figures. In case C it is possible to follow the evolution of the GC in the experimental setup until it approaches the self-similar phase. In this case, the higher initial aspect ratio R (shorter lock length) causes the lighter fluid to reflect from the end wall much earlier compared to cases A and B.

It is observed that the flow in the initial moments after the lock release (e.g., compare Figures 2a and 3a corresponding to $t < 2t_0$, $t_0 = h/u_b$) is similar in all three cases, in the sense that a current of denser fluid moving downstream (right) develops at the bottom of the domain. The head region of the GC becomes unstable due to the amplification of the KH instabilities on the interface between the GC and the ambient lighter fluid, and strongly coherent relatively 2D billow structures are forming. The propagation speed of the KH billows is slowly decaying in time. These billows mix the ambient fluid with the heavier GC fluid. This results into a relatively well mixed fluid within their cores. Eventually the KH billows grow in size, become disturbed by the 3D flow instabilities as the flow in the head region becomes turbulent, break into smaller scale structures that eventually diffuse. As a result, the mixing between the ambient fluid and the upper part of the GC is enhanced (Figures 3d to 3j). As most of the coherence of the KH billows is lost, the small scale mixing becomes dominant and the interface region above and behind the head becomes mildly stratified with no sharp density interface present behind the front region.

Looking specifically at the GC evolution for Case B in Figure 2, one can observe that the overall shape and structure of the GC, including the nose region, appear to be reasonably well predicted by the simulation over the whole time interval over which experimental data is available ($t = 6.6t_0$). The simulation was run until about $t = 20t_0$, when the GC started interacted with the exit boundary. Careful inspection of the structure of the nose region as shown by experimental visualizations, particularly the waviness at the top of the head region, suggests that some of the large billows predicted in the simulations are also present in the experiments. The correlation between the crests observed near the current-ambient fluid interface in simulations and experiments is strong especially for the first few eddies behind the front of the GC (e.g., see the first three KH billows in Figure 2c). It is

Copyright © 2006 Taylor & Francis Group plc, London, UK

also interesting to point out that the good agreement observed for the relative position and size of some of the large billows in Figures 2c to 2e is in spite of the fact that in the experiment the gate removal has clearly introduced secondary motions that have altered the symmetry of the GC (compare concentration contours in simulation and experiment in Figure 2a, see also discussion in Hacker et al., 1996).

The simulation results a short time after the gate removal ($t = 1.4t_0$) show that the flow is practically symmetric around $x/h = 1.0$ (the gate position) except for the regions very close to the bottom wall and free surface, where different boundary conditions (no-slip vs. slip) were used. In this respect, numerical simulations have the advantage of allowing 'ideal' initial conditions to be specified. However, by $t = 4.6t_0$ (Figure 2c) the overall shape and length of the head region are quite similar in experiment and simulation. A large billow is present at the rear of the head region ($x/h \sim 1$) in frames c to e. The region of high mixing corresponding to this large eddy at the back of the head region is well predicted by the simulation. If one follows the evolution of this billow one can observe that the passage of the reflected bore is energizing the KH billow. Some of the denser fluid from the rear of the head region is in fact drawn upwards into this structure as the bore is passing (Figures 2c and 2d). The main difference between the simulation and experiment is observed between $x/h = 2$ and $x/h = 3$ in Figures 2d and 2e. While in the simulation a large, relatively coherent, KH billow can be observed around $x/h = 2.2$, in the experiment the mixing in the interface region appears to be stronger and no large scale eddy can be observed.

For case C experimental visualizations are available until $t = 12.4t_0$ close to the end of the slumping phase. Comparison of concentration contours in Figure 3 between experiment and simulation show that the structure of the gravity current is fairly well captured over the entire duration of the slumping phase (Figures 3d to 3j) once the influence of the initial mixing induced by the removal of the gate in the experiment becomes negligible. The KH billows, as visualized by concentration contours, appear to be slightly more coherent in the simulations. However, the main success of the 3D simulation is to predict fairly accurately the mildly stratified region present behind the head region and near the interface between the head and the ambient fluid, as well as the associated break up of the KH billows into smaller 3D eddies that are responsible for the high efficiency of the mixing in these regions. At the Grashof number of this simulation, the turbulence in the head region is strong enough to generate strong instabilities and energetic small scale eddies that can produce the relatively mildly stratified region behind the nose observable in the experiments (Figures 3f to 3j).

The predicted front positions in cases B and C shown in Figures 2 and 3 are close to the ones shown in the experimental visualizations. The corresponding range of Froude numbers ($Fr = U_f/\sqrt{g'h}$) defined with the front velocity U_f varies between 0.44 and 0.45 during the slumping phase for cases A, B and C (see Table 1) which compares reasonably well with the experimental values, $Fr = 0.45/0.46 \pm 0.01$. For the Reynolds number, the values from the simulations in the slumping phase are Re = 6,890, Re = 19,650, and Re = 10,875 which are very close to the experimental values of Re = 7,000, Re = 19,700, and Re = 11,000 for case A, B, and C respectively.

The propagation of the bore in the slumping phase is difficult to infer directly from the concentration contours because the bore propagates into the mixing layer created by the advancing head region of the GC. A more accurate way of determining the bore position is to look at the concentration vs. time variation on a line at a certain distance from the bottom. Such a plot is shown in Figure 4a for case B and in Figure 4b for case C at a relative distance of $y/h = 0.1$ from the

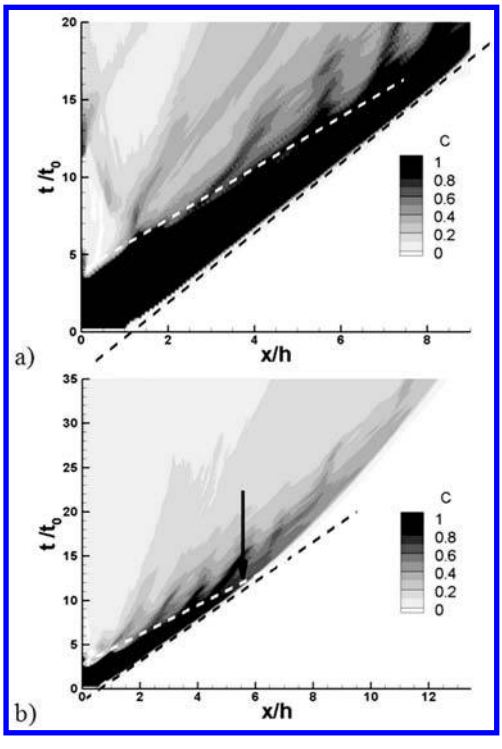

Figure 4. Evolution of concentration (density) with time along the x axis at a distance of $y/h = 0.1$ from the bottom. a) Case B; b) Case C. B	0.61	0.45	1.35
C	0.62	0.45	1.35

bottom. In the frames of Figure 4, one can observe the presence of a dark region in the form of a triangle with a very sharp angle corresponding to the intersection of the trajectories followed by the front and the bore. As these trajectories are close to straight lines, one deduces that the associated front and bore velocities are approximately constant. The slope of the lower dashed line corresponds to the speed of the front while the slope of the top dashed line, which sometimes cuts through the traces induced by the KH billows (observe the dark streaks present above the top dashed line), corresponds to the speed of the reflected bore. One can see that the slope, relative to the time axis, of the top dashed line is slightly higher than the one of the lower dashed line confirming that the bore velocity is higher than the front velocity. Table 2 summarizes the predicted values of the front and bore velocities. For all simulations the ratio of U_{bore}/U_f is between 1.35 and 1.36 which is within the experimental observed range (Rottman and Simpson, 1983).

For case B (Figure 4a) the two dashed lines do not intersect. This proves that the GC is still in the slumping phase at $t = 20t_0$ when the current approaches the right boundary. In contrast to that, incase C (Figure 4b) the intersection of the two trajectories (dashed lines) takes place inside the computational domain at $x/h \sim 5.5, t \sim 12.0t_0$ corresponding to a nondimensional streamwise length of $l \sim 8.9$, ($l = (x_f - x_0)/x_0$, x_f is the front position). The values of l obtained for cases A ($l = 7.4$) and C ($l = 8.9$) are consistent with experiments and theory (Rottman and Simpson, 1983). As the bore overtakes the front in Figure 4b, the border between the ambient fluid and the GC starts curving up. This signifies that the velocity of the front starts decaying in time, as expected to happen once the current transitions to the self-similar inviscid phase. Figure 5 shows the front position as a function of time in log-log scale for cases A, B and C. As expected, during the slumping phase all curves have a practically constant slope equal to 1 which corresponds to a constant front velocity in a log-log plot. As the bore overtakes the front, the GC begins to decelerate and the slope of the trajectory $l = l(t)$ decreases over a relatively short time period corresponding to the transition between the two phases before regaining a fairly constant value of 0.64 very close to the theoretical value of 2/3. This slope corresponds to a decay of the velocity in time proportional to $t^{-1/3}$.

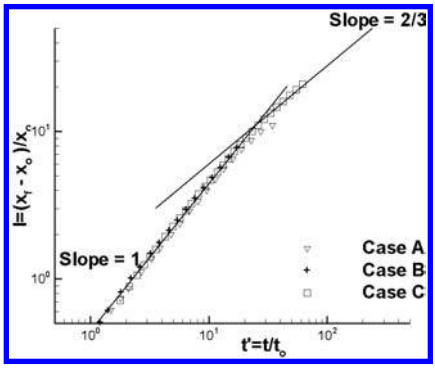

Figure 5. Nondimensional front position l, vs nondimensional time t'. Triangle indicates Case A, cross indicates case B; square indicates case C.

This is especially clear for case C for which the transition starts early at $t \sim 12t_0$ and simulation was run until close to $40t_0$, but less evident for case A where the domain was too short to allow the GC to evolve well into the self-similar phase.

Figure 6 shows the GC interface for case C visualized using a concentration isosurface (C = 0.5) at a time $t \sim 16t_0$ well past the transition into the self-similar phase. In the front part of the advancing head, shifting lobes divided by deep clefts can be observed. The lobe-and-cleft structure of the front region induces strong 3D perturbations of the cores of the KH billows. The width of the largest lobes is of the order of $0.18h$ (see inset in Figure 6 near the front of GC) at this stage of the evolution of the GC. The size of the penetration of the ambient fluid in the clefts is of the same order as the lobe size. Billows formed due to the amplification of the KH instabilities are observed in the shear zone (mixing layer) at the upper part of the head between the front ($x \sim 7.2\,h$) and $x \sim 6.0\,h$. Though these structures are considerably deformed in the spanwise direction, in part due to the presence of the lobes in the front region, the billows appear to span most of or the entire width of the computational domain (h) suggesting that the formation of these structures is a predominantly 2D process. The amplitude of the interface oscillations associated with the presence of these billows is growing between the front region, where they form, and the end of the head region. Downstream of the head region, the energy associated with the small scales is growing substantially, and the coherence of the KH billows is practically lost. This is because downstream of the front region the flow inside the GC head becomes turbulent. The 3D eddies from the near bottom-wall region (see also discussion of Figure 7) get swept into the upper parts of the head where they disturb the mixing layer and KH billows at the interface and force transition to turbulence. Thus, the GC region between x ~ 6 h and x = 2h situated behind the head

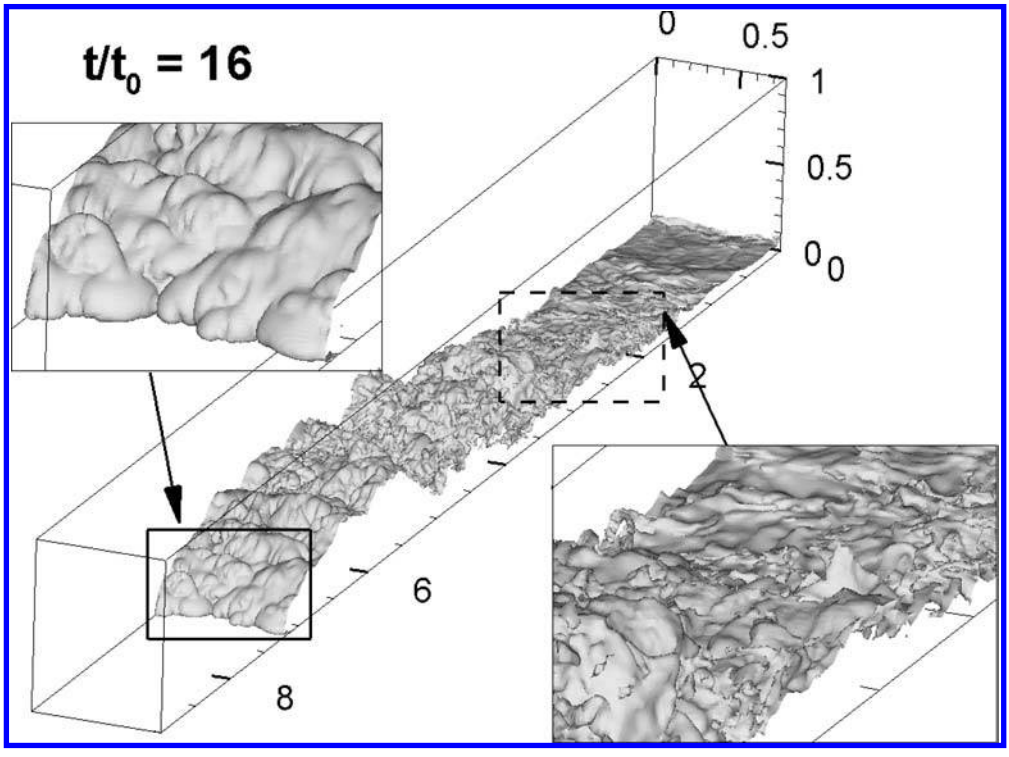

Figure 6. Visualization of gravity current interface for case C (concentration isosurface, $C = 0.5$) at $t/t_0 = 16$ with inset showing details at the front of the current where the lobe-and-cleft instability is captured and at the rear of the current where a the turbulence decay is strong.

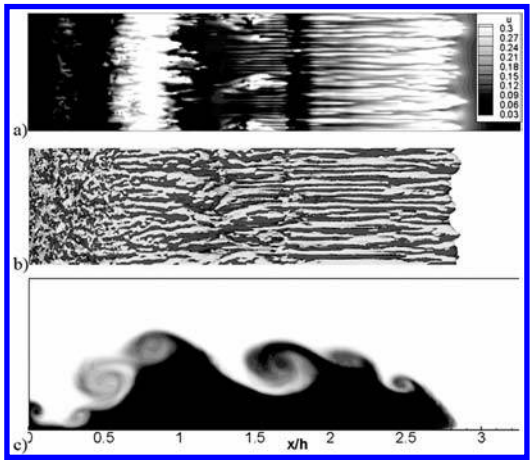

Figure 7. Visualization of the structure of the GC in the near-wall region for case B at $t/t_0 = 5$. (a) Streamwise velocity streaks in a horizontal plane situated at $y^+ \approx 11$ from the bottom wall; (b) Out of plane vorticity at the bottom wall (2 vorticity levels corresponding to $\omega_y = \pm 2u_b/h$ are shown); (c) Cross-sectional profile showing position of the GC using concentration contours.

is populated with small scale energetic eddies that are very effective in enhancing the local mixing. In fact, the flow in this region has most of the characteristics of a turbulent channel flow, including the presence of a broad energetic velocity spectrum with a small inertial range (not shown). This produces the mildly stratified region behind the head of the GC observed in Figures 3f to 3j. The simulation also capture the details of the mixing process in the interface region where wisps of heavier fluid from the downstream part of the head and from the near bed region behind the head are entrained first into the upper parts of the domain by the highly energetic 3D structures that resulted from the breaking of the KH billows before the action of the small scale eddies takes over the mixing process. The wisps are highly three-dimensional as seen in Figure 6. Eventually, these small-scale eddies that loose energy by mixing the lock and ambient fluid dissipate and the flow starts to relaminarize (see second inset in Figure 6). At $t \sim 16t_0$, this corresponds to the region with $x < 2\,h$ where the interface deformations are relatively negligible.

One of the interesting questions which the development of a high Grashof number GC in a channel

Copyright © 2006 Taylor & Francis Group plc, London, UK

raises is whether or not the turbulence content of the near bed region, over the area where the GC is turbulent, resembles the one observed in a constant density turbulent channel flow.

As the Reynolds number defined with the height of the GC in the head region and the front velocity is above 5,000 in all three cases both over the slumping phase and over the initial part of the self-similar phase simulated in the present work, one would expect that high and low speed velocity streaks will form very close to the bed and ejection and sweeps phenomena will be present. As the fluid in this region is in average stably stratified, the intensity of some of these phenomena is expected to be smaller than that observed in an equivalent channel flow. To investigate this, the streamwise velocity contours in a horizontal plane situated at about $y^+ = 11$ from the bottom wall are plotted in Figure 7a along with the out-of-plane vorticity contours on the bottom wall (2 vorticity levels corresponding to $\omega_y = \pm 2u_b/h$ are shown in Figure 7b) for case B at $t/t_0 = 5$. To help investigate the structure of the near-wall flow relative to the position of the head of the GC, the concentration contours in a x-y plane at the same time instant (between frames c and d in Figure 2) are shown in Figure 7c. Clearly, very close to the bottom wall a streaky structure is present in the vorticity contours over the entire length of the head of the GC. These vorticity streaks are clearly associated with the high and low streamwise velocity streaks that develop in the immediate vicinity of the bed as observed from the comparison of the corresponding velocity and vorticity streaks in Figures 7a and 7b. However, the velocity streaks at that position ($y^+ \approx 11$) appear to extend only from the front position ($x = 2.8\,h$) to about $1.3\,h$. Between $x = 2.8\,h$ and the end of the nose region ($x = 0.4\,h$) the streamwise velocity variations appear to be associated mostly with the presence of KH billows at the interface. These billows induce relatively large spanwise bands of low and high streamwise velocity (see discussion of Figure 8). The spanwise low velocity band present at $x \sim 1.7\,h$ is also associated with one of the KH billows. In fact, as shown in Figure 7b, these streaks are present up to the rear of the head region but the additional velocity induced by the billows present in the interface region sometimes masks their presence. Behind the head region the streaks disappear as the local Reynolds number is decaying below values at which turbulent streaks can form or be maintained. The average width of these streaks is about $0.025\,h$ and their average length decays from about $0.8\,h$ in the upstream part of the nose to about $0.5\,h$ in the downstream part of the nose. The streaks appear to be well resolved given the grid density used in the spanwise direction. The presence of these streamwise velocity streaks is associated in channel flows with the legs of the hairpin like vortices that are present over the near-bed region. We suspect a similar phenomenon is

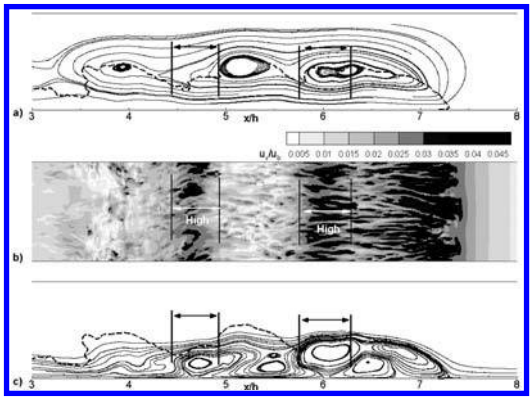

Figure 8. Visualization of GC and bed friction velocity distribution for case C at $t/t_0 = 16$ (a) Instantaneous streamlines in an x-y section. Dashed line corresponds to the GC interface; (b) Instantaneous distribution of bed friction velocity u_τ/u_b; (c) Instantaneous streamlines in the same x-y section in a moving frame of reference translating with the front velocity.

present in the head region where these counter-rotating vortices can displace fluid from the immediate vicinity of the bottom wall toward higher levels, thus promoting mixing. Their presence should also explain the streaky structure of the concentration field observed underneath the head of the GC (not shown). This is especially important in the region close to the front of the nose where the action of these longitudinal vortices can induce further perturbations of the front region that can amplify the instabilities responsible for the formation and growth of the lobes. In fact, one can speculate that some of these counter-rotating vortices can help accelerate the entrainment of some of the lighter ambient fluid overrun by the propagating GC toward higher levels inside the GC.

One of the most important quantities for practical consequences related to the formation and action of compositional GC in rivers and estuaries is the amount of sediment these currents can entrain and carry before the sediment deposits again (e.g., lock structures at dam facilities). To be able to estimate global quantities related to the entrainment (e.g., the scour produced by each passage of such a current), the spatio-temporal distribution of the bed shear stress has to be known, especially in numerical models in which the entrainment is generally function of the difference between the actual bed shear stress and the critical bed shear stress value given by Shields diagram. In this regard, accurate prediction of this quantity is of critical importance for the overall practical use of the model. In this paper, we are going to discuss just one realization corresponding to the distribution of the friction velocity for case C at $t = 16t_0$ well into the self-similar phase. The first obvious feature observed in Figure 8b is the

Copyright © 2006 Taylor & Francis Group plc, London, UK

streaky structure of the zones characterized by high bed shear stress (friction velocity) values in the region beneath the head of the GC. Its position can be inferred from Figure 8a in which the concentration contours and 2D streamlines were represented in an x-y section at the same moment in time. These streaks of high bed shear stress are obviously related to the high velocity of the front and to the presence of high speed velocity streaks in the near bed region beneath the head of the GC as shown in Figure 7.

The other feature is the presence of several spanwise bands of high and respectively low friction velocity values in the downstream part of the GC. Interestingly, the bands of high friction velocity values do not always (in fact animations of the bed shear stress distributions for all the three simulations show that this is the case most of the time) correlate with the presence of a KH billow in the interface region just above it. A good example is the high friction velocity band present at $x \sim 4.7\,h$ which appears to form in between two KH billows (compare Figures 8a and 8b). However, if one draws the same 2D instantaneous streamlines in a frame of reference translating with the front velocity, one can observe that the position of the bands of high bed shear stress correlates quite well with the presence of vortices inside the GC that practically touch the bottom wall. As the friction velocity values inside these spanwise bands are comparable to those observed in the upstream part of the head region, it is clear that the GC will entrain sediment over a relatively large distance behind its front. Whether or not the position and intensity of the bed shear stress inside these bands can be accurately captured by a 2D model needs further investigation.

The streamline patterns (x-y section) drawn in Figure 9 in a coordinate system advancing with the front velocity at two time instances of the evolution of the GC in case C indicate that for gravity currents developing in channels with a lateral wall the foremost point (nose) is not a stagnation point. This is similar to the case of a compositional GC developing into an infinite channel with no end walls at a lower Grashof number studied by Hartel et al. (2000a). The topology of the nose region is similar to the one observed by Hartel et al. (2000a) not only over the slumping phase (see Figure 9a) when the front velocity is constant in both cases and the physics of the GC is similar but also over the inviscid phase (see Figure 9b). The only difference with the patterns observed over the slumping phase is that the flow beneath the nose, but outside the current head, becomes more mixed (Figure 9b). This make us to expect the lobe-and-cleft instability in the case of finite lock volume GC is driven by the same mechanism (unstable stratification region between the nose and the stagnation point) identified by Hartel et al. (2000a) for the case of an infinite lock volume GC. The vertical distance Δy_n between the

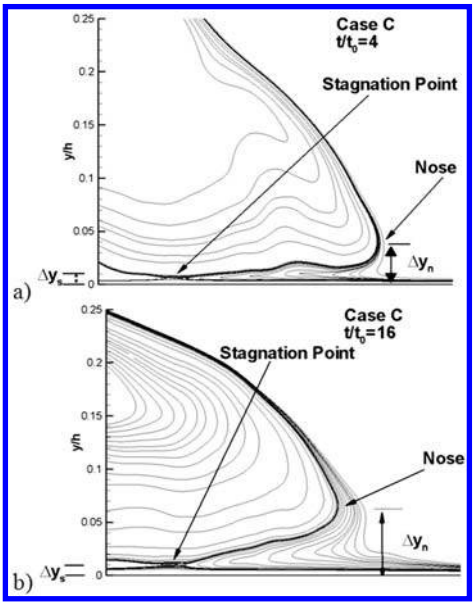

Figure 9. Structure of the head of the gravity current for case C in a moving frame of reference during (a) Slumping phase; (b) Self-similar phase.

nose and the bottom wall appears to increase with time. For instance, $\Delta y_n = 0.039\,h$ at $t = 4t_0$ during the slumping phase and $\Delta y_n = 0.065\,h$ at $t = 16t_0$ during the self-similar phase.

5 CONCLUSIONS

Several high resolution LES simulations of compositional gravity currents at Grashof numbers in the range of 10^8–10^9 ($Re \sim 10^4$, $Sc \sim 600$) were performed. The simulations were carried out using a dynamic model that limited the amount of dissipation introduced into the flow domain and a discrete energy-conserving Navier-Stokes non-dissipative solver than allowed to obtain robust and accurate solutions on meshes that are much coarser than DNS requirements. The present finite-volume lock-exchange simulations allowed the study of the evolution of the current well into the self-similar phase for one of the simulations (case C). Previous 3D highly resolved simulations considered only the case of an infinite channel (no lateral wall) compositional current (Hartel et al., 2000a) where the self-similar phase is not present and the case of a particulate current developing in a finite channel (Necker et al., 2002, 2005) where the physics in the latter stages of evolution of the current is very different from that of a compositional current due to the deposition of the particles. In these previous simulations the values

Copyright © 2006 Taylor & Francis Group plc, London, UK

of the Grashof numbers were around 10^6–10^7 corresponding to Reynolds numbers defined with the front velocity of less than 1,000, about an order of magnitude lower than the ones considered in the present study. This allowed the study of the evolution of the GC and associated instabilities for cases in which the flow in the head region was strongly turbulent.

Three configurations with a different depth over length ratio of the initial lock fluid were considered, corresponding to the cases studied experimentally by Hacker et al. (1996). The results from the 3D LES simulations were found to exhibit the classic characteristics of gravity currents, including the lobe-and-cleft structure at the leading edge of the GC head, the shedding of quasi-2D KH billows from the front region and their subsequent breaking into small scale 3D structures that strongly enhanced the mixing at the interface between the top of the GC and the surrounding fluid. In addition, the simulation results were able to accurately replicate the observed evolution of the nose region, the ratio between the bore and front velocities over the slumping phase, the variation of the front speed over the slumping and self-similar phases and the position of the transition between these two phases. The topology of the flow in the front region was not found to change significantly as the current transitioned between the slumping phase and the self-similar phase and to be similar to the one observed in 3D DNS simulations at lower Reynolds numbers (Hacker et al., 2000) suggesting that the unstable stratification region between the nose and the stagnation point is the main cause for the lobe-and-cleft instability. High and low speed velocity streaks, very similar to the one observed in channel turbulent flows, were identified in the near-bed region beneath the upstream part of the head of the current. As the turbulence started decaying and the flow transitioned back to laminar regime in the region behind the head, the streaky structure was found to disappear. Details of distribution of the bed friction velocity on the bottom wall that controls the entrainment of the sediment in the case in which the compositional current propagates over a loose bed were investigated.

ACKNOWLEDGEMENTS

We would like to thank Prof. S.B. Dalziel for allowing us to use some of his published experimental results for validation of our method.

Bedload transport in the case of seepage flow

Simona Francalanci[1], Gary Parker[2] & Luca Solari[1]
[1] *University of Florence, Department of Civil Engineering, Florence (Italy)*
[2] *University of Illinois, Department of Civil and Environmental Engineering and Geology, Urbana, Illinois (USA)*

ABSTRACT: The Shields number provides a classical non-dimensionalization expressing the relative mobility of a sediment particle on the bed of a river. It is not commonly recognized, however, that the Shields number implicitly contains the assumption of a hydrostatic pressure distribution in the water immersing the particles. If the concept underlying the Shields number is correct, however, the Shields number should be generalizable to non-hydrostatic pressure distributions. Here such a generalization is attempted for the case of a non-hydrostatic pressure distribution produced by a vertical seepage flow: the effect of both upward and downward seepage flow on bedload transport was investigated (Francalanci, Parker and Paris 2005), suggesting that an appropriately generalized Shields number is needed to capture the effect of a seepage flow on sediment mobility. A theoretical and numerical model is here proposed to account the effect of seepage flow on sediment mobility and bedload transport.

1 INTRODUCTION

The effect of an upward seepage flow on incipient sediment motion has been studied by Cheng and Chiew (1999): they found that the critical shear velocity is reduced in the presence of upward seepage. The same authors studied a turbulent open-channel flow with upward seepage and found out that the bed shear stress also shows a steady reduction with increasing upward seepage velocity (Cheng and Chiew 1998a; Cheng and Chiew 1998b). Also, recently the velocity distribution of turbulent open-channel flow with bed suction was theoretically and experimentally investigated (Chen and Chiew 2004).

In the case of seepage flow, the sediment bed mobility is affected by the vertical distribution of the pressure gradient, which is varying from the hydrostatic distribution, and this deviation creates an increased or decreased buoyant force which can give more or less mobility to the sediment particles. The Shields number itself is affected by the seepage-induced non-hydrostatic pressure distribution.

The effect of vertical seepage flow on bedload transport was recently experimentally investigated (Francalanci 2005; Francalanci, Parker and Paris 2005): the results showed that in the case of upward seepage net scour was observed in the zone of seepage, while the opposite effect was observed in the case of downward seepage.

The main goal of the present contribution is to quantify the effect of seepage flow on bedload transport, underlying the effects which play an important role on the Shields parameter. To this aim, a theoretical and numerical model is developed to solve the morphodynamic evolution of the bed elevation in the case of seepage flow, and to substantiate the generalized Shields formulation, which accounts the effect of the buoyant force on bedload transport due to the seepage flow.

2 EXPERIMENTAL RESULTS

Experiments were carried out in a glass-sided sediment-recirculating, water-feed flume that was 15 m long, 0.61 m wide and 0.4 m deep. A skecth of the experimental set-up is shown in Figure 1. Upward or downward groundwater flow was introduced in a reach between 9 m and 10.1 m downstream of the upstream end of the flume. The seepage flow passed through a seepage box buried underneath the flume bed.

A relatively uniform sediment was chosen for the experiments in order to minimize sorting effects and to avoid the presence of bedforms in flume bed. The sediment in the flume equilibrated to a median size D_{50} and geometric mean size D_g both near 0.84 mm, a size D_{35} near 0.69 mm, a size D_{90} near 1.48 mm and a geometric standard deviation σ_g near 1.62. 6	12	30, 60, 90

conductivity K was measured with a D'Arcy tube and found to be near 0.0025 m/s.

Velocity measurements were performed using a micro-propeller with a diameter of 14 mm. A point gage was used to measure water surface elevations and the elevation of the bed. Five bed elevation points were measured for each transverse cross-section; the average of these values was assumed as the crosssectional mean value of the bottom elevation for the purpose of characterizing long profiles. Measurements of sediment transport in the flume were obtained by diverting slurry from the sediment recirculation pipe and measuring the sediment mass collected as a function of time.

The experimental protocol was designed around Table 1. The table encompasses inflow discharges Q_w ranging from 12 to 20.6 liters/sec, upward seepage discharges $Q_{seepage}$ ranging from 20–140 liters/min and downward seepage discharges $Q_{seepage}$ ranging from 30–90 liters/min, for a total of 27 experimental conditions, 18 of which pertained to upward seepage and 9 of which pertained to downward seepage. In principle, each experimental condition corresponded to a set of three experiments, one with no seepage, one with data acquired after 10 minutes of seepage (short-term experiment) and one with data acquired after 2 or 4 hours of seepage (the longer time span corresponding to lower seepage rates).

The experimental set-up and protocol are described in Francalanci (2005), Francalanci et al. (2005), Francalanci et al. (2006), and the results are here briefly summarized in order to discuss the appropriately generalized Shields number able to capture the effect of a seepage flow on sediment mobility. Indeed, the described set-up allowed to measure the scour or fill produced by the seepage flow in a region of the erodible bed.

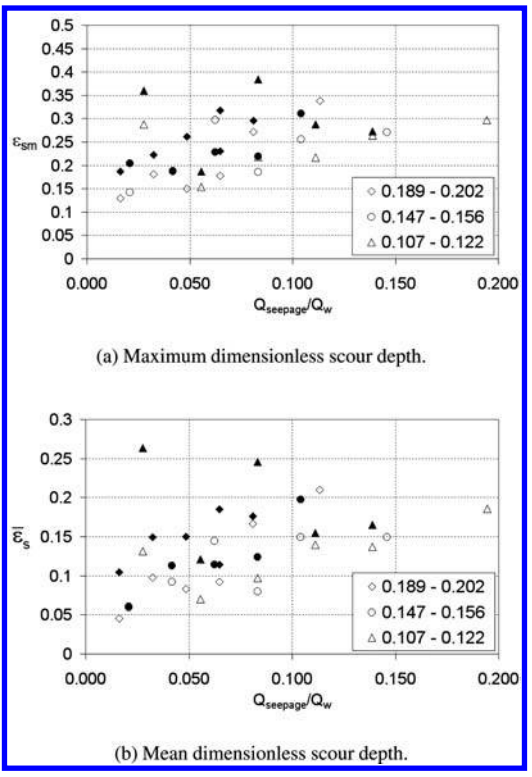

Figure 2. Maximum and mean dimensionless scour depth plotted against discharge ratio $Q_{seepage}/Q_w$ for different range of the average Shields parameter in the case of zero seepage at the equilibrium conditions, for the short-term experiments (white dots – 10 minutes) and for the long-term experiments (black dots – 4 hours, gray dots – 2 hours).

The experiments on the effect of seepage on bed morphodynamics induced to the following observations: the channel has scoured in the zone of upward seepage in the case of both short-term and long-term experiments, the scour in the seepage zone has been accompanied by some bed aggradation in the zone upstream. This latter pattern is dictated by the constraint of sediment recirculation; since the total mass of sediment is conserved, the mass of sediment eroded from the seepage zone must be deposited elsewhere. As a summary of the experimental results, the dimensionless maximum scour depth ϵ_{sm} and the mean scour depth $\overline{\epsilon}_s$ is plotted against the discharge ratio $Q_{seepage}/Q_w$ in Figure 2(a)–2(b). Both the previous quantities were made dimensionless using the mean

Copyright © 2006 Taylor & Francis Group plc, London, UK

flow depth H that prevailed at mobile-bed equilibrium before the onset of seepage. The overall tendency is for both measures of scour to increase with increasing discharge ratio. The experimental results in the case of downward seepage flow showed opposite trend and are not reported here.

3 EFFECT OF SEEPAGE ON SEDIMENT MOBILITY

The experimental results, briefly reported in the section above, clearly indicate that upward seepage induces scour and downward seepage induces deposition. It is of value to provide an overview as to how flow-sediment interaction in the presence of seepage gives rise to scour or deposition. Three effects play important roles: the effect of seepage on the bed shear stress, the direct effect of seepage on the Shields number itself, and the effect of seepage on the critical Shields number for the onset of motion.

Cheng and Chiew (1998a,b) have shown that over a wide range of conditions upward seepage reduces the bed shear stress τ_b in the zone of seepage. The same model implies that downward seepage increases the bed shear stress. The effect can be illustrated in terms of the St. Venant equations for conservation of water and flow momentum in the presence of seepage, which take the forms in the one-dimensional case:

$$\frac{\partial H}{\partial t} + \frac{\partial UH}{\partial x} = v_s \tag{1}$$

$$\frac{\partial UH}{\partial t} + \frac{\partial U^2 H}{\partial x} = -gH\frac{\partial H}{\partial x} + gHS - \frac{\tau_b}{\rho} \tag{2}$$

where x is the streamwise distance, t is time, H is the water depth, U is flow velocity and S is the mean longitudinal slope. The continuity equation (eq. 1) shows the presence of the seepage velocity v_s as boundary velocity at the bottom, which is related to the vertical pressure gradient inside the sand layer by means of the hydraulic conductivity K from the Darcy's law. Reducing the above-two equations for steady flow, Cheng and Chiew (1998a) found that:

$$\tau_{*b} = \rho u_*^2 = \rho g H \cdot sin\alpha - \\ -\rho g H \cdot \frac{dH}{dx}\left(cos\alpha - \frac{\beta U^2}{gH}\right) - 2\beta\rho U v_s \tag{3}$$

In the above relation $u_* =$ shear velocity and $\alpha =$ longitudinal bed slope angle. A deeper analysis of the latter relation, which is discussed in details in Francalanci et al. (2006), proved that the net effect of seepage was always to reduce the bed shear stress relative to the value that would prevail in the absence of seepage.

Two further effects of seepage act to change the mobility of the sediment itself. One of these is the direct effect of the seepage-induced non-hydrostatic pressure gradient on the denominator of the Shields number; the Shields parameter was evaluated with the following generalized expression, which accounts the effect of vertical seepage by means of an additional term on the denominator given by v_s/K:

$$\tau_* = \frac{\tau_b}{\left(\rho_s - \rho\left(1 + \frac{v_s}{K}\right)\right) gD} \tag{4}$$

Hence, when the velocity v_s is positive (upward groundwater flow) the particle is effectively lighter and more movable, and the Shields parameter is increased, while when the velocity is negative (downward groundwater flow) the Shield parameter is decreased.

Hence, there are two combined and opposite effects on the dimensionless Shields parameter in the presence of seepage: the effect of an upward seepage leads to a reduction of the bed shear stress, but also a reduction of the denominator of the Shields parameter due to a non-hydrostatic pressure gradient. The opposite behavior is expected in the case of downward seepage.

The last effect on sediment mobility is associated with a change in the critical Shields number τ_{*cr} in the presence of upward or downward seepage, as elucidated by Cheng and Chiew (1999). The seepage velocity corresponding to the maximum hydraulic gradient is defined as the critical seepage velocity, at which the inception of the quick condition takes place, and is evaluated from Cheng and Chiew (1999) data. The equation derived by Cheng and Chiew (1999):

$$\left(\frac{u_{*c}}{u_{*oc}}\right)^2 = 1 - \left(\frac{v_s}{v_{sc}}\right) \Rightarrow \left(\frac{\tau_*}{\tau_{*oc}}\right) \tag{5}$$

was used to evaluate the ratio between the critical shear velocities, with and without seepage, under the initial condition for sediment transport, as a function of the ratio between the seepage velocity v_s and the critical seepage velocity in the case of quick sand v_{sc}, in the performed experimental conditions. The above relation indicates that upward seepage decreases the threshold Shields number for the onset of sediment motion, as demonstrated by the experiments of Cheng and Chiew (1999). Conversely, downward seepage should increase the threshold Shields number for the onset of motion.

4 THEORETICAL AND NUMERICAL MODEL

The experimental results clearly indicate that upward seepage induces scour and downward seepage induces deposition. A theoretical and numerical model of the morphodynamics of erodible-bed open-channel flow

Copyright © 2006 Taylor & Francis Group plc, London, UK

in the presence of seepage was employed to understand which is the effect on sediment mobility and on the Shields parameter.

The effect of seepage can be modeled numerically using a 1D formulation. Where η denotes bed elevation, the Exner equation of sediment conservation takes the form:

$$(1-\lambda_p)\frac{\partial \eta}{\partial t} = -\frac{\partial q_b}{\partial x} \tag{6}$$

The bedload discharge, q_*, made dimensionless in terms of the Einstein number $\sqrt{(\rho_s-\rho)gD^3/\rho}$, was evaluated with the interpolated relationship from experimental data, measured during the experiments with no seepage:

$$q_* = 0.0201 \cdot \left(\frac{\tau'_*}{\tau_{*cr}}\right)^{2.5266} \tag{7}$$

which agrees well with the Ackers and White (1973) relationship, which was derived in the absence of seepage. Such relation was needed in order to test the Shields number as a characterization of sediment mobility in terms of a sediment transport relation based on the Shields number. The critical Shields number τ_{*cr} takes the above-quoted value of 0.0388, while τ'_* is the reduced Shields number, related to the skinfriction only, and hence to sediment transport.

In a sediment-recirculating flume, the boundary condition on eq. 6 is cyclic; i.e. where $x=0$ denotes the upstream end of the flume and $x=L$ denotes the downstream end,

$$q_b|_{x=L} = q_b|_{x=0} \tag{8}$$

The classical quasi-steady approximation was used in conjunction with the standard shallow water equations in calculating the flow, so that eq. 1 and 2 take the form:

$$\frac{\partial UH}{\partial x} = v_s \tag{9}$$

$$\frac{\partial U^2 H}{\partial x} = -gH\frac{\partial H}{\partial x} + gHS - \frac{\tau_b}{\rho} \tag{10}$$

Bed shear stress τ_b was evaluated from a logarithmic formulation;

$$\tau_b = \rho C_f U^2, C_f^{1/2} = 2.5ln\left(11\frac{H}{k_s}\right) \tag{11}$$

where C_f denotes a bed friction coefficient and k_s denotes a roughness height. The roughness height k_s was compute as $k_s = n_k D_{50}$. The dimensionless parameter n_k was found to vary from flow to flow due to the effect of bedforms. Here the value of n_k was calibrated using experimental data for mobile-bed equilibrium flows in the absence of seepage, and the same value of n_k was applied to a corresponding experiment with seepage.

The system of equations 6–9–10 was solved numerically using a decoupling between flow dynamics and morphodynamics. The latter assumption is reasonable in the case of subcritical flow and in the case of slow changing of bed elevation compared to the flow dynamics. The equations could be solved by integrating upstream from the downstream end of the flume. First, the steady solution of the subcritical backwater profile was evaluated from the flow equation imposing the downstream water depth at the end of the flume. The numerical schemes is explicit, with predictor – corrector steps, and upwinding differencing. The bedload discharge q_b was evaluated, and the input bedload discharge was assumed to be equal to the ones in the downstream cross-section. The wall at the downstream end of the flume, however, imposed a set bed elevation instead. A quasi-equilibrium calculation using the backwater profile evaluated at the previous time step allowed an estimate of the downstream depth that a) led to the satisfaction of sediment conservation and b) specified a downstream boundary condition for a backwater calculation of the flow field which takes into account the constraint of inerodibility of the bed near the overflow wall at the downstream end of the flume. Finally, Exner's equation was solved to estimate the new bed elevation at the following time step.

An abrupt change from a vanishing seepage velocity to a finite seepage velocity at $x=9$ m, and a similar abrupt change to vanishing seepage velocity at $x=10.1$ m tended to result in numerical instability in the model. Spurious oscillations were suppressed in two ways. Firstly, an artificial diffusion term was added to eq. 6, modifying it to

$$(1-\lambda_p)\frac{\partial \eta}{\partial t} = -\frac{\partial q_b}{\partial x} + D_f\frac{\partial^2 \eta}{\partial x^2} \tag{12}$$

Values of D_f in the range $10^{-5}-10^{-4}$m^2/s were found to be adequate for this purpose. Secondly, the abrupt change in seepage velocity at the upstream and downstream ends of the seepage reach was replaced with very short zones over which seepage velocity varied in smoothly according to a sinusoidal function. In addition, the seepage rate was slowly increased at the beginning of each numerical experiment until it attained its asymptotic value. Two input parameters for the model were set as follows: porosity $\lambda_p = 0.3$ and hydraulic conductivity $K = 0.0025$ m/s.

4.1 *Numerical results*

The capability of the numerical model to describe the effect of seepage on sediment mobility is here discussed. As a preliminary result, the numerical model

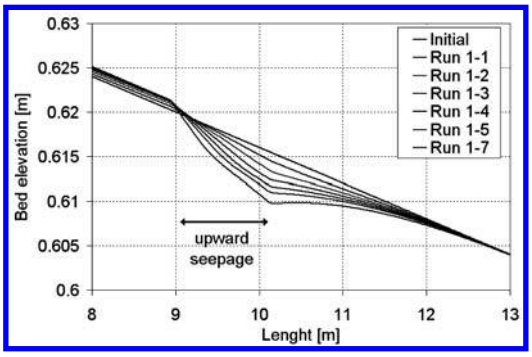

Figure 4. Local bed profiles of scour in the case of hydrostatic pressure. The deeper scour depths are related to the higher seepage flows.

was solved in the case of upward seepage flow at the bed but without considering the effect on the Shields parameter, which was evaluated with the following well-known equation:

$$\tau_* = \frac{\tau_b}{(\rho_s - \rho)gD} \tag{13}$$

In Figure 3 the maximum scour, measured for the short term experiments with increasing upward seepage, is compared with the numerically evaluated scour. The local bed profile at the end of the short term experiments is shown in Figure 4 in the case of hydrostatic pressure distribution in the sand layer, while the evolution of the maximum scour depth in time is shown in Figure 5. The latter results show that this implementation of the model is not able to catch the maximum scour in the area of upward seepage and to reproduce the local bed evolution, in terms of space and time.

Hence, the generalized expression of the Shields parameter (eq. 4) was used in the numerical model to consider the effect of non-hydrostatic pressure and the critical Shields parameter was corrected to take into account the effect of upward seepage (eq. 5). The local

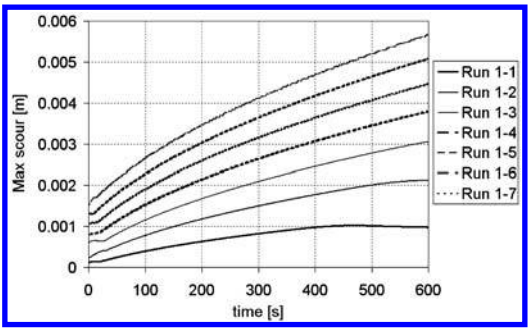

Figure 5. Maximum scour versus time in the case of hydrostatic pressure: the higher scour depths are related to the higher seepage flows.

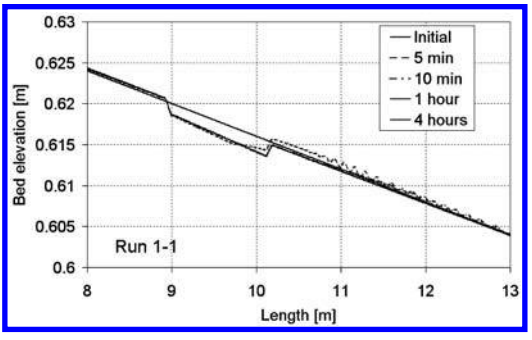

Figure 6. Numerical experiment Run 1-1 ($Q_w = 20.5$ l/m, $Q_{seepage} = 20$ l/m).

bed profile at different times during the experiment is shown in Figures 6 and 7 for two different values of seepage flows, $Q_{seepage} = 20$ l/m, 60 l/m, and the same value of the main flow $Q_w = 20.5$ l/s. As the seepage flow increases, the maximum scour is increased, in well agreement with the experimental evidence. After 5 minutes of groundwater flow the scour is close to the maximum value, while deposition phenomena is

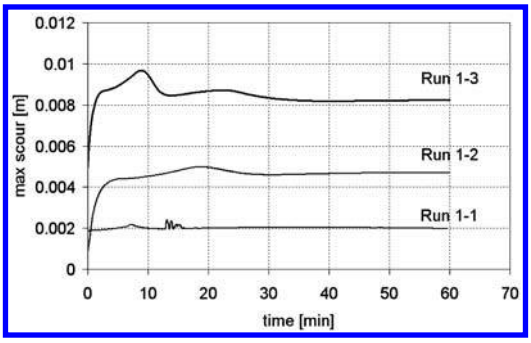

Figure 8. Maximum scour versus time.

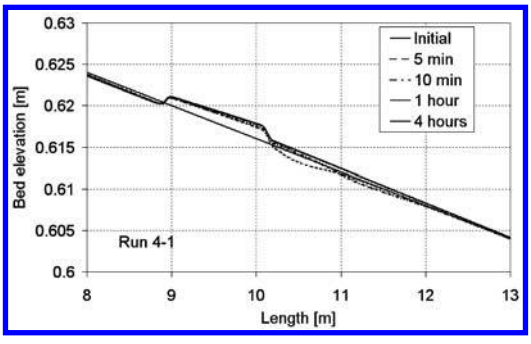

Figure 9. Numerical experiment Run 4-1 ($Qw = 20.5$ l/m, $Q_{seepage} = 30$ l/m).

established downstream and upstream of the seepage area. After 10 minutes the local bed profile is close to the equilibrium configuration, and the bed profile shows deposition upstream and reduced erosion downstream of the seepage area. After 1 hour the bed profile does not change anymore, and it is approximately the same after 4 hours.

The time evolution of the maximum scour depth predicted by the numerical model is plotted in Figure 8 for three different experiments with the same flow Q_w, and increasing seepage flow, $Q_{seepage}$. The maximum scour in time along the flume reaches the maximum value after 10–20 minutes of groundwater flow, after which it stabilizes around a mean value.

The numerical results of a downward seepage experiment are shown in Figure 9. The bed profile shows exactly opposite features of deposit and erosion than in the case of upward seepage flow.

Moreover, it can be observed that the mean slope of the bed in seepage area, numerically computed, is increased in the case of upward seepage flow and decreased in the case of downward seepage flow. The mean slope evaluated from the numerically computed profile is plotted versus the discharge ratio in Figure 10, showing a quasi-linear relationship.

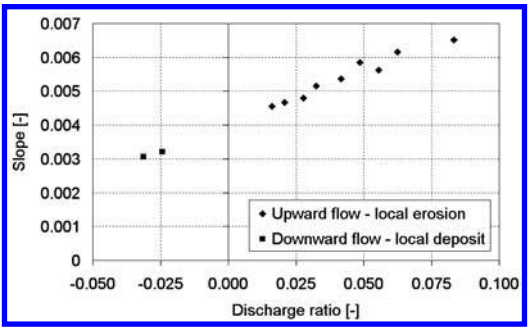

Figure 10. Average local slope, numerically computed, in upward/downward seepage area.

5 COMPARISON OF EXPERIMENTAL AND NUMERICAL RESULTS

The results of the numerical computed profiles are compared to the measured short-term and long term bed profiles. The comparison of the initial measured and numerical bed profiles with the final ones are shown in Figure 11 for Run 1-1. The features of the bed profile which were revealed experimentally are well reproduced by the numerical model. Both the experiments and the numerical model show net scour in the seepage zone, even if the long-term measured scour seems to be under-estimated by the model.

In the case of Run 1-3, Figure 12 shows that the numerical model reasonably captures the observed pattern of seepage-induced scour both in the short and long terms. Also deposit upstream and erosion downstream are shown to be in good agreement. The numerically calculated profiles are smoother than the observed profiles because the numerical model does not capture the individual bedforms.

The comparison of the downward seepage measured profiles with the numerical ones is shown in Figure 13 for Run 4-1. The numerical model somewhat underpredicts the pattern of deposition induced by downward seepage, but the overall patterns of the experiments are clearly reflected in the model results.

Figure 14 allows comparison between predicted and observed mean scour depths/deposition thicknesses. Values are shown for 9 experiments with upward seepage and 2 experiments with downward seepage. The negative scour depths in Figures 14(a) and 14(b) indicate deposition. Figure 14(a) pertains to short-term experiments, and Figure 14(b) pertains to long-term experiments. Dimensionless scour is plotted against the discharge ratio $Q_{seepage}/Q_w$.

Besides some experimental scattering, the agreement is good and the experimental scour is only lightly underestimated: the trends are very similar, and most of the predicted values fall within the scatter of the observed values.

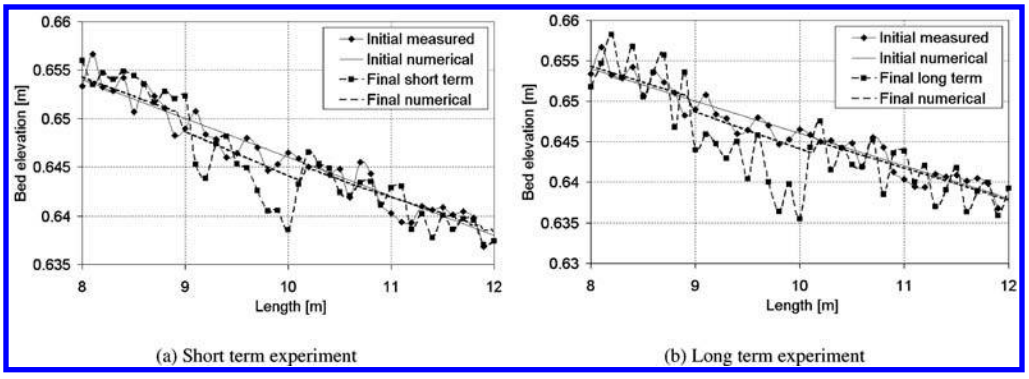

Figure 11. Comparison of experimental and numerical results, Run 1-1 ($Q_w = 20.5$ l/m, $Q_{seepage} = 20$ l/m).

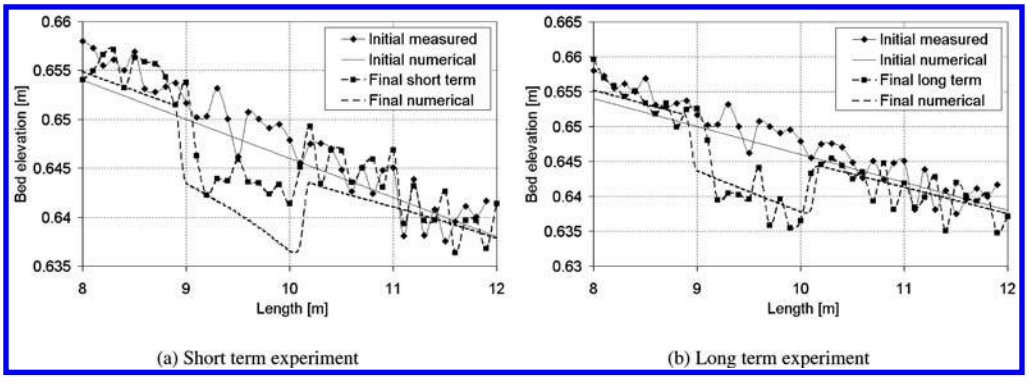

Figure 12. Comparison of experimental and numerical results, Run 1-3 ($Q_w = 20.5$ l/m, $Q_{seepage} = 60$ l/m).

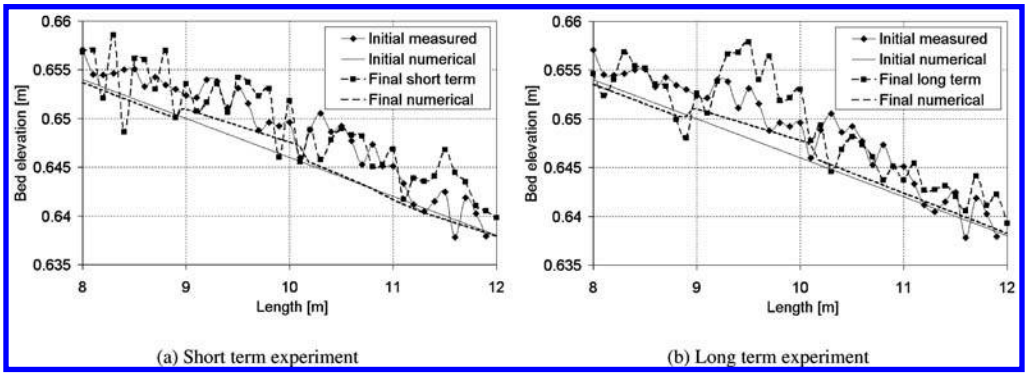

Figure 13. Comparison of experimental and numerical results, Run 4-1 ($Q_w = 20.5$ l/m, $Q_{seepage} = 30$ l/m).

The results of Figure 14 allow for the following tentative conclusion. Incorporation of the effect of seepage so as to a) correct the prediction of the bed shear stress, b) correct the critical Shields number and c) correct the expression for the Shields number itself so as to account for the non-hydrostatic vertical pressure gradient induced by seepage allows the numerical model to capture with reasonable accuracy the effect of seepage on bed morphodynamics. It can similarly be tentatively concluded that the bedload transport equation 7 determined in the absence of seepage effects can be applied to the case where a seepage-induced non-hydrostatic vertical pressure gradient prevails by means of the generalizations 5 and 4.

6 CONCLUSIONS

The dimensionless Shields number, or Shields stress, implicitly includes the assumption of a hydrostatic pressure distribution in its denominator. The assumption is reasonable for quasi-steady, quasi-uniform rectilinear sediment transport, but breaks down in the case of sediment transport near an obstacle such as a bridge pier. A generalization of the Shields number is proposed for the case of a near-bed non-hydrostatic pressure gradient in the vertical direction. Such a gradient can be produced by upward or downward groundwater flow.

In the present work the experimental results of the study of sediment transport over a bed with vertical groundwater flow, obtained by Francalanci (2005), are analyzed to estimate the effect of seepage flow on bedload transport. The experimental observations showed a clear effect of seepage on sediment transport: in the case of upward seepage net scour was observed in the zone of seepage; the opposite effect was observed in the case of downward seepage.

A theoretical and numerical model has been implemented to analyze bed morphodynamics in the presence of seepage: the experimentally measured patterns of scour/deposition were predicted reasonably well by the numerical model of morphodynamic evolution that incorporated the following seepage-induced effects: a) modification of the bed shear stress, b) modification of the critical Shields number for the onset of motion and c) modification of the Shields number itself to account for the non-hydrostatic pressure distribution. Comparison of experimental and numerical results show that the sediment transport relation, evaluated in the case of hydrostatic pressure distribution, can be applied to the non-hydrostatic pressure distribution, employing a generalized expression for the Shields parameter, which considers the non-hydrostatic pressure gradient in the sand-layer to drain water, and for the critical conditions of the onset of motion, to estimate the local average scour or deposit depth.

ACKNOWLEDGEMENTS

The authors are grateful to Prof. Enio Paris, University of Florence (Italy), for useful discussions and scientific support on carrying out this work. CERAFRI Research Center is acknowledged for sustaining the publication of this work.

Long-term morphological behavior of Verbois reservoir (Geneva)

DIAE, Geneva, Switzerland

ABSTRACT: This paper presents a study of the long-term morphological behaviour of the Verbois reservoir in Geneva, Switzerland. The reservoir has been constructed on the Rhone River downstream of Geneva in 1942 and has a total length of 12 km. Sedimentation problems appeared immediately after dam construction, with an averaged yearly deposited volume of fine sediments of about 400,000 m^3. To minimize sedimentation, flushing events have been performed on a tri-annual basis. These generate huge environmental impact. To deal with this, a study has been performed of the potential morphological behaviour of the reservoir in the absence of further flushing events for the next 50 years. Analytical and numerical computations have been performed over a total river and reservoir length of about 25 km. These indicate that the reservoir will continue its sedimentation rather quickly during the first 10-15 years after stoppage of flushing, followed by a progressive stabilization of the sedimentation, resulting in a dynamic equilibrium on the long term. This equilibrium corresponds to a main meandering channel with sediments along the inner bends of the former Rhone River.

1 INTRODUCTION

1.1 *Purpose of the study*

This paper presents a study of the long-term morphological behavior of the Verbois reservoir in Geneva, Switzerland. The reservoir has been constructed in 1942 on the Rhône River downstream of Geneva and has a total length of 12 km. Significant sedimentation occurred after dam construction. To minimize sedimentation, flushing events have been performed on a tri-annual basis. These allow maintaining a minimum free volume. However, they also generate huge environmental impact downstream. To deal with this impact, a detailed study has been performed of the potential morphological behavior of the Verbois reservoir in the absence of any further flushing events for the next 50 years.

The main purpose of the study is to generate detailed hydraulic and morphologic characteristics necessary to answer the following questions:

- What are the eventual risks one encounters in case of no further flushing at Verbois Dam?
- What would be the main reasons to maintain flushing events?
- In case of no further flushing, what would be the necessary accompanying measures?

Hence, a detailed study of the hydraulic and morphologic conditions on the long term (=50 years) should allow predicting in a plausible manner all possible effects of stoppage of flushing of the Verbois reservoir. Especially future flood risks and necessary protection at the Junction of Arve and Rhône River in the center of Geneva should be quantified.

This study has been performed within the framework of a more general project aiming at a synergy between the following aspects: juridical framework, hydraulics and sediment transport (morphology), security issues, maintenance and finally sustainable development. For each of these aspects, a study is planified on the following states:

- actual state
- transitional state with/without flushing
- equilibrium state with/without flushing
- end of dam exploitation with/without flushing

The study on hydraulics and sediment transport is the first one to be accomplished yet. Its main results will be used as input to the remaining issues,

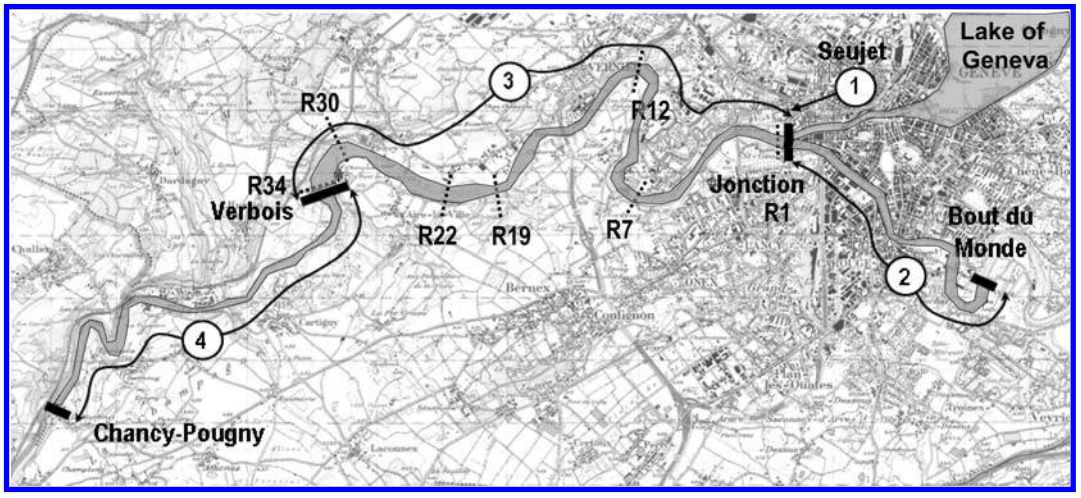

Figure 1. General study area and subdivision into 4 main sections.

followed by a close interaction between all issues and eventually additional hydraulic and sediment transport computations that might reveal necessary.

1.2 *Study area*

The general study area is illustrated in Figure 1 and shows the 4 main river sections that have been studied:

1. Section "Seujet – Jonction": outlet of Lake of Geneva between Seujet and junction with the Arve River (=Jonction)
2. Section "Bout du Monde – Jonction": Arve River upstream of the «Jonction»
3. Section "Jonction – Verbois": Rhône River between junction with Arve and Verbois dam 12 km downstream
4. Section Verbois – Chancy-Pougny: Rhône River between Verbois Dam and Chancy-Pougny Dam 8 km downstream

The present paper specifically deals with section N°3 (Verbois reservoir).

2 DATA COLLECTION

2.1 *Available data*

A huge amount of data has been collected for the 4 main sections of the general study area as illustrated in Figure 1, amongst which:

– cross-sectional profiles and detailed bathymetric surveys before and after flushing events (data available since 1987)
– hydrology of the Arve catchment area and of Seujet power station (Lake of Geneva)
– hydraulic functioning of the main elements of the catchment area (weirs, dams, hydropower stations, etc.)
– sediment concentrations measurements of both fine and coarse material for a large period
– detailed grain size curves along the Arve River and the 12 km long Verbois Reservoir

Table 1. Hydrology of the Mont-Blanc catchment area.

Return period [Years]	Q Arve [m^3/s]	Q Jonction [m^3/s]	Q Chancy-Pougny [m^3/s]
Yearly avg.	79	337	340
1	400	850	850
5	620	1000	1100
10	700	1050	1200
100	950	1250	1500
1000	1200	1450	1900
PMF	1800	2100	2400

2.2 *Hydrology*

The catchment area has a total surface of about 2,000 km^2 and extends towards the Mont-Blanc. Its hydrology is depicted at Table 1.

2.3 *Suspended sediment transport*

Suspended sediment concentration measurements have been made in the Arve River upstream of the Verbois Reservoir since 1890. The measurements made from 1965 to 1989 have been transformed into a general concentration law by Peiry (1989). As shown,

Copyright © 2006 Taylor & Francis Group plc, London, UK

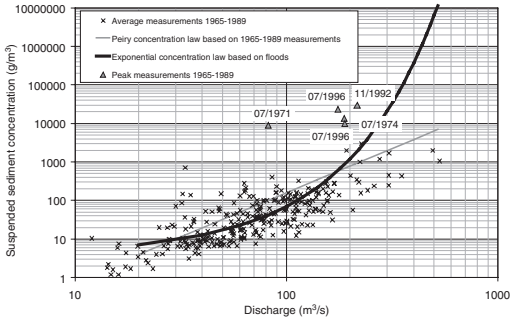

Figure 2. Suspended sediment concentration measurements in the Arve River since 1890 (Peiry, 1989).

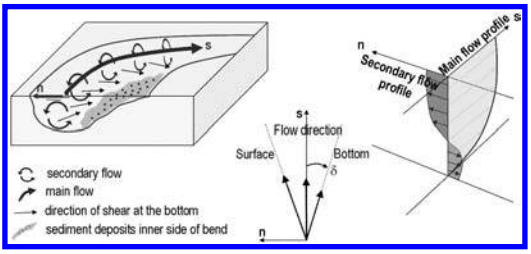

Figure 3. Helical flow pattern along river bend and major influence on sediment deposition.

instantaneous peak measurements during floods may attain concentrations of several tens of g/l. These peak values can be represented by using an exponential concentration law.

Most of the sediments are transported by suspension, with an average yearly transported volume of about 715,000 m^3 (GEOS 2000), from which 355,000 m^3 is trapped in the Verbois reservoir, the remaining being transferred towards downstream (section 4).

Typical grain sizes are between 0.01 and 0.2 mm, corresponding to fine sands and sandy silts. Almost no cohesive material has been detected. During floods, depositing diameters are between 0.2 at the Verbois Dam and 0.7 mm at the Junction.

2.4 *Bed load sediment transport*

Bed load sediment transport in the Arve River has been strongly influenced in the past by major extractions at gravel quarries. About one century ago, the yearly average bed load has been estimated at 150,000 m^3, while systematic and massive extractions in the 20th century have finally led to a lack of material that is actually being estimated at about 10 mio. m^3. The actual yearly average bed load transport is estimated at 60,000 m^3.

2.5 *Morphology of Verbois reservoir*

The actual morphology of the Verbois reservoir is dictated by two major periods:

1. 3-years accumulation period between two consecutive flushing events
2. Flushing event (normal duration about one week)

Sediment volumes evacuated during a typical flushing are between 1.0 and 1.4 mio. m^3 and are mostly situated in the downstream part of the reservoir, i.e. within the last few km upstream of the dam. Flushing events have no substantial influence on the bed morphology at the junction in the center of Geneva. The areas eroded during a flushing event are mostly situated along the inner sides of the Rhône river bends. These are effectively the locations where significant accumulation takes place between two flushing events. Accumulated volumes are between 0.98 and 1.37 mio. m^3, i.e. the efficiency of the current flushing events turns around 89% on the average.

During the past 20–25 years, the total accumulated volume in the reservoir stayed more or less constant, thanks to optimized flushing, but since dam construction in 1942, the reservoir lost already 18% of its total free volume.

3 METHODS OF ANALYSIS

Both analytical and numerical methods have been applied to predict long-term morphological behavior of the Verbois reservoir with or without flushing events. Analytical methods make use of a critical shear stress or flow velocity and have the advantage of ease of application. They allow a global assessment of the problem but do not account for significant physical phenomena such as helical flow patterns in river bends. Numerical methods allow a much more detailed prediction of the morphology, but need a lot of data input and computational time. In the following, the results of both analytical and numerical methods are presented and compared. The applied numerical software is the MIKE-21C curvilinear grid model (Danish Hydraulic Institute, Copenhagen, Denmark), which allows accounting for quasi-3D suspended sediment convection and diffusion as well as helical flow effects on morphology along river bends (see Figure 3).

Helical flow is modeled by using a simplified approach based on De Vriend (1981). The magnitude of the secondary flow (i_s) is assumed proportional to the flow depth (h) and inversely proportional to the radius of curvature of the main stream line (R). This results in a difference between the angle of the bed shear stress δ and the angle of the depth-averaged shear

Copyright © 2006 Taylor & Francis Group plc, London, UK

stress and/or velocity (Figure 3, middle). The former angle is expressed as follows:

$$\tan(\delta) = -\alpha \cdot \frac{2}{\kappa^2} \cdot \left(1 - \frac{\sqrt{g}}{\kappa C}\right) \cdot \frac{h}{R} \qquad (1)$$

where α = calibration constant; κ = Von Karman constant; and C = Chézy number. For the present computations, its value has been set to 1. This means that helical flow effects are of significant importance in the river bends, as has been observed based on bathymetric surveys.

4 LONG TERM RESERVOIR MORPHOLOGY

4.1 *Analytical modeling*

The actual state of the reservoir has been computed for a yearly averaged discharge of 400 m^3/s and for different critical entrainment criteria (Figure 4). The results show that only some tenths of a N/m^2 are needed to erode fine particles in the downstream half of the reservoir, while several N/m^2 are needed in the upstream half. Corresponding critical velocities were computed between 0.20 and 0.60 m/s.

Related stable particle diameters have been computed based on the Shields (1936) criterion and were found between 0.12 and 0.22 mm for 400 m^3/s and between 0.34 and 1.20 mm for 800 m^3/s (~yearly peak discharge at junction upstream).

In a next step, for the same discharge, the reservoir bottom has been artificially heightened from its actual level to about 368 m a.s.l., with steps of about 1 m. This allowed computing the flow velocities and bottom stresses for different future degrees of filling of the reservoir. These were then compared with the critical entrainment criteria explained before at three different cross-sections presented in Figure 1.

As shown in Figure 5, bottom shear stresses computed for 400 m^3/s suddenly increase for reservoir bottom elevations of 363 m a.s.l. or higher. To generate stresses above the critical stresses valid in the upstream part of the dam (see Figure 4), bottom elevations of 362.5 to 364.5 m a.s.l. would be needed. This would more or less correspond to the future new dynamic equilibrium level of the reservoir in the absence of flushing events. In the downstream part of the reservoir, however, critical stress values seem to be attained already with the today's bottom elevation. This, however, is only valid along the main flow, the local flow velocities and shear stresses along the banks being generally much lower and thus allowing sediment deposition and increase of the bottom level. Prediction of an equilibrium bottom level in this downstream part is difficult to define.

Based on critical flow velocities, equilibrium bottom elevations of 363 m a.s.l. have been found in the upstream part of the reservoir and equilibrium conditions are predicted for the downstream part.

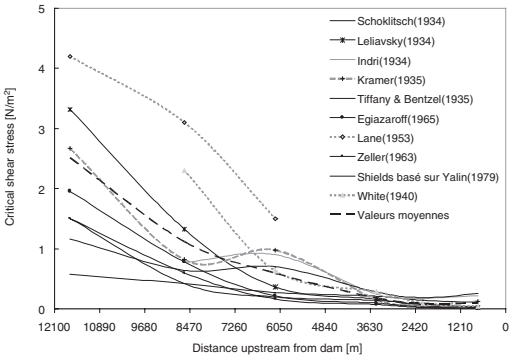

Figure 4. Critical shear stress in Verbois reservoir for an average discharge of 400 m^3/s and different entrainment criteria.

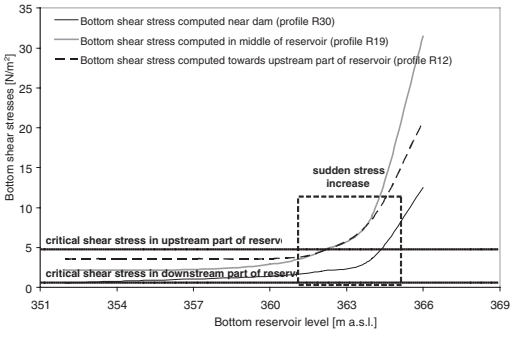

Figure 5. Bottom shear stress in Verbois reservoir for an average discharge of 400 m^3/s and for different fictitious future reservoir bottom elevations.

4.2 *Quasi-3D numerical modeling*

A quasi-3D numerical modeling has been performed accounting for vertically integrated profile functions for both the flow velocities and the suspended sediment concentrations. These have been used to determine helical flow effects along the river bends on local morphology and sediment deposition. The model uses the depth-averaged Navier-Stokes equations together with a convection-diffusion equation for the suspended sediment. Non-equilibrium effects are accounted for by means of a fall velocity factor. Turbulence model is a constant eddy viscosity model. The following parameters have been used during the different model runs:

– sediment transport equation: Van Rijn (1984) or Engelund & Hansen (1967)
– particle diameters (2 or 4 particles)

– sediment fall velocity (FV factor)
– sediment concentration (Peiry 1989)

A summary of the most important runs is given at Table 2. Calibration of the model has been performed by comparing the computed morphology with the measured morphology between two consecutive flushing events. Surprisingly, the runs with only 2 particle diameters provided better agreement than the ones with 4 particle diameters. Also, the fall velocity factor (FV) was found to be on the order of 0.05. In other words, non-equilibrium transport effects are of importance, as could be expected based on the fine material that is transported. The Van Rijn expression generated better spatial distribution of sediment deposits than the Engelund & Hansen expression and has been preferred to perform long-term morphologic predictions.

Comparison is made in Figure 6 of the total accumulated volumes per cross-section along the reservoir (profiles R1 at junction to R34 at dam) with and without future flushing events. The total time period is 48 years, with flushing every 3 years. The total reservoir deposition mounts up to 3.2 mio. m^3 with flushing events and 5.7 mio. m^3 without flushing events. Most of the deposits are situated in the last few km upstream of the dam. Very few deposits are observed just downstream of the junction.

Figure 7 shows a summary of the time evolution of the totally deposited volume of sediments in the Verbois reservoir for the different runs of Table 1. The computations performed with only 2 particle diameters show somewhat lower total deposited volumes than the ones with 4 particle diameters. The former computations generally had a much better agreement with bathymetric surveys, the reason for this is not clear.

When maintaining triennial flushing events in the future, reservoir filling will continue, but at a lower rate than without flushing events. Nevertheless, for some runs, the volumetric difference between runs with and without flushing events is not so important.

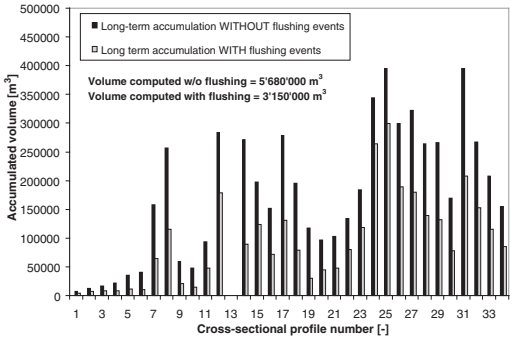

Figure 6. Comparison of total accumulated volumes after 48 years with or without triennial flushing events.

As a first-hand conclusion, it may be stated that, regardless of the future sediment management of the Verbois reservoir, morphology will apparently reach a state of dynamic equilibrium. In case of no further flushing, this equilibrium seems to be reached already after 10-15 years, while in case of further triennial flushing events, much more time would be needed.

Also, as illustrated in Figure 8, the long-term equilibrated morphological state of the reservoir bottom would correspond to a rather small main meandering channel with significant deposits along the inner sides of the actual bends and along the actual enlargements of the river. The deposits are indicated in dark grey and the lower parts of the bathymetry in light grey. Flow is from the right (Junction) to the left (Verbois Dam).

It is pleasant to notice that the equilibrium bottom levels of the main meandering channel have been computed between 361 and 364 m a.s.l., in agreement with preliminary analytical predictions.

Figure 9 compares long term deposits in different cross-sections, with or without flushing events. The computed deposits are also compared with bathymetric measurements made between two consecutive flushing operations in 1997 and 2000. These measurements provide an estimate of the sediment deposits that may occur within a 3-years time period between flushing events. Computed and measured morphologies are generally in reasonable to good agreement. The numerical model is clearly able to simulate erosion along the outer side of bends together with deposition on the corresponding inner side. Also, spatial distribution of deposits along the 12 km long reservoir is correctly simulated by the model. Nevertheless, a detailed quantitative agreement inside each cross-section seems hard to obtain. As could be expected, the long term computations of sediment deposits show significant differences with or without flushing events, particularly in the river bends as well as in the vicinity of the dam.

5 WATER SURFACE LEVELS AT JUNCTION

5.1 *Discharge of 400 m^3/s*

For a discharge of 400 m^3/s, the actual and future water surface lines have been compared in Figure 10 for both cases with and without future flushing events. An increase of about 40 cm of the water surface level at the junction in the center of Geneva can be noticed. In case of maintaining flushing events on a triennial basis, no significant heightening of the water level is computed.

5.2 *Discharge of 800 m^3/s*

For a discharge of 800 m^3/s, the actual and future water surface lines have been compared in Figure 11, for both cases with and without future flushing events. An increase of about 60–100 cm of the water surface level at the junction in the center of Geneva can be noticed.

However, even in case of maintaining flushing events on a triennial basis, an increase of the water level of about 30 cm may reasonably be expected.

6 CONCLUSIONS

The present analytical and numerical computations have shown that, regardless of future sediment management (with or without triennial flushing events) that will be applied to the Verbois reservoir, a state of morphological equilibrium will be reached.

In case of no further flushing events, this state will most probably correspond to a small and meandering main channel together with significant sediment deposits along the banks, mainly along the inner sides of the actual bends. This state of dynamic equilibrium

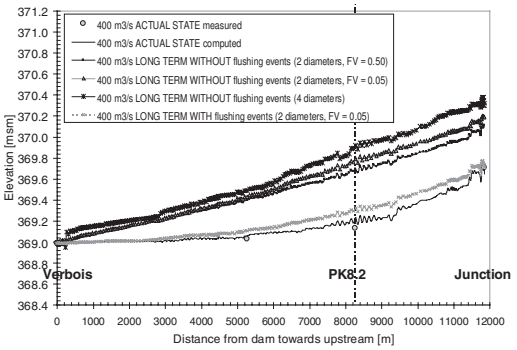

Figure 10. Actual and future water surface lines for 400 m^3/s.

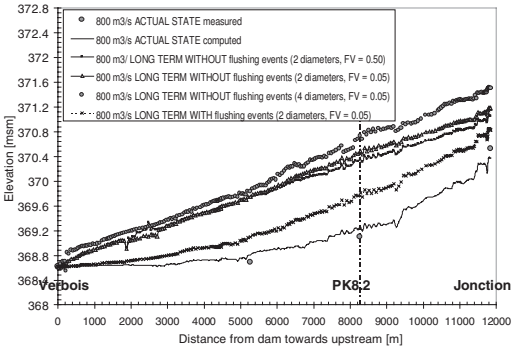

Figure 11. Actual and future water surface lines for 800 m^3/s.

is expected to be reached rather quickly, i.e. within the next 10–15 years.

The future water surface lines at the junction in the center of Geneva will increase regardless of the future sediment management. Nevertheless, in case of no further flushing events, this increase becomes much more important and can reach for example up to 1 m for an annual peak discharge of 800 m^3/s. For extreme floods, increases of about 1.5 m may be expected. These will not only generate flooding in the Junction area in the center of Geneva, but might also create problems for the local sewer system with multiple outlets towards the Arve and Rhône Rivers.

Hence, future sound and plausible sediment management will be necessary in case of no further flushing events. This management could be imagined to be either active, for example by means of new reservoir operating rules during floods to transfer more sediments towards downstream, or rather passive, for example by simply raising the river banks in the center of Geneva.

Subsequent detailed numerical computations will be made of the morphological evolution in the vicinity of the dam to check for potential sediment burying of the bottom outlet gates and the water intakes.

7 RECOMMENDATIONS

The present study only identifies the general concept of long term morphology and points out a few major questions to be answered in case of stoppage of flushing events. It is obvious that numerous other aspects merit to be studied in detail, such as for example:

– Functioning of the intakes to the turbines
– Functioning of the bottom outlets on the long term
– Functioning of specific water intakes on the dam, such as for fish pass
– Functioning of waste water treatment plants along the reservoir
– Functioning of sewer system along reservoir
– Influence of reservoir level drawdown on local bank stability

These aspects are actually being studied to provide answers to the most important hydraulic and morphologic questions and to generate an input to the other main aspects of this project, as for example environmental issues.

ABSTRACT: In order to simulate reservoir sedimentation processes and to enhance sediment management strategies, a deterministic, process-based one-dimensional modelling approach has been developed within the framework of an international research consortium. The reservoir sedimentation module simulates the sediment transport along the longitudinal profile of a reservoir. The reservoir is divided into cross sections to elaborate the sediment budget.The sediment transport component is calculated using a non-uniform sediment transport approach based on the concept of sediment carrying capacity. Up to four different sediment-transport equations can be selected for the simulations. The reservoir sedimentation model was applied to the 92.2 Mm^3 Barasona Reservoir, located in in the foothills of the Central Pyrenees (Aragon, Spain). For this study, the reservoir model was parameterised using input parameters derived from an extensive field study within and upstream the Barasona Reservoir. This research presents, tests and discusses the simulation results of the computed sediment deposition and the bed elevation changes of the Barasona reservoir along a longitudinal profile using the different transport equations, a varying number of sediment size classes, and a varying number of cross-sections for the representation of the complex reservoir characteristics.

1 INTRODUCTION

The construction of a dam can significantly affect the balance of sediment inflow and outflow in the impounded reach, resulting in very low flow velocities and efficient sediment trapping. The consequences of reservoir sedimentation can be economically serious. On the one hand, sedimentation leads to quantitative problems, such as storage capacity losses, obstruction of water intakes, sediment deposition in the delta region and streambed aggradation. On the other hand, as a by-product of the human activities upstream of the dam, the fine fraction of the incoming suspended sediments may carry adsorbed pollutants. Its deposition may have disturbing environmental consequences.

In order to simulate bed aggradation and degradation in reservoirs and to enhance sediment management strategies, a deterministic, process-based, one-dimensional modelling approach, named SEMRES Model has been developed within the framework of the SESAM Project, an international cooperation programme between the University of Potsdam (Germany), the GFZ Potsdam (Germany), the University of Lleida (Spain), the Forestry and Technology Center of Catalonia (Spain) and the Federal University of Ceara (Brazil). Overall, the goal of the SESAM Project is to develop an integrated model concept, which enables the simulation of erosion processes at the hillslope and sub-basin scale, the sediment transport processes in rivers and sediment deposition and management in reservoirs.

2 MODEL STRUCTURE

The reservoir sedimentation model is implemented as a module in the WASA model, which was developed at Potsdam during the past five years (Güntner

Copyright © 2006 Taylor & Francis Group plc, London, UK

et al., 2004a; Güntner et al., 2004b). The WASA model is a deterministic, spatially semi-distributed model, which simulates in detail the rainfall-runoff processes for the quantification of water availability and is currently being extended to model sediment transport processes at the hillslope and river scale.

The reservoir sedimentation routine was included into the WASA model to enable the calculation of non-uniform sediment transport along the longitudinal profile of a reservoir and of the reservoir bed changes caused by deposition and erosion processes. Additionally, it is planned to implement routines for the simulation of sediment management scenarios that evaluate the potential reduction of sediment accumulation in reservoirs.

In order to perform the simulation of sediment transport in reservoirs, four processes have to be considered: (1) water balance of the reservoir, (2) reservoir water body hydraulics, (3) sediment transport along the longitudinal profile of the reservoir and (4) reservoir bed elevation changes. The computation of the water balance is based on the continuity equation, which considers all inflows, outflows and changes in storage of the reservoir. For the calculation of the hydraulic properties, the reservoir is divided into two spatial components: the river sub-reach component and the reservoir sub-reach component, as presented in Figure 1. In the river sub-reach, hydraulic calculations are based on the standard step method for a gradually varied flow (Graf & Altinakar, 1998), while in the reservoir sub-reach, a modelling approach adapted from the GSTARS model is used (Yang, 2002). For the calculation of sediment transport within the reservoir, a 1-D equation of non-equilibrium transport of various size groups of sediment particles is used, adapted from Han (1980). Finally, the reservoir bed elevation changes are calculated through the sediment balance in each cross section, considering three conceptual layers above the original bed material. The lowest layer is used for storage where the deposited sediments are compacted and protected against erosion. In the intermediate layer, the sediment can be deposited or re-suspended. In the top layer, a sediment-laden flow occurs.

2.1 *Water balance of the reservoir*

The water-balance module accounts for the interactions between various forms of water going into and out of the reservoir over daily intervals or shorter.

In general, the reservoir water balance can be written as showed in the following equation assuming that the physical properties of the fluid are constant.

$$\Delta V = Q_{in} + Q_{prec} + Q_{gr} - (Q_{evap} + Q_{inf} + Q_{over} + Q_{ws}) \quad (1)$$

where Q_{in} = direct runoff from the tributary rivers; Q_{gr} = groundwater inflow; Q_{prec} = direct rainfall on the reservoir water surface; Q_{ws} = withdrawals for water supply; Q_{sm} = withdrawals for sediment management; Q_{over} = overflow discharges through the spillway; Q_{evap} = direct evaporation from the water surface of the reservoir; and Q_{inf} = groundwater outflow by infiltration. Groundwater inflow and outflow was assumed negligible relative to other inflow and outflow components.

The reservoir water balance computations used in the reservoir module of the WASA Model are summarized within each timestep as follows:

(a) given the initial water volume and the inflow discharge obtained from the river module of the WASA model, determine the overflow discharges in the case that the storage capacity of the reservoir is exceeded by the actual storage volume after inflows.
(b) compute the storage volume reduction of the reservoir by evaporation. Evaporation values are calculated in the climate module of the WASA model.
(c) determine the storage volume increase by rainfall directly into the reservoir. If storage capacity of the reservoir is exceeded by the actual storage volume after precipitation, overflow discharge is updated.
(d) determine the volume of water withdrawn from the reservoir for water supply. The outflow is a fraction of Q_{90}, i.e., the annual runoff from a reservoir, which is provided with a probability of 90% (in 90% of all years). Q_{90} is based on simple hydrological modelling for dryland environments (Güntner, 2004b).
(e) compute the volume of water withdrawn from the reservoir for sediment management proposes as a fraction of the maximum discharge released through the bottom outlets. This fraction is calculated by interpolation between the storage capacity of the reservoir and a minimum reservoir volume, which allows withdrawals through the bottom outlets, given by user.
(f) calculate the actual reservoir level by using a stage-volume curve.

2.2 *Hydraulic calculations in the reservoir*

The determination of hydraulic properties is a prerequisite for sediment transport modelling in general. Here, the reservoir is divided in the river sub-reach component and the reservoir sub-reach component (Fig. 1), taking into account the variation of the reservoir level. Obviously, the length of the river sub-reach becomes longer for lower reservoir levels, whereas length of the reservoir sub-reach decreases.

For the definition of limits between the two spatial components, the normal depth of each cross section is calculated, not taking into account the existence of the reservoir, and then, it is compared to the depth related to water stage of the reservoir at the same cross

Copyright © 2006 Taylor & Francis Group plc, London, UK

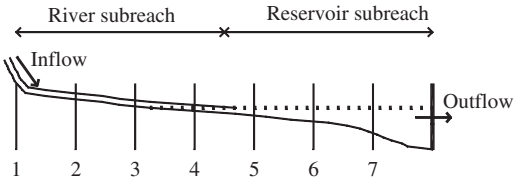

Figure 1. Longitudinal profile of the reservoir (division into river and reservoir sub-reaches).

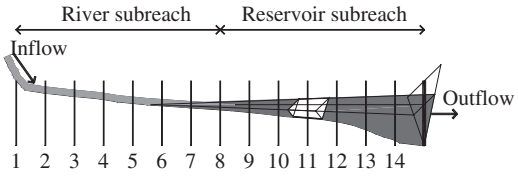

Figure 2. Fraction of the reservoir volume represented by cross section 11.

section. The normal depth is the maximum water depth for a uniform flow, computed by the Manning formula. If the value of normal depth is greater than the depth of the reservoir at the same cross section, it belongs to the river sub-reach.

2.2.1 *Reservoir routing*

The computation of reservoir routing is based on the modelling approach of the GSTARS model (Yang & Simoes, 2002), with some modifications, that will be explained in the following. In the reservoir sub-reach, the water discharge is computed for each cross section from upstream to downstream using a weighting factor, which represents the influence of input discharges and output discharges on that cross section. In the GSTARS model, the weighting factor is the reservoir's surface area represented by each cross section. Here, the weighting factor is calculated from the volume represented by the respective cross section, as showed in Figure 2. The water discharge for each cross section is calculated as follows:

$$Q_j = Q_{in} - (Q_{in} - Q_{out}) \cdot \sum_{k=m}^{j} v_k \qquad (2)$$

where v_k = fraction of reservoir volume represented by that cross section ($v_k = V_k/V_{res}$); V_k = volume represented by cross section k; V_{res} = reservoir volume; m = first cross section belonging to the reservoir sub-reach; Q_{in} = input discharge; and Q_{out} = output discharge. Given the water discharge and water elevation at a cross section, its hydraulic parameters can be calculated.

2.2.2 *River routing*

For the calculation of the hydraulic properties at the river sub-reach, the standard step method for a gradually varied flow (Graf & Altinakar, 1998) was selected. This method will give a water-surface profile for subcritical or supercritical flow regimes, but a constant of integration must be supplied. In the case of subcritical flow, the cross section of control is the first section at the reservoir sub-reach, which has known physical properties. For supercritical flow regime, the water surface profile is computed from known upstream boundary condition. No mixed flow is computed. Calculations must begin at the control section and proceed in the direction in which the control operates, i.e. from the control section to upstream for subcritical flow and to downstream for supercritical flow.

In its general form, the equation of motion was written as

$$\frac{d}{dx}\frac{(Q/A)^2}{2} + \frac{dh}{dx} - S_f = -S_e \qquad (3)$$

where Q = water discharge (m^3/s); A = wetted surface (m^2); h = water depth (m); S_f = slope of the bed (-); and S_e = slope of energy-grade line (-).

The dynamic Equation (3), is rewritten below for the computation of hydraulic properties at the river sub-reach between the current section and the downstream section (Graf & Altinakar, 1998):

$$H_j - H_{j+1} = S_f . L_j + K_{ss} \frac{Q^2}{2g} \left| \frac{1}{A_j^2} + \frac{1}{A_{j+1}^2} \right| \qquad (4)$$

where H = elevation of the energy-grade line; L_j = distance between the current section and the upstream cross section (or downstream cross section if a supercritical profile is being calculated); V = average flow velocity; n = Manning's friction coefficient for the current section; R_h = hydraulic radius of the current section; K_{ss} = head-loss coefficient for a singularity as caused by a change between two consecutive sections or other possible irregularities. For subcritical flow regime, it is internally set to 0.1 for contractions and to 0.3 for expansions. Typical values for gradual transitions in supercritical flow would be around 0.05 for the contraction coefficient and 0.1 for the expansion coefficient (Brunner 2002).

In Equation 4, S_f is the representative friction slope between two sections. It is computed from Manning's equation as follows:

$$S_f = \left(\frac{2Q}{K_1 + K_2} \right)^2 \qquad (5)$$

where K_1 and K_2 = conveyance at the cross section 1 and 2, respectively.

2.3 *Reservoir sediment transport*

Most sediment transport models applied in engineering practice are based on an equilibrium sediment-transport approach using the concept of sediment carrying capacity. However, for the case of reservoir sedimentation and scouring process of river channel in the downstream of a reservoir, the sediment carrying capacity is not equal to the actual sediment concentration. Han (1980) proposed the following equation for non-equilibrium sediment transport:

$$\frac{dS}{dx} = \frac{\alpha\omega}{q}(S^* - S) \tag{6}$$

where S = sediment concentration; S* = sediment carrying capacity; ω = settling velocity; and α = coefficient of saturation recovery. Han (1980) recommended 0.25 for reservoir sedimentation and 1 for scouring during flushing of reservoir.

After some rearrangements, the integrated equation from Equation 6 can be expressed as:

$$S_j = S_j^* + (S_{j-1} - S_j^*).e^{-\left(\frac{\alpha.\omega.L}{q}\right)} \tag{7}$$

The sediment carrying capacity S* is computed by four different equations selected from the literature, as presented in Table 1. The criterion to select them was based on the fact that all four equations enable the calculation of both bed load transport and suspended load transport. The sediment transport equations were developed for uniform sediment load. Nevertheless, they are frequently used for non-uniform sediment transport problems.

2.3.1 *Wu et al.*

Wu et al. (2000) developed a fractional formula for bed load transport and a fractional formula for suspended load. The transport rate of the k-th fraction of bed load per unit width ($q_{b,q}$) can be calculated as follows:

$$q_{b,k} = P_k.\phi_{b,k}\sqrt{\left(\frac{\gamma_s}{\gamma} - 1\right).g.d_k^{\,3}} \tag{8}$$

where P_k = percentage of material of size fraction k available in the bed; γ and γ_s = specific weights of fluid and sediment, respectively; g = gravitational acceleration; d_k = diameter of the particles in size class k; and $\phi_{b,k}$ = dimensionless transport parameter for fractional bed load yields. The parameter $\phi_{b,k}$ is computed from

$$\phi_{b,k} = 0.0053.\left[\left(\frac{n'}{n}\right)\frac{\tau_b}{\tau_{c,k}}\right]^{2.2} \tag{9}$$

where $\tau_{c,k}$ = critical shear stress (N/m^2); τ_b = bed shear stress (N/m^2); and n′ = Manning's roughness related to grains (s/m$^{1/3}$).

The suspended load transport rate of the k-th fraction per unit width can be written as:

$$q_{s,k} = P_k.\phi_{s,k}\sqrt{\left(\frac{\gamma_s}{\gamma} - 1\right).g.d_k^{\,3}} \tag{10}$$

where $\phi_{s,k}$ = dimensionless transport parameter for fractional suspended load yields. The parameter $\phi_{s,k}$ is calculated as follow

$$\phi_{s,k} = 0.0000262.\left[\left(\frac{\tau}{\tau_{c,k}} - 1\right)\frac{V}{\omega_k}\right]^{1.74} \tag{11}$$

where τ = bed shear stress on the entire cross section (N/m^2).

The fractional sediment transport capacity for total sediment load (m^3/s) is the sum of the bed load transport rate and the suspended load transport rate.

$$C_k = (q_{b,k} + q_{s,k}).B \tag{12}$$

2.3.2 *Ashida & Michiue*

Ashida & Michiue (1973) proposed a fractional bed load transport equation, as written below:

$$q_{b,k} = 17.P_k.u_e.d_k.\tau_{e,k}\left(1 - \frac{\tau_{c,k}}{\tau_k}\right)\left(1 - \sqrt{\frac{\tau_{c,k}}{\tau_k}}\right) \tag{13}$$

where τ_k = shear stress of the particles in size class k (N/m^2); $\tau_{e,k}$ = effective shear stress (N/m^2); and u_e = effective shear velocity (m/s).

The suspended load transport is adapted from the method of Ashida & Michiue (1970), as proposed by Yang & Simoes (2002) in the GSTARS Model.

$$q_{s,k} = C^*V(e^{-p.a} - e^{-p.h}).\frac{e^{p.a}}{p} \tag{14}$$

where C* = concentration at a reference level (a = 0.05h); p = coefficient computed based on the von Kàrmàn constant.

Copyright © 2006 Taylor & Francis Group plc, London, UK

2.3.3 *Tsinghua university*

The empirical Tsinghua University Method (IRTCES, 1985) was developed to calculate the transport capacity of flushing flows in reservoirs. No distinction was made between bed load and suspended load. The method is based on observations flushing in reservoirs in China, where the predominant practice is annual flushing and so relatively little consolidation occurs between flushing operations. Extrapolation to other reservoirs and conditions should be done with caution.

$$Q_s = \Omega \frac{Q^{1.6} S^{1.2}}{B^{0.6}} \tag{15}$$

where Qs = sediment transport capacity at the current section (tons/s); Q = water discharge (m^3/s); S = bed slope; and Ω is a constant set from the sediment type: 1600 for loess sediments; 650 for other sediments with median size finer than 0.1 mm; 300 for sediments with median size larger than 0.1 mm; and 180 for flushing with a low discharge.

2.3.4 *Ackers & White*

The Ackers & White transport function (1973) is a total load function developed under the assumption that fine sediment transport is best related to the turbulent fluctuations in the water column and coarse sediment transport is best related to the net grain shear with the mean velocity used as the representative variable. The general transport equation for the Ackers & White function for a single grain size class k is represented by:

$$q_{t,k} = P_k . K_k . V . d_k . \left(\frac{V}{u}\right)^{n'_k} . \left(\frac{F_{gr,k}}{Fc_{gr,k} . \xi_k}\right)^{m'k} \tag{16}$$

where $F_{gr,k}$ = sediment mobility number (-); n′, m′, K and Fc_{gr} = dimensionless coefficients. These coefficients depend on the dimensionless particle size d*, calculated as follows:

$$d*_k = d_k \left\{ \frac{\left[\left(\gamma_s / \gamma\right) - 1\right] . g}{\nu^2} \right\}^{1/3} \tag{17}$$

Ackers & White (1973) make a distinction between particles with $1 < d* < 60$ and particles with $d* \geq 60$. Later revisions were made for the K and m′ coefficients (Wallingford, 1990), because there were uncertainties in the original formula in the sediment transport for relatively fine and coarse sediments. Nevertheless, Van der Scheer (2000) showed that the results of the Ackers & White-formula with the modified parameters are slightly worse than the predictions of the original formula. Therefore, the 1973 Ackers & White-formula was included in the reservoir sedimentation model. The parameters of that formula can be found in Table 2.

Table 2. Coefficients of the formula proposed by Ackers and White (1973).

Coefficients	$1 < d* < 60$	$D* \geq 60$
n′	$1 - 0.56.\log(d*)$	0.
m′	$9.66/d* + 1.34$	1.5
log(K)	$-3.53 + 2.86\log(d*) - \log^2(d*)$	0.025
Fc_{gr}	$0.23/(d*^{0.5}) + 0.14$	0.17

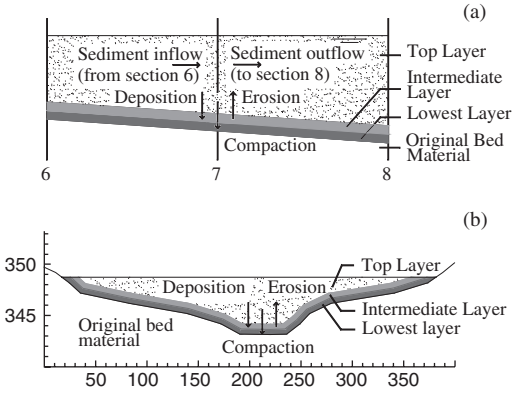

Figure 3. Longitudinal view (a) and cross section (b) with the sediment balance for the three conceptual layers.

2.4 *Reservoir bed elevation changes*

For the calculation of bed elevation changes, each cross section is divided into three conceptual layers above the original bed material as illustrated schematically in Figure 3. The lowest layer is used for storage. There, the sediment is compacted and permanently protected against erosion. In the intermediate layer, the sediment can be deposited or resuspended. In the top layer, the sediment-laden flow occurs.

The time-dependent mobile bed variation can be computed from the following sediment balance equation, as proposed by Han (1980)

$$\frac{\partial(Q.S)}{\partial x} + \frac{\partial M}{\partial t} + \frac{\partial(\rho_d . A_d)}{\partial t} = 0 \tag{18}$$

where Q = water discharge; S = sediment concentration M = the sediment weight in water column with unit length in longitudinal direction; A_d = the total area of deposition; and ρ_d = density of deposited material. If the time span for deposition in a reservoir is not too large, the consolidation of deposits can be neglected and the initial density of deposits is used.

The weight of deposits W can be computed for each grain size k and each cross section j from

$$W_{j,k} = Q_{j-1} . P_{j-1,k} . S_{j-1,k} - Q_j . P_{j,k} . S_{j,k} \tag{19}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

The amount of incoming sediment at the first cross section of the reservoir is obtained from the river module of the WASA model. Erosion of the bed takes place when the sediment transport capacity at the current cross section exceeds the load incoming into the reach, whereas deposition occurs when the sediment transport capacity is exceeded by sediment inflow. Finally, the amount of sediment transported out of the reach of a cross section is constrained by the sediment transport capacity.

The sediment transport capacity is calculated for each grain size from one of the four available sediment transport formulae presented above, assuming that the entire bed is composed of that size fraction alone. According to the Yang & Simoes (2002), the fractional sediment transport capacity can be written as:

$$C_{j,k} = [r.P_{j,k} - (1-r).P^*_{j,k}].C_{j,k} \quad (20)$$

where: $P^*_{j,k}$ is the percentage of material of size fraction k incoming into the reach represented by the cross section; $P_{j,k}$ is the percentage of material of size fraction k available in the bed; r is a weighting factor that enables the inclusion of incoming sediment into the reach ($0 \leq r \leq 1$); and $C_{j,k}$ is obtained from the sediment transport equations presented above.

The geometry of the cross section is updated whenever deposition or entrainment at the intermediate layer occur. When erosion takes place, sediment transport may be constrained by availability at the intermediate layer. The area of deposited material (A_{dep}) and resuspended material (A_{ero}) are computed by the following equations

$$[A_{dep}]_j = \frac{\sum_{m=1}^{k} [V_{dep}]_{j,m}}{L'_j} \quad (21a)$$

$$[A_{ero}]_j = \frac{\sum_{m=1}^{k} [V_{ero}]_{j,m}}{L'_j} \quad (22b)$$

where L'_j = length of the reach of the subsection, computed from the arithmetic average of the distances L_j and L_{j+1}; V_{dep} = volume of the deposited material; and V_{ero} = volume of the resuspended material.

The area of deposition or entrainment is then used to adjust the bed geometry of the cross section. In the case of deposition, the cross section bed elevation changes using a weighting factor, computed as a ratio between the water depth represented by each point (h) and the maximum water depth at the cross section (h_{max}). For entrainment, a symmetrical distribution of bed thickness at the active layer is assumed adapted from the equilibrium channel width model proposed by Foster & Lane (1983)

$$e / e_{max} = 1 - (1 - 2X_*)^{2.9} \quad (23)$$

where e = bed thickness of the active layer; e_{max} = maximum bed thickness of the active layer, proportional to the geometric mean of the largest size class (the constant of proportionality is user defined); and X_* = a normalized distance along the wetted perimeter starting at the water surface.

3 APPLICATION

3.1 *Study area*

The modelling approach presented above was applied to the 71 Mm^3 Barasona reservoir in the Pre-Pyrenees. The Barasona Reservoir was constructed on the Esera River in Spain in 1932 for irrigation purposes and power generation. In 1972, the crest elevation of the Barasona Dam was increased and the maximum storage capacity reached 92.2 Mm^3. Until the early 1950 the deposited sediments were flushed out yearly through the bottom outlets. After that time, the bottom outlets were not opened every year, resulting in a higher effective sedimentation rate. A bathymetric survey of the reservoir in 1993 indicated that its original storage capacity had been reduced by 24.8 Mm^3. Finally, a complete drawdown of the reservoir was performed after the irrigation season for the three consecutive years 1995–1998 (Valero-Garcés et al., 1999).

The dam controls 1224 km^2 of the Esera catchment (Fig. 4). The climate of the Esera catchment is a typical Mediterranean mountainous type with a mean annual precipitation rate of 600 to 1200 mm and an average potential evaporation rate of 550 to 750 mm. Most floods occur due to the passing of cold fronts in spring and to local thunderstorms in autumn.

The vegetation of the Esera Catchment includes evergreen oaks and pines in the valley bottoms and deciduous oaks in the upper areas.

Erosion processes are very intense in many parts of the basin even under normal precipitation conditions. A significant part of the erosion processes occur on badlands. Badlands are a typical landform of this region within the upper middle part of the catchments, dominated by Mesozoic carbonate rocks and marls. Badlands are heavily dissected barren terrain that is composed of poorly cemented debris and marls lacking any vegetation cover. Badlands are vulnerable to flash flood erosion and produce large amounts of eroded material, that are then transported downstream as suspended sediments in the Esera and Rivers. The large amount of suspended sediments at the outlet of the Esera-Isábena Rivers creates severe sedimentation in the Barasona reservoir.

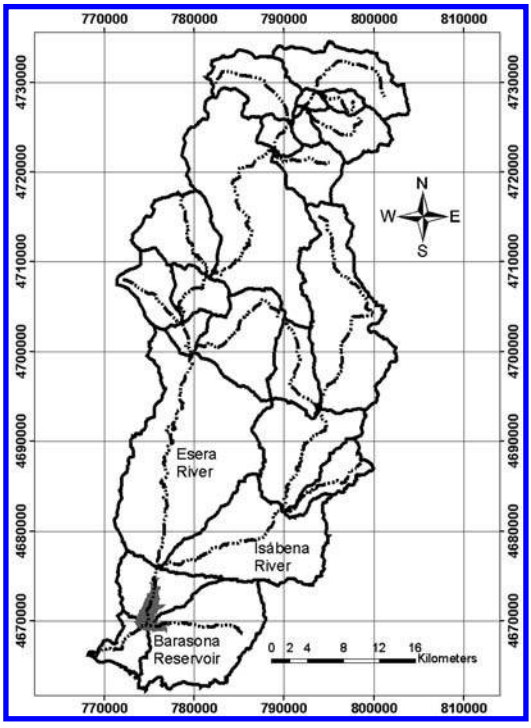

Figure 4. Location of the Barasona Reservoir and the controlled Esera Catchment in Spain (Projection: UTM 30N).

3.2 *Field measurements and parameterisation of the reservoir modelling*

A fieldwork campaign was carried out in autumn 2005 to gain a better understanding of the sedimentation processes of the Barasona Reservoir at the outlet of the Esera Watershed, NE Spain. In particular, field data are required for the parameterisation and validation of the reservoir module of the WASA model. For this purpose, parameters associated with sedimentation processes were collected in and around the reservoir.

Forty-three samples of the deposited material were collected immediately upstream of the Barasona Lake within the inundation area to characterize the deposited material in terms of their physical properties. The results show that the collected material is predominantly silt, with an average percentage of about 70%, as showed in Figure 5, according to the German soil classification.

The collection of water samples at the upstream and downstream sites of a reservoir is very important for the calibration and validation of the simulated reservoir sediment balance. With measured values of suspended sediment concentration at the inlet point, it is possible to obtain a correlation between water input

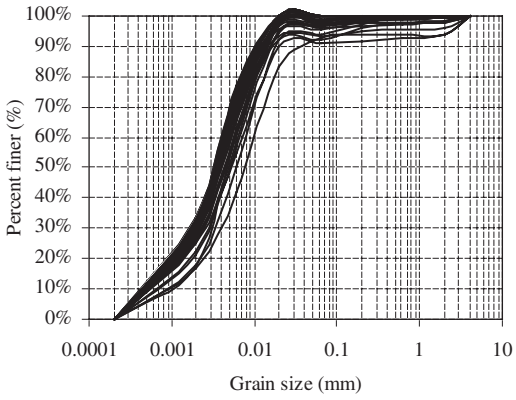

Figure 5. Grain size distribution of the deposited sediment in the Barasona Reservoir, collected during the fieldwork (autumn, 2005).

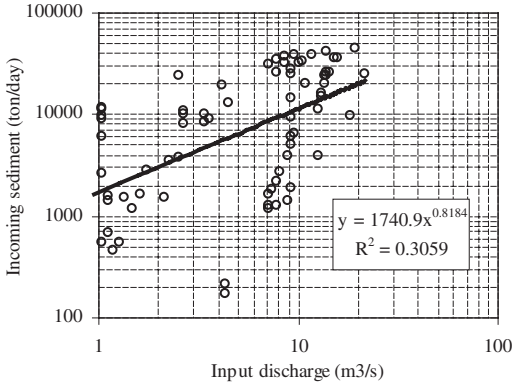

Figure 6. Correlation between incoming sediment and input discharge at the upstream part of the reservoir.

and sediment input into the reservoir, when there is no data available on incoming sediment. From discharge and suspended sediment concentration data obtained during several flood events in the Isabena River a preliminary rating curve was obtained (Fig. 6).

This correlation is used to convert available data of water discharge into the reservoir into suspended sediment input, which in turn is used as a boundary condition for the modelling.

3.3 *Results*

The model simulated 8 years of sediment deposition in the Barasona Reservoir (from 1986 to 1993, when the bathymetric surveys were carried out). The longitudinal profile of the reservoir was initially divided into 51 cross sections. Some results are given here to show the applicability of the reservoir sedimentation model.

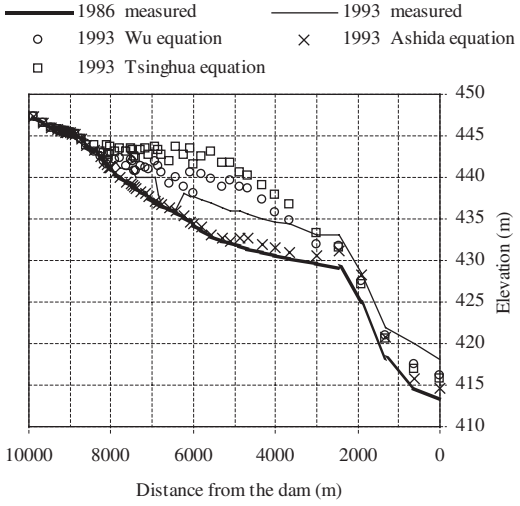

Figure 7. Reservoir bed elevation changes along the longitudinal profile of the Barasona Reservoir, computed by three different sediment transport equations.

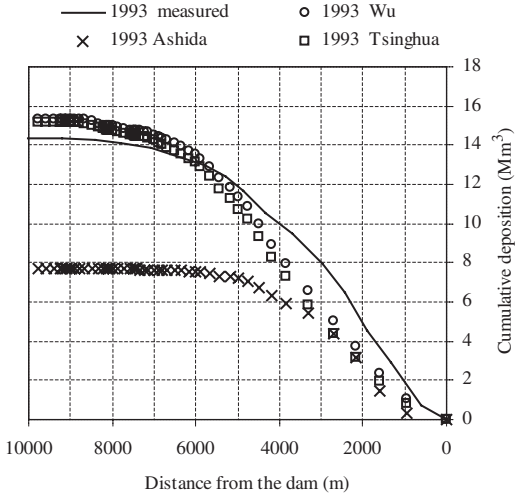

Figure 8. Cumulative sediment deposition along the longitudinal profile of the Barasona Reservoir, computed by three different sediment transport equations.

Figure 7 shows the bed elevation changes along the longitudinal profile of the reservoir for three different sediment transport equations, referring to the lowermost point of each cross section, whereas Figure 8 illustrates the cumulative deposition along the longitudinal profile of the Barasona Reservoir. The results presented in Figures 7 and 8 shows that the Tsinghua University Equation overestimates the sediment deposition at the upstream part of the reservoir,

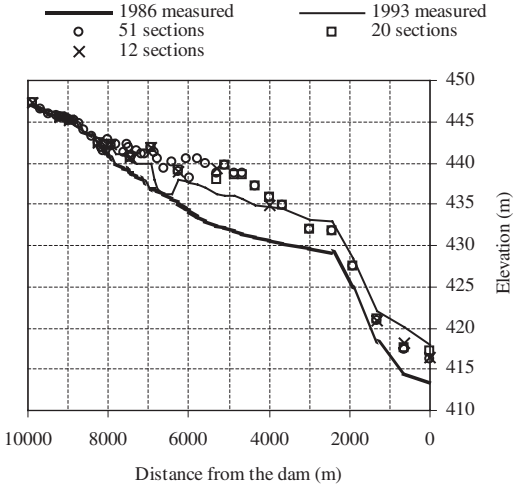

Figure 9. Computed reservoir bed elevation of the Barasona Reservoir using a varying number of cross sections.

whereas the Ashida & Michiue Equation underestimates it in relation to the measured longitudinal profile of the reservoir as derived from the high-resolution bathymetric survey. The Wu equation showed the best results in the simulation of deposition along a longitudinal profile of the Barasona Reservoir. The sediment transport equation proposed by Ackers & White (1973) was not used here because it is not recommended for grain sizes below 0.04 mm.

In order to assess the sensitivity of the model in terms of the number of employed cross sections and number of sediment classes, the Wu equation was selected. The results of the bed elevation change for three different numbers of cross sections (12, 20 and 50 cross sections) are shown in Figure 9. The results shows that the simulation with 51 cross sections can reproduce better the sinuosity of the longitudinal profile.

The sensitivity analysis of reservoir bed elevation changes for a varied number of sediment size classes is presented in Figure 10. The results indicate that a decrease in the number of sediment classes causes an increase of the sediment deposition at the upstream part of the reservoir and a decrease of the sediment deposition at the downstream part of the reservoir.

Results on reservoir bed elevation change along a cross section are presented in Figure 11, exemplarily for the cross sections 25 and 45. The bed elevation change at a cross section is computed as explained in Section 2.4. The results are in good agreement with the topography of the cross sections obtained from the 1993 bathymetric survey, although one-dimensional models have limitations to reproduce bed elevation changes in cross sections with irregular geometry.

4 CONCLUSIONS AND FURTHER WORK

The paper presented a modelling approach for the simulation of reservoir sedimentation, taking into account non-equilibrium transport processes of non-uniform sediments in reservoirs of dryland environments. Furthermore, related field studies carried out for the model parameterisation, the first model application and preliminary simulation results for sedimentation processes at the Barasona Reservoir in the Pre-Pyrenees of NE Spain were presented and discussed.

A three-layer modelling approach was used to compute separately the sediment transport at the top layer, the sediment exchange between the top layer and intermediate layer caused by deposition and entrainment and the sediment storage at the lowest layer. Overall, the implemented modelling framework for the sediment balance at several cross sections of the Barasona Reservoir enabled a realistic reproduction of non-uniform sediment transport, deposition pattern and bed elevation change along the longitudinal profile of the Barasona Reservoir.

The sediment-transport equation after Wu (2000) yielded the best results in the simulation of bed elevation changes along the longitudinal profile of the Barasona reservoir. Nevertheless, the selection of the appropriate equation depends on the problem at hand.

The reservoir sedimentation model underestimated to some extent the deposition patterns at the downstream part of the Barasona Reservoir in comparison to the measured deposition patterns as were derived from two high-resolution bathymetric surveys of 1986 and 1993. The discrepancy may be explained by

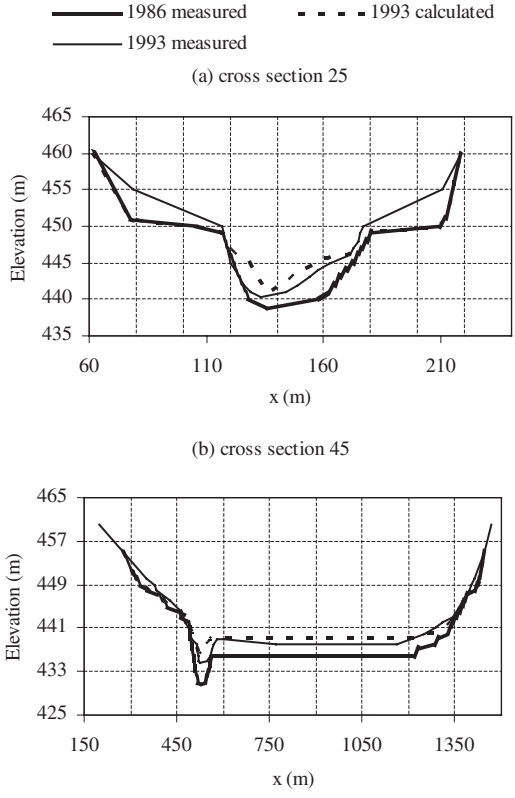

Figure 11. Bed elevation changes at two different cross sections computed from the Wu sediment transport equation: (a) cross section 25 and (b) cross section 51.

the simplified assumption of the correlation between water and sediment input into the reservoir generated from field studies and by the assumption of a constant grain size distribution of the incoming material. A correlation between water and sediment input can either overestimate or underestimate the incoming sediment, while a constant grain size distribution of the incoming material can change strongly the deposition and entrainment along the reservoir. Therefore, the temporal variability of the grain size distribution requires future consideration in the modelling approach. An extensive monitoring program is currently being installed to gain a more in-depth knowledge of the water and sediment fluxes into the reservoir.

Two important physical processes that occur in reservoirs, the turbid density current and cohesive sediment transport were not considered in this study. Currently, an additional module is being developed to assess the influence of the two processes on reservoir sedimentation and thus to enable a more complete description of the involved sedimentation processes.

Deposition of fine particles varying with their cohesiveness

G. Hillebrand & F. Nestmann
Institute for Water and River Basin Management, Universität Karlsruhe, Germany

ABSTRACT: Rivers carry enormous amounts of fine particles in suspension compared to the bed load. These particles tend to deposit in regions of low turbulence such as reservoirs, polders or on floodplains. The influence of their respective cohesiveness on the depositional behavior is investigated in a research project. The laboratory study aims to quantify the effect of the cohesive properties of the sediment particles on the deposition process. The cohesiveness is varied by using sediments of different mineralogical composition and by varying the pHvalue of the ambient water.

The experiments are realized in an annular flume with a free water surface, where the flow is driven by the rotation of the inner flume boundary. Two artificial muds of silica and alumina particles and a natural mud taken from a reservoir in the black forest are studied. The results show that the steady state concentrations and the deposition rates differ significantly between the diverse configurations.

1 INTRODUCTION

Rivers carry enormous amounts of fine particles in suspension compared to the bed load. These particles tend to deposit in regions of low turbulence.

The deposition of fine sediments in reservoirs and shipping lanes is of economic interest because its dredging represents a considerable expense. There are also ecological aspects involved as contaminants such as heavy metals or organic pollutants tend to adsorb to fine sediment particles.

Literature on sediment transport mainly focuses on bed load transport. A first theory on sediment transport in suspension is given by Dupuit (1865). A material possessing a density larger than water be still transported in water due to a velocity gradient along the particle causing negative pressure.

In the 1930s, the diffusion theory was established (Schmidt 1925; Rouse 1937), which attributes sediment transport in suspension to a balance of upward movement due to turbulence and downward movement due to the self-weight of the particles.

State-of-the-art approaches on sediment transport often distinguish cohesive and non-cohesive sediments. Especially in the case of cohesive sediments, results of those approaches differ strongly (Schweim et al. 2001) and are therefore unreliable for engineering purposes. The significant discrepancies in the results of diverse formulae indicate that the interaction of flow and cohesive sediment is not completely understood.

Sediment characteristics have a significant influence on the deposition process. This paper addresses the cohesiveness as one aspect of this vital matter.

2 LITERATURE REVIEW

Deposition of fine sediments has been investigated by various authors with varying objectives. Key parameters which were examined are the suspended sediment concentration depending on the bottom shear stress and velocity gradients in the flume, the settling velocity or the deposition rate of particles and flocs respectively, and the characteristics of the flow, the ambient water and the sediment itself influencing the deposition process.

Many of the studies have been carried out in annular flumes. Typically, those annular flumes consist of a circular channel with a rotating lid on the water surface, which drives the flow in the flume. Oftentimes, the channel may be rotated in the opposite direction in order to reduce secondary currents and achieve a relatively uniform distribution of the bottom shear stresses along a virtual flume cross-section.

Typical findings from the experiments on deposition are the following:

- The suspended sediment concentration initially decreases rapidly. Afterwards, the decrease abates and the concentration finally reaches a constant value, frequently termed *equilibrium concentration* C_{eq} (Partheniades et al. 1966; Krishnappan and Engel 1997; Verbeek et al. 1993).
- The ratio of C_{eq} and the initial concentration C_0 is a function of the bottom shear stress τ in the flume. High shear stresses keep larger portions of sediment in suspension (Haralampides et al. 2003; Mehta and Partheniades 1975).

Copyright © 2006 Taylor & Francis Group plc, London, UK

– The ratio C_{eq}/C_0 does not change with variable C_0 (Mehta and Partheniades 1975; Krishnappan and Engel 1997; Verbeek et al. 1993).
– A minimum bottom shear stress exists below which no amount of material can remain in suspension indefinitely (Mehta and Partheniades 1973; Kuijper et al. 1991). On the other hand, there appears to be a critical shear stress above which there is no net deposition (Krone 1993).
– Fine-grained sediment settles in flocculated form. Only flocs with strong interparticle bonds settle through the region of high shear stresses near the bed can deposit to the bed. Weaker flocs are broken up and are brought back into suspension (Krishnappan and Engel 1997).
– The floc size depends on the velocity gradients, but does not directly correlate with the bottom shear stress τ due to two competing processes: The flocculation is improved with increasing τ, as particle collision is enhanced. On the other hand, high shear stresses result in an increased floc break-up, limiting the maximum floc size (Partheniades 1965; Haralampides et al. 2003).
– The strength of interparticle bonds dominates the deposition process rather than the particle weight in case of fine-grained sediment (Partheniades et al. 1966; Krone 1962).
– The flow structure is not significantly influenced by the suspended sediment, nor is the roughness of the flume bed by the deposited sediment (Haralampides et al. 2003).
– For application on field conditions, the shear stresses obtained by laboratory experiments have to be adapted and can not be transferred directly (Krishnappan and Engel 1997; Krone 1993).
– No exchange occurs between suspended and deposited material, i.e. there is no erosion during the experiments (Mehta and Partheniades 1975).

Several authors stress the importance of the particle interaction on the settling and deposition process, for example Partheniades et al. (1966) and Krone (1962). Verbeek et al. (1993) furthermore emphasize that the settling velocity has a large effect on the results of numerical models.

So, the calibration of numerical models relies on the knowledge of upper and lower limits between which the model parameters can vary depending on the particle interaction. The determination of those limits ought to be possible by performing similar deposition experiments using sediments which represent the two supposable extremes in their depositional behavior.

3 MATERIALS AND METHODS

Experiments on deposition behavior of fine particles were carried out in an annular flume using two artificial muds of different cohesiveness and a natural mud for comparison.

3.1 *Annular flume*

Two annular flumes of different diameter are available at the Institute for Water and River Basin Management, Universität Karlsruhe, Germany. They consist of a circular water-filled basin with a rotating cylinder within the basin as shown in Fig. 1. This setup forms a ring-like channel with free water-surface with the flow being driven by a rotation of the inner boundary. By shifting the position of the rotating cylinder within the basin, the channel may be narrowed on one side and expanded on the other side.

The channel width is 0.375 m for both annular flumes, the mean diameters are 1.2 m and 3.6 m, respectively. All presented experiments were carried out in the small annular flume with a flow depth of 0.28 m.

3.1.1 *Bottom shear stresses in annular flume*

The flow in the annular flume is driven by the rotation of the inner boundary. Therefore, the flow velocity is largest at this boundary and decreases gradually towards the outer boundary. The bottom shear stresses accordingly vary across a flume section.

The flow velocities for different rotational speeds of the inner cylinder were measured by a three-dimensional Acoustic-Doppler-Velocimeter. The bottom shear stress is calculated based on the flow measurements by a regression analysis.

The velocity distribution in the main flow direction follows the logarithmic law for turbulent, smooth flow in the lower 20% of the water depth ($y \leq 0.2\,h$) (Nezu and Nakagawa 1993):

$$\frac{u(y)}{u_*} = \frac{1}{\kappa} \ln\left(\frac{y \cdot u_*}{\nu}\right) + C_1 \qquad (1)$$

with the friction velocity u_*, the von Karman constant $\kappa = 0.4$, the kinematic viscosity ν and

$$C_1 = 5.5 \qquad (2)$$

Figure 2 shows the resulting bottom shear stresses along the flume cross-section for different rotational speeds. For the sake of simplification, the shear stresses are normalized by the shear stress $\tau_{b/2}$ at the middle of the flume cross-section. The bottom shear stress is highest at the rotating, inner boundary ($x = 0$) and decreases towards the outer boundary ($x = b = 37.5$).

The bottom shear stresses $\tau_{b/2}$ at the middle of the flume section ($x = b/2$) are shown in Table 1. The values marked by (*) are interpolated between those derived from the measurements.

8.8	0.0070*
5.5	0.0032

* Interpolated values.

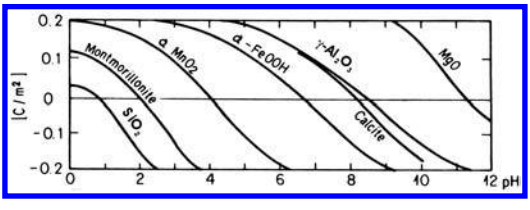

Figure 3. Sediment surface charge depending on pH-value.

3.2 *Investigated sediments*

Silica and alumina powder are used as sediment materials of well-known and unchanging characteristics. Furthermore, the particle surface charge shows a strong dependency on the pH-value (Fig. 3), which implies a significant difference in cohesiveness in deionized water (pH = 7.0).

The term *cohesiveness* in this paper expresses a tendency towards flocculation or aggregation of particles. According to DLVO theory, the interaction of fine particles is characterized by attraction due to van der Waals forces and repulsion due to electrostatic forces. Detailed information on the DLVO theory can be found in literature, for example in Sigg and Stumm (1994).

For high surface charges, the repulsive electrostatic forces dominate the interaction process and the suspension remains stable for a long time. Low surface charges are unable to override the pH-independent van der Waals attraction, so the particles flocculate and the deposition rate increases due to the larger floc size compared to the size of the single particle.

In deionized water, silica has a high negative surface charge, whereas alumina has a surface charge close to zero enhanced by its strong buffer capacity which somewhat alkalinizes the water.

For comparison, a natural mud taken from the reservoir of a pumped-storage power plant is investigated. The sediment from the Wehra reservoir has a mean

Copyright © 2006 Taylor & Francis Group plc, London, UK

particle diameter of $d_{50} = 0.046$ mm and an organic content of about 14%. The d_{50} of both silica and alumina particles is about 0.005 mm.

Silica and alumina are investigated in deionized water. For the Wehra sediment experiments, tap water is used since a transport of original Wehra water was impractical.

3.3 *Experiments on deposition*

Experiments on deposition of silica, alumina and the Wehra sediments in the annular flume are carried out as follows: Prior to inserting the sediment into the annular flume, the sediment is dispersed in deionized water by means of a laboratory stirrer.

The suspension is then gradually inserted into the steady flow in the annular flume at high rotational speeds of the inner cylinder.

The settling process is observed continuously as change in turbidity by a turbidity meter. Additionally, samples are taken from the suspension periodically for the determination of the correlating particle concentrations. Thus, by a correlation function between turbidity and concentration, a continuous monitoring of the decrease in concentration of the suspended particle with time is obtained.

4 RESULTS AND DISCUSSION

4.1 *Equilibrium concentration*

Diffusion theory attributes sediment transport in suspension to a balance of upward movement due to turbulence and downward movement due to the self-weight of the particles. So, for a given flow, i.e. a given turbulence, there is an associated capacity of particles with certain characteristics which may be transported in suspension.

If the particle concentration is higher than this specific capacity, deposition will occur. The deposition will continue until a steady state, the so-called *equilibrium concentration*, is reached, at which point the turbulence just balances the settling process.

Figure 4 shows the deposition of silica particles in deionized water in the annular flume at four different rotational speeds of the inner cylinder. After a duration of about 50 hours, the equilibrium concentration is reached for three experiments.

The final ratios of current to initial concentration range between 0.66 and 0.73. However, the magnitude of the equilibrium concentration does not seem to correlate directly with the flow velocity.

At the lowest tested rotational speed of 8.8 rpm, all particles deposit eventually and no state of equilibrium is reached. The necessary settling time was found to be several hundred hours.

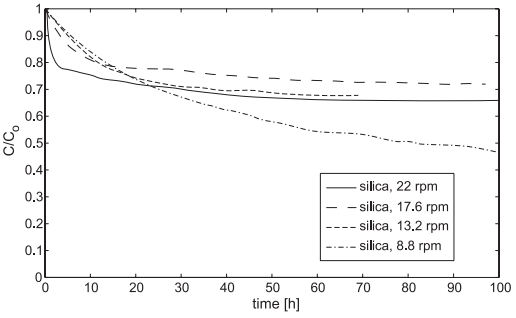

Figure 4. Deposition of silica particles in deionized water for different rotational speeds of the inner cylinder.

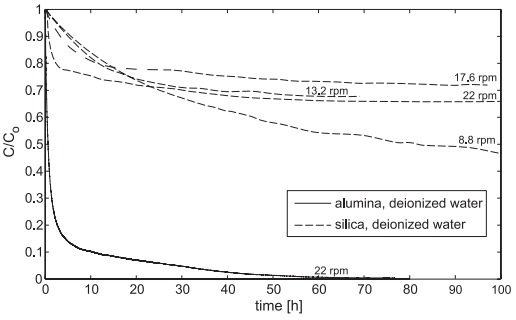

Figure 5. Deposition of particles with different cohesiveness for different rotational speeds of the inner cylinder.

To determine the influence of particle cohesiveness on the equilibrium concentration, a similar experiment was carried out with alumina particles (Fig. 5).

The results clearly indicate the different behavior of the two minerals which is to be attributed to their cohesiveness. Even at the highest rotational speed of the inner cylinder, all alumina particles settle down quickly. After about 50 hours, at which time the equilibrium concentration is reached for the corresponding silica suspension, the alumina concentration has decreased strongly to about $0.02C_0$. After another 25 hours, all alumina particles have deposited.

As aforementioned in Chapter 3.2, the surface charge of alumina in deionized water is very low. Thus, there are no surface forces preventing flocculation. Although the mean diameters of the single particles are equal for both sediments, the change in suspended concentration differs strongly due to the aggregation of the alumina particles and the resulting deposition of flocs rather than single particles.

4.2 *Deposition fluxes*

In addition to the magnitude of the steady state concentration, the change in concentration with time, i.e. the

Copyright © 2006 Taylor & Francis Group plc, London, UK

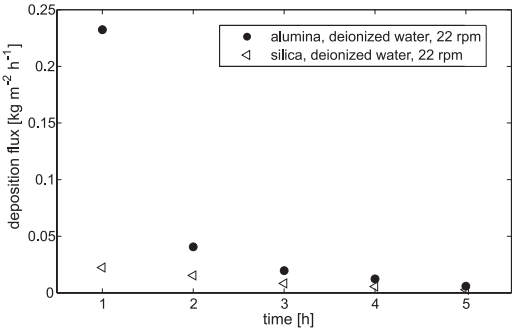

Figure 6. Deposition fluxes for the first 5 hours after start of the experiments.

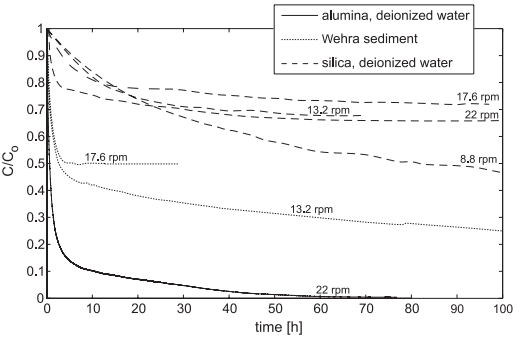

Figure 7. Comparison of depositional behavior for silica, alumina and natural mud.

deposition rate, is a matter of particular interest. The deposition rate is often multiplied by the water depth to get a *deposition flux*.

Exemplarily, the deposition fluxes for alumina and silica suspensions at a rotational speed of 22 rpm are presented in Fig. 6. The initial concentration for both experiments is $C_0 = 2.5\,\mathrm{g/l} = 2.5\,\mathrm{kg/m^3}$. To analyze the concentration time series, a time step of $\Delta t = 1\,\mathrm{h}$ is chosen.

The figure only depicts the deposition flux for the first 5 hours after the start of the experiments, as the deposition rate per hour decreases strongly afterwards.

The deposition flux apparently is a function of the particle concentration in suspension. Nevertheless, the deposition flux of alumina for the first hour is approximately $\Phi_{dep,al} = 0.232\,\mathrm{kg/m^2h}$, which is about ten times the corresponding deposition flux of silica of $\Phi_{dep,si} = 0.022\,\mathrm{kg/m^2h}$.

Analogously to the equilibrium concentration, the only difference between the two experiments evaluated in Fig. 6 is the cohesiveness of the particles used.

At first, when the particle concentration in suspension is still relatively high, the flocculation of the alumina particles immensely enhances the deposition. Afterwards, when the alumina concentration has declined significantly, the deposition rate also decreases, until finally the deposition fluxes for alumina and silica converge.

4.3 *Comparison to natural mud*

Silica and alumina were chosen as sediments which represent the two extremes of cohesiveness in deionized water, silica particles being strongly repulsive and alumina particles aggregating easily.

For comparison, sediment from the Wehra reservoir was used as sediment with "in-between-cohesiveness". Natural muds are a mixture of diverse minerals of different cohesiveness, the clayey fraction for the most part having a negative surface charge at pH 7. The resulting repulsive inter-particle forces are weakened by the natural ionic content of the ambient water and counteracted by the particle-binding effect of organic components.

The data obtained in the deposition experiments with theWehra sediment are added to the afore shown graph (Fig. 7). For a rotational speed of 17.6 rpm, an equilibrium is reached after 10 hours at $0.5\,C_0$. At 13.2 rpm, all sediment particles deposit eventually after several hundred hours.

Evidently, the Wehra sediment shows a depositional behavior which is in between that of silica and alumina concerning the level of the equilibrium concentration and the flow velocities at which an equilibrium (greater than zero) is reached at all.

5 CONCLUSIONS

The two minerals chosen to represent two extremes of cohesiveness in the experiments display a definitely different behavior, although the flume setup and the primary grain sizes were equal.

Alumina particles form aggregates which settle down at high deposition rates. Furthermore, the maximum flow velocity in the small annular flume did not suffice to maintain a steady state suspension.

The silica particles repel each other and therefore stay in suspension for a much longer time. In addition, the equilibrium concentration is reached at a relatively high level for a wide range of flow velocities.

The initial deposition flux of the alumina suspension significantly exceeds that of the silica suspension, even though the experiments were carried out with the same flow velocity and initial concentration, which is supportive of the aforementioned process description.

The investigated natural mud proved to represent a mean cohesiveness in between silica and alumina. Thus, silica and alumina appear to be adequate sediments to define extreme behavior of fine particle suspensions.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The results of those experiment with oppositional materials can serve to test numerical models and to narrow down the range of the values of input parameters to the simulations.

Measurement of flow patterns within an Alpine reservoir

H. Knoblauch, H. Badura & J. Schneider
Institute of Hydraulic Engineering and Water Resources Management, Graz University of Technology

ABSTRACT: Reservoir sedimentation at the Margaritze reservoir, Austria, has already caused problems in the operation of the bottom outlet. At present, the sediments are being transferred within the reservoir to the shallow part. Partly the deposited material is remobilized and conveyed back to the steep part of the water body. In summer 2004 and 2005 measurements were conducted in order to survey the flow patterns. The flow velocities were determined by two Acoustic Doppler Current Profilers. The measurements were taken considering various boundary conditions, such as water level, transfer under progress, amount of inflows and outflows. Different cross sections and singular spots were carefully chosen for receiving the best overview of the reservoirs flow patterns. The results of the measurements demonstrate that the remobilization and transport of the deposited sediment are directly linked to the transfer of sediment to the shallow part of the reservoir.

1 SEDIMENTATION OF THE RESERVOIR

Situated in the heart of the alpine region, Margaritze reservoir is part of the Kaprun Hydro Power Scheme. Its major water inflow area lies at the foot of a glacier. These inflows exhibit average annual sediment concentrations of 40,000 m^3. As a consequence of the increasing sediment deposition in the reservoir, two phenomena can be observed. On the one hand, its storage capacity – and at the same time its benefit for power economy – decreases. On the other hand, sedimentation tends to cause problems in the mechanical equipment parts. In order to keep reservoir facilities in full operation, incoming sediment loads have been removed since the late nineties. By means of a submersible pump a mean daily amount of 3,000 m^3 of water containing glacial silt (average concentration: 1.3 g/l) is dredged from the gorge section and conveyed to the shallow portion of the reservoir, where it is deposited under certain conditions. So far it is unclear why parts of the sediment load which have been moved to the shallower section of the basin are later on remobilized and at an average 10 to 20% of the transferred material gets back to the gorge section of the basin (Figure 1). The slope of the bottom between the shallow and the gorge parts is about 2%.

Moreover, the question remains to be answered, as to whether sediment conveyance back to the gorge portion is probably already happening during ongoing excavation works. Water level fluctuations inside the reservoir as well as hydraulic inflow fluctuations and sediment flows already during dredging works, respectively, may cause a continuous sediment transfer.

Figure 1. Margaritze reservoir.

The 2004 and 2005 measurement campaigns were aimed at explaining all relevant details regarding the reservoir flow situation. In addition to this, a possible change in current conditions during the dredging process is to be investigated.

2 MEASURING APPLIANCES

Apart from two 3-D velocity probes (an ADCP® and an Aquadopp® Profiler), a density current probe as well as a temperature and a conductivity probe were employed for the measurements at Margaritze reservoir in August 2004 and August 2005.

Table 1. Overview of the measuring appliances.

Measuring appliances	Conducted measurements
3D – Aquadopp Profiler®	3D – velocity measurements in transverse profiles and continuous single point meas.
3D – ADCP® Workhorse	3D – Velocity measurement (in profiles and continuous single point meas.)
Temperature and conductivity probe	Temperature and conductivity probes in transverse profiles and single points
Density current probe	Density current probes in transverse profiles and single points
Tracer (sodium chloride) and conductivity probe	Tracer tests

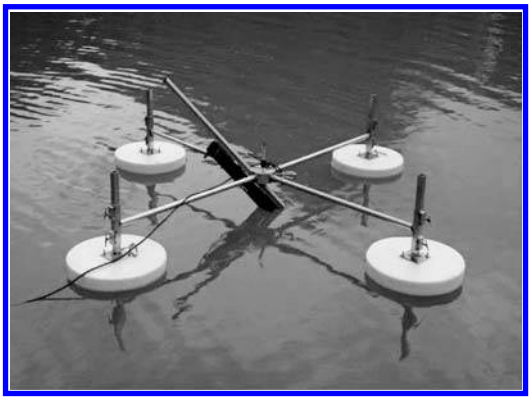

Figure 2. Fixation of the Aquadopp®.

3 THE 3-D ULTRASONIC PROBES

For this project the AQUADOPP® Profiler and the ADCP® Workhorse have been employed measuring velocities by means of Doppler-technology. Unlike single point measurements, these two profilers depict velocities at certain, pre-defined intervals along a depth profile. Compared to single point measurements, its fundamental advantage is its ability to produce a comprehensive recording of the depth profile by way of only a single test. Consequently, a lot of time is being saved. Apart from its high, three-dimensional dissolution, a further advantage of these profilers is the fact that it can be used for extremely low velocities. The employment of the probes required particular adaptations.

The Aquadopp® 3D – velocity probe was fastened to a measuring device, which had been exclusively manufactured for this measuring campaign (Figure 2 and Figure 3). The device comprised four floats and an aluminium framework, to the latter of which the Aquadopp® Profiler had been secured in a 45° angle. This "pontoon" was fastened to a guide rope which was stretched along the profile all across the artificial water basin. In this way, the measuring device was gradually drawn over the cross-section while measurements were conducted at intervals ranging from 4 to 12 meters. While velocity measurements were taking place, also temperature and conductivity measurements were carried out. The respective measuring devices were again fixed to the meter-marked rope and then submerged meter after meter at every single measuring point.

Table 2. Technical data of the ultrasonic probes.

	AQUADOPP®	ADCP®
Acoustic frequency	2000 kHz/3 beams	600 kHz/4 beams
Max. ranges	5 m–12 m	<70 m
Min. cell size	0.1 m	0.25 m
Measuring area	±10 m/s	±3 m/s
Measuring accuracy	1% of the data	0.25% of the data

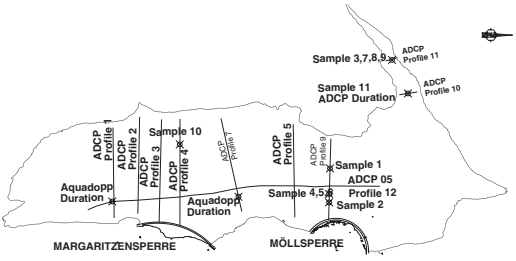

Figure 3. Location of measurements.

The results gained in all theses measurements clearly reflect a connection between the sediment transport at the bottom of the basin and the operation of the submersible pump. During dredging operations, a suspended sediment load accumulated in the bed of the shallow portion of the reservoir, which then flowed at a speed of about 0.1 m/s and a concentration of approx. 1 g/l towards the gorge section.

4 PARAMETERS OF THE MEASURING CAMPAIGNS

4.1 *Overview*

In August 2004 as well as in August 2005 two measuring campaigns were launched to realize the flow pattern situation according to different parameters at the reservoir (inflow, outflow and water level). Great efforts have been taken to ensure that each transverse

Copyright © 2006 Taylor & Francis Group plc, London, UK

profile measurement was performed under approximately the same conditions. That is to say that, as long as a measurement was conducted, there would not be any substantial variation as far as the inflow and outflow conditions, the water level or the dredging system were concerned. Any kind of change in the factors mentioned above was recorded by continuous velocity measurements. As for the arrangement of continuous measurements, altered velocity distributions caused by the dredging system were particularly taken into consideration.

With regards to the results gained in the 2004 and 2005 measurement campaigns, profile measurements may be distinguished from single point measurements (Figure 3). In profiles 1 to 5 velocity ADCP® and AQUADOPP®, turbidity, temperature and conductivity were dealt with whereas in profiles 6 to 11 only turbidity, temperature, conductivity and velocity with the ADCP® probe could be measured because of the considerable water depth. Additionally further 10 single points were largely located in the gorge section, where details concerning temperature, turbidity and conductivity were gathered.

Permanent velocity measurements took place at the marked points in the transverse profiles ("Aquadopp Duration", Figure 3). On average, each profile measurement took two hours depending, however, on both measurement duration and the number of marks on each transverse profile. Measurements on each point took between 150 and 300 sec.

Measurements at Margaritze reservoir can be classified as follows.

4.2 *Transverse profile measurements ("ADCP Profile x" in Figure 3)*

- Velocity transverse profiles (3-dimensional)
- Temperature transverse profiles
- Conductivity transverse profiles
- Density current transverse profiles

4.3 *Single point measurements*

- Continuous velocity measurements (3-D)
- Temperature depth profiles
- Conductivity depth profiles
- Density current depth profiles
- Tracer tests

5 BOUNDARY CONDITIONS

In Figure 4 the rate of inflow respectively outflow of the Margaritze reservoir, the hydrograph of the water level and the working hours of the dredging system are illustrated, exemplary for 2005. The graphs for 2004 show a similar output.

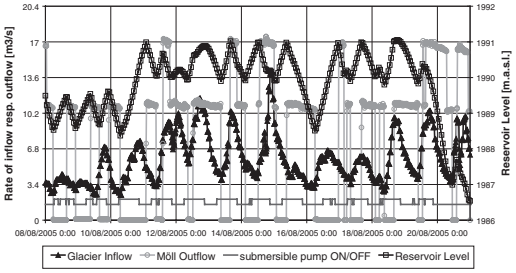

Figure 4. Hydrological situation of the Margaritze reservoir in August 2005.

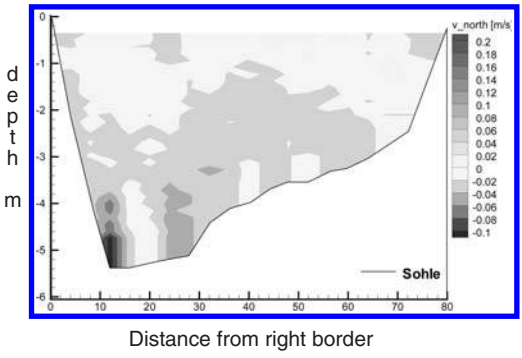

Figure 5. Profile 1, submersible pump OFF, interpolated velocity profile towards the north.

6 RESULTS

6.1 *Profile 1, submersible pump OFF*

When this described measurement of profile 1 (shallow part, Figure 3) was performed, the submersible pump was out of order. The stemming level rose from 1989.0 to 1989.6 masl, which corresponds to a rising speed of 17 cm/h. The velocity profile towards the north (Figure 5) shows mainly negative velocity patterns. Water flows towards the south. This process may be explained by the increase in the hydrograph. This fact principally involves that water has to flow from the northern section of the reservoir to the southern part.

Velocities to the east and vertical are less relevant. However, it can be observed that the flow direction in the upper half of the profile tends to head westwards and downwards whereas it moves rather eastwards and upwards in the lower half of the profile. Suspended sediment concentration comes virtually throughout the whole profile to a standard rate of 0.25 g/l. The temperature profile illustrates a layer structure which is most typical for a lake. Near the bottom of the basin the temperature was 4°C while in higher layers it was up to 8°C.

Copyright © 2006 Taylor & Francis Group plc, London, UK

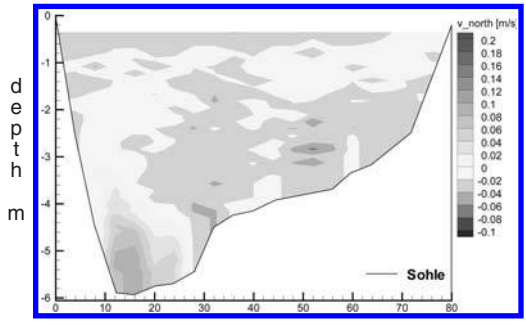

Figure 6. Profile 1, submersible pump ON, interpolated velocity profile towards the north.

6.2 *Profile 1, submersible pump ON*

Unlike the above under 6.1 described measurement of profile 1, the submersible pump was in operation during measurement 2. The pipe ended in the southern section of the reservoir. The stemming level remained virtually constant on 1989.8 masl. The velocity profile towards the north (Figure 6) now distinctly reveals positive velocity patterns in the deep channel. Water flows to the north. Positive velocities came to 10 cm/s. Compared to measurement 1, velocities to the east and upwards changed only to an inconsiderable degree. Suspended sediment concentration, however, increased drastically from 0.25 g/l to 1.3 g/l in exactly those areas of the deep channel in which northwards velocity had remarkably risen.

6.3 *Profile 9, submersible pump ON*

The location of the transverse profile 9 is illustrated in Figure 3. This profile is located at the border between the shallow and the gorge part of the reservoir. The submersible pump was in operation during this measurement. The pipe ended in the southern section of the reservoir. The stemming level remained virtually constant on 1990.0 masl. The velocity profile towards the north (Figure 7) now distinctly reveals positive velocity patterns in the deep channel. Water flows to the north. Positive velocities came to 13 cm/s. Suspended sediment concentration, however, came to 1 g/l in exactly those areas of the deep channel in which northwards velocity had remarkably risen.

7 IMPACT OF THE DREDGING SYSTEM

Judging from the measurements described under 6.1, 6.2 and 6.3, it has become evident, that the operating dredging system has a direct impact on the deep channel sediment transport of profile 1. While

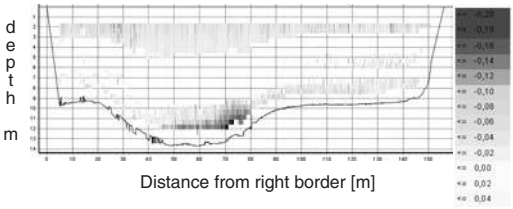

Figure 7. Profile 9, submersible pump ON, interpolated velocity profile towards the south.

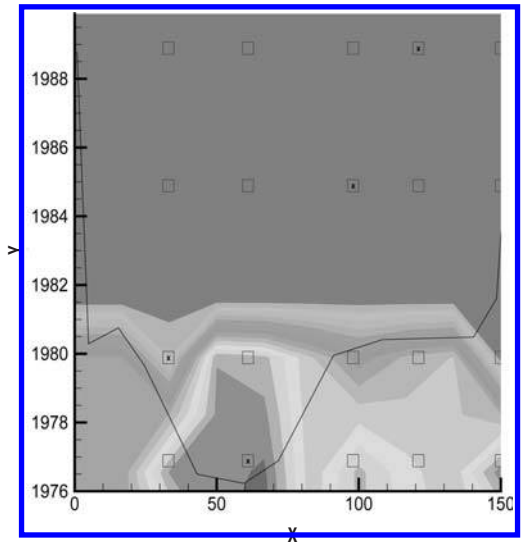

Figure 8. Profile 9, submersible pump ON, interpolated suspended sediment concentration, towards the south.

during the measurements without submersible pump no conspicuous flows or suspended sediment concentrations had been detected, in measurements when the submersible pump was operating exceptionally high velocities towards the north combined with high suspended sediment concentrations (Figure 8) have been found.

8 TRACER TEST RESULTS

During measurement the sediment inflow mark was located in the southern section of the reservoir. Conductivity was measured at a distance of 160 m from the point where the excavator pump pipes had been submerged. The tracer inflow took place at 00:00 o'clock. The measurement was conducted in various water depths at intervals of 30 sec. 40 kg of dissolved sodium chloride were added to the sediment-water-mixture. The result has been illustrated in Figure 9. The x-axis

Copyright © 2006 Taylor & Francis Group plc, London, UK

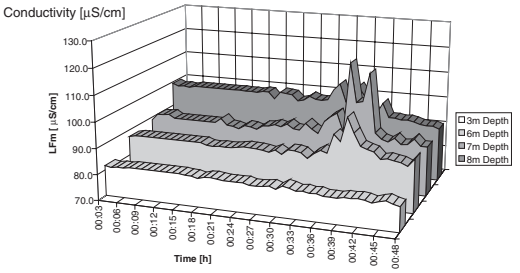

Figure 9. Tracer test results.

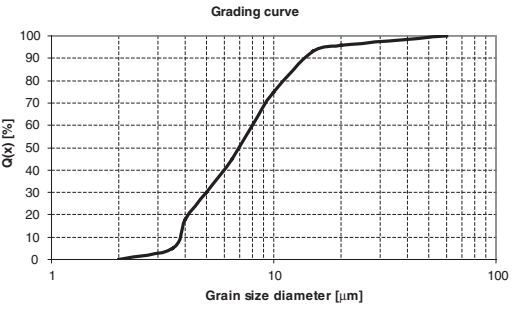

Figure 10. Profile 9, grading curve, water depth 1977 masl.

of the graph shows the measuring duration whereas the z-axis provides data concerning the conductivity in [μ S/cm]. A distinct conductivity increase in t = 6 m, t = 7 m and t = 8 m can be observed with its maximum rate occurring at t = 7 m, whereas in t = 3 m no kind of conductivity increase could be found. Flowing time was 10 cm/s.

The tracer method made it possible to determine the origin of the density current. Similarly, it worked most effectively when it came to detecting the average flowing time. In particular, flowing times accurately correspond with the velocity patterns gained in the Aquadopp® Profiler measurements.

Finally, the density current distribution along the bottom of the basin matches the velocity distribution in the ultrasonic measurements. The results obtained from the conductivity profile draw attention to the fact that inside the deep channel increased conductivity has been recorded. Rates rise from average 100 µS/cm to 115 µS/cm. The extent of increased conductivity corresponds to that of increased suspended sediment concentration

9 GRADING CURVE OF THE SUSPENDED SEDIMENTS

Apart from the long term measurements in 2005 a set of 12 samples were collected to determine the suspended sediment concentration of the supposed density current. The sieve analysis show similar results concerning similar parameters (inflow and outflow to the reservoir, operating hours of the dredging system, water level). The graph in Figure 10 shows the results from profile 9 at a depth of approximately 13 m.

10 MODEL OF STREAM PATTERNS

On account of the results gained in all the measurements dealt with in this study, various models have been designed to provide a detailed description of the various processes going on inside the reservoir. In the following the concept for a model which includes the operation of a submersible pump will be presented in the diagram of Figure 11. The illustration depicts a longitudinal section of the reservoir.

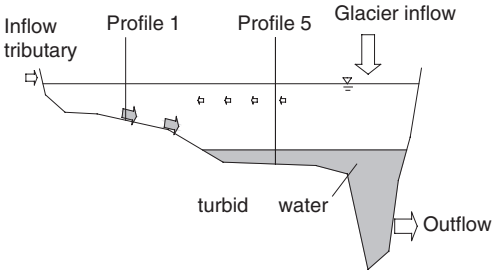

Figure 11. Model of stream patterns, submersible pump ON.

If sediment transfer is performed at constant water level by means of a submersible pump, sediment loads will flow along the bottom of the basin towards the north. This fact has been proven to be accurate by both velocity and density current measurements in profiles 1 to 11.

11 CONCLUSIONS

The substantial glacial silt inflow at Margaritze reservoir results into an average annual sediment deposition of as much as 40,000 m^3. In order to keep the mechanical facilities in full operation, incoming sediment loads are currently transferred by means of a submersible pump from the gorge section to the shallower portion of the basin. It has been unclear, why some of the transferred sediments are remobilized and how they are transported back into the gorge section of the reservoir. Furthermore, it was unknown as to whether the conveyance back to the gorge portion was already happening during the dredging.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The task of the 2004 and 2005 measurement campaigns were to explain all the facts about the reservoir flow situation as well as to investigate possible changes in current conditions due to sediment transfer by dredging. Measurements comprised transverse profile measurements, single point measurements and continuous measurements in single points as well as tracer tests.

The results gained in all theses measurements clearly reflect a connection between the sediment transport at the bottom of the basin and the operation of the submersible pump. During dredging operations, a suspended sediment load accumulated in the bed of the shallow portion of the reservoir, which then flowed at a speed of about 0.1 m/s and a concentration of approx. 1 g/l towards the gorge section.

Reservoir sedimentation: 1D model of turbidity currents and delta deposits

J. González, A. Tamburrino & Y. Niño
Department of Civil Engineering, University of Chile, Santiago, Chile

ABSTRACT: A 1D mathematical-numerical model simulating the flow and sediment deposition in a reservoir is presented. The flow is modeled using Saint-Venant equations discretized with a finite volume numerical scheme capable of dealing with transcritical flows. Evolution of coarse sediment deposits is accounted for by using a choice of four different available bedload relationships. Two of them are based on the surface grain-size distribution and include hiding effects. Modeling of fine sediment transport and deposition is accomplished by the simulation of a turbidity current, for which minor modifications to classical depth-averaged equations allow for a complete representation of the fine sediment fall velocity effect. The numerical scheme used for the flow is adapted and used for turbidity current modeling. The full model is tested in a real reservoir application. Results show that the model is able to reproduce the co-evolution of sediment deposits capturing all the unsteady effects, including the internal hydraulic jump development in the ponded turbidity current and its time evolution in response to variable boundary conditions.

1 INRODUCTION

A dam construction in a natural river breaks the balance between affluent and effluent sediment, and starts its accumulation inside the reservoir. The most important consequence in the long term is the loss of storage capacity. To recover this loss by constructing new dams is not necessarily a feasible choice, so planned management of sediments, supported by modeling tools is required.

Being Chile a mountainous country, most of its rivers have in their upper reach high slopes and an extended grain-size distribution. Most existing reservoirs in the country have been placed in the upper reaches and sediment deposition is a critical aspect of their design and evaluation. It affects directly the projected reservoir life and the mitigation procedures to be considered during operation. Not only the total volume of sediment affluent to the reservoir is a matter of interest, but the sediment deposit distribution is very important when sediment removing measures are developed and executed.

In the presence of high slopes, it is common to find that the river flow regime is nearly transcritical or supercritical. On the other hand, coarse-grain sediment transport and deposition in such flows are complex and nonlinear effects leading to vertical sorting and hiding are everywhere present on the bed. Finally, in most cases, a non-negligible amount of fine suspended sediment is present, thus, in the case of a reservoir, the development of a turbidity current is very probable.

At this time, we do not know of a 1D commercial model that can put all these phenomena together. Most of the existing software have problems to deal with supercritical flow regime, and poorly sorted grain-size distribution and turbidity current development are not considered or must be modeled with additional expensive modules. Here a 1D mathematical-numerical model is presented. The flow is solved numerically using a modified version of the conservative upwind finite volume scheme developed by Ying (2004), which requires no special treatment to capture steep gradients or discontinuities in the solution, being capable of dealing with transcritical and mixed-regime flows typical of Chilean rivers. For bedload computation four relationships are available in the model: the classical relations of Meyer-Peter & Müller (1948) and Ackers & White (1973) which are based on a single representative diameter and the relations of Parker (1990) and Wilcock & Crowe (2003) which are based on bed surface grain-size distribution and apply to poorly sorted sediments and account for hiding effects. In the turbidity current modeling the classical approach for entrainment velocity is modified and fall velocity effect is taken into account, resulting in a continuity equation that captures all the necessary

Copyright © 2006 Taylor & Francis Group plc, London, UK

hydrodynamic effects. A new formulation proposed by Toniolo (2003) is used for the computation of the plunging of the turbidity current.

2 FLOW MODEL

2.1 *Governing equations*

1D unsteady flow in a natural river with irregular cross-sections may be described by Saint-Venant equations. The conservative form of the equations is written as:

$$\frac{\partial \mathbf{U_f}}{\partial t} + \frac{\partial \mathbf{F}(\mathbf{U_f})}{\partial x} = \mathbf{S}(\mathbf{U_f}) \tag{1}$$

Where $\mathbf{U_f}$, $\mathbf{F}(\mathbf{U_f})$ and $\mathbf{S}(\mathbf{U_f})$ are, respectively, the vectors of conserved variables, fluxes and sources, defined as follows:

$$\mathbf{U_f} = \begin{bmatrix} A \\ Q \end{bmatrix}, \quad \mathbf{F}(\mathbf{U_f}) = \begin{bmatrix} Q \\ Q^2/A \end{bmatrix}$$

$$\mathbf{S}(\mathbf{U_f}) = \begin{bmatrix} 0 \\ -gA\dfrac{\partial Z}{\partial x} - g\dfrac{n^2 Q|Q|}{AR_h^{4/3}} \end{bmatrix} \tag{2}$$

where A = cross-sectional area; Q = discharge; g = gravitational acceleration; Z = water level; n = Manning coefficient; and R_h = hydraulic radius. Saint-Venant equations written in the above form have the advantage of using one source term to represent the pressure effect and the bed slope does not appear explicitly.

2.2 *Numerical scheme*

Since reservoir sedimentation simulations are often performed considering an extended period of time, a computationally efficient model is required. It is preferable then, that the numerical scheme be explicit performing the least number of operations per time interval as possible.

The numerical scheme used here was developed by Ying (2004). It consists of an explicit, conservative upwind finite volume scheme, which uses a weighted average for the pressure term, based on local Courant conditions. The scheme is robust and stable when the flow has a unique direction, but it presents some instabilities in the case of reversal flows. In this paper, a minor modification is applied to the flux computation in the case of reversal flows, making the scheme more stable when modeling a reservoir, where high depths and high cross-sectional area values are involved. The local direction of the flow when solving the momentum equation is determined based only on the flow direction at the node. The grid used is cell centered as shown in Figure 1. The grid has N grid points along x.

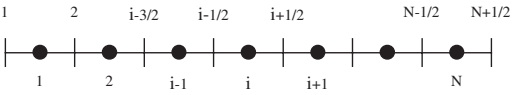

Figure 1. Definition sketch of the grid.

The variables are defined in the nodes and the fluxes are calculated at the interfaces.

Equation 1 integrated over the ith cell, yielding the following discretized equation:

$$\mathbf{U_f}_i^{n+1} = \mathbf{U_f}_i^{n} - \frac{\Delta t}{\Delta x_i}\left(\mathbf{F}_{i+1/2}^n - \mathbf{F}_{i-1/2}^n\right) + \Delta t \mathbf{S}_i \tag{3}$$

where Δx_i is the distance between interfaces surrounding node i and Δt is the time discretization. Superscript n indicates the time step. The flux at the interface is defined as:

$$\mathbf{F}_{i+1/2}^n = \begin{bmatrix} Q_{i+k}^n \\ \left(Q_{i+k}^n\right)^2 / A_{i+k}^n \end{bmatrix} \tag{4}$$

where $k = 0$ if $Q_i^n > 0$ and $Q_{i+1}^n > 0$; and $k = 1$ if $Q_i^n < 0$ and $Q_{i+1}^n < 0$. If reversal flow occurs at the interface, meaning that Q_i and Q_{i+1} have opposite sign, the flux is computed as:

$$\mathbf{F}_{i+1/2}^n = \begin{bmatrix} F_{i+1/2,1}^n \\ F_{i+1/2,2}^n \end{bmatrix} \tag{5}$$

$$F_{i+1/2,1}^n = \frac{Q_i^n + Q_{i+1}^n}{6} - \frac{2}{3} g A_i^n \Delta t \frac{Z_{i+1}^n - Z_i^n}{x_{i+1} - x_i} \tag{6}$$

$$F_{i+1/2,2}^n = \frac{\left(F_{i+1/2,1}^n\right)^2}{A_i^n} \tag{7}$$

This formulation could be interpreted as a correction for the average discharge at the interface, based on water surface gradient information. To evaluate the source term of Equation 3, the local flow direction is defined based on the discharge sign at the node. The source term is then evaluated as:

$$\mathbf{S}_i = \begin{bmatrix} 0 \\ -gA_i^{n+1}\left[w_1\left(\dfrac{\partial Z}{\partial x}\right)_{down} + w_2\left(\dfrac{\partial Z}{\partial x}\right)_{up}\right] - g\dfrac{n^2 Q_i^n |Q_i^n|}{\left(R_{h_i}^n\right)^{4/3} A_i^n} \end{bmatrix} \tag{8}$$

where w_1 and w_2 are weighting factors. The downstream and upstream water surface gradients are defined as:

$$\left(\frac{\partial Z}{\partial x}\right)_{down} = \frac{Z_{i+1-j}^{n+1} - Z_{i-j}^{n+1}}{x_{i+1-j} - x_{i-j}} \tag{9}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

$$\left(\frac{\partial Z}{\partial x}\right)_{up} = \frac{Z_{i+j}^{n+1} - Z_{i-1+j}^{n+1}}{x_{i+j} - x_{i-1+j}} \quad (10)$$

The weighting factors w_1 and w_2 are evaluated based on numerical local Courant number as follows:

$$w_1 = 1 - c_r^{down}, \quad w_2 = c_r^{up} \quad (11)$$

$$c_r^{down} = \frac{\Delta t}{x_{i+1-j} - x_{i-j}} \frac{V_{i+1-j}^n + V_{i-j}^n}{2} \quad (12)$$

$$c_r^{up} = \frac{\Delta t}{x_{i+j} - x_{i-1+j}} \frac{V_{i+j}^n + V_{i-1+j}^n}{2} \quad (13)$$

$$V_i^n = \left|Q_i^n\right| / A_i^n \quad (14)$$

The subscript j is defined as:

$$j = \begin{cases} 0 & if \quad Q_i^n > 0 \\ 1 & else \end{cases} \quad (15)$$

The scheme is subject to the Courant-Friedrichs-Lewy stability condition, that is:

$$N_{CFL} = \max\left[\frac{\Delta t}{\Delta x_i}\left(\left|V_i\right| + \sqrt{gA_i / l_{wi}}\right)\right] \le 1 \quad (1 \le i \le N) \quad (16)$$

where l_{wi} is the top width of the channel at cell i.

Boundary conditions are treated by introducing two ghost cells to the computational domain. For the reservoir modeling, water surface level is specified at the downstream ghost cell and discharge is determined by a zero order extrapolation from the last interior node. At the upstream ghost cell, discharge is always specified. In the case of subcritical inflow, water surface level is calculated by a linear extrapolation based on values of two adjacent interior cells. If the inflow is supercritical the water level surface is specified at the upstream ghost cell.

3 BEDLOAD TRANSPORT MODEL

3.1 *Governing equations*

Since trapezoidal cross-sections are being used to represent the river and the reservoir, bed evolution must be calculated using an appropriate conservative form of Exner's equation. Conservation of mass over the control volume of Figure 2 states that:

$$\frac{\partial A_s}{\partial t} + \frac{1}{1-\lambda_s}\frac{\partial Qs}{\partial x} = 0 \quad (17)$$

where $A_s =$ deposit cross-sectional area; $Q_s =$ volumetric bedload discharge; and λ_s is porosity of the deposit.

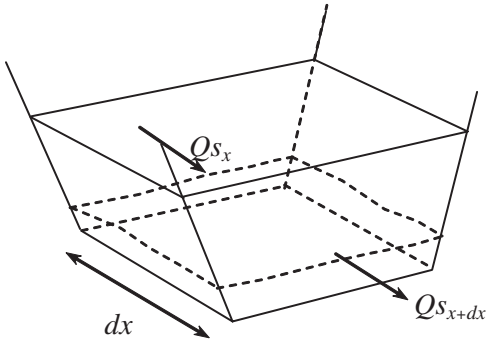

Figure 2. Control volume sketch for sediment mass conservation.

Figure 3. Definition sketch for bedload transport model.

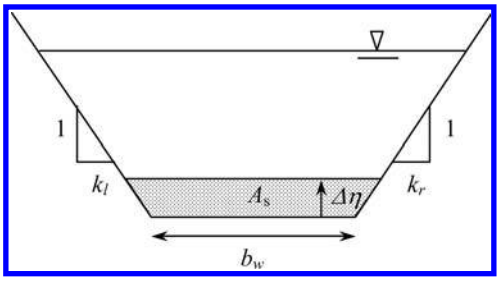

Figure 4. Sketch of cross-section with a sediment deposit.

3.2 *Numerical scheme*

Volumetric bedload discharge is determined from the hydraulic conditions, which are known at the nodes. In order to get a discretized equation for bed evolution, the integration of Equation 17 must be performed with a control volume with interfaces located at cell nodes. The grid used for integrating Equation 17 is shown in Figure 3.

The integration is carried out over the control volume, which involves nodes $i-1$ and i and between instants t and $t+\Delta t$. The increment of deposited sediment cross-sectional area is given by:

$$\overline{A_s}^{n+1} = -\frac{\Delta t}{1-\lambda_s}\frac{Qs_i^n - Qs_{i-1}^n}{x_i - x_{i-1}} \quad (18)$$

where the bar over A_s denotes a spatial mean sediment deposit cross-sectional area between nodes i-1 and i, and it has been considered that the mean volumetric bedload discharge over the time interval can be approximated by its value at the beginning. Figure 4 shows

Copyright © 2006 Taylor & Francis Group plc, London, UK

the relation between the cross-section of the sediment deposit and bed elevation.

$$A_s = k_m \Delta\eta^2 + b_w \Delta\eta \tag{19}$$

$$k_m = \frac{k_l + k_r}{2} \tag{20}$$

The mean cross-sectional area of sediment deposit is defined by averaging the geometric properties of cross-sections at nodes $i-1$ and i.

$$\overline{A_s} = \overline{k_m}\Delta\eta^2 + \overline{b_w}\Delta\eta \tag{21}$$

$$\overline{k_m} = \frac{k_{mi} + k_{mi-1}}{2}, \quad \overline{b_w} = \frac{b_{wi} + b_{wi-1}}{2} \tag{22}$$

Replacing Equation 21 into Equation 18 yields the expression for the bed elevation change at the end of the time interval Δt:

$$\overline{k_m}\Delta\eta_i^2 + \overline{b_w}\Delta\eta_i + \frac{\Delta t}{1-\lambda_s}\frac{Qs_i^n - Qs_{i-1}^n}{x_i - x_{i-1}} = 0 \tag{23}$$

At this point, the volumetric bedload discharge must be calculated in order to get the bed elevation change. For this purpose, four relationships have been implemented in the model and can be selected by the user. These are the relations by: Meyer-Peter & Müller (1948), Ackers & White (1973), Parker (1990), and Wilcock & Crowe (2003). They have been extensively described in literature. The first two relationships are based on incipient motion criteria and are recommended for uniform sediment. Many comments can be found in literature regarding the bedload rates overestimation given by Meyer-Peter & Müller relation (Jäggi 1983, Smart 1984, and Hunziker & Jäggi 2002). The parameters appearing in the Ackers & White formulae were calibrated from flows with Froude numbers less than 0.8 and very few experiments were made using particles larger than 2.5 mm. On the other hand, the relationships proposed by Parker, and Wilcock & Crowe have been developed for gravel mixtures and are based on bed surface grain-size distributions. They include hiding effects and are more appropriate for rivers whose bed exhibits poorly sorted grain-size distributions. The four relations were implemented in the model in order to observe the differences between their results when they are applied to steep mountains rivers.

The boundary condition for inflowing sediment load is treated following the same ideas used for the liquid flow, i.e. the volumetric bedload discharge at upstream ghost cell, is obtained by a linear extrapolation from the interior domain.

4 TURBIDITY CURRENT MODEL

The fine sediment transport is modeled here considering the development of a turbidity current along the reservoir bottom. Since the cross-sections used in the model are not rectangular, cross-section averaged equations of motion were developed. However, these equations contain many unknown shape factors resulting from the similarity hypothesis, which are impossible to estimate, as the required empirical data are not currently available. Because of this, only the classical depth-averaged per unit width equations were used.

When a turbidity current reaches the reservoir dam, an internal hydraulic jump is developed and the flow regime changes from supercritical to subcritical. The supercritical zone of the current has high levels of turbulence which render a diffuse interface between the current and the quiescent water above it, enhancing water entrainment across the interface. In addition, entrainment of sediment into suspension from the bottom is possible. In the subcritical regime the turbulence decays and the interface become sharp and well defined. In this regime, the entrainment of water and sediment from the quiescent water body and the bottom of the reservoir is damped.

Although there is no outflow of the turbidity current, a steady interface in the subcritical zone can be developed. The continuous inflow of water is evacuated through the interface while the inflowing sediment is deposited at the reservoir bottom. Recently, Toniolo (2003) has developed a set of equations that represent adequately both regimes of a ponded turbidity current, by integrating the equations of motion between the bed and the interface of the current. In this paper, an equivalent set of corrected equations is presented, in which suspended sediment fall velocity effect is incorporated in the water entrainment.

4.1 *Fall velocity effect*

The depth-averaged volume continuity equation of a turbidity current is (Parker et al.1986):

$$\frac{\partial h_c}{\partial t} + \frac{\partial U h_c}{\partial x} = w_e \tag{24}$$

where U is the depth-averaged velocity; h_c is the thickness of the boundary layer; and w_e is a water entrainment velocity arising from the nature of boundary layer approximations used through integration. This velocity is commonly related to the depth-averaged velocity, U, through a dimensionless entrainment coefficient, e_w, as follows:

$$w_e = e_w U \tag{25}$$

The entrainment coefficient depends on the Richardson number, Ri:

$$Ri = \frac{RgCh_c}{U^2} \tag{26}$$

where R is the submerged specific gravity of the sediment; and C is the depth-averaged volumetric concentration of suspended sediment.

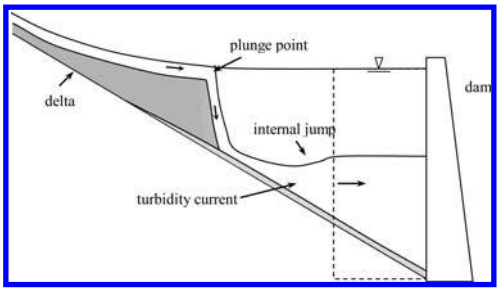

Figure 5. Definition sketch of a reservoir with a ponded turbidity current.

A model for the entrainment coefficient e_w has been proposed by Parker et al. (1986):

$$e_w(Ri) = \frac{0.00154}{0.0204 + Ri} \tag{27}$$

This model states the vanishing of water entrainment with the increase of the Richardson number, representing adequately this phenomenon in the subcritical regime, where Ri becomes large. Replacing Equation 25 into Equation 24, the continuity equation becomes:

$$\frac{\partial h_c}{\partial t} + \frac{\partial U h_c}{\partial x} = e_w U \tag{28}$$

This equation cannot be applied to model a ponded turbidity current. This can be seen when the control volume shown in Figure 5 is considered in the volume conservation analysis. If Equation 28 is integrated in the longitudinal direction along the volume, between positions x_0 and x_m, and considering that in the subcritical regime the water entrainment vanishes, it is found that:

$$\frac{\partial}{\partial t}\int_{xo}^{xm} h_c dx = U h_c\big|_{xo} \tag{29}$$

Since the affluent volume of the turbidity current is positive, Equation 29 states that the turbidity current elevation is rising. This is due to the fact that Equation 28 does not recognize the role played by the sediment fall velocity in the continuity of volume. If the advection would be negligible at the current, fall velocity would make the interface to settle down toward the bed. Water would escape from the solid-water mixture forming the turbidity current while its depth is decreasing at a rate equal to fall velocity, v_s. Thus, entrainment velocity, w_e, would not be null but negative since water is leaving the current. Thus, an alternative representation of entrainment velocity is proposed in this paper:

$$w_e = e_w^* U - v_s \tag{30}$$

where e_w^* is a new dimensionless entrainment coefficient which must tend to zero as the Richardson number increases, just like the original e_w coefficient. Since the model of Parker et al. (1986) for entrainment coefficient has been extensively used for modeling supercritical turbidity currents, it will be used here by introducing the parameter δ such that:

$$w_e = e_w U - \delta v_s \tag{31}$$

The value of δ is equal to unity for the subcritical regime and zero for the supercritical one. Finally, considering that the turbidity current is purely depositional, the equations used to modeling the ponded turbidity current, (volume conservation, suspended sediment mass conservation and momentum conservation respectively) are:

$$\frac{\partial h_c}{\partial t} + \frac{\partial U h_c}{\partial x} = e_w U - \delta v_s \tag{32}$$

$$\frac{\partial C h_c}{\partial t} + \frac{\partial U C h_c}{\partial x} = -v_s C \tag{33}$$

$$\frac{\partial U h_c}{\partial t} + \frac{\partial U^2 h_c}{\partial x} = -\frac{1}{2} Rg \frac{\partial C h_c^2}{\partial x} + RgSCh_c - c_f U^2 \tag{34}$$

where S denotes the bed slope and c_f is a friction coefficient for the turbidity current.

4.2 *Numerical scheme*

In order to use Ying's numerical scheme for solving the turbidity current equations, Equation 34 is rearranged as:

$$\frac{\partial U h_c}{\partial t} + \frac{\partial U^2 h_c}{\partial x} = -\frac{1}{2} Rgh_c^2 \frac{\partial C}{\partial x} - RgCh_c \frac{\partial Z_c}{\partial x} - c_f U^2 \tag{35}$$

where Z_c is the elevation of the current interface. Equations 32, 33 and 35 are written in conservative form as:

$$\frac{\partial \mathbf{U}_{ct}}{\partial t} + \frac{\partial \mathbf{F}_{ct}(\mathbf{U}_{ct})}{\partial x} = \mathbf{S}_{ct}(\mathbf{U}_{ct}) \tag{36}$$

where $\mathbf{U}_{ct}$, $\mathbf{F}_{ct}$ and $\mathbf{S}_{ct}$ are the corresponding variables, fluxes and source terms vectors defined as follows:

$$\mathbf{U}_{ct} = \begin{bmatrix} h_c \\ Ch_c \\ Uh_c \end{bmatrix}, \quad \mathbf{F}_{ct}(\mathbf{U}_{ct}) = \begin{bmatrix} Uh_c \\ UCh_c \\ U^2 h_c \end{bmatrix}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

$$\mathbf{S}_{ct}(\mathbf{U}_{ct}) = \begin{bmatrix} e_w U - \delta v_s \\ -v_s C \\ -\frac{1}{2} R g h_c^2 \frac{\partial C}{\partial x} - R g C h_c \frac{\partial Z_c}{\partial x} - c_f U^2 \end{bmatrix} \quad (37)$$

The grid used to discretize Equation 36 is the same that was used for the flow (Fig. 1). Following the same procedure used for the flow, yields:

$$\mathbf{U}_{ct\,i}^{\,n+1} = \mathbf{U}_{ct\,i}^{\,n} - \frac{\Delta t}{\Delta x_i}\left(\mathbf{F}_{ct\,i+1/2}^{\,n} - \mathbf{F}_{ct\,i-1/2}^{\,n}\right) + \Delta t \mathbf{S}_{ct\,i} \quad (38)$$

The velocity of the current is taken here to be positive so the fluxes are computed as:

$$\mathbf{F}_{ct\,i+1/2}^{\,n} = \begin{bmatrix} U_i^n h_{c\,i}^n \\ U_i^n C_i^n h_{c\,i}^n \\ \left(U_i^n\right)^2 h_{ci} \end{bmatrix} \quad (39)$$

The source term vector is evaluated as:

$$\mathbf{S}_{ct\,i} = \begin{bmatrix} S_{ct\,i,1} \\ S_{ct\,i,2} \\ S_{ct\,i,3} \end{bmatrix} \quad (40)$$

where:

$$\begin{aligned} S_{ct\,i,1} &= e_{wi}^{\,n} U_i^n - \delta_i^n v_s \\ S_{ct\,i,2} &= -v_s C_i^n \\ S_{ct\,i,3} &= -\frac{1}{2} R g \left(h_c^2\right)_i^{n+1} \sum w_k \left(\frac{\partial C}{\partial x}\right)_k \\ &\quad - R g \left(C h_c\right)_i^{n+1} \sum w_k \left(\frac{\partial Z_c}{\partial x}\right)_k - c_f \left(U_i^n\right)^2 \end{aligned} \quad (41)$$

The dimensionless entrainment coefficient is evaluated from:

$$e_{wi}^{\,n} = \frac{0.00154}{0.0204 + Ri_i^n} \quad (42)$$

$$Ri_i^n = \frac{R g C_i^n h_{c\,i}^n}{U_i^n} \quad (43)$$

$$\delta_i^n = \begin{cases} 0 & if \quad Ri_i^n < 1 \\ 1 & else \end{cases} \quad (44)$$

The weighted sums in the momentum source term are computed from:

$$\begin{aligned} \sum w_k \left(\frac{\partial C}{\partial x}\right)_k &= w_1 \left(\frac{\partial C}{\partial x}\right)_{down} + w_2 \left(\frac{\partial C}{\partial x}\right)_{up} \\ \sum w_k \left(\frac{\partial Z_c}{\partial x}\right)_k &= w_1 \left(\frac{\partial Z_c}{\partial x}\right)_{down} + w_2 \left(\frac{\partial Z_c}{\partial x}\right)_{up} \end{aligned} \quad (45)$$

where the downstream and upstream gradient are defined as:

$$\left(\frac{\partial C}{\partial x}\right)_{down} = \frac{C_{i+1}^{n+1} - C_i^{n+1}}{x_{i+1} - x_i} \quad (46)$$

$$\left(\frac{\partial C}{\partial x}\right)_{up} = \frac{C_i^{n+1} - C_{i-1}^{n+1}}{x_i - x_{i-1}} \quad (47)$$

$$\left(\frac{\partial Z_c}{\partial x}\right)_{down} = \frac{Z_{c\,i+1}^{\,n+1} - Z_{ci}^{\,n+1}}{x_{i+1} - x_i} \quad (48)$$

$$\left(\frac{\partial Z_c}{\partial x}\right)_{up} = \frac{Z_{ci}^{\,n+1} - Z_{c\,i-1}^{\,n+1}}{x_i - x_{i-1}} \quad (49)$$

the weighting factors are computed in the same way they are for the flow, but this time using the turbidity current velocity, i.e:

$$w_1 = 1 - c_{rct}^{down}, \quad w_2 = c_{rct}^{up} \quad (50)$$

$$c_r^{down} = \frac{\Delta t}{x_{i+1} - x_i} \frac{U_{i+1}^n + U_i^n}{2} \quad (51)$$

$$c_r^{up} = \frac{\Delta t}{x_i - x_{i-1}} \frac{U_i^n + U_{i-1}^n}{2} \quad (52)$$

The stability condition now reads:
