Persistent urinary incontinence after AC can result from several issues. Leakage that only occurs at night is often of multifactorial origin. Potential causes include decreased urethral resting pressure, nocturnal polyuria, and failure of the sphincter to increase its resting tone in response to bladder contractions. Failure to diagnose an incompetent outlet preoperatively can lead to symptoms of stress urinary incontinence. For patients with NGB who use a wheelchair, this complication is often noted with complaints of leakage of urine during transfers or pressure release. Patients may also leak secondary to inadequate bladder augmentation. This complication could result from the use of an inadequately short piece of intestine, an impaired blood supply to the augment segment, either of which can lead to decreased capacity or compliance, or the presence of bowel mass contractions.

Evaluation of persistent urinary incontinence after bladder augmentation typically includes completion of a voiding diary and urodynamics. Voiding diaries can be very helpful in identifying potential reversible causes such as excessive fluid intake and patients who perform IC too infrequently. If the voiding diary is unremarkable, urodynamic studies allow for evaluation of the bladder and the outlet to ascertain the cause of the urinary leakage. Therapy can

then be directed accordingly. Potential therapies for an inadequate sphincter include pubovaginal sling, bladder neck reconstruction, bladder neck closure, and artificial urinary sphincter. A study of 11 such patients with follow-up of at least 45 months revealed that insertion of bladder neck artificial urinary sphincter cuff alone was enough to achieve continence in eight (73%) patients.[72]

Simultaneous outlet procedures may be performed at the time of bladder augmentation in the setting of low valsalva leak point pressure or in those with neurogenic incontinence not expected to void spontaneously postoperatively.[73] In a large pediatric cohort of 2831 patients, 16.8 % underwent simultaneous bladder neck surgery.[12] In a cohort of patients undergoing simultaneous bladder neck sling, 88% achieved complete passive urinary continence for 4–6 daytime hours and 6–8 nighttime hours, as well as no stress urinary incontinence. Complications included two wound dehiscences that were subsequently closed. Bladder neck slings are generally safe and effective in well-selected patients.[73] In a series investigating AC and artificial urinary sphincter placement, there were a total of 195 sphincters placed with 35% failing from infection, 5% from tissue atrophy, and 25% from mechanical failure. Significant complications were found in 7% of patients including pelvic abscess, rectal perforation, deep venous thromboembolism, acute urinary retention, urethral strictures and pseudomembranous colitis. The risk of sphincter infection was increased by simultaneous augmentation.[74]

If the bladder was not adequately augmented with the initial procedure, an anticholinergic can be considered. Botulinum toxin has also been used with considerable success in patients with high-pressure NGB, although the use of this agent in patients with treatment failure after bladder augmentation has not been described.[75] If this approach does not resolve the problem, repeat AC with ileum was reported to be successful in five patients in whom prior AC with either stomach or colon failed.[76]

PREGNANCY

A potential issue in young women undergoing bladder augmentation is future pregnancy, including management of the delivery. The most common complication of pregnancy after AC is UTI or pyelonephritis. Other possible issues include premature labor, renal deterioration, and ureteral obstruction.[77] In a review of 15 patients with bladder augmentation, Hill and Kramer[78] reported development of pyelonephritis in 60% and premature labor in 25% of patients. Therefore frequent urinalysis needs to be performed and infections need to be treated early and aggressively.

No consensus exists on whether delivery should be done by a vaginal or cesarean approach in patients with an augmented bladder. Hill and Kramer[78] recommended proceeding with standard vaginal delivery in patients who had undergone AC alone. In patients who had undergone a concomitant procedure for the outlet, the investigators recommended proceeding with cesarean section to minimize potential disruption to the continence mechanism. However, other investigators did not find this to be an issue and reported vaginal delivery to be safe for all patients who had prior AC, even those with prior bladder neck reconstruction.[79,80] If cesarean section is considered, the obstetrician must understand the anatomy of the reconstruction (including the segment utilized) and should have a urologist available for intraoperative consultation.

Conclusions

Bladder augmentation remains a viable alternative for patients with small capacity bladders and refractory overactive bladder and those with impaired compliance, when more conservative strategies have failed. Still, 5–42% of patients will require reoperation following augmentation cystoplasty, and 28% of patients will experience a complication within 30 days of the procedure including UTIs, wound complications, small bowel obstruction, and transfusion.[1,10] Fairly common long-term complications include symptomatic UTIs and bladder or renal stones. And while uncommon, bladder perforation and carcinoma may also occur, and thus patients require lifelong urologic surveillance following augmentation cystoplasty.

Chapter 48 Questions

1. Which of the following is a correct statement regarding augmentation cystoplasty?
   a. The possibility of requiring intermittent catheterization (IC) is much higher in necturus gallbladder (NGB) than with idiopathic conditions
   b. Stone disease is the most common complication
   c. Most perforations can be managed conservatively
   d. Gastrocystoplasty results in hyperchloremic metabolic acidosis
   e. Most bladder tumors following augmentation cystoplasty are seen within 5 years

2. Which of the following is not correct about recurrent urinary tract infection (UTI) after augmentation cystoplasty?
   a. Incidence of bacteremia ranges from 65% to 100% after augmentation
   b. NGB patients may not present with typical symptoms of UTI
   c. There is strong evidence that using a sterile catheter reduces the risk of recurrent UTI
   d. Gram-negative bacteria are the most common organisms
   e. Gentamicin irrigation of the bladder is safe and may be effective in preventing recurrent UTI

3. Which electrolyte abnormality is typically not seen following an ileocystoplasty?
   a. Hyponatremia
   b. Hyperchloremia
   c. Hypokalemia
   d. Hyperkalemia
   e. Hypovitaminosis B_{12}

4. Which of the following mucoregulatory agent has been shown to be effective in reducing stone formation in the bladder augmented with an intestinal segment?
   a. *N*-acetylcysteine
   b. Aspirin
   c. Urea
   d. Ranitidine
   e. None of the above

5. What is the most common short-term complication after bladder augmentation?
   a. Small bowel obstruction
   b. Wound infection
   c. Urinary tract infection
   d. Augment perforation
   e. Transfusion

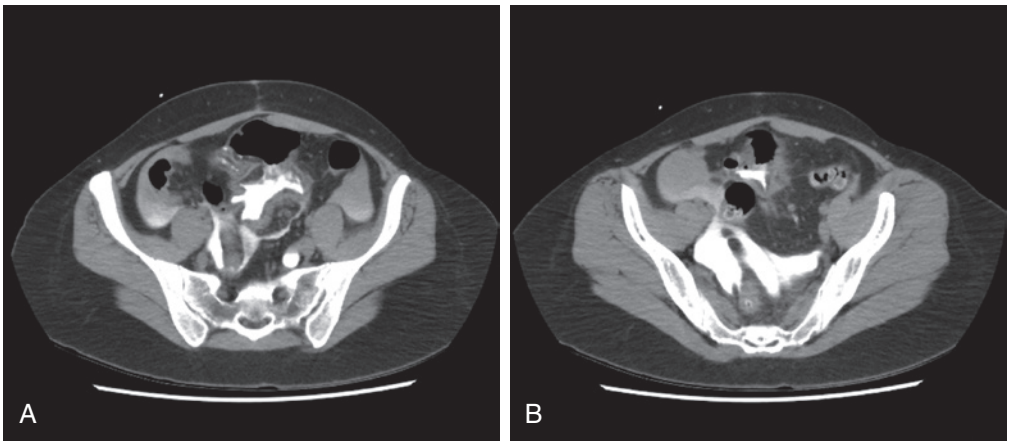
6. Which recent therapeutic intervention has had the greatest impact on decreasing the rate of bladder augmentations performed?
   a. Percutaneous tibial nerve stimulation
   b. OnabotulinumtoxinA
   c. Intermittent catheterization
   d. Auto augmentation
   e. Sacroneuromodulation

7. What techniques do NOT help decrease the risk of ventriculoperitoneal shunt infections at the time of bladder augmentation?
   a. Urine sterilization
   b. Extraperitoneal bladder augmentation
   c. Conversion to extraperitoneal shunt
   d. Bowel preparation
   e. Manipulation of the ventriculoperitoneal shunt (VPS) intraoperatively

8. What is the most common sign of latex allergy intraoperatively?
   a. Tachycardia
   b. Hyperthermia
   c. Precipitous hypotension
   d. Rash
   e. Bleeding

9. Which segment of bowel is associated with hematuria-dysuria syndrome?
   a. Stomach
   b. Ileum
   c. Sigmoid
   d. Jejunum
   e. Cecum

10. What is the most common carcinoma found after bladder augmentation?
    a. Urothelial carcinoma
    b. Adenocarcinoma
    c. Squamous cell carcinoma
    d. Renal cell carcinoma
    e. Small cell carcinoma



Case Studies

CASE 1

A 33-year-old woman with history of prior Indiana pouch 3 years earlier presents with acute abdominal pain and peritoneal signs after failing to catheterize her pouch for 12 hours. CT cystogram images (Case Fig. 48.1) are shown. Note intraperitoneal contrast. Similar radiographic findings would be noted with leak following augmentation.

1. Which of the following is NOT a risk factor for bladder augmentation perforation?
   a. Competent bladder outlet
   b. Inconsistent intermittent catheterization
   c. Recurrent UTIs
   d. Spontaneous voiding
   e. None of the above

2. Of the following bowel segments used for augmentation, which segment has the lowest rate of perforation?
   a. Sigmoid colon
   b. Transverse colon
   c. Ileum
   d. Jujenum
   e. None of the above

Case Figure 48.1

3. She presents to the emergency room 20 years after her pouch surgery with acute abdominal pain, oliguria and emesis. Peritoneal signs are documented on physical exam. The CT cystogram performed does not reveal a leak. What is the next best step?
   a. Perform a routine cystogram with emptying images
   b. Admit for observation and start broad spectrum IV antibiotics for possible "pouchitis"
   c. Admit for observation, place indwelling catheter and start broad spectrum IV antibiotics pending culture results
   d. Exploratory laparotomy
   e. Place bilateral nephrostomy tubes to divert urine away from pouch and start on broad spectrum IV antibiotics

CASE 2

A 25-year-old female with spina bifida underwent augmentation cystoplasty at age 8 and presents to the clinic for the first time as an adult. She reports no incontinence, but intermittent hematuria for the last year and a strong odor to her urine. Renal ultrasound and a kidney, ureters, and bladder investigation were performed demonstrating multiple bladder stones. She underwent open cystolithotomy. See Case Fig. 48.2.

1. After bladder augmentation, which patient is at lowest risk for bladder stones?
   a. Patient catheterizing via abdominal stoma.
   b. Patient with bladder augmentation and pubovaginal sling on intermittent catheterization
   c. Patient voiding spontaneously with low post-void residuals
   d. Patient with large volume of mucus requiring regular irrigations
   e. Patient with recurrent UTIs

2. What is the most common composition of bladder stones after bladder augmentation?
   a. Calcium phosphate
   b. Calcium oxalate
   c. Struvite
   d. Uric acid
   e. Pure carbonic apatite

Case Figure 48.2

3. What is the most common composition of renal stones after bladder augmentation?
   a. Calcium phosphate
   b. Calcium oxalate
   c. Struvite
   d. Uric acid
   e. Pure carbonic apatite

Answers

1. **a.** IC rates vary from 26% to 100%, generally increase with time, and are higher in the NGB of patients. Greenwell et al. reported a 60% IC rate in NGB compared with 6% in idiopathic patients.[11]
2. **c.** A recent Cochrane review including 31 different trials regarding IC concluded that there is no convincing evidence that the incidence of UTI is affected by use of aseptic or clean technique, coated or uncoated catheters, single (sterile) or multiple-use (clean) catheters,

self-catheterization or catheterization by others, or by any other strategy.[23]

3. **a.** Hyperchloremic metabolic acidosis is the most commonly noted metabolic. Hyponatremia is seen with jejunal augment.
4. **e.** Use of mucoregulatory agents (*N*-acetylcysteine, aspirin, urea, ranitidine, and octreotide) to reduce mucus in every patient with augmentation is questionable and is not recommended, as multiple studies including a randomized trial didn't show any benefit of routine use of these agents.[36]
5. **c.** Urinary tract infections are the most common short-term complication after augmentation.
6. **b.** OnabotulinumtoxinA has decreased the rate of bladder augmentation since 2000.
7. **e.** Minimal contact with the VPS intraoperatively is recommended to avoid contamination.
8. **c.** Latex allergy is common in the neurogenic population and practitioners should have a high index of suspicion and take precautions to prevent this potentially life-threatening complication.
9. **a.** This complication has been noted in 26–37% of patients undergoing gastrocystoplasty and is related to irritation of the bladder mucosa from acid produced by the stomach segment used for augmentation.
10. **b.** Adenocarcinoma is the most commonly identified tumor in augmented bladders and is typically found in the region of the anastomosis of the bowel and bladder; however, transitional cell carcinoma has been reported as well.

CASE 1

1. **d.** Patients with a competent bladder outlet requiring intermittent catheterization are at increased risk of perforation, especially in the setting of recurrent UTIs and poor catheterization compliance.
2. **c.** Gastroplasty and ileoplasty are associated with lower rates of spontaneous perforation than are other segments of bowel or ureteral augmentation.
3. **d.** Twenty-four percent of patients with a perforation will have a negative cystogram; therefore patients require a high index of suspicion for perforation. Treatment is exploration in the OR with maximal drainage of the bladder and peritoneum.

CASE 2

1. **c.** Risk factors for bladder stones include recurrent UTIs and incomplete emptying secondary to outlet procedures or catheterizable channel, as well as large-volume mucus. Patients able to void spontaneously with good emptying have a lower risk of infection and subsequent stones.
2. **c.** Infectious stones are the most common type of bladder stones following bladder augmentation with struvite the most common composition.
3. **a.** Calcium phosphate is the most common type of renal stone after bladder augmentation.

Chapter 49 Questions and Answers

KEY POINTS

1. The popularity of midurethral polypropylene slings has changed the types of complications commonly seen in surgical treatment of stress urinary incontinence (SUI).
2. Intraoperative trocar injury to the bladder during midurethral sling placement is not uncommon, and replacement of the trocar can be accomplished with minimal morbidity.
3. Currently, few or no data on overall complications support one choice of midurethral slings over another (i.e., retropubic vs transobturator) as causing less morbidity; however, some of the complications reported with each of these procedures are unique to that approach.
4. In comparing midurethral slings, obstructive complications are more common with retropubic slings while neuromuscular complications are more likely in the transobturator approach.
5. New voiding symptoms including overactive bladder symptoms or recurrent urinary tract infections (UTIs) following SUI surgical procedures may indicate iatrogenic bladder outlet obstruction (BOO), which is a very difficult and subtle diagnosis in many patients.
6. Attention to technique, experience of the surgeon, and careful endoscopic examination of the urinary tract following anti-UI surgical procedures are important factors in reducing perioperative and postoperative complications.
7. Intradetrusor botulinum toxin injections and sacral neuromodulation have become the mainstay for treatment of refractory overactive bladder and urgency urinary incontinence.

Stress urinary incontinence (SUI) affects 4–10% of women per year with an estimated prevalence of up to 50% of adult women.[1] *Urinary incontinence* (UI) is defined as the complaint of involuntary leakage of urine.[2] Patients with UI may have numerous related problems including depression as a result of the perceived lack of self-control, loss of independence, and lack of self-esteem, and they often curtail their activities for fear of an "accident."[3,4] UI and related overactive bladder may also have serious medical and economic ramifications for untreated or undertreated patients, including perineal dermatitis, worsening of pressure ulcers, urinary tract infections (UTIs), and falls.[5] For these reasons, many individuals suffering from this condition seek treatment. Surgery plays a major role in the therapy of some types of UI. Surgical procedures for UI are some of the most commonly performed operations in the United States by urologists. Thus, understanding how to avoid, and when necessary how to treat, complications related to these surgical procedures is important.

Types of Incontinence

Simply stated, UI may result from abnormalities of the urethra (including the bladder outlet and urinary sphincter), or the bladder, or may be caused by a combination of abnormalities of both structures (Table 49.1).[6] Abnormalities may result in underactivity or overactivity of the urethra or bladder with the subsequent development of UI.

Urethral underactivity results in stress UI (SUI). *Urodynamic SUI* is the involuntary leakage of urine associated

Table 49.1 Functional Classification of Urinary Incontinence

Abnormality	Type of Clinical Incontinence
Bladder overactivity	Urge
Bladder underactivity	Overflow
Urethra overactivity	Overflow
Urethra underactivity	Stress

with an increase in intraabdominal pressure in the absence of a detrusor contraction.[2]

Surgical correction of female SUI is directed toward either of the following: (1) repositioning the urethra or creating a backboard of support or otherwise stabilizing the urethra and bladder neck in a well-supported retropubic position that is receptive to changes in intraabdominal pressure (i.e., sling), or (2) creating coaptation or compression or otherwise augmenting the urethral closure forces provided by the intrinsic sphincteric unit (i.e., periurethral injectables) that affect urethral and bladder neck support.

Urgency UI is the involuntary leakage of urine associated with the symptom of urgency, defined as a sudden compelling desire to void that is difficult to defer.[2] This disorder is generally attributed to detrusor overactivity, as shown by urodynamic assessment. Both phasic bladder overactivity (involuntary bladder contractions) and tonic overactivity (decreased compliance) can contribute to UI. Careful urodynamic evaluation may be necessary in these patients to ascertain lower urinary tract physiology, to assess the risk of deterioration to the upper urinary tract, and to search for coexisting urethral or sphincteric UI.

Most of these patients are treated with a combination of behavioral modification, pelvic floor physical therapy, and oral pharmacologic agents. However, for patients with refractory conditions, the goal of surgical intervention is either to reduce or abolish bladder overactivity and the sensation of urgency or to provide a reservoir of adequate size for the low-pressure storage of adequate volumes of urine.

Types of Incontinence Operations

Except in unusual circumstances, the surgical repair of UI is elective. The decision to treat *symptomatic* UI surgically should be based primarily on the premise that the degree of bother or lifestyle compromise to the patient is sufficient to warrant an *elective* operation and that nonoperative therapy is either undesired or has been ineffective. Therefore, it is particularly troublesome to both the surgeon and the patient when complications arise during or after performance of these elective procedures. In some instances, these complications may be life threatening or may considerably worsen symptoms or quality of life. Thus, the surgeon should clearly describe and counsel patients regarding potential complications preoperatively. Fortunately, however, complications of the surgical treatment of UI are uncommon and when they occur are often amenable to treatment.

Table 49.2 Goals of Surgical Options for Stress Urinary Incontinence

Surgical Option	Goal
Anterior repair	Repositioned urethra or "plicated" sphincter
Retropubic approach Marshall-Marchetti-Krantz vesicourethropexy Burch colposuspension	Repositioned or stabilized urethra or creation of a "backboard" of support for urethral compression during increased intraabdominal pressure
Vaginal needle suspension Stamey Raz	Same as retropubic approach with avoidance of a large abdominal incision and associated morbidity
Sling	
Autologous, cadaveric, synthetic, vaginal wall, etc.	Same as retropubic approach with or without direct urethral coaptation or compression
Tension-free vaginal tape and other polypropylene midurethral slings	Dynamic midurethral support
Artificial urinary sphincter	Intermittent, dynamic urethral coaptation and compression
Bulk agents (injectables)	Improved urethral coaptation

STRESS INCONTINENCE OPERATIONS

The goal of surgical treatment of SUI is to augment urethral closure forces to prevent the egress of urine from the urethra during periods of increased abdominal pressure while at the same time preserving voluntary, low-pressure, and complete bladder emptying. This treatment may involve the use of retropubic or transvaginal suburethral support or compression (slings), periurethral injection (e.g., collagen), or circumferential compression (artificial genitourinary sphincter) (Table 49.2). The precise manner in which each operative procedure improves urethral closure forces and thereby restores urinary continence is not well understood. Nonetheless, >100 different operations have been designed to treat female SUI.

For many years, the transabdominal approach to vesicourethropexy including procedures such as the Marshall-Marchetti-Krantz (MMK) vesicourethropexy and the Burch colposuspension were very popular interventions for female SUI. The goal of these procedures is to elevate or, in some cases, simply prevent rotational descent of the urethra and bladder neck by securing the paraurethral or paravesical fascia to a fixed retropubic structure. Additionally, these procedures may also provide a stable "backboard" on which the urethra and bladder neck are compressed during increases in intraabdominal pressure.

The transvaginal or "needle" suspension procedures were proposed as alternatives to the retropubic operations for urethral UI resulting from vesicourethral hypermobility. These techniques have largely fallen out of favor, especially following a comprehensive meta-analysis published in 1997 suggesting that these procedures were less durable in the long term as compared with slings and retropubic suspensions.[7] A subsequent American Urological Association (AUA) guideline document did not even include these procedures in the update as there were no new publications on

their utilization.[8] Therefore such procedures will not be further discussed in this chapter.

Bone-anchoring techniques emerged as an alternative method of suture fixation for both transvaginal needle suspensions and some types of slings in the 1990s. Numerous proprietary fixation systems had been developed including transvaginal and suprapubic delivery bone-anchoring systems, all of which deliver a suture secured to a metallic screw into the cortical bone of the pubic rami on either side of the midline. The initial enthusiasm for these adjunctive procedures was somewhat dampened by the lack of a demonstrable long-term durable benefit over other techniques as well as the cost and potential associated morbidity, including osteomyelitis and osteitis pubis. Bone-anchoring techniques have largely fallen out of favor.[9–11]

Pubovaginal sling surgery was originally described more than 100 years ago. Fascial slings are generally placed at the level of the bladder neck and proximal third of the urethra and use either autologous tissue harvested from the patient intraoperatively (e.g., anterior rectus sheath, fascia lata) or xenograft or allograft fascia. The fascia may be full length (extending from the abdominal wall through the retropubic space, under the urethra, and back up to the abdominal wall) or rectangular (extending into the retropubic space on either side but secured to the anterior abdominal wall with sutures attached to either end of the sling) (Fig. 49.1).

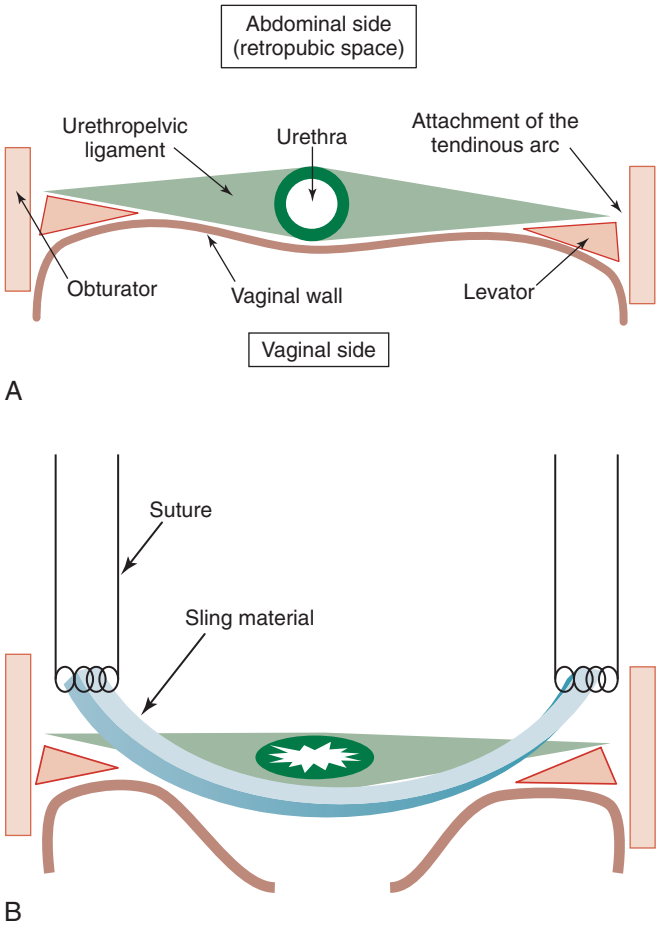

Figure 49.1 Diagrams of the vaginal anatomy in a coronal plane before (A) and after (B) placement of a fascial sling.

The midurethral polypropylene sling (MUS) has become the most common type of sling procedure performed in the United States.[12] This popularity is likely the result of the low morbidity, technical ease, and speed of the procedure; its long-term durability and safety; and the rapid recovery and convalescence. These slings, of which many proprietary types are available, are similar in the completely tension-free, minimally invasive technique in which they are placed under the midurethra. Depending on the choice of device, these slings may be placed through a transvaginal incision utilizing either a suprapubic or transobturator approach. US Food and Drug Administration (FDA) notifications regarding transvaginal mesh placement surfaced in 2008 and 2011. In October 2008, the FDA issued a Public Health Notification regarding the use of transvaginal mesh for pelvic organ prolapse (POP) and SUI,[13] and in July 2011, the FDA released a Safety Communication on serious complications associated with transvaginal mesh for POP but not SUI.[14] The implications of these FDA statements were quite broad including medico-legal ramifications and ongoing nationwide litigation. As the FDA continues its literature review of transvaginal mesh for the treatment of SUI it has reiterated that the standard polypropylene mesh MUS is safe and effective in the treatment of SUI.[15] Despite the FDA statements, it is important to recognize that there has not been a mandatory FDA recall of any transvaginal mesh product. As a result of many converging and complex factors, several mesh manufacturers have voluntarily withdrawn some or all of their POP and/or SUI mesh products but this was not due to a product recall by the FDA.

Periurethral injectable agents have been used for the treatment of SUI in women for decades. Most periurethral agents are injected in a retrograde fashion under direct cystoscopic guidance as an office-based procedure. The exact means by which periurethral injectable agents exert their favorable effects on continence has not been well defined, although an obstructive mechanism or an improved "seal" effect has been suggested.[16] Furthermore, the eventual mechanism of failure for most of these agents is not well understood, although it is believed that biologic reabsorption, particle migration, and ongoing degeneration of the sphincteric apparatus may be contributing factors. Generally, these agents are safe and have good initial efficacy but lack long-term durability.

The artificial urinary sphincter is used in some centers as primary therapy for female SUI. However, in the United States, this device is only very infrequently used in female patients.

URGE INCONTINENCE OPERATIONS

Sacral neuromodulation, intradetrusor injection of botulinum toxin, and augmentation enterocystoplasty have been used for individuals undergoing surgical treatment of urgency UI. Sacral neuromodulation has been used since the 1980s but was finally approved by the FDA for use in the United States in 1997 as a therapy for urinary frequency, urgency, and urge UI. A staged implantation technique or an office-based peripheral nerve evaluation is the initial step in sacral neuromodulation. In either case a good response leads to implantation of a permanent implantable

pulse generator and neurostimulator lead electrode. Low-frequency stimulation of the S3 nerve root results in modulation of neural activity in the lower urinary tract and pelvic floor. The exact mechanism by which sacral neuromodulation exerts its therapeutic effects remains unclear.

In 2011 the FDA approved intradetrusor injection of botulinum toxin A (BT) for the treatment of refractory neurogenic detrusor overactivity, and in 2013 the FDA approved its use for refractory idiopathic detrusor overactivity.[17] BT is produced by the bacterium *Clostridium botulinum* and is the most potent biologic neurotoxin known. The current approved dose for idiopathic detrusor overactivity is 100 units, and for neurogenic detrusor overactivity the approved dose is 200 units. The toxin is injected into the detrusor muscle through the cystoscope with a long, fine needle in a series of 20–30 injections. This treatment is most commonly performed using local anesthesia as an office-based procedure.

BT is thought to produce its efferent motor paralytic effects by inhibiting acetylcholine release at the presynaptic cholinergic neuromuscular junction by cleaving SNAP-25, an intracytoplasmic protein, which blocks the binding and fusion of the synaptic vesicles to the presynaptic membrane terminal. This prevents release of acetylcholine as well as a variety of other neurotransmitters and neuropeptides into the synapse. Clinically this results in muscle weakness, diminished contractility, and muscle atrophy at affected sites some 3–14 days following injection. The effect is reversible in 3 to 12 months, but the mechanism by which smooth muscle regains contractility over time is not well understood and is not fully explained by axonal sprouting. The mechanism of action of BT in reducing urinary urgency may also involve modulating some aspects of the afferent limb of the micturition reflex as well.[18]

Although there is sparse literature available, it appears that augmentation enterocystoplasty as a treatment for urgency incontinence has become less utilized with the increasing widespread use of BT and neuromodulation.[19] Further discussion and complications related to the use of intestine in the urinary tract are reviewed elsewhere in this textbook and are not considered further here (see Chapter 48).

Prevention of Complications

Although most complications related to the surgical treatment of female UI are treatable and generally reversible, the optimal situation is to prevent or minimize the potential for an adverse outcome. This process begins in the preoperative period and is initiated during the diagnostic evaluation and workup. Many factors should be considered in determining the optimal surgical therapy for the patient with UI. These include the origin and type of UI, bladder capacity, renal function, sexual function, medical comorbidities, severity of the leakage, the presence of associated conditions such as vaginal prolapse or concurrent abdominal or pelvic disease requiring surgical correction, prior abdominal and pelvic surgical procedures, and finally the patient's suitability for and willingness to accept the risks of surgery. All these factors may affect both the choice of surgical treatment and the risk of surgical complications.

The proper choice of candidate for an anti-UI operation cannot be overemphasized. One study found the most common reason cited for failure of the previous operation was poor surgical technique, and the next most common reason was the wrong surgical indication.[20] Both of these factors certainly can be addressed and minimized preoperatively. The diagnosis of SUI must be firmly established to propose outlet-enhancing surgery for the treatment of SUI. Other diagnoses that may mimic SUI should be definitively eliminated including fistula, ureteral ectopy, bladder calculi, urethral diverticula, and overflow UI. Overflow UI, in particular secondary to a neurogenic or myogenic disorder, can be mistaken for SUI and this misdiagnosis can lead to inappropriate intervention and surgical treatment failure. The patient's history should be consistent with and confirmed by findings on physical examination and, when appropriate, radiographic or urodynamic testing.

Reversible factors should be addressed. For patients with postmenopausal, hypoestrogenic vaginal atrophy, topical estrogen replacement may reduce the incidence of postoperative vaginal wound dehiscence or extrusion of sling material.[21] UTI and genital tract infection (e.g., candidiasis) should also be treated before surgical intervention. Nutritional disorders should be assessed and corrected preoperatively before elective surgical treatment is performed. Finally, treatment of any medical comorbidities (e.g., diabetic control, hypertension) should be optimized.

Another preoperative factor associated with risk of complications is operative experience with a given procedure.[22,23] The "learning curve" for "simple" procedures such as midurethral slings should not be underestimated and the number of cases performed may correlate with risk of complications.[24,25]

Complications

The field of SUI surgery has advanced rapidly. As noted previously, the types of procedures performed have evolved from transvaginal needle suspensions and retropubic suspensions to various types of slings, most commonly the midurethral polypropylene slings. This shift has implications for the types of complications seen in contemporary practice as compared with complications seen even a few short years ago. Therefore the majority of the discussion that follows concerns the midurethral slings.

CHOICE OF APPROACH

The relative risks of each complication among various types of surgical procedure, especially within a single category such as midurethral slings, are impossible to determine because of the limited amount of randomized controlled trials comparing procedures and approaches. Currently, no published literature provides sufficient evidence to recommend one procedure or approach absolutely over another based only on complication rates. However, it is important to recognize that some types of complications are unique or more likely to occur with one procedure as compared to another. For example, in a randomized controlled trial (RCT), Albo and colleagues[26] compared Burch colposuspension with pubovaginal sling and in this trial

the investigators found that the risks of urinary tract infections, voiding dysfunction, and postoperative urge incontinence were greater in the women who underwent sling procedure but the risk of incidental cystotomy was greater in the Burch group. Comparing results within a single category, the 2010 TOMUS RCT compared the outcomes of retropubic and transobturator midurethral slings.[27] There was a higher rate of voiding dysfunction requiring surgery in the retropubic group, but neurologic symptoms were greater in the transobturator group. These findings have been confirmed by several additional studies and documented in a 2015 Cochrane review on midurethral slings.[28]

RISK FACTORS

Identifying preoperative risk factors such as age, obesity, prior surgical treatment, and impaired contractility that consistently predict for intraoperative and postoperative complications has also been difficult. Most of the data available in the literature are from retrospective studies. In regard to vaginal mesh exposure, one study of 1439 women found that older age, diabetes mellitus, smoking, vaginal incision >2 cm, and recurrent vaginal incisions increase the risk of vaginal mesh exposure.[29,30] Some investigators have found that prior surgical treatment is a predictor of intraoperative bladder injury.[22,23,31] This may be related to the type of prior SUI surgical treatment: Prior retropubic procedures such as Burch or MMK may lead to retropubic scarring and a risk of bladder injury,[31] whereas a prior transvaginal operation such as a Kelly plication, in which the retropubic space is not violated, may not. While there is no standard to evaluate and ascertain which patients will have postoperative voiding dysfunction, it is reasonable to speculate that women with preoperative voiding dysfunction (emptying phase dysfunction) will have a higher risk of postoperative voiding dysfunction and urinary retention.[22]

COMPLICATIONS RELATED TO STRESS URINARY INCONTINENCE SURGERY

Intraoperative Complications

Bleeding. The risk of blood loss greater than 200 mL during SUI surgery is small. The incidence ranges from 0.22% to 8%, with autologous fascial sling associated with the greatest risk[8] and transobturator midurethral sling associated with the least risk of substantial bleeding.[8,32] The risk of blood transfusion ranges from 0.6% to 9% with a reported risk of only 0.6–2% in midurethral slings and 7–9% in Burch suspensions.[8,22]

The risk of bleeding during surgical treatment of SUI can be minimized, but not entirely eliminated, by good operative technique. Multiple blood vessels traverse the deep pelvis including large venous channels in the retropubic space. Named vessels in the obturator fossa, along the pelvic sidewall including the iliac vessels, and within the vascular pedicle of the bladder are at risk for injury, especially during vaginal surgical treatment of UI, because of the lack of direct visualization of these structures during passage of trocars or needles. Major vascular injury can quickly lead to life-threatening hemorrhage if it is not recognized intraoperatively and may result in large retropubic hematomas postoperatively.[33,34]

Bleeding during retropubic bladder neck suspension is usually easily visualized and controlled with a combination of cautery, suture ligature, and, if necessary, direct compression. Occasionally, sponge sticks and readjustment of the retractors may be needed to visualize the bleeding vessels optimally. The retropubic anatomy is very familiar to most urologic surgeons, and bleeding during these procedures is rarely problematic.

In contrast to bleeding during retropubic surgical procedures, bleeding during transvaginal operations can be more problematic at times and more difficult to control. The initial dissection of the vaginal wall from the underlying fascia should be associated with minimal bleeding. Bleeding encountered during this early dissection may indicate an excessively deep and incorrect surgical plane within the wall of the bladder or urethra. In this circumstance, immediate recognition and reevaluation are necessary to avoid inadvertent entry into the urinary tract and to minimize bleeding. Following identification of this situation, dissection should then proceed in the proper surgical plane, which, in reoperative surgical procedures, may be difficult to identify.

Another common site of bleeding during transvaginal SUI surgical procedures occurs when the endopelvic fascia is traversed. Entry into the retropubic space from the transvaginal side or placement of the suprapubic needles or trocars from the abdominal side may be associated with copious bleeding as the endopelvic fascia is perforated. Again, knowledge of the anatomic features, careful attention to technique, maintenance of countertraction, and proper positioning of the perforating scissors (with the tips curved away from the bladder) or trocar in three planes minimize most bleeding (Fig. 49.2). An initial gush of venous bleeding is not unusual during this maneuver, and, although it may be unsettling to the operating surgeon, the bleeding dissipates quickly without further manipulation.

If the bleeding continues and is brisk, the vagina can be packed. It can be very helpful to elevate the anterior vaginal wall manually and compress it anteriorly directly against the posterior symphysis pubis for several minutes using the surgeon's hand, a sponge stick, or a retractor. These maneuvers effectively tamponade bleeding in the retropubic space. It is not advisable to "chase" this bleeding using a transvaginal approach. Only very rarely is the exact bleeding point identified and controlled in this manner.

Transvaginal exploration for bleeding results in ongoing blood loss as the surgeon struggles with relatively poor exposure and visualization. Packing and compression lead to adequate control in most cases, and if not the surgeon should expeditiously complete the procedure, close the incisions, and pack the vagina.[35] Occasionally, in addition to vaginal packing, a Foley catheter inserted through the urethra with the balloon overinflated and then placed on traction adds additional security. Brisk bleeding that does not respond to manual compression for an extended period may suggest a major vessel injury and mandates retropubic exploration or consideration of angioembolization in interventional radiology.

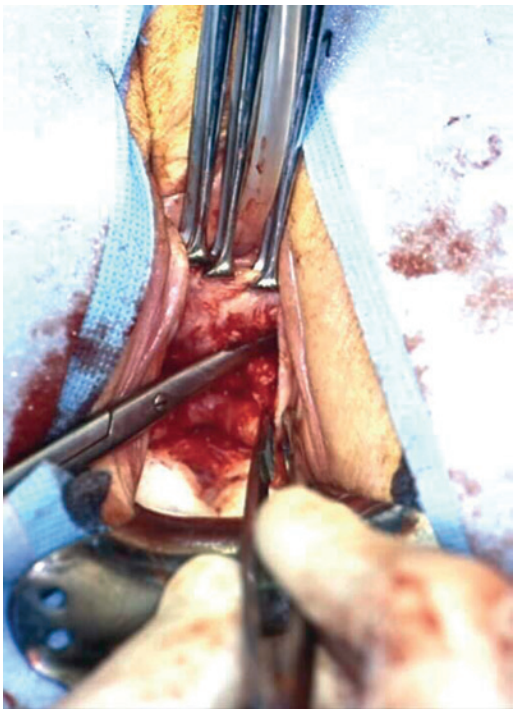

Figure 49.2 The proper plane of dissection. The scissors are directed toward the patient's ipsilateral shoulder. Countertraction is applied to the vaginal wall.

Urinary Tract Injury

During surgical procedures for SUI, the urethra, bladder, or much more rarely the ureters may be injured. The key to the management of each of these injuries is immediate recognition and repair. Long-term sequelae resulting from unrecognized urinary tract injury can be devastating to the patient and can have potentially substantial medico-legal implications for the physician.

Urethral Injury. From the transvaginal side, injury to the urethra may occur during initial dissection of the vaginal wall off the underlying fascia. As noted earlier, excessively deep dissection, especially in reoperative surgical procedures, risks urethral injury. This injury is usually, although not invariably, heralded by an unexpected amount of bleeding. Placement of a urethral catheter before incision will help to identify the urethra intraoperatively and in the case of urethral injury will allow immediate recognition as the catheter becomes visible in the operative field.

If a urethral injury is suspected, urethroscopy may be performed. The urethra should be repaired immediately and closed primarily in two layers by using absorbable sutures in a watertight fashion. The urethra can be repaired over a ≥14Fr catheter. It is not necessary to leave a drain other than the urethral catheter. The integrity of the repair can be tested by injecting saline through a syringe attached to an angiocatheter (intravenous [IV]) sheath into the urethral meatus adjacent to the catheter with the balloon snugged up against the bladder neck. Failure to recognize the injury or failure to repair it properly risks urethrovaginal fistula.

The urethra may also be injured during trocar placement in midurethral sling procedures, needle placement for transvaginal suspensions, or cystocele repair. Countertraction during the initial dissection, maintenance of adequate exposure, and a working knowledge of the anatomy are helpful in avoiding urethral injury.

The incidence of urethral perforation during midurethral sling placement is low, ranging from 0.2% to 2.7%;[8,23,27,32] however, in the event of a concomitant urethral injury during a planned synthetic sling, it is advisable to repair the urethra and abort the sling procedure until the urethra is completely healed.[7] An autologous sling is considered a safer alternative than a synthetic sling in the setting of a urethral injury as a SUI procedure, but there are few if any data supporting this notion.

The urethra is rarely injured during retropubic surgical procedures because the middle and distal thirds are protected by the symphysis pubis.

Bladder Injury. Intraoperative bladder injury may occur during transabdominal and transvaginal SUI surgical procedures. The potential for urinary tract injury varies considerably with the experience of the surgeon,[23,36] as well as with the operative approach. Several studies have reported a bladder perforation rate of 1–8% during passage of needles or trocars for placement of pubovaginal or midurethral slings.[8,22,32,37] Most literature documents a higher risk of bladder injury with the retropubic approach (3–6%) as compared with the transobturator approach (0.4–0.7%) during midurethral sling operations.[23,32,37,38] Repeat surgical procedures are almost certainly associated with a higher risk of urinary tract injury in patients undergoing midurethral sling operations.[23,31]

Injury to the bladder during midurethral sling procedures is diagnosed intraoperatively by careful endoscopic examination of the bladder and bladder neck with a flexible cystoscope including retroflexion and examination of the bladder outlet region, or a rigid cystoscope using a 70-degree lens. Inspection is performed with a completely full bladder following passage of the trocars but before deployment of the midurethral sling. The bladder should be filled and then examined to ensure that a small injury does not go unrecognized in a fold of the bladder wall. To avoid injury during trocar needle passage, the urethra should be clearly palpated, the bladder drained, and the pelvic anatomy well delineated. If a bladder injury is noted intraoperatively, the trocar should be removed and reinserted after draining the bladder. The bladder is then reinspected to assure that the re-passing of the trocars was successful.

Bladder injury from a trocar usually does not require primary closure and when addressed intraoperatively has not been shown to have long-term adverse sequelae.[37] Postoperative Foley catheter drainage of the bladder after trocar cystotomy has not been extensively studied, and there are a paucity of published data evaluating the need for prolonged catheterization. In a retrospective review of 30 patients experiencing trocar cystotomy at the time of suprapubic midurethral sling placement, Crosby et al.[39] found that 80% passed a voiding trial the day of surgery and were discharged home without a catheter. The 20% who failed a voiding trial were sent home with a Foley catheter and successfully voided within 4 days. At 6-week follow-up, no patient experienced voiding dysfunction or irritative bladder symptoms and no patient required additional intervention.

Although not mandatory, prolonged catheterization may be desired in patients with a larger cystotomy to avoid urinoma, fistula formation, and pelvic abscess. Also, catheterization and continuous bladder irrigation may be required if there is significant gross hematuria after cystotomy.

During a transvaginal pubovaginal sling procedure or during performance of urethrolysis, it is common to perforate the endopelvic fascia intentionally to gain entry to the retropubic space. This perforation maneuver is often done sharply with curved scissors. The surgeon must be aware of lower urinary tract anatomy during this maneuver to avoid injury. Countertraction on the pelvic fascia away from the side of interest as the scissor perforates into the retropubic space will help to avoid injury. If injury occurs, lower urinary tract perforation in this setting is often larger than that seen with the passage of the trocars during a midurethral sling. The injury should be isolated and closed in two layers. A suprapubic drain can be placed and the lower urinary tract drained for several days to ensure healing. In addition, ureteral patency should be assessed in this setting because the injury can track proximally on the trigone.

Injury to the bladder during retropubic operations is usually confined to the anterior bladder wall. This complication is usually easily recognized and repaired. Postoperative Foley catheter drainage is mandatory. During a Burch or MMK procedure, a stitch may be inadvertently placed transmurally into the bladder or urethral lumen. Intraoperative cystoscopic examination identifies these injuries and permits removal and replacement of the suture.[40]

Ureteral Injury. Ureteral injury during surgical treatment of UI is uncommon. The reported incidence of ureteral injury for all incontinence procedures is 0.18–4%.[8,32] With the advent of midurethral slings, these injuries are becoming more rare (0.18–1.22%)[32] given the expected location of the sling at the level of the midurethra. However, the ureter may be kinked or obstructed during Burch or MMK procedures or during vaginal prolapse repair. Virtually all these injuries can be identified by intraoperative cystoscopy. The administration of IV vital dyes such as indigo carmine permits obvious visualization of ureteral efflux that confirms ureteral patency. Suspected ureteral injuries are confirmed by retrograde pyeloureterography. Most of these injuries are related to suture placement. When found, ureteral injuries may be treated by removal of the offending suture and placement of a temporary indwelling ureteral stent. Ureteral transection requires ureteroneocystostomy.

Intraoperative Cystoscopy. Cystoscopy is a low-morbidity procedure that requires little additional time, effort, or resources. However, some additional expense is incurred in performing cystoscopy, and the practitioner requires advanced training in endoscopic examination of the lower urinary tract. Nevertheless, careful cystoscopic examination of the lower urinary tract following SUI surgical procedures enables the surgeon to evaluate the patient for almost all lower urinary tract injuries. If IV vital dye is given, ureteral injury can also be excluded by visualizing efflux from the ureters. In the most recent AUA Guideline on Surgical Management of Female Stress Urinary Incontinence,[8] intraoperative cystourethroscopy is a treatment standard in all patients undergoing a sling procedure. The bladder must be examined when it is full, and careful attention should be paid at the 2- and 10-o'clock positions at the bladder neck and just inside the bladder neck because these are the locations of a majority of lower urinary tract injuries during SUI surgical procedures.

Inexperience with cystoscopy leads to a high rate of missed intraoperative perforations.[36] If perforations are recognized intraoperatively, the lower urinary tract can be quickly repaired and drained if necessary. Unrecognized urinary tract injuries can lead to infection, sepsis, fistula, stones, and other complications.[41] Transobturator slings can be associated with injury to the lower urinary tract 0.4–0.7% of the time,[23,37,38,41] and thus intraoperative cystoscopy should be performed in these cases as well.

Bowel Injury. Multiple reports of bowel injury during surgical procedures for SUI have been reported.[42,43] Fortunately this complication is rare. Bowel injury may occur during retropubic dissection for a Burch or MMK procedure, on entry into the retropubic space during an autologous pubovaginal sling or urethrolysis, or during passage of needle passers or trocars during midurethral sling procedures. These injuries can be devastating complications leading to sepsis, abscess, and even death.[29] Unfortunately, most of these injuries are not recognized until the postoperative period, when they lead to considerable morbidity. Initial signs and symptoms heralding a bowel injury may be subtle, including low-grade fever, abdominal pain, and ileus. If bowel injury is suspected, a diagnostic evaluation including plain and upright abdominal radiographs to ascertain the presence of intraabdominal free air and cross-sectional imaging should be pursued expeditiously. Laparotomy, repair of the bowel injury, and, possibly, bowel resection are necessary for definitive treatment. In some cases, temporary proximal bowel diversion may be necessary.

Postoperative Complications

Voiding Dysfunction and Urinary Retention. Bladder outlet obstruction (BOO) may occur following SUI surgical procedures. This complication manifests as prolonged complete urinary retention, persistently elevated post-void residual urine volume, or as variably bothersome and poorly categorized lower urinary tract symptoms including combinations of obstructive symptoms and urinary urgency or UI and recurrent urinary tract infection. These last two groups are difficult to identify and are often not recognized as having BOO by many investigators. The incidence of postoperative voiding problems across various procedures is variable and difficult to compare. A meta-analysis published in 2014 found urinary retention rates <6 weeks postoperatively to be higher in Burch suspension (17%) followed by pubovaginal slings (12%), and that number was reduced to 7.6% and 7.5%, respectively, at >6 weeks, while midurethral slings had a retention rate of 2.3–3.1% in both groups.[32] While the incidence of retention was higher in Burch suspension, the need for intervention was zero. Meanwhile, midurethral slings require intervention for retention or voiding dysfunction in 1–3% of women.[26,27,32] The incidence of voiding dysfunction, including urinary retention (16.6%)[22] and de novo urgency and urge UI following midurethral sling procedures ranges from approximately 2% to 25%.[42–46] In the TOMUS multicenter prospective study, transobturator slings

had fewer "obstructive" complications than did retropubic midurethral slings.[27] This has been verified by additional studies and summarized in the 2015 Cochrane review of midurethral slings.[28] The minimally invasive midurethral sling procedures are mechanistically tension free, and as such it is not surprising that they likely result in an overall lower incidence of postoperative voiding dysfunction than that seen with other types of open SUI procedures.

The finding of absolute prolonged urinary retention makes the diagnosis of obstruction fairly straightforward if the patient had relatively normal voiding dynamics preoperatively. One potential exception is the patient who voids primarily by pelvic floor relaxation. Female patients may void without a perceptible increase in intravesical pressure, and in these individuals, even a modest increase in outlet closure forces, such as that caused by a sling, may result in urinary retention. In many other patients, the diagnosis of BOO is extremely difficult. Urodynamic studies, especially video urodynamic studies, are often pursued diagnostically but may not be helpful in many cases because the classic "high pressure–low flow" pattern may not be present. Nitti and colleagues have suggested that the radiographic finding of a discrete area of narrowing in the urethra in combination with dilation of the proximal urethra is highly suggestive and potentially diagnostic of female BOO.[47] However, in spite of this, no pressure-flow urodynamic criteria accurately predict successful voiding following urethrolysis.

Various nomograms have been developed for the diagnosis of female BOO but none is absolutely accepted as the gold standard. For patients not in frank urinary retention, the diagnosis of BOO is strongly suggested by the postoperative onset of irritative voiding symptoms, recurrent UTIs, and a poor urine stream. Physical examination may be completely normal or suggest an oversuspended midvaginal segment ("swan neck deformity") or the lack of mobility of the urethra following insertion of a metal sound. De novo prolapse should be excluded as a cause of postoperative BOO. An unrecognized and thus unrepaired cystocele may result in BOO following SUI surgical procedures.

Before surgical intervention for postoperative urinary retention is considered, many transient causes should be considered. These are potentially unrelated to iatrogenic BOO and the mechanical effects of the procedure. In the immediate postoperative period, pain is a common reason for delayed micturition. Similarly, postoperative pain relief from narcotic analgesics may suppress micturition as well. These effects are temporary and a period of catheterization for several days postoperatively allows resumption of normal voiding in most cases. Other potential causes of temporary postoperative urinary retention include patient immobility, edema at the operative site, and retropubic hematomas.

Management options for prolonged voiding difficulties include repeated voiding trials, initiation of intermittent urethral catheterization, and incision of the sling or urethrolysis. Some investigators recommend conservative therapy for postoperative voiding dysfunction for ≤3 months before surgical revision is attempted.[48] Most patients resume normal voiding following midurethral slings within 1 to 2 days of the procedure. However, some patients may be delayed for 1 to 2 weeks and those with a history of prior SUI surgical procedures or those undergoing concomitant prolapse repair may be further delayed.[49,50] A prolonged time to intervention for BOO may be associated with long-term, potentially irreversible bladder dysfunction, even following successful urethrolysis.[46,51]

As compared with obstructive symptoms such as hesitancy, straining, and poor force of urine stream, overactive bladder symptoms resulting from iatrogenically induced BOO following an anti-UI surgical procedure are less likely to improve despite a technically successful operation.[52] In one series, voiding symptoms resolved in 82% of obstructed patients following urethrolysis, whereas overactive bladder (storage) symptoms resolved in only 35%.[53] In this series, increased time to intervention did not correlate with persistence of OAB symptoms after urethrolysis.

Once the diagnosis of BOO is considered or established, options include long-term intermittent urethral catheterization, transvaginal or retropubic urethrolysis, or transvaginal incision of the sling. Care must be taken to avoid urethral injury while performing a sling incision because the urethral wall may be draped over the taut sling and may be inadvertently pinched and perforated during dissection and isolation of the sling for incision. Generally, the longer the time from sling surgery to sling incision, the more difficult it can be to find the sling during repeat exploration. Following isolation and division of the sling, the edges of the cut sling often separate by 1–2 cm, a finding indicating a satisfactory result. Iatrogenic obstruction resulting from autologous fascial slings is often treated in this manner as well.[54] However, historically, some investigators waited up to 3 months before consideration of sling incision for obstructing fascial slings (Fig. 49.3).

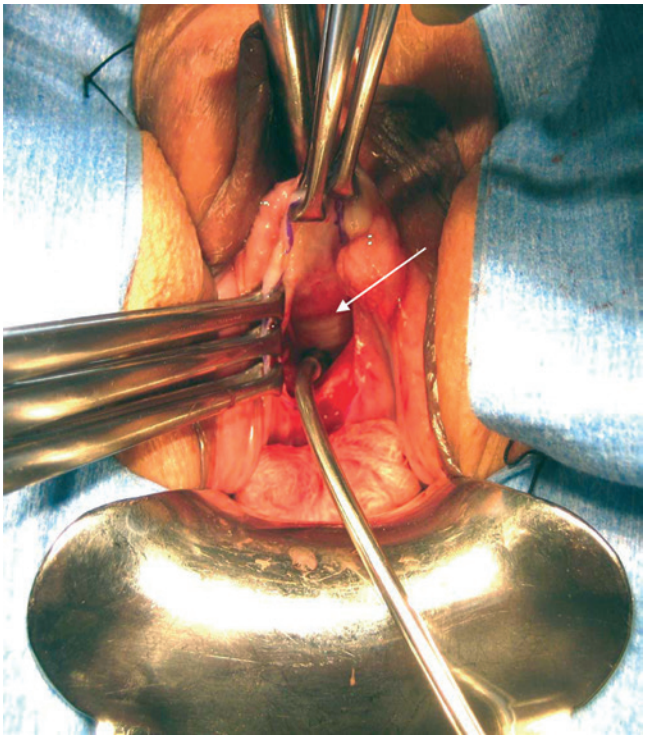

Figure 49.3 Transvaginal incision of a fascial sling. The sling in this case is seen between the tip of the sucker and the white arrow as a shiny band of tissue.

For patients in whom transvaginal incision fails, or in patients who underwent a nonsling procedure as the cause of their BOO, urethrolysis may be performed.[55] Through a transvaginal or retropubic approach,[55–57] the retropubic space is entered and the urethra is sharply dissected off the posterior surface of the symphysis pubis and is freed from the surrounding scar. The limbs of the sling or other retropubic attachments are isolated and divided in the retropubic space. Lateral attachments to the pelvic sidewall are incised as needed for patients who previously underwent a Burch or paravaginal repair. A transvaginal, suprameatal approach to urethrolysis has also been described and may be particularly applicable to those patients who previously underwent an MMK procedure.[57]

Recurrence of SUI symptoms following urethrolysis or sling incision may occur in 9–28% of patients.[46,58,59] Patients should be counseled regarding this possibility preoperatively because some may wish to continue performing intermittent catheterization rather than risk recurrent SUI.

Vaginal Exposure and Urinary Tract Erosion. *Vaginal exposure* refers to the finding of exposed sling material in the vaginal canal postoperatively, whereas *erosion* implies the finding of material within the lumen of the urinary tract at some time interval postoperatively that was clearly documented as not being within the urinary tract intraoperatively. The incidence of these complications in midurethral slings ranges from 2.5% to 4.7%.[8,29,32,60]

Exposure of material in the genital tract may be related to surgical technique, infection, or the physical properties of the implanted material. The exposed material may be located in the midline at the prior vaginal incision line or at the anterolateral vaginal wall at the fornix, or anywhere in between. Midline exposures imply wound dehiscence. Lateral exposures may result from an unrecognized vaginal wall perforation or injury at the time of sling placement.

Patients are usually symptomatic and have complaints suggesting an exposure, including a malodorous vaginal discharge, vaginal spotting, vaginal pain, and dyspareunia. Patients may present several days to months postoperatively. On physical examination, the exposed material is often visible, but physical findings may also be quite subtle (Fig. 49.4).[61] Granulation tissue suggests the presence of an exposure. Exposed synthetic mesh is often palpable within the vagina, although the patient's discomfort may preclude a complete examination.

Factors responsible for exposure include the physical nature of the implanted material, the quality of the vaginal tissues of the host, sling tension, wound healing, and infection.[62] It appears that multifilament materials are at greater risk for exposure than monofilaments.[63] In keeping with this, in the United States only monofilament transvaginal mesh products are currently available. In addition, a pore size that is large enough to permit fibroblast and macrophage infiltration and subsequent tissue ingrowth (generally considered to be >75 microns) is an important factor in preventing exposure.[64] Synthetic material other than polypropylene slings, such as Stamey bladder neck suspension bolsters, placed years earlier for the treatment of SUI may eventually become infected and create a draining sinus or may become a nidus of pelvic infection or recurrent UTIs.[65] These materials will require exploration and explantation.

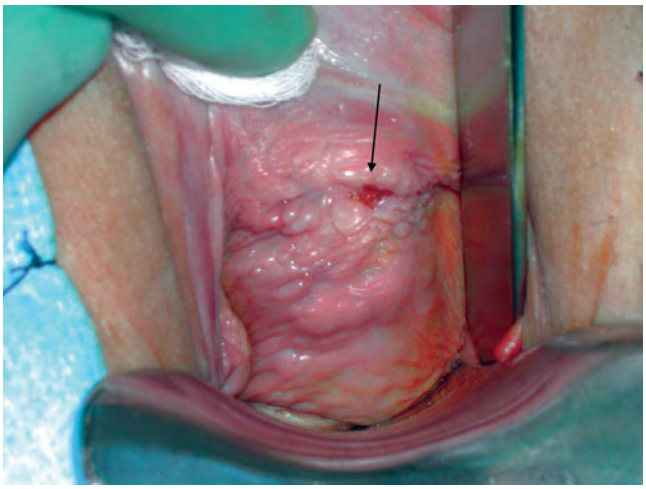

Figure 49.4 A small area of beefy granulation tissue (black arrow) is seen along the anterior vaginal wall in this patient, a finding suggesting vaginal extrusion.

In the absence of significant symptoms such as pain, small genital sling exposures may heal with conservative management including the application of topical estrogen creams for up to 6 weeks.[66] Larger exposures can be managed with copious irrigation and secondary closure in the operating room by widely mobilizing and rotating vaginal wall flaps with coverage of the exposed material. Some patients with large exposures, or with significant pain or dyspareunia, may benefit from excision and removal of a variable amount of the exposed segment of the sling and rotational vaginal wall flap closure of the defect.

In the immediate postoperative period, avoiding vaginal intercourse or vaginal tampon use should be strongly encouraged for the first 4 to 6 weeks following vaginal surgery to avoid disruption of the vaginal incision and subsequent exposure of the sling material.

Urinary tract erosion may occur with synthetic, biologic, or autologous materials.[67] This is a devastating complication that, unlike vaginal exposure, is almost always managed operatively. Whether urinary tract erosion results from a missed intraoperative urinary perforation or from migration of the material into the urinary tract sometime following the surgical procedure is unclear. Patients may complain of irritative lower urinary tract symptoms, recurrent UTIs, hematuria, dysuria, and pelvic pain. The definitive diagnosis is usually made endoscopically (Figs. 49.5 and 49.6A, B).

For intravesical erosions, endoscopic scissor or laser transection of the intravesical portion of the eroded sling may permit the remaining sling material to retract outside the urinary tract.[68–72] However, an endoscopic approach risks ongoing pain as well as recurrent erosion of the synthetic material into the urinary tract. If this procedure fails or is technically not feasible, then open[73] or laparoscopic[74] exploration with removal of the eroded material, closure of the urinary tract, and postoperative drainage will be necessary. Explantation of an eroded mesh sling in the urethra can usually be done completely through a transvaginal approach.[75]

Neuromuscular Injury. Several nerves traverse the deep pelvis as well as superficially within the lower abdominal soft tissues. These nerves are at risk for injury during SUI surgical procedures in female patients. Stretch or compression injury to the femoral nerve can result from positioning. This complication results in sensory changes to the anterior thigh or, in more severe cases, weakness of hip flexion. Severe abduction and external rotation of the thigh should be minimized during positioning to avoid this complication.

The peroneal nerve can be injured by direct compression while the patient is in the lithotomy position. Lateral direct pressure on the peroneal nerve between the stirrup at the lateral aspect of the knee joint and the fibular head for a prolonged period may result in peroneal nerve palsy and foot drop.[76] This injury may also occur with compression of the fibular head against the stirrup holder, especially when candy cane stirrups are used, because the leg rotates externally after placement in the holders. The ilioinguinal and iliohypogastric nerves may be injured by suprapubic trocar placement or dissection resulting in pain in the suprapubic region.[77]

Groin pain or neurologic symptoms following midurethral sling are more likely to occur after the transobturator approach compared to the retropubic approach.[27,28,78] The incidence ranges from 6.4% to 17% in most series,[28,79–81] and a majority will have resolution within a few weeks.[82,83] The pain may occur secondary to adductor muscle injury or nerve injury, and therefore such an approach may be less desirable in an active person or athlete. In addition to avoiding technical errors during sling placement, positioning the patient's legs with increased hip flexion provides a greater distance between the trocar and obturator neurovascular structures.[84,85]

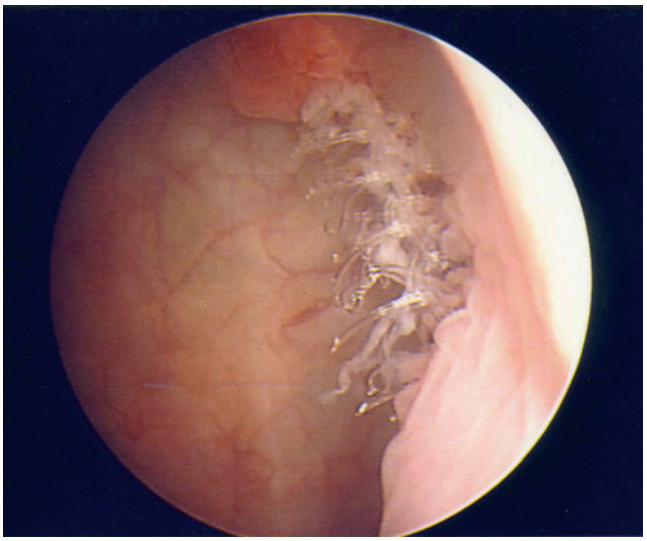

Figure 49.5 Intravesical erosion of a polypropylene sling.

Pain. Some patients present months to years following midurethral sling with vaginal and/or pelvic pain without evidence of mesh exposure or erosion. All patients with pain potentially related to sling placement or SUI surgery should be treated with conservative measures initially. These may include nonsteroidal antiinflammatories, physical therapy, pelvic floor massage, and vaginal estrogen creams either individually or in combination. A careful physical exam must be performed specifically to evaluate for vaginal "bands" and reproducible pain upon palpation of these "bands" or trocar sites in the suprapubic area or inner thigh. Pain elucidated on exam, especially if associated with a vaginal band, often, though not invariably, responds favorably to excision. At the time of excision it is often found that the sling is on excessive tension or there is excessive scarring and fibrosis. It is not recommended to remove asymptomatic mesh without associated complications as side effects related to nearby tissue damage and/or recurrence of SUI may occur.[86]

Patients with generalized pelvic pain following sling placement that is not reproducible on examination and has not responded to conservative measures may or may not respond to excision of the synthetic material. In such cases, the choice to proceed with surgery should be made with extreme caution in extraordinary cases and only when there is a temporal relationship between placement of the sling and the onset of the pain. Generalized pain is often difficult to treat and may or may not respond to sling excision, and patients should be thoroughly counseled regarding this potential outcome.

In all cases of surgical excision of the sling due to pain, it is controversial whether the entire sling has to be removed. Removing the entire retropubic or transobturator portions of the sling is a large surgical undertaking with potentially

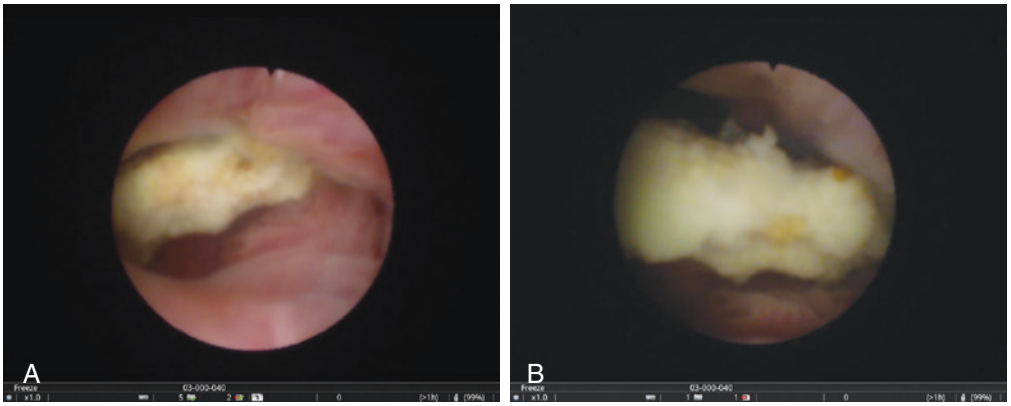

Figure 49.6 A, Calcification on urethral erosion of a midurethral sling. B, Calcification on the bladder neck erosion of a midurethral sling.

significant morbidity. Whether this extensive procedure is necessary in all cases is not well defined. Alternatively, only removing the transvaginal portion of the sling may adequately treat many patients' pain. Typically, when the pain can be localized on physical examination, we prefer to remove only the portion to which the pain has been localized. When applicable this includes the sling material up to the level of the inferior pubic ramus bilaterally and results in improvement of pain in up to 80% of individuals.[87] This can be done as a day surgical procedure and avoids potential major complications associated with removal of the pelvic portion of the sling such as neuromuscular injury, major vascular injury and bleeding, and injury to the urinary tract. As discussed earlier, the transobturator midurethral sling is more likely to be associated with groin pain or neurologic symptoms compared to retropubic midurethral slings.[27,28,88] Patients with recalcitrant pain often require removal of the arm of the transobturator sling, which can be technically challenging. Innovative approaches have been described for removing residual sling in these difficult cases.[83]

Sexual Dysfunction. Historically the effect of stress urinary incontinence surgery on sexual function has been controversial and inconsistently reported. Some investigators have found that female sexual function and coital incontinence improves following surgical treatment of SUI,[89–92] while others have reported deterioration,[93] and yet others reported no change in sexual function.[94–98] The risk of postoperative sexual dysfunction or dyspareunia following SUI surgery is low,[28,93] but any such complaint should be assessed by a thorough physical examination as it may be related to vaginal scarring, banding or narrowing, or mesh sling exposure.[99]

Dyspareunia is only one form of sexual dysfunction, but it may occur following anti-UI surgical procedures. Vaginal anatomy is altered by the surgical treatment of SUI. The vaginal axis can be shifted, thus changing the angulation of the vaginal canal. Circumferential narrowing of the vagina may result from excessive trimming of vaginal wall during prolapse repair or simply as a result of aberrant scarring. Dissection along the anterior vaginal wall may cause nerve injury and neuroma formation. Other ill-defined and poorly understood factors contributing to postoperative sexual dysfunction may exist.

Other Postoperative Complications. Urinary fistula following SUI surgical procedures is quite rare. Nevertheless, an unrecognized and unrepaired intraoperative injury to the ureter, bladder, or urethra may result in ureterovaginal, vesicovaginal, or urethrovaginal fistula, respectively. Intraoperative recognition of the injury is critical to prevent fistula formation, and thus the importance of a careful intraoperative endoscopic examination and confirmation of urinary tract patency cannot be overemphasized.

De novo vaginal prolapse including cystocele and enterocele may also occur following anti-UI surgical procedures. Alteration of the vaginal axis especially with open retropubic procedures such as the Burch or MMK may result in anatomic changes that predispose patients to postoperative vaginal prolapse. Predicting which patients will develop postoperative vaginal prolapse is exceedingly difficult.

Urethral Bulking Agents

In general, the morbidity associated with peri- or transurethral injectable bulking agents is low. UTI, short-term voiding dysfunction[100] including urinary retention, and hematuria are seen with all the urethral injectable agents. Transient dysuria and short-term elevated post-void residual urine are not uncommon following urethral bulking injections. For those individuals with persistent symptoms, UTI should be excluded. Calcium hydroxyapatite (Coaptite, Boston Scientific) is associated with the same complications mentioned above. In addition, one study reported serious adverse events in two patients related to Coaptite injection. These included vaginal erosion and tracking of the injectable agent under the trigone.[101] Urethral prolapse after Coaptite injection has also been reported in two patients with resolution after local excision.[102,103] Along with the more commonly reported adverse events, silicone particles (Macroplastique, Uroplasty Inc) have a reported transient urinary retention rate of 6–10%,[104,105] and carbon beads (Durasphere, Boston Scientific) have been associated with local lymphatic and periurethral migration, periurethral abscess, and urethral prolapse in a few cases.[106–108] Distal and systemic migration of urethral injectable agents including Teflon and carbon-coated beads has been reported. The long-term ramifications of these synthetic materials in the lymph nodes, lungs, and other organs are unknown.[109]

COMPLICATIONS RELATED TO URGE INCONTINENCE SURGERY

Botulinum Toxin A

Although BT is potentially quite toxic, few complications have been reported with its use. Local and self-limited complications such as hematuria, dysuria, pain, and infection occur at acceptable rates; however, the most worrisome potential complication, respiratory suppression, has not been reported with urinary tract injection of BT. Urinary retention and elevated post-void residual following intradetrusor injection in nonneurogenic detrusor overactivity has been reported in 5–16% and 35–60% of patients, respectively.[110,111] Because the pharmacologic effects of BT are not manifest for 3 to 14 days following injection, immediate urinary retention following BT injection is likely related not to the agent itself but rather to other factors including instrumentation. Urinary retention or voiding dysfunction resulting from BT usually occurs 1 to 2 weeks following injection. Kuo and colleagues[110] reported that risk factors for acute urinary retention include male gender, age greater than 75 years, and baseline PVR greater than 100 mL. There is a limited amount of literature in regard to urinary retention risk with injection of Botox at the bladder base or trigone; however, what is available has not shown an increased risk.[110,112,113]

Scattered reports of systemic adverse effects have been noted with the use of the Dysport formulation of BT, which is currently not available in the United States. These reactions have included generalized muscle weakness and hyposthenia in ≤6% of individuals and appear to be dose related because they have not been reported with the use of lower doses of the material.[114] Botox is currently the only BT for-

Table 49.3 Adverse Events Related to Sacral Neuromodulation (InterStim Implantation) in 202 Patients

Adverse Event	Percentage (%)
Malfunction secondary to trauma	8.9
Lead migration	5.9
Lack of efficacy	3.5
Infection	3.5
Pain at stimulator site	2.9
Hematoma requiring re-exploration	1.5

(Adapted from White WW, Mobley JD, Doggweiler R, et al. Incidence and predictors of complications with sacral neuromodulation. Urology. 2009;73:731-35.)

mulation that is FDA approved for urologic indications in the United States. One case of mild arm weakness has been reported with the use of the Botox formulation in the United States; however, this was after use in a nonurologic application.

Sacral Neuromodulation

Several complications related to sacral neuromodulation have been well documented. Overall, the reported surgical revision or removal rate has been reported to be ≤16% to 32%.[115–117] White and colleagues[118] reported adverse events in 202 patients (Table 49.3); in these patients, device malfunction secondary to trauma and lead migration were the most common. Pain at the stimulator site is the most frequently reported complication in many series.[116,117,119,120] Physical examination may reveal a fluid collection around the device requiring drainage or infection requiring explantation of the IPG and lead. In the setting of pain at the IPG site that is reproducible on palpation of the device, and which does not respond to conservative measures, the patient should be treated with surgical relocation of the IPG. Generally, relocation of the device into a superior or inferior position on the buttock or lower abdominal site improves the pain. For those with pain at the IPG site that is not reproduced on palpation, the device should be turned off for a period of time and the patient reexamined. If the pain resolves, then further investigation should commence. Although not considered a complication, patients should be well informed of the inability to obtain a lumbar, sacral, or pelvic MRI with the implanted device. If MRI of these areas is imperative the device should be explanted with the option of reimplantation after the MRI if the patient so desires.

Conclusions

Surgical treatment of urinary incontinence has changed significantly over the last 20 years. With the development and popularity of the midurethral polypropylene sling the types of complications seen in the surgical treatment of SUI have also changed. Thankfully, these complications are uncommon and in the current environment surrounding the use of transvaginal mesh, the FDA has reiterated that the standard polypropylene mesh midurethral sling is safe and effective in the treatment of SUI.[15] It is imperative to select the proper patient for the appropriate anti-UI operation, as the optimal situation is to prevent or minimize the risk of adverse outcomes. We hope this chapter will be a valuable resource in your practice should the complications reviewed above arise.

Chapter 49 Questions

1. A 52-year-old woman is undergoing a retropubic midurethral sling procedure. Cystoscopy after placement of the trocars reveals a bladder perforation. What is the most likely location in which the trocar will be seen?
   a. Bladder dome
   b. Bladder trigone
   c. 2- or 10-o'clock location of the anterior bladder wall
   d. 5- or 7-o'clock location of bladder neck
   e. Urethra

2. A patient returns to the office 2 years after a midurethral sling with complaints of mixed urinary incontinence, weak urinary stream, and sensation of incomplete bladder emptying. Physical exam reveals an oversuspended anterior vaginal wall with little mobility on Valsalva. Catheterized post-void residual is 200 mL. Serum creatinine is in the normal range, and urinalysis and urine culture are negative. What is the next step in definitive management?
   a. Retropubic urethrolysis
   b. Transvaginal sling incision
   c. Place suprapubic tube
   d. Alpha-blocker therapy
   e. Antimuscarinic therapy

3. During the dissection for placement of a retropubic midurethral sling in a healthy 52-year-old female, it is noticed that there is a very small urethral injury. Prior to surgery the patient was very adamant that she must have her stress incontinence fixed now as work and family obligations make this the only time she can have surgery and adequate recovery time. What is the next step after repairing the urethral injury?
   a. Proceed with retropubic midurethral sling placement
   b. Place a transobturator midurethral sling
   c. Placement of an autologous fascial pubovaginal sling
   d. Cystoscopic injection of Coaptite
   e. Intradetrusor injection of Botox

4. What is the most common complication of Botox injection?
   a. Guillain-Barre syndrome
   b. Sepsis
   c. Striated muscle weakness
   d. Respiratory suppression
   e. Elevated post-void residual

5. A healthy female patient had a sacral neuromodulation lead and implantable pulse generator (IPG) placed 6 months ago for refractory overactive bladder. She now complains of pain over the IPG site. Physical exam is unremarkable. What is the next step in management?
   a. Explant the device
   b. Relocate the device into a new pocket either superiorly or inferiorly in relation to the old pocket
   c. Broad-spectrum antibiotics for 21 days
   d. Interrogate the device and turn device off to see if the pain resolves
   e. Replace IPG

6. A 78-year-old female returns 4 days following injection of a urethral bulking agent with complaints of urinary urgency and frequency. What is the next step in management?
   a. Place a Foley catheter
   b. Trial of antimuscarinic medication
   c. Treatment with 7 days of Augmentin
   d. Urinalysis and urine culture
   e. Repeat cystourethroscopy

7. A healthy female undergoes surgical treatment of pelvic organ prolapse and stress urinary incontinence. One hour following sacrospinous ligament fixation and transobturator sling she complains of right sided foot drop. The most likely cause is injury to which of the following nerves?
   a. Sciatic nerve
   b. Femoral nerve
   c. Obturator nerve
   d. Peroneal nerve
   e. Ilioinguinal nerve

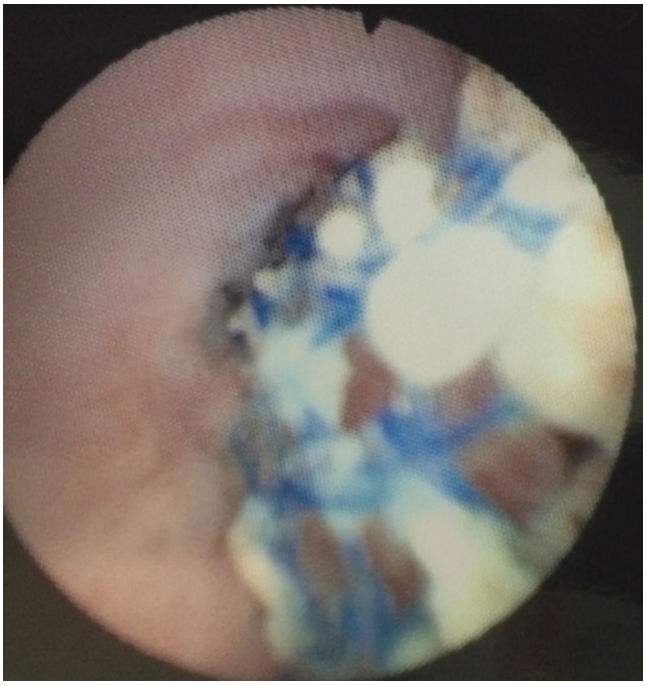
8. The retropubic space is entered transvaginally during placement of a pubovaginal sling, and brisk bleeding is encountered. What is the next step in management?
   a. Place vaginal packing and manually compress the anterior vaginal wall
   b. Transvaginal exploration of the retropubic space
   c. Transabdominal exploration of the retropubic space
   d. Abort the procedure and transfer the patient to interventional radiology for angiography and possible angioembolization
   e. Retroperitoneal exploration and ligation of the ipsilateral iliac vessels

9. Three months following a transobturator midurethral sling placement a 58-year-old female complains of dyspareunia, urgency, frequency, and recurrent urinary tract infections. On vaginal examination a 1-cm area of exposed mesh is identified. There are no areas of vaginal or pelvic tenderness. Her catheterized post-void residual is 200 mL. What is the next step?
   a. Vaginal estrogen cream
   b. Alpha-blocker
   c. Both vaginal estrogen and alpha-blocker
   d. Transvaginal sling incision and removal of exposed portion of the mesh sling
   e. Transvaginal and transperineal exploration and removal of the entire mesh sling

10. During a retropubic midurethral sling the trocar is seen intravesically on endoscopic examination. The next step is:
    a. Remove the trocar and abort the procedure
    b. Remove the trocar, abort the procedure, and repair the bladder in two layers with absorbable synthetic suture

c. Abort the procedure and place an autologous fascia pubovaginal sling
d. Remove and reinsert the trocar in an extravesical location and proceed with placement of retropubic midurethral sling
e. Remove the trocar and change to placement of a transobturator midurethral sling

Case Studies



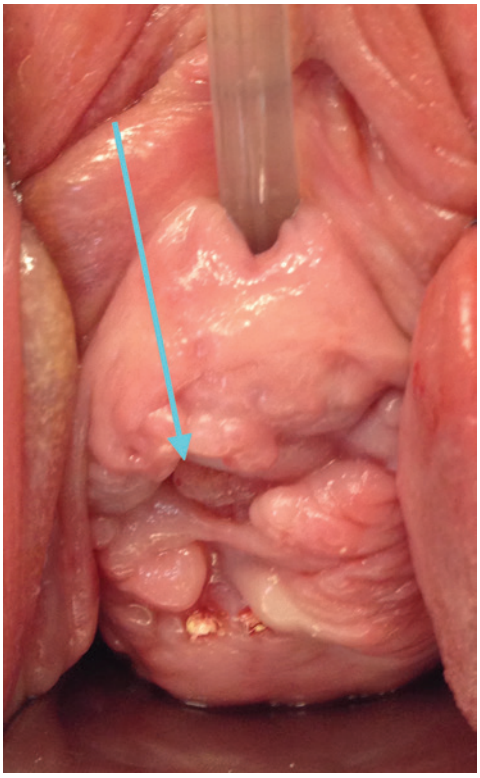
CASE 1

A 30-year-old healthy female presents with complaints of recurrent urinary tract infections (UTIs) for the last 2.5 years. Her past medical and surgical histories are remarkable only for a retropubic midurethral sling placed 3 years ago. She has failed multiple courses of antibiotic therapy. Her physical exam reveals slight tenderness to palpation of the anterior vaginal wall overlying the urethra, but is otherwise unremarkable. Her post-void residual by bladder scan is 20 mL. Urinalysis and culture are consistent with UTI, and she is started on appropriate antibiotic therapy.

1. What is the next step in management?
   a. Start on intermittent self-catheterization
   b. Cystourethroscopy
   c. Postcoital antibiotic prophylaxis
   d. Vaginal estrogen cream
   e. Prophylactic nightly antibiotic for 3 months

2. On cystourethroscopy the finding presented in Case Fig. 49.1 is noted. What is the next step required for treatment?
   a. Endoscopic removal of foreign body
   b. Retropubic exploration, removal of entire mesh sling, and urethral repair
   c. Transvaginal exploration, intraurethral mesh excision, and urethral repair
   d. Transvaginal mesh excision, urethral repair, and placement of a new midurethral sling
   e. Placement of suprapubic tube

3. Six months after mesh excision and urethral repair she returns complaining of recurrent stress urinary incontinence (SUI). Her UTIs have not returned, she continues to void to completion, and she has no other urologic complaints. What options are available to her for treatment of her recurrent SUI?
   a. Autologous pubovaginal sling
   b. Transobturator midurethral sling
   c. Retropubic midurethral sling
   d. Injection of urethral bulking agent
   e. All of the above



Case Figure 49.1

CASE 2

A 57-year-old sexually active woman is referred for dyspareunia and bothersome recurrent SUI 5 years after a transobturator midurethral sling. She has no voiding complaints. Vaginal exam reveals the finding shown in Case Fig. 49.2. On physical exam she demonstrates SUI in the supine position and empties her bladder adequately with a post-void residual of 25 mL.

1. What is the next step in management?
   a. Topical estrogen cream for 6 weeks
   b. Six-week course of empiric antibiotics in addition to topical estrogen cream

Case Figure 49.2

c. Excision of exposed mesh in the office using local anesthesia
d. Transvaginal excision of exposed mesh, placement of autologous fascial sling, creation of vaginal wall flaps, and closure of vaginal epithelium
e. Transvaginal excision of exposed mesh and placement of biologic dermal graft to close vaginal defect

2. Six months after mesh excision and placement of an autologous fascial sling she complains of urinary frequency and urgency that were not present preoperatively. Vaginal exam is unremarkable, her incision is well healed, there is no evidence of urethral oversuspension, and there is no tenderness to palpation of the anterior vaginal wall. Her Qmax on noninvasive uroflow is 12 mL/s and her post-void residual is 175 mL. What is the next step in definitive management?
   a. Placement of sacral neuromodulation test lead
   b. Placement of suprapubic tube
   c. Video urodynamics
   d. Trial of antimuscarinics
   e. Endoscopic intradetrusor injection of Botox

3. The video urodynamics reveal low-pressure involuntary bladder contractions, a maximum cystometric capacity of 425 mL, and normal compliance. SUI was not demonstrated. She voided with a sustained detrusor pressure in excess of 40 cm H_2O with a flattened urinary flow pattern and Qmax of 11 mL/s. Voiding images were remarkable for nonopacification of the urethra. Post-void residual was 150 mL. What is the next step in management?
   a. Transvaginal sling incision
   b. Suprapubic exploration and incision of the sling sutures below the level of the rectus fascia
   c. Placement of suprapubic tube
   d. Retropubic exploration and sling removal
   e. Prescribe VESIcare 5 mg by mouth daily

Answers

1. **c.** Bladder injury is a common occurrence during trocar passage in the performance of a midurethral sling. The most common location where the trocar injury will be seen is the anterior bladder wall, usually in the 2- or 10-o'clock position. It is important to inspect the bladder while full and use a flexible cystoscope or rigid 70-degree cystoscope.
2. **b.** Retropubic urethrolysis is more invasive, and suprapubic tube placement would not be a definitive treatment of this patient. Alpha-blocker therapy will not improve the likely anatomic obstruction. Antimuscarinic therapy may offer some symptomatic relief; however, this will not treat the underlying problem.
3. **c.** Placement of mesh after urethral injury is contraindicated. Given this patient's young age Coaptite would have inferior long-term efficacy compared to midurethral and fascial slings and would require repeat injections. Botox is indicated for the treatment of overactive bladder and urinary urge incontinence.
4. **e.** Guillain-Barre syndrome has never been reported after intradetrusor botulinum injection for lower urinary tract dysfunction. While urinary tract infections are not uncommon following intradetrusor botulinum injections, sepsis has not been reported. Generalized muscle weakness has been reported with Dysport; however, this formulation is currently not available in the United States. Respiratory suppression has not been reported with use of botulinum toxin in the urinary tract.
5. **d.** Explantation or replacement of the IPG or relocation of the IPG would be premature at this point. Antibiotics are not indicated as there are no signs of infection. Treatment for an infected device would be removal of the device.
6. **d.** Indwelling Foley catheter would potentially mold the recently placed bulking agent leading to inferior results. Transient urgency, frequency, and dysuria are not uncommon following injection of a urethral bulking agent; however, a urinary tract infection should be excluded prior to treatment with an antimuscarinic or empiric antibiotic therapy.
7. **d.** While the sciatic and obturator nerves can be injured during the aforementioned procedures, these injuries will result in buttock pain and inability to adduct the thigh, respectively. Injury to the femoral nerve would result in sensory defect in the anterior thigh and inability to extend the knee. The ilioinguinal nerve provides sensory innervation to the mons pubis and labia majora. The peroneal nerve may be injured with patients in lithotomy position from compression of the nerve at the level of the fibular head.
8. **a.** Most retropubic bleeding encountered during transvaginal surgery will resolve with vaginal packing and compression. For persistent brisk bleeding after an adequate time of compression, retropubic exploration or angiography may be necessary to identify and control bleeding.
9. **d.** Small areas of exposed vaginal mesh may resolve with application of vaginal estrogen; however, larger exposures will require more invasive intervention for treatment. The elevated post-void residual and urgency frequency suggest that there is also a component of bladder outlet obstruction and this will not be treated by estrogen therapy alone. Alpha-blockers will not treat the iatrogenically created bladder outlet obstruction. The patient does not complain of groin or perineal pain, and therefore removal of the entire sling is not indicated.
10. **d.** Recognition of trocar entry into the bladder during midurethral sling is treated by removal and reinsertion of the trocar outside of the bladder. These injuries typically heal without need for formal bladder repair or prolonged catheter drainage. Transobturator trocar passage has a lower risks of bladder perforation; however, the risk still remains, and therefore intraoperative cystoscopy should also be performed in these cases as well. Urethral injury during mesh sling placement requires repair of the urethra and aborting the midurethral sling procedure.

CASE 1

1. **b.** Her post-void residual is minimal, and therefore self-catheterization is unnecessary. Estrogen replacement

would not be indicated in this young, otherwise healthy female without vaginal atrophy. Postcoital antibiotics eventually may be warranted; however, she needs further evaluation of her urinary tract to identify the source of the recurrent infections, which chronologically may be related to her sling placement. Prophylactic antibiotics would not be appropriate before full evaluation is complete.

2. **c.** Endoscopic removal of mesh may be possible for intravesical erosions; however, urethral mesh erosion requires open surgical excision of the eroded mesh. Retropubic exploration and removal of the entire mesh is not required, and placement of another synthetic sling is contraindicated. The patient is emptying her bladder adequately; therefore suprapubic tube is not required.
3. **e.** She has had adequate time to heal after excision of eroded urethral mesh; therefore any of the above options are available to her for treatment of the recurrent SUI. Some patients refuse replacement of mesh products after prior complications; therefore autologous sling and urethral bulking agents are alternative options. Given the patient's young age she should be counseled that urethral bulking agents do not have long-term durability and efficacy. Therefore repeat injections may be required to maintain desired effect.

CASE 2

1. **d.** This woman has SUI and a mesh exposure vaginally. Small defects can be managed conservatively with topical estrogen cream or local excision of the exposed mesh in the office; however, larger defects, such as in the image shown, require secondary closure or excision in the operating room. Furthermore, her SUI is unlikely to be adequately treated with estrogens alone. Antibiotics have not been shown to promote healing of vaginal mesh erosion. Given her recurrence of SUI a fascial sling can be placed during the same operative procedure.
2. **c.** Despite the lack of physical exam findings, there is concern for bladder outlet obstruction following sling in this symptomatic female with elevated post-void residual. Sacral neuromodulation can be used to treat refractory overactive bladder and nonobstructive urinary retention; however, neuromodulation, antimuscarinics, or Botox injections will not treat bladder outlet obstruction if present. A suprapubic tube will indeed drain the bladder; however, it will not aid in definitive treatment of what is likely bladder outlet obstruction from the pubovaginal sling. Antimuscarinics may exacerbate the elevated post-void residual.
3. **a.** Placement of a suprapubic tube will not provide definitive treatment of this patient's bladder outlet obstruction. Suprapubic incision of the sling sutures will not "release the sling." Transvaginal sling incision is required to relieve the obstruction. Retropubic exploration is unnecessarily invasive for sling incision. Overactive bladder symptoms may persist after sling incision, at which point a trial of antimuscarinics would be appropriate.

- De Novo Urgency
- Obstruction
- Prolonged Pain and Paresthesia
- Osseus Complications
- Recurrent Incontinence

Conclusions
Chapter 50 Questions and Answers

KEY POINTS

1. Most intraoperative complications are inconsequential if recognized and treated at the time of surgery. On the other hand, urethral injury typically requires aborting the procedure.
2. To facilitate detection of an unrecognized urethral injury, saline or dilute indigo carmine can be instilled alongside the Foley or through the Foley catheter while moving it in a retrograde fashion.
3. Artificial urinary sphincter (AUS) tubing should be handled with rubber-shod clamps, and care should be taken not to injure the device with sharp instruments or needles. Damage to the device can result in leakage of fluid from the device and mechanical failure.
4. Early infection of the AUS, and most likely the male sling, is typically the result of bacterial contamination at the time of implantation.
5. Erosion of an AUS is commonly caused by prolonged catheterization, catheterization without cuff deactivation, or repeated endoscopic manipulation of the urethra. Patients with prior AUS placement or radiation are at an increased risk.
6. Urinary retention that presents as a late complication following AUS or male sling requires endoscopic evaluation for infection or erosion, and to evaluate the urethra and bladder neck for stricture or contracture.
7. De novo urgency following male sling should be evaluated to rule out obstruction or recurrent stress incontinence.
8. Iatrogenic obstruction following placement of a male sling is rare, but not impossible.
9. Patients with an infected male sling may present with chronic low-grade symptoms, such as mild perineal pain or swelling or an intermittently draining sinus tract.
10. The AUS is a mechanical device that inherently carries a risk of mechanical malfunction as well as the need for device revision or replacement.

Introduction

Stress urinary incontinence (SUI) is a potential complication following surgical treatment of benign prostatic hyperplasia (BPH) or prostate cancer or following pelvic radiation. For the men affected, SUI has a significant impact on quality of life.[1,2] The majority of incontinence following radical prostatectomy and some of the incontinence caused by BPH or radiation treatments is the result of sphincteric insufficiency.[3,4]

The artificial urinary sphincter (AUS) is the current gold-standard treatment for male SUI and was first developed in 1983. Male slings were developed in the 1990s as an alternative to the AUS that did not require mechanical manipulation and surpassed the AUS as the most common SUI procedure in 2010.[5] Inflatable balloon compression devices are the final procedural option for male urinary incontinence and have been available since 2002 outside the United States.

In this chapter, we discuss preoperative evaluation of the patient that can influence potential complications. We then briefly describe the surgical procedures most commonly performed for male urinary incontinence, providing context for the reader to appreciate when and why certain complications occur, and, finally, we discuss the potential complications encountered during the procedures with respect to their temporal occurrence (Table 50.1).

Preoperative Considerations

Traditionally most urologists have agreed that patients should be followed for approximately 12 months before pursuing surgical management of postprostatectomy incontinence. However, patients' early recovery of continence and comorbidities predict their likelihood of eventually achieving continence with the incremental improvements that occur during the first year following surgery.[6,7] More recently, earlier intervention, e.g., at 6 months, has been recommended in severe cases where no temporal improvement is seen.[8,9]

The evaluation of a patient with postprostatectomy incontinence should include a thorough history and physical exam. Important aspects of the history include precipitating factors and associated symptoms (frequency, urgency, nocturia, weak stream). The severity of incontinence based on typical pad use and the resultant impact on quality of life are critical to the assessment, especially as these subjective responses directly correlate with 24-hour pad test data.[10] History should address the patient's voiding symptoms prior to prostate surgery as well as history of neurologic disease or symptoms, radiation therapy, additional surgeries/procedures, and prior attempts at treating the incontinence. During the physical exam the patient should be instructed to cough or Valsalva with a moderately full bladder in order to demonstrate the presence of SUI. A focused neurologic exam should be performed.[9]

When the severity of incontinence is in question we perform a 24-hour pad test for objective assessment as well as to help guide our discussion with the patient regarding surgical options and outcome expectations. In a study by Fisher et al., the only preoperative factor predictive of success following a male perineal sling was having a 24-hour pad weight less than 423 grams. Patients with high-grade incontinence and those with very low-grade incontinence have inferior results with a male sling.[11] The reason for the very low-grade incontinence patients being less satisfied was thought to be due to very high expectations in that group.

Urodynamic testing is optional in the evaluation of postprostatectomy incontinence and is thought to be most useful in cases where SUI is not demonstrated, when there is significant bladder overactivity, or in cases of radiation where impaired bladder compliance is suspected. Urodynamic testing allows for determination of the etiology and guides the treatment of male urinary incontinence.[12] The main goals of the urodynamic evaluation are to determine the presence of sphincteric insufficiency and/or bladder dysfunction, to evaluate for obstruction, and to assess detrusor contractility. It is crucial that the study reproduce the patient's symptoms, which in this case would be incontinence. When urodynamics are performed we follow the protocol described by Huckabay et al., which includes evaluation both with and without a urethral catheter.[13] This urodynamic protocol addresses the subset of men with postprostatectomy SUI that do not leak with the catheter in place[4] and allows for documentation of sphincteric insufficiency in these men. In addition, a flow rate without the catheter allows corroboration of free Qmax and Qmax in those patients that have suspected obstruction based on pressure-flow analysis. Some recommend documenting the degree of posterior urethral mobility to determine whether the patient would benefit from retroluminal support with a male sling.[14]

Table 50.1 Complications of Male Incontinence Surgery

	Intraoperative	Early	Late
AUS	Corporal injury Urethral injury Device injury Bleeding	Hematoma Retention Infection Erosion	Infection Erosion Urethral atrophy Mechanical Retention
Male Sling	Bleeding Urethral injury Obturator nerve injury	Hematoma Retention Infection Pain Paresthesia	Infection Erosion De novo urgency Obstruction Prolonged pain Prolonged paresthesia

Procedures for Male Incontinence

ARTIFICIAL URINARY SPHINCTER

Since the introduction of the American Medical System (AMS) 800 in 1983, there have been incremental improvements to the design of the AMS 800 with antibiotic coating introduced in 2008 and 3.5-cm cuff sizing in 2010. Various techniques exist for implantation of the AUS (AMS 800, Boston Scientific Corporation, Marlborough, MA; Fig. 50.1). A perineal and a lower abdominal incision (either transverse

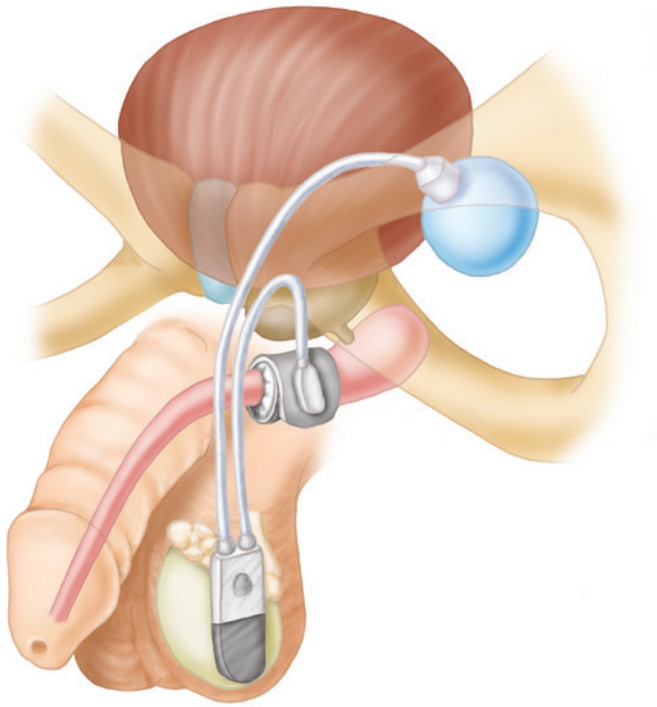

Figure 50.1 Artificial urinary sphincter. (With permission from Trost L, Elliott DS. Male stress urinary incontinence: a review of surgical treatment options and outcomes. Advances in Urology. 2012:2012:289489.)

or midline) is the classic and the preferred approach according to the International Continence Society AUS Consensus group.[9] Others have described placement through a single peno-scrotal incision.[15] Traditionally, after placement of a Foley catheter, a midline perineal incision is made and the bulbospongiosus muscle is exposed. The bulbospongiosus muscle can be split or preserved: It is our practice to split the muscle. The urethra is dissected circumferentially with special attention being given to mobilization of the urethra from the intracrural septum. A 2-cm window is made between the corpora cavernosa and the urethra. The urethra is inspected for injury visually and then by irrigating the urethra. This can be done by injecting normal saline through an angiocath into the urethra alongside the catheter, obviating the need for catheter removal. Alternatively, the Foley can be withdrawn into the distal urethra and saline injected through the catheter while the meatus is compressed. The urethra is then measured, and the appropriate sized cuff is placed.

We use a transverse lower abdominal incision for placement of the reservoir; however, a midline incision is also an option. The reservoir can be placed preperitoneally, intraperitoneally, or in the retropubic space. We retract the rectus muscle medially, open the transversalis fascia, and place the reservoir in the retropubic space. Typically, a 61–70 cm H_2O pressure reservoir is used and filled with 23 mL of saline. The tubing from the cuff is passed over the pubic bone into the suprapubic incision. Finally, a plane is developed between the suprapubic incision and the ipsilateral hemiscrotum, and a pocket is created in a dependent position for the pump. The components are then connected, and the device is cycled and left in the deactivated state.

MALE SLINGS

Male slings have been an active area of research and innovation in the last 20 years and are the most commonly utilized alternative to AUS placement. There have been a variety of slings manufactured in the past that one may encounter in practice today, for example, during a revision surgery. Slings can be divided into fixed slings and adjustable slings (Fig. 50.2). The latter allow for manipulation of the sling post implant. The highest level of evidence of data is available for fixed slings.

Fixed Male Slings

Bone-Anchored Sling. The InVance bone-anchored sling (American Medical Systems, Minnetonka, MN) is no longer commercially available in the United States; however, it remains of interest as one can still see complications of bone-anchored slings. It was designed to compress the bulbar urethra and is affixed to the pubic bone. If confronted with a case for revision, it is important to note the position of the three bone anchors with attached polypropylene suture placed bilaterally in the pubic rami utilizing a drill. The first is placed at the junction of the pubic symphysis and the pubic ramus, the second is placed 3 cm below the first, and the last splits the distance between the two.

Transobturator Sling. The retrourethral transobturator slings (RTSs) theoretically restore continence by repositioning the proximal urethra. Tensioning causes proximal movement of the dorsal portion of the proximal bulb, which in turn affects closure of urethral lumen and advances the membranous urethra cranial and posteriorly.[18] While this theory has been advocated, it is also plausible that the majority of the effect on continence is caused by compression of the proximal bulb. This sling is most effective in men with some degree of retained continence (defined by pad weight or a Valsalva leak-point pressure >100 mm Hg).[19] RTSs have been shown to have a durable success rate with a 53–90% improvement rate after 1–3 years follow-up reported in the literature.[20–24]

The AdVance sling (Boston Scientific Corporation, Marlborough, MA) has become the most commonly used type of male sling since its introduction in the mid 2000s. A Foley catheter is placed, and a midline perineal incision is made. The bulbospongiosus muscle is identified, split in the midline, and dissected off the urethra. The urethra is dissected to the level of the perineal body and genitourinary diaphragm, and the urethra is partially separated from the perineal body. A mark is made on the skin approximately 2 cm below and 1.5 cm lateral to the insertion of the adductor longus. A spinal needle may be used to ensure that the obturator fossa lies at the level of the mark, and a small skin incision is made. A helical passer is passed through the skin, the obturator fossae, the obturator externus muscle, and the obturator membrane. The triangle formed by the urethra, the bulbospongiosus, and the bulbocavernosus muscles is palpated and the trocar is guided onto the index finger. A similar procedure is performed on the contralateral side. Cystoscopy is performed to ensure that there is no injury to the bladder or urethra. The sling is then attached and brought out through the skin. It is secured proximally

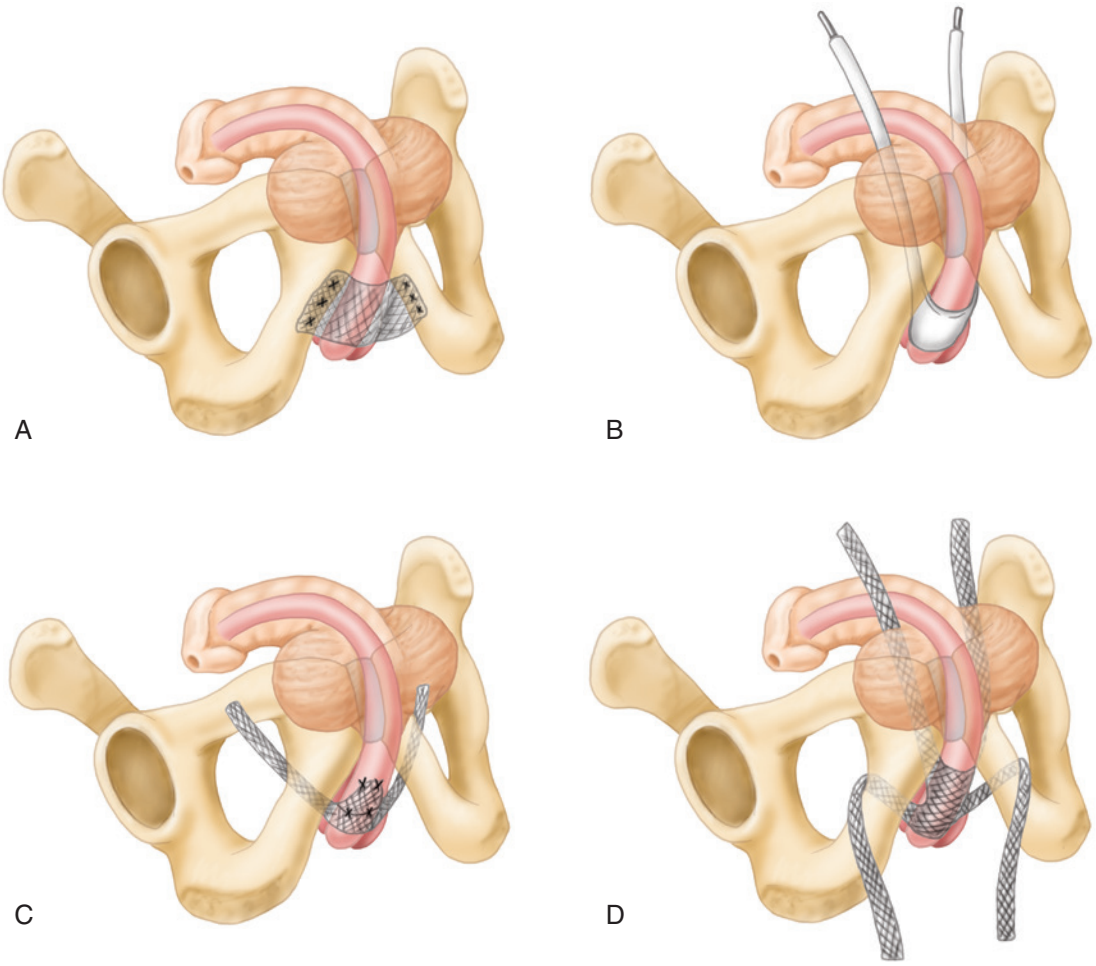

Figure 50.2 Male slings (A-BAS; B-ARS; C-TMS; D-quadratic). (With permission from Trost L, Elliott DS. Male stress urinary incontinence: a review of surgical treatment options and outcomes. Advances in Urology. 2012:2012:289489.)

and distally in the midline with suture, and tension is placed to provide elevation of the urethra. Cystoscopy is repeated to evaluate urethral coaptation.[18]

The I-Stop TOMS (CL Medical, Lyon, France) is commercially available in Europe; however, it is not approved for use in the United States. The procedure is akin to that for the AdVance male sling; however, this sling has two transobturator arms on each side.[25]

Quadratic Sling. The quadratic sling, Virtue sling (Coloplast, Humlebaek, Denmark), was introduced in 2012. Initially the sling was hypothesized to provide improved continence outcomes by generating greater urethral compression than prior slings.[26] The sling causes proximal urethral relocation and bulbar urethral compression. Increased efficacy was found if the sling was fixed to the urethra, preventing loosening in the early postoperative period before it was able to scar into place.[27]

During sling placement, the urethra is dissected from the perineal body while the bulbospongiosus muscle is left intact. Using the sling passer, each arm is passed from the medial aspect of the descending ramus to the ipsilateral groin crease. The prepubic arm introducers are placed from a superior position 2 cm above the pubic symphysis, each 2 cm lateral to midline, and exit at the perineum lateral to the urethra. The four mesh arms are released after appropriate tensioning is performed. The sling can be further fixated by tunneling the transobturator arms back to the midline and suturing them to each other as well as by adding a figure of eight suture at the junction of the rami and pelvis. This fixation approach improved 1-year success rates from 41.9% to 70.9%. Success was achieved in 57.1% of patients with severe incontinence.[27]

Adjustable Male Slings

The data on the relative and absolute efficacy of these slings comprise single-institution descriptive series, with varying inclusion and exclusion criteria and definitions of success.[28] Given the paucity of level one efficacy data,[6,29] the choice of intervention relies on patient and physician preference, which should be informed by the complication profile associated with each of these procedures.

Adjustable Retropubic Slings. The adjustable retropubic sling (ARS) provides suburethral support and is anchored by retropubic mesh arms with reported success rates of 72–85%.[17,30,31] The most commonly used ARS is the Argus adjustable male sling (Promedon SA, Cordoba, Argentina). A specialty needle is used to pass the sling from a perineal incision through the rectus fascia following

immediately inferior to the pubic bone. Under direct visualization with cystoscopy, the sling is adjusted by moving the washers until adequate urethral wall coaptation is appreciated.[30,32]

The Reemex system for placement of the male readjustable sling (Neomedic International, Barcelona, Spain) has also been described in a multinational study by Sousa-Escandon and colleagues.[31] Per their description, a 60-degree modified Stamey needle, loaded with the lateral traction thread, is passed on each side in a retrograde fashion to the level of a suprapubic incision. The threads are then pulled through to place the monofilament sling flush with the bulbocavernosus muscle, and the sling is sutured in place. The threads are placed into a varitensor device. This has an external manipulator that allows for thread adjustments.

Adjustable Transobturator Slings. The adjustable transobturator hydraulic mesh system (ATOMS; AMI, Vienna, Austria) has been available in Europe since 2009[34]. The central silicone cushion is fitted onto the surface of the urethra and bulbospongiosus. Mesh arms are attached to the helical trocar and passed around the inferior pubic ramus. The mesh is then sutured to the proximal end of the silicone cushion to stabilize the system. The titanium port is tunneled over the pubis and placed in a subcutaneous left suprapubic location with two anchoring sutures.[34,35]

INFLATABLE BALLOON COMPRESSION

Prostate Adjustable Continence Therapy (ProACT; Uromedica, Plymouth Minn, Fig. 50.3) has been introduced as a minimally invasive treatment for postprostatectomy incontinence. The ProACT has recently been approved for use in the United States though it has been used commonly in other countries around the world for several years, with 55–68% satisfaction in small contemporary series.[36–38] The patient is placed in lithotomy and 50–100 mL of contrast is instilled into the bladder. Through a perineal incision, a Kelly clamp was previously used to perforate the pelvic floor;[39,40] however, a tissue expansion device now facilitates the development of the periurethral space.[41] Two balloons are then placed beneath the bladder neck, bilaterally dorsal to the urethra. The balloons are filled with 1–5 mL of contrast medium and sterile water. Cystoscopy is performed to confirm balloon position and exclude urethral injury. The balloon ports are placed bilaterally just beneath dartos fascia in the scrotum. This allows for percutaneous needle access for future inflation or deflation of the balloons.[39,40]

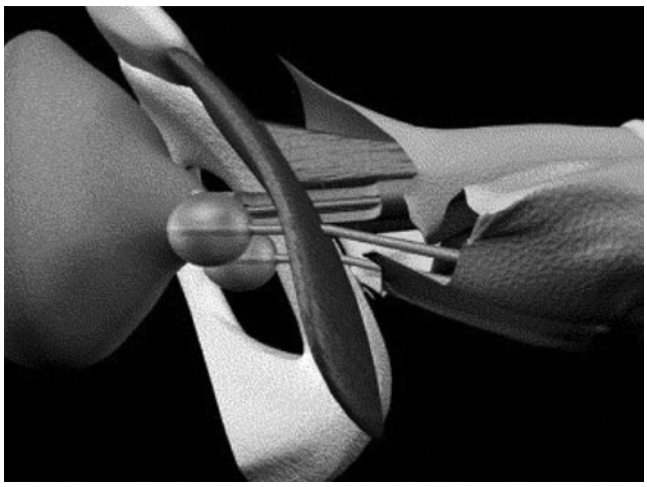

Figure 50.3 ProACT device. Relationship to bladder neck and genitourinary diaphragm. (With permission from Trigo-Rocha F, Gomes CM, Pompeo AC, Lucon AM, Arap S. Prospective study evaluating the efficacy and safety of Adjustable Continence Therapy (ProACT) for post radical prostatectomy urinary incontinence. Urology. 2006;67(5):965-9.)

Intraoperative Complications

ARTIFICIAL URINARY SPHINCTER

Most intraoperative complications are inconsequential if recognized and treated at the time of surgery. The exception to this is an injury to the urethra that requires aborting the procedure in most cases.

Bleeding

Most significant bleeding with AUS placement occurs as a result of a corpora cavernosa or spongiosum injury. Bleeding can also occur with placement of the reservoir from epigastric or retroperitoneal vessels.

Corporal Injury

When performing AUS placement corporal injury can occur during mobilization of the urethra from the intracrural septum. Corporal injury may result in significant bleeding that can impair visualization. Adequate exposure is the key to identifying the injury. Once the injury is identified it can be repaired with absorbable suture.

Urethral Injury

Urethral injury is another potential intraoperative complication, and one that should not go unrecognized. Urethral injury typically occurs dorsally where the spongiosum is thinnest. To detect an unrecognized urethral injury, saline or dilute indigo carmine can be instilled alongside the Foley catheter or through the Foley catheter while moving it in a retrograde fashion. If a urethral injury is identified, it should be repaired in multiple layers with absorbable suture. Most surgeons would abort AUS placement and leave a Foley catheter for an appropriate period of time. In rare cases if the injury is small and away from the intended site of implantation, the cuff can be placed, although this must be done with extreme caution. If there is any question regarding the repair, or if the cuff cannot be placed away from the sight of injury, then the procedure should be aborted. Injury to the corpus spongiosum but not involving the urethra is usually inconsequential, especially when it occurs ventrally where the spongy tissue is thick. Such injuries can simply be oversewn to control bleeding. Dorsally, where the spongiosum is thin, it is common to have a concomitant urethral injury.

Device Injury

Care must also be taken to avoid any injury to the device. Damage to the device can result in leakage of fluid from the

device and mechanical failure. The tubing should be handled with rubber-shod clamps, and care should be taken not to injure the device with sharp instruments or needles. If a device injury is noted, the "injured" component should be replaced. Unrecognized injury will result in device malfunction as fluid leaks out of the system.

MALE SLING

Intraoperative complications with sling placement are unusual, the most common with a bone-anchored sling being bleeding. Based on technique, obturator nerve injury would seem to be a possibility, but has not yet been reported in transobturator and quadratic sling placement.

Bleeding

Significant intraoperative bleeding during male sling placement is rare and none of the major series has reported transfusions.[11,16,17,24,27,42,43] Corporal injury and bleeding can occur during dissection. Bleeding from a main or accessory obturator vessel would be possible with a transobturator sling placement. With transobturator sling placement, it is not unusual to encounter bleeding as the urethra is dissected to the perineal body. It occurs as a result of small injuries to the spongiosum that can be oversewn with a fine absorbable suture (e.g., 4-0 polyglycolic acid). Also with transobturator sling placement, bleeding can occur from injury to small vessels along the route of needle passage through the obturator fossa. When this occurs tensioning of the sling may control bleeding. Injury to a major obturator vessel is possible, but rare.

Urethral Injury

Urethral injury with the bone-anchored sling is not reported in the literature but is certainly possible and should be treated as described above for the AUS.

Romano et al. reported a "potential" urethral perforation rate of 6% with the Argus ARS. This was addressed intraoperatively by repositioning the needle and resulted in no further complications.[30] With transobturator sling placement, urethral injury is rare, though possible from a needle perforation, usually near the bladder neck.[43] Thus cystoscopy after sling placement is essential. If such an injury is seen, the needle or sling should be removed. The injury is usually not in a position that can easily be repaired, so treatment is with catheter drainage for up to 7 days depending on the size of the injury. The sling may be replaced in the same setting at the surgeon's discretion depending on the site and size of the injury.

Early Postoperative Complications

ARTIFICIAL URINARY SPHINCTER

Hematoma

Scrotal hematoma is a common minor postoperative complication associated with AUS implantation. Hematomas typically resolve spontaneously without intervention; evacuation is rarely indicated.

Retention

Another common early complication is urinary retention as a result of postoperative edema.[44] Patients who undergo transcorporal AUS placement are at an increased risk for developing postoperative retention.[45] We sometimes leave a 14Fr Foley catheter overnight in an attempt to avoid this problem. Bladder neck dilatation for anastomotic stenosis is a risk factor for retention beyond 24 hours, secondary to temporary swelling. If retention occurs, the first step should be examination of the device to ensure deactivation with the cuff in an open position. If catheterization is required it should be performed carefully with a small 10–14Fr Foley and catheterization time should be kept to a minimum, preferably under 48 hours.[9,46] Also, if there is even the slightest difficulty in replacing a catheter, it should be done under endoscopic guidance or a suprapubic tube should be placed. If the patient is unable to void after 48 hours suprapubic catheter placement may be considered.[47]

Early Infection

Early infection can occur and may manifest with erythema, induration or edema around the pump, as well as with purulent drainage, fever, or pain in the scrotum, groin, or perineum. Early infection is most typically the result of bacterial contamination at the time of implantation. The most common organism in early infection is *Staphylococcus aureus* and *S. epidermidis*, with increasing rates of methicillin resistance.[48] The introduction of Inhibizone in 2008 was meant to decrease early infections by providing an antibiotic coating. However, the only clinical data published did not show a change in the rates of AUS infections over 4 years of use.[49]

Another potential etiology of early infection is unrecognized urethral injury. Urethroscopy should be performed at the time of device removal.[9] Infection requires removal of the entire device and reimplantation after at least 3 months. In select cases, one may consider replacement at the time of removal, after aggressive wound irrigation with antibiotics as described by Bryan et al.[50]

Early Erosion

Erosion can also occur with or without infection. It is likely the result of unrecognized iatrogenic urethral injury, urethral thinning, or early postoperative replacement of a Foley catheter.[51] Erosion may present with pain or swelling in the scrotum or perineum, pain referred to the tip of the penis, recurrent incontinence, dysuria, hematuria, or bloody discharge. If erosion occurs without infection the tubing can be capped at the time of cuff removal. If associated with infection the entire device should be removed. The urethra is repaired with absorbable suture at the site of erosion and a Foley catheter is left indwelling. A voiding cystourethrogram (VCUG) is performed to ensure that the urethra has healed prior to the removal of the catheter, and at the time of reimplantation a different site is selected for the cuff.

MALE PERINEAL SLING

Hematoma

Postoperative hematoma is a rare event. There is one study reporting 1 of 136 patients affected in a single cohort and

2 of 50 patients in a single BAS cohort. All cases resolved spontaneously.[21,52]

Acute Retention

Retrourethral transobturator slings are associated with a 3–21% risk of postoperative retention, compared to 14% in ARS.[17] In the initial study of the quadratic male sling, there were no occurrences of postoperative retention.[27] Postoperative pain and inflammation may contribute to early urinary retention. In truth, acute retention can be expected in a certain number of cases and is more of an unfavorable early outcome than a true "complication." Retrourethral transobturator slings generally have a higher rate of acute retention, which can take up to 12 weeks to resolve.[17] Sling lysis for protracted retention has been reported, but remains an extremely rare event.[43]

Pain and Paresthesia

Postoperative pain and paresthesia have been reported in all types of male slings and have been the most disappointing aspects of male slings in our experience. They are hypothesized to result from injury to the superficial perineal nerves. Interpretation of the incidence and severity of postoperative pain is limited by the differing criteria and categorization of postoperative discomfort in the literature. For example, from 4% to over 50% of patients reported perineal buttock pain after BAS or RTS in several large cohort studies, although all resolved by 3 months.[16,17,53,54] Notably, Romano et al. reported a 21% rate of dysuria associated with perineal discomfort or moderate pain following placement of the ARS that resolved or became very mild after 1–2 months of analgesic and NSAIDs. Perineal and thigh pain or paresthesias occurred in 68% of patients in the series of adjustable transobturator sling placement by Hoda et al.;[34] however, this pain was also managed conservatively with NSAIDs for up to 4 weeks. Decreasing the adjustment pressure to 45 cm H_20 is also purported to reduce risk of postoperative perineal pain.[30] There are only two cases of reported persistent discomfort after 6 months with conservative management.[27]

Persistent pain should be further evaluated. We obtain a CT and/or bone scan in appropriate cases. In cases of severe or persistent pain consideration should be given to sling removal.

Infection

Early postoperative infection is possible with male slings. Like the AUS, it is probably the result of bacterial contamination at the time of implantation. Infection of the device was more common when silicone coated implants were used. With the advent of polypropylene this has become an unusual complication and most can be managed conservatively. A single series did report early post-infection requiring explant in 4 of 99 patients.[34] Although early infection remains rare in the literature, BAS were the most likely to be associated with early infections.[17] A single perineal incision has been associated with significantly fewer early skin infections in ARS placement compared to a dual incision approach in a prospective study comparing 36 consecutive patients.[33]

INFLATABLE BALLOON COMPRESSION

Acute urinary retention has been reported in 1–6% of patients after ProACT placement. Treatment consisted of withdrawing a small amount of solution from the balloons via the injection ports. Infection, erosion, and balloon migration and rupture have also been reported, but the time to occurrence was not specified.[36,39–41] They will be discussed under delayed complications.

Delayed and Long-term Complications

ARTIFICIAL URINARY SPHINCTER

The majority of delayed AUS complications require a surgical intervention, either revision or explant. The rate of repeated surgical intervention has been reported as 31–53% in large contemporary series following patients for over 5 years.[55–57] Thus the known revision rate of 4–5% per year after implantation should be explained to the patient.

Infection and Erosion

Rates of infection reported in large series range from 0% to 14%.[55,58–62] Most report higher infection rates in patients' status post–pelvic radiation, including a systematic review of 15 studies.[46,63–65] In contrast to early infections, in which the most common cultured pathogens are skin flora, late infections, those occurring >4 months after implantation, are thought to be the result of hematogenous seeding secondary to bacteremia from another source.[47,66] Late infections most commonly present with scrotal pain, but may also present with erythema, edema, or induration around the pump or fever. Infection is most commonly managed by removing all components of the device; however, management of patients with a salvage technique similar to that used for salvage of penile prostheses has been described.[43] Cystoscopy is performed to rule out urethral erosion. All prosthetic parts are removed, wounds are copiously irrigated according to a seven-solution protocol, and a new device is implanted.[50]

Erosion rates ranging from 2.2% to 6.5% have been reported with a median time to erosion of 20 months.[55,58–61] Common causes include prolonged catheterization,[51] catheterization without cuff deactivation, or repeated endoscopic manipulation of the urethra. Patients at a higher risk for erosion include patients with a history of hypertension and coronary artery disease, as well as prior radiation, prior AUS revision (especially for erosion), and prior urethral stent.[61,67] One patient cohort study spanning 30 years did not find any preoperative risk factors for erosion.[56] Patients undergoing revision for erosion are at risk for worse postoperative continence rates than those undergoing revision for other reasons.

Potential manifestations of urethral erosion include pain or swelling in the perineum or scrotum, pain referred to the tip of the penis, recurrent incontinence, dysuria, hematuria, or bloody discharge. Erosion is typically into the urethra, but erosion of tubing to the skin can also occur. Urethral erosion typically occurs on the dorsal side of the urethra

where the spongiosum is thinnest, but can occur anywhere, especially if associated with trauma (Figs. 50.4 and 50.5). When urethral erosion occurs, at a minimum, the cuff has to be removed. If there is any suspicion of associated infection, the entire device should be removed. The site of erosion may be repaired with absorbable suture if it can be easily accessed. Dorsal erosions are the most common and are often left unrepaired and simply allowed to heal with a period of catheterization; however, immediate urethral repair has been shown to decrease the risk of stricture formation and increase the likelihood of AUS reimplantation.[68] In either case a Foley catheter is left indwelling until closure, which is evidenced by voiding cystourethrogram after 1–2 weeks. Reimplantation is performed 3–6 months later. Prior to reimplantation, cystourethroscopy is performed to ensure adequate healing and to rule out formation of a stricture at the site of previous erosion. The new cuff is positioned away from the erosion site. Transcorporal cuff placement[69] and utilization of biologic grafts can help buttress the urethra and decrease the recurrence of erosion.

Recurrent Incontinence

Recurrent incontinence can be due to bladder or sphincteric dysfunction. If it is due to sphincteric insufficiency then it is likely related to urethral atrophy or mechanical malfunction of the device, as discussed below. Recurrent incontinence can also be a manifestation of infection or erosion as previously discussed. If it is not clear whether the incontinence is due to bladder or sphincteric dysfunction, then urodynamic evaluation can be helpful. When performing urodynamics in a patient that has an AUS, the device should be deactivated with the cuff deflated prior to inserting the catheter. Once the catheter is in place, the AUS should be reactivated for filling and stress testing.

Urethral Atrophy. The introduction of the narrow-backed cuff has improved urethral pressure transmission; however, urethral atrophy still accounts for a significant portion of nonmechanical AUS revisions.[56] Rates of urethral atrophy have been reported ranging from 0% to 14%,[56,58–61] which vary with length of follow-up.

Urethral atrophy manifests as new-onset incontinence. Exam demonstrates a normally functioning pump. Cystourethroscopy may reveal incomplete coaptation of the urethra, and the urethra may appear thin and pale. Multiple management options have been proposed for urethral atrophy including downsizing of the cuff,[70] placing the cuff in a more proximal location,[71] placement of tandem cuffs,[72] increasing reservoir pressure, or transcorporal placement of the cuff.[69] Downsizing of the cuff has become a more effective management option since the introduction of the 3.5-cm cuff, which addresses urethral thinning, in addition to the decreasing caliber of the proximal urethra, allowing for cuff placement around the unaffected portion of the urethra.[73] In addition one report demonstrated that in patients who deactivated their cuff at night, recurrent incontinence secondary to urethral atrophy was decreased from 21% to 10%.[74]

It is our preference to downsize the cuff if possible as the first-line treatment for urethral atrophy. A second choice would be to move the cuff to another position, usually proximally. Placing a transcorporal cuff is also a good option in cases where adequate urethral circumference cannot be obtained. Rahman et al. have also described wrapping the urethra with a biologic material to increase bulk.[75] Cadaveric studies have shown the use of additional cuffs do not improve leak point pressure and one should rather focus on proximal placement of the device to achieve complete urethral coaptation.[76]

Mechanical Malfunction. Mechanical malfunctions can include leakage from one of the components, kinking of the tubing, pump malfunction, and connector separation. Reported rates of mechanical malfunction in large contemporary series range from 6% to 25.3%.[56,58–61] A greater than 50% decrease in mechanical failure rates has been attributed to improvements in the material used to make the AUS and introduction of the narrow back cuff.[59] Mechanical malfunction typically presents with recurrent incontinence, but can also present with urinary retention. Physical exam often reveals a pump that is difficult to compress, one that is partially decompressed, or one that takes too long to refill. Pelvic ultrasound (US) can also be used to measure the volume of the reservoir to assess for a leak. Using preoperative US was 100% sensitive and specific when used in determining fluid status. When pressure regulating balloon (PRB) was full, management consisted of cuff downsizing, transcorporal cuff placement, and total removal/replacement. In all cases of device leak, an entire removal/replacement was performed.[77] Intraoperative methods of evaluating component leakage including Ohm testing and volumetric-pressure measurements are available. If a component-specific malfunction is identified, the component can be replaced. If the problematic site (e.g., point of leakage) cannot be found or the device is more than 5 years old, removal and replacement of all components should be done.

Urinary Retention

Urinary retention that presents as a late postoperative complication requires endoscopic examination to evaluate the AUS and the bladder neck for contracture or urethral stricture. The latter two are usually the result of prostate surgery and not the AUS per se, but these, nevertheless, need to be checked. Difficulty voiding or retention can also be a sign of an AUS erosion or late infection. Retention may also be the result of mechanical malfunction.

MALE SLING

Infection and Erosion

The rate of infection is as high as 15% for BAS, compared to 4–6% for ARS, 0–3% for RTS, and 0% for the quadratic sling in its initial trial.[27,78] None of the cohorts in this systematic review reported urethral erosion with BAS or RTS, although there was a 1.9% and 12% rate of erosion with the Reemex system and Argus ARS, respectively (Figs. 50.6 and 50.7).[78] The most recent series involving the Reemex system reported a 4.7% rate of late infection and no urethral erosions in 64 patients.[79] In the most mature cohort in the literature, there were no instances of infection or erosion with the RTS after 3 years of follow-up.[80] In our experience with BAS, patients most commonly present at

Figure 50.4 Urethral erosion of artificial urinary sphincter – cystoscopic view; color indicates that this is likely a longstanding erosion.

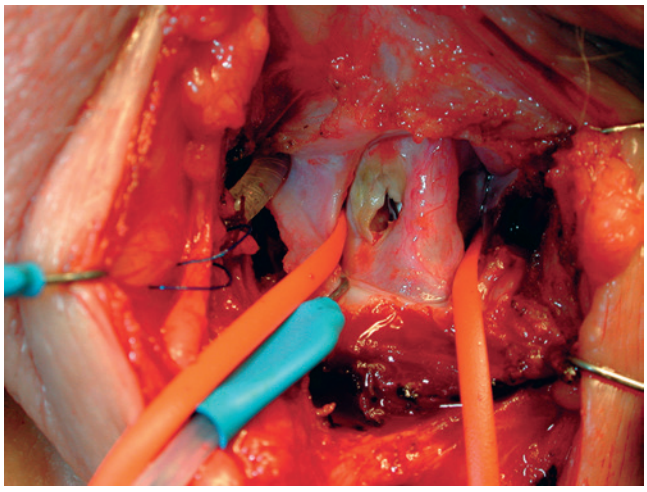

Figure 50.5 Urethral erosion of artificial urinary sphincter – gross view.

6–9 months postoperatively. We have noted that patients with infection often present with chronic, low-grade symptoms including mild perineal pain or swelling or a sinus tract that intermittently drains small amounts of fluid (Fig. 50.8) as opposed to acute or systemic symptoms. We have seen patients present with chronic infections and draining sinus tracts in slings implanted years ago. There are no defined risk factors for sling infection or erosion,[47] including pelvic radiation, which is conversely associated with poor outcomes after AUS placement. However, we recommend careful counseling of the potentially increased risks prior to sling placement, especially as there is evidence that a history of radiation leads to decreased efficacy of male slings.[24]

Removal of the sling is the typical treatment of infection or erosion. However, we have found that despite infection some patients are very reluctant to undergo sling removal secondary to improvement in their continence. We attempted salvage of the sling in two of these patients using the irrigation protocol previously described for salvage of the AUS.[50] This was unsuccessful and both slings subsequently required removal. In addition, we have one patient who was managed with intermittent antibiotics and fulguration of a chronic sinus tract for more than 10 years due to his reluctance to have the sling removed. The infection eventually resolved clinically with resolution of the sinus tract.

De Novo Urgency

To our knowledge, de novo urgency was first described in our series after one patient (1.6%) developed de novo urge incontinence 6.5 months post placement of a BAS.[11] It is theoretically caused by an increase of bladder outlet resistance by compression of the bulbar urethra. De novo urgency has since been reported in up to 14% of BAS placements, although it has not been reported in other sling types.[17] De novo urgency should always be evaluated to rule out possible obstruction or recurrent stress incontinence. Uroflow and post-void residual may be used; however, if definitive diagnosis is required urodynamic testing may be used. If there is no evidence of obstruction then a trial of anticholinergics is recommended. In one series, a patient underwent sling lysis for refractory symptoms.[52]

Obstruction

Iatrogenic obstruction following placement of a male sling is rare but not impossible. Prolonged postoperative retention has been described in 7–8% of patients following RTS, managed conservatively or with sling lysis.[80,81] No new episodes were seen to occur after the first year.[80]

To address obstruction and maintain some improvement in continence, the sling can be loosened. The sling can be isolated in the midline and partially cut (Fig. 50.9). Alternatively, or if this does not help, the sling can be completely transected. Other options for sling revision include removal and replacement of the sling or releasing one side of the sling and replacing sutures more laterally on the sling. In our experience, the latter has not been an option because the excess sling has typically been excised at the time of sling placement.

Prolonged Pain and Paresthesia

The majority of patients have perineal pain after placement of a bone-anchored sling; however, most published series have reported resolution of the pain 3–4 months postoperatively.[16,53] We found that 8.1% of patients experienced prolonged (>3 months) paresthesia or perineal pain.[11] In addition, Fassi-Fehri et al. reported a 12% occurrence of prolonged pain requiring analgesic management.[52] In our experience, patients with prolonged paresthesia following bone-anchored slings typically located the symptoms to the scrotum and those who had prolonged pain experienced it in the perineum. The majority of our patients were managed effectively with watchful waiting and antiinflammatory

medications. However, in patients with severe persistent pain we obtain a bone scan and a CT scan to evaluate for osseus or infectious complications. Pain can be a manifestation of sling infection. One patient in our series had persistent pain severe enough to require removal of the sling. Despite unremarkable imaging, the sling was infected at the time of removal.

Similarly, persistent pain following retropubic sling placement is very rare; to our knowledge, only two studies report pain >3 months – 5–6% prolonged pain following ARS placement and 3% prolonged pain following RTS.[17,82]

Osseus Complications

There is a potential for risk for osseus complications after bone-anchored sling placement. There is no report in the English literature of such an occurrence; a single case report was described in the French literature[83].

Recurrent Incontinence

Following a bone-anchored sling, recurrent incontinence should be evaluated with urodynamics and a pelvic radiograph should be obtained to evaluate for bone anchor dislodgement. Comiter reported bone anchor dislodgement in 4.2% (2/48) of patients. In their series, patients presented with recurrent incontinence, screw dislodgement was confirmed with pelvic radiograph, and successful sling revision was performed.[16] When bone anchor dislodgement is not the etiology of recurrent stress incontinence, other treatment options include bulking agents, repeat male sling placement (if it is thought that compression is not adequate), or placement of an AUS.

Recurrent incontinence following an ARS is managed with a retightening procedure. Rather than a complication of the procedure, this is precisely what the adjustment mechanisms are provided for. Utilizing the Reemex system, this can be accomplished on an outpatient basis. Patients with a history of radiation are more likely to require an adjustment[17,79,84].

Conclusions

The artificial urinary sphincter, male sling, and ProACT balloon compression (not currently available in the United

States) are the current surgical treatment options for sphincteric insufficiency following prostate surgery. Each has acceptable complication rates that can be minimized with attention to detail and meticulous surgical and aseptic technique. Patients should be informed of the potential complications associated with the procedures. Along with more minor complications, the AUS, male sling, and the ProACT balloon compression device each have a risk of infection and erosion that can result in the need for explantation. In addition, the AUS is a mechanical device that inherently carries a risk of mechanical malfunction and the need for device revision or replacement. Although it is typically not severe, patients undergoing male sling placement should also be made aware of the possibility of prolonged pain and/or paresthesia. Patients who understand their treatment options and are well-informed regarding potential risks and complications are more likely to be satisfied following surgery.

Chapter 50 Questions

1. What is most common area of injury to the urethra during artificial urinary sphincter (AUS) insertion?
   a. Dorsal bulb
   b. Ventral bulb
   c. Lateral at the perineal body
   d. Membranous urethra
   e. Medial at the perineal body

2. A substantial injury is made in the proximal urethra, near the site of cuff implantation, during AUS placement. What is the best next step in management?
   a. Abort the case
   b. Repair the urethra and abort the implantation of the device
   c. Repair the urethra and implant the device
   d. Convert to male sling
   e. Consult general surgery

3. A 64-year-old man presents with dysuria 2 months after AUS insertion. Urine analysis is negative and cystoscopy shows no evidence of erosion. The next step is:
   a. Watchful waiting
   b. Antibiotics
   c. Deactivation of the device
   d. Removal of AUS cuff
   e. Removal of all AUS components

4. A 54-year-old man presents 6 months after tranbsobturator male sling placement complaining of bothersome frequency and urgency that he did not experience prior to surgery. The next most appropriate step is:
   a. Antibiotics
   b. Anticholinergic
   c. Uroflow and post-void residual (PVR)
   d. Loosening of the sling
   e. CT scan

5. A 67-year-old male 14 months following an AUS presents with urinary retention. Which of the following is the most appropriate next step?
   a. Renal US
   b. Cystoscopy
   c. Insert Foley
   d. CT scan
   e. Assess for mechanical malfunction of pump

6. A 67-year-old male 14 months following an AUS presents with scrotal erythema, swelling, and pain around the pump of 3 days evolution. Which of the following is the most appropriate next step in management?
   a. CT scan
   b. Scrotal sonogram
   c. Watchful waiting
   d. Renal bladder ultrasound
   e. Surgical exploration of device

7. Which of the following has been shown to be associated with poorer outcomes after AUS insertion?
   a. Diabetes mellitus
   b. Hypertension
   c. Obesity
   d. Urethral stricture
   e. History of radiation therapy to pelvis

8. A 62-year-old male patient presents with complaints of gradually worsening incontinence 6 years after AUS insertion. Physical examination reveals the pump in a dependent position and no signs of infection. Cystoscopy reveals no erosion. AUS revision is performed and urethral atrophy is identified. What is the best next step in management?
   a. Insertion of male sling
   b. Increase pressure in pressure regulating balloon
   c. Place tandem cuffs
   d. Downsize the cuff
   e. Replace the entire AUS

9. A 69-year-old male patient, 4 years post AUS insertion, presents with scrotal swelling, pain, and urinary retention. Cystoscopy reveals erosion of cuff into the urethra. Purulent material is found around the device. What is the best next step in management?
   a. Watchful waiting
   b. Removal of the cuff with capping of the tubing and repair of the urethra
   c. Removal of the cuff with capping of the tubing without repair of the urethra
   d. Removal of the entire device with repair of the urethra
   e. Removal of the entire device without repair of the urethra

10. A patient with postprostatectomy incontinence and erectile dysfunction 6 years post AUS insertion presents with gradually worsening incontinence. Surgical exploration reveals severe urethral atrophy, and the circumference of the urethra measures 3 cm. What is the best next step in management?
    a. Watchful waiting
    b. Moving the cuff to a more distal position
    c. Moving the cuff to a more proximal position
    d. Transcorporal cuff placement
    e. Abort the procedure

Cases Studies

CASE 1

A 59-year-old male 2 years post AUS placement presents for follow-up complaining of recent onset of recurrent urinary incontinence. On physical exam, stress incontinence is demonstrated with cough and the device cycles appropriately.

1. The next step in management of this patient is:
   a. Cystoscopy
   b. CT scan
   c. Surgery to reposition or downsize the cuff
   d. Surgery to remove and replace the AUS
   e. Watchful waiting

Case Figure 50.1

Cystoscopy is performed and reveals the following (Case Fig. 50.1). The cuff is removed and a Foley catheter is left in place. The patient returns for follow-up 2 weeks later.

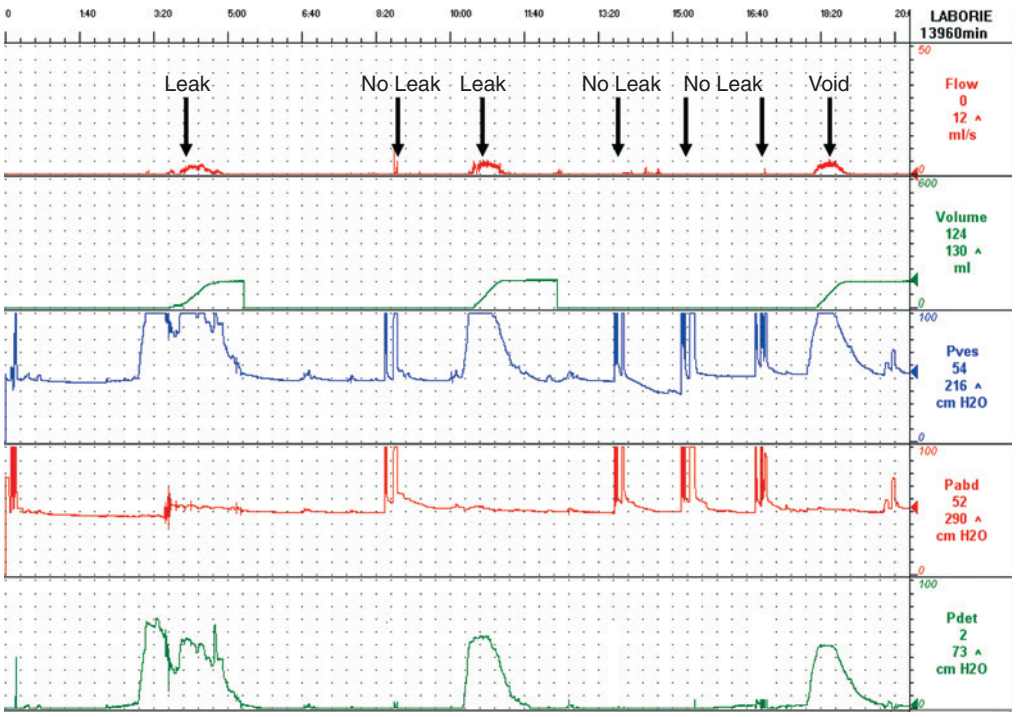
2. The next step in management is:
   a. Removal of Foley catheter and follow up in 2 weeks
   b. Cystoscopy
   c. Voiding cystourethrogram (VCUG)
   d. Urodynamic evaluation
   e. Schedule patient for Foley removal in >2 weeks

VCUG reveals that the urethra is healed and the Foley catheter is removed. Cystoscopy 3 months later reveals a well-healed urethra without evidence of stricture. The patient subsequently undergoes AUS replacement. Three months after AUS activation, the patient complains of persistent incontinence and is wearing 1–2 pads per day. Urodynamic testing reveals the following (Case Fig. 50.2).

3. An appropriate treatment option at that time would include:
   a. Removal of AUS
   b. Placement of tandem cuff
   c. Downsizing the cuff
   d. Clean intermittent catheterization
   e. Trial of anticholinergic therapy

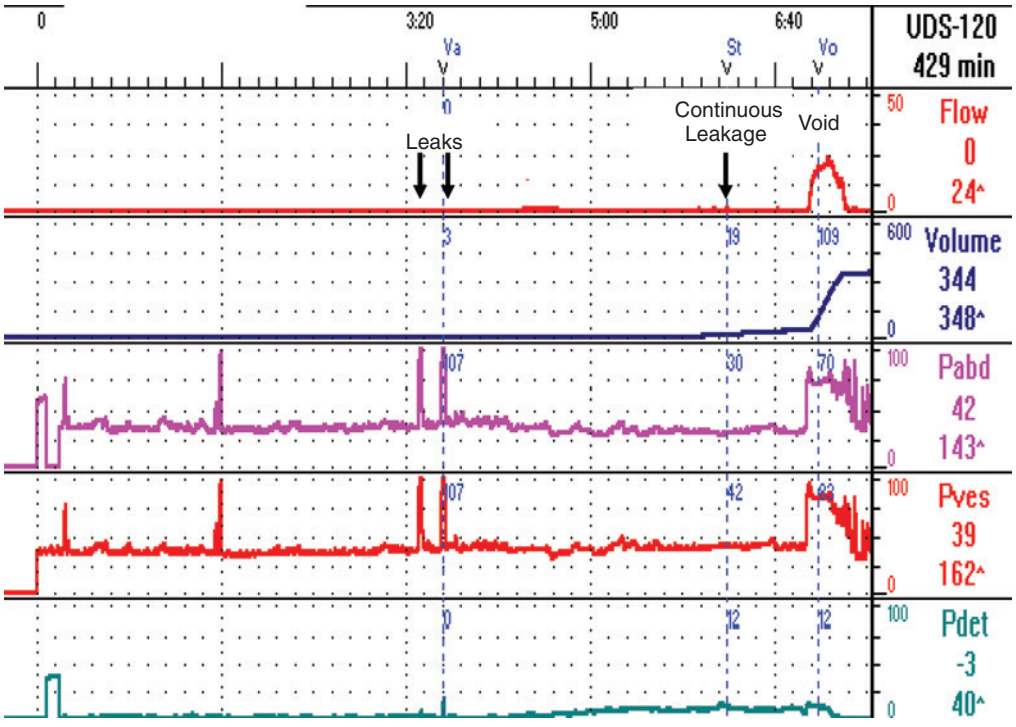
CASE 2

A 67-year-old male presents with recurrent incontinence 16 months after placement of a transobturator male sling. The incontinence is mixed stress and urgency.



1. The best next step is:
   a. Urodynamic testing
   b. Sling revision
   c. Injection of bulking agent
   d. Repeat sling procedure
   e. AUS

2. According to the tracing in Case Fig. 50.3 the recurrent incontinence is:
   a. Due to detrusor overactivity
   b. Related to impaired compliance
   c. Stress incontinence
   d. Unable to be characterized by the above study
   e. Overflow incontinence



3. Which of the following is the most appropriate next step?
   a. Anticholinergics
   b. CT scan
   c. Repeat sling procedure
   d. AUS
   e. Remove the sling

Answers

1. **a.** Urethral erosion typically occurs on the dorsal side of the urethra where the sponge is thinnest, but can occur anywhere, especially if associated with trauma.
2. **b.** In rare cases if the injury is small and away from the intended site of implantation, the cuff can be placed, although this must be done with extreme caution. If there is any question regarding the repair, or if the cuff cannot be placed away from the sight of injury, then the procedure should be aborted.
3. **a.** Romano et al. reported a 21% rate of dysuria associated with perineal discomfort or moderate pain that resolved or became very mild after 1–2 months of analgesic and NSAIDs.
4. **c.** De novo urgency should always be evaluated to rule out possible obstruction or recurrent stress incontinence. Uroflow and PVR may be used; however, if a definitive diagnosis is required urodynamic testing may be used. In one series, a patient underwent sling lysis for refractory symptoms.[52]
5. **e.** If retention occurs, the first step should be examination of the device to ensure deactivation with the cuff in an open position.
6. **e.** Infection requires removal of the entire device and reimplantation after at least 3 months. In select cases, one may consider replacement at the time of removal, after aggressive wound irrigation with antibiotics as described by Bryan et al.[50]
7. **e.** Pelvic radiation is conversely associated with poor outcomes after AUS placement.
8. **e.** If the problematic site (e.g., point of leakage) cannot be found or the device is more than 5 years old, removal and replacement of all components should be done.
9. **d.** If erosion occurs without infection the tubing can be capped at the time of cuff removal. If associated with infection the entire device should be removed. The urethra is repaired with absorbable suture at the site of erosion and a Foley catheter is left indwelling.

Case Figure 50.2

Case Figure 50.3

10. **d.** It is our preference to downsize the cuff if possible as the first-line treatment for urethral atrophy. A second choice would be to move the cuff to another position, usually proximally. Placing a transcorporal cuff is also a nice option in cases where adequate urethral circumference cannot be obtained.

CASE 1

1. **a.** Cystourethroscopy should be performed to inspect the urethra for signs of atrophy or erosion. This may reveal incomplete coaptation of the urethra, and the urethra may appear thin and pale.
2. **c.** A VCUG is performed to ensure that the urethra has healed prior to removal of the catheter.
3. **e.** If there is no evidence of obstruction, then a trial of anticholinergics is recommended.

CASE 2

1. **a.** De novo urgency should always be evaluated to rule out possible obstruction or recurrent stress incontinence. Uroflow and PVR may be used; however, if definitive diagnosis is required urodynamic testing may be used.
2. **a.** Detrusor overactivity is when involuntary detrusor contractions occur during the filling cystometry. These contractions cannot be suppressed by the patient.
3. **a.** If there is no evidence of obstruction, then a trial of anticholinergics is recommended.

51 Complications of Urethral Reconstruction

JOEL GELMAN and ERIC S. WISENBAUGH

CHAPTER OUTLINE

Complications of Urethral Stricture Disease
Complications of Diagnostic Procedures
Complications of Urethral Dilation
Complications of Internal Urethrotomy
Complications of Endoscopic Treatment of Posterior Urethral Injuries
Complications of Urethral Stents
Complications of Open Surgical Procedures
Patient Positioning
Suprapubic Tube Placement
Excision and Primary Anastomosis for Posterior Disruptions
Excision and Primary Anastomosis for Proximal Anterior Strictures
Graft Harvest
Tissue Transfer Reconstruction
Flap Reconstruction
Graft Reconstruction
Conclusions
Chapter 51 Questions and Answers

KEY POINTS

1. The evaluation of urethral stricture disease, prior to treatment, generally includes urethroscopy, a retrograde urethrogram, a voiding cystourethrogram, and bougie calibration for distal disease. Treatment with dilation using a cystoscope or other instruments should not be performed before a complete evaluation and a discussion of all options with the patient.
2. Stricture recurrence is the most common complication of dilation or direct vision internal urethrotomy (DVIU). Because the recurrence rate is high after repeated endoscopic management, the standard of care is generally open reconstruction after a failed dilation or DVIU.
3. Factors that favor the successful outcome of a urethral reconstruction with excisional repair include spatulation of the proximal and distal ends to 30Fr after scar excision and a tension-free anastomosis.
4. Factors that are associated with complications of tissue transfer urethral reconstruction include the use of hirsute skin, mobilization of flaps with compromise to the blood supply, and/or inadequate fixation of a graft to the recipient bed.
5. Strictures associated with lichen sclerosis should not be managed "conservatively" with distal dilations because without relief of the distal obstruction, there can be progression from distal to panurethral stricture disease.

Complications of Urethral Stricture Disease

Observation is always a management option, and the potential complications of observation must be discussed when patients are counseled and giving informed consent. Patients often present with obstructive voiding symptoms, and it would be a mistake for a patient to conclude that having to live with obstructive voiding symptoms would be the only potential drawback of observation.

Distal obstruction is associated with high-pressure voiding. The bladder compensates by thickening with the development of trabeculation, and the urethra proximal to the obstruction can become distended (Fig. 51.1). High-pressure voiding through the prostatic urethra can be associated with extravasation of urine in retrograde fashion into the prostatic ducts. In a physiologically normal patient, extravasation of contrast material into the prostatic ducts is not seen during retrograde urethrography, but this finding is not uncommon in patients with strictures. Retrograde flow of urine through these ducts can lead to complications such as recurrent prostatitis or epididymitis. Eventually, diverticular formation and/or bladder decompensation can develop with an increased capacity and residual or urinary retention. Secondary reflux with or without associated recurrent pyelonephritis can also occur. Ultimately, although it is not common, acute or chronic renal failure can develop as a complication of untreated stricture disease.

Figure 51.1 Markedly dilated posterior urethra proximal to a narrow-caliber bulbar stricture seen on voiding cystourethrography.

Figure 51.2 Lichen sclerosis can manifest with whitish skin color changes and meatal stenosis (A) or with a more severe deformity including a total loss of the coronal sulcus and loss of penile length and girth (B).

In patients with *lichen sclerosis* (LS), also known as *balanitis xerotica obliterans* (BXO), a disease of the penile skin, glans penis, and urethra (Fig. 51.2), stricture progression is common. The obstruction is generally initially within the distal urethra. Often, extravasation into the periurethral glands of Littre is seen during urethral imaging studies in patients with LS (Fig. 51.3), and it is thought that the

Figure 51.3 Retrograde urethrography with extravasation into the periurethral glands of Littre.

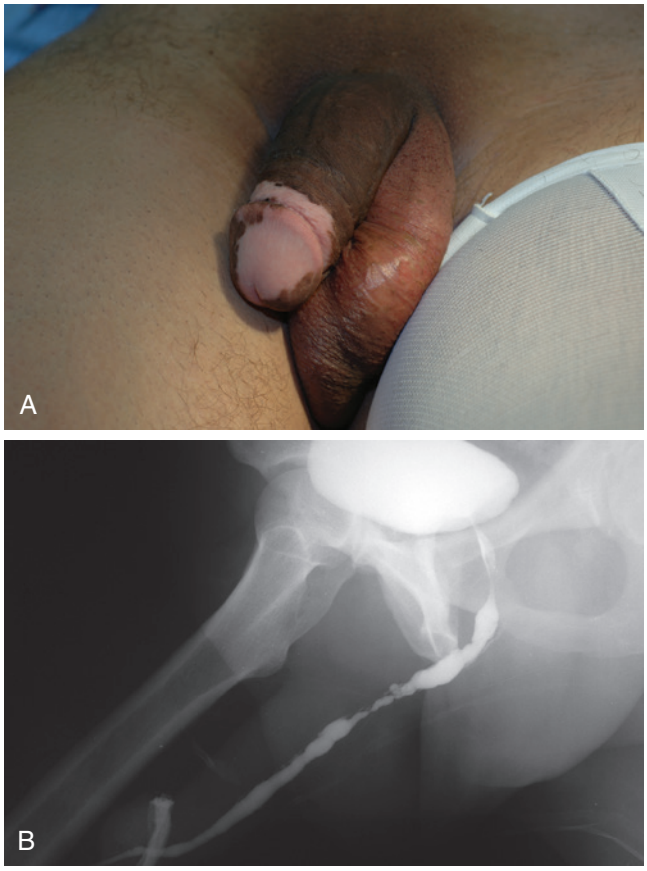

Figure 51.4 (A) Appearance of the penis and (B) retrograde urethrography of the same patient with lichen sclerosis.

extravasation of urine into the periurethral glands may be associated with proximal stricture progression. It is not at all unusual for patients with LS who are conservatively managed to undergo their first retrograde urethrogram and be diagnosed with a >20-cm panurethral stricture (Fig. 51.4). Patients who are clinically diagnosed with LS on physical examination and who have stricture disease limited to the distal urethra are best managed with open staged urethral reconstruction or extended meatotomy.[1,2] In summary, the complications of treatment with observation include, but are not limited to, prostatitis, bladder

decompensation, urinary retention, secondary vesicoureteral reflux, pyelonephritis, renal deterioration, and stricture progression in addition to obstructive symptoms.

Complications of Diagnostic Procedures

Diagnostic testing procedures for known or suspected urethral strictures include urethral calibration with bougie à boule, urethroscopy, retrograde urethrography (RUG), and voiding cystourethrography (VCUG). Bougie calibration, properly performed to assess the caliber of the urethral meatus and fossa navicularis, does not dilate the urethra and therefore is generally not associated with complications. When urethroscopy is performed, the most common complication is urethral trauma. This trauma is intentional when scope dilation is performed in an effort to visualize the stricture in its entirety and enter the bladder. This situation represents treatment with dilation before the extent of the stricture is first assessed and the patient is informed of all treatment options. Should the patient be a candidate for open repair, the operation must be delayed for several months following scope or other dilation because open reconstruction is best performed when the stricture is mature and stable.

Urethral contrast imaging is necessary to assess the length and exact location of the stricture because urethroscopy usually identifies only the distal aspect of the disease. Complications of urethral imaging include urinary tract infection with or without sepsis and extravasation. Urine studies should be performed prior to imaging to ensure the urine is sterile, or allow time for treatment if bacteriuria is present. Improperly performed studies can be associated with a higher complication rate. At our institution, diagnostic testing is performed with flat plate imaging, and this includes both RUG and VCUG. The patient is placed in the oblique position. After a scout film is obtained, gauze is wrapped around the coronal sulcus and the penis is placed on stretch. A 60-mL syringe connected to a cone-shaped adaptor is placed into the urethral meatus to form a seal, and RUG is performed during the injection of contrast material. The bladder is then slowly filled in a retrograde fashion similarly until the patient has the urge to void. VCUG is performed while the patient is voiding.

Extravasation into the corpus spongiosum or venous system is rare when contrast material is instilled gently. However, this complication can occur (Fig. 51.5). Sepsis is a concern with extravasation, and when extravasation occurs, prophylactic antibiotics are given. When imaging is performed with alternative techniques at radiology imaging centers, we have observed a high complication rate related to poor technique.

Often RUGs are performed with catheter insertion into the urethra and inflation of a balloon within the urethra and subsequent contrast injection through the catheter. We measured the caliber of the balloons of 12 to 16Fr catheters after inflation with 1–3 mL of water. With only 2 mL of inflation, the caliber of the balloon was >50Fr (Fig. 51.6), and even 1 mL creates a 39Fr caliber balloon. The caliber of the penile urethra is approximately 30Fr, except for the glans and fossa navicularis, which are generally <25Fr in caliber, and this painful RUG technique often dilates and traumatizes normal urethra. Forceful attempts to insert a catheter through a stricture will both compromise the diagnostic value of the study and damage the urethra (Fig. 51.7).

Figure 51.5 Extravasation into the corpus spongiosum and venous system during retrograde urethrography injection.

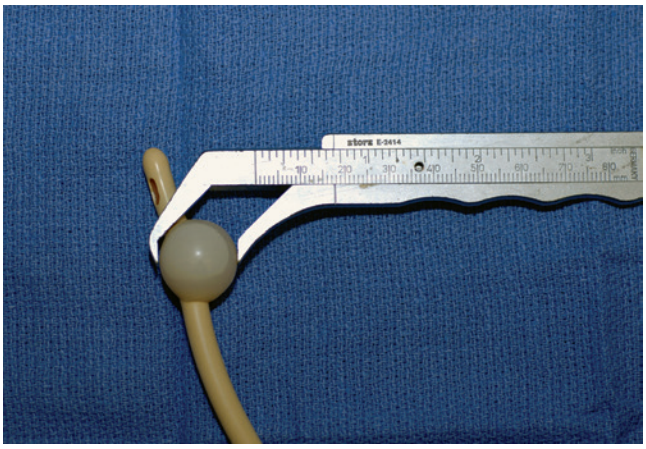

Figure 51.6 Foley catheter after balloon inflation with 2 mL of water. The caliber is >50Fr (1.7 cm diameter).

In addition, errors in technique are associated with an incorrect diagnosis of the length and location of the strictures, and this misdiagnosis can compromise subsequent treatment. For example, if the films are taken when the patient is not in the oblique position, the length of the stricture can be significantly underestimated (Fig. 51.8). Furthermore, if the penis is not on stretch, the length of the stricture will likely be underestimated.

When RUG is performed, the normal posterior urethra is coapted and narrowing in this area is a normal finding. Any disease of the posterior urethra cannot be diagnosed or excluded from the injection film. During voiding, however, the bladder neck and posterior urethra are normally widely patent and are often hydrodistended, as shown in Fig. 51.1. Wide patency of the posterior urethra confirms the absence of bladder neck and membranous urethral stenosis. Patients with anterior strictures in the absence of pelvic fracture

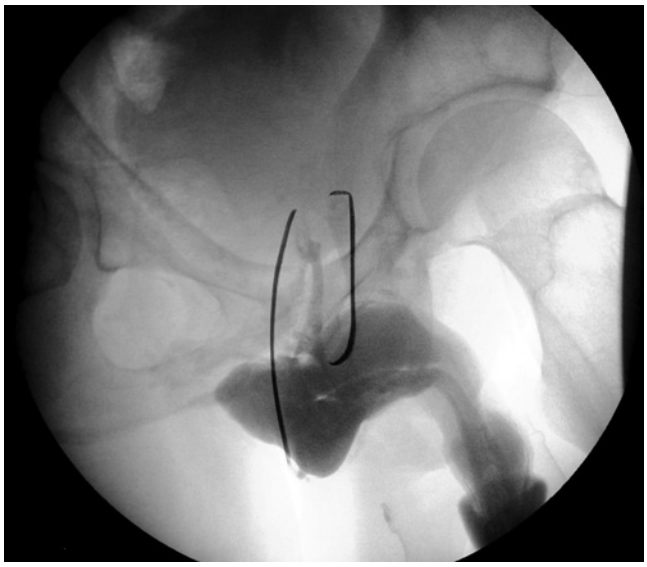

Figure 51.7 Outside retrograde urethrography obtained during a forceful attempt to advance the catheter for the injection procedure. The prostatic urethra and bladder neck cannot be assessed.

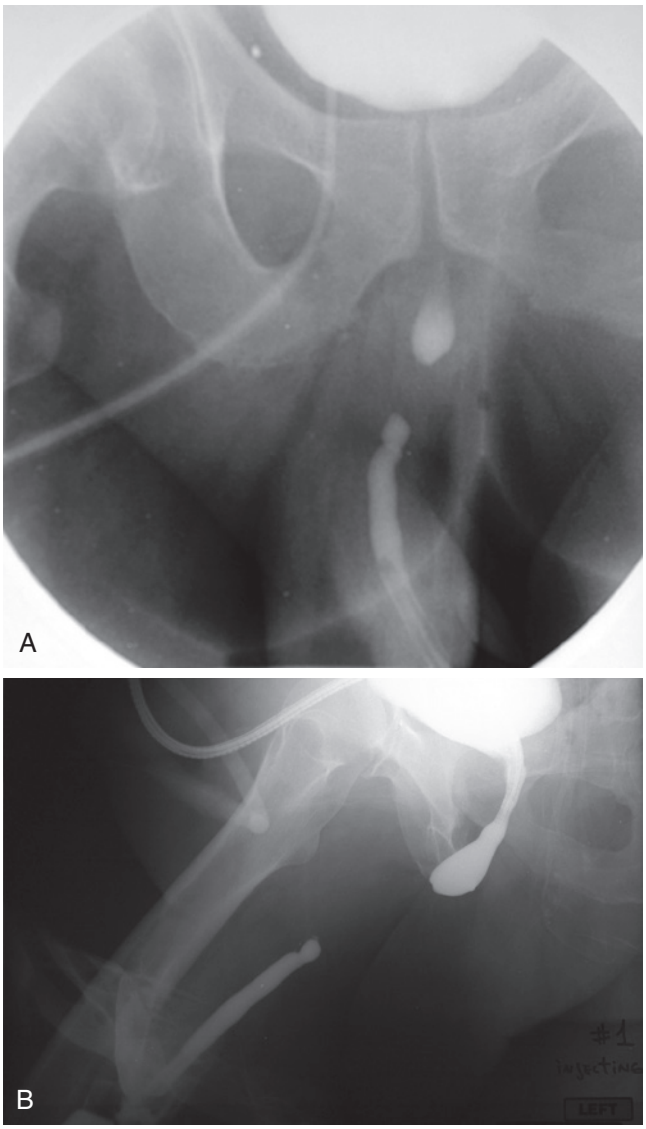

Figure 51.8 A, Contrast imaging with the patient in the supine position suggests a 2-cm obliteration. B, Repeat study with the same patient appropriately placed in the oblique position confirms that the obliteration is actually 8 cm in length.

trauma or prior prostate surgical or radiation therapy rarely have disease proximal to departure of the bulbar urethra. However, patients with bulbar strictures can also have membranous strictures, particularly when there has been prior endoscopic treatment. When VCUG is not performed, one possible consequence of incomplete imaging is an error in diagnosis that can compromise treatment outcomes.

Complications of Urethral Dilation

Urethral dilation is commonly used to manage urethral strictures. Dilation techniques include the use of metal sounds, filiforms and followers, catheters, and high-pressure balloons. Ideally, dilation should be performed in the absence of urinary tract infection or colonization. Intraoperative complications include the creation of a false passage, bleeding, urethral perforation, rectal injury, and failure to achieve the intended increase in urethral caliber. Balloon dilation with direct visualization was designed to minimize the risk of these severe complications.[3] Early postoperative complications include sepsis and urinary retention.

Urethral perforation, generally associated with significant bleeding, can be managed with gentle attempts at insertion of an indwelling catheter. The use of a flexible cystoscope to insert a flexible guidewire may facilitate the placement of a Council-tipped catheter. Suprapubic tube placement is a very reasonable option when a catheter cannot be placed without further trauma.

The most frequent long-term complication of urethral dilation is stricture recurrence, and recurrent strictures after multiple dilations may be longer and denser. Ideally, dilation is meant to only stretch the scar tissue, but in reality it tears open the strictured area, as evidenced by even minor urethral bleeding after the procedure. This tear then heals with more scar tissue, which can be more extensive than prior to treatment. Dilation represents a potentially curative treatment, although only for very discreet strictures with minimal associated spongiofibrosis.[4] Urethral squamous cell cancer is rare. However, chronic irritation from frequent dilations and self-catheterization is associated with an increased risk of developing this malignant disease. In patients with a history of chronic irritation who develop a fistula to the scrotum, priapism, or a very unusual appearance of the urethral mucosa seen on urethroscopy or contrast imaging, squamous cancer should be suspected.

Complications of Internal Urethrotomy

The Otis urethrotome was routinely used to incise urethral strictures blindly before the development of endoscopic

equipment that permitted direct vision internal urethrotomy (DVIU) with the use of a cold knife or a laser fiber. Incision of the scar into the corpus spongiosum increases the caliber of the urethra, and generally a catheter is subsequently placed. As with dilation, immediate complications can include bleeding, which is generally managed with catheterization and is usually self-limited, and damage to the urethra, which prevents subsequent catheter placement. Suprapubic tube placement is then indicated. Extravasation of blood or irrigation fluid into the scrotum or penis can occur and generally resolves with conservative management. However, extravasation into the periurethral tissues can significantly complicate dissection and mobilization of the urethra if subsequent open repair is required. Early complications include urinary tract infection and sepsis.

The most common complication is stricture recurrence. Along the circumference of the urethra epithelium is present, except where the urethra was incised. As healing occurs, the outcome is favorable when epithelialization results and leads to a stable increase in the caliber of the urethra. However, more commonly, wound contracture dominates, and the stricture recurs.

The actual recurrence rate after DVIU is not clearly defined in the literature because the multiple reports published on the subject do not include long-term objective follow-up. However, it is known and clearly established that long-term cure with urethrotomy is a reasonable expectation only for strictures that are not recurrent, are <1–1.5 cm long, and have minimal associated spongiofibrosis.[4,5] The recurrence rate with repeated urethrotomies is extremely high, and the standard of care for the initial management of longer strictures or of strictures that recur after incision is open reconstruction.[6,7] Investigators have reported that in patients who require open reconstruction after multiple failed DVIUs, the success rate is lower than when open surgical procedures are performed for initial management.[8,9]

Both DVIU and dilation have been reported to increase the risk of recurrence after urethroplasty, perhaps by worsening the degree of spongiofibrosis or lengthening of the stricture.[10,11] We have not found prior dilation or DVIU to compromise urethroplasty outcomes in our own experience, but we have observed strictures lengthen after endoscopic treatment, which may then require tissue transfer reconstruction when the original stricture would have been amenable to an excision and primary anastomosis.

Other complications of DVIU include erectile dysfunction that may be veno-occlusive because a deep dorsal urethral incision can extend into the corpus cavernosum and create a vascular shunt.[12] This complication was reported to be successfully treated with open urethral mobilization and fat pad interposition.[13] The overall rate of erectile dysfunction was 5.3% in one meta-analysis.[14] High-flow priapism following DVIU has also been reported and can be successfully treated with embolization.[15] Multiple incisions other than at the 12-o'clock position may reduce the incidence of this complication. Incontinence is generally not a complication of urethrotomy unless incisions involve the membranous urethra when the bladder neck is already compromised (e.g., after radical prostatectomy) or when the bladder neck is incised in patients whose membranous urethra is not fully intact.

Complications of Endoscopic Treatment of Posterior Urethral Injuries

In men who suffer pelvic fracture trauma and associated membranous posterior urethral disruption, immediate treatment options include a gentle attempt at catheter placement when a partial tear is diagnosed on RUG and suprapubic tube placement with delayed reconstruction. Immediate open urethral reconstruction is not indicated except when the injury is at the level of the bladder neck.[16]

Early primary realignment is a procedure that can be performed immediately in a stable patient or within the first week after the injury when the patient is stabilized. The technique involves endoscopic antegrade and retrograde urethral instrumentation in an effort to place a urethral catheter. As the pelvic hematoma is reabsorbed and healing occurs, the hope is that the catheter will guide the urethra back together in proper alignment, and the patient can then avoid the need for subsequent urethral reconstruction. If a stricture develops after catheter removal, the goals are for the realignment to reduce the length of the stricture or any misalignment and thus to facilitate subsequent repair. The success rate of primary realignment is not clearly established, although this technique is reported to be of possible benefit.[17–19] At this time, it is considered very reasonable to manage posterior urethral disruptions acutely with primary realignment or suprapubic tube placement and delayed reconstruction.

The most common complication of primary realignment is the development of a urethral stricture or total obliteration of the urethra after urethral catheter removal. One significant drawback of primary realignment is that recurrent strictures are then often managed with DVIUs and self-catheterization in an effort to avoid open reconstruction, subjecting the patient to multiple procedures and significantly delaying the time to resolution of stenosis.[20] When a recurrent stricture develops subsequent to urethral catheter removal, delayed open posterior urethral reconstruction is the standard of care and is generally performed approximately 3 months after urethral catheter removal.

In the past an endoscopic alternative to delayed open reconstruction for obliterative distraction defects was a "cut-to-the-light" procedure. This technique involved simultaneous antegrade and retrograde cystoscopy with "core through" incisions into the obliteration toward the light of the other scope until continuity was established. The failure rate was very high, and this technique fell out of favor and is not recommended.

Complications of Urethral Stents

The UroLume stent (American Medical Systems, Minnetonka, MN) was taken off the market as of January 2013 and is no longer manufactured, but patients who have had these placed may still suffer from future complications. Complications that have occurred with high frequency include pain, infection, incontinence, and recurrent strictures within the stent or proximal or distal to the stent.[21] Development of a panurethral stricture can also occur in

patients with hypospadias.[22] Recurrent strictures that develop after stent placement can be successfully managed with open stent removal using excision and primary anastomosis for relatively short proximal strictures or with tissue transfer reconstruction for longer strictures. Individualized open reconstruction can generally be performed in one stage and has a high long-term success rate.[23]

Complications of Open Surgical Procedures

Open surgical procedures for urethral reconstruction include excision and primary anastomosis and tissue transfer reconstruction with skin flaps or grafts. The remainder of this chapter is a discussion of complications associated with patient positioning, excisional repair for posterior and anterior bulbar strictures, graft harvest, and tissue transfer reconstruction.

PATIENT POSITIONING

Distal strictures involving the urethral meatus, fossa navicularis, and penile urethra are often repaired with the patient in the supine position. If care is taken to prevent pressure points, positioning complications generally do not occur. In contrast, more proximal strictures are repaired by a perineal approach that requires placement of the patient in the lithotomy position, often an exaggerated lithotomy position (Fig. 51.9). This position is associated with many complications including neuropraxia (peroneal nerve in particular) that is often temporary but can be permanent, back pain, compartment syndrome, and rhabdomyolysis.[24–26]

Proper positioning can reduce the incidence of these serious complications. A modified Skytron table (developed by Gerald Jordan, MD) provides pelvic tilt, and modified stirrups allow additional extension of the lower extremities to prevent extreme hip or knee flexion with associated nerve stretch. Proper adjustment of the boots of the stirrups prevents pressure on the calves and reduces the risk of compartment syndrome, a condition that when diagnosed is generally managed with emergency fasciotomies. Investigators have shown that the time spent in the lithotomy position is related to the risk of the development of compartment syndrome, neuropraxia, and rhabdomyolysis.[27, 28] Therefore, when possible, any portion of the surgical procedure (e.g., buccal graft harvesting when indicated) that can be done without the patient being in the exaggerated lithotomy position should be done with the patient supine. This can be facilitated by obtaining proper imaging preoperatively, which allows the surgeon to accurately determine how much buccal graft is needed, if any, prior to positioning in lithotomy. When neuropraxia develops, it is usually a temporary sensory impairment along the lower leg and the dorsum of the foot in particular. One report of 185 patients found 12 patients with neuropraxia, which was by far the most common positioning-related complication, but only one of these was severe.[24] Normal sensation usually returns without treatment in 2 to 3 days. However, more significant and long-term disability can occur along with motor deficits, including but not limited to impaired dorsiflexion of the foot.

Figure 51.9 Exaggerated lithotomy position.

Rhabdomyolysis is a potentially serious complication of prolonged lithotomy positioning with associated painful muscle damage. The serum creatine kinase level is markedly elevated, and myoglobin may be detected in the dark brown urine. Acute renal failure with oliguria and elevation of the serum creatinine may occur. Aggressive treatment is indicated to prevent renal damage, and appropriate management includes hydration and urine alkalization. Temporary dialysis is required in severe cases. In addition, deep vein thrombosis and pulmonary embolism have been reported as possible complications of high lithotomy positioning, although a large population-based study of 126,891 patients undergoing urologic surgery actually found that the lithotomy position conferred a lower risk of these complications than did the supine position.[29]

SUPRAPUBIC TUBE PLACEMENT

Suprapubic tubes are critical for the initial management of pelvic fractures associated with urethral injuries and are also routinely placed at the time of anterior urethral reconstruction at some centers. Potential benefits include the ability to use a smaller stenting urethral catheter yet maintain adequate bladder drainage postoperatively and the establishment of a secondary source of bladder drainage should one tube become plugged. Potential complications include bleeding and posterior bladder injury. The most serious complication of percutaneous suprapubic tube placement is bowel injury. During suprapubic tube placement, it is important that the bladder be distended, and this can be achieved through slow retrograde filling with saline solution through a flexible cystoscope with the tip of the scope distal to the stricture. The tube should be inserted no more than 2 to 3 cm cephalad to the midline pubic symphysis, and open tube placement or ultrasound guidance should be considered in patients who have a history of prior lower abdominal or pelvic surgery.

EXCISION AND PRIMARY ANASTOMOSIS FOR POSTERIOR DISRUPTIONS

The most common complication of posterior urethral reconstruction with excision and primary anastomosis is recurrence of the stricture or obliteration. Technical success is defined as durable wide patency of the entire urethra without the need for any subsequent or other intervention. At referral centers for urethral surgery, the success rate of posterior urethral reconstruction (including both initial treatment and revision) is 90–98%.[30,31] Factors that increase the probability of a technically successful outcome include the administration of culture-specific antibiotics perioperatively, complete scar excision so the proximal and distal segments of the urethra are widely spatulated to >30Fr with healthy mucosa circumferentially, and a tension-free repair.[32]

Maneuvers that promote a tension-free repair include midline separation of the corporal bodies along the triangular ligament and, when indicated, infrapubectomy. In rare cases, corporal rerouting has been reported to reduce tension. Investigators have stressed in the literature that posterior reconstructions and urethral reconstructions in general are best performed by urologists with expertise and specialization in urethral stricture surgery because a poor outcome increases the complexity and difficulty of subsequent surgical treatment.

Long recurrent total obliterations that develop as early complications of failed surgical procedures (Fig. 51.10) are likely caused by inadequate proximal exposure and scar excision. Fortunately, these patients can usually undergo corrective treatment with a very high success rate with repeat excisional repair.[33] The finding that revision surgery was highly successful with the same operation that previously failed before referral suggests that the experience of the surgeon may be significantly related to the success of the operation. Discrete nonobliterative anastomotic recurrences can be successfully managed with urethrotomy. In contrast to the low success rate of DVIU for the initial treatment of strictures, this technique has a high success rate when it is used to treat anastomotic strictures, presumably because these discrete recurrent strictures are not associated with any significant spongiofibrosis.[34]

Figure 51.10 Urethral imaging in a patient who previously underwent a technically unsuccessful posterior urethral reconstruction.

A potential complication of posterior urethral reconstruction is ischemic stenosis of the anterior urethra.[35] The anterior urethra has a dual blood supply. The bulbar arteries provide antegrade supply to the anterior urethra within the corpus spongiosum. In addition, the dorsal arteries supply the glans penis and the anterior urethra in retrograde fashion. Posterior urethral reconstruction cannot be performed without compromising the bulbar arteries at the time of urethral transection. Therefore, the anterior urethra is subsequently supplied predominantly by the dorsal arteries. If this blood supply is bilaterally compromised by arterial injury, ischemic stenosis can develop as a complication of posterior urethral reconstruction.[36]

Vascular evaluation enables the surgeon to identify patients who may be at risk of developing this complication. Patients with normal erectile function invariably have adequate urethral vascularity. A penile duplex study with pharmacologic erection in patients with postinjury erectile dysfunction identifies patients with bilateral arterial inflow compromise. Patients with severe inflow impairment should then undergo a pudendal arteriogram, and when bilateral dorsal artery compromise is evident, penile revascularization (generally inferior epigastric to dorsal artery) should be performed before urethral reconstruction. One study reported successful urethroplasty in all patients with bilateral complete obstruction of the deep internal pudendal arteries who underwent revascularization.[37]

In men who sustain pelvic fracture trauma and associated urethral disruption, erectile dysfunction from nerve or vascular injury is not uncommon.[35] Although erectile dysfunction is a possible complication of posterior urethral reconstruction, impotence is usually secondary to the initial injury. Given that urethral reconstruction generally cures the urethral stricture but does not address the associated erectile dysfunction caused by the initial injury, the most common long-term urologic problem is erectile dysfunction. A recent meta-analysis found de novo erectile dysfunction present in 34% of patients after a pelvic fracture urethral injury *before* urethroplasty, with only an additional 3% reporting de novo erectile dysfunction after definitive urethroplasty.[38]

Incontinence is also a possible complication of urethral reconstruction. However, when this complication occurs, it is generally at least in part related to the initial injury. The typical location of the urethral injury following pelvic fracture trauma is the membranous urethra. Surgical reconstruction of the urethra does not involve dissection proximal to the apex of the prostate, and the dissection is definitely distal to the bladder neck. When the membranous urethra is damaged but the bladder neck is intact, the ability to stop voiding voluntarily is affected, but continence is generally preserved. Incontinence after posterior urethral reconstruction, when present, is therefore related to associated bladder, nerve, or bladder neck damage and not the reconstructive surgical procedure, on the assumption that the anastomosis is made at the most distal area of the patent proximal segment distal to the verumontanum of the prostate. Urodynamic evaluation is recommended if incontinence occurs after urethral reconstruction.

Other potential complications include bleeding, although transfusion should be very rarely indicated. Wound infection is always a potential complication of open urethral

surgical procedures. Superficial wound infections should be promptly recognized and managed with incision and drainage if fluctuance is noted. Antibiotics are effective treatment for cellulitis.

EXCISION AND PRIMARY ANASTOMOSIS FOR PROXIMAL ANTERIOR STRICTURES

Stricture excision and primary anastomosis have long been the open procedures of choice for relatively short strictures of the bulbar urethra. When the surgical procedures are properly performed at a referral center for urethral reconstruction, the success rate is reported as high as 98.8%.[39] Strictures 1–2 cm long are highly amenable to excisional repair, whereas lengthier excisions may lead to penile shortening or ventral curvature with erection. However, longer bulbar strictures can be managed with primary repair without the development of chordee in selected patients with adequate elasticity of the corpus spongiosum located within the proximal bulbar area.[40]

Anterior urethroplasty with excisional repair shares many of the complications noted with posterior repair including recurrence, positioning complications, bleeding and infection, and chordee. Other sexual complications that have been reported include ejaculatory dysfunction and change in glans fullness or sensation.[41] It is important to note that we have not found these complications to be common or unique to this technique in our own experience. Fistula and diverticula formation are not at all commonly seen with excisional repair because the corpus spongiosum is present circumferentially to provide support and to prevent diverticular change, and the perineal skin is separated from the urethral lumen by subcutaneous fat, the bulbospongiosus muscle (especially along the mid-proximal bulbar urethra), and the corpus spongiosum, which is most prominent along the ventral aspect of the urethra.

GRAFT HARVEST

When tissue transfer with grafting is required for urethral reconstruction, the most commonly used graft material currently is buccal mucosa. Grafts are usually harvested from the lateral cheeks, although the lower lip and tongue can be used and, occasionally, the upper lip can be a source of additional graft material.[42–44] Short-term speech impairment and dysgeusia can be encountered after lingual grafts, while deformity and tightness are greater concerns when grafts are harvested from the lower and especially the upper lip, and therefore it is preferable to harvest grafts from the lateral cheeks. When a lateral buccal graft is harvested, Stensen's duct is identified adjacent to the second upper molar, and the area for graft harvest is then incised inferior to the opening of the duct (Fig. 51.11).

Injury to Stensen's duct is a possible complication of buccal graft harvesting, but it can usually be avoided by proper identification of the duct. The morbidity associated with buccal mucosa graft harvest was previously reported.[45] In this report, most patients experienced significant postoperative pain that was worse than expected. Postoperative side effects included periorbital numbness that persisted for >6 months in 9% of the patients, initial difficulty with mouth opening, and changes in salivation. One patient developed a mucus retention cyst that required excision. Some surgeons close the donor site, and others leave the harvest site open. Recently, however, a randomized controlled trial of 50 patients showed that those patients whose donor site was left unclosed reported lower early pain scores, an earlier return to a full diet, an earlier return to full mouth opening, and a decrease in bothersome perioral numbness at 6 months postoperatively.[46]

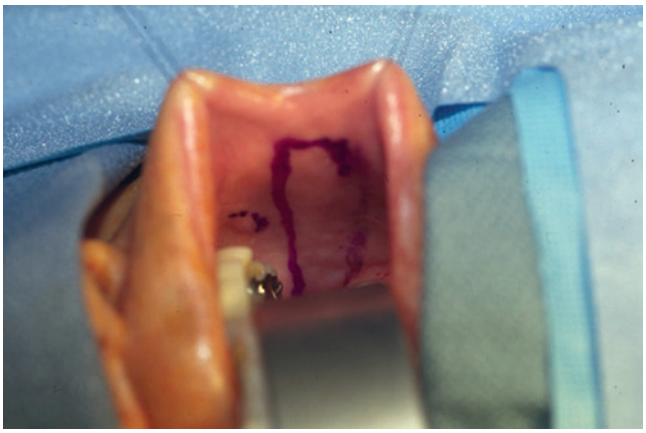

Figure 51.11 Buccal mucosa is marked for harvest, and Stensen's duct is identified.

In addition to buccal grafts, other autologous graft materials used in urethral reconstruction are split-thickness skin grafts (STSG), often harvested from the thigh and temporalis fascia. The harvest of any graft can be associated with bleeding, scarring, contracture (generally not with split-thickness grafts), and infection. However, these grafts can generally be harvested with low morbidity.

TISSUE TRANSFER RECONSTRUCTION

All tissue transfer reconstructions, and stricture repairs in general, can be complicated by stricture recurrence, urethrocutaneous fistula, post-void dribbling, and sexual dysfunction.

Significant incontinence of urine from the bladder is generally not a complication of anterior urethral reconstruction because the surgical procedure is performed distal to both the bladder neck and the external urethral sphincter. However, after tissue transfer reconstruction in particular, the urethra does not coapt normally, and pooled urine present within the reconstructed segment of the urethra after voiding can dribble out after urination.[47] This phenomenon may be worse in patients who have had a ventral onlay repair, as the graft bed is less robust than if placed dorsally against the corporal bodies.[48] Patients who report this complication should be instructed to "milk" their urethra with their hand from behind the scrotum toward the urethral meatus after urination.

Sexual dysfunction can occur after anterior urethral reconstruction, but one study revealed that the incidence of erectile dysfunction was no higher after urethroplasty than after circumcision.[49] However, another study reported that patient satisfaction with the outcome of urethroplasty was related not only to relief of obstructive symptoms but

also to an absence of chordee or tethering.[50] When penile skin is repeatedly used to repair recurrent strictures after failed hypospadias repair, and subsequent salvage procedures fail, patients are at risk for significant compromise of sexual function (Fig. 51.12). It is important not to compromise the stretched and erect penile length significantly during repeat urethral reconstruction and not to proceed with tubularization during a staged repair if any chordee has not been fully addressed.

Additional complications may include bleeding, urinary tract infection with or without sepsis, and wound infection, and breakdown of the repair also may occur. However, specific complications are generally associated with flap and graft reconstructions.

FLAP RECONSTRUCTION

Skin flaps by definition retain their blood supply because they are mobilized on a vascular pedicle and are relocated to augment the caliber of the urethra. The most commonly used flap is a penile skin flap. The penile skin is supplied by branches of the superficial external pudendal arteries. These vessels course along the tissue deep to the skin and superficial to Buck's fascia. The supply is axial as opposed to random and is defined. During the elevation of a penile skin flap, under optical magnification, a tissue plane is developed between the superficial and deep plexus of the fascia. Careful attention to technical detail is required so that blood supply is maintained both to the skin flap and to the remaining penile skin.

Potential complications of flap elevation include ischemic changes to the penile skin, especially along the distal aspect, and flap ischemia.[51] Penile skin sloughing was reported in 4% of patients undergoing a penile circular fasciocutaneous skin flap, and 3% developed a urethrocutaneous fistula.[52] Distal penile skin ischemia and necrosis are generally managed with debridement of devitalized tissue and wound care. In general, the skin is adequately redundant so that the loss of a small amount of penile skin is not disabling. In patients who previously underwent flap repair and who develop a recurrent stricture, a penile flap may be elevated again by some surgeons. However, once a flap is used, the blood supply of the penile skin is not axial and well defined, but rather random in distribution. Therefore repeated use of skin flaps can be associated with a higher rate of ischemic flap failure and recurrent stricture formation.

Although currently not commonly used as a urethral replacement, scrotal skin can be used for urethral reconstruction. When scrotal skin is rotated as a flap, it must be nonhirsute. In addition, the skin must be marked on stretch to avoid redundancy that can be associated with diverticula formation (Fig. 51.13). Penile skin flaps must also be nonhirsute. In general, the foreskin and distal penile shaft skin are not hair bearing. However, before shaving and draping, when skin flaps are to be used, the skin should be evaluated under optical magnification to ensure that only nonhirsute skin is selected. When hair-bearing skin is used to repair the urethra, hair will then grow within the lumen of the reconstructed urethra (Fig. 51.14) and may be a source of infection, stone formation, or recurrent obstruction[53].

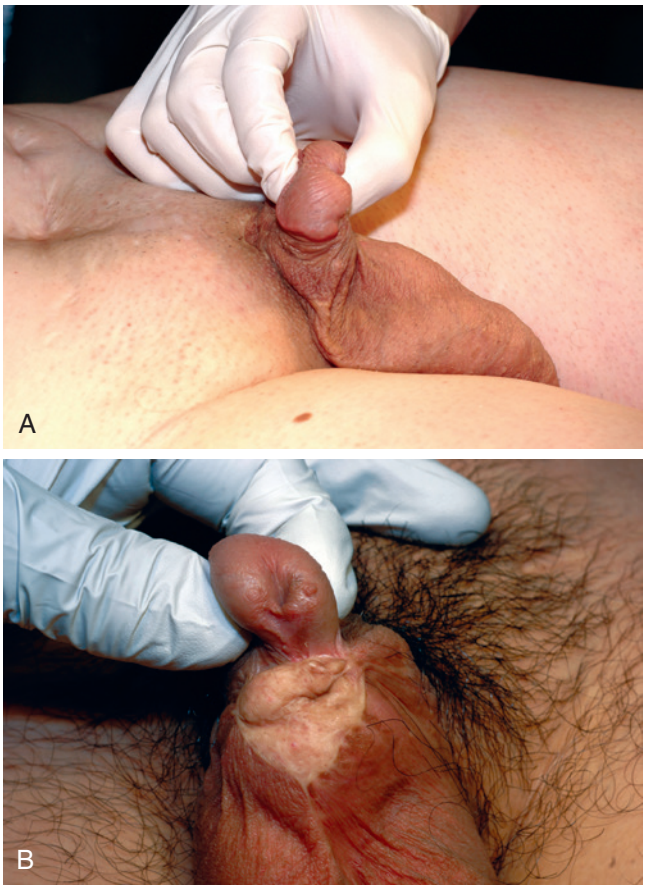

Figure 51.12 A and B, These two patients previously underwent multiple failed hypospadias repair procedures. The stretched penile length, as shown, is <2 inches.

GRAFT RECONSTRUCTION

Grafts are detached from their blood supply at the donor site and are transferred to a recipient bed. Grafts obtain blood supply through a process of graft take. Initially, the graft receives nutrients by passive diffusion, a process called imbibition. Then, neovascularization occurs. This is called inosculation. One possible complication is failure of the graft to take. Proper surgical technique significantly reduces the likelihood of graft-take failure. The graft must be firmly approximated to the recipient bed. This is facilitated by creating small slits within the graft to allow blood to escape that may elevate the graft from the recipient bed and prevent neovascularization. In addition, grafts are now often quilted to the recipient bed by using multiple fine absorbable sutures to provide further fixation because graft movement during the process of imbibition and inosculation is deleterious to graft take.

Buccal grafts can be used for one-stage reconstructions as a dorsal, ventral, or lateral onlay or for staged repairs. STSGs are generally only used for staged repairs when there is not enough oral mucosa. Buccal mucosa is a better graft material than is STSG because success rates are higher with buccal grafts than with skin grafts, and chordee occurs less, given that skin is much less elastic than is buccal mucosa.[50] However, the supply of buccal mucosa is limited.

As with other techniques of urethral reconstruction, stricture recurrence is the main complication with graft

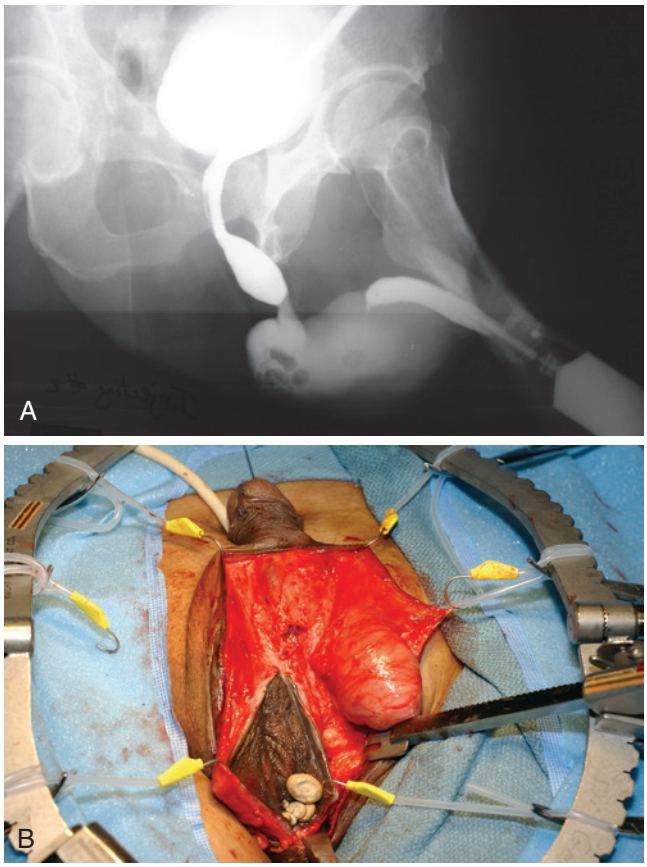

Figure 51.13 A, Retrograde urethrography demonstrates a markedly dilated proximal penile and distal bulbar urethral diverticulum that contains filling defects in a patient who previously underwent a one-stage tubed tissue transfer repair with scrotal skin. B, At the time of surgery, the massive diverticulum contained multiple stones.

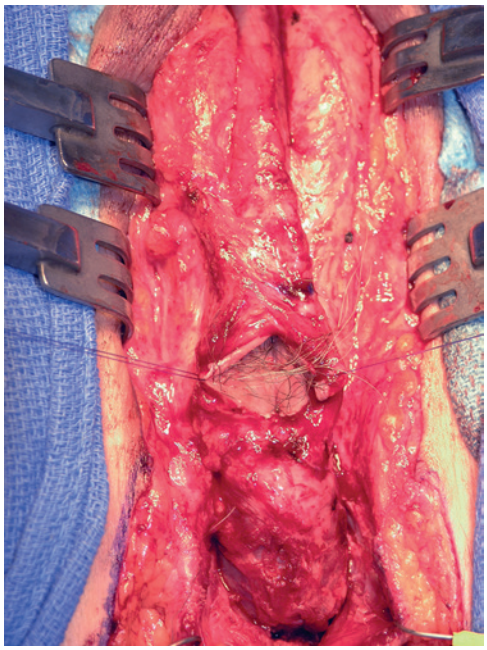

Figure 51.14 Hair developed within the lumen of the urethra after reconstruction using hair-bearing genital skin.

repairs. In addition to attention to surgical detail, procedure selection is a factor that influences the success rate. In general, the success rate is higher when transferred tissues are used for onlay repair than for tubed reconstruction.[54] In comparison with STSGs and penile skin flaps, buccal grafts appear to have a higher success rate.[55] The results with onlay buccal mucosa grafts are excellent regardless of whether the graft is placed dorsally and is quilted to the corporal bodies, as originally described by Barbagli and associates,[48] or is placed ventrally or laterally.[56]

Urethral stricture disease associated with LS was previously commonly managed with penile skin flap repair. However, investigators showed that, although short-term success rates with flap procedures were high, the long-term failure rate 10 years postoperatively was extremely high.[57] As a result, the shift in management has been toward staged repairs using extragenital tissues.[58] LS is a frustrating disease that can recur and lead to stricture recurrence even after technically successful staged repairs. Extended meatotomy or proximal urethrostomy has been proposed for complex cases as the most appropriate surgical treatment.[2]

Diverticula formation and the development of urethrocutaneous fistulas are rarely seen when buccal mucosa is used for urethral reconstruction in patients without hypospadias because the urethra is circumferentially well supported and the penile skin is separated from the urethral lumen by the corpus spongiosum. However, when staged repairs and skin flaps are performed, particularly in patients with *hypospadias*, which is a condition associated with a poorly developed distal corpus spongiosum, urethrocutaneous fistula is a more common complication.[59] These fistulas, when persistent, can be closed primarily but may then recur. Recurrent fistulas may require more complex closure with the interposition of a tunica vaginalis flap.

Conclusions

Urethral reconstruction, when properly performed using modern techniques, is generally associated with a high long-term success rate and a low complication rate. For all repairs, recurrence is the most common complication. Many published reports include follow-up with urethroscopy or contrast imaging 3–12 months after treatment to assess the short-term outcome. This testing is less frequently done after urethrotomy or dilation but is certainly not less indicated given the higher stricture recurrence rate with endoscopic treatment than with open treatment. A low early recurrence rate suggests technical success. However, long-term follow-up reveals that even when short-term success is objectively confirmed, a stricture may recur 5–10 or more years after the surgical procedure. This is especially true in patients with LS and after substitution urethroplasty.[60] Therefore indefinite periodic follow-up is recommended because the previously mentioned complications of stricture observation are also the possible complications of unrecognized and untreated recurrence.

Chapter 51 Questions

1. Which of the following is not a complication of observation as a management strategy for a significant urethral stricture?
   a. Recurrent epididymitis
   b. Penile curvature
   c. Urinary tract infections
   d. Bladder decompensation
   e. Poor quality of life

2. What is the ideal technique when performing a retrograde urethrogram?
   a. Patient in oblique position, injection of contrast through a catheter with 1 mL in the balloon
   b. Patient in supine position, injection of contrast through a catheter with 1 mL in the balloon
   c. Patient in oblique position, injection of contrast through a coned tip adaptor
   d. Patient in supine position, injection of contrast through a coned tip adaptor
   e. Patient in oblique position, injection of contrast through a catheter with 2 mL in the balloon

3. What is the best imaging test to assess for stenosis of the posterior urethra?
   a. Retrograde urethrogram
   b. Voiding cystourethrogram
   c. Ultrasound
   d. MR-urogram
   e. CT-urogram

4. What is the most common complication from repeat urethral dilation and direct internal visual urethrotomy?
   a. Bleeding requiring transfusion
   b. Urinary tract infection
   c. Creation of a false passage in the urethra
   d. Positioning-related complications
   e. Stricture recurrence

5. The main blood supply to a penile skin flap is derived from:
   a. Common penile arteries
   b. Internal pudendal arteries
   c. Superficial external pudendal arteries
   d. Circumflex arteries of the penis
   e. Neovascularity after the tissue "takes"

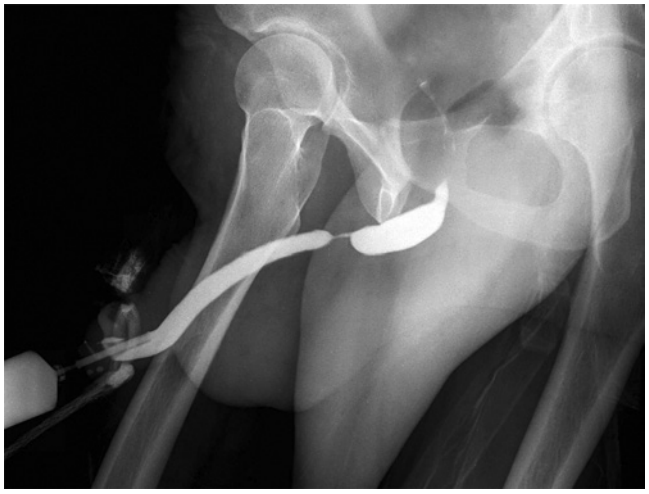
6. What is the most common positioning-related complication that results from the extended lithotomy position?
   a. Transient neuropraxia
   b. Impaired gait
   c. Acute renal failure from rhabdomyolosis
   d. Stress fracture in the lower extremity
   e. Compartment syndrome

7. A patient with which of the following histories should have an abdominal ultrasound performed at the time of placement of a suprapubic catheter?
   a. Hypospadias
   b. Prior suprapubic tube placement
   c. Prior repair with penile skin flap
   d. Prior ureteral reimplant
   e. Panurethral stricture

8. Erectile dysfunction following an excision and primary anastomosis for a urethral distraction injury related to pelvic fracture is most likely due to:
   a. The initial injury
   b. Failed attempts at early endoscopic primary realignment
   c. Early suprapubic tube placement
   d. The definitive repair with excision and primary anastomosis
   e. Persistent bacteriuria associated with indwelling catheters

9. A complication that appears to be unique to the harvesting of a lingual graft is:
   a. Postoperative pain
   b. Short-term difficulty eating solid foods
   c. Contracture of the graft site
   d. Difficulties with speech
   e. Worse bleeding complications

10. Leakage of a small amount of urine after voiding is most likely seen after which of the following procedures?
    a. Urethral dilation
    b. Direct vision internal urethrotomy
    c. Excision and primary anastomosis
    d. Ventral onlay flap
    e. Dorsal onlay graft



Case Studies

CASE 1

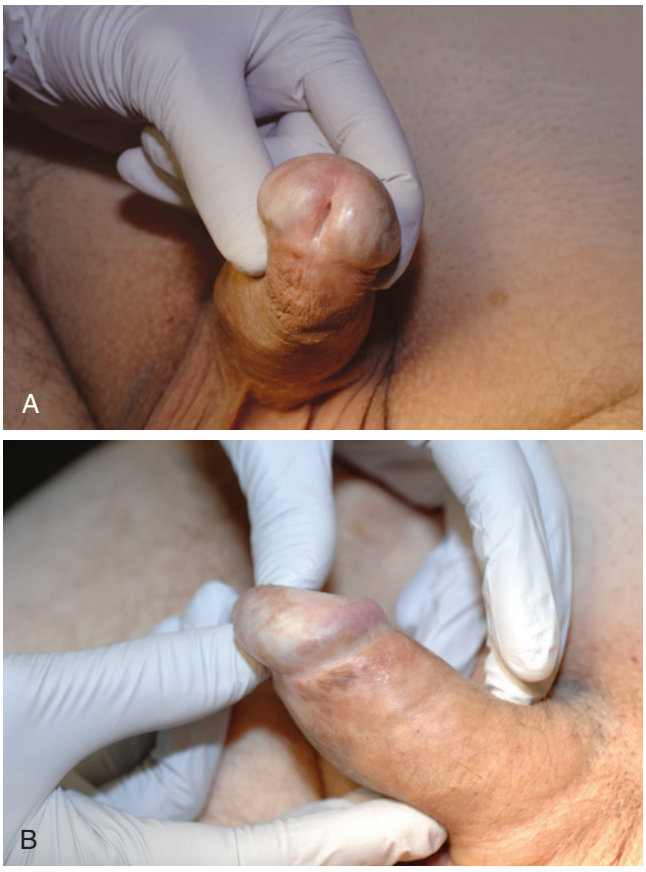
A 27-year-old man with no significant history presents with progressive weakening of his stream over the past year. His physical exam is unremarkable but his peak flow is diminished on a flow study. During the course of the work-up, cystoscopy is performed that reveals a stricture in the bulbar urethra.

1. While you are visualizing the distal aspect of the stricture, what is the appropriate next step?
   a. Advance the cystoscope through the stricture with gentle dilation if necessary, to determine the length and visualize the bladder
   b. Terminate the cystoscopy and schedule for an endoscopic internal urethrotomy
   c. Terminate the cystoscopy and perform a retrograde urethrogram
   d. Terminate the cystoscopy and schedule for a suprapubic tube placement
   e. Terminate the cystoscopy and schedule for a urethral reconstruction

2. Retrograde urethrogram is shown in Case Fig. 51.1. Which management option is likely to have the highest success rate?
   a. Urethral dilation
   b. Direct vision internal urethrotomy
   c. Excision and primary anastomosis

Case Figure 51.1

d. Dorsal buccal onlay urethroplasty
e. Ventral onlay penile skin flap



3. What can be done during the procedure to minimize positioning-related complications?
   a. Minimize the time in exaggerated lithotomy
   b. Ensure hips are flexed as much as possible
   c. Ensure knees are flexed as much as possible
   d. Avoid the use of a retractor
   e Ensure the elbows are fully extended

CASE 2

A 53-year-old man presents with a long history of a distal stricture. His previous urologist has dilated him many times in the past. He was most recently dilated 3 weeks ago, but his obstructive symptoms have already returned. His physical exam reveals meatal stenosis with a whitish discoloration of the glans and distal penile shaft skin as seen in Case Fig. 51.2.

1. What is his likely underlying diagnosis?
   a. Prior trauma
   b. Urethritis secondary to a sexually transmitted infection
   c. Lichen sclerosis, otherwise known as balanitis xerotica obliterans (BXO)
   d. Paget's disease
   e. Idiopathic meatal stenosis

2. The patient desires definitive intervention, but tells you his flow is worsening rapidly and may go into retention in the next few days to weeks. You check a post-void residual and it is 350 mL. What is the appropriate next step?
   a. Schedule for urethroplasty within the next few days
   b. Place a suprapubic tube and delay his definitive work-up and repair for another 2–3 months
   c. Dilate him in the office so that an immediate workup with cystoscopy and retrograde urethrogram can be performed

Case Figure 51.2

   d. Place him on self-dilation until a definitive repair can be scheduled
   e. Place him on a topical steroid until definitive repair can be scheduled

3. After placement of a suprapubic tube, a retrograde urethrogram 3 months later reveals a 5-cm stricture involving the fossa navicularis and most of the penile urethra. Which of the following options is most likely to fail?
   a. Extended meatotomy
   b. Perineal urethrotomy
   c. Staged procedure with buccal grafting
   d. One-stage urethroplasty with penile skin flap
   e. All of the above have excellent long-term success

Answers

1. **b.** High-pressure backflow in the urethra may cause reflux into the prostatic ducts leading to prostatitis or epididymitis. Bladder diverticula, poor emptying, and urinary tract infections may also arise from high pressure voiding. There is no association of strictures with penile curvature.
2. **c.** Imaging performed while supine can severely underestimate the stricture length and therefore should be done in the oblique position. Even placing 1 mL creates a balloon that is 39Fr in caliber, which is far greater than a normal 24Fr fossa navicularis and may

therefore create a new stricture due to the trauma of such forceful dilation.

3. **b.** Posterior urethral stenoses are not readily appreciated because the bladder neck and external sphincter are both closed at rest. During a retrograde urethrogram, it is normal for the posterior urethra to be coapted and therefore a contracture or stenosis could not be distinguished. Voiding cystourethrogram is the only option that visualizes the posterior urethra while these structures are opened.
4. **e.** Long-term stricture recurrence rates for repeat dilations or urethrotomies is unacceptably high, and therefore these procedures are recommended only for short strictures that have not been previously treated.
5. **c.** The penile skin is supplied by branches of the superficial external pudendal arteries that course along the tissue deep to the skin and superficial to Buck's fascia. Unlike grafts, flaps are transferred with their blood supply intact and do not rely on "take."
6. **e.** Transient neuropraxia, particularly on the dorsum of the foot, is the most common positioning-related complication in the lithotomy position. This will typically resolve within days.
7. **d.** Patients with prior lower abdominal or pelvic surgery are at higher risk of having bowel in the path of the ideal suprapubic tract.
8. **a.** While performing a posterior urethroplasty carries some risk of de novo erectile dysfunction, the literature suggests that the large majority of these patients had ED since their initial injury. There is no evidence that the other options are correlated with erectile dysfunction in this scenario.
9. **d.** Difficulty with speech is often reported postoperatively after the harvesting of a lingual graft, while pain, short-term difficulty with solids, and contracture of the graft site can occur with buccal and lower lip grafts as well. There is no evidence that bleeding is worse with lingual grafts.
10. **d.** Post-void dribbling is common after any substitution urethroplasty because the substitute material does not coapt like normal urethra, leaving a small amount of urine within the repaired section. Ventral onlay repairs, either with a graft or a flap, are more likely to be associated with this issue than are dorsal repairs, which are fixated to the firm corporal bodies that supply more support than the ventral repairs.

CASE 1

1. **c.** Cystoscopy is not an adequate procedure to determine the length of a stricture. Therefore, it should be terminated and a retrograde urethrogram should be performed to determine the exact length and location as these factors are needed to determine the best treatment option.
2. **c.** The retrograde urethrogram shows an approximately 1 cm bulbar urethral stricture. In this case, excision and primary anastomosis has been shown to have the highest success rate.
3. **a.** Extended time in exaggerated lithotomy has been associated with positioning complications such as neuropraxia or even compartment syndrome, although the latter is rare.

CASE 2

1. **c.** The whitish discoloration of the glans and distal penile shaft as seen is classic for lichen sclerosis, it is typically not seen with the other options.
2. **b.** Given his recent dilation 3 weeks ago, the stricture is likely still maturing. If immediate intervention is taken, it will be difficult to tell how proximal the stricture disease truly extends. Placement of a suprapubic tube allows excellent bladder drainage while the stricture matures and then can be appropriately worked up 2–3 months later. A topical steroid may help prevent future recurrence, but would not cure his current stricture.
3. **d.** As lichen sclerosis is a cutaneous disease, use of a penile skin flap is contraindicated as recurrence is highly likely in this situation. The other 3 procedures mentioned have acceptable success rates.

52 Complications of Surgery for Erectile Dysfunction and Peyronie's Disease

BOBBY B. NAJARI and JOHN P. MULHALL

CHAPTER OUTLINE

Introduction
Penile Prosthesis Surgery
Infection
Antibiotic-impregnated Prostheses
Mechanical Malfunction
Erosion
Crural Perforation
Supersonic Transporter Deformity
Penile Necrosis
Complications of Penile Vascular Surgery
Peyronie's Disease Surgery Complications
Indications
Intralesional Treatments
Procedures
Penile Plication Complications
Plaque Manipulation Surgery
Penile Prosthesis Surgery
Conclusions
Chapter 52 Questions and Answers

KEY POINTS

1. Infection remains a significant concern, with rates between 1% and 8%.
2. In the setting of infection, device removal is highly recommended. Immediate reinsertion of the prosthesis is associated with long-term success in 45 of 55 patients in one study.
3. Despite the potential complications of the penile prosthesis, satisfaction rates remain high.
4. Peyronie's disease surgery should be undertaken in the properly selected patient with realistic expectations of the potential outcome.
5. Complications of Peyronie's procedures include hematoma formation, decreased penile sensation (anesthesia, dysesthesia), erectile dysfunction, bother from palpable suture material, penile skin necrosis, penile length loss, and recurvature.

Introduction

Surgical treatments for erectile dysfunction and Peyronie's disease are always elective procedures that a patient chooses to improve his quality of life. As a result, complications associated with any of these procedures are especially disappointing to the patient and disheartening for the surgeon. Communicating the possible complications of these surgeries is vital to ensuring that the patient is making a fully informed decision about whether to proceed with surgery. An extensive knowledge of the possible complications associated with these surgeries will also help the surgeon to prevent, as well as skillfully manage, these complications such that outcomes are optimized.

Penile Prosthesis Surgery

Penile prostheses are generally of two types: malleable (semirigid, noninflatable, nonhydraulic) and inflatable (hydraulic) devices. The malleable devices have an outer shell with a central core of metal or plastic. These prostheses are paired solid devices implanted in the corpora cavernosa that produce constant penile rigidity. The primary advantage of these devices is their ease of implantation, whereas the disadvantages include a constantly rigid penis that resembles neither normal erection nor flaccidity, difficulty with concealment, and an increased risk for device erosion.

Inflatable devices are of two varieties: two-piece and three-piece devices. Since its introduction in 1973, the inflatable penile prosthesis has undergone multiple changes in design and manufacturing. American Medical Systems (AMS, Boston Scientific, Marlborough, MA) produces both types of inflatable devices (Fig. 52.1). Coloplast (Minneapolis, MN) produces only three-piece devices (Fig. 52.2). Numerous modifications have been made to improve function and survival of the devices. Such modifications include, but are not limited to, a reservoir or pump lockout valve to prevent autoinflation, antibiotic or antiadherence

Figure 52.1 AMS 700 series three-piece inflatable implant.

Figure 52.2 Coloplast Titan series three-piece inflatable implant.

Figure 52.3 AMS Ambicor two-piece penile implant.

Box 52.1 Patient Populations to Consider a Two-piece Prosthesis

Has undergone, or is planning to undergo, a renal transplant
Has had a bilateral inguinal herniorrhaphy (especially with mesh)
History of spinal cord injury and uses condom catheter (solid distal 2 cm of cylinders support the condom catheter)
Certain patients who have undergone radical prostatectomy (it can be challenging to develop enough space to prevent autoinflation in 5–10% of men)
Older men whose manual dexterity makes using the three-piece deflation mechanism difficult to use

coating to reduce infection, Parylene (a polyxylylene polymer) coating for the AMS three-piece devices to improve cylinder longevity, and modifications of the scrotal pump to improve ease of use for the patient.

The AMS two-piece device (Ambicor) consists of two cylinders with the distal 2 cm made of solid silicone (Fig. 52.3). The cylinders are connected to a ball-shaped pump, which is seated within the scrotum. Compression of the pump results in transfer of fluid from the basal part of the cylinders into the middle portion, with subsequent rigidity. The deflation mechanism involves simple bending of the cylinders midshaft to return the fluid to the basal section. Three-piece inflatable implants have paired cylinders, a small scrotal pump, and a large-volume fluid reservoir. These devices have a greater flaccidity profile that leads to a more natural-type erection.

The ideal penile prosthesis will permit a man to control when he has an erection and will allow penile flaccidity and erection that approximate their natural counterparts as closely as possible. To achieve these goals, fluid must be transferred into expandable cylinders for erection and must back out of the cylinders for flaccidity. A device with a fluid reservoir is required, thus necessitating placement of the reservoir in the retropubic space, although it may be placed in the peritoneal cavity when such an extraperitoneal space does not exist.

Placement of the fluid reservoir into a submuscular location that is posterior to the rectus abdominis muscle but anterior to the transversalis fascia has been described as a means of safely placing three-piece devices in men with prior pelvic surgery.[1] Stember et al. reported a higher rate of reservoir herniation and revision for palpable reservoir utilizing this submuscular technique as opposed to a traditional placement in the retropubic space.[2]

It is our practice to place a three-piece device where possible. We routinely use the Coloplast device; however, other centers use the AMS three-piece device with excellent results. In certain populations we consider implanting the Ambicor two-piece device (Box 52.1). Other authorities use three-piece devices in some of these populations with both excellent safety and satisfaction.

In men who have a fibrotic penis and who are undergoing secondary (repeat) prosthesis implantation, it is our practice to implant a narrow three-piece device, usually in conjunction with the use of a Cavernotome (UROAN 21, Baleares, Spain) or sharp corporal tissue excision. Surgeons in centers that use AMS 700 devices suggest that in men who have had previous cylinder erosion or crossover, CX/CXR rather than LGX cylinders should be used because avoidance of length expansion (as can occur with the LGX device) in these situations is preferable.

The advantages of two-piece over three-piece devices are explained to the patient to enable him to make a more informed choice. We insist that all patients read the device-related literature, view videos of the device, and speak to a patient who has undergone implant surgery. Our patients also have a routine lengthy counseling session with the implant surgeon before they commit to the procedure. Ensuring that the patient has realistic expectations before implant surgery is undertaken is essential to ensuring high postoperative satisfaction profiles. Specifically, we discuss infection rates, rates of reoperation, and the lack of penile length increase with penile prosthesis surgery.

Infection

Infection associated with prosthetic surgery is a significant problem. The reported incidence of initial penile prosthetic surgical infections is between 1% and 8% (Table 52.1).[3,4] Modern techniques with antibiotic-coated devices have brought the infection rate to approximately 1%.[5] Investigators have reported an increase in this rate with second and third reoperative procedures.[6] Additionally, the risk of prosthetic infection is also increased in patients with poorly controlled diabetes mellitus (glycosylated hemoglobin >11.5%), spinal cord injuries, or a history of urinary tract infection.[7–12]

Skin-dwelling bacteria are usually responsible for operative wound contamination. Historically, the most common bacterium associated with penile implant infection is *Staphylococcus epidermidis*. A recent review of infected prostheses at 25 institutions revealed that 73% of positive cultures grew gram-positive bacteria, 39% grew gram-negative organisms, and 25% grew multiple organisms.[13] Highly virulent organisms such as methicillin-resistant *S. aureus* (MRSA), *Pseudomonas aeruginosa*, *Enterococcus* species, *Prevotella* species (*Bacteroides* subspecies), and fungi have been associated with penile implant infections. Patients with infected penile implants usually present between 1 and 8 weeks postoperatively with fever, pain, and swelling overlying the prosthesis often (but not always) accompanied by purulent wound drainage. Other signs and symptoms of a developing infection are persistent pain over parts of the implant on palpation, elevated white blood cell count, elevated erythrocyte sedimentation rate, cellulitis, fever, chills, erosion (Fig. 52.4), or fixation of parts of the prosthesis (tubing or pump) to the scrotal wall. Although it is uncommon, infection may manifest after 8 weeks within the first year after the surgical procedure. Such an infection is usually caused by *S. epidermidis* and manifests in an indolent fashion.

Anecdotally, reports have noted implant infection occurring years after implantation. This phenomenon is believed to result from hematogenously disseminated bacteria leaked into the bloodstream after a surgical or dental procedure. Carson and Robertson described a series of delayed prosthetic infections presumably caused by hematogenous bacterial spread from a remote focus.[3] All six patients underwent uncomplicated prosthesis implantations and had an extended problem-free period of use before the inset of infection. All the devices in this series were explanted.

If the penile prosthesis is infected, it must be removed. Systemic administration of antimicrobial agents alone is ineffective in destroying all offending bacteria. On an

Figure 52.4 Eroding implant cylinder through urethral meatus.

ultrastructural level, biofilm produced by bacteria surrounds the implanted device and thereby radically reduces the ability of antimicrobial agents to penetrate the area where the bacteria are located.[14] Additionally, the human body produces a fibrotic capsule that surrounds the prosthesis. This fibrotic capsule has minimal blood supply, a feature that also reduces the efficiency of antibiotic penetration.

Once the prosthesis is removed, the surgeon must decide whether to reimplant another prosthesis several months later or to perform a salvage procedure. Traditionally, following removal of the prosthesis, the area is copiously irrigated with antibiotic solution. Some experts leave drains in place, and the incision is closed. This appears to be a matter of choice because no evidence-based medicine has addressed this issue. Based on intraoperative wound and blood cultures, the patient is treated with appropriate systemic antimicrobial agents. If placed, drains may be irrigated two to three times per day with antibiotic solution for several days. A new penile prosthesis may be reinserted 2–6 months later.

An alternative approach is to reimplant a new prosthesis immediately, during the same operative session as the explantation. Procedurally, all parts of the infected prosthesis are removed, the wound is copiously irrigated with a series of antibiotic or antimicrobial solutions, the patient is prepared and draped again, and the new prosthesis is inserted.[15] The benefit is that this approach allows for easier cylinder insertion and abrogates the penile shortening that occurs secondary to corporal fibrosis if the cylinders are removed and are not immediately replaced.[15,16] Mulcahy reported long-term success in 45 of 55 (82%) men who underwent salvage of their penile prostheses in the setting of infection.[16]

Occasionally, the surgeon may determine that only the prosthesis cylinder or pump is infected, not the reservoir. In this instance, although it is controversial, we have on occasion attempted and succeeded in salvaging only the cylinders (acting as stents to prevent penile shortening) and returned later for pump and reservoir placement. Exclusion criteria proposed for salvage include any degree of being immunocompromised, sepsis, tissue necrosis, and copious amounts of pus within the corporal bodies.[15] Other relative indications are erosion of the cylinders and the presence of uncontrolled diabetes. Habous et al. have also reported conservative therapy utilizing oral antibiotics in 37 men with localized infection.[17] However, this approach should only be used in highly compliant patients who understand that this is not the standard of care.

In 2001, Montague and colleagues conducted a retrospective review of 491 patients who received a three-piece inflatable penile prosthesis.[18] These investigators reported infection rates and risk factors in these recipients. Of the 491 total patients, 10 infections (2.0%) occurred. Seven of the infections were in first-time prosthesis recipients and three were in recipients of secondary inflatable penile prostheses. The presence of diabetes played a minor role in the development of inflatable penile prosthesis infection because three of the total 10 infections were in the 137 men with diabetes mellitus. The remainder of infections occurred in patients who did not have diabetes. Surprisingly, this study did not find statistically significant differences in infection rates between first-time and secondary prosthesis recipients or between diabetic and nondiabetic recipients, findings dissimilar to the conclusions published in studies by Jarow[4] and by Lynch and colleagues.[19]

Jarow reported a higher infection rate in patients undergoing a secondary procedure for corporal reconstruction versus prosthesis revision versus first-time insertion of an inflatable penile prosthesis (21.7% vs 13.3% vs 1.8%).[4] This finding is in contrast to the results of the study by Montague and associates.[18] Jarow found convincing evidence not only that reoperation is associated with higher rates of device-related infections but also that complex corporal reconstruction further increases the chance of postoperative infection of inflatable penile prostheses.[4]

Diabetes mellitus, a reported risk factor for the development of implant infections, has been the subject of articles by luminaries in the field of sexual medicine. One of the first reports in the modern era noted a 22% incidence of infection in patients with diabetes but a 6.7% infection rate in patients who did not have diabetes.[19] Subsequent reports by Wilson and colleagues failed to link diabetes (regardless of mean glycosylated hemoglobin levels) to a higher risk of prosthesis infection.[20,21]

Given that many prostheses are implanted by low volume surgeons, population-based studies are useful for capturing outcomes potentially incongruent with those reported by high volume surgeons. Utilizing a New York State database of 14,969 men, Onyeji and colleagues reported infectious complications in 2.3% of implants.[22] Grewal et al. reported on 1824 virgin penile implants using a California database and found a 3.2% infection rate.[23]

ANTIBIOTIC-IMPREGNATED PROSTHESES

In an effort to decrease the rate of prosthetic-associated infection, specially modified implants have been developed. AMS introduced InhibiZone prostheses (which are coated with rifampin and minocycline), and Coloplast marketed a device with a low-friction, antibiotic-absorbing coating on its Titan prostheses. In nonrandomized studies, both these coatings were shown to decrease the incidence of implant-related infections.

Carson in 2004 retrospectively reviewed the difference in infection rates between patients who received AMS penile implants impregnated with a combination of rifampin and minocycline and those who received untreated prostheses.[24] He reported that the infection rate was initially 1.59% in the noncoated implant and it decreased to 0.2% at 12 months in the coated implant.[24] These data are based on the use of patient information forms completed at the time of the surgical procedure by the surgeon. Thus, these data are not generated from a randomized study, nor is the surgeon blinded to the device type.

In 2006, Abouassaly and colleagues assessed the impact of prosthesis replacement for mechanical failure on infection rates with an AMS antibiotic-coated prosthesis (coated with rifampin and minocycline).[25] Although the investigators excluded salvage procedures for clinically infected prostheses, one of 55 patients experienced postoperative device infection in the 32-month follow-up period. The investigators concluded that insertion of an antibiotic-coated inflatable penile prosthesis may result in lower infection rates in this cohort of men.[25]

In a large study, Wilson et al. reported that InhibiZone-coated inflatable penile prostheses showed reduction in infection in multiple scenarios.[26] Specifically, in 467 patients receiving InhibiZone-coated implants, no infections developed among the 223 first-time implants in nondiabetic patients, one of 83 diabetic patients developed an infection, four infections were found in 39 patients who underwent implant revisions, and infections developed in four of 123 men when a salvage operation was combined with antibiotic washout.[26]

The impact of antibiotic coating on infection rates is also supported by population-based studies. Onyeji et al. reported that the infection rate in New York State decreased from 4.2% in the era before antibiotic coating was used to 1.5% afterward.[22]

Mechanical Malfunction

Although infection may be the most serious penile prosthetic complication, mechanical malfunction remains the most frequent reason for reoperation (Table 52.2).[27] Common reasons for malfunction are cylinder aneurysm, tubing leakage, reservoir leakage, cylinder leakage, and connector fracture. Failure rates have been reported to be 15% at 5 years and 30% at 10 years.[28] In the event of malfunction, we believe that replacement of the entire device is prudent if initial insertion occurred >2 years previously, because this approach will increase the likelihood of longevity of the device. Frequent updates and revisions of the penile implant devices make it difficult to ascertain their true mechanical longevity scientifically.

Levine and colleagues retrospectively reviewed reliability, complication, and patient satisfaction rates in 131 men with the two-piece AMS Ambicor penile prosthesis.[29] Ten patients had complications, six of which resulted from mechanical failure. The Ambicor penile prosthesis historically has had high satisfaction rates coupled with reliable function.

A review by Carson and associates of the reliability of and satisfaction with the AMS 700 CX three-piece penile prosthesis encompassed a median follow-up of 47.7 months and had two phases.[28] Phase 1 reviewed the medical record of 372 patients and phase 2 was a telephone interview of 207 patients. Medical record review found that the devices were functionally reliable 92.1% of the time after 3 years and 86.2% after 5 years. Seventy-nine percent of the patients with a device used it at least twice monthly, and

88.2% would recommend an implant to a relative or friend. The investigators concluded that the AMS 700 CX penile implant was reliable, provided excellent patient and partner satisfaction, and had a low postoperative morbidity profile.[28]

Ferguson and Cespedes prospectively evaluated the long-term reliability of and patient satisfaction with the AMS Dura-II malleable penile prosthesis.[30] In this study, the 94 patients who underwent implantation with the Dura-II device were prospectively examined and asked to complete standardized questionnaires regarding sexual activity, prosthesis function, intercourse satisfaction, and overall quality of life. During the follow-up period of nearly 6 years, 76% and 87% of patients reported satisfactory rigidity and ease of concealing the device, respectively. Quality of life was enhanced by the implant in 87% of men, and 88% would recommend this prosthesis to a friend. Malleable penile prostheses appear to be as effective and satisfactory as are fluid-filled models. Patient selection and recipient expectations undoubtedly play large roles in determining the likelihood of a satisfactory outcome.

Wilson and associates published a large, long-term, historical prospective study of 2384 patients to estimate mechanical and overall revision-free survival of four different inflatable penile prostheses (Mentor Alpha 1, Mentor Alpha NB, AMS 700 CX, and AMS 700 Ultrex).[31] At 10 and 15 years, mechanical reliability was 79.4% and 71.2%, respectively. More recent Mentor Alpha models improved 10-year survival to ≤88.6%. The newer iterations of the AMS CX devices had a reported 97.9% freedom from mechanical breakdown at 3 years. This large study conducted in 2007 further lends credence to the excellent mechanical durability of modern inflatable penile prostheses. Ji et al. reported similar long-term mechanical reliability rates of 76.5% and 64.8% at 10 and 15 years, respectively, using the AMS CXM model in 74 patients in Korea.[32]

Onyeji and associates reported a noninfectious reoperation rate of 4.1% in 14,969 implants done in New York State with a median follow-up of 95.1 months.[22] Grewal et al. reported a similar 4.17% revision rate for noninfectious causes in 1824 cases; however, their follow-up was at most 4 years, with no reported median.[23]

In an effort to elucidate the chronology of patient satisfaction after implantation of a penile prosthesis, we prospectively evaluated men with the International Index of Erectile Function (IIEF) questionnaire preoperatively as well as at 3, 6, and 12 months postoperatively. The investigators also administered the Erectile Dysfunction Inventory of Treatment Satisfaction (EDITS) questionnaire postoperatively at 3, 6, and 12 months. The study of 96 men found that 6- and 12-month scores were higher than baseline, but satisfaction was statistically higher at 12 months as measured by the IIEF satisfaction domain. This first-of-its-kind study elucidated that satisfaction with penile implant further increases after 6 months, but more importantly it provided physicians with additional information to impart to patients.[33]

Erosion

Erosion of a component of the prosthesis is not rare. The device can erode through skin (cylinder or reservoir) or erode through tunica (cylinder), such that it lies subcutaneously. When erosion through skin occurs, the device is inherently infected and probably eroded in the first place because of a low-grade infection. Our approach to this complication depends on the nature of the erosion.

Erosion of the corporal cylinders extracorporally through the distal portions of the corporal bodies may occur iatrogenically from overenthusiastic corporal dilation or oversizing of the cylinders.[34] Patients with decreased distal sensation such as those with spinal cord injury or diabetes mellitus may have an increased incidence of distal erosion.[35] In addition, we have seen this complication in patients who have received previous pelvic irradiation.

Techniques of distal corporal erosion repair include creation of a new pocket for the tip of the cylinder through a hemicircumferential incision for established or impending distal erosion. In cases of lateral extrusion of corporal cylinders, Mulcahy described the creation of a new corporal cavity to reseat the prosthetic device.[36] In this situation, a hemicircumcising incision is made and the cylinder tip is exposed. Next, a 3-inch lateral longitudinal corporotomy is made proximally over the cylinder. The back wall of the fibrotic sheath is then incised transversely and a new plane of dissection is developed. Finally, the cylinder is inserted into this new cavity.

Crural Perforation

Proximal (crural) perforation is not uncommon, although no data exist in the literature. This complication usually results from overly vigorous or misdirected proximal dilation such that the dilating instrument perforates the tunica and lies in the perineum. If perforation is noted intraoperatively, no long-term concern exists, but failure to identify this complication at the time of implantation may result in proximal migration of the cylinders out of the glans and into the perineum.

Certain surgical approaches are aimed at preventing proximal slippage of the cylinder without direct repair of the crural tunica. Historically, this goal has been accomplished by wrapping the proximal end of the cylinder in a "windsock" made of either synthetic or available natural material such as cadaveric pericardium or intestinal submucosa (Fig. 52.5). This windsock is then sutured to the tunica to prevent proximal migration of the cylinder. A second method is to suture the rear-tip extender (if used) to the corporal tunica with nonabsorbable monofilament suture. The cylinder of the prosthesis is then securely seated into the rear-tip extender. A newer approach to this problem is the simple use of a suture hammock around the exit tubing at the proximal end of the cylinder. A simple U-type suture in this setting prevents proximal cylinder migration.

Supersonic Transporter Deformity

The supersonic transporter (SST) deformity is the name given to the glans of the penis when it appears to bend or hang most commonly downward (but also occasionally upward) limply from the erect penile shaft. This condition

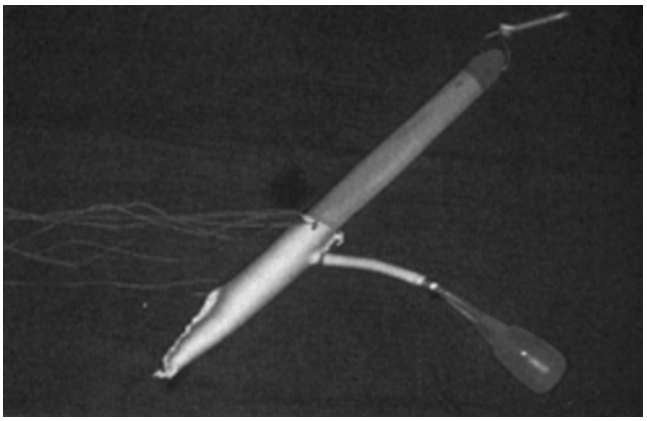

Figure 52.5 Fashioning a windsock around the rear end of the cylinder to prevent proximal migration in the setting of crural perforation. The windsock contemporarily uses an off-the-shelf material such as cadaveric pericardium or intestinal submucosa.

may lead to difficulty with penetration or irritation of tissue overlying the ends of the corporal body. The deformity may be the result of inappropriately sized implant cylinders, inadequate distal corporal dilation, or a constitutionally hypermobile glans. This issue may be remedied through a subcoronal incision and dissociation of the glans penis from the distal ends of the corporal bodies. With care taken to avoid neurovascular bundle injury, the glans is then repositioned more proximally on the corporal bodies and is fixed using two nonabsorbable sutures (No. 1 polyester, Ti-Cron, Tyco Healthcare, Waltham, MA) placed on either side of the midline in a horizontal mattress fashion. These sutures are ideally placed through the tunica albuginea on the corporal body and through the fascial layer on the undersurface of the glans penis.[37,38]

Penile Necrosis

The most devastating complication following penile prosthesis insertion is penile necrosis. This rare complication is most often precipitated by local infection; however, pressure dressing or the prolonged presence of a urethral catheter may contribute to the development of necrosis.[39] Adherence to the following basic principles may help avoid this issue:

1. Rigorous sterility of the operative field
2. Limited use of an indwelling catheter
3. Avoidance of circumferential penile compression bandages
4. Proper sizing of penile corporal cylinders
5. Avoidance of prolonged cylinder inflation.

Although we have no way to predict who will develop this problem, aggressive treatment may be lifesaving. The prosthesis should be removed, the corporal bodies irrigated, and necrotic tissue debrided. Care must be taken to preserve as much viable tissue (and to avoid amputation) as possible for future penile reconstruction. In the setting of superficial penile gangrene, avoidance of prosthesis removal may be possible but is not recommended.[40] Perfusion and healing may be enhanced with hyperbaric oxygen, warm compresses, or vasodilators, although no data exist in the medical literature on these strategies and thus they are purely empirical.

Complications of Penile Vascular Surgery

Vascular surgery encompasses penile revascularization and crural ligation surgery for venous leak. Vascular surgery is the only treatment modality that has the potential to allow the permanent return of spontaneous erections without the need for pharmacologic or device support. Specifically, the goal of the surgical procedure is to increase the cavernosal arterial perfusion pressure and inflow in patients with erectile dysfunction resulting from pure arterial insufficiency. The ideal patient is a young man with pure arteriogenic erectile dysfunction who has no other vascular risk factors.

Penile revascularization has undergone many refinements since its first description by Vaclav Michal and associates in 1973.[41] Many variations have been described by Michal and associates,[42] Virag,[43] Hauri, Crespo and colleagues,[44] and Hatzichristou and Goldstein.[45] No further revolutionary changes have occurred in the realm of penile revascularization surgery, nor does consensus exist among experts with regard to the definitive technique.

Complications of penile revascularization occur in approximately 25% of patients.[46–48] Postoperative arterial hemorrhage with hematoma formation may result from disruption of the microvascular anastomosis. This is the culmination of the repetitive stretching and tearing of the vascular anastomosis during coitus or masturbation. In our practice, we recommend abstention from sexual activities involving an erect penis for at least 6 weeks postoperatively.

Another rare complication is glans hyperemia, which occurs when the dorsal vein has been arterialized (inferior epigastric artery or dorsal artery to deep dorsal vein anastomosis).[46,48] The treatment is to ligate the deep dorsal vein distally. Diminished penile sensation may result from dorsal nerve injury but is uncommon because an operating microscope is used for dorsal vessel dissection.[49]

Crural ligation for venous leak has seen a resurgence in use at major referral centers. In an effort to correct isolated venous leak from crural veins, this procedure entails ligation (or exclusion) of the proximal corpora with umbilical tape.[50,51] Two of the more influential studies of this procedure are by John Mulhall and Tom Lue and their associates. Mulhall and colleagues[50] described success using a transscrotal approach, whereas Lue and colleagues[51] favored a 3-inch inguinoscrotal approach. The most common complications in these studies were scrotal hematoma, infection, and continued erectile dysfunction. We had a single case of infection of the umbilical tape, which was removed. We now treat all patients with preoperative, perioperative, and postoperative oral antibiotics.

Peyronie's Disease Surgery Complications

Peyronie's disease is a fibrotic disorder of the tunica albuginea that results in penile deformity, penile pain, and, in

some patients, erectile dysfunction.[52] The etiology and pathophysiology of this disorder have not been completely elucidated.[53–55] Prevalence estimates range from 1% to 8.9%.[56,57] The natural history of Peyronie's disease was initially described by Williams and Thomas in 1970.[58] In this small study, the investigators reported a spontaneous resolution rate of 50%.[58] As a result of this study, many patients with Peyronie's disease are prescribed conservative treatment. In a later report, Gelbard and colleagues described resolution of penile curvature in 13% of patients with nonsurgical treatment.[59]

In 2006, we reported an analysis of the natural history of Peyronie's disease in 246 untreated patients.[60] Mean follow-up was 18 months, at which time 12% of men had an improved curvature, 40% remained stable, and 48% worsened. The most important information from this report is that the average improvement in curvature was 15 degrees, but in patients who experienced worsening of curvature, the mean change was 22 degrees. These and other articles suggest that spontaneous resolution of penile curvature from Peyronie's disease is uncommon.

Peyronie's disease has two phases: acute (inflammatory) and chronic. It is best to correct the penile deformity surgically after the acute phase has passed. Typically, this is 12 to 18 months after the onset of the condition. In the chronic phase, the penile curvature has stabilized and, although penile plaque may be prominent and calcified, it is not associated with penile pain. This is the optimal time for surgical intervention.

INDICATIONS

Tornehl and Carson published criteria for the surgical intervention of Peyronie's disease.[61,62] In our practice, we communicate to patients that no absolute indications exist for curvature correction. However, if the patient can answer any the following questions in the affirmative, if he is ≥12 months from the initial onset of symptoms, and if he has had a stable deformity for ≥3 months, he is then considered to be a candidate for surgical correction of the penile deformity:

1. Does the patient hate the appearance of his penis?
2. Is the patient unable to have penetrative sexual relations?
3. If the patient is able to have penetrative sexual relations, is the experience cumbersome or unsatisfactory?

INTRALESIONAL TREATMENTS

While surgical treatment of Peyronie's disease offers correction of the deformity in a single treatment session, the less invasive nature of intralesional treatments may appeal to some patients. Intralesional therapies come in the form of verapamil, interferon alfa-2b, and collagenase *Clostridium histolyiticum*. Only intralesional collagenase clostridium histolyticum is FDA approved for treatment of Peyronie's disase.

Intralesional verapamil is a calcium channel blocker thought to inhibit fibroblast formation. Evidence for its use in treating stable disease is mixed.[63] However, it can be used in the acute phase, resulting in stabilization of curvature in 60% of patients and reduction of curvature in 20% of men.[64] Complications include pain at the site of injection in 15% of men, bruising in 25% of men, and a 10% rate of dizziness/nausea.[63]

Intralesional interferon alfa-2b is a cytokine thought to inhibit the proliferation of fibroblasts. It reduces penile curvature by 13.5 degrees and is indicated in men with stable disease, curvature >30 degrees, and no plaque calcification.[65] Patients should be counseled that 40–100% of men will have flu-like symptoms and minor penile swelling.[63]

Intralesional collagenase clostridum histolyticum is indicated in men with stable disease and curvature >30 degrees and less than 90 degrees. The average improvement in curvature is 35%, with 75% of men achieving a >25% curvature improvement.[66] Adverse events are experienced by 85% of men and include bruising in 80%, swelling in 50%, and penile pain in 50%. Additionally, 0.5% of men experience corporal rupture, hence the recommendation for 2 weeks without sexual activity after each treatment.

PROCEDURES

Once the decision to proceed with operative intervention has been made, the surgeon must choose the most appropriate method of curvature correction based on physical examination (nature and magnitude of deformity) during maximal rigidity erection, baseline erectile function, and penile dimensions. Surgical procedures for correcting curvature resulting from Peyronie's disease fall into three major categories. For a full review of these categories, the reader is referred to the article by Tornehl and Carson[62] in *Urologic Clinics of North America*:

1. Plication: Nesbit, 16-dot, corporoplication, Kelami's corporoplasty, or incisional corporoplasty, Yacchia procedure
2. Plaque manipulation: removal or incision of the plaque with subsequent coverage of the corporal defect with synthetic or nonsynthetic graft material
3. Penile prosthesis insertion.

Selecting the correct surgical approach for the individual patient is critical to optimizing results. Patients with complex deformities or those who have at baseline a foreshortened penis are not good candidates for penile plication surgery. Patients with preexisting erectile dysfunction or low-degree simple curvatures are not excellent candidates for plaque incision and grafting surgery. Patients with normal erectile function should probably not undergo penile implant surgery unless they have a complex deformity or a significant hourglass deformity.

Plication-type procedures are best used in the patient with congenital penile curvature. This approach has a short surgical time, is relatively simple, and has little impact on existing erectile capacity. Plaque manipulation techniques are used in patients with complex deformities, hourglass deformities, normal erectile function, or preexisting penile shortening. Unfortunately, the disadvantages of this method are degeneration of erectile function or dysfunction and dorsal nerve entrapment or damage leading to penile neurosensory alterations. The use of a penile prosthesis in Peyronie's disease is reserved for men with preexisting

moderate-to-severe erectile dysfunction who have unsuccessfully tried oral and injectable agents.

PENILE PLICATION COMPLICATIONS

Complications of plication procedures include hematoma formation, decreased penile sensation (anesthesia, dysesthesia), erectile dysfunction, and bother from suture material palpable after the operation. We perform all dorsal plication procedures after neurovascular bundle elevation.[67,68] This approach minimizes the risk of decreased penile sensation in the postoperative setting. We recommend incising Buck's fascia and using loupe magnification to visualize the dorsal penile nerve bundles. We also use braided nonabsorbable suture (No. 1 polyester [Ti-Cron]) when performing plications because this material is less palpable and may reduce the incidence of patient bother from suture knots.

In 1998, Pryor reported data from 359 patients dating from 1977 to 1992 who had penile plication performed using the Nesbit technique.[69] The investigators convincingly argued that this technique translates into a high patient satisfaction rate (≤90%) while minimizing postoperative complications. These investigators found that Nesbit-related penile shortening was not a significant problem in this patient population; only six men were unable to have penetrative sexual relations because of this issue.[69]

A more contemporary series of 68 patients from Spain confirmed the findings of other reports.[70] At 36 months of mean follow-up, 20% of patients had penile shortening of >1.5 cm, but 85% of the men were satisfied with the cosmetic result of Nesbit technique. Complications of the surgical procedure were minimal; two men developed phimosis, and two needed a second procedure for recurrent curvature.[70] Pertinent results of these and other studies are contained in Table 52.3.

PLAQUE MANIPULATION SURGERY

The risk of complications from plaque-based surgery is low. Initial complications include hematoma (supragraft and subgraft) formation and, rarely, infection. Hematoma formation may be limited by the use of watertight suture lines, small-diameter suture needles, and narrow-gauge needles when erectogenic drugs are administered to generate an artificial erection. Intermediate and late complications are penile skin necrosis, penile length loss, and recurvature. Loss of penile skin, although rare, is caused by the circumferential skin incision. Because the skin of the penile shaft and the skin of the glans have a separate but anastomotic blood supply, we advocate the use of a single circumcising incision. If needed, a transverse scrotal incision can be made in addition to provide access to the proximal corpora.

The recurrence of curvature within a short period postoperatively is the result of either suture failure (we use 4-0 polydioxanone [PDS]) or an inadequately sized graft. Nonabsorbable or delayed-absorption suture must be used in grafting because the tunical forces developed during an erection far exceed the tensile strength of partially absorbed polyglactin (Vicryl, Ethicon, Somerville, NJ) or synthetic polyester (Biosyn, Syneture/US Surgical, Norwalk, CT).

The choice of the best grafting material has been the subject of quiet debate. Synthetic materials (e.g., Gore-Tex) are of historical significance because autologous and cadaveric (processed, prepackaged) grafts are readily available and provide fewer complications. Autologous material (e.g., buccal, dermal, tunical, vein), although available, incites minimal host reaction and infection risk and requires an auxiliary procedure to harvest.

An Italian group led by Montorsi assessed the long-term outcome of vein grafting in 50 patients with Peyronie's disease.[71] After a mean follow-up of 32 months, complete resolution of penile curvature in 40 men (80%), minor

residual curvature of ≤30 degrees in seven men (14%), and recurrence of curvature in three men (6%) were reported. The procedure was complicated by penile hypoesthesia, penile hematoma, wound infection, and glandular ischemia. Plaque incision with vein grafting is able to achieve satisfactory clinical results for a majority of men.[71] Wimpissinger et al. reported on 10-year outcomes of 30 men who underwent grafting with vein and 43.3% reported perceived penile shortening, 20% experienced penile hyposensitivity, and 23% experienced disease recurrence.[72]

As opposed to autologous grafts, processed or prepackaged material (pericardium, dura mater, intestinal submucosa) offers the ability to tailor the graft specifically to the appropriate size, minimizes the host inflammatory response, and abrogates the need for harvesting tissue. Levine and Estrada published their experience with human cadaveric pericardium.[73] Over a 4-year period, 40 men underwent penile curvature correction with pericardium. Postoperatively, 98% of these men had a straight penis and 95% were able to have penetrative sexual relations; 12 (30%) patients required pharmacologic assistance to achieve a penetration-quality erection. Most interesting is that no major complications occurred in this cohort of men.[73]

Breyer and Lue and their colleagues[74] retrospectively reviewed outcomes with and complications of using intestinal submucosa in the correction of penile curvature in Peyronie's disease. Nineteen patients were treated with tunical incision or excision and grafting with small intestine submucosa. Of these patients, 37% (seven of 19) had significant recurrent penile curvature, whereas five of 19 (26%) had recurrent Peyronie's disease plaque. The investigators reported a 37% complication rate, including graft site hematoma and graft infection, as well as reoperation for Peyronie's disease recurrence in a single patient.[74] Despite the ease of use of small intestine submucosa, the high complication rate makes the use of this material less desirable. The results of these and other studies are presented in Table 52.4.

PENILE PROSTHESIS SURGERY

Implant surgery for Peyronie's disease is indicated when the patient has both Peyronie's disease and erectile dysfunction that is not responsive to erectogenic pharmacotherapy. General complications of penile prosthesis insertion are listed elsewhere, but penile modeling deserves special comment. Modeling or molding entails powerfully bending the penis in an effort to break or crack the Peyronie's plaque when residual curvature remains after inflation of the device intraoperatively. This method was embraced by Wilson and Delk in 1994 and showed an initial 86% success rate.[75]

The specific technique is begun with the device partially inflated and the tubing cross-clamped with rubber shod hemostats. The penis is forcibly bent in a direction opposite to the curvature in a maneuver similar to breaking a twig in both hands for 90 seconds. The procedure is repeated for another 90 seconds. The device is deflated and then reinflated to reseat the cylinders within the corporal bodies.[76] Certain devices are ill advised when penile modeling may be required. The AMS Ultrex, with its girth- and length-expanding capabilities, may cause an increased risk of aneurysm formation when forcibly deformed. Furthermore, the Ultrex device lacks the axial rigidity to straighten a penile curvature.[77] Follow-up studies by Wilson and associates confirmed that implantation and modeling appeared to provide permanent straightening without an increase in revisions as compared with implantation alone.[76]

The major complication of corporal modeling is urethral laceration, which occurs in approximately 4% of cases.[76] This ulceration is usually visible and is repaired using fine absorbable sutures (Table 52.5).

Concomitant use of penile plication or plaque manipulation and penile prosthesis may be helpful in men with more significant Peyronie's disease and ED. Egydio and associates reported a 4.8% rate of decreased sensation and a 1% rate of infection in men who had circular and longitudinal

grafting.[78] Rolle et al. reported a 3.5% significant bleeding rate and 7% infection rate in 28 men who had severe penile shortening and underwent a sliding technique.[79]

Conclusions

Penile prosthesis insertion is associated with patient high satisfaction rate. Infection of a penile prosthesis and malfunction are the most common postoperative complications; however, advances in both device technology and surgical technique continue to lower the rates of these complications. Surgeons must also be aware of and know how to navigate other intraoperative and postoperative complications such as crural perforation, erosion, and drooping of the glans.

Surgical management of Peyronie's disease continues to play a vital role in the management of the disease. The complications associated with each of the surgical management options is an important factor in deciding which approach to take with each patient. Penile length, baseline erectile function, and degree of deformity are important factors to consider in counseling which surgical technique is most appropriate for any individual patient.

Chapter 52 Questions

1. What are the most common organisms that are associated with penile prosthesis infections?
   a. Multiple organisms
   b. Gram-negative organisms
   c. Gram-positive organisms
   d. Anaerobes
   e. Fungi

2. In the placement of a malleable penile prosthesis, during salvage of infection, which of the following principles is associated with penile necrosis?
   a. Limited use of an indwelling catheter
   b. Proper sizing of the corporal cylinders
   c. Circumferential penile compression bandage to minimize hematoma
   d. Rigorous sterility of the operative field
   e. Minimized prolonged cylinder inflation

Case Study 1

A 65-year-old man with a history of insulin-dependent diabetes and renal transplant has erectile dysfunction (ED) nonresponsive to PDE5 inhibitors and intracavernosal injections. He elects implantation of a penile prosthesis.

1. What device and technique has the highest rate of complications in this setting?
   a. 2-piece penile prosthesis
   b. 3-piece penile prosthesis with retropubic placement of the reservoir through the inguinal ring
   c. 3-piece penile prosthesis with submuscular reservoir placement anterior to the transversalis fascia
   d. Malleable prosthesis
   e. 3-piece penile prosthesis with counter incision for reservoir placement

2. The patient elects a 3-piece penile prosthesis with submuscular reservoir placement. During the operative procedure, the right distal corporal length is 10 cm, left distal corporal length is 10 cm, right proximal corporal length is 8 cm, and left proximal corporal length is 13 cm. What is the next best step?
   a. Insert an 18-cm cylinder length prosthesis with 5 cm of rear tip extenders on the left cylinder
   b. Place a Foley catheter and stop the procedure
   c. Insert an 18-cm cylinder length prosthesis and secure the left tubing at the corporotomy
   d. Dilate or use a Cavernotome to incise the fibrosis of the right corpora
   e. Create a mesh "windsock" in the left proximal corpora to buttress the left cylinder

3. The patient returns to you after two months reporting dissatisfaction with his glans. Specifically, he says that when penetrating his glans is bending ventrally, which causes some difficulty with sexual activity. The next step is to:
   a. Perform a glanuloplasty
   b. Replace the short cylinders with longer ones
   c. Advise him to take a phosphodiesterase-5 inhibitor to increase blood flow to glans
   d. Advise him to use a vacuum erection device to engorge the glans
   e. Remove the device to prevent erosion

4. He is continuing to complain of chronic penile pain that is exacerbated by inflation of the device 3 months postsurgery. His exam is negative for erythema, edema, fluctuance, and pump fixation. Your next step in management is:
   a. Reassurance that pain is common at this point after the procedure
   b. Refer to neurology for diabetic neuropathy
   c. Advise topical lidocaine, such as that used for premature ejaculation
   d. Refer to pain clinic
   e. Urinalysis, urine culture, serum chemistries, complete blood count, erythrocyte sedimentation rate

5. His test results are normal with the exception of a white blood cell count of 13, with 75% neutrophils and an ESR of 85 mm/h (normal 0–20). Which option is the LEAST appropriate step in management?
   a. Initiate broad-spectrum antibiotics after obtaining blood cultures
   b. Remove all components of the penile prosthesis and plan for delayed reimplant
   c. Remove all components of the penile prosthesis, perform extensive washout, and immediately reimplant prosthesis
   d. Meticulous control of blood glucose
   e. Observe

Case Study 2

A 57-year-old man presents with painful penile curvature for 2 months. He has right-sided plaque with 45-degree curvature in the middle third of his penile shaft. There is no instability or hourglass deformity.

1. Which of the following is the best treatment option?
   a. Penile plication
   b. Plaque incision and grafting
   c. Intralesional collagenase clostridium histolyticum
   d. Placement of penile prosthesis
   e. Observation

2. Which of the following is NOT an indication for penile curvature correction surgery?
   a. He dislikes the appearance of the penis
   b. He is unable to penetrate his partner
   c. His deformity is stable for at least 3 months
   d. The patient is going on a cruise with his partner next month and wants to have the deformity corrected before this
   e. He and his partner find sexual activity cumbersome or unsatisfactory

3. After 3 months of observation, the patient's deformity is unchanged and stable. When discussing penile plication, which of the following complications is LEAST likely?
   a. Erectile dysfunction
   b. Altered penile sensation
   c. Recurrence of disease
   d. Palpable sutures
   e. Hematoma

Answers

1. **c.** Seventy-three percent of positive cultures grow gram-positive bacteria, 39% grow gram-negative organisms, and 25% grow multiple organisms.
2. **c.** While it is tempting to place circumferential penile compression bandages to minimize hematoma and further chance of infection, these can be associated with penile necrosis.

CASE STUDY 1

1. **b.** A 3-piece penile prosthesis is often desired by the patient because it more closely reproduces physiologic erections. Placing the reservoir into the retropubic space through the inguinal ring is a common technique that is generally safe. However, very rarely, it is associated with serious complications, such as injury to bowel, bladder, or pelvic vascular structures. This is more likely in patients with pelvic surgery such as renal transplant. While retropubic placement of the reservoir through the inguinal ring can often be safely done, it does have the highest rate of these complications.
2. **c.** Be suspicious of any significant discrepancy in corporal length. The patient has a left crural perforation. While placing a mesh windsock is one option, it is often easier and just as effective to secure the exit tubing to the corporotomy with a suture hammock.
3. **a.** The patient has a dropping glans or supersonic transporter (SST) deformity, named after the discontinued supersonic commercial airplane which required the cockpit to droop downward in order to enhance the pilot's visualization. This issue may be remedied through a subcoronal incision and dissociation of the glans penis from the distal ends of the corporal bodies with subsequent fixation.
4. **e.** By 3 months postsurgery, his postsurgical pain should be significantly improved. You should be concerned about a late infection of the penile prosthesis.
5. **e.** The patient likely has a late infection of the penile prosthesis and should be started on broad-spectrum antibiotics. Given his insulin-dependent diabetes, glucose control, possibly with the assistance of the endocrinology team, is important. Removal with either delayed or immediate reimplantation is a viable option, but observation is not.

CASE STUDY 2

1. **e.** The patient has pain and is 3 months into his disease, and thus he is still in the active phase. All the other options are only appropriate for patients with stable disease.
2. **d.** It is inappropriate to perform a surgical correction on a patient with active disease, regardless of how eager the patient is to proceed with surgery.
3. **a.** Unlike plaque incision and grafting, plication does not alter the veno-occlusive mechanism important to maintaining erections. While the other options are all possible complications, erectile dysfunction is not expected after plication.

Radical and Partial Orchiectomy Procedure
Management of Specific Complications
Conclusions
Chapter 53 Questions and Answers

KEY POINTS

1. Scrotal surgical procedures are among the most common performed by urologists. With proper surgical planning, meticulous operative technique, and thoughtful postoperative care, the risk of complications can be minimized.
2. Blood-thinning agents should be stopped at appropriate time points preoperatively and scrotal gauze compression dressings with ice should be used postoperatively in order to decrease the risk of bleeding and scrotal hematoma formation after scrotal procedures.
3. Even if a patient has had a successful vasectomy (i.e., azoospermia or rare non-motile sperm on a fresh post-vasectomy semen analysis test), he still has a 1 in 2000 risk of future pregnancy. This complication is due to recanalization of the vas deferens.
4. The use of an operating microscope not only improves technical outcomes, but also decreases the risk of postoperative complications for surgical procedures such as microsurgical varicocelectomy and micro-TESE.
5. Scrotal ultrasonography is a noninvasive, inexpensive, and readily available imaging modality that can provide invaluable information when concerns arise regarding scrotal surgical complications.

Introduction

Surgery of the scrotum and its contents constitutes a significant proportion of outpatient and physician office-based surgeries. Despite many of the procedures being considered minor surgery, there is potential for significant complications that may be a source of tremendous pain and cost to the patient and health-care system.

Anatomy

An understanding of the anatomy of the scrotum and its contents is essential to executing safe and effective operative techniques required to treat intrascrotal pathology and minimize complications.

The scrotum is a two-layer musculocutaneous sac consisting of an outer skin layer and an inner smooth muscle

Table 53.1 Incidence of Common Scrotal Surgical Complications

Scrotal Surgical Complication	Vasectomy (%)	Varicocelectomy (%)	Sperm Extraction Procedures (%)	Vasectomy Reversal (%)	Hydrocelectomy (%)	Spermatocelectomy (%)	Orchiectomy (%)
Hydrocele	<1%	1–2% (microsurgical) 7% (nonmagnified)	<1%	<1%	1–6% (recurrence)	5–10%	N.A.
Scrotal hematoma	1–2%	1–2%	1–2%	1–2%	1–5%	1–5%	1–2%
Infection	1–2%	<1%	<1%	<1%	1–4%	1–4%	1%
Chronic pain	1–15%	<1%	<1%	<1%	<1%	<1 %	1–2%

dartos layer.[1] The dartos layer is continuous with Scarpa's fascia and is responsible for the ruggae of the scrotal wall. Dissection through the skin and dartos layers brings the surgeon to the external spermatic fascia, which is a thin connective tissue continuation of the external abdominal oblique aponeurosis. Dissection through the external spermatic fascia reveals the cremasteric fascia, which is a continuation of the aponeurosis of the internal oblique and transverse abdominal muscle. The innermost scrotal fascial layer is the internal spermatic fascia and is a continuation of the transversalis fascia. Dissection through all three intrascrotal fascial layers (external spermatic, cremasteric, and internal spermatic) reveals the tunica vaginalis. The tunica vaginalis is an enclosed peritoneal sac that is composed of a parietal tunica vaginalis that is adjacent to the internal spermatic fascia, and the visceral tunica vaginalis that is adjacent to the testicle.

The testicle surface is almost entirely surrounded by the visceral tunica vaginalis, except on its posteriolateral surface where it is connected to the epididymis.[2] The epididymis is composed of a head (caput), body (corpus), and tail (cauda) sections, which connect to the vas deferens.

Familiarity with the blood supply to the scrotum, testicle, epididymis, and vas deferens are essential in order to reduce the risk of complications during surgery. The blood supply to the scrotum is divided into the anterior and posterior scrotal arteries; the anterior arteries arise from the external pudendal branches of the femoral artery, while the posterior scrotal arteries arise from the perineal branch of the internal pudendal artery.[1] The scrotal vein drainage accompanies the arterial supply. The blood supply to the testicle is via the testicular artery (arising from the aorta), artery of the vas deferens (arising from the inferior vesical artery), and the cremasteric artery (arising from the inferior epigastric artery). The major testicular venous drainage is via the pampiniform plexus into the testicular vein, which drains into the inferior vena cava on the right and the renal vein on the left. Additional routes for venous drainage include the deferential and cremasteric veins.[3] Lymphatic drainage of the right testicle is to the paracaval, interaortocaval, and, to a lesser degree, the para-aortic nodes. The left testicle drains to the para-aortic and interaortocaval nodes.[2]

General Considerations in Scrotal Surgery

Procedures involving the scrotum and its contents are performed for a variety of indications, including malignancy, infection, infertility, contraception, pain, and cosmesis. Common, nonprocedure-specific scrotal surgical complications include hematoma, hydrocele, infection, and chronic pain (Table 53.1).

One of the most common and easily preventable complications of scrotal surgery is postoperative hematoma formation. Given the highly vascular nature of the scrotum and its contents, it is imperative that meticulous hemostasis is achieved prior to and during closure of the layers of the tunica albuginea, tunica vaginalis, fascia, dartos, and scrotal skin. Any unrecognized oozing vessel or vessel in spasm that is missed can result in considerable hematoma formation.

For most scrotal procedures, access to the scrotal contents can be obtained via a vertical median raphe incision or a transverse hemiscrotal incision. During closure of the scrotum, the forgiving nature of ruggae permits good cosmetic results even when using a running horizontal mattress closure.

Bleeding with hematoma formation is a major complication concern that can be reduced in patients taking antiplatelet and anticoagulation medications. In general, antiplatelet agents and nonsteroidal antiinflammatory agents (NSAIDs) should be stopped approximately 1 week prior to surgery, with the approval of the prescribing physician. Anticoagulant agents should also be stopped prior to scrotal surgery, with use of bridging therapy based upon clinical indication. Again, it is important to involve the prescribing physician in any changes made in the administration of these medications. Additional information regarding hematologic surgical considerations are discussed in Chapter 4, "Hematologic Complications," of this book.

Preoperative scrotal shaving should be performed at the time of surgery, as opposed to the night before, in order to reduce the risk of surgical site skin infection.[4] The removal of excess scrotal hair helps with visualization of the tissue and avoids hair entanglement with suture material. When hair removal is undertaken, the use of razors results in lower risk of infections than with clippers.[5]

Preoperative and postoperative antibiotic administration is operation dependent.

Anesthesia for scrotal procedures can be provided by general, spinal, epidural, or local anesthesia (with or without sedation). In practice, general and local anesthesia are the most commonly utilized forms of anesthesia, depending on the procedure.

Local anesthesia, administered via a spermatic cord block, is of paramount importance to master and is routinely used for numerous scrotal surgical procedures. With

a spermatic cord block, many procedures can be performed in the office setting with the patient awake. A spermatic cord block is commonly achieved using 10 mL of a 50:50 mix of 0.5% Marcaine and 1% lidocaine. The scrotal skin is initially injected with 2–3 mL of local anesthetic over the site of intended incision in order to create a wheal. Distraction techniques, such as gentle jiggling of the surrounding tissue, can be employed to help reduce the discomfort associated with the injection. The vas deferens is then isolated with the thumb and forefinger, and approximately 5 mL of local anesthetic solution is injected around it using a 25-gauge (or smaller) needle. An additional 2–3 mL of local anesthetic is injected while withdrawing the needle. Repeated advancement of the needle "in and out" during the injection should be avoided, as this approach increases the risk of vessel injury, bleeding, and scrotal hematoma formation. During closure, additional local anesthetic can be injected into the layers between the tunica vaginalis and dartos or the dartos and skin. Infiltration of the skin can be performed following skin closure.

Complications Common to Scrotal Surgery

Postoperative hematoma formation is a risk common to all types of scrotal surgery, but its incidence varies with the degree of scrotal violation. Scrotal hematomas commonly arise due to inadequate hemostasis at the time of wound closure, and they often result from inadequate visualization of a vessel in vasospasm. Nonexpanding hematomas can be managed conservatively with rest and scrotal compression using scrotal gauze dressings, ice packs, and an athletic supporter. While the diagnosis is usually self-evident, most specialists will typically order a scrotal ultrasound at the time of presentation to characterize the hematoma and quantify its size (Fig. 53.1). Hematomas typically resolve without surgical intervention over the following weeks and months, and they can be followed serially by physical examination. A hematoma that is expanding or is accompanied by evidence of infection requires surgical intervention with evacuation of the hematoma and hemostasis of the bleeding vessels. In most cases, no identifiable vessel is found during surgical exploration. A Penrose drain should be left in place postoperatively after clot evacuation to ensure drainage during the healing process. The risk of bleeding varies from 1% to 2% with vasectomy, varicocelectomy, and vasectomy reversal; to 4% in hydrocele aspiration and sclerosis; up to 5% in spermatocelectomy; and 1–5% in hydrocelectomy.[6] While bleeding following orchiectomy can occur, only 2% of men require intervention. More concerning is the risk of a retroperitoneal bleed due to cord retraction at the time of inguinal orchiectomy. While this is rarely severe bleeding, even small hematomas can mimic recurrent disease on follow-up CT. Use of preoperative CT or postoperative MRI with subtraction sequences may help in avoiding this problem.

The risk of scrotal hematoma and postoperative bleeding after scrotal surgery can be mitigated through the use of scrotal dressings that apply direct pressure to the scrotum circumferentially (Fig. 53.2). In cases of chronically inflamed or large hydrocele sacs, a trans-scrotal Penrose drain can be used to help reduce the risk of hematoma.

The risk of postoperative infection is low with most scrotal surgical procedures, and it is greatest in the setting of postoperative hematoma. Use of prophylactic antibiotics is individualized by case; they should be routinely used in hydrocele and orchiectomy, but rarely used, for example, in vasectomy. In high-risk patients, such as the immunocompromised individual or those with diabetes mellitus, antibiotics can be used at the surgeon's discretion. Infections should be treated aggressively to prevent Fournier's gangrene.

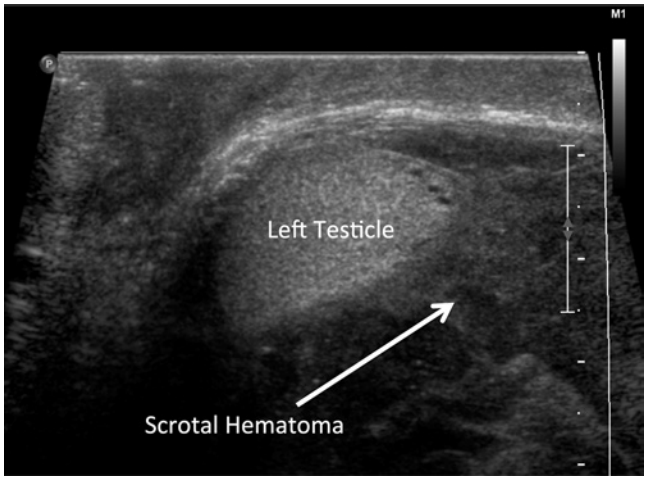

Figure 53.1 Ultrasound image revealing a left hemiscrotal hematoma surrounding the left testicle.

Figure 53.2 A scrotal supportive pressure dressing comprised of copious amounts of gauze that is form-fitted around the scrotum and secured in place by an athletic supporter. This pressure dressing minimizes the risk of postoperative bleeding and scrotal hematoma formation.

Vasectomy

Vasectomy is the only form of permanent male contraception, and this procedure is performed on more than 500,000 men annually in the United States.[6] Despite being a fast, low risk, and cost-effective form of contraception, it still remains an underutilized form of permanent contraception compared to tubal ligation in women. In couples in the United States between the ages of 15 and 45, 17% of female partners elected to undergo tubal ligation, compared to 6% relying on the male partner to undergo a vasectomy.[7,8] Despite the increased cost, procedure time, and risk of complications associated with tubal ligation, it remains the more utilized permanent sterilization procedure due to many factors, including cultural issues and a limited awareness of vasectomy.[8]

A pre-vasectomy consultation is essential in preparing the patient and the physician for the procedure and informing the patient about possible complications. Some states mandate that the consultation occur at least 1 week (in some states such as New York, at least 1 month) prior to vasectomy in order to give the patient time to consider treatment alternatives. A full history and physical examination is required, as well as counseling to assess his interest in future paternity, his knowledge and expectations about the procedure, and postoperative contraception requirements. Studies have shown that 10–19% of males harbor a desire to father children post vasectomy, with approximately 6% of men undergoing a vasectomy reversal within a 5-year period afterward.[9–11] This emphasizes the importance of informing the patient about the permanency of a vasectomy during the preoperative counseling. While "post-vasectomy regret" is not commonly regarded as a procedural complication, proper counseling might avert a procedure in a patient who is uncertain about his actual desire for future paternity.

An examination of the vas deferens in the pre-vasectomy consultation is critical to ensure the anatomy is conducive to performing the procedure under local anesthesia in the office setting. Patients with challenging anatomy due to morbid obesity, a high riding testicle, a spermatic cord lipoma, or a hypoplastic scrotum might be better served by having their procedure performed under intravenous sedation or general anesthesia. This approach can help optimize patient comfort and technical feasibility of the procedure.

VASECTOMY PROCEDURE TECHNIQUES

Vasectomy is typically performed in the physician's office or in the outpatient surgery center, usually under local anesthesia. The patient is placed in the supine position in a warm room to permit scrotal relaxation. Prophylactic antibiotics are not required (although some high-volume surgeons do administer them). For a right-handed surgeon, the right vas deferens is isolated while standing on the right side of the patient using the thumb (anteriorly) and middle finger and index fingers (posteriorly). The mid-to-upper scrotal vas deferens should be isolated high in the scrotum, and then a spermatic cord block is placed using the previously mentioned local anesthetic solution. As described in the American Urological Association Vasectomy Guidelines, the procedure can be performed using a "minimally invasive vasectomy" (MIV) technique to isolate the vas deferens, such as the "no-scalpel vasectomy" (NSV) technique. The NSV approach has shorter procedure times and less risk of infection, bleeding, and hematoma formation.[12]

No-scalpel vasectomy is performed with a sharp curved hemostat instead of a scalpel. After the spermatic cord block is placed, dissection through the skin is accomplished using a single arm of the sharp curved hemostat followed by dilating the skin with the hemostat. Continued dissection to the vas deferens through the dartos and peri-vasal sheath is accomplished with the hemostat. The vas deferens is secured and brought out through the incision with a vasal clamp. Once a 1.5–2 cm segment of vas deferens has been dissected out of the sheath, a 1-cm segment of vas deferens is sharply excised. This segment does not need to be sent for pathologic confirmation under the current AUA guidelines. The vas deferens is doubly ligated with either hemoclips or 2-0 silk ties. Vasal occlusion of the vasal ends is achieved via electrocautery to the vasal edges and lumen. Fascial interposition is achieved by securing spermatic fascia between the testicular and abdominal vasal ends. This combination of ligation, cautery, and fascial interposition has been shown to reduce vasectomy failure rates.[13] There is no need for skin suturing due to contraction of the wound to 2 mm in size after cautery.[14]

After vasectomy, the following steps can be taken to promote healing and minimize the risk of complications. Scrotal ice packs, scrotal gauze dressings, and a compressive scrotal supporter are applied for approximately 24 hours to reduce pain as well as the risk of swelling and hematoma. Exercise and strenuous physical activity should be limited for 5–7 days, although driving can resume after 1–2 days if the patient is not taking narcotics. Patients should refrain from ejaculation for 7 days after the vasectomy. Analgesia with scheduled acetaminophen is usually sufficient for postoperative pain management. Per the AUA Vasectomy Guidelines, it is critical that patients use an alternate form of contraception until the mandatory post vasectomy semen analysis (PVSA) test reveals one test with azoospermia at any point post vasectomy, or rare nonmotile sperm (<100,000/mL) in one well-mixed, uncentrifuged fresh post-vasectomy semen specimen. In the past, the recommendation had been for two negative PVSA.[15] Compliance with the requirement for a negative semen analysis is low, with only 50% of patients supplying one or more negative semen analyses in contemporary studies despite verbal and written instructions provided to the patients.[16] The time period is variable for men to achieve an azoospermic PVSA and typically requires at least 20 ejaculations.[17] Recent 2016 British Best Practice guidelines recommend the first PVSA should occur at a minimum of 12 weeks and be analyzed within 4 hours.[18] PVSA performed >12 weeks post vasectomy have a 93% likelihood of having a negative analysis.[15,19] It is important to inform patients that even in the setting of an azoospermic PVSA, there still remains a risk of recanalization and, with that, a 1 in 2000 risk of future pregnancy.[20]

MANAGEMENT OF SPECIFIC COMPLICATIONS

Common complications associated with vasectomy procedures are listed in Table 53.1.

Testicular artery injury/ligation can occur during the course of the vasectomy procedure. In most instances, collateral flow from the cremasteric artery and deferential artery will sustain the testicle. Care should be taken, however, to avoid testicular artery injury or ligation, because these collateral vascular structures might not be well developed in all men. Furthermore, men who have undergone a prior herniorrhaphy, orchidopexy with Fowler-Stephens approach, or varicocelectomy might have had either intentional or inadvertent ligation of the testicular, deferential, and/or cremasteric arterial vessels in the course of those procedures. For men with such prior surgical history, extreme care should be taken to avoid an arterial injury during vasectomy that could lead to ischemic loss of the testicle. There are no substantial published data on testicular artery repair in the setting of vascular injury during vasectomy.

Vasectomy failure is defined by the presence of motile sperm on PVSA and can be divided into early or late. *Early failure* occurs in 0.3–13% of vasectomies and results from early recanalization or technical error with failure to divide the vas deferens.[21] If motile sperm are found on the first PVSA at 8–16 weeks, management includes repeat semen analysis every 4–6 weeks because spontaneous occlusion of early recanalization can occur in over 50% of men, resulting in "delayed vasectomy success."[21] If motile sperm persist >6 months post vasectomy, a repeat vasectomy is required as vasectomy failure has occurred.

"Late failure" This complication occurs due to recanalization of the vas deferens months or even years after sterilization has been performed. The risk of pregnancy is 1 in 2000 for men who achieve azoospermia or have rare nonmotile sperm in their postvasectomy semen analysis.

Sperm granulomas occur in less than 5% of vasectomized men.[20] They result from inflammation triggered by leakage of sperm from the testicular vasal end, and, although they can occur following any type of vasectomy, they are most commonly associated with the open testicular end approach. Sperm granulomas may be palpable and symptomatic, but pain is usually temporary. In rare patients, the associated discomfort may become chronic in nature. For patients with symptomatic sperm granuloma's, conservative management with oral NSAIDs is usually effective at alleviating inflammation and tenderness. If, however, there is persistent pain or continued granuloma enlargement, excision of the sperm granuloma can be considered.

Post vasectomy pain syndrome (PVPS) has been reported in up to 15% of patients, but only 1% of these men report an impact on their quality of life.[24] Among men with PVPS, only about 1% choose to undergo additional surgical intervention.[25] The pain is most commonly caused by chronic epididymal congestion with or without inflammation (epididymitis), but other causes include nerve entrapment, neuroma, or sperm granuloma formation. Surgical interventions available include vasectomy reversal, epididymectomy, spermatic cord denervation, sperm granuloma excision, and, if all else fails, orchiectomy. Vasectomy reversal in carefully selected patients with PVPS has been shown to result in an 82% chance of pain improvement, with one-third of patients reporting complete resolution of their pain.[26,27] Epididymectomy is associated with a 93% success rate in reducing pain in men with PVPS, and close to 25% of men undergoing this procedure report resolution of all pain.[28] Spermatic cord denervation is being increasingly used to treat chronic scrotal pain, including PVPS. In the setting of PVPS, 76% of patients who underwent spermatic cord denervation were found to have resolution of their pain, and the remaining 24% experienced an improvement in their discomfort.[29]

Fistula formation is a rare complication that can occur in the form of a vasovenous or vasoarterial fistula.[30,31] Vasovenous fistula may present with an initial postoperative hematoma that progresses over weeks or months to hematuria. The mechanism is believed to be fistula formation due to chronic inflammation at the site of clip or suture placement. Cystoscopy may demonstrate blood emanating from the ipsilateral ejaculatory duct. Treatment consists of scrotal exploration, ligation, and excision of the fistula. Vasoarterial fistulas are also rare but may occur when a suture perforates an artery resulting in a vasoarterial connection. Scrotal exploration is indicated in these patients, and attempts are made to spare the arterial structure if possible.

LONG-TERM CONSIDERATIONS

Some controversy has arisen over the years regarding the possible association between vasectomy and the risk of developing aggressive *prostate cancer*. However, evidence to date suggests that there is no correlation between vasectomy and the future risk of prostate cancer.[15,32] Likewise, a concern about the association between vasectomy and testicular cancer arose following small case control studies in the 1980s.[33,34] However, a subsequent large-scale population analysis involving close to 74,000 vasectomized men found no increased risk of either testicular cancer or acceleration of preexisting testicular carcinoma in situ.[35]

Initial concerns about an association between vasectomy and an increased risk of *coronary heart disease* (CHD) arose following studies on vasectomized monkeys, where advanced atherosclerosis was identified.[36,37] The authors hypothesized that post vasectomy anti-sperm antibody immune complexes may have contributed to atherosclerosis. The overwhelming body of evidence in humans has found no association between vasectomy and future risk of CHD, with one study showing that men who underwent vasectomy actually had a lower risk of CHD[15,38,39]

Primary progressive aphasia (PPA) is a rare variant of frontotemporal dementia that was found in a small case control study to be associated with a prior history of vasectomy and anti-sperm antibodies.[40] The association between anti-sperm antibodies and dementia has not been further established in larger studies nor has there been any association of anti-sperm antibodies with severe immune-related diseases.[41,42]

Vasectomy was also not found to be associated with an increased overall *mortality* following a retrospective study comparing 14,000 vasectomized and nonvasectomized men.[43]

The AUA Guidelines on Vasectomy state that the above issues need not be discussed with patients given the lack of evidence supporting an association between them and vasectomy.

Varicocelectomy

A varicocele is an abnormal dilation of the pampiniform venous plexus within the spermatic cord. Varicoceles represent the most common surgically correctable form of male infertility with approximately 37,000 varicocelectomies performed annually in the United States.[44] An estimated 15% of the general male population have clinically evident varicoceles. This prevalence increases to 35% of males with primary infertility and 80% of males with secondary infertility.[45–47] Varicoceles are associated with reduced semen parameters (specifically sperm concentration and motility), hypogonadism, and testicular atrophy.[48,49] Left-sided and bilateral varicoceles account for the majority of cases, and solitary right-sided varicoceles should prompt retroperitoneal imaging to rule out pathologic processes obstructing the right gonadal vein. Varicoceles are most commonly asymptomatic, but they may present with pain or a scrotal mass.

INDICATIONS FOR REPAIR

Indications for intervention include the presence of a clinically palpable varicocele with:

1. Abnormal semen parameters in an infertile male whose partner has either no female factor issues or else a correctable female factor issue
2. Abnormal semen parameters in a male not currently trying for a pregnancy but who is interested in repair
3. Ipsilateral testicular volume discrepancy
4. Varicocele symptoms (reproducible pain that is elicited when the patient is erect or sitting) that are typically relieved when the patient is in the supine position.

Varicocelectomies should *not* be performed on asymptomatic men with normal semen parameters or in cases of subclinical (nonpalpable) varicoceles.

VARICOCELE REPAIR TECHNIQUES

Interventions include surgical correction and percutaneous radiologic embolization. Surgical options include high ligation via an open retroperitoneal or laparoscopic approach, or low ligation via inguinal and subinguinal approaches.

The open retroperitoneal approach was initially described by Palomo in 1948 and involves isolation of the internal spermatic vessels above the internal inguinal ring via an incision made 3–4 cm medial to the anterior superior iliac spine.[50] Dissection proceeds down through Campers and Scarpa's fascia, continuing through the external and internal oblique (with care to avoid to the ilioinguinal nerve) and transversus abdominis muscles. Once in the retroperitoneum, the vessels can be identified, ligated, and divided. The retroperitoneal technique has a high recurrence rate (up to 15%), as it fails to ligate the external spermatic vessels. The hydrocele formation rate is also higher than with other approaches, as the lymphatics vessels are ligated en bloc with the surrounding vessels. Testicular atrophy is uncommon due to collateral arterial supply via the external spermatic and vasal arteries. Once the internal spermatic vessels are ligated and divided, each layer of the abdominal wall is closed. The advantage of the retroperitoneal approach is its speed and need to typically ligate only one to three veins.

The laparoscopic approach has similar outcomes to the open retroperitoneal approach, as it targets ligation of the internal spermatic vessels above the internal ring. Although artery-preserving laparoscopic techniques have been described, the majority of laparoscopic procedures fail to preserve arteries or lymphatics. As a result, the recurrence and hydrocele rates are similar to the open retroperitoneal approaches. Given that this approach is intraperitoneal, the laparoscopic approach also runs the risk of injury to viscera and vasculature.

The microsurgical open approach has largely replaced the open nonmagnified approach, as magnification optimizes identification and isolation of the veins, arteries, and lymphatics. Magnification assists in reducing the risk of recurrence, testicular atrophy, and hydrocele formation.

The microsurgical inguinal approach is performed via a 3- to 4-cm incision above the external ring, with dissection down to and through the external abdominal oblique. The spermatic cord is identified and brought to the skin surface. The operating microscope is then maneuvered into the field to assist in visualization, identification, and preservation of arteries and lymphatic vessels. Additionally, the operating microscope assists in identification and ligation of the external and internal spermatic veins. The inguinal approach is not fascia sparing, which might increase the postoperative recovery time and pain in some patients over the subinguinal technique.

The microsurgical subinguinal approach is a fascia-sparing procedure that avoids dissection through the external aponeurosis. A 3-cm incision is made over the external ring, and dissection proceeds down through Campers and Scarpa's fascia until the spermatic cord is identified (Fig. 53.3A). The cord is then isolated and brought out through the incision site. Some surgeons will deliver the entire testicle into the field in order to identify, ligate, and divide the gubernacular veins.[51] The external and internal spermatic fascia of the spermatic cord are opened, revealing the internal spermatic veins, testicular artery, lymphatic vessels, and vas deferens. Anatomic studies have shown that the more distal subinguinal approach is slightly more time consuming due to the increased number of veins that require ligation, as well as the increased number of arterial branches that need to be avoided. Despite this, the subinguinal approach has become the preferred choice for most subspecialists due to the reduced postoperative pain levels and recovery times, as well as the lowest rates of recurrence, hydrocele formation, and testicular atrophy.[52,53] A microsurgical Doppler unit can be used intraoperatively to help identify and preserve the testicular artery. This piece of equipment is extremely important in minimizing the risk of testicular artery injury, inadvertent testicular artery ligation, and potential loss of the testicle (Fig. 53.3B).

MANAGEMENT OF SPECIFIC COMPLICATIONS

Common complications associated with varicocelectomy procedures are listed in Table 53.1.

While varicocelectomy is not truly an intrascrotal procedure, many of the same complications that can occur as a

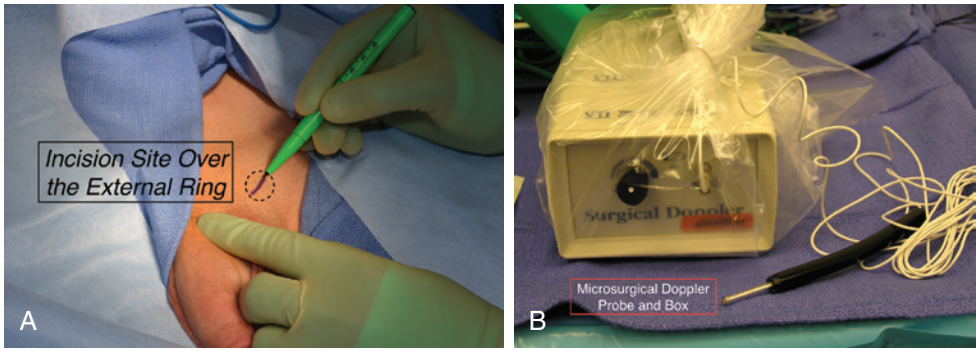

Figure 53.3 A, Intraoperative photograph depicting a left subinguinal incision site marked over the left external ring. The subinguinal approach is used in microsurgical subinguinal varicocelectomy, and this technique has lower recurrence rates and lower overall complication rates than do laparoscopic, retroperitoneal, and inguinal approaches. B, The microvascular Doppler ultrasound (20 megahertz) unit facilitates intraoperative identification and preservation of arterial vascular structures during microsurgical varicocelectomy.

result of intrascrotal surgery can also arise during and after varicocelectomy procedures (Table 53.1). Several complications are unique to varicocelectomy, however, and these vary depending on the surgical approach used.

The fascia-sparing subinguinal approach has the lowest level of associated postoperative pain and the fastest associated time for return to work, with a median time of 8 days.[54] The laparoscopic approach has a similarly rapid recovery period and a relatively low level of postoperative pain. The open, muscle splitting inguinal and retroperitoneal procedures have the greatest relative postoperative pain and time to return to work outcomes.

Ilioinguinal nerve injury can result in paresthesia or pain over the scrotum and medial thigh. These symptoms usually resolve over a period of weeks to months with conservative management. Severe pain may develop due to *ilioinguinal nerve entrapment* following an inguinal approach. In patients with persistent, intractable pain who have relief following a nerve block, a neurectomy or microsurgical cord denervation procedure have both been shown to improve pain control.[55,56] *Varicocele persistence or recurrence* can occur when there is failure to ligate venous collaterals in the internal and external spermatic venous system. Rates of recurrence are lowest with the microsurgical subinguinal approaches (0–2.6%) and higher in the open nonmagnified inguinal approach (5–17%).[51,54,57] The open retroperitoneal and laparoscopic approaches have comparably high recurrence rates of 5–15%. This high rate is due to ligation of only the internal spermatic vein(s) at the level of the internal ring, and the untreated external spermatic veins can contribute to persistence or recurrence.

It is common for the ligated varicocele to remain palpable for months following the procedure. In the setting of suspected varicocele recurrence/persistence, a scrotal ultrasound demonstrating dilated veins with reversal of flow on Valsalva maneuver confirms the diagnosis. If there is evidence of recurrence/persistence, then treatment options include reoperation via a microsurgical subinguinal/inguinal approach or radiographic embolization. If reoperation with a microsurgical approach is pursued, delivery of the testicle with gubernacular vessel ligation can be considered to reduce the likelihood of ongoing recurrence/persistence.

Hydrocele formation following varicocelectomy results from deliberate or inadvertent ligation of the lymphatic vessels.[58] Microsurgical approaches carry the lowest risk of hydrocele formation (0–0.69%) due to enhanced visualization of lymphatic vessels, which facilitates their preservation. Hydrocele risks are significantly higher for the open nonmicrosurgical inguinal (3–30%), retroperitoneal (15–25%), and laparoscopic approaches (5–15%) when compared to lower subinguinal approaches.[51,54,57] Asymptomatic small hydroceles can be managed conservatively while large symptomatic hydroceles might require intervention, based on degree of patient bother. Postoperative hydrocele formation will require a hydrocelectomy in 10–15% of patients.[59]

Interestingly, ligation of the lymphatic vessels can cause in rare cases a dramatic increase in testicular size, which is due to biopsy-proven interstitial testicular edema.[60] This edema-induced *pseudohypertrophy* is associated with impaired spermatogenesis. Pseudohypertrophy, particularly in adolescent males, should be suspected in the setting of rapid testicular enlargement in the 6 weeks–6 months following a varicocelectomy, as physiologic "catch up growth" takes considerably longer in adolescents with varicocele-induced testicular size discrepancy.

Testicular atrophy results from injury to the testicular arterial supply (testicular artery, external spermatic artery, and vasal artery) and is uncommon, occurring in <1% of all approaches.[52,61] The lowest rates of arterial ligation occur with the microsurgical approaches due to superior visualization, identification, and preservation of the arteries. During the open retroperitoneal and the laparoscopic approaches, the internal spermatic artery is commonly ligated along with the vein. However, testicular perfusion is maintained via the collateral vasal artery and the external spermatic artery blood supplies.[62] Chan et al. reported on testicular artery microsurgical repair after accidental ligation during varicocelectomy. These authors repaired the injured vessels in two patients, although the deleterious impact of each event might have been mitigated because each patient also had an intact vasal artery and one additional intact testicular artery. In order to mitigate the risk of vascular injury in men with a solitary testicle or a history of previous inguinal surgery, microsurgical techniques are advisable.

Superficial dorsal penile vein thrombosis is a rare complication that has been reported to occur in 2.1% of subinguinal varicocelectomies.[63] This condition can present 2–3 weeks

after varicocelectomy, after resumption of sexual activity, with pain and a thickened cord-like induration on the dorsal aspect of the penis. This condition typically arises due to injury of the superficial dorsal penile vein as it traverses the groin to drain into the left femoral or great saphenous vein. The injury likely initiates thrombus formation with retrograde propagation, causing the pain and induration on the dorsum of the penis. The management is conservative measures with NSAIDs and abstinence from sexual activity until resolution occurs after 3–6 weeks.

Sperm Extraction Procedures

Substantial advancements have been made in the field of reproductive medicine over the past 25 years, and these have given rise to improved paternity rates via assisted reproductive technologies such as IVF/ICSI. For many patients with azoospermia, surgical sperm retrieval is required in order to extract sperm for use in assisted reproduction. This approach has expanded the role of microsurgical techniques, which have largely replaced macroscopic approaches for many sperm extraction procedures.

SPERM EXTRACTION PROCEDURE TECHNIQUES

Sperm retrieval procedures are performed in both cases of obstructive and nonobstructive azoospermia. Obstructive azoospermia occurs in the setting of congenital bilateral absence of the vas deferens, idiopathic and acquired epididymal obstruction, ejaculatory duct obstruction, vasectomy, and failed vasectomy reversal. In the case of obstructive azoospermia, spermatogenesis is intact, which permits sperm retrieval via either microsurgical epididymal sperm aspiration (MESA) or percutaneous epididymal sperm aspiration (PESA) techniques. In the event that sperm are not retrieved via epididymal aspiration, testicular sperm extraction (TESE) or microdissection testicular sperm extraction (Micro-TESE) can be attempted.

In patients with nonobstructive azoospermia, the absence of sperm in the ejaculate is not necessarily synonymous with complete absence of sperm in the testicle. In greater than 50% of patients with nonobstructive azoospermia, viable sperm will be found using the micro-TESE technique.[64] Micro-TESE has emerged as the gold standard for testicular sperm retrieval in nonobstructive azoospermia due to higher sperm retrieval rates (SRRs) and a lower risk of complications.[65–67] In certain instances of nonobstructive azoospermia, such as genetic mutations of the entire AZFa and AZFb regions of the Y chromosome, there is no benefit to attempting sperm retrieval due to complete absence of spermatogenesis.[68] The main surgical options for nonobstructive azoospermia are Micro-TESE, TESE, percutaneous testicular biopsy (PTB), and fine needle aspiration (FNA).

Micro-TESE utilizes an operating microscope with 15–25 × magnification to inspect the seminiferous tubules for evidence of spermatogenesis and usually involves a midtesticular horizontal incision. The testicle is delivered into the field and the tunica vaginalis is incised exposing the testicle. The microscope is brought into the field to optimize visualization prior to making the single midtesticular horizontal incision. Microsurgical magnification assists in preserving the subtunical vessels, minimizing the risk of bleeding, identifying the larger, more opaque seminiferous tubules that are more commonly associated with spermatogenesis (Fig. 53.4A). Seminiferous tubules are excised with a curved iris scissors, and a wet prep slide is prepared to assess for the presence of sperm using phase contrast microscopy at high power (× 400) magnification. Bipolar electrocautery is used for hemostasis. Meticulous attention to hemostasis during closure is essential in order to minimize the risk of postoperative hematoma formation (Fig. 53.4B).

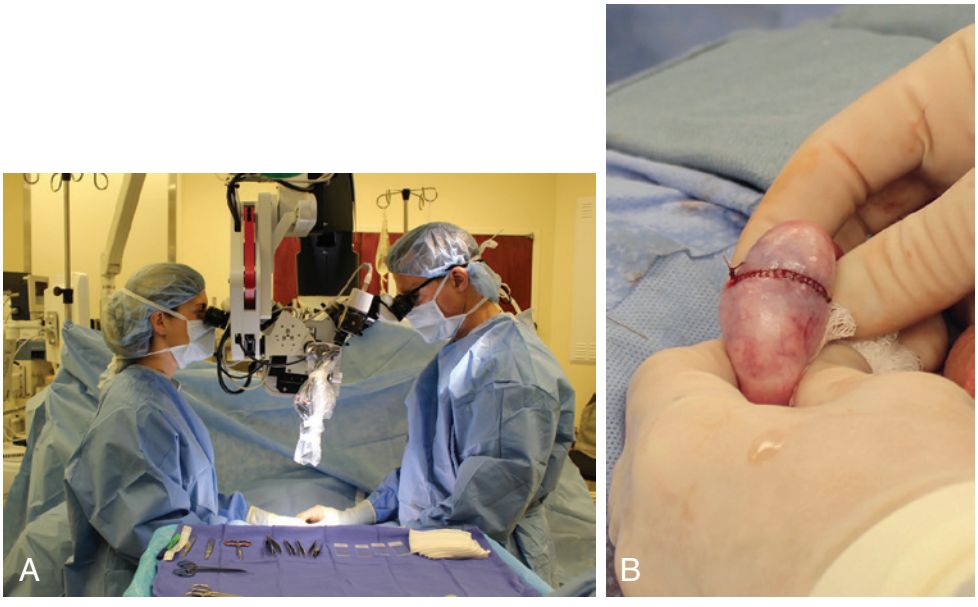

Figure 53.4 A,The operating microscope provides up to 25X magnification and guides seminiferous tubule dissection and sampling during the Micro-TESE procedure. The operating microscope also enables identification and preservation of testicular vascular structures during the procedure, thus minimizing postoperative bleeding risk. B, Meticulous attention to hemostasis during testicular and scrotal closure is essential in order to minimize the risk of postoperative hematoma formation.

Percutaneous biopsy and FNA are less commonly used as they are "blind procedures" and have higher complication rates and lower SRRs. PTB and FNA are both of relatively short duration and can be done under local anesthesia. After placement of a spermatic cord block, a small weal of anesthesia is injected at the site of a tiny scrotal skin incision. With the FNA approach, a tiny incision is made, a 23-gauge needle is attached to a 20-mL syringe that is passed into the testicle, and negative pressure is generated. Using back and forth movements, fluid and seminiferous tubules are aspirated. A percutaneous biopsy involves the use of a 14-gauge or 16-gauge automatic biopsy gun, which is advanced through the scrotal incision and through the tunica albuginea. The biopsy gun is then triggered, and it collects the testicular biopsy core. The core is then removed, placed in solution, and inspected using microscopy. With both the PTB and FNA approaches, a single suture is placed and scrotal pressure dressing and ice are applied for 24 hours.

Microdissection epididymal sperm aspiration (MESA) and percutaneous epididymal sperm aspiration (PESA) techniques can be used in cases of obstructive azoospermia to obtain sperm from the epididymis. PESA, although relatively quick and cost effective, has a lower SRR and has a greater risk of vascular injury than does MESA. PESA involves percutaneous aspiration of epididymal fluid from the dilated epididymal caput using a 23-gauge or 25-gauge butterfly needle. MESA, however, involves open exposure of the epididymis to facilitate epididymal fluid aspiration under microsurgical vision.

Overall, nonobstructive azoospermia SRRs for FNA, TESE/multiple open biopsies, and Micro-TESE are 11–47%, 17–45%, and 42–62%, respectively.[67,69–73] Success for PESA and MESA in obstructive azoospermia is up to 92% and 100%, respectively.[74]

MANAGEMENT OF SPECIFIC COMPLICATIONS

Common complications associated with sperm extraction procedures are listed in Table 53.1.

The risk of clinical *hematoma* with Micro-TESE is low. The risk of subclinical hematoma detected on testicular ultrasound is 12% following Micro-TESE and 51% after TESE at 1 month.[67] Chronic changes are not typically seen following Micro-TESE, but are seen in up to 23% of patients who underwent TESE. The significance of these subclinical findings on ultrasound is yet to be determined. Although hematoma is uncommon, scrotal ecchymosis is common and can be limited by scrotal support and ice following the procedures.

Decreased testicular volume occurs in only 2.5% of patients undergoing Micro-TESE but up to 10% of patients undergoing TESE.[67] In part, this is related to a lower volume of tissue extracted during Micro-TESE than during TESE.[67] This impact of the procedure on testicular size may in part be responsible for the associated 20% decrease in serum testosterone at 3–6 months post Micro-TESE and TESE. Testosterone levels usually return to 95% of baseline at 18 months in Micro-TESE patients, but only to 85% of preoperative baseline in TESE patients.[75] There has been one report of a patient who underwent a TESE and became hypogonadal secondary to bilateral testicular ischemia and atrophy, ultimately requiring exogenous testosterone therapy.[67] TESA has not been shown to be associated with a decrease in testicular volume or serum testosterone.

Postoperative inflammation can result in *testicular fibrosis* and *scar formation*, which can be detected on scrotal ultrasound. Some studies have shown fibrosis following TESE in up to 23–30% of patients compared to 0–3.3% in patients after Micro-TESE.[65,67]

Vasectomy Reversal (Vasovasostomy and Vasoepididymostomy)

Approximately 6% of the 500,000 men that undergo a vasectomy annually will eventually elect to have a vasectomy reversal requiring either a vasovasostomy (VV) or vasoepididymostomy (VE).[76] Vasectomy reversal remains the most common indication for VV or VE but others include epididymal obstruction as a result of congenital bilateral epididymal agenesis, epididymitis, and trauma or iatrogenic injury.[77] A VV may also need to be performed to treat post vasectomy pain syndrome, following traumatic injury to the vas deferens, or after iatrogenic injury sustained during an inguinal hernia repair.

The evolution of VE and VV from their macrosurgical origins (in 1902 and 1911, respectively) to current-day microsurgical procedures was accompanied by improvement from relatively low patency rates to rates of approximately 68% and 95%, respectively. These advances have come as a result of technologic and procedural innovation, an understanding of the implications of vasal fluid quality and intraoperative decision making, and the impact of female partner factors.[77–80] Technical optimization with the microsurgical approach requires regular exposure to microsurgery in order to remain technically proficient. This has resulted in a subspecialized shift of the procedures to fellowship-trained urologists, especially when VE is performed.[81]

Patients undergoing a vasectomy reversal procedure should be informed that secondary epididymal obstruction can occur following vasectomy. For such patients, microsurgical reconstruction woud require a VE, which has a lower patency rate than VV. Epididymal obstruction after vasectomy is caused by intraluminal backpressure that leads to epididymal tubule "blowout" (rupture) with subsequent scarring and stenosis.[82] Post vasectomy epididymal obstruction is most commonly associated with an interval of >15 years since vasectomy, although it can occur at any time interval after the vasectomy. In 62% of patients who were >15 years post vasectomy, a unilateral or bilateral VE was required due to concurrent epididymal obstruction.[83] Despite having a lower patency than VV, VE still has reported patency rates of 65–80%.[84] Patients should be informed that after patency is confirmed, it takes on average 12 months to achieve a pregnancy.[84]

VASECTOMY REVERSAL PROCEDURE TECHNIQUES

VVs and VEs are ideally done under general anesthesia, although they can be performed under regional or local

anesthetic. The patient is placed in the supine position and prepped following shaving. The incision for a VV or VE can be made through a midline raphe incision or more commonly via a high scrotal vertical incision. Dissection is continued down to the vas deferens to the site of the vasectomy. A healthy segment of the vas deferens is identified 1 cm from the vasectomy site. Mobilization of the vas deferens is essential in order to perform a tension-free anastomosis, and this requires dissection of the surrounding tissue with preservation of the vasal blood supply in order to avoid subsequent anastomotic stricture.

Fluid from the testicular vas deferens is assessed macroscopically for the color and consistency, and microscopically for the presence or absence of whole sperm or sperm parts. If no vasal fluid is seen, VE should be performed. If the fluid found is clear or opalescent with sperm or sperm parts, then a VV can be performed.[84,85] A VE should be performed if thick, toothpaste-like fluid without sperm returns, as this is consistent with epididymal obstruction. The abdominal vas deferens is then assessed for patency by gentle irrigation with 5 mL of normal saline through a 24-gauge angiocatheter. Once patency is confirmed the anastomosis of the two ends of the vas deferens can occur.

Anastomosis is most commonly done via a two-layer approach, although similar patency rates have been found with a modified single-layer anastomosis.[86] The two-layer anastomosis uses 10-0 nylon sutures to reapproximate the mucosa, and 9-0 nylon to reapproximate the muscularis. The modified single-layer closure utilizes 9-0 nylon. Whichever technique is used, the anastomosis should be leak proof and tension free.

If a VE is performed, the tunica vaginalis is opened and the testicle delivered. The abdominal vas deferens is mobilized sufficiently to ensure adequate length to the epididymis. Given the importance of the epididymis in sperm maturation, anastomosis is performed as distally as possible.[87] A VE is typically performed via a traditional end-to-side anastomosis or an intussuscepted end-to-side anastomosis.

Postoperatively patients are typically discharged home the day of surgery with scrotal support and ice packs for 24–48 hours. Return to light work duties can occur after 5–7 days postoperatively, but the patient should refrain from substantial physical exertion and sexual activity for at least 2 weeks in order to minimize the risks of increased inflammation, anastomotic leak, and stricture. Semen analysis is typically performed at 6–8 weeks and then every 2–3 months until motile sperm are detected or pregnancy occurs.

Postoperative patency may not be evident on semen analysis testing for up to 12 months following a VV and up to 24 months following a VE. Overall patency and pregnancy rates for VV are 86–99% and 46–92.5%, respectively.[80,84,88] VE is associated with lower patency and pregnancy rates, 65–80% and 30–40%, respectively.[80,89]

MANAGEMENT OF SPECIFIC COMPLICATIONS

Common complications associated with vasectomy reversal procedures are listed in Table 53.1.

Postoperative *infection*, *hematoma*, and *testicular atrophy* are rare, and preoperative, prophylactic antibiotics are routinely given to reduce the risk of infection. Postoperative scrotal edema and orchalgia can occur but usually resolve spontaneously.[90]

Vasovasostomy *primary anastomotic failure* is suspected if there is an absence of sperm on SA after 12 months. Early failure may result from an anastomotic leak causing inflammation and luminal stenosis. Leaks can result from inadequate approximation of the vasal ends, puncture of the vasal lumen, or misalignment of the anastomosis.[91] In rare circumstances leaks can arise due to infection. Unrecognized epididymal obstruction following previous vasectomy can also be a cause of VV failure. In the setting of early failure, patients can undergo "re-do" VV or IVF/ICSI. Repeat reversals have reasonable patency rates of 78% and pregnancy rates of 44%.[92,93] A repeat reversal has also been shown to be 2.4 times less expensive than undergoing IVF /ICSI.[94]

Delayed anastomotic failure occurs in up to 12% of patients and is defined by sperm seen on postoperative SA that subsequently decreases with time. This usually occurs 9 months postoperatively.[80,95,96] This secondary azoospermia/oligospermia is caused by vasal scarring and can be treated with NSAIDs or steroids to reduce the inflammatory process. Patients should also be offered cryopreservation of sperm in the event azoospermia does ultimately occur. If secondary azoospermia does indeed occur, a "redo" VV or a VE can be undertaken.

Vasoepididymostomy has lower success rates due not only to the technical difficulty associated with the procedure, but also due to the role the epididymis plays in imparting sperm maturation and sperm motility. The closer to the caput of the epididymis the VE anastomosis is placed, the less likely motile sperm will be found on SA.[87] There is also a risk of *ischemic epididymal fibrosis* and/or *testicular atrophy* with VE, but these are rare events and usually occur in the setting of multiple reconstructions. For patients with a failed VE (absence of sperm after 15–24 months), a repeat VE or IVF/ICSI are both options. Recently pre- and postoperative nomograms have been created to help counsel patients on the likelihood of requiring a VV or VE preoperatively and the likelihood of success postoperatively.[97]

Hydrocelectomy

A hydrocele is an abnormal collection of fluid between the testicle and the tunica vaginalis. Hydroceles are believed to occur when fluid resorption, which typically occurs in the space between the visceral and parietal layers of tunica vaginalis, does not occur normally. Hydroceles affect 1% of the male population, predominantly occurring in men over the age of 40.[98] Hydroceles are divided into "communicating" and "noncommunicating" categories, based on whether or not they are in continuity with the peritoneal space. Hydroceles are further divided into primary (idiopathic) or secondary (infection, malignancy, trauma, lymphatic obstruction, iatrogenic) types and may be septated or nonseptated.

Following a history and physical examination (including transillumination of the scrotum), a scrotal ultrasound is typically performed in order to assess for any underlying testicular pathology. In cases of a moderate or large hydrocele where an optimal testicular examination is

impeded by the intrascrotal fluid volume, the scrotal ultrasound is essential in order to rule out a testicular tumor. In the setting of a reactive hydrocele secondary to testicular tumor, an inguinal approach is of course used, rather than the more commonly used trans-scrotal hydrocelectomy approach used in cases of benign etiology. Secondary hydroceles caused by infection or trauma can often be managed conservatively, as many of these will resolve spontaneously with time and will not require surgical intervention.

HYDROCELE TREATMENT OPTION TECHNIQUES

Aspiration and Sclerotherapy

Aspiration and sclerotherapy of a hydrocele has a higher persistence/recurrence rate when compared to hydrocelectomy, and aspiration and sclerotherapy is an alternative reserved only for poor surgical candidates as this technique can be performed under local anesthesia. Sclerotherapy is used in conjunction with aspiration to induce an inflammatory reaction, producing fibrosis that ultimately impedes fluid accumulation. If aspiration is used alone, recurrence ranges from 82% to 100%.[99,100] Historically, success rates with aspiration and sclerotherapy vary between 60% and 75% compared to 84–98% with hydrocelectomy.[101–103] However, a recent study using doxycycline sclerotherapy was found to have an 84% success rate with single treatment in hydroceles of less than 750 mL.[100] At this time, doxycycline is the most commonly used sclerosing agent.

For aspiration and sclerotherapy, a spermatic cord block is performed and an angiocatheter (16–19Fr) is inserted through the anterosuperior lateral aspect of the scrotal skin and advanced into the hydrocele. The hydrocele fluid is drained using a syringe, and the sclerosing agent is infused into the cavity of the hydrocele sac.

Hydrocelectomy

Hydrocelectomy remains the main surgical intervention with three techniques described: the bottleneck, Lord, and window procedures. The bottleneck is effective for large hydroceles, while the Lord and window are options for smaller hydroceles. For each procedure, a trans-scrotal incision is made (transverse or longitudinal) over the hydrocele, with dissection down through dartos muscle, external spermatic, cremasteric and internal spermatic fascia in order to deliver the hydrocele sac and testicle into the operative field. The hydrocele sac is then opened longitudinally and the fluid drained. It is important to identify the vas deferens, epididymis, and spermatic vessels in order to avoid injury.

MANAGEMENT OF SPECIFIC COMPLICATIONS

Common complications associated with hydrocelectomy procedures are listed in Table 53.1.

Care must be taken during hydrocelectomy to avoid injury to the structures contained within the fluid sac (Fig. 53.5). These cases are often regarded as being relatively "straightforward," but the normal anatomic relationships between the tunica vaginalis, epididymis, vas deferens, and vascular structures are often markedly distorted. Furthermore, many patients will have inflammatory changes and obliteration

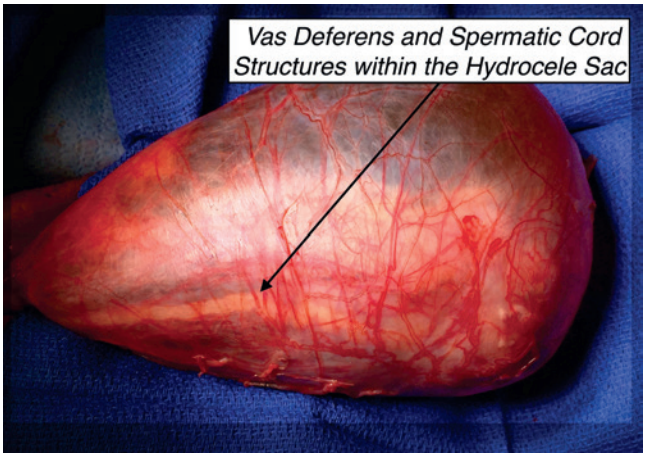

Figure 53.5 Intraoperative photograph depicting the close anatomic proximity of the vas deferens and other spermatic cord structures to the hydrocele sac. Care must be taken to avoid inadvertent injury to these important structures during dissection and resection of the redundant tunica vaginalis that comprises the sac.

of normal tissue planes with adherence of the tunica vaginalis to the key scrotal structures. This is borne out by the fact that *epididymal or vas deferens injuries* may occur in 5.6% of hydrocelectomies.[104] These injuries may occur during excision of redundant tunica or imbrication of the everted tunica, or from an electrocautery injury, and they can result in epididymal or vasal obstruction and obstructive azoospermia.[105] In patients with resultant obstructive azoospermia who are interested in fertility, microsurgical reconstruction is possible, with 5/6 (83%) of patients in one series having return of sperm to the ejaculate; however, it is best to use careful surgical technique and avoid this surgical complication altogether.[106] Just as hydrocelectomy can result in epididymal obstruction, the aspiration with sclerotherapy approach can also cause secondary epididymitis and resultant epididymal obstruction.[101]

Postoperative pain following hydrocelectomy is usually temporary, but development of *chronic pain syndrome* can occur in 0.6–1% of patients undergoing hydrocelectomy.[107,108] Aspiration with a sclerotherapy typically results in pain that resolves in 2–3 days.[100]

Although postoperative hydrocelectomy swelling is common, occurring in up to 9.3% of patients, this is self-limited and usually resolves within weeks to months. *Hydrocele recurrence* following a successful hydrocelectomy has been reported in up to 6% of cases.[107,109] Recurrence rates are far higher for aspiration alone, approaching 100% in some studies.[99,100] Aspiration and instillation of a sclerosing agent has far lower hydrocele recurrence rates (40–60%) than does aspiration alone, but may require multiple treatments.[101,102]

Spermatocelectomy

A spermatocele is a benign, extratesticular, sperm-containing cystic outpouching from the caput of the epididymis.[110] It arises from a dilation of an efferent ductule exiting the rete testes to the caput of the epididymis and is likely related to obstruction of the duct. Spermatoceles are found in up

to 30% of males and are usually small and asymptomatic. Intervention is an option if they become large or painful despite conservative medical management, such as NSAIDs. Spermatoceles are differentiated from epididymal cysts, which are not in direct connection with an efferent ductule and thus do not need to have a connection identified and ligated. In patients who have failed medical management, the gold standard treatment is spermatocelectomy. Treatment such as aspiration of the spermatocele with or without sclerotherapy has been tried but resulted in suboptimal results due to the risk of recurrence, epididymal injury with subsequent obstruction, and sclerotherapy-induced chemical epididymitis.[111]

SPERMATOCELECTOMY PROCEDURE TECHNIQUES

Spermatocelectomies are usually performed under general anesthesia, but they can potentially be performed with regional or local anesthesia. The scrotum is shaved and prepped. Through a midline median raphe or transverse hemiscrotal incision, the tunica vaginalis is opened, and the testicle, epididymis, and spermatocele are delivered. Recent studies have shown the benefit offered by the microsurgical spermatocelectomy approach in reducing postoperative complications, particularly the risk of injury to the epididymis.[112] Dissection continues until the spermatocele neck is identified and subsequently ligated and excised (Fig. 53.6). In order to reduce the risk of injury to the surrounding vessels, the epididymis, and the testicle, bipolar cautery is ideally employed. Once the spermatocele has been excised and hemostasis is confirmed, closure of the tunica vaginalis, dartos, and skin is accomplished using 3-0, 3-0, and 4-0 absorbable sutures, respectively.

Figure 53.6 A spermatocele is shown arising from the caput epididymis. Further dissection was subsequently undertaken to isolate the efferent ductule from which the spermatocele arose. Meticulous operative technique is essential in order of avoid epididymal injury during this procedure.

MANAGEMENT OF SPECIFIC COMPLICATIONS

Common complications associated with spermatocelectomy procedures are listed in Table 53.1.

Complication rates without use of magnification have been as high as 10–30% but drop to 5% with the use of magnification.[108,112–114] The major complications include pain, vasal or epididymal obstruction, spermatocele recurrence, hematoma, hydrocele, infection, and testicular atrophy.

Epididymal injury is of primary concern, particularly in men of reproductive age, as it can result in infertility due to epididymal obstruction.[115] Rates of epididymal injury using the nonmicrosurgical approach have been as high as 17–50% based on pathologic analysis of the resected spermatocele that demonstrated the presence of epididymal tissue.[104,115] This decreased to 0% in a series of 36 microsurgical spermatocelectomies. This study also demonstrated no evidence of reduced semen parameters on postoperative semen analysis.[112]

Recurrence rates as high as 5–10% have been reported in those undergoing nonmicrosurgical approaches, but were 0% at 17 months in those having undergone the microsurgical approach.[112]

Pain associated with spermatocele is improved in 94–100% of patients that undergo surgery for a symptomatic spermatocele.[112,116]

Radical, Partial, and Simple Orchiectomy

Radical orchiectomy is performed for testicular and paratesticular malignancies, while a partial orchiectomy is sometimes an option for a polar testicular lesion (<2 cm) in a solitary testicle or in patients with bilateral testicular masses. Simple orchiectomy is performed for surgical castration (bilateral orchiectomy), nonviable testicle due to torsion or atrophy, recurrent testicular infection/abscess, and refractory testicular pain/scrotal pain.

RADICAL AND PARTIAL ORCHIECTOMY PROCEDURE

An inguinal orchiectomy is performed through a 3- to 5-cm inguinal incision. Care must be taken to identify and avoid injury to the ilioinguinal nerve, which is often adherent to the underside of the external oblique fascia. Once the nerve has been identified, it can be isolated and retracted laterally. The spermatic cord is then isolated from the canal, encircled with a 1/4-inch Penrose drain, and secured proximally with a hemostat. Proximal dissection of the cord to the internal inguinal ring is done to mobilize the cord further, and the testicle is delivered via scrotal pressure from below and gentle traction on the cord from above. Once the testicle is delivered into the inguinal incision, the gubernacular attachments are released and a clamp is then placed proximally securing the cord at the internal ring. The cord is

separated into two bundles for separate ligation and transection, and a 0-silk tie is placed proximally on each bundle and is followed by a more proximal 2-0 silk suture ligature. The clamp at the internal ring is removed to ensure hemostasis of the cord. Closure then occurs with care to avoid injury to the ilioinguinal nerve.

If a partial orchiectomy is being performed, rubber shods instead of a heavy clamp can be placed on the cord to reduce the risk of injury to the vasculature. Some have advocated not clamping at all to reduce the risk of ischemia.[117] A partial orchiectomy can be performed under cold ischemia using ice slush to minimize the risk of ischemic injury to the testicle. An ultrasound is used to define the margins of the tumor, and then the tumor is excised using bipolar electrocautery and blunt dissection. A rim of 5-mm normal parenchyma typically provides an adequate surgical margin. The mass is sent for frozen section, and if it returns benign, closure can commence. If it is malignant, biopsies of the resection bed are needed to confirm complete tumor excision. Biopsies of the surrounding parenchyma are performed to assess for testicular intraepithelial neoplasia (TIN), which is present in the surrounding parenchyma in up to 82% of patients who are found to have a malignancy on frozen section.[117] Closure of the testicle following hemostasis and removal of the rubber shods is accomplished using 5-0 absorbable suture.

A simple orchiectomy is performed through a transscrotal approach with either a midline raphe incision or transverse hemiscrotal incision. The spermatic cord is identified and divided in a manner similar to inguinal orchiectomy. Testicular prosthesis can be placed at the time of radical or simple orchiectomy in patients who have concerns about the cosmetic scrotal appearance.

MANAGEMENT OF SPECIFIC COMPLICATIONS

Common complications associated with orchiectomy procedures are listed in Table 53.1.

The overall risk of *infection* following radical orchiectomy is 1%, with few patients requiring surgical intervention.[118] The risk is higher in the special setting of simple orchiectomy for a nonviable testicle secondary to recurrent orchitis/testicular abscess. In these cases a Penrose drain should be left for 24–48 hours to reduce the risk of postoperative infections. Concurrent insertion of prosthesis at the time of radical orchiectomy is not associated with an increased risk of abscess formation (0–1.3%).[119,120]

Significant postoperative *pain* is experienced in 60% of patients in the hours following surgery, which decreases to 8% several weeks after surgery and to 1.8% at a year postoperatively.[118] *Injury to the ilioinguinal nerve* is rare and can cause immediate postoperative pain and/or hyperesthesia or hypoesthesia. In the event of *ilioinguinal nerve entrapment, patients typically present with pain that presents in a more delayed fashion*. Although incision site pain is usually transient, *phantom testis syndrome* is a phenomenon that has been shown to occur in 25% of patients postorchiectomy, with higher rates among patients who experienced preoperative testicular pain. On average, phantom testis syndrome symptoms begin >2 months following surgery, with 40% of patients having a specific trigger such as urination, exercise, or sexual activity/ejaculation. Although 43% of patients experienced the pain monthly, 28% of patients who report phantom testis syndrome experience permanent pain. Treatments used by patients include analgesics, homeotherapy, thermotherapy, and acupuncture.

Reduced semen parameters are seen in up to 50% of patients with testicular germ cell tumors prior to radical orchiectomy.[121,122] Preorchiectomy azoospermia has been reported in up to 11% of patients.[123] Most patients who do not undergo adjuvant therapy experience an improvement in semen parameters by 2 years following radical orchiectomy, but some will have worsening of semen parameters. Twenty percent of patients will remain persistently oligospermic and 5% azoospermic.[121,123,124] This emphasizes the importance of considering pre-orchiectomy sperm cryopreservation.

Following a partial orchiectomy, 50% of eugonadal males have preservation of fertility.[125] A *hernia* may develop in <1% of patients.[118] *Testicular atrophy* occurs in 3–5% of cases after partial orchiectomy.[126]

Conclusions

Surgical procedures involving the testicle, vas deferens, epididymis, and scrotum are among the most common procedures performed by urologists. Despite the widespread perception that these tend to be straightforward procedures, they are the source of a relatively high percentage of urologic surgical complications. Common themes among these procedures that help mitigate the risk of intraoperative and postoperative complications include proper preoperative evaluation and planning, including cessation of antiplatelet and other blood thinning agents at appropriate time points before surgery. Intraoperative considerations that help diminish the risk of complications include a clear understanding of the relevant anatomy, in particular the vascular anatomy of the spermatic cord. Careful dissection and resection techniques are imperative in order to avoid inadvertent injury to important structures such as the vas deferens, epididymis, and arterial vascular structures. Use of bipolar electrocautery can decrease the risk of thermal cautery injury to the relatively delicate spermatic cord and scrotal structures, and employment of microsurgical techniques can assist in visualization and surgical precision, and thus diminish the risk of operative complications in appropriate cases. Finally, postoperative complications can be minimized through the use of ice packs and compressive scrotal dressings, as well as the avoidance of physical overexertion in the days after surgery.

Chapter 53 Questions

1. Two days following an elective right hydrocelectomy, a 65-year-old male presents with a temperature of 101.5°F and a large, tender right scrotal hematoma with ipsilateral erythema. Scrotal US imaging confirms the presence of a large right scrotal hematoma, and normal intratesticular blood flow is seen bilaterally. Empiric intravenous antibiotic therapy is initiated. The next best step in management is:
   a. Scrotal support, icing, analgesia, and observation
   b. Scrotal exploration and hematoma evacuation
   c. Interventional radiology arterial embolization
   d. Interventional radiology venous embolization
   e. Percutaneous hematoma aspiration

2. A 38-year-old male undergoes an elective bilateral vasectomy, and 3 weeks postoperatively he provides a fresh semen analysis that reveals one twitching sperm per high power field. The next step is to counsel the patient that:
   a. He should initiate antiinflammatory therapy
   b. His vas deferens was not divided during the procedure
   c. He should ejaculate 10–20 more times and then provide another semen sample
   d. He is cleared to resume unprotected sexual activity
   e. He has experienced vasal recanalization

3. A 38-year-old male presents for consultation regarding correction of a grade III/III symptomatic left varicocele. He asks about the advantages of a microsurgical approach over other approaches. You tell him that the microsurgical approach:
   a. Has a lower risk of recurrence than the nonmagnified inguinal approach
   b. Has a lower risk of infection compared to the nonmagnified inguinal approach
   c. Has an equivalent risk of hydrocele formation compared to the nonmagnified inguinal approach
   d. Has a greater risk of hydrocele formation compared to the laparoscopic approach
   e. Has a greater risk of recurrence compared to the laparoscopic approach

4. A 35-year-old male undergoes a bilateral vasovasostomy procedure, and 2 years postoperatively he still has no sperm on semen analysis testing. He and his wife desire to move forward with efforts for a pregnancy. An intraoperative event that might have resulted in his complication of persistent azoospermia is:
   a. Division of the ilioinguinal nerve
   b. Devascularization of cremasteric muscle
   c. Misalignment of the vasal anastomosis
   d. Preservation of lymphatic vessels
   e. Mobilization of the vas deferens

5. A 46-year-old male initially has a normal sperm concentration and normal motility on postoperative semen analysis testing following a bilateral vasovasostomy procedure. However, four consecutive semen analyses show a progressively declining sperm concentration and motility. He now has rare motile sperm in the ejaculate. The next step in his management is to:
   a. Repeat the semen analysis in 3 months
   b. Schedule a bilateral "redo" vasovasostomy procedure
   c. Schedule a bilateral vasoepididymostomy procedure
   d. Start antiinflammatory therapy or prednisone therapy
   e. Start topical testosterone replacement therapy

6. An advantage of hydrocele aspiration and sclerotherapy over surgical hydrocelectomy is:
   a. A lower recurrence rate
   b. Less postprocedural inflammation
   c. It can be performed under local anesthesia at the bedside
   d. Less postprocedural tissue fibrosis
   e. Better testicular function

7. During an inguinal partial orchiectomy procedure, a patient sustains an ilioinguinal nerve injury. His postoperative symptoms as a result might include:
   a. Decrease of scrotal ruggae
   b. Loss of seminal emission
   c. Epididymal tenderness
   d. Decreased force of cremasteric reflex
   e. Numbness of the scrotum and medial thigh

8. When comparing male surgical contraception (vasectomy) to female surgical contraception (tubal ligation), vasectomy has:
   a. Higher cost
   b. Greater utilization in the United States
   c. Lower risk of injury to visceral organ structures
   d. Shorter postoperative time to sterility
   e. Lower risk of granuloma formation

9. A 42-year-old male undergoes a nonmagnified inguinal varicocelectomy procedure for a grade III/III symptomatic left varicocele. The surgeon does not spare the lymphatic vessels, and the most likely complication to arise from this approach is:
   a. Recurrent varicocele
   b. Testicular ischemia
   c. Epididymal "blowout"
   d. Sperm granuloma
   e. Hydrocele

10. A 50-year-old male undergoes a left partial orchiectomy for a tumor that is found to be benign on final pathology. The patient presents with purplish discoloration and moderate swelling of his left hemiscrotum 3 days later. Scrotal ultrasound reveals intact blood flow to both testicles and a moderate-sized left scrotal hematoma that is not increasing in size. The patient is afebrile, and his pain is well controlled with acetaminophen. The next step is:
    a. Embolization
    b. Completion orchiectomy
    c. Scrotal support, icing, and observation
    d. Percutaneous drain placement
    e. Aspiration

Answers

1. **b.** In the setting of a scrotal hematoma with fever, an infected hematoma is the likely diagnosis. Conservative management with scrotal support, limited activity, and analgesia are insufficient to address the infected hematoma, which requires evacuation. Arterial and venous embolization are generally not indicated in cases of scrotal hematomas and would not address the infected hematoma. Percutaneous aspiration of an infected scrotal hematoma would similarly not provide sufficient drainage and would not facilitate inspection for the bleeding vessel. The correct answer is thus scrotal exploration and hematoma evacuation.
2. **c.** A patient may have viable sperm present in the ejaculate at 3 weeks post vasectomy in the setting of a technically successful vasectomy procedure. This patient is not yet cleared to resume sexual activity given the presence of motile sperm in the semen, and he should thus be instructed to ejaculate 10–20 more times and then provide another semen sample. There is not a role for antiinflammatory therapy in this patient's care at this time.
3. **a.** The microsurgical varicocelectomy procedure is associated with lower rates of recurrence and hydrocele formation than are the nonmagnified inguinal and the laparoscopic techniques. There is no difference in infection rates among these procedures.
4. **c.** Misalignment of the vasal anastomosis can obstruct the vasal lumen and result in vasectomy reversal failure. The other events would not lead to azoospermia on postoperative semen testing.
5. **d.** The decline in sperm concentration following a previous vasovasostomy is suggestive of the complication of delayed failure and may respond to antiinflammatory therapy or prednisone. The patient should be offered sperm banking in the mean time. A "redo" vasovasostomy or a vasoepididymostomy procedure would only be pursued if conservative management efforts fail. There is no role for topical testosterone replacement therapy in a male trying to conceive, as the testosterone inhibits spermatogenesis.
6. **c.** Hydrocele aspiration and sclerotherapy has a significantly higher rate of recurrence than does surgical hydrocelectomy. Given the increased risk of recurrence complications, hydrocele aspiration and sclerotherapy is typically reserved only for seriously ill patients who cannot tolerate a general anesthetic and the risks associated with surgical hydrocelectomy. The aspiration and sclerotherapy procedure is associated with substantial inflammation and fibrosis, and the tissue plane scarring that results from the procedure obliterates the potential space between the tunica vaginalis and the tunical albuginea where the hydrocele fluid collects.
7. **e.** Injury to the ilioinguinal nerve can present as pain, hyperesthesia, or hypoesthesia. The ilioinguinal nerve innervates the scrotum and medial thigh in males, so injury to the ilioinguinal nerve can result in numbness of the scrotum and medial thigh.
8. **c.** Vasectomy is less expensive and has lower utilization rates than does tubal ligation among couples in the United States. While females are sterile immediately after a tubal ligation procedure, it typically takes men months to clear sperm from their ejaculate and be approved to resume unprotected sexual activity. Vasectomy sites occasionally develop sperm granulomas, although these structures do not typically cause substantial bother and rarely require treatment. The correct answer is c (lower risk of injury to visceral organ structures), given that tubal ligation is an intraabdominal procedure and vasectomy is an intrascrotal procedure.
9. **e.** Inguinal and scrotal surgical techniques that do not spare the lymphatic vessels increase the risk of ipsilateral hydrocele formation. Use of microsurgical techniques for varicocelectomy is associated with a decreased risk of hydrocele formation when compared to nonmagnified approaches.
10. **c.** This patient has developed the complication of a scrotal hematoma after his partial orchiectomy. Given that the hematoma is stable and that he is afebrile, observation and supportive measures such as scrotal support, icing, and analgesia are appropriate next steps. Most scrotal hematomas will resolve spontaneously over time with this conservative approach.

SECTION IX

Complications of Pediatric Urologic Surgery

54 Special Considerations in the Pediatric Patient

MADELINE J. CANCIAN and ANTHONY A. CALDAMONE

CHAPTER OUTLINE

Introduction
Preoperative Considerations
Psychological Preparation
Preoperative Workup
Medical Evaluation
Laboratory Evaluation
Important Medical Considerations
Bowel Preparation
Preoperative Fasting
Intraoperative Considerations
Robotic and Laparoscopic Considerations
Latex Precautions
Perioperative Antibiotics
Anesthesia
Hypothermia
Surgery Specific Complications
Complications of Circumcision
Complications of Inguinal Surgery
Orchidopexy
Hernia Repair and Inguinal Hydrocele Repair
Complications of Pyeloplasty
Postoperative Considerations
Postanesthesia Care Considerations
Airway Obstruction
Nausea and Emesis
Surgical Site Infections
Fluid and Electrolyte Management
Pain Management
Ethics
Conclusions
Chapter 54 Questions and Answers

KEY POINTS

1. Preoperative family counseling is crucial to a successful outcome.
2. Medical work up is not needed except in high risk patients.
3. Laparoscopic settings, perioperative antibiotics and body temperature differ from adults with child physiology.
4. Airway obstruction, nausea and emesis are the most important immediate post operative concerns.

Introduction

The field of pediatric surgery has greatly advanced since the days when children were treated as small adults. A deeper understanding of pediatric physiology has allowed anesthesia to be administered safely and under the care of specialized providers. Surgeons must also recognize the unique challenges posed by pediatric patients. The majority of patients are healthy and require minimal medical workup. Managing perioperative stress goes beyond counseling the patient and is optimized when a multidisciplinary team is utilized and the entire family is involved. Intraoperative considerations differ from those with adults, ranging from room temperature to insufflation pressures. Postoperative pain control becomes more complex in patients who are unable to verbalize feelings.

In this chapter we aim to review these and many other important issues surrounding pediatric urologic perioperative care. In addition, we will discuss common complications following circumcisions, inguinal surgeries, and pyeloplasties.

Preoperative Considerations

PSYCHOLOGICAL PREPARATION

Perhaps the most demanding task of preoperative surgical preparation for the pediatric population is managing the stress of the patient and parents or other caregivers. While commonly underestimated by the surgeon, operatively induced anxiety can have long-term effects, including nightmares, separation anxiety, eating problems, and increased fear of physicians and health-care institutions.[1] Often the key to reducing stress is to allay the fears of the caregiver, as parental anxiety is known to be transferred to the child.[2] Surgical education begins with the parent or

parents. Confronting parents' fears begins with a comprehensive understanding of the nature, risks, and benefits of the surgical procedure. Reduced anxiety among parents diminishes the patients' anxiety. Depending on the age of the patient, the physician should offer patients the opportunity to speak privately, away from their parents, to address the concerns that the patient may have but is embarrassed to discuss in front of the parents. Additionally, it is imperative to ask appropriately aged children if they have any questions or concerns. Providing age-appropriate reading materials to patients has also been shown to help reduce anxiety.[3]

Preoperative hospital visits provide invaluable educational opportunities for both patients and parents. Arranging for families to meet the anesthesia team preoperatively allows for an introduction to the multidisciplinary approach to modern-day surgery. It also facilitates addressing parental concerns regarding anesthesia as well as patient anxiety surrounding pain control and induction of anesthesia. In addition, many children's hospitals offer behavioral preparation programs run by child life specialists, which have been shown to help reduce perioperative stress levels if conducted 5–7 days prior to surgery.[4] Familiarizing families with the facilities, staff, and surgical process preoperatively helps to alleviate some of the stress associated with the procedure.

Methods to help distract or calm patients on the day of surgery, including video games, music, and sedative premedication, have been shown to be effective in reducing stress levels surrounding surgery.[5,6] However, the most stressful aspect of surgery is the induction of anesthesia. In an effort to ease anxiety, many hospitals allow a parent to accompany the patient into the operating room to be present during induction. While the anxiolytic effect of this intervention on the patient is controversial, parents who accompany their children have been found to have less stress associated with the separation process and have a higher satisfaction level with the overall care provided during the surgical encounter.[7,8]

Many factors outside of our control affect perioperative stress, including previous hospitalizations, patient personalities, and severity of disease.[9] However, there are many programs in place to help ameliorate family anxiety both at the time of preoperative discussion, in the days leading up to the surgery, and also on the day of surgery itself. By optimizing these interventions we not only allow for a smoother day of surgery, but also improve overall satisfaction with the surgical process and decrease postoperative behavioral complications.

PREOPERATIVE WORKUP

Medical Evaluation

The majority of patients undergoing elective pediatric urologic operations are healthy and are having relatively minor procedures. As such, extensive preoperative evaluation is usually not indicated. All patients should undergo a history, including personal or family history of anesthesia complications, bleeding disorders, and a physical examination with special attention to the cardiopulmonary system, to detect any heart murmurs belying structural cardiac anomalies. This evaluation is often done by the pediatrician prior to specialty consultation.

There are a few findings on the day of surgery that can cause complications and potentially lead to surgery being delayed. A skin rash at the site of the surgery is a contraindication to an elective procedure. The presence of an active lower respiratory tract infection is likewise cause for postponement of the procedure. In an otherwise healthy child, an upper respiratory tract infection (URI) is also often an indication for delay. Having had a URI within the last 4 weeks increases the risk for adverse respiratory events with anesthesia.[10] Events include hypoxia, cough, breath holding, laryngospasm, bronchospasms and increased secretions. However, the body of literature suggests that if the anesthesiologist is aware of the URI he or she can accommodate the patient and, in some cases, can safely proceed with the procedure.[11] As such, the decision to cancel surgery is based on many factors relating to the patient's overall health level, age, urgency of the procedure, distance traveled, parental anxiety, and anesthesiologist preference.

Laboratory Evaluation

Most children undergoing elective surgeries do not require routine preoperative laboratory testing.[12] Abnormalities found on CBCs or UAs are typically not clinically significant and do not disclose conditions that lead to the cancellation of the surgery.[13] A hemoglobin of >10 g/L optimizes oxygen delivery so values under this can pose risks during anesthesia.[14] However, the likelihood of finding anemia in an asymptomatic child is small, and thus routine CBCs are not recommended.[15] CBC may be obtained, at the discretion of the surgeon, in populations with higher incidence of anemia, including infants, growing premature infants, and children with chronic disease.[12,16]

More comprehensive testing may be indicated in children undergoing complex surgical procedures. Surgeries with a high risk of hemorrhage or major reconstruction, either within the gastrointestinal or urinary tract, may require a preoperative CBC and chemistries. Additionally, patients with known chronic kidney disease should have preoperative chemistries.

Routine preoperative urinalysis and urine culture are not indicated except in patients undergoing endourologic procedures. Many urologic surgeries involve correcting anatomic abnormalities, and thus these patients are predisposed to urinary tract infections (UTIs). Patients with a history of UTIs should have a urine culture prior to any instrumentation of the urinary tract. For patients who are potty-trained a clean catch specimen is sufficient if it is negative. For younger children, a bladder tap is the gold standard; however, a catheterized specimen is sufficient to provide a representative urine sample.

IMPORTANT MEDICAL CONSIDERATIONS

Premature infants have higher risks when undergoing anesthesia, principally with postoperative apnea. The presence of anemia, specifically with a hematocrit <30%, significantly increases the risk of apneic episodes and elective surgery should be delayed until anemia resolves.[17] The postconceptual age (PCA) is also an important factor in postanesthesia risk. Among patients undergoing herniorrhaphy,

former premature infants who have a PCA of >60 weeks had a <5% incidence of apnea.[18] There is some evidence that using spinal anesthesia instead of general anesthesia decreases rates of postoperative apnea in premature infants and allows for outpatient procedures.[19]

Asthma is another common medical condition in patients undergoing elective procedures. Severity of asthma can often be confused with how well controlled the disease is; mild asthma if not well controlled can appear worse than well-controlled severe asthma. Medical management should be optimized prior to any elective procedure, and, as much as possible, patients should strive to be compliant with all medications preoperatively. All asthma medications should be taken the day of surgery, including inhaled agonists or leukotriene inhibitors. Intraoperatively endotracheal intubation is felt to induce more respiratory complications than a laryngeal mask airway (LMA), and for short procedures standard mask anesthesia is preferred if feasible.[20] Patients may require inhaled agonists intraoperatively to treat bronchospasms or, if on chronic oral or inhaled steroids, may require stress dose steroids to prevent adrenal crisis.

Obesity is an increasing disease among children and has an impact on surgical care. Obese patients are more likely to have comorbidities that affect anesthesia care, including hypertension, type 2 diabetes, and bronchial asthma. Preoperative evaluation should be comprehensive enough to screen for these underlying conditions. Office physical exams may be less accurate at defining true testicular position in obese patients and may lead to use of anesthesia to facilitate exams.[21] Additionally, obese patients are more likely to have anesthesia complications such as difficult intubation, postanesthesia care unit (PACU) upper airway obstruction, and prolonged PACU stays.[22]

Other medical conditions that require special recognition are sickle cell anemia, Down syndrome, and diabetes. Sickling conditions can cause acute chest syndrome, stroke, and myocardial infarction when red blood cells form sludge in vasculature during the perioperative period. Historically it has been recommended to give perioperative transfusions to reduce the Hgb S levels to less than 40%; however, more recent evidence suggests that oral hydration may be sufficient to avoid serious complications after minor, elective surgical procedures.[23] Patients with Down syndrome have a 10–30% risk of having atlantoaxial instability, which can put them at risk for cervical subluxation or dislocation during general anesthesia when the neck is maximally extended for intubation.[24] While routine screening is not generally performed, a plain film of the cervical spine is sufficient to diagnose the condition. Along with the increase in obesity, type 2 diabetes is becoming more prevalent in the pediatric population. Diabetics should have cases scheduled early in the day, and crystalloid fluid containing 5% glucose should be started upon establishment of intravenous access. Half of the patient's morning insulin should be given, and glucose levels should be monitored intraoperatively and in the PACU.

BOWEL PREPARATION

Preoperative bowel preparation serves two roles: For urinary tract reconstruction involving the gastrointestinal tract it reduces gross spillage of enteric contents that theoretically decrease bacterial load if there is a violation of the bowel, and it reduces intraabdominal fecal mass to increase work space in laparoscopic cases. As laparoscopy becomes more prevalent among the pediatric urologic population, bowel preparation becomes an important consideration. A porcine model showed significant increases in intraabdominal volume following bowel preparation,[25] space that can be important in the already cramped confines of a pediatric peritoneum. However, studies examining augmentation cystoplasties in children both via open as well as robotic-assisted laparoscopic approaches have shown no increased operative complications, similar hospital stays, and equivalent results when done without a bowel prep as compared to with a bowel prep.[26,27]

Preferred bowel preparations vary by institution; however, a light mechanical bowel preparation for a laparoscopic case typically involves clear liquids for ≥24 hours preoperatively and a weight-adjusted dose of magnesium citrate (0.5 mL/kg, usually not >200 mL in total dose). More aggressive regimens, including GoLYTELY solution and possible oral antibiotics, can be used in surgeries requiring manipulation of bowel.

Often patients are admitted preoperatively to undergo bowel preparations. This allows for careful monitoring of electrolytes and individual titration of regimen to ensure the bowel is clean. Magnesium citrate can cause hypermagnesemia while Phospho soda-based bowel regimens can lead to hyperphosphatemia and hypocalcemia. Furthermore, patients with chronic kidney disease or neuropathic bowel require special consideration as they are at higher risk for electrolyte compromise.

PREOPERATIVE FASTING

The goal of preoperative fasting is to reduce the volume and acidity of gastric contents to lower the risk of aspiration events during anesthesia and postoperatively. However, there is no literature linking higher gastric volumes to increased aspiration events. In children there is a fine balance between anesthesia risks and risks of dehydration and hypoglycemia. Current guidelines recommend fasting periods of 2 hours for clear liquids, 4 hours for breast milk, and 6 hours for formula, solids, or nonhuman milk[28] (Table 54.1). Studies show that periods of fasting are often longer than recommended, leading to significant preoperative discomfort.[29] In addition, time of fasting does not correlate well with gastric volume.[30] Despite this, aspiration events can

Table 54.1 Guidelines for the Recommended Perioperative Fasting Duration for Healthy Children Undergoing Elective Surgical Procedures

Diet	Hours of Fast
Clear liquids, chewing gum	2
Breast milk	3
Infant formula	4
Nonhuman milk	6
Light meals	6

have serious consequences and fasting times, if violated, will most likely lead to postponement of elective procedures.

Intraoperative Considerations

ROBOTIC AND LAPAROSCOPIC CONSIDERATIONS

Mirroring trends in adult urologic surgery, laparoscopic and increasingly robotic-assisted laparoscopic procedures are becoming more common. Potential advantages to minimally invasive techniques include better cosmesis, improved visualization of anatomic structures, reduced postoperative pain, and shorter hospital stays.[31] While surgical outcomes have generally been found to be equivalent, these results come out of large-volume centers and are likely not reproducible by surgeons with inadequate training in robotic technique.

There are aspects of pediatric physiology that lead to special considerations when utilizing laparoscopy in children. Children have higher incidences of right to left cardiac shunts, high chest wall compliance, rate-dependent cardiac output, and diaphragmatic respirations, all of which could be negatively affected by CO_2 insufflation.[32] While various hemodynamic and respiratory variables have been seen to change significantly following insufflation for both intra- and extraperitoneal procedures, conscientious anesthesiologists have been able to safely manage patients without complications.[33]

The size of the patient also effects aspects of laparoscopic surgery. The smaller surface area for surgery requires more precise port placement to decrease the likelihood of trocar collisions. Foley decompression during intraperitoneal surgery is essential as the bladder commands a more abdominal position in children. Additionally, a child's abdominal wall is more compliant so lower pressures are used to create adequate working space. Infants (0–2 years), children (2–10 years), and adolescents (>10 years) require pressures of 8–10 mm Hg, 10–12 mm Hg, and 15 mm Hg, respectively.[34] Patients are at higher risk of developing fluid overload due to less insensible losses than with open procedures and reduced glomerular filtration due to increased abdominal pressures.

LATEX PRECAUTIONS

Latex is produced from the sap of *Hevea brasilinesis*, a rubber tree. In the 1980s the rise of transmittable diseases prompted increased use of latex products, and the 1990s saw a rise in latex allergies caused by type I immediate anaphylactic-type reactions as well as type IV delayed-type hypersensitivity reactions in sensitized patients. Pediatric urologists need to be cognizant of latex allergies, as spina bifida patients in particular are the highest-risk population. Historically, up to 60% of spina bifida patients have been found to carry the allergy, with the major risk factor being number of surgical procedures.[35] Latex allergies can be life threatening if children develop intraoperative anaphylaxis, a condition that can be difficult to detect early as warning signs are hidden under surgical drapes.[36] As latex has become a well-recognized allergen, it has increasingly been removed from contact with high-risk patients. Performing latex-free operations on spina bifida patients has shown a decrease in latex sensitization and allergies, with one study finding a decrease in symptoms from 55% to 5%.[37] As latex substitutes become functionally equivalent to latex products, it is prudent to avoid using latex around all high-risk patients.

PERIOPERATIVE ANTIBIOTICS

Currently there are no guidelines for perioperative antibiotic prophylaxis in pediatric urologic procedures. The goal of prophylaxis is to reduce postoperative infections while not exposing the patient to undue harm in the form of allergic reactions, side effects, or resistant organisms. Colonization with "superbugs" is a major concern among our patient population, especially since many have anatomic abnormalities that predispose them to forming UTIs. Perioperative antibiotics are best administered within 60 minutes of the start of a procedure and should end within 24 hours of the procedure.

A recent survey of pediatric urologists revealed that >75% would give antibiotics before open pyeloplasty, hypospadias repair with anticipation of indwelling catheter, reconstructive bladder surgery, endoscopic procedures, and open ureteral reimplantation; most would not give perioperative antibiotics for orchidopexies, circumcisions, simple chordee repairs, or hernia/hydrocele repairs.[38] There is evidence to suggest that the risk of infection is related to the wound class of the procedure. Regardless of procedure site, wound class 2 procedures (clean contaminated) had a 6.7-fold higher rate of infections compared to wound class 1 procedures (clean), suggesting that prophylaxis should be targeted at higher wound class surgeries.[39]

Without any formal recommendations, surgeon judgment should be used when deciding to use antibiotic prophylaxis. In our institution, we use prophylaxis for procedures involving skin incisions in the genital region in pubertal children, in addition to the common procedures listed above. Perioperative antibiotics are also given to children undergoing endoscopic manipulations who take daily prophylaxis.

ANESTHESIA

The fear of anesthesia looms large when parents are considering surgery for their children, often overshadowing concern for the procedure itself. Preoperative hospital visits that allow the parents and patient to meet with the anesthesia team are a powerful tool to reduce anxiety. Often recognition that the anesthesiologists are specially trained to take care of pediatric patients can reassure parents.

Risks associated with pediatric anesthesia have decreased dramatically as the medical field has recognized that child physiology is different from the adult's. Modern anesthesia has proven to be very safe. A single center observational study of pediatric surgeries over a 30-month period showed a perioperative adverse event rate of 79:1000 anesthetics.[40] The majority of intraoperative events were respiratory involving children <1 year of age while 77% of the PACU events comprised vomiting among older patients. There were no anesthesia-related deaths. Despite the overall safety, independent of ASA score, age <1 year predicted adverse events; therefore, all procedures in this population should

involve a specialist provider. A recent systematic review confirmed the safety of pediatric anesthesia, finding that the risk of acute severe complications of anesthesia, defined as "an unexpected perioperative event in a pediatric patient which without intervention by the anesthesiologist within 30 minutes may lead to disability or death," was <1%.[41]

Recently there has been some concern over pediatric anesthetics and neurocognitive development. Rodent models have shown early anesthesia can impair synaptogenesis, causing neuronal apoptosis and subsequent learning and behavioral problems.[42] Overall, observational studies have shown mixed results in the human population. There is evidence suggesting anesthesia, either as a single or multiple exposure(s) during childhood, increases the likelihood of developing a learning[43] or behavioral[44] disability. Bartels et al. conducted a twin study that compared anesthesia exposures prior to age 3 to educational achievement and cognitive problems at age 12. They concluded that anesthesia is a marker for later cognitive impairment, but anesthesia itself is not causal.[45] Currently, more data are needed to determine the effect, if any, of early childhood anesthesia on cognitive development.

HYPOTHERMIA

Intraoperative hypothermia of as little as 1.5–2°C is known to have adverse outcomes, including increased wound infection risk, morbid myocardial outcomes, coagulopathy and need for transfusion, and prolonged recovery and hospital stays.[46] Infants are at high risk for hypothermia due to their thin skin, increased body surface area to weight ratio, and decreased ability to thermoregulate. The most influential factors for decreasing intraoperative body temperature in infants and neonates are OR temperature less than 23°C and major versus minor surgery.[47]

The ideal temperature in the operating room varies by patient age; however, it should approximate the temperature at which the child's oxygen consumption and metabolic rate are minimal. This corresponds to 24–26°C in a newborn or small infant and 21°C in a child.[48] Methods used to maintain the patient's temperature include overhead radiant heat or heated room, warmed blankets and air blankets, prewarmed skin-preparation fluids, warmed IV fluids, and waterproof drapes.

Surgery Specific Complications

COMPLICATIONS OF CIRCUMCISION

Approximately one in three men worldwide are circumcised, with regional prevalence ranging from 75% in the United States to 6% in the UK.[49] Complications occur in approximately 1.5% of these procedures.[50] Complication rates vary depending on how old the patient is when the surgery is completed and whether the procedure is being done as part of a religious ceremony or by a medical practitioner.

Early complications include bleeding, infection, and penile or urethral injury. By far the most common complication is bleeding. Circumcisions performed with a Gomco clamp usually bleed from the frenulum and can be stopped with pressure or with a frenular stitch. If bleeding is coming from a cut skin edge, a hemostatic agent such as silver nitrate can be applied to the area. If there is a large surface area that is oozing with no apparent bleeding vessel, epinephrine-soaked gauze can be used as a compressive dressing to help achieve hemostasis. Often continued bleeding can be due to removal of too much penile shaft skin. The shaft will eventually re-epithelize and no skin grafting is needed but the patient will likely need close follow-up for local wound management for 1–2 weeks. Bleeding that is refractory to the above management, or that results in a large peri-penile hematoma may require surgical exploration.

Infection is a rare early complication. While the penile skin can be difficult to keep clean, the robust blood supply to the organ likely contributes to a low rate of infection.

Although rare, the most serious complications are partial or full-thickness excision of the glans, penile necrosis, urethral injury, or penile amputation. Necrosis typically occurs when "excessive" electrocautery is utilized during the circumcision or if it comes into contact with a metal Mogen or Gomco clamp. It is prudent to use bipolar cautery if needed for hemostasis. Excision of glans tissue is most common with a Mogen clamp when glans tissue is inadvertently pulled into the clamp with the foreskin. Inadequate lysis of adhesions or a high frenular attachment is often the underlying cause of this complication. Proximal migration of the Plastibell plastic ring can occur when it is retained for too long and can cause necrosis of the penis and erosion into the urethra. Additionally, in religious circumcisions the foreskin is often pulled up and pinched between the fingers, which can cause entrapment of the glans tissue. If the glans is amputated it should be wrapped in soaked gauze and placed on ice. Reattachment of the amputated tissue can be successful within 8 hours, and microsurgical technique is usually not needed.[51]

Late complications include meatal stenosis, urethrocutaneous fistulas, skin bridges, and trapped penises. Meatal stenosis can develop in the setting of subclinical inflammation of the meatus unprotected by the foreskin. It has also been hypothesized that ligation of the frenular artery may contribute to stenosis. Stenosis, if symptomatic, requires surgical correction.

Urethrocutaneous fistulas likely develop after crush injuries to the ventral surface of the penis or excessive mobilization of the urethra during freehand circumcisions. Repair is delayed to allow for maturation of the fistula and growth of the penis to facilitate tissue handling.

Penile adhesions following circumcisions are common and do not always require treatment. If symptomatic, adhesions can be managed with a topical steroid cream; however, if they are refractory they may require a circumcision revision. If adhesions become epithelialized they form skin bridges, which will not respond to steroid cream or physical manipulation. Skin bridges require division.

A concealed or trapped penis can develop when the circumcision heals abnormally. A concealed penis occurs in the presence of a prominent suprapubic fat pad that subsumes the penile shaft resulting in deficient shaft skin. A hidden penis typically occurs when too much shaft skin is removed causing inward telescoping of the glans with subsequent scarring of the peri-penile skin over the glans, which may lead to secondary phimosis. This is more likely to occur if there is a preexisting ventral skin deficiency

Figure 54.1 Contraindications to neonatal circumcision. A, Buried penis; B, penoscrotal webbing; C, epispadias; D, micropenis. (With permission from Anthony Caldamone.)

(penoscrotal webbing) that is unrecognized prior to circumcision. Conservative management with betamethasone cream to the scarred skin is effective in 79% of children, the remainder of whom require surgical intervention.[52] If surgery is required, the penis should be degloved and the skin fixed to Buck's fascia to prevent recurrence.

Certain anatomic abnormalities make neonatal circumcisions riskier and should be deferred. The presence of penoscrotal webbing, abnormal urethral meatus, including hypospadias or epispadias, micropenis, or buried penis all warrant a neonatal urology consult (Fig. 54.1). Typically circumcision for these patients is deferred until after 6 months of age and is completed under general anesthesia.

COMPLICATIONS OF INGUINAL SURGERY

Orchidopexy

Orchidopexy is a common urologic procedure with approximately 1% of boys having an undescended testis at 6 months of age. The goal of orchidopexy is to place the testis in a scrotal location to facilitate testicular self-exams at puberty, decrease the risk of testicular cancer, and improve fertility potential. Rates of testicular cancer among boys who have undergone a prepubertal orchidopexy are approximately two to three times greater than unaffected individuals; however, the risk of cancer among uncorrected men is six times greater.[53,54] Semen parameters have traditionally been thought to improve with orchidopexy, especially in patients with bilateral cryptorchidism and when surgery is done at an early age.[55] There are also fertility concerns for unilateral cryptorchidism, as shown by a two-fold increase in the inability to father children among men with unilateral undescended testes.[56] However, the relationship between cryptorchidism, timing of repair, and infertility is still not understood, and recent data suggest orchidopexy, even before 1 year of age, may not improve semen parameters.[57]

Orchidopexy outcomes vary by anatomic position of the undescended testis. Success rates according to testicular position are 74% for abdominal, 82% for peeping, 87% for canalicular, and 92% for beyond the external ring.[58] Reasons for failure are twofold: Either the testicle is located superior to

the scrotum or the testicle has atrophied. Testicular retraction can occur due to inadequate mobilization of the cord, incomplete excision of cremasteric fibers, or inadequate fixation of the testis in the scrotum. Mobilization of the cord requires separation of the processus vaginalis from the spermatic vessels and vas deferens, with a high ligation at the level of the internal inguinal ring necessary if the processus is patent. Mobilization of the cord should be taken to the level of the internal ring. If after these steps there is still tension on the testis, additional length can be gained by preforming the Prentiss maneuver to bring the cord medial to the inferior epigastric vessels, creating a more medial internal ring. Placement of the testis in the scrotum is best accomplished by creating a dartos pouch.

Testicular atrophy results from any injury to the blood supply to the testicle. Inadvertent damage to the spermatic vessels can occur if there is excessive skeletonization of the cord or liberal use of electrocautery. The Fowler-Stephens repair relies on adequate collateralization from the deferential artery and can result in testicular atrophy if the blood supply is not robust. Additionally, inadvertent twisting of the cord when the testicle is pexied into the scrotum can cause ischemia and atrophy.

Neuralgia can develop after inguinal surgery, typically characterized by transient numbness in the distribution of the disturbed nerve or, less frequently, hyperesthesia along the course of the nerve. The ilioinguinal nerve is most commonly encountered during orchidopexy as it runs superficial to the spermatic cord with the cremasteric fibers in the inguinal canal and passes through the external inguinal ring. Care should be taken to identify the nerve and sweep it away from the cord structures to ensure it is not transected or incorporated into the closure of the external oblique. Transection can cause transient numbness of the skin of the inner thigh, upper scrotum, and base of penis. The genital branch of the genitofemoral nerve travels through the inguinal canal where it is vulnerable to injury. Transection of the genital branch causes lateral scrotal skin numbness. The iliohypogastric nerve overlies the internal oblique and perforates the external oblique just lateral to the rectus muscle and superior to the inguinal canal. The sensory distribution of this nerve is similar to the ilioinguinal distribution. The incidence of nerve injuries during inguinal surgeries in children is not reported in the literature. However, among adults undergoing mesh-free inguinal hernia repairs, the incidence of groin pain was 10% and numbness was 25%,[59] suggesting that inguinal surgery can cause a meaningful number of neuropathic complications. Of note, these nerves can also be damaged during laparoscopic orchidopexy with the genitofemoral nerve being the most at risk for injury.

Injury to the vas deferens during inguinal surgery is rare. Blood supply to the vas deferens is delicate, as such excessive skeletonization of the cord, aggressive electrocautery around the vas, and clamping over the vas can all result in unrecognized damage to the vas, which, with time, can lead to obstruction. Inadvertent transection of the vas deferens occurs in 0.2% of pediatric hernia repairs.[60] This most commonly occurs when the processus vaginalis is ligated and will be discovered in the pathology specimen. If a vasal injury is recognized intraoperatively microsurgical repair can be attempted.

Hernia Repair and Inguinal Hydrocele Repair

Hernia and inguinal hydrocele repairs have a similar complication profile to orchidopexies. The genitofemoral, ilioinguinal, and iliohypogastric nerves can all be injured. Dissection of the hernia sac off the cord can cause damage to the vessels, resulting in testicular atrophy, or damage to the vas. Other complications include infection and hematoma formation. The rate of recurrent hernia is 0.4% and need for contralateral repair is 2–8%.[61–63] Scrotal hydrocele repairs have a lower risk of injury to the cord structures but carry a higher risk of infection, hematoma, and recurrence.[64]

COMPLICATIONS OF PYELOPLASTY

Ureteroplevic junction obstruction (UPJO) is a congenital condition caused by a variety of possible etiologies, including intrinsic stenosis, abnormal insertion, aperistaltic segment, and extrinsic crossing vessels or fibrous bands. In the era of prenatal imaging most UPJOs are diagnosed at an early age; however, some children present later with flank pain, flank mass, and UTIs. Indications for repair include symptoms, impaired renal function, or progressive renal loss. In this section we will discuss open and laparoscopic pyeloplasty.

Choice of surgical approach depends on severity of disease, age of the child, and experience of the provider. The most common technique is the Anderson-Hynes dismembered pyeloplasty, with the spiral pyeloplasty typically reserved for long-segment stenosis. Laparoscopic and robotic pyeloplasty are increasingly utilized, with data showing a steeper learning curve versus open procedures; however, experienced surgeons have similar complication rates.[65] Robotic or laparoscopic procedures may have an advantage over open procedures, especially in older children where smaller incisions offer better cosmesis and less pain; however, this is in exchange for higher costs and longer operative times.[66]

The most common complications of pyeloplasty are UTIs and urinary leak. Postoperative UTIs can cause inflammation at the site of the surgery leading to fibrosis and subsequent failure. Preoperative urine cultures should be checked and the urine should be sterile when starting the procedure. Tal et al. found a 12.6% rate of positive urine cultures postoperatively, with a higher rate, although not statistically significant, among stented patients.[67] Infection rates vary widely in the literature depending on definition, with Mufarrij et al. quoting a 2.9% rate of febrile UTI.[68]

Persistent urinary leakage is usually identified by sustained high output from the Penrose drain, which is placed at the site of anastomosis intraoperatively. Other symptoms include pain refractory to typical analgesic regimen, prolonged postoperative fever or ileus, and flank mass. Urinary leaks can be managed conservatively, by retaining the Penrose drain for 5–7 days, but if leakage persists, drainage of the kidney may be required either via a double J ureteral stent or nephrostomy tube. Like UTIs, leaks can cause inflammation and fibrosis at the site of anastomosis and thus may increase failure rates. Ozayar et al. found that early intervention at a median of 4.5 days postoperatively with placement of a nephrostomy tube achieved the same rates of radiographic and symptomatic success as patients

who did not have a complication.[69] The incidence of urinary leaks likely varies depending on the procedure, with one review of the literature finding a 3% rate of leak among stented pyeloplasties versus 8% among unstented pyeloplasty.[70] However, this series found a higher rate of UTIs among stented patients, suggesting there is a trade off when leaving a stent. Stented patients also require a second anesthesia for stent removal. Additionally, proximal migration or breaking of stents can further complicate this procedure. A more recent case series of 367 pyeloplasties found no difference in complication or failure rates between stented and unstented procedures, with the only statistically significant differences being a longer length of stay for stented patients of 0.5 day and a longer period for drains of 6 days in unstented patients.[71]

Pyeloplasty failure is defined by persistent or delayed obstruction. Early obstruction often presents as urinary leak and can be managed conservatively as described above. However, persistent or delayed onset of worsening hydronephrosis or symptoms requires more aggressive treatment. Failure rates are low at 4%[72] and are thought to occur due to fibrosis and restenosis at the anastomosis. Acute complications of UTIs and urinary leak might contribute to fibrosis, along with poor tissue handling, ischemia to the ureter, missed crossing vessels, and tension at the anastomosis. While avoiding an open reoperation for correction is tempting, endopyelotomy[73] and endoscopic balloon dilation[74] have had low success rates when compared to open, laparoscopic, or robotic reoperation. Redo operations may require a spiral technique to traverse a large segment or a ureterocalicostomy if there is a dependent calyx. Salvage rates approach 100% but can require more than one additional procedure. Refractory obstruction in the setting of poor renal function may require nephrectomy.

Postoperative Considerations

POSTANESTHESIA CARE CONSIDERATIONS

Airway Obstruction

Postoperative airway complications involve laryngospasms or stridor. Laryngospasms typically occur directly after extubation but can be seen while patients recover in the PACU. Laryngospasms are more likely to occur in children with blood or secretions in the pharynx or those with a history of upper tract respiratory infections.[75] Initial management includes bag-mask ventilation; however, additional medications or reintubation may be necessary if it persists.

Postoperative stridor is caused by subglottic edema. Risk factors include a history of croup, a history of intubation as a neonate, the use of too large an endotracheal (ET) tube, and the presence of Down syndrome with head manipulation intraoperatively. Traditionally, uncuffed ET tubes were recommended in all children <8 years to prevent stridor; however, recent trends focus on using correctly sized pediatric-specific ET tubes instead of uncuffed tubes.[76] When encountered, stridor should be treated with humidified oxygen and racemic epinephrine. There is also evidence that intraoperative corticosteroids can be used to treat or prevent postextubation stridor.[77]

Nausea and Emesis

Postoperative nausea and vomiting is the leading cause of delayed discharge from the PACU and can lead to unplanned admissions. Risk factors include age >3 years, surgery longer than 30 minutes, and a personal or family history of nausea or vomiting, with the combination of all three leading to a 55% risk of vomiting.[78] Postoperative administration of opioids also greatly increases the risk for nausea and emesis; therefore alternate classes of pain medication should be used if possible. Prophylactic administration of two to three antiemetics is recommended in children at higher risk of emesis. Additionally, oral fluids should be withheld until the child states he or she is thirsty or asks for a drink.

SURGICAL SITE INFECTIONS

Surgical site infections (SSI) cause morbidity for the patient, compromise the cosmesis and occasionally the success of a procedure, and increase the overall costs to the health-care system. The risk of SSIs is related to the wound class and duration of the surgery and appears to be independent of the underlying disease state of the patient.[79] As discussed above, prophylactic antibiotics are indicated in some procedures and can reduce SSIs. However, care should be taken to use prophylaxis correctly. All antibiotics, with the exception of vancomycin, should be administered within 24 hours of incision and should not be continued past 24 hours postoperatively.

There are additional measures that can be taken to decrease SSIs besides antibiotic prophylaxis. A recent quality improvement study showed a 21% reduction in SSIs among high-risk surgeries after initiating a bundle that included preoperative bathing with chlorhexidine gluconate (soap and water for infants <2 months), clippers for hair removal, and chlorhexidine gluconate skin prep (povidone-iodine for infants <2 months) in addition to proper adherence to antibiotic prophylaxis.[80] Chlorhexidine-alcohol skin preparation has been shown to be more effective than povidone-iodine in preventing SSIs and has been approved for use in children above the age of 2 months.[81] Other interventions that have been shown to decrease SSIs include maintaining intraoperative normothermia[82] and avoiding perioperative hyperglycemia in diabetic patients.[83]

FLUID AND ELECTROLYTE MANAGEMENT

Children are more at risk for electrolyte disturbances than are adults due to their smaller size, larger ratio of surface area to volume, and less developed homeostatic mechanisms. Additionally, surgical patients often have net fluid deficits due to preoperative fasting and gastrointestinal losses if a bowel regimen was employed. Intraoperatively, blood loss, third spacing of fluids, vasodilation secondary to anesthesia, and insensible losses, especially in open abdominal cases, compound hypovolemia. Maintenance fluid rates are a standardized method to replete and maintain normovolemia; however, this method must be used with caution as each patient is unique and clinical indicators must be used to determine true volume state. Maintenance rates were initially calculated based on energy metabolism, which itself is a function of surface area and can be calculated based on

weight. In children, maintenance rates can be determined using the Holliday-Segar 4-2-1 rule (Table 54.2). Isotonic solution should be used for hydration in the first 12 hours following surgery, followed by hypotonic fluid.

Postoperative fluid losses should be recorded and appropriately repleted. Patients with diarrhea or nasogastric tube decompression may require different types of fluid replacement as the electrolyte concentration of the fluids lost is unique. Postoperative patients are at risk for hyponatremia; the combination of salt and water retention with high stress-induced ADH levels in the face of ongoing fluid and electrolyte predisposes to hyponatremia. Electrolytes should be checked in patients on prolonged IV hydration. While severe postoperative hyponatremia is a rare event at 0.34%, it has a mortality rate of 8% in otherwise healthy children.[84]

PAIN MANAGEMENT

Adequate pediatric pain management requires a team approach, with opportunities to maximize patient comfort preoperatively, intraoperatively, and postoperatively. While previously misunderstood, it is now widely recognized that infants have well-developed pain perception pathways and require analgesia. One challenge of pediatric pain control is titration, as many infants and children cannot verbalize what they are feeling. Important markers of pain in infants include tachycardia, hypertension, sweating, posturing, facial expressions and crying. Children should be given a visual analog scale, such as the Wong-Baker FACES Pain Rating Scale (Fig. 54.2), to obtain objective ratings.

Regional anesthesia can be very effective at controlling initial postoperative pain. Common blocks in urology include caudal blocks, ilioinguinal/iliohypogastric nerve blocks, and penile blocks. Anatomic landmarks are used to identify the site of injection; however, if they are difficult to palpate ultrasound is increasingly being utilized. Blocks typically contain ropivacaine or bupivacaine with a maximum dose of 2.5 or 3 mg/kg respectively and provide relief for 2–8 hours. When administered prior to the incision, regional anesthesia decreases the amount of general anesthetic needed and, depending on the duration of the procedure, postoperatively decreases pain scores, opioid use,[85] and nausea.[86]

After major surgery patient controlled analgesia (PCA) can be an effective option in children ≥5 years. PCAs allow frequent patient-initiated administration of low-dose narcotics with parameters for lock-outs and total dosage maximums. Among patients who cannot self-initiate medications due to age, developmental, or physical limitations, nurses or caregivers can safely serve as a proxy and provide the stimulus for medication delivery.[87] Basal rates of analgesia can be administered and aid in promoting sleep at night; however, this can cause undue sedation, and therefore frequent monitoring is needed. Morphine is administered at 25 μg/kg/dose and hydromorphone is administered at 4 μg/kg/dose, both with a lockout at 8–10 minutes. For patients with lower analgesia requirements, IV narcotics, including morphine, hydromorphone, and fentanyl, can be administered every 2–4 hours,as needed.

Nonnarcotic IV analgesics are an important adjunct as they do not carry the same side effects of sedation, respiratory depression, and constipation. Ketorolac is an IV NSAID that has been shown to have similar efficacy to morphine.[88] Ketorolac is safe in infants >1 month old; however, it should not be used in patients with renal impairment or an abnormal coagulation profile. It is dosed at 0.5 mg/kg every 6–8 hours and use should not exceed 48–72 hours. IV acetaminophen is another nonnarcotic that is safe in infants

Table 54.2 Maintenance Intravenous Fluids for Pediatric Patients Undergoing Surgical Procedures

Patient Age Group	Initial 12 Hours	Maintenance Thereafter
Infants (<6 mo)	D5 ¼ NS at 1.5 (MR)	D5 ¼ NS at MR
Children (>6 mo)	D5 LR at 1.5 (MR)	D5 ½ NS + 10 mEq KCl/L at MR
Adolescents	D5 LR at 1.5 (MR)	D5 ½ NS + 20 mEq KCl/L at MR
Renal Failure	Avoid potassium	

D5, 5% dextrose; KCl, potassium chloride; LR, lactated Ringer solution; MR, maintenance rate; NS, normal saline

MR: for 0–10 kg give 4 mL/kg/hr
for 10–20 kg give 40 mL/hr + 2 mL/kg/hr
for 20–40 kg give 60 mL/hr + 1 mL/kg/hr

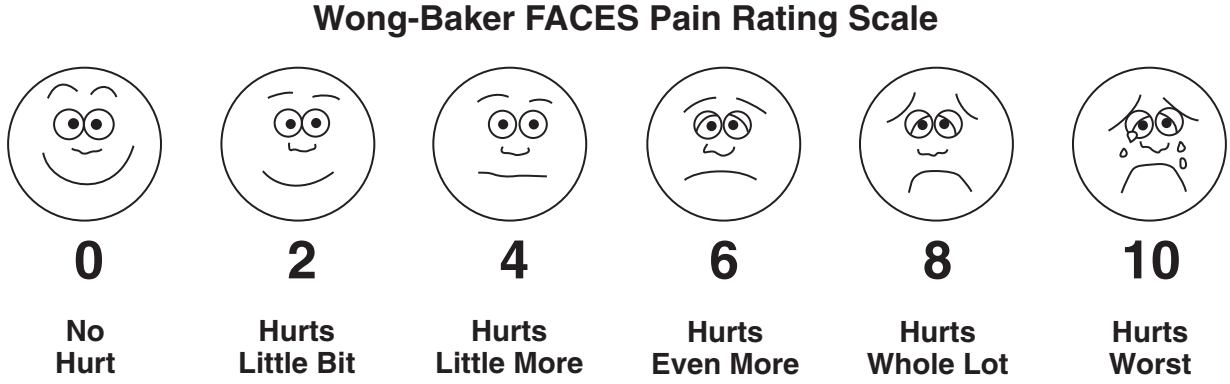

Figure 54.2 Wong-Baker FACES scale. (With permission from Wong-Baker FACES Foundation (2015). Wong-Baker FACES Pain Rating Scale. Retrieved March 17, 2016 from http://www.WongBakerFACES.org.)

and children, dosed at 10 mg/kg/dose every 6 hours with a maximum 24 hour dose of 40 mg/kg. The combination of IV ketorolac and acetaminophen has been shown to halve the use of narcotics and the resultant unwanted narcotic side effects.[89]

For outpatient surgery, there are a number of oral agents that have proven to be effective. Common oral narcotics include combination formulations of codeine or hydrocodone with acetaminophen. Both of these medications come in pill or elixir form and are safe in children >2 years old for hydrocodone and >3 years old for codeine. Dosing is based on the narcotic component with a maximum of 1 mg/kg/dose every 4 hours for codeine and 0.2 mg/kg/dose every 4 hours for hydrocodone. Acetaminophen alone and ibuprofen are two nonnarcotic oral options. Acetaminophen metabolism is delayed in neonates and therefore should be dosed on a 6-hour instead of 4-hour schedule. If prescribing acetaminophen as well as an acetaminophen-containing narcotic, parents should be counseled on maximum dosing of 90–100 mg/kg or 4 g in 24 hours. Ibuprofen is dosed at 10 mg/kg every 6 hours; however, it should be used cautiously if there is a concern for postoperative bleeding. Ketorolac can also be given orally; however, oral use should not exceed 5 days (Table 54.3).

ETHICS

Medical ethics is a nuanced and often enigmatic field that becomes even more complex in the context of pediatric patients. One of the bedrocks of modern medicine, informed consent, weakens when patients are unable to consent for themselves. When approaching an ethical issue, physicians should be aware of the four principles of bioethics: nonmaleficence (avoiding harm), beneficence (providing benefit), autonomy (informed consent), and justice (access to care). In accordance with these moral pillars, prior to any procedure the surgeon should have an open discussion with the parent and child of the risks and benefits of the proposed surgery.

Table 54.3 Dosages for Common Pediatric Pain Medications

Route of Administration	Medication	Dosage
PCA	Morphine	
	Basal	0.03 mg/kg/hr
	Intermittent	0.25 mg/kg/dose
	Hydromorphone	
	Basal	0.004 mg/kg/hr
	Intermittent	0.04 mg/kg/dose
IV	Morphine	0.05 mg/kg/dose
	Hydromorphone	0.01–0.02 mg/kg/dose
	Ketorolac	0.5 mg/kg/dose
Oral	Hydrocodone	0.2 mg/kg/dose
	Codeine	1 mg/kg/dose
	Acetaminophen	10 mg/kg/dose
	Ibuprofen	10 mg/kg/dose

Ethics intersects with pediatric urology practice in a variety of settings. Procedures that are largely cosmetic pose a dilemma, especially when patients are not old enough to participate in the discussion. Circumcision is one such procedure. While the American Academy of Pediatrics' most recent statement in 2012 states the benefits of circumcision outweigh the risks,[90] dissenters argue this guideline has a cultural bias that leads to overstatement of the medical benefits of the procedure.[91] Circumcisions should not be undertaken in the absence of parental consent and consensus.

Disorders of sexual differentiation (DSD) challenge physicians from a medical, surgical, and psychological standpoint. These patients require a multidisciplinary approach with collaboration from urology, endocrinology, genetics, and psychiatry. It is crucial that parents have a firm understanding of their child's condition and realistic expectations for development. Timing of genitoplasty for these patients is very controversial and should not be undertaken until there is some certainty as to which gender the child will identify with. While medical interventions are reversible, surgical procedures are often impossible to undo. Congenital adrenal hyperplasia is the most common DSD and XX patients almost universally identify as females. The majority of specialists would recommend genitoplasty before 2 years of age;[92] however, whether it should be done with a simultaneous reduction clitoroplasty is controversial. Historically, in DSD cases where there was not adequate tissue at birth to perform a phalloplasty, feminizing surgery was undertaken. This practice did not account for the many factors that make up gender identity among this population and is no longer recommended. Huge strides have been made in phallic reconstruction such that phalloplasty is possible before or after puberty.

Neonatal medicine provides another ethical challenge for pediatric urologists. Prenatal ultrasound findings of bilateral hydronephrosis, megacystitis, and oligohydramnios portend poorly for the fetus, and parents turn to the urologist for answers. Ultimately there is no right answer, and it is the urologist's job to give a realistic picture of prognosis using all available clinical data and to present options for both prenatal and postnatal interventions. Long-term healthy survival is now achievable for many of these infants, but requires a team of medical professionals and truly committed parents.

Conclusions

Quality pediatric urologic care requires attention to detail in the preoperative, intraoperative, and postoperative period. Though pediatric patients offer many unique challenges, caring for this population can be a very rewarding experience.

Chapter 54 Questions

1. Allowing a parent to be present for induction of anesthesia on his or her child has been shown to:
   a. Decrease patient anxiety about anesthesia
   b. Increase operative times
   c. Increase parent satisfaction with surgical experience
   d. Improve quality of anesthesia delivery
   e. Increase risk of surgical site infection

2. A 10-year-old male is having a bladder augmentation. Preoperative urine culture was negative, and there is no history of urinary tract infections (UTIs). What would be the most appropriate perioperative antibiotic regimen?
   a. Ceftriaxone administered 90 minutes prior to incision and continued for 72 hours after the surgery
   b. Vancomycin administered 30 minutes prior to incision and continued for 24 hours after the surgery
   c. No antibiotics are necessary
   d. Gentimycin administered 30 minutes prior to incision and continued for 72 hours after the surgery
   e. Ancef administered 30 minutes prior to incision and continued for 24 hours after the surgery

3. During a religious circumcision in the patient's home the glans is accidentally amputated. How should the family proceed?
   a. Place the glans on ice and transport to the nearest children's hospital
   b. Arrange for transportation to a tertiary center where microsurgical repair could be performed
   c. Wrap the glans in soaked gauze and surround with ice and transport to the nearest children's hospital
   d. Place the glans in the freezer, finish the ceremony, then proceed to the nearest children's hospital
   e. Place a dressing and allow for the wound to heal before a delayed repair

4. When comparing results from stented versus unstented pyeloplasties, stented patients:
   a. Have shorter lengths of hospital stays following pyeloplasty
   b. Have lower rates of urinary leakage from pyeloplasty site
   c. Have lower rates of postoperative UTIs
   d. Have longer periods of Penrose drain postoperatively
   e. Have lower pyeloplasty failure rates

5. A 9-year-old boy with a history of posterior urethral valves with chronic kidney disease and a history of UTIs is undergoing cystoscopy with injection of onabotulinumtoxin A. Which of the following is not indicated?
   a. Basic metabolic panel
   b. Urine culture
   c. Auscultation of the heart and lungs
   d. Questions regarding family history of bleeding disorders
   e. Complete blood count

6. Which of the following is NOT true regarding laparoscopy in children compared with adults?
   a. Lower intraabdominal pressures are needed to create adequate working space
   b. Smaller surface area of skin requires more precise placement of trocars
   c. The bladder is smaller and so does not require decompression with a Foley catheter
   d. CO_2 insufflation can have a larger effect on child physiology due to a higher incidence of right to left cardiac shunts
   e. Both populations accrue similar benefits with improved cosmesis, shorter hospital stays, and reduced postoperative pain

7. All of the following are relative contraindications to neonatal circumcisions except:
   a. Penoscrotal webbing
   b. Micropenis
   c. Abnormal urethral meatus
   d. Buried penis
   e. Dorsal hood with orthotopic meatus and no curvature

8. The nerve at most risk for injury during a laparoscopic orchidopexy is:
   a. Ilioinguinal
   b. Iliohypogastric
   c. Genitofemoral
   d. Pudendal
   e. Obturator

9. An 8-year-old female who 3 years ago had a pyeloplasty for congenital UPJ obstruction presents with left flank pain. Ultrasound shows grade 4 hydronephrosis without ureteral dilation, and a Lasix renogram shows 35% function of the left kidney with delayed wash out. The best surgical option is:
   a. Endopyelotomy of the left UPJ
   b. Endoscopic balloon dilation of the left UPJ
   c. Left ureteral stent placement
   d. Robotic redo left pyeloplasty
   e. Left open nephrectomy

10. Which of the following conditions would not prompt delay of an elective surgery?
    a. Active lower respiratory tract infection
    b. Skin rash at the site of surgery
    c. Consumption of breast milk 5 hours prior to surgery
    d. Poorly controlled asthma
    e. Newly preoperatively detected heart murmur

Answers

1. **c.** While studies have shown mixed results regarding patient metrics, parents have been seen to have an overall improved experience when allowed to accompany their child for the induction of anesthesia.
2. **e.** While there are no specific pediatric urologic guidelines for perioperative antibiotics, an antibiotic should be chosen that covers skin flora, is given within 60

minutes of the operation, with the exception of vancomycin, which should be given at least 60 minutes before the incision. Perioperative antibiotics should not be continued for more than 24 hours.

3. **c.** The amputated tissue should be wrapped in soaked gauze prior to being placed on ice. Direct contact with ice can cause frostbite and compromise the tissue. The repair should be completed within 8 hours of the amputation. Microsurgery is typically not needed so care should not be delayed by trying to reach a hospital where microsurgery is available.
4. **b.** Leaving a ureteral stent appears to lower rates of immediate urinary leakage from the anastomosis site, with rates of leakage being 3% versus 8% without a stent. The literature has shown that stented patients tend to have slightly longer lengths of stay, have higher rates of UTIs, and have the Penrose drain removed earlier. Outcomes of pyeloplasty are the same regardless of stent status.
5. **e.** This patient has a history of chronic kidney disease so a preoperative chemistry is indicated. Likewise, a urine culture prior to instrumentation in a patient with a history of UTIs is warranted. Every patient should have a full history, including family history, and auscultation of heart and lungs prior to surgery. CBC is not indicated in this patient as he has no risk factors for anemia.
6. **c.** The bladder takes up a more abdominal location in children and thus necessitates decompression with a Foley catheter for any laparoscopic procedure. The remainder of the statements are true.
7. **e.** An abnormal urethral meatus is a contraindication as the foreskin may be needed for a surgical repair when the child is older. However, a patient with a dorsal hood in the setting of otherwise normal anatomy can be safely circumcised at birth. Penoscrotal webbing, micropenis, and buried penis all put the patient at risk of having too much skin taken, so it is best to wait until the child is older and a formal circumcision can be performed under anesthesia.
8. **c.** While the ilioinguinal and iliohypogastric nerves are at risk during all orchidopexies, the genitofemoral nerve is the most likely to be injured as it courses with the vas deferens through the inguinal canal.
9. **d.** After initial failed pyeloplasty, redo pyeloplasty either open, laparoscopically, or robotically provides salvage rates approaching 100% in children. Both endopyelotomy and endoscopic balloon dilation have far inferior outcomes. Ureteral stent placement may temporarily relieve the pain; however, it does not treat the underlying condition. Nephrectomy is not indicated in a kidney that has 35% function.
10. **c.** Breast milk can safely be consumed until 4 hours prior to surgery. Active lower respiratory tract infection increases the risks of adverse respiratory events during anesthesia. Skin rash at the site of surgery is an absolute contraindication to an elective procedure. Treatment of medical conditions such as asthma should be optimized prior to an elective anesthesia. A heart murmur can indicate underlying structural heart issues, and the patient should be assessed by a cardiologist prior to surgery.

55 Complications of Pediatric Endoscopic Surgery

DAVID I. CHU, PASQUALE CASALE, and GREGORY E. TASIAN

CHAPTER OUTLINE

Cystoscopic Interventions
Puncture of Ureterocele
Endoscopic Correction of Vesicoureteral Reflux
Incision of Posterior Urethral Valve
Nephrolithiasis
Introduction
Goals of Therapy
General Considerations
Radiation
Residual Fragments
Ancillary Procedures/Anesthesia
Ureteroscopy
Percutaneous Nephrolithotomy
Conclusions
Chapter 55 Questions and Answers

KEY POINTS

1. Technological advances and miniaturization have increased the ability to treat certain urologic conditions endoscopically.
2. Though complications are generally less common with endoscopic surgery than corresponding open approaches, they can still be significant and warrant equal caution in preventing.
3. Due to the increasing burden of nephrolithiasis among children, the need for optimizing surgical treatment has never been higher.

Cystoscopic Interventions

The miniaturization of optics and instrumentation has allowed endoscopic approaches to certain urologic pathologies. Common cystoscopic procedures include puncture of ureteroceles, endoscopic injection for vesicoureteral reflux, and ablation of posterior urethral valves.

PUNCTURE OF URETEROCELE

A ureterocele is a cystic dilation of the distal aspect of the ureter where it enters the bladder. Embryologically, it is thought to be a remnant of Chwalla's membrane. Ureteroceles are classified into intravesical, extravesical, or ectopic and can be found in both single and duplicated collecting systems. A ureterocele can cause obstruction of the ipsilateral collecting system, leading to loss of kidney function and occasionally obstructive urosepsis if not recognized and addressed in a timely fashion. When intervention is needed, or planned, initial surgery usually entails a cystoscopic ureterocele puncture. Different techniques have been described for ureterocele puncture, but the goal remains the same: Unobstruct and decompress the ureterocele and its accompanying upper tract system, without causing de novo vesicoureteral reflux. The authors prefer incision with a monopolar hot knife or Holmium laser at the base of the ureterocele. Others have described a "watering can" puncture technique with purported lower de novo vesicoureteral reflux, although larger studies are needed for external validation.

Success rates of ureterocele puncture are varied, depending on the number of collecting systems and the type of ureterocele. Some studies report better success – meaning resolution of obstruction and lack of additional procedures – for intravesical ureteroceles compared to extravesical or ectopic ureteroceles. A systematic review and meta-analysis of outcomes following ureterocele puncture revealed a significantly higher risk of reoperation after puncture of an extravesical ureterocele.[1] Rates of reoperation ranged from 0% to 50% for intravesical ureterocele punctures, compared to 48–100% for extravesical ureterocele punctures. This finding remained robust on sensitivity analyses restricting the meta-analysis by duration of follow-up, age at surgery, and duplex systems only. However, heterogeneity and publication bias were both present. Similarly, in the same systematic review and meta-analysis, duplicated systems were at greater risk for reoperation than were single-system ureteroceles after cystoscopic puncture.[1] Rates of reoperation ranged from 0% to 25% for single-system ureterocele punctures, compared to 31–83% for duplicated systems. Heterogeneity was absent, although only three studies were included in this meta-analysis.

One notable complication after puncturing a ureterocele is de novo vesicoureteral reflux into the same

collecting system, although most cases are low grade that self-resolve. Two studies published after the aforementioned meta-analysis demonstrate wide variability in rates of new reflux. At a mean follow-up of 3.8 years, one study of 46 duplicated-system ureteroceles noted decompression of the ureterocele moiety in 56% (26 of 46) of patients with a single puncture and an additional 37% (17 of 46) after two punctures, for a cumulative success rate from cystoscopic intervention alone of 93%.[2] However, these authors did not define de novo reflux as surgical failure. New ipsilateral same-moiety vesicoureteral reflux was noted in five patients (four after one puncture, one after two punctures), with three ultimately requiring endoscopic correction of reflux and two experiencing spontaneous resolution. Another single-institution study reviewed 83 patients (26 single-system, 57 duplicated-system) who underwent ureterocele puncture with a mean follow-up of 24 months.[3] Cure rates, including lack of de novo reflux, were 56% and 15% in single-system versus duplicated-system ureteroceles, respectively. New vesicoureteral reflux into the ureterocele moiety was found in 28% and 56% of single-system and duplicated-system ureteroceles, respectively. Spontaneous resolution of the de novo reflux occurred in four of the five single-system patients, compared with six of the 18 duplicated-system patients.

In summary, cystoscopic puncture of ureterocele offers a minimally invasive approach for initial decompression and the potential for a permanent cure. The rates of success vary by ureterocele location and type of associated collecting system, but repeat puncture can salvage initial failures. New postoperative vesicoureteral reflux may be monitored as with any child with reflux, but spontaneous resolution may be lower in children with duplicated systems.

ENDOSCOPIC CORRECTION OF VESICOURETERAL REFLUX

Vesicoureteral reflux is a common urologic anomaly where urine can reflux from the bladder retrograde to the kidneys. It can be treated cystoscopically with injection of material, such as dextranomer/hyaluronic acid or Deflux, that better coapts the ureterovesical junction to prevent urine from passing retrograde up to the kidney. More details about this procedure and its complications are reviewed in Chapter 56 with the other minimally invasive surgical techniques for treatment of vesicoureteral reflux.

INCISION OF POSTERIOR URETHRAL VALVE

Posterior urethral valves (PUV) are the most common urologic causes of chronic kidney disease renal failure during childhood.[4] They are embryologically related to posterior urethral folds. Because PUV develop early in gestation, the impact on bladder, renal, and pulmonary function can be severe. In a newborn boy with PUV, urethral catheterization is needed to bypass the valves and decompress the urinary system. Once the infant is medically stabilized, he then undergoes a cystoscopic ablation or incision of his PUV. Though there are many methods described of ablating PUV,[5] the follow-up period is critical to monitor for persistent or recurrent obstruction and other complications.

Some experts, including the authors, recommend using a 6Fr or 7.5Fr cystoscope and incising the valves with either a cold knife or monopolar electrode at the 5-, 7-, and 12-o'clock positions to obtain maximum ablation without injuring the external urinary sphincter. The probability of residual valves (i.e., incomplete ablation) ranges from 10% to 33%,[6,7] and 11% of patients have been reported to develop postablation urinary retention.[5] Over a median follow-up of 6.5 years, one of the largest published retrospective cohorts of PUV patients demonstrated other short-term and long-term complications of PUV ablation.[5] Urinary extravasation was noted in three patients, one of whom experienced a rectal injury and subsequent diverting colostomy during antegrade ablation through a suprapubic tract. Gross hematuria occurred in two patients, one of whom required cystoscopic fulguration. At a mean follow-up of 64 months, six of 291 total patients developed urethral stricture disease, with the strictures developing a mean 24 months after valve ablation. All of the patients were treated with direct vision internal urethrotomy, some requiring multiple rounds of urethrotomy, without any need for formal urethroplasty.

Besides persistent and recurrent obstruction, a rarer but just as significant complication following PUV ablation is injury to the urinary sphincter with subsequent urinary incontinence. This can happen when the ablation extends too distally into the external sphincter. One single-institution retrospective review of 67 boys with PUV noted that 34% (23 of 67) had urinary incontinence on median follow-up of 9 years, with only one of the 23 being directly related to surgical etiology of sphincteric incontinence.[8] The remaining boys were thought to have urinary incontinence secondary to bladder dysfunction. Similarly, in another single-institution retrospective cohort of 50 newborn males with PUV, two of the 50 boys had sphincteric incontinence caused by surgical technique at a mean follow-up of 6.8 years.[9] Thus, though injury to the sphincter happens seldomly during PUV ablation, it can occur and must be carefully prevented. The authors stress the importance of small movements of the scope during ablation, with erring on the side of smaller ablative cuts. Immediately following the ablation, a catheter that passes easily into the bladder should be placed for at least 24 hours to dilate the ablated valves. The authors do not place a Foley catheter due to the potential danger of inflating the balloon in the posterior urethra and the theoretical risk of obstruction of the ureteral orifices from an intravesical balloon. We prefer a coudé mentor catheter appropriate to the size of the patient's urethra (e.g., 6Fr in a newborn). Should a patient develop persistent inability to void after initial ablation, then the clinical threshold should be low to trigger a repeat cystoscopic evaluation and repeat ablation if necessary, versus a vesicostomy should a repeat ablation be deemed too risky for sphincteric incontinence. Should suspected sphincteric incontinence occur, the authors recommend confirming with a videourodynamics study once the child is toilet-trained. Depending on the severity and progression of bladder dysfunction when the child is older, construction of a catheterizable channel with bladder augmentation and bladder neck closure may be needed.

Nephrolithiasis

INTRODUCTION

Nephrolithiasis is now a disease that is increasingly being diagnosed during childhood. A recent population-based study demonstrated that the annual incidence of nephrolithiasis has increased 5% per year among 15–19 year olds since the 1990s.[10] The rising prevalence of nephrolithiasis has resulted in an increased need for surgical intervention for younger patients. However, there is substantial variability in the utilization of surgical interventions for children with nephrolithiasis, with the hospital where the surgery takes place one of the most important factors in determining which type of surgery is used.[11] Therefore the need to determine optimal interventions – those that maximize efficacy and minimize risk – is great. This section reviews complications of endoscopic stone surgery for children, namely ureteroscopy (URS) and percutaneous nephrolithotomy (PCNL). Shock wave lithotripsy (SWL) is not covered.

While historically most stones in children were treated with SWL, technologic advancements in miniaturization and optics of endoscopy have allowed an increase in utilization of URS and PCNL.[12,13] According to the American Urological Association 2016 guidelines, URS is considered first-line surgical treatment along with SWL for children with ureteral or renal calculi.[14,15] PCNL is usually reserved for large staghorn stones, large infection stones where clearance is essential, or renal stones in kidneys with abnormal anatomy, such as patients with horseshoe kidneys or urinary diversions.[12] Although the 2016 guidelines state either SWL or PCNL could be performed for children with renal stones >2 cm, we recommend PCNL for large renal stones because of the higher stone-free rates and lesser need for additional procedures, assuming the treating urologist has the appropriate training and experience with percutaneous renal surgery.

A recent systematic review and meta-analysis comparing SWL, URS, and PCNL in adults for lower pole stones <2 cm in size favored PCNL over SWL and URS over SWL, particularly in stones 10–20 mm in size.[16] Another recent systematic review and meta-analysis compared PCNL to URS in adults for any kidney stone and noted higher stone-free rates with PCNL techniques but also higher complication rates, greater blood loss, and longer hospital stay.[17] Whether these results in adults transfer completely to children remains controversial and certainly warrants higher-quality pediatric-specific studies. Additionally, the comparative effectiveness of newer techniques such as mini-PCNL, ultra-mini-PCNL, and micro-PCNL remains to be determined for children with nephrolithaisis.[18]

GOALS OF THERAPY

The goals of surgical intervention for nephrolithiasis are the same for children as they are for adults, i.e., to render the patient stone free with the minimal number of procedures and complications. The choice of intervention is determined primarily by the size and location of the stone and patient anatomy. Secondary considerations include patient comorbidities, composition of stone (if known), experience of the urologist, equipment availability, and wishes of the parents and patient. Additionally, the choice of SWL versus URS is heavily influenced by the site where the child obtains care.[11] One potential explanation for this variation in care is that URS requires greater technical skill and experience than does SWL.

GENERAL CONSIDERATIONS

Radiation

Patients with nephrolithiasis are often exposed to radiation during diagnosis, surgical treatment, and for surveillance after definitive intervention.[19–21] URS and PCNL both typically use fluoroscopy, which delivers ionizing radiation. Cumulative radiation exposure is a particularly important consideration for children with nephrolithiasis given that they are more likely than adults to require future diagnostic imaging and surgical interventions that use ionizing radiation.[22,23] Additionally, the cumulative risk of radiation exposure may be higher in children than in adults because of a longer life expectancy and greater sensitivity of developing tissues to the effects of radiation.

Recent studies have quantified radiation exposure during endoscopic surgery for nephrolithiasis in children. Ristau and colleagues performed a cross-sectional study of all children who underwent ureteral stent placement, URS, and PCNL at the University of Pittsburgh between 2005 and 2012. The median fluoroscopy times for unilateral URS, bilateral URS, and PCNL were 1.6 minutes, 2.5 minutes, and 11.7 minutes, respectively.[24] This was equivalent to 3 mSv for URS and 16.8 mSv for PCNL. Importantly, each patient received a median of one (IQR 1-3) CT scan and three (IQR 1-8) abdominal x-rays for the associated stone episode. The average cumulative radiation exposure for a patient who underwent a CT scan, PCNL, and three x-rays in a 1-year period was 32 mSv. The radiation safety concept – as low as reasonably achievable (ALARA) – emphasizes using the minimal amount of radiation necessary to achieve the desired outcome. Current guidelines recommend a maximum dose of 50 mSv in a 12-month period, and an average of <20 mSv/year over a 5-year period.[25] Thus a therapeutic plan for a single large stone requiring PCNL approaches the limits of recommended ionizing radiation exposure.

Nelson and colleagues also demonstrated substantial radiation exposure for children undergoing ureteroscopy. They note that while fluoroscopy time was the most important determinant of radiation exposure, other factors, such as source-to-skin distance, use of ureteral access sheaths, and dose rate setting, also contributed to total radiation dose.[21] Indeed, three of the four categories that determine the patient's total radiation exposure are modifiable. Of fluoroscopy time, source-to-skin distance, fluoroscopy settings, and patient abdominal wall thickness, only patient abdominal wall thickness cannot be adjusted to decrease delivered radiation. Implementing a 6-item checklist designed to reduce radiation exposure during pediatric URS resulted in a 67% reduction in fluoroscopy time, 78% improvement in skin-to-image intensifier distance, and >90% utilization of appropriate dose settings. Compared to patients who underwent URS prior to implementation of the checklist, radiation exposure was reduced by 87%

among patients who were treated after implementation.[26] Additionally, recent techniques that utilize ultrasound for URS[27] and PCNL[28] help to minimize radiation exposure in children. At the authors' institutions, percutaneous access for PNCL is gained using renal ultrasound. We also use intermittent rather than continuous fluoroscopy when fluoroscopy is needed for URS and PCNL. Fluoroscopy technicians also operate the C-arm and reduce kVp, maximize skin-to-source distance, and narrow the image window to minimize radiation exposure while maintaining image integrity. We avoid routine magnification. Efforts are also ongoing to assess the role of ultrasound-guided URS.

Residual Fragments

Various studies have compared stone-free rates among the surgical treatment modalities. These rates for PCNL range from 70% to 97%, and from 85% to 88% for URS.[29] However, a widespread limitation of the existing literature on endoscopic interventions for pediatric nephrolithiasis means that there is an inconsistency in the definitions of stone-free status after surgery. Often, stone-free rates include ancillary procedures such as SWL. Additionally, different cut-offs for "clinically insignificant" residual fragments are used, which limits effective comparison of outcomes for alternative surgical interventions. Finally, the means by which stone clearance was assessed after surgery are variable. Endoscopy, ultrasound, fluoroscopy, CT scan, and plain film have all been used to define the presence of residual fragments; however, the sensitivity and precision of these methods are highly variable. There is a need to determine a universally accepted and utilized method to define stone clearance after surgical intervention in children.

Ancillary Procedures/Anesthesia

Surgical indications for children with nephrolithiasis are similar to adults. However, the smaller size of children's ureters and kidneys often require additional ancillary procedures to completely and safely remove stones. For example, the smaller size of children's ureters often precludes direct access with a ureteroscope secondary to the risk of ureteral perforation and stricture associated with active dilation. Therefore a ureteral stent is often placed prior to the ureteroscopy to allow for passive dilation of the ureter.[30,31] We routinely "pre-stent" children undergoing URS for kidney stones, particularly if a ureteral access sheath is used; however, we do not typically place a stent prior to URS for ureteral stones. Consequently, the increased stone-free rate with URS compared to SWL needs to be weighed against the greater number of procedures per stone. Future comparative and cost-effectiveness studies should examine the disadvantages and potential harms of surgical interventions along with their efficacy. Such studies will be critical for the development of patients' decision-making tools and their understanding of the impact of alternative interventions on the quality of life for themselves and their families.

URETEROSCOPY

URS has been used to treat children with ureteral and kidney stones since the late 1980s. Initially, the majority of stones extracted were located in the mid-to-distal ureter. Advances in technology, namely miniaturization and improved flexibility, have contributed to the increased use of URS for children and allowed treatment of stones located in the proximal ureter and all areas of the kidney. At our institutions, children undergoing URS are placed in the lithotomy position, similar to adults. However, it is important to use the appropriate-size stirrups to avoid pressure wounds and nerve injuries. We use three sizes of stirrups to provide the appropriate positioning for children of different sizes. For infants, we use gel rolls underneath the knees to provide a modified lithotomy position. Care is taken to ensure all pressure points are padded and the weight of the legs rests on the heels and not the calves or the knees where peroneal nerve injuries may occur.

The success of URS is dependent on stone size. URS should not be considered a first-line treatment for patients with stones larger than 15–20 mm. Additionally, although the efficacy of URS is less dependent on stone position than SWL, consideration must be given to the smaller size of children's kidneys. Smaller kidneys have less room to maneuver a ureteroscope and have sharper angles, which may make accessing stones in the lower pole difficult. Given these technical considerations, we recommend using 150-µm holmium laser fibers to access stones in the lower pole kidney, which have improved deflection compared to larger fibers.[32] We routinely use a 200-µm fiber for ureteral stones and stones located in the mid and upper pole calyces. Studies that compare the efficacy of stone "dusting" and fragmentation with basketing, which are currently ongoing among adult patients, have not been performed among children or adolescents. The authors frequently use a ureteral access sheath if basketing is required.

The complications of URS include ureteral injury, urinary tract infection, and bleeding. Serious complications (greater than Clavien III) are, in most reports, uncommon. In a recent systematic review, the overall stone-free rate for URS was 85.5% and complications occurred in 12% of patients. Only 2% were greater than Clavien grade III.[33] However, the definition of "success" is ill defined and varies substantially among studies. The method of assessing stone-free status ranges from visual inspection at the time of ureteroscopy to postoperative ultrasound or CT. It is thus difficult to directly compare the results and complications associated with different techniques, stone sizes, and stone locations. Generally, stone-free rates are lower for renal compared to ureteral stones (Fig. 55.1).

Although the comparative effectiveness of pre-stenting versus active ureteral dilation to allow primary passage of the ureteroscope has not been systematically examined, adverse outcomes such as ureteral perforation and stricture may be more common if placement of a ureteral stent is not placed prior to the URS to allow for passive ureteral dilation.[12,34] Complications that occurred among patients in whom a ureteral stent was not placed prior to URS include ureteral injury, ureteral stricture, and conversion to open surgery. In one recent report, 19% of children undergoing URS who did not have a ureteral stent placed prior to URS required open ureterotomy with or without ureteroneocystostomy due to a small ureteral orifice.[35] As mentioned above, if the scope or access sheath cannot be advanced easily up the ureter, a 4.6 or 4.7Fr ureteral stent is placed to passively dilate the ureter for at least 2 weeks before

Figure 55.1 Ureteropelvic junction obstruction that resulted from impacted proximal ureteral stone. The patient underwent a successful robotic pyeloplasty.

returning for the formal URS. We recommend against active dilation of the distal ureter because of the risk of ureteral injury and because the diameter of the ureter proximal to the ureteral orifice also limits safe ureteroscopy, particularly if an access sheath is used.

If a ureteral stricture is encountered or develops after ureteroscopy, a retrograde pyelogram can show the degree, length, and location of narrowing. Short midureteral strictures can undergo prolonged stent placement. Balloon dilation is used sparingly by the authors, with laser incision being preferred. We recommend formal reconstruction, which can often be performed robotically, for longer, denser, or recurrent strictures. Distal strictures may be treated with a ureteroneocystostomy. Proximal or midureteral strictures may necessitate pyeloplasty or excision and primary anastomosis, respectively.

A selection of contemporary studies on URS among children is shown in Table 55.1 along with a selected few studies from early in the URS experience to allow comparison of patients and stone characteristics, ureteroscopes, outcomes, and complications.

PERCUTANEOUS NEPHROLITHOTOMY

Percutaneous nephrolithotomy is the preferred intervention for larger renal calculi. The size cut-off has not been well established for children. A poor-quality randomized trial demonstrated that stone-free rates are higher after PCNL than after URS for children with renal calculi >2 cm;[36] however, the risk of complications is also higher. Complications associated with PCNL include blood loss requiring transfusion, noninfectious fever, sepsis, injury to the kidney (including renal pelvis and ureter), pleural injury leading to hydro or pneumothorax, and prolonged urine leak. Chest complications are higher with a supracostal access, particularly when performed above the 11th rib.[37] At the authors' institution, we use a lower pole access for most stones and use upper pole access staying below the 11th rib for large renal pelvis stones that extend past the UPJ.

The proportion of children who experience some complication after PCNL ranges from 15% to 39%. Although most of these complications are minor, complications greater or equal to Clavien III occur in 1–16% (Table 55.2). The probability of operative blood loss requiring transfusion is consistently <10%. Desai and colleagues demonstrated that the risk of bleeding increases with access tract size.[38] Standard access tracts for adults are 24–30Fr; however, the relative size of 24 to 30Fr tracts in pediatric patients has been estimated to be 72Fr due to the smaller size of children's kidneys.[39] Should significant bleeding occur, we recommend aborting the operation, placing either a Foley catheter or reentry catheter as a nephrostomy tube, and treating as clinically indicated and as one would do for adult patients. Should a renal pelvis injury occur, we recommend stopping the operation and placing an antegrade ureteral stent, if feasible. Treatment of known complications of PCNL in children, including hydrothorax and postoperative bleeding, is similar to adults. Due to the possibility of bleeding requiring embolization or hydrothorax requiring chest tube, we recommend that PCNL only be performed at children's hospitals with a pediatric interventional radiology team capable of performing these procedures.

Miniaturization of access sheaths and nephroscopes and improvements in stone fragmentation technology have allowed the use of smaller access tracts while maintaining stone-free rates at or above 75%. Mini- and micro-PCNL have become increasingly common for large renal stones for both children and adults; however, the terminology is not standardized. Mini-PCNL usually refers to access tracts of <20–24Fr whereas micro-PCNL refers to tracts <10Fr. At the authors' institutions, we obtain renal access in the operating room at the time of the PCNL. We first perform cystoscopy and place an open-ended ureteral catheter to just below the UPJ, which can be used for retrograde pyelograms or instillation of saline to distend the collecting system. We then position the patient prone over gel bolsters and obtain renal access with ultrasound. Rarely, if CT guidance is required for renal access in a child with spinal dysraphism or an aberrantly positioned kidney, a nephrostomy tube is placed by interventional radiology prior to the scheduled PCNL. After placement of two wires (with the safety wire preferentially down the ureter), we use a Cook 18Fr balloon dilator and PTFE sheath for renal access. Children's kidneys, and especially infants' kidneys, are more mobile than adults' kidneys and often push away when obtaining initial needle access and placing the access sheath. Attention to the location of the tip of the balloon in the collecting system and bony landmarks is critical when advancing the sheath under fluoroscopy. If necessary, a retrograde pyelogram can be performed through the ureteral catheter to redefine the collecting system anatomy. Prior to placing a sheath in small children, we trim it to shorten the extracorporal component, which we find improves maneuverability and limits torque on the kidney. After obtaining access, we use a 15/18Fr rigid nephroscope and the ShockPulse lithotripter, which uses both ultrasonic and mechanical energy to fragment and remove the stone(s). The ShockPulse was a paradigm shift for us in the care of children with large renal stones because it combined the greater efficacy of the CyberWand (compared to holmium

laser) with probes that are small enough (2.1–11.3Fr) to be used in mini-nephroscopes and semi-rigid ureteroscopes. Due to the sharper angles and narrower infundibula of children's kidneys, we often use a flexible pediatric cystoscope and/or flexible ureteroscope to confirm stone clearance and access midpole calyces for residual fragments. Following stone clearance, we routinely place a nephrostomy tube, the size of which depends on the child's age. The authors use a 10 to 12Fr Malecot in infants and a 14Fr Malecot or Foley catheter in adolescents. If there is substantial stone burden and/or substantial edema at the UPJ, we place a ureteral stent in addition to the nephrostomy tube. In this setting, the nephrostomy tube is removed after the urine clears and the patient is safe for discharge, usually on POD 1. At this time there is insufficient evidence that tubeless PCNL is a safe option for children.

The probability of complications in contemporary practice in the United States is uncertain and hard to ascertain. Most of the case series on PCNL, mini-PCNL (access tract <24Fr), and micro-PCNL (~5Fr) have been performed in India, Turkey, and China, often in areas with endemic stone disease and a large volume of children with complex renal calculi. Accordingly, the reports often reflect a high institutional and surgeon experience with PCNL. It is uncertain whether similar results would be found in centers in the United States, where nephrolithiasis among children has become more common only recently.

In conclusion, despite the recent AUA guidelines that state both SWL and PCNL are options for children with renal stones >2 cm, we recommend PCNL for these patients because SWL is simply less effective than PCNL for large renal stones. We also have concerns about the safety of SWL in pediatric patients. It is possible that the recently reported association between SWL to the kidney and hypertension[40] may be greater among children because of the larger area of the kidney affected by the shock waves and the longer life span over which hypertension may develop. However, PCNL and percutaneous renal access in children should be performed only by experienced urologists who have the necessary training and equipment. In order to maximize stone-free rates and minimize complications, we recommend that children with large renal stones be referred to high-volume pediatric kidney stone centers.

Conclusions

In summary, pediatric endoscopic surgery has made tremendous progress with advances in technology. From cystoscopes small enough to ablate a newborn's posterior urethral valves to ureteroscopes thin and flexible enough to retrieve lower pole stones, technology has allowed endoscopic procedures in urology to become safer for our smallest patients.

Chapter 55 Questions

1. The type of ureterocele with the *least* chance of successful puncture is:
   a. Single-system intravesical ureterocele
   b. Single-system extravesical ureterocele
   c. Duplex-system intravesical ureterocele
   d. Duplex-system extravesical ureterocele
   e. All the above

2. The recommended locations to incise for ablation of posterior urethral valves are:
   a. 3 o'clock only
   b. 6 o'clock only
   c. 12, 5, and 7 o'clock
   d. 3, 6, and 9 o'clock
   e. 3 and 9 o'clock

3. The following is true about ablating posterior urethral valves:
   a. Ablation should be done as soon as the child is born
   b. Do not attempt to ablate or remove all remnants of the valves for fear of sphincteric incontinence
   c. Urethral strictures never occur after ablation of posterior urethral valves
   d. If the patient is too unstable for cystoscopic ablation of the valves, it is acceptable to wait without bladder catheterization
   e. Most urethral strictures from valve ablation will require formal urethroplasty for repair

4. The risk of operative blood loss requiring transfusion for children undergoing percutaneous nephrolithotomy is generally:
   a. <10%
   b. 10–15%
   c. 25–30%
   d. 50%
   e. >50%

5. Risks of percutaneous nephrolithotomy include all of the following EXCEPT:
   a. Radiation exposure
   b. Sepsis
   c. Pleural injury
   d. Steinstrasse
   e. Blood loss

6. Relative to the size of children's kidneys, 24 to 30Fr access tracts have been estimated to be the equivalent to what size tracts for adult kidneys?
   a. 10Fr
   b. 24Fr
   c. 50Fr
   d. 72Fr
   e. 100Fr

7. What is the most important determinant of radiation exposure during ureteroscopy?
   a. Fluoroscopy time
   b. Source-to-skin distance
   c. Fluoroscopy setting
   d. Patient thickness
   e. Ureteral access sheath

8. What is the maximum recommended radiation exposure for a 12-month period?
   a. 50 mSv
   b. 10 rad
   c. 50 gray
   d. 25 mSv
   e. 50 rad

9. What is the upper size limit for stones for which ureteroscopy could be considered a first-line treatment?
   a. 5 mm
   b. 7 mm
   c. 10 mm
   d. 20 mm
   e. 30 mm

10. Which of the following has been associated with balloon dilation of the ureteral orifice?
    a. Vesicoureteral reflux
    b. Sepsis
    c. Ureteral stricture
    d. Easier placement of ureteral access sheath
    e. Successful blind basketing of ureteral stone

Case Study 1

A newborn male is just delivered. Examination of his abdomen shows a very distended lower abdomen. A quick review of his antenatal history reviews bilateral hydroureteronephrosis and distended bladder on ultrasound all throughout pregnancy.

1. What is your clinical suspicion at this point?
   a. Bilateral high-grade vesicoureteral reflux
   b. Posterior urethral valves
   c. Bilateral ureteroceles
   d. Bilateral primary obstructive megaureters
   e. Bilateral ureteropelvic junction obstructions

2. What is the most immediate urologic intervention at this point?
   a. Circumcision
   b. Insertion of urethral catheter
   c. Cystoscopic ablation of posterior urethral valves
   d. Suprapubic tube
   e. Antibiotic prophylaxis

3. Once the patient is stabilized, you take him to the operating room. You insert a cystoscope and find posterior urethral valves. You must be careful about all the following during ablation of the valves EXCEPT for:
   a. Where you incise the valves
   b. How aggressively you incise the valves
   c. Location of the external urinary sphincter
   d. Location of urachus at dome of bladder
   e. Location of valves

Case Study 2

A 14-year-old patient presents with a possible kidney stone to the emergency room.

1. Which of the following imaging modalities to diagnose stone carries the greatest risk of radiation exposure?
   a. Renal and bladder ultrasound
   b. Abdominal plain film x-ray
   c. Noncontrast computerized tomographic scan
   d. Magnetic resonance imaging
   e. Computerized tomographic urography

2. The patient is found on imaging to have a 7-mm stone in his right renal pelvis. Which of the following is NOT recommended as initial treatment modality?
   a. Observation if asymptomatic
   b. Ureteroscopy
   c. Shock wave lithotripsy
   d. Percutaneous nephrolithotomy
   e. Cystoscopy with ureteral stent placement if concerned for infection and obstruction

3. On ureteroscopy, the flexible scope cannot be advanced up the ureter easily. What is the next best step?
   a. Flip the patient into prone position and access antegrade through a percutaneous nephrolithotomy tract
   b. Place a ureteral stent, allow passive dilation, then return in a few weeks
   c. Balloon dilate to 18Fr to allow passage of the flexible scope
   d. Abort the procedure and reschedule ureteroscopy for another day
   e. Abort the procedure and schedule shock-wave lithotripsy for another day

Answers

1. **d.** Duplex-system extravesical ureteroceles have the lowest probability of successful puncture.
2. **c.** Recommended locations for valve ablation are at 12, 5, and 7 o'clock.
3. **b.** Valve ablation should be performed without attempting to removal all remnants of the valves, which an increase the risk of sphincteric incontinence.
4. **a.** Operative blood loss requiring transfusion usually happens in <10% of children undergoing PCNL.
5. **d.** Radiation exposure, sepsis, pleural injury, and blood loss are all risks of PCNL.
6. **d.** 24 to 30Fr access tracts in children's kidneys are equivalent to a 72F tract in adult kidneys.
7. **a.** Fluoroscopy time is the most important determinant of radiation exposure during ureteroscopy.
8. **a.** The maximum recommended radiation exposure for a 12-month period is 50 mSv.
9. **d.** The upper size limit for stones for which ureteroscopy could be considered first-line treatment is 15–20 mm.
10. **c.** Balloon dilation of the ureteral orifice has been associated with injury leading to ureteral stricture formation.

CASE STUDY 1

1. **b.** Posterior urethral valves should be suspected in male infants with bilateral hydroureteronephrosis and distended bladder on antenatal imaging.
2. **b.** Immediate decompression of the urinary system with a bladder catheter should be top priority.
3. **d.** Location of incision, aggressiveness of incision, and location of sphincter should all be considered during valve ablation.

CASE STUDY 2

1. **a.** Renal bladder ultrasound is the first-line imaging modality for pediatric patients presenting with a possible kidney stone.
2. **d.** PCNL is usually reserved for larger stones or staghorn stones.
3. **b.** If the ureteral orifice is too tight for a ureteroscope, passive dilation with a stent placement is the safest and most prudent next step.

Chapter 56 Questions and Answers

KEY POINTS

1. Indications for minimally invasive surgery in pediatric urology are rapidly expanding.
2. Minimally invasive surgical procedures carry unique complications that must be recognized and minimized.
3. Success rates for most minimally invasive operations are comparable to traditional open surgical success rates, but longer-term follow-up is needed.

Advances in surgery have often depended on both technologic *innovation* and *diffusion*. Minimally invasive surgery (MIS) constitutes one such innovation that has revolutionized many fields of surgery. Its diffusion into pediatric urology, though slower than in adult urology, has been accelerating. Indications and opportunities for MIS within pediatric urology have rapidly expanded with the development of robotic-assisted laparoscopic techniques that facilitate complex intracorporeal suturing and reconstruction. Furthermore, improvements in optics and instrument miniaturization have enabled MIS to be used in smaller and younger patients. Additionally, spurred by earlier exposure to MIS procedures during residency training, the next generation of pediatric urologists may be better equipped and more likely to utilize MIS to treat their patients.[1,2]

The growth in MIS procedures, however, must be balanced carefully with their potential limitations and risks. One downside has been the opportunity cost during training of the decreased volume of open procedures that constitute much of reconstructive pediatric urology.[2] Another is the lack of standardized requirements for MIS procedures during residency that may result in variable experience, skill, and ultimately success.[3] The last, but arguably the most significant for the patient, is the unique set of associated surgical complications that can arise during MIS procedures.[4]

Although reported rates of postoperative morbidity following most pediatric urology procedures are low, MIS operations require careful planning and execution similar to open surgery. Not every surgery that could be done through a MIS approach must be done that way. Some surgeries such as redo operations may be more conducive to an open approach. However, if the indication is appropriate, the surgeon's expertise is valid, and the patient is counseled extensively and desires to proceed, then MIS offers the potential for quicker convalescence and less pain compared to traditional open surgery.[5] This chapter is a review of the current indications, techniques, complications, and outcomes of the most common MIS procedures in pediatric urology.

General Principles of Laparoscopy in Children

ADVANTAGES AND DISADVANTAGES

Given appropriate indications for surgery, MIS may confer particular advantages over standard open techniques. Specifically, MIS, which includes both pure laparoscopic and robotic-assisted laparoscopic techniques, has been associated with improved magnification, quicker recovery, shortened length of stay, less pain and analgesic requirements, and more favorable cosmetic outcomes.[5] Two smaller incisions have been mathematically theorized to cause less tension and therefore pain than a single larger incision of the same total size.[6] Conversely, opponents of MIS often prefer the tactile haptic feedback, arguably shorter operative time, and occasional ability to avoid transperitoneal surgery offered by standard "hands-on" open approaches.

Ideally, the well-trained pediatric urologist should feel comfortable with both open and MIS techniques, with tailoring of the approach defined by patient- and disease-specific characteristics. However, for those pediatric urologists who offer MIS surgeries, studies suggest that MIS experience level is the primary predictor of complications.[4,7] Thus, exposure to MIS techniques during the training process and the position of the primary surgeon on the MIS learning curve play critical roles in determining surgical outcomes.

LAPAROSCOPIC ACCESS AND APPROACH

The first key step in MIS once the patient is appropriately positioned and under anesthesia is access to the target anatomic space, which is usually either the peritoneum or the retroperitoneum. Access denotes insertion of trocars, with a plethora of techniques and devices available that have been developed. Access can be broadly dichotomized into open-entry techniques including the Hasson technique[8] and insertion of single-incision laparoscopic surgery (SILS) ports versus closed-entry techniques including Veress needle entry, direct trocar entry, and direct optical trocar entry.[9] At our institution, a modified Veress needle entry is commonly used where a skin incision is brought down to fascia, which is then tented up away from underlying bowel and through which a Veress needle is inserted. The abdomen is then insufflated before a camera trocar is inserted bluntly through the same site where the Veress needle had been inserted.

The traditional MIS access, even to retroperitoneal organs such as the kidney, has been transperitoneal. Retroperitoneoscopic access requires adequate knowledge of and comfort with anatomic landmarks in the retroperitoneum. Given the more limited space in the retroperitoneum, various techniques of trocar insertion, such as, for example, with a balloon trocar, have been described with the primary advantage being avoidance of entering the peritoneal cavity and risking abdominal organ injury or future bowel adhesions.[10,11] Additionally, the development of any postoperative hematoma or urinoma may be contained by the retroperitoneal space providing tamponade. The retroperitoneoscopic approach, in experienced hands, has been shown to be comparable in terms of success and complications to the traditional transperitoneal approaches – as with the laparoscopic pyeloplasty.[12,13]

COMPLICATIONS OF ACCESS AND PORT SITE CLOSURE

In general, MIS compared to open surgery possesses its own unique set of perioperative complications related specifically to gaining and closing access. Misplaced trocars may cause subcutaneous emphysema if insufflation occurs above the fascial plane. At worst, misplaced trocars can cause major vascular or visceral organ injuries that necessitate immediate conversion to open surgery. Conversely, trocar sites that are not closed appropriately raise the possibility of bowel herniation and incarceration (Figs. 56.1 and 56.2).

Overall, complication rates from gaining access are low with no definitive evidence favoring any method over others. A recent Cochrane systematic review of 46 randomized controlled trials compared 13 published techniques of laparoscopic access with regard to mortality, visceral, vascular, and solid organ injuries, gas embolism, and failed entry.[9] In general, complication rates were very low and not all outcomes could be assessed. An open-entry technique such as the Hasson technique was associated with less probability of failed entry compared to a closed-entry technique. Direct trocar entry compared to a Veress needle entry conferred a reduction of failed entry and vascular injury rates. However, the authors cautioned that the overall evidence was of too poor quality to support a single superior technique.[9] By comparison, a survey study of 251 pediatric urologists who performed pure laparoscopic surgery revealed a self-reported overall complication rate of 6%, with the majority being preperitoneal insufflation.[7] The survey respondents demonstrated a significantly higher complication rate with

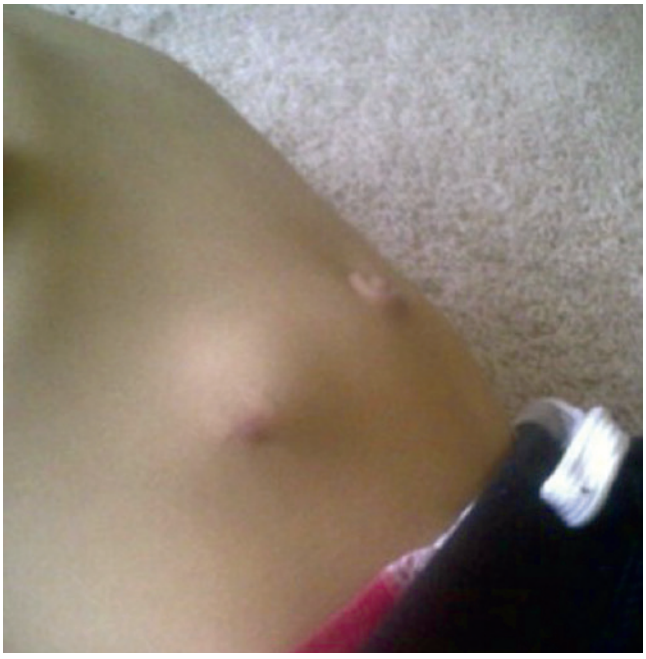

Figure 56.1 Trocar site hernia following robotic-assisted laparoscopic ureteral reimplantation – external view.

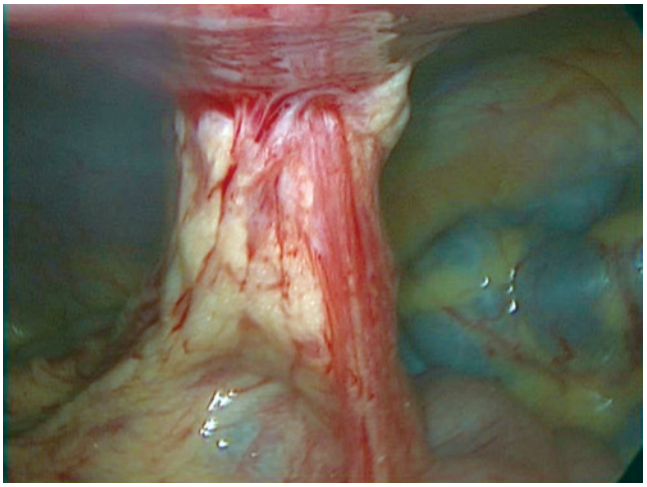

Figure 56.2 Trocar site hernia following robotic-assisted laparoscopic ureteral reimplant – internal view.

Table 56.1 Physiologic Effects of Pneumoperitoneum in Children

System	Effect of Pneumoperitoneum/ Intraabdominal Pressure >10 mm Hg	Potential Complications
Cardiovascular	Increased systemic vascular resistance	Impaired cardiac output Right-to-left flow through cardiac shunts
Pulmonary	Restrictive syndrome	Hypoxemia/hypercarbia, decreased compliance, decreased functional residual capacity
	Increased airway pressures	Barotrauma
Renal	Decreased renal perfusion	Impaired renal function/ oliguria

Veress entry than with open techniques, though the rate of bowel, vascular, or bladder injury requiring surgical repair was still low at 0.39%. Lastly, a retrospective review of more than 800 laparoscopic cases from 1995 to 2005 found an overall complication rate of 2%, including a 1.6% complication rate related to access.[4] The authors noted a higher complication rate with the Veress needle entry (2.3%) than with the open entry (0.8%), but the difference was not statistically significant.

Gas embolism is a notable complication found only in MIS surgery where insufflated carbon dioxide gas inadvertently enters the circulation, leading classically to a mill-wheel cardiac murmur, hypotension, hypoxia, and cyanosis. Treatment entails immediate desufflation of the abdomen and placement of the patient into a left lateral decubitus Trendelenburg position to trap the air before it reaches the pulmonary circulation.

Unique complications may also arise during port site closure. A systematic review of 19 adult studies and three pediatric studies of laparoscopic surgery found a port site hernia rate ranging from 0% to 5.2%.[14] The authors recommended closure of all port sites in younger children (<5 years), referencing one study that found a significantly higher rate of port site hernia in this age group compared to older children.[15] Another study noted that even smaller 5-mm trocars are at risk for bowel herniation, with the authors concluding that all port sites should be closed regardless of size.[16]

ANESTHESIA

The physiologic effects of pneumoperitoneum in children have been well-studied (Table 56.1). In general, pneumoperitoneum to pressures of >8–10 mm Hg adversely affects the heart, lungs, kidneys, and brain during extended exposure. From a cardiopulmonary standpoint, pneumoperitoneum decreases total lung compliance, increases airway pressures, and can affect cardiac output adversely if patients are hypovolemic at the start of surgery or have baseline cardiopulmonary disease.[17] If carbon dioxide is used as the insufflation gas, it can be easily absorbed in children. One prospective study in children found that elimination of carbon dioxide increased after 15 minutes of pneumoperitoneum, continued to climb for another 1 hour, and was significantly higher the younger or smaller the patient.[18] Another observational study of infants <1 year old noted increased peak inspiratory pressures and end-tidal carbon dioxide concentrations and decreased average expiratory tidal volumes and oxygen saturations.[19] Thus, younger patients who undergo MIS may warrant closer observation during and after surgery.

Of note, the cardiopulmonary effects of gas insufflation occur regardless of surgical approach. Both transperitoneal and retroperitoneal laparoscopic surgery were noted retrospectively to increase respiratory rate and peak airway pressures and decrease oxygenation levels.[20] Prospective analyses confirmed increases in end-tidal carbon dioxide levels in both approaches.[21,22]

In addition to its cardiopulmonary impact, pneumoperitoneum may increase systemic vascular resistance. Consequently, renal perfusion may be adversely affected and glomerular filtration rate may decrease. A systematic review of the impact of pneumoperitoneum on renal perfusion and function demonstrated that both were adversely affected in the majority of studies included in the review.[23] Some variability was noted depending on the baseline hydration status of the patient. Regardless, urine output monitoring is critical during MIS procedures, particularly if the case duration is prolonged. Patients with advanced chronic kidney disease may also be at higher risk for worsening renal function and should be counseled accordingly.

SUMMARY

In appropriately selected and counseled patients, MIS is safe, well-tolerated, and is associated with rare, but serious, complications from access and anesthesia. All aspects of gaining and closing MIS access to the peritoneum or retroperitoneum should be performed under careful scrutiny, even if they are not considered the "bulk" of the operation. Though complications are rare, they have the potential to be devastating and could lead to conversion to open surgery or need for reoperation. Without a proven single superior technique for gaining access, we recommend that MIS

surgeons use the access techniques they are most comfortable with and have the most experience doing. Common sense also applies – for example, an open-entry technique such as the Hasson technique may be more appropriate than a Veress technique in a patient with multiple prior intraabdominal surgeries or a thin abdominal wall as in prune belly syndrome. Without safe access before a MIS operation, the rest of the operation may not be possible. Special attention during insufflation with open communication with the anesthesiologist intraoperatively is crucial. Finally, even after a difficult intraoperative procedure is completed via MIS, we recommend increased vigilance during closure of the port sites with special attention to approximation of the rectus fascia even for 5-mm port sites in children.

Kidney Surgery

PYELOPLASTY

The introduction of MIS into pediatric urology has arguably transformed the surgical approach to the dismembered Anderson-Hynes pediatric pyeloplasty. First described as an open approach to correcting a retrocaval ureter in 1949,[24] the technique is utilized to repair the ureteropelvic junction obstruction. Other types of the pyeloplasty such as the Foley Y-V, Culp-DeWeerd spiral flap, and Fenger pyeloplasty have also been developed, but the Anderson-Hynes pyeloplasty remains the mainstay given its successful ability to adapt to crossing renal vessels or intrinsic narrowing at the ureteropelvic junction.

A paradigm shift has been evident in the surgical approach to pyeloplasty. A recent analysis of temporal trends of pyeloplasty from 2003–2010 showed a decline in percentage of open pyeloplasty, a plateauing of pure laparoscopic pyeloplasty, and an increase in robotic-assisted laparoscopic pyeloplasty.[25] Of note, the majority of robotic-assisted laparoscopic pyeloplasties were performed in older children ages 11–18, with most of the open pyeloplasties being performed in infants younger than age 1.

Overall success rates have been over 95% across all open and MIS techniques.[5,12,13,26] Overall complications of pyeloplasty range from 0% to 30% in a systematic review and meta-analysis.[5] These complications include urine leaks, ileus, infections, failures, need for additional interventions, and rare avulsions of the primary renal pedicle or lower pole vessels and bowel injuries. Within this meta-analysis, comparison of MIS versus open approach to pyeloplasty demonstrated similar complication rates. Similarly, robotic-assisted laparoscopic pyeloplasty compared to pure laparoscopic pyeloplasty among children had similar complication rates. Some surgeons, however, posit that the added degrees of movement conferred by the robotic wrist and improved magnification allow for easier intracorporeal suturing than the pure laparoscopic approach. This argument has been supported by evidence of shorter operative times with robotic-assisted laparoscopic versus pure laparoscopic approaches.[5]

Small retrospective studies have examined the role of retroperitoneoscopic pyeloplasty. No significant differences were found between retroperitoneoscopic and transperitoneal laparoscopic techniques in terms of success rates (93% vs 100%, respectively) or complications.[12] The operative time was significantly longer for retroperitoneoscopic pyeloplasty, presumably due to the increased difficulty in suturing the anastomosis in a smaller confined space. Likewise, success rates were comparable between retroperitoneoscopic (97%) and open pyeloplasty (96%) with similar complication rates (29% vs 27%, respectively).[13] Retroperitoneoscopic pyeloplasty did have a 6% conversion rate to open and had a significantly higher rate of anastomotic leakage despite being more commonly stented. Open pyeloplasty, by comparison, had a higher rate of abdominal wall palsy.

In conclusion, pyeloplasty for ureteropelvic junction obstruction remains amenable to MIS approaches with high success rates and complication rates no different from those associated with open techniques. The ability to perform complex intracorporeal reconstruction demonstrated by the robotics platform makes it particularly fitting for pyeloplasty. We therefore expect the temporal trends noted above to continue to increase with a predominance of the robotic-assisted laparoscopic approach in the near future.

TOTAL AND PARTIAL NEPHRECTOMY

Similar to reconstructive kidney surgery in pediatric urology, extirpative kidney surgery also offers opportunities to avail of the benefits of MIS techniques. The vast majority of MIS nephrectomies among children have been for benign pathologies, such as nonfunctional renal units or moieties that continue to cause infections or hypertension. The role of MIS nephrectomies for malignant pediatric pathology, however, continues to be defined.

Initial experiences with MIS nephrectomies predominantly used a laparoscopic approach and were for benign indications.[27–29] One small noncomparative retrospective case series of 26 patients who underwent laparoscopic nephrectomy found no complications, including no urine leak among six patients who underwent heminephrectomy and one who underwent partial resection of a horseshoe kidney.[29] Another study compared 10 children who underwent laparoscopic nephrectomy with 10 children who underwent open nephrectomy, all for benign indications.[27] While operative time was longer in the MIS group, overall hospitalization was shorter. While complication rates were not statistically compared between the two groups, the laparoscopic nephrectomy group had two minor complications, including one colonic serosal injury managed conservatively, compared with five in the open nephrectomy group.

MIS heminephrectomy in duplex kidneys for a nonfunctional moiety possesses certain unique complications compared to total nephrectomy. One such major concern is injury to the blood supply leading to the healthy moiety. Though the exact rates of renal devascularization are unknown, one study of 142 retroperitoneoscopic heminephrectomies in duplex systems found that at a median follow-up of 4.5 years, seven children (5%) ultimately lost function in the preserved moiety requiring completion nephrectomy.[30] The authors note that six of these seven children had previously undergone an upper pole

heminephrectomy, with half of these six experiencing an immediate postoperative complication following the completion nephrectomy. They surmise that unrecognized injury to the renal vessels may occur given the technical difficulty of upper pole heminephrectomy, but they also speculate on the role of pneumoperitoneum and younger patient age as another potential cause of the decline in function in the preserved renal moiety.

Another complication unique to heminephrectomy is the urine leak and formation of urinoma, either due to incomplete excision of the upper moiety renal parenchyma or inadvertent injury to the lower pole moiety collecting system. The rates of urinoma formation range from 0% to 12%, with most usually being asymptomatic and able to be managed conservatively.[31]

Studies have assessed the feasibility and effectiveness of retroperitoneoscopic nephrectomy. One study compared 10 children who underwent retroperitoneoscopic nephrectomy with 13 children who underwent retroperitoneal open nephrectomy.[32] Operative time was no different, but the MIS group had overall shorter hospitalization. Only one complication was noted, a wound site complication in the open nephrectomy group. A systematic review was performed comparing retroperitoneoscopic with transperitoneal laparoscopic approaches for nephrectomy.[28] While the review found many missing surgical indications among the 51 studies included, the vast majority of them were for benign conditions. The overall complication rates were 4.3% for retroperitoneoscopic nephrectomy and 3.5% for transperitoneal laparoscopic nephrectomy. The most common complications were bowel and vascular injuries, hematomas, urinomas, and port site hernias. Subgroup analyses noted vascular injuries in 2/346 and 0/288 kidneys in the retroperitoneoscopic and transperitoneal laparoscopic groups, respectively, with bowel injuries in 2/346 and 1/285 kidneys, respectively.

Though the gold standard for malignant renal tumors such as Wilms' tumors remains open resection through a transverse abdominal incision, small case series have been performed describing MIS nephrectomy. An analysis of 24 children who underwent laparoscopic nephrectomy following neoadjuvant chemotherapy while enrolled in a large European Wilms' tumor trial (International Society of Pediatric Oncology 2001) showed only one complication, a splenic injury, with no cases of tumor rupture.[33] At a median follow-up of 47 months, event-free survival was 96%. However, lymph node sampling, which is a mainstay of surgical Wilms' tumor resection for staging purposes, was inadequately performed in this study in 22 of the 24 children. Another series included 17 children who underwent laparoscopic nephrectomy for various renal malignancies, including Wilms' tumor, renal cell carcinoma, and clear cell sarcoma.[34] Two required conversions to open due to difficulty dissecting free the renal pedicle, but otherwise no other complications were seen. Of note, in this cohort, lymph node sampling was successfully performed in 12 children with a mean yield of 3.4 nodes. One comparative study retrospectively analyzed outcomes of laparoscopic nephrectomy (n = 13) against open nephrectomy (n = 32) for primary renal tumors in children.[35] No cases of tumor rupture occurred, and no difference in operative time was noted, though hospitalization was significantly shorter for the laparoscopic nephrectomy patients. One patient in each group developed an incisional hernia, and one patient in the open nephrectomy group developed a small bowel obstruction. In a subgroup analysis of tumors <10 cm in size to adjust for confounding due to indication, the authors found longer operative time for the laparoscopic nephrectomy patients but still overall shorter hospitalization.

In summary, total nephrectomy for benign conditions remains a suitable indication for the MIS approach, whether transperitoneal or retroperitoneal, with shorter hospital duration compared to open nephrectomy. Conversely, heminephrectomy via MIS techniques is also appropriate, but surgeons must remain wary of the unique risks of complete renal functional loss and urine leak, which may be higher in smaller children. MIS nephrectomy for malignant renal tumors remains exploratory, given the varied ability to sample lymph nodes adequately.

Bladder and Lower Ureteral Surgery

URETERONEOCYSTOSTOMY

The treatment paradigm for vesicoureteral reflux (VUR) continues to rely on the pillars of observation alone, antibiotic prophylaxis, or surgical repair of the congenital defect that facilitates the retrograde flow of urine from the bladder to the renal collecting system while increasing the risk for pyelonephritis. Since antibiotic prophylaxis was recently shown to be superior to observation alone in effectively reducing the risk of pyelonephritis in children with VUR, surgery in the modern era is increasingly reserved for patients with severe grades of VUR who have repeatedly failed prophylaxis.[36]

MIS options for the surgical correction of VUR include the cystoscopic subureteral injection of dextranomer/hyaluronic acid copolymer (Deflux), as well as the pure laparoscopic and robotic-assisted laparoscopic ureteral reimplantation (RALUR). Each procedure conveys varied success rates and, importantly, varying complication profiles.

The endoscopic injection of material into or near the ureteral orifice to coapt the ureteral insertion is arguably the least invasive of the surgical options available for correction of VUR. Though the overall morbidity of endoscopic injection is low, success rates vary greatly. In a meta-analysis of over 5500 patients who underwent endoscopic treatment of VUR, overall success rate as defined radiographically ranged from 78% for low-grade VUR to 51% for high-grade VUR.[37] However, some experts point out that the meta-analysis included other injected material beyond Deflux and believe the volumes of material injected were suboptimal and possibly even half of what should be given.[38] A single-institutional retrospective series of Deflux injections reported much higher success rates of 90% radiographically at 3-month voiding cystourethrogram and 94% clinically.[39] Besides the concern of persistent VUR and pyelonephritis, other complications of endoscopic injection include contralateral de novo VUR and ipsilateral ureteral obstruction. An initial single-institution case series noted 4.5% of patients developed de novo contralateral VUR on follow-up voiding cystourethrogram, leading the authors to inject the contralateral ureteral orifice if it had an abnormal

configuration on cystoscopy.[40] Caution must be taken in overdoing the coaptation. A multi-institutional retrospective analysis of 1155 ureters in 745 patients following Deflux injection from four centers revealed an incidence of ipsilateral ureteral obstruction in seven ureters in five patients that required endoscopic stent placement.[41] Of these five patients, four had secondary VUR from myelomeningocele or severe bladder and bowel dysfunction. Thus, while rare overall, ureteral obstruction may be a higher risk in bladders with abnormal function.

RALUR is most commonly performed using an intraperitoneal, extravesical approach using the technique of Lich-Gregoir, whereas intravesical laparoscopic (or vesicoscopic) ureteral reimplantation is performed less commonly. In the vesicoscopic approach, the bladder is insufflated with carbon dioxide gas and trocars are inserted directly into the lumen of the bladder, and the ureters are mobilized intravesically using the cross-trigonal technique of Cohen.[42]

Various studies have compared the outcomes of RALUR with open ureteral reimplantation, demonstrating mixed results (Table 56.2). One study compared 25 extravesical RALUR patients (mean age 69 months) with 25 open reimplantation patients (mean age 50 months) and noted rates of success in eliminating VUR of 97% and 100%, respectively.[43] While operative time was longer in the robotics group, the length of stay and narcotic pain medication use were less. Three children in the robotics group undergoing bilateral RALUR experienced transient urinary retention. Another retrospective single surgeon series compared 20 extravesical RALUR patients with 20 open extravesical ureteral reimplantations.[44] The authors found comparable success rates, a longer mean operative time in the RALUR group, but significantly less postoperative analgesic requirement. One RALUR patient developed a urine leak and another developed a ureteral stricture that the authors attributed to possible excessive manipulation of the ureter, leading to devascularization of the distal ureter. Another retrospective study compared 20 extravesical RALUR patients to 17 matched extravesical open ureteral reimplantations.[45] Success was >90% across both groups. Extravesical RALUR patients had no difference in operative times, lengths of stay, or analgesia requirements compared to extravesical open reimplantation patients. However, two extravesical RALUR patients experienced urine leaks.

Contrary to the aforementioned studies demonstrating comparable success rates between open and robotic surgical approaches, a retrospective cohort study of 61 patients with a mean age of 6.7 years who underwent RALUR showed a 72% radiologic success rate in eliminating VUR at an average follow-up of 11.7 months.[46] Additional complications of urine leak were noted in 2%, and bilateral ureteral obstruction requiring stents was seen in 5%. Of note, these authors pooled published success rates from 12 RALUR studies, including their own, and found a pooled success rate of 91%, though with evidence of strong heterogeneity across studies.

Other studies have analyzed the outcomes of pure laparoscopic intravesical ureteral reimplantation. The initial description of the technique in 23 refluxing ureters showed a success rate of 96%, but two children experienced transient subcutaneous suprapubic and scrotal emphysema.[42]

Table 56.2 Pediatric Robotic-assisted Laparoscopic Ureteral Reimplantation – Key Studies

Reference	No. MIS Procedures and Approach	No. Open Procedures and Approach	Mean Operative Time (min)	Mean Hospital Stay (hr)	Mean/Median Follow-up (mos)	Success Rate (%)	No. Complications
Smith (2011)[43]	25 extravesical RALUR	25 intravesical open	MIS: 185 Open: 165	MIS: 33 Open: 53	MIS: 16 Open: 29	MIS: 97 Open: 100	MIS: 3 (transient urinary retention, all bilateral cases) Open: 0

MIS, minimally invasive surgery; RALUR, robotic-assisted laparoscopic ureteral reimplantation

Another case series of 113 reimplanted ureters showed a success rate of 92% with seven patients, all successful cases, developing postoperative urinary tract infection.[47] A third case series of 27 VUR patients who underwent vesicoscopic reimplantation had a success rate of 92%, but two patients developed intraperitoneal urine leaks through port sites in the bladder and one patient who underwent a tapered reimplant developed an anastomotic stricture.[48] One study compared vesicoscopic reimplantation with open reimplantation, with success rates of 91% and 97%, respectively.[49] Operative time was greater and analgesia requirement was less for the vesicoscopic group, with no difference in length of stay. Urine leakage, bladder stone, and bilateral ureteral obstruction were each noted in one child apiece in the vesicoscopic group with none in the open reimplantation group. Lastly, a study comparing 19 intravesical RALUR patients with 22 intravesical open ureteral reimplantation patients demonstrated success rates of greater than 90% in both groups.[45] Intravesical RALUR patients had longer operative time, shorter length of stay, and less narcotic analgesia requirement compared to the intravesical open reimplantation group. However, the RALUR cohort included one child experiencing transient urinary retention, and four patients experienced bladder leak through trocar sites before the closure technique was improved.

The success rates of MIS approaches to resolve VUR are as varied as the surgical options. The possibility that inconsistencies in surgical success rates are secondary to comparisons across heterogeneous cohorts and increasingly selective criteria for surgery must be considered. The results underscore that RALUR is an emerging surgical option that should be utilized by experienced surgeons prepared to address the potential for rare but significant complications including urine leaks, ureteral obstruction, and urinary retention. Multi-institutional studies examining safety and efficacy are underway.

URETEROURETEROSTOMY

In duplex renal collecting systems with ectopic ureters, ureteroceles, or vesicoureteral reflux, the ipsilateral ureteroureterostomy offers a viable surgical option beyond the heminephrectomy of a poorly functional moiety discussed in a previous section. The ureteroureterostomy diverts the offending ureter – typically the upper pole ureter – while obviating the risk of avulsion or injury to the functional lower pole moiety. While the lower pole, or recipient ureter, may be rendered vulnerable during the ipsilateral ureteroureterostomy, published studies seem to suggest that placement of a ureteral stent into the lower pole moiety significantly reduces the risk of stenosis or urine leak.

The initial pediatric MIS experience with ipsilateral ureteroureterostomy was described in eight kidneys in six children in 2007.[50] All cases were performed via transperitoneal laparoscopy with the recipient ureter being prestented. No intraoperative complications were noted. At a mean follow-up of 10.7 months, two patients developed postoperative febrile urinary tract infections but no residual hydronephrosis was seen at 1, 3, and 9-month postoperative ultrasounds.[50] Another retrospective initial case series of the transperitoneal pure laparoscopy approach in seven patients with recipient ureteral stenting reported no intraoperative or postoperative complications.[51] The largest single institutional experience for open and laparoscopic ureteroureterostomy included 41 patients, 12 of whom were treated laparoscopically.[52] After an overall mean follow-up of 2.8 years for the whole cohort, one of the patients developed an anastomotic stricture and one developed a ureterovesical junction stricture thought secondary to stent placement, though the authors did not directly specify whether these patients were from the laparoscopic or open group. No other comparisons were made between the laparoscopic and open groups.

Experience is rapidly increasing with the robotic-assisted laparoscopic ureteroureterostomy (RALUU), and several institutions have reported outcomes while confirming the safety profile of the technique when incorporating prestenting of the recipient ureter.[53–56] A two-institution retrospective series compared 25 RALUU cases with 19 open ureteroureterostomy cases in duplex systems or obstructed single systems.[54] The RALUU patients were more likely to undergo cystoscopy and stent placement, but at mean follow-ups of 16 and 12 months for the RALUU and open groups, respectively, there were no differences in operative times, blood loss, or postoperative complications measured with the Clavien system. Four febrile urinary tract infections were treated in each group, and length of stay favored the RALUU group. Of note, 86% of the RALUU patients had resolved or improved hydronephrosis on follow-up ultrasound, compared with 53% in the open surgery group. While pyelonephritis may be the most commonly reported postoperative morbidity with the RALUU, one published experience posits that the risk of pyelonephritis may be reduced by leaving recipient ureters with indwelling stents (requiring cystoscopic removal) rather than facilitating stent removal with a "dangler" stitch affixed to the distal stent tip.[55] Another study reported an 8-year period of outcomes of robotic-assisted laparoscopic surgery in duplex renal anomalies, including 14 patients who underwent transperitoneal RALUU.[56] All 14 patients had prestenting of their recipient ureter with resolution of hydronephrosis on postoperative imaging for a success rate of 100%. One of the 14 developed a port site hernia. The authors did not report mean follow-up for this subset of RALUU patients.

One of the earlier historical concerns of performing a ureteroureterostomy in duplex systems was the anecdotal "yo-yo" effect, where urine excreted from one moiety would reflux up to the other moiety, potentially contaminating the recipient moiety with infection or urinary stasis. Studies from open ureteroureterostomy cohorts, however, have not substantiated this hypothesized effect. Though admittedly limited, over a mean follow-up of 12 months, all 39 patients undergoing 41 open ureteroureterostomies were noted to have no dilation of the recipient ureter consistent with a "yo-yo" effect or anastomotic stricture.[57]

The results from the MIS ureteroureterostomies, as mentioned previously, note overall good success rates though an outcome of dilation of the recipient ureter may not be specifically listed. As such, longer follow-up in larger cohorts is needed to provide definitive evidence against this particular risk of ureteroureterostomies. One important comparison to make when deciding the surgical approach to a duplex system anomaly is weighing the risk of "yo-yo" pyelonephritis after a ureteroureterostomy against the risk of lower

pole moiety devascularization after an upper pole moiety heminephrectomy, which is 5–8%.[30]

MIS ureteroureterostomy, particularly the RALUU, provides an excellent alternative for the surgical treatment to heminephrectomy for duplex system anomalies. The recipient ureter does require prestenting, but the surgical procedure has high success rates with relatively low complications. While the risk of anastomotic stricture or "yo-yo" reflux remains theoretical at this time, the defined risk of injury to the lower pole moiety in heminephrectomy approaching 10% offers a reasonable argument for continuing to investigate the RALUU as a serious option for the management of duplex system anomalies in children.

APPENDICOVESICOSTOMY AND AUGMENTATION CYSTOPLASTY

As surgeons gain experience with laparoscopic and robotic-assisted surgery, many are beginning to offer even the most complex reconstructive surgical procedures including the appendicovesicostomy (APV) and augmentation enterocystoplasty. The goals of these two procedures overlap: Improve urinary storage and facilitate emptying via a catheterizable channel.

The continence mechanism of the APV is a tunnel through the detrusor layer of the bladder that functions via the flap-valve principle as described first by Mitrofanoff.[58] A small case series of four patients undergoing a pure laparoscopic APV showed a 100% continence rate at a mean follow-up of 12 months, though one was converted to open due to inability to pass the catheter at the end of the case.[59] Mean operative time was 3.5 hours and mean hospitalization was 3.7 days. A slightly larger case series compared 10 patients who underwent robotic-assisted laparoscopic APV against 10 age- and diagnosis-matched patients who underwent open APV.[60] Of the robotic-assisted laparoscopic APV patients, one was converted to open due to an inadequate appendix and one patient developed pulmonary distress postoperatively related to his baseline comorbidities. Median hospitalization was 5 days for the MIS group compared to 8 days for the open group. At a median follow-up of 14 months, three of the 10 MIS patients developed urinary leakage, including one that ultimately required an augmentation cystoplasty. By comparison, at a median follow-up of 18 months, four of the 10 patients in the open group developed postoperative complications, including stomal stenosis in two and pyelonephritis in two. A more recent and larger comparative series included 28 open and 39 robotic-assisted laparoscopic APV patients.[61] At a mean follow-up of 2.7 years, there were no differences between the open and MIS groups in terms of acute complications (29% vs 26%, respectively), overall reoperations (29% vs 33%, respectively), or reoperations within 12 months of surgery (14% vs 26%, respectively). The authors did note, however, that the complications requiring revision surgery differed, with primarily urinary incontinence seen in the MIS group compared to stomal prolapse or stenosis experienced in the open group. Additionally, three patients in the MIS group experienced small bowel obstruction from an internal hernia requiring secondary surgery.

An APV is often constructed in conjunction with simultaneous augmentation enterocystoplasty, particularly for patients with poor compliance or a contracted small bladder. The largest published MIS case series to date compared 15 patients who underwent robotic-assisted laparoscopic augmentation enterocystoplasty with 13 patients who underwent an open augmentation enterocystoplasty.[62] All the augmentations were performed using ileum. Operative time was far greater for the MIS group (623 vs 287 minutes in the open group), though hospitalization was shorter (6 vs 8 days in the open group). At a median follow-up of 43 and 45 months in the MIS and open groups, respectively, complications were not statistically significantly different between the groups. Bladder stones required removal in three patients in each group, but the MIS group also had three patients require stomal revisions.

The cumulative experience with the MIS approach to APV and augmentation cystoplasty remains preliminary at this stage, and larger studies to assess the efficacy and safety of these complex procedures are needed. Preliminary data are certainly promising, though the novice MIS surgeon must be wary of the far longer operative times with the MIS approach – with attendant anesthetic risks – as well as surgical complexity and difficulty.

Testicular and Groin Surgery

DIAGNOSTIC LAPAROSCOPY

Cryptorchidism is one of the most commonly encountered diagnoses in a pediatric urology practice. Of patients with a unilateral undescended testicle, an estimated 20–30% are nonpalpable. Of these, an estimated 50–60% are intraabdominal, 30–40% are inguino-scrotal, and 10–20% are truly vanishing testes.[63] The management of nonpalpable testes has evolved significantly with the development of diagnostic laparoscopy. Pediatric urologists may now easily insert a small laparoscope intraabdominally to determine testicular location and presence or absence of the spermatic vessels and vas deferens on the affected side. Vanishing testes are marked by blind-ending spermatic vessels and vas, whereas the presence of both vessels and vas passing through the internal inguinal ring warrants an inguinal exploration.

Various studies have examined the utility of diagnostic laparoscopy in cryptorchidism. A prospective study of 126 nonpalpable testes in 104 children found that diagnostic laparoscopy was accurate in localizing the testes in 90% of cases, with location confirmed by surgical exploration.[64] Laparoscopy was inadequate in 8% of cases, largely due to preperitoneal insufflation. As such, complications of diagnostic laparoscopy alone likely are similar to those of gaining laparoscopic access, as mentioned in the "Complications of Access and Port Site Closure" section above. By comparison, a retrospective case series of 263 nonpalpable testes in 225 patients noted that 18% of the nonpalpable testes were actually palpable under anesthesia.[65] Of those who underwent diagnostic laparoscopy, 13.2% of cases were prevented from undergoing unnecessary abdominal exploration.

Despite smaller studies discounting the benefits of laparoscopy in obviating an inguinal exploration alone for the nonpalpable testis,[66] others have argued effectively that an

inguinal exploration alone can be inconclusive in as many as 66% of cases.[65] The treatment paradigm practiced at most institutions today is examination under anesthesia first, followed by diagnostic laparoscopy if the testes are still nonpalpable.

LAPAROSCOPIC ORCHIOPEXY

For those nonpalpable testes found to be intraabdominal, laparoscopic orchiopexy offers a viable and possibly preferred option to open abdominal exploration. The laparoscopic approach consists of three strategies: primary orchiopexy with preservation of the spermatic vessels; one-stage Fowler-Stephens orchiopexy with transection of the spermatic vessels and simultaneous transposition of the testicle down into the scrotum; and two-stage Fowler-Stephens orchiopexy with transection of the spermatic vessels and delayed transposition of the testicle down into the scrotum usually at least 6 months later. Of note, among these three laparoscopic approaches, there may be differences by indication, with primary laparoscopic orchiopexy used primarily for lower-lying intraabdominal testes and Fowler-Stephens approaches reserved for higher intraabdominal testes with severely limited mobility.

Various systematic reviews and meta-analyses have been performed comparing these three laparoscopic approaches to each other and to open approaches (Table 56.3). One of the first reviews analyzed 64 studies and found a pooled estimate of success of 74% for intraabdominal testes, regardless of technique.[67] Two-stage Fowler-Stephens approach had a pooled estimate of 77% success compared to 67% success for one-stage Fowler-Stephens approach and 81% for primary intraabdominal orchiopexy. The author did not comment on open versus laparoscopic approach, though it is likely all studies included in the older review reflected the open approach. A more contemporary systematic review and meta-analysis compared single-stage with two-stage Fowler-Stephens orchiopexies and included 61 studies, which included both open and laparoscopic techniques.[68] Of the subset of laparoscopic Fowler-Stephens orchiopexies, the pooled success rates were 83.4% and 88.8% for single-stage and two-stage approaches, respectively. Of note, the authors of the review found a much higher reporting of complications among the two-stage studies, with the most common complications being ileus, hematoma, and infections. Another recent systematic review found seven studies, most of which included laparoscopic approaches, comparing primary orchiopexy with Fowler-Stephens orchiopexy for intraabdominal testes, and noted higher success rates and lower atrophy rates with the former.[69] The authors point out, however, that confounding by indication may explain the difference, with primary orchiopexy being performed for lower-lying intraabdominal testes that have more favorable outcomes compared to higher-lying intraabdominal testes. A fourth systematic review compared open orchiopexy against laparoscopic orchiopexy for intraabdominal nonpalpable testes.[70] The authors had strict inclusion criteria and ultimately included sevn total studies in their review. No differences were seen with respect to operative time, success rate, atrophy rate, or recurrence, but length of stay was shorter in the laparoscopic group.

In conclusion, diagnostic laparoscopy is generally very safe and informative in cases of nonpalpable testes. If testes are located in the abdomen, laparoscopic instruments may be introduced to complete the orchiopexy safely and bring the testes down to the scrotum. If the spermatic vessels require division, then a staged laparoscopic Fowler-Stephens

orchiopexy is preferable with higher success rates than a single-stage approach.

LAPAROSCOPIC VARICOCELECTOMY

The adolescent scrotal varicocele is commonly identified and typically a benign process. In select cases, however, the process may progressively impair spermatogenesis in the testicle and ultimately contribute to infertility. As such, certain adolescents with varicocele undergo repair if the condition causes chronic pain, contributes to testicular size differences, or is associated with abnormal semen parameters that may be used as a surrogate for future fertility potential. Currently, treatment options for varicocelectomy include open inguinal (Ivanessevich), high retroperitoneal (Palomo ligation of testicular artery and veins), subinguinal microscopic, laparoscopic (Palomo-like mass ligation or artery-sparing), and embolization or sclerotherapy approaches.[71] Each technique has its own advantages and disadvantages, with complications primarily including varicocele persistence or recurrence, hydrocele or hematoma formation, and testicular atrophy or loss (Table 56.4).

A recent systematic review and meta-analysis found 11 studies during a 10-year period specifically limited to adolescents that compared laparoscopic versus open techniques in varicocele repair.[72] Recurrence rates were 4.7% and 8.6%, and hydrocele formation rates were 9.5% and 6.7% for the laparoscopic and open groups, respectively (not significant). Another systematic review from the adult literature examined 33 studies and concluded that of all techniques mentioned above, the subinguinal microsurgical technique conferred the highest pregnancy rates with the lowest complications.[73] Laparoscopic varicocelectomy was examined in nine studies with a pooled pregnancy rate of 27.5%, pooled recurrence rate of 11.1%, and pooled hydrocele formation rate of 7.6%. Of note, scrotal subcutaneous emphysema and scrotal pain were complications reported only among the laparoscopic varicocelectomy patients. No cases of testicular atrophy were reported.

The laparoscopic varicocelectomy traditionally included ligation of both testicular veins and artery, but techniques have been described that spare the testicular artery due to concern for impaired spermatogenesis. One prospective study compared laparoscopic artery-sparing versus artery-ligating techniques in the same institution.[74] Overall, semen analyses showed significantly better parameters in the artery-sparing group. Of 63 patients in the artery-ligating group, eight developed postoperative hydrocele, compared with one among 59 patients in the artery-sparing group. However, varicocele persistence/recurrence was noted in six patients in the artery-sparing group compared to none in the artery-ligating group. Thus, sparing the testicular artery laparoscopically may decrease hydrocele risk but increase the possibility of failing to correct the varicocele, presumably due to missed testicular veins. It is important to note that those patients in whom the testicular artery is ligated should be counseled that their testicle may subsequently depend on blood supply from the deferential artery, and thus that future vasectomy could potentially further devascularize the testicle.

The laparoscopic varicocelectomy, then, is a viable MIS approach for correction of symptomatic varicoceles. Hydrocele formation may be higher compared to open nonmicrosurgical techniques, but recurrence rates seem to be lower. Artery-sparing techniques can improve semen quality, but carry the risk of varicocele persistence or recurrence.

LAPAROSCOPIC INGUINAL HERNIA REPAIR

Inguinal hernias occur in approximately 1–5% of children <18 years old. The risk of bowel incarceration is highest during infancy, but persists in older children. Traditionally, open inguinal exploration has been performed to find the hernia sac, careful separation from the cord structures must be carried out, and a high ligation of the hernia sac has performed at the level of the internal ring. Laparoscopic hernia repair has been studied as a viable alternative to the open inguinal approach, particularly when there is a question of a contralateral inguinal hernia.

A recent systematic review analyzed 53 studies that compared laparoscopic and open hernia repairs in children.[75] Conversion rates to open among those children who underwent laparoscopic inguinal hernia repairs ranged from 0% to 1.7%. Pooled estimates of hernia recurrence were no different between the laparoscopic cases (1.6%) and the open cases (1.4%). Among infants only, hernia recurrence and wound infections were higher among the open than among the laparoscopic cases. The authors of the systematic review pooled all other complications including hydrocele formation, wound infection, testicular atrophy, and iatrogenic cryptorchidism and noted a lower rate among laparoscopic cases (0.9%) compared to the open cases (2.7%). Another systematic review and meta-analysis with more stringent inclusion and exclusion criteria found three randomized controlled trials and four higher-quality observational studies that compared open and laparoscopic hernia repairs in children.[76] The authors found no differences in hernia recurrence, hydrocele formation, testicular

atrophy, or wound infection between the groups. Of note, while operative time was no different between the groups for unilateral hernia repair, among patients undergoing bilateral hernia repair, the laparoscopic group required significantly less operative time. Also, because laparoscopic hernia repair is performed in a transperitoneal manner, the approach carries additional risk of bowel or vascular injury and future intraabdominal adhesions.

The laparoscopic hernia repair appears to be safe, with acceptable success rates, though not widely implemented. The approach may be advantageous for older children with a concern for a contralateral inguinal hernia. The diagnostic laparoscopy at the beginning of the case may show whether the contralateral internal ring is open or closed, and the laparoscopic technique could then be utilized to close the defect if a contralateral hernia is present.

Conclusions

Indications for MIS in pediatric urology have expanded, particularly with the diffusion of robotic-assisted laparoscopy that allows more complex intracorporeal reconstruction. Pure laparoscopic surgeries retain a significant role in extirpative cases and those not requiring intracorporeal suturing, such as the laparoscopic orchiopexy, varicocelectomy, hernia repair, and simple nephrectomy. As a surgeon transitions from open surgery to MIS approaches, recalling the importance of visual cues where tactile feedback lacks, maintaining focus on atraumatic tissue handling, and exercising care and diligence during introduction and removal of working port trocars remain crucial. Knowledge of anatomy is essential, and the surgeon must be experienced with the key steps of each procedure that the carry highest risk to the patient.

With proper patient selection, MIS confers potential advantages over open surgery including smaller incisions, less postoperative pain, and shorter hospitalization while offering similar rates of surgical success. It is important here to restate that the implementation of MIS in pediatric urology marked an exciting, novel phase in clinical practice, but cumulative experience in the field – beyond a few high-volume centers – is still developing. It is incumbent upon practitioners to maintain focus on examining longer-term outcomes and develop robust multi-institutional efforts to confirm safety and efficacy. We expect the cycle of innovation and diffusion to continue, leading to advances in surgery that may not only potentially revolutionize operations, but also carry the promise of optimizing care of our patients.

Chapter 56 Questions

1. Which of the following that happens to the pulmonary system during pneumoperitoneum >10 mm Hg is FALSE?
   a. Decreased functional residual capacity
   b. Decreased oxygen saturation
   c. Increased end-tidal carbon dioxide levels
   d. Improved pulmonary compliance
   e. Increased airway pressures

2. Which of the following is TRUE about comparisons of techniques for gaining laparoscopic access?
   a. Hasson technique has highest risk of vascular injury
   b. Veress technique has the lowest risk of subcutaneous emphysema
   c. No technique has been shown to be superior to the others
   d. Optical trocar entry has the highest risk of bowel injury
   e. Modified Veress technique carries zero risk of bowel or vascular injury since fascia is tented up

3. Which of the following is FALSE regarding pyeloplasty outcomes?
   a. Robotic-assisted laparoscopic approaches have shorter operative time than pure laparoscopic approaches
   b. Retroperitoneoscopic pyeloplasty has significantly worse outcomes than transperitoneal approaches
   c. Success rates across open and minimally invasive approaches are all >95%
   d. Possible complications of pyeloplasty include urine leak, ileus, and rare bowel injuries
   e. Increasing percentage of pyeloplasties are being performed with robotic-assisted laparoscopic approaches

4. Which of the following is a complication unique to heminephrectomy compared to simple total nephrectomy?
   a. Port site hernia
   b. Urinoma formation
   c. Bowel injury
   d. Vascular injury
   e. Hematoma

5. Which of the following is FALSE about treatment of vesicoureteral reflux?
   a. Robotic-assisted laparoscopic ureteral reimplantation usually has shorter hospital stay compared to open techniques
   b. The patient population under reimplantation has changed now compared to 20 years ago
   c. Bladder leak through trocar sites is a major complication of intravesical minimally invasive laparoscopic ureteral reimplantation
   d. Robotic-assisted laparoscopic ureteral reimplantation can be performed only in extravesical fashion
   e. Urinary retention is a complication especially following bilateral extravesical reimplantation

6. Which of the following is FALSE about ureteroureterostomy?
   a. The ureteral stent is usually placed into the recipient ureter and collecting system
   b. The "yo-yo" effect is worrisome for causing pyelonephritis in the "bad" moiety
   c. Ureteroureterostomy provides a viable alternative in duplex renal anomalies compared to heminephrectomy
   d. Success rates of minimally invasive laparoscopic ureteroureterostomy are not significantly different from open ureteroureterostomy
   e. Complication rates of minimally invasive laparoscopic ureteroureterostomy are not significantly different from open ureteroureterostomy

7. Which of the following is FALSE regarding robotic-assisted laparoscopic appendicovesicostomy?
   a. The continence mechanism is based on the Mitrofanoff principle
   b. Robotic-assisted laparoscopic appendicovesicostomy has much higher success rates than open appendicovesicostomy
   c. Longer follow-up is needed with the minimally invasive laparoscopic approach
   d. Stomal stenosis and urinary incontinence are complications of appendicovesicostomy
   e. Secondary surgeries may be necessary if internal hernias occur following appendicovesicostomy and cause small bowel obstruction

8. Which of the following is TRUE regarding diagnostic laparoscopy?
   a. Vanished testes are marked by blind-ending vas but normal-appearing spermatic vessels
   b. Diagnostic laparoscopy is poor at accurately localizing nonpalpable testes
   c. Inguinal exploration first before diagnostic laparoscopy for nonpalpable testes may be inconclusive in up to 66% of cases
   d. Up to 50% of nonpalpable testes may be actually palpable under anesthesia
   e. Preperitoneal insufflation is not a possible complication of diagnostic laparoscopy

9. Which of the following is FALSE regarding laparoscopic varicocelectomy?
   a. Laparoscopic varicocelectomy is very similar to the open Ivanessevich repair
   b. Varicocele recurrence rates following laparoscopic varicocelectomy range from 4% to11%
   c. Hydrocele formation rates following laparoscopic varicocelectomy range from 8% to 10%
   d. Unique complications of laparoscopic varicocelectomy include scrotal subcutaneous emphysema and scrotal pain
   e. Artery-sparing techniques of laparoscopic varicocelectomy have been associated with improved

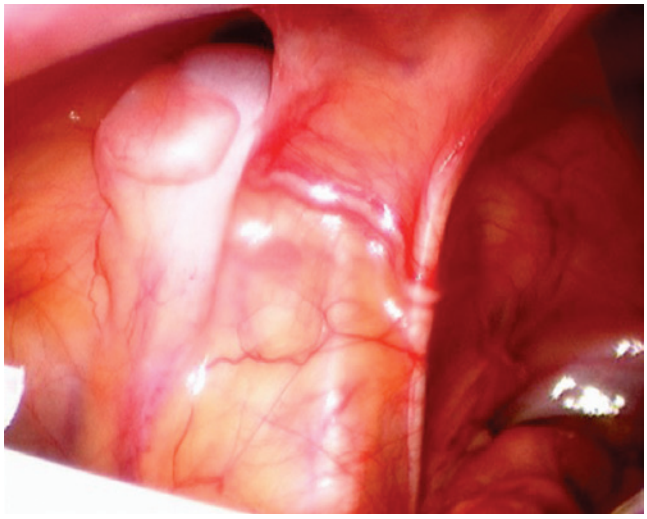
semen parameters but higher risk of varicocele recurrence/persistence

10. Which of the following is FALSE regarding laparoscopic inguinal hernia repair?
    a. Hernia recurrence rates are no different between laparoscopic and open inguinal hernia repairs
    b. Complication rates of laparoscopic inguinal hernia repair are not significantly different and may possibly be lower than those of open inguinal repair
    c. Transperitoneal laparoscopic inguinal hernia repair carries the risk of bowel or vascular injury
    d. Laparoscopic hernia repair allows examination and repair of a contralateral hernia if one is suspected
    e. Laparoscopic inguinal hernia repair may only be done safely in children age 10 or older

Case Studies

CASE 1

A 7-month-old boy presents to your office for evaluation of a unilateral undescended testicle. You cannot palpate the left testicle in clinic. The patient is otherwise healthy and is developing well.



1. What is the next best step in localizing the nonpalpable testis?
    a. Ultrasound of the abdomen and groin
    b. MRI of the abdomen and pelvis
    c. Unilateral groin exploration in the OR
    d. Diagnostic laparoscopy in the OR
    e. Examination under anesthesia in the OR

2. If the examination under anesthesia in the OR does not reveal a palpable testicle, what is the next step?
    a. Ultrasound of the abdomen and groin
    b. MRI of the abdomen and pelvis
    c. Unilateral groin exploration in the OR
    d. Diagnostic laparoscopy in the OR
    e. Laparotomy

3. If diagnostic laparoscopy reveals the testicle located in the abdomen next to the internal ring (Case Fig. 56.1), which of the following is the LEAST logical next step?
    a. Open inguinal exploration and primary orchiopexy
    b. Open first-stage Fowler-Stephens orchiopexy
    c. Laparoscopic primary orchiopexy
    d. Laparoscopic single-stage Fowler-Stephens orchiopexy
    e. Laparoscopic first-stage Fowler-Stephens orchiopexy

CASE 2

During the workup for recurrent RIGHT flank pain, an 8-year-old girl was diagnosed with complete duplication of the RIGHT collecting system, an ectopic upper pole moiety ureter, and upper pole urinary tract dilation (Case Fig. 56.2). The child is normal sized and otherwise healthy. Voiding cystourethrogram showed no vesicoureteral reflux. Differential renal function showed 10% function in the RIGHT kidney upper moiety, 30% function in the RIGHT kidney lower moiety, and 60% function in the LEFT kidney.

Case Figure 56.1

Case Figure 56.2

1. What is the most reasonable next step in the management of this child?
    a. Observation
    b. Open RIGHT upper pole moiety heminephrectomy
    c. Minimally invasive RIGHT upper pole moiety heminephrectomy
    d. Common-sheath ureteral reimplantation of both RIGHT ureters
    e. Minimally invasive RIGHT upper-to-lower ipsilateral ureteroureterostomy

2. A robotic-assisted laparoscopic ipsilateral ureteroureterostomy is chosen as the procedure. Before access is obtained in the OR, what is the first step?

a. Cystoscopic retrograde insertion of ureteral stent into the upper pole ureter
b. Cystoscopic retrograde insertion of ureteral stent into the lower pole ureter
c. Percutaneous antegrade insertion of ureteral stent down the upper pole ureter
d. Percutaneous antegrade insertion of ureteral stent down the lower pole ureter
e. On-table voiding cystourethrogram

3. During access, the first attempt of Veress insertion causes subcutaneous emphysema. The second attempt is advanced deeper in the same location and blood is aspirated. What vessel has been punctured and what is the next best step?
   a. Left common iliac vein – remove the Veress needle and abort the procedure
   b. Left common iliac vein – leave the needle in place and explore either open or laparoscopically via other location
   c. Right common iliac artery – remove the Veress needle and abort the procedure
   d. Right common iliac artery – leave the needle in place and explore either open or laparoscopically via other location
   e. Inferior vena cava – insert a laparoscope in another location and repair laparoscopically

Answers

1. **d.** Compliance decreases with pneumoperitoneum. All the remaining answers are TRUE. Hypoxemia, hypercarbia, and barotrauma are all risks of increased pneumoperitoneum.
2. **c.** A Cochrane review of 13 various techniques for gaining access showed no superior single technique.
3. **b.** In a recent meta-analysis, retroperitoneoscopic pyeloplasty had no significantly different success rates than transperitoneal laparoscopic approaches with similar complication rates.
4. **b.** Urinomas may form from unrecognized injury to the collecting system of the remaining moiety or leaving functional parenchyma of the excised moiety. All other complications may occur with either hemine-phrectomy or simple total nephrectomy.
5. **d.** Robotic-assisted laparoscopic ureteral reimplantation can be performed in either an extravesical or an intravesical manner.
6. **b.** The "yo-yo" effect where urine from the "bad" moiety refluxes up the recipient ureter is worrisome for causing infection in the "good" recipient renal moiety.
7. **b.** Robotic-assisted laparoscopic and open appendicovesicostomies appear to have equivalent success rates. The types of complications appear to differ.
8. **c.** Vanished testes are marked by blind-ending vessels. Diagnostic laparoscopy is excellent at localizing nonpalpable testes. Roughly 18% of nonpalpable testes may be actually palpable under anesthesia. Lastly, preperitoneal insufflation is a possible complication of access and thereby diagnostic laparoscopy.
9. **a.** Laparoscopic varicocelectomy is similar to the Palomo repair, not the Ivanessevich repair.
10. **e.** Laparoscopic hernia repair has been safely and successfully performed in children as young as infants and is not restricted by age alone.

CASE 1

1. **e.** Studies have suggested that a substantial portion of nonpalpable testes may actually be palpated under anesthesia, which would guide surgical management to either diagnostic laparoscopy or inguinal exploration next under the same anesthetic.
2. **d.** Diagnostic laparoscopy provides excellent localization of nonpalpable testes. It can identify viable intra-abdominal testes, presence or absence of blind-ending spermatic vessels or vas, and any question of contralateral hernia.
3. **d.** Given the relatively low-lying intraabdominal/inguinal location of the testicle, any of the options are feasible and logical, except for a single-stage Fowler-Stephens orchiopexy. If division of the spermatic vessels is needed to allow the testicle to reach the scrotum, then a staged approach is preferable to a single-stage, given the better success rates and lower atrophy rates.

CASE 2

1. **e.** Given some preserved renal function in the upper moiety, an ipsilateral ureteroureterostomy is preferable over a heminephrectomy. Ureteral reimplantation of both ureters, in the absence of vesicoureteral reflux, may put the lower pole moiety ureter at risk.
2. **b.** The recipient ureter is usually prestented before the anastomosis is performed to "protect" the functional "good" renal moiety. No repeat VCUG is needed as one was done preoperatively.
3. **d.** The most common vessel that is injured during access is the right common iliac artery. Since it is arterial, the needle should be kept in place. The injury should then be explored via either conversion to open surgery or via insertion of a laparoscope in another location.

57 Complications of Surgery for Posterior Urethral Valves

ELLEN SHAPIRO and JACK S. ELDER

CHAPTER OUTLINE

In Utero Intervention
Outcomes
Initial Management of Patients With Posterior Urethral Valves
Primary Valve Ablation
Alternatives to Valve Ablation: Cutaneous Vesicostomy and Upper Tract Diversion
Controversies in Initial Management of Posterior Urethral Valves
Prognosis Following Initial Therapy
Vesicostomy Closure
Vesicoureteral Reflux
Bladder Dysfunction
Delayed Presentation of Posterior Urethral Valves
Progression to End-stage Renal Disease and Renal Transplantation
Conclusions
Chapter 57 Questions and Answers

KEY POINTS

1. Posterior urethral valves (PUV) usually are diagnosed during antenatal sonographic screening, but some patients present in infancy with an abdominal mass, failure to thrive, urosepsis, or urinary ascites, and a minority present following toilet training.
2. Antenatal intervention is considered for bilateral hydroureteronephrosis and a distended bladder when hypotonic electrolytes are found on serial vesicocenteses.
3. A voiding cystourethrogram is the gold standard for diagnosing PUV.
4. Renal function is determined postnatally by monitoring the change in the serum creatinine level following bladder decompression.
5. Primary valve ablation is the treatment of choice when the urinary tract decompresses and renal function improves with catheter drainage.
6. A serum creatinine concentration <0.8 mg/dL 1 month following initial treatment or at 1 year of age is associated with favorable renal function.
7. Hydronephrosis may be chronic as a result of reflux, incomplete bladder emptying, and/or poor detrusor compliance.
8. Bladder dysfunction is manifested primarily by detrusor overactivity and incomplete bladder emptying.
9. Pop-off mechanisms, including posterior urethral valves, unilateral vesicoureteral reflux and renal dysplasia (VURD) syndrome, bladder diverticulum, patent urachus, and urinomas, are thought to protect the bladder, but might not protect long-term renal function.
10. Delayed presentation of PUV should be considered in boys >5 years old who present with diurnal incontinence, urinary tract infection, voiding pain, or urinary frequency.
11. In boys with a history of PUV, graft survival and serum creatinine following renal transplant are similar to patients without bladder outlet obstruction, because meticulous attention is paid to the management of lower urinary tract dysfunction.

Posterior urethral valves (PUV) occur in 1/8000 boys and are the most common form of obstructive uropathy causing end-stage renal disease (ESRD) in children, ultimately occurring in as many as 40% with PUV. In addition, PUV are associated with vesicoureteral reflux (VUR), pyelonephritis, overactive bladder, underactive bladder, polyuria, and incontinence.

The management of PUV has evolved since the late 1990s. With antenatal diagnosis and in utero intervention, the spectrum of the problems associated with this anomaly poses new challenges to the neonatologist, pediatric urologist, pediatric nephrologist, and transplant surgeon. Despite these advances, some children present in childhood or adolescence with subtle findings often overlooked during routine pediatric care. This chapter addresses complications of in utero intervention, urethral valve ablation, ureteral tailoring and reimplantation, and delayed presentation.

The evaluation and treatment of bladder dysfunction are also reviewed because this condition directly affects the success of ureteral surgery and kidney transplantation and dictates the need for augmentation cystoplasty.

In Utero Intervention

Since the mid-1980s, surgeons have been cautiously optimistic about the role of antenatal bladder decompression for obstructive uropathy and oligohydramnios.[1] The purpose of this intervention is to restore the amniotic fluid to a more normal volume and thereby prevent pulmonary hypoplasia, which is the pulmonary complication of oligohydramnios. Techniques used include vesicoamniotic shunt placement and cutaneous vesicostomy through hysterotomy.

Moderate enthusiasm for this new technology was generated following a report by Manning and associates[2] of the International Fetal Surgery Registry that suggested that fetal intervention resulted in survival of <44% of cases with oligohydramnios. However, a careful review of all reported cases of fetal intervention for suspected obstructive uropathy yielded only two documented cases in which antenatal bladder drainage could have improved the outcome.[3] More recently, refinements in the technology and better criteria for intervention have allowed the diagnosis and appropriate selection of candidates who may benefit from in utero therapy.[4,5]

Although fetal sonographic techniques have improved, in some cases, upper urinary tract changes that result from PUV are not apparent before 24 weeks of gestation.

Fetuses with PUV and normal-appearing anatomic features at 20 weeks of gestation are more likely to have normal renal function than those with severe early hydronephrosis. Consequently, antenatal therapy probably would not be beneficial in this group with a better prognosis.[6] A structural ultrasound scan performed at 20 weeks permits systematic evaluation of the urinary tract. The kidneys appear echodense in most cases. Large kidneys with mild parenchymal changes are seen in early obstruction, whereas small kidneys suggest significant parenchymal damage. Discrete focal cysts are a common sonographic manifestation of renal dysplasia.[5,7–13]

The ureters are assessed for dilation. Abnormal patency and dilatation of the ureterovesical junction (UVJ) suggest advanced urinary tract changes with poor prognosis. Bladder distention is almost always noted, and the classic "keyhole" sign is observed at times (Fig. 57.1). Bladder wall thickening also should be characterized. Symmetric thickening suggests PUV, whereas asymmetric thickening of the lower half of the bladder relative to the dome region suggests the prune belly syndrome.[4,10–13]

Because oligohydramnios can be present on the initial examination, amniotic infusion with warm lactated Ringer solution restores the amniotic fluid volume for antenatal sonographic surveillance.[5] The incidence of chorioamnionitis has been reduced by the routine administration of parenteral antibiotic therapy at the time of the infusion followed by 10 days of oral antibiotics. Fetal karyotyping is performed with chorionic villous sampling or cordocentesis to rule out aneuploidy and to confirm the fetal sex. Knowledge of the sex of the fetus is important because shunting of dilated urinary systems in patients who were later found to be female with cloacal malformations provides no benefit in this setting.[5]

Another important selection criterion for antenatal intervention is electrolyte determination on serial vesicocentesis performed at 48- to 72-hour intervals.[5,13–15] Normally, fetal urine is hypotonic, whereas urine in renal dysplasia is more likely to be isotonic.[13] Normal fetal urine has a sodium concentration <100 mEq/L, chloride concentration <90 mEq/L, and osmolality <210 mOsm/L. Analysis of fetal urine aspirated from the bladder allows analysis of fetal renal function; urine with normal electrolyte values suggests that fetal renal function will be adequate following bladder decompression. The other important parameter to measure is urinary β_2-microglobulin; levels >10 mg/L are highly suggestive of irreversible renal dysplasia.[16] Abnormal fetal urinary values on a single bladder aspiration may be misleading because this value may represent stale urine.[17] Instead, sequential aspiration is more reliable. If the fetal urine parameters improve to normal values, fetal renal function following urinary tract decompression may be acceptable. Using serial vesicocentesis, Freedman et al. reported a 60% survival and a 33% incidence of renal failure in high-risk fetuses identified in the first trimester with severe bilateral hydroureteronephrosis, bladder distention, and oligohydramnios.[18]

Although percutaneous vesicoamniotic shunts have been used for nearly 3 decades, these shunts have significant limitations.[2,3] Vesicoamniotic shunts become obstructed or displaced in 25% of cases, a situation necessitating additional procedures that can cause increased morbidity in the mother and the fetus, with a 5% procedure-related fetal loss rate.[5] The shunt provides only palliative therapy and does not treat the anomaly or the pulmonary hypoplasia and renal dysplasia that are responsible for up to half of the deaths in patients with PUV.

Despite the advances of the Rodeck shunt, which places the proximal and distal pigtails at 90-degree angles, shunt displacement occurs in 25–30% of cases.[19,20] The site of shunt placement is important. The shunt must avoid the dome and be positioned in the midline just above the pubic symphysis. Even when no problems with shunt placement and function are noted in the appropriate candidate, unusual and unexpected outcomes can occur. For example, even with appropriate selection criteria and shunt placement, some fetuses have persistent oligohydramnios that leads to fetal demise. These fetuses typically have small kidneys with significant fibrocystic dysplastic changes suggesting progressive degeneration despite successful intervention.

The first reports of percutaneous fetal cystoscopy at 19 weeks and subsequent endoscopic fulguration of the valves were published in 1995.[1,21] At the time of the initial vesicocentesis, a 0.7-mm fiberoptic endoscope was threaded through the lumen of an 18-gauge thin-walled needle, similar to the technique used to perform transabdominal embryofetoscopy. At 22 weeks' gestation, a 10-gauge trocar was inserted through the maternal abdomen and into the fetal bladder. A 2.5-mm steerable endoscope with a 1.3-mm operating channel was passed through the trocar. A soft-tip 0.025-inch guidewire was used and the endoscope was advanced along the wire. The valves were electrocauterized with a 2Fr ball-tip monopolar flexible electrode with 25 W

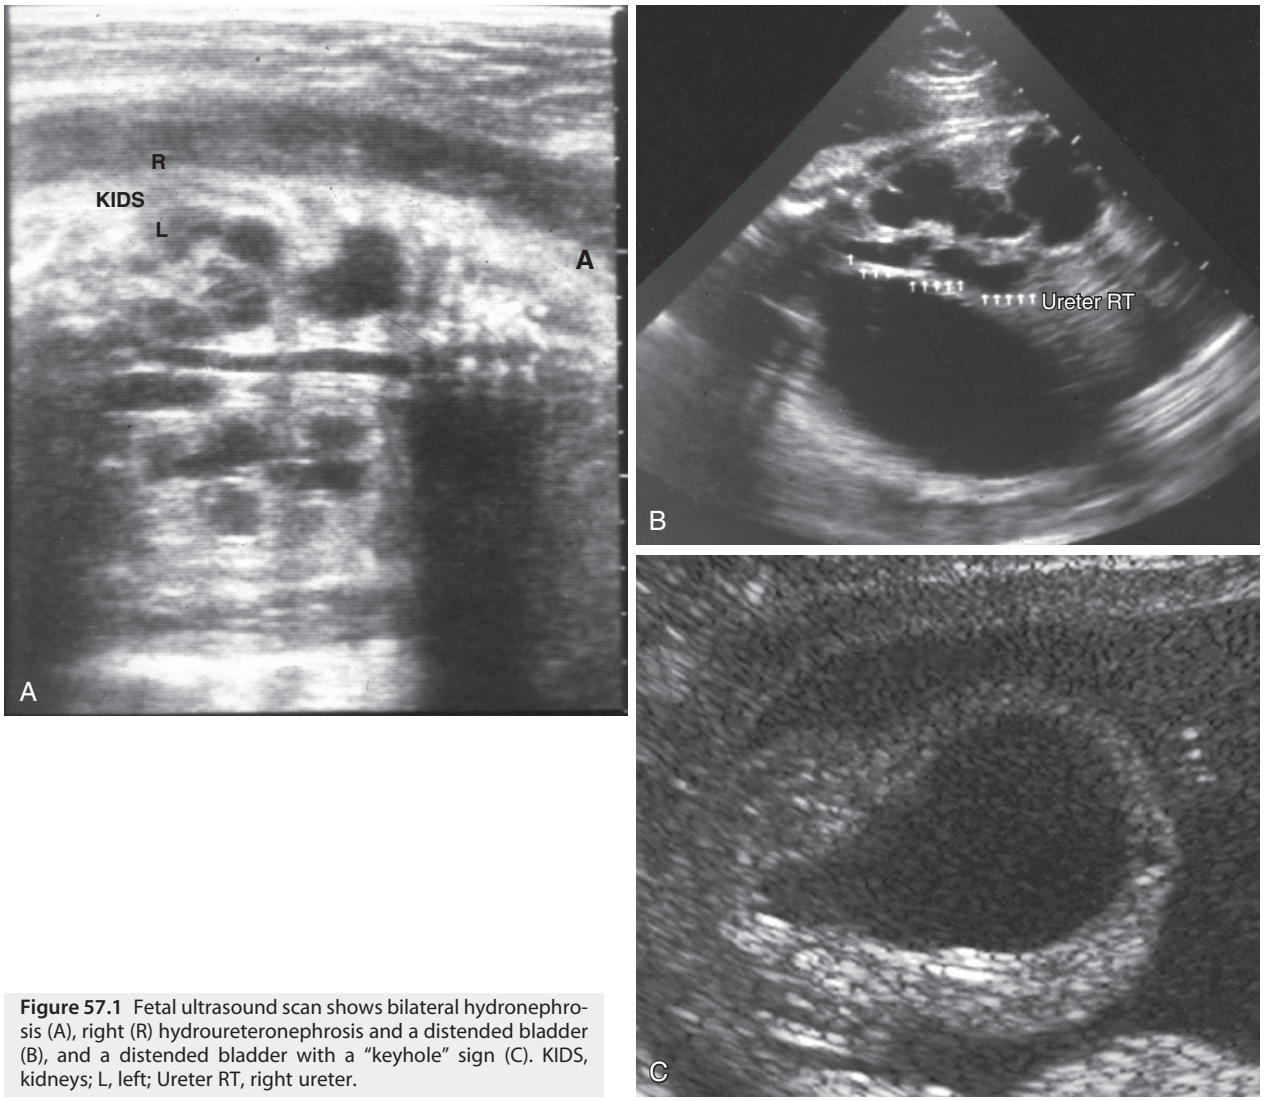

Figure 57.1 Fetal ultrasound scan shows bilateral hydronephrosis (A), right (R) hydroureteronephrosis and a distended bladder (B), and a distended bladder with a "keyhole" sign (C). KIDS, kidneys; L, left; Ureter RT, right ureter.

of coagulating current. Following the 2-hour procedure, improvement in the urinary tract dilation with restoration of the amniotic fluid was seen on the posttreatment ultrasound scan. Delivery occurred at 31 weeks as a result of preterm labor, and the infant had a postnatal diagnosis of PUV. The remaining patients had prune belly syndrome or were females with urethral atresia or urogenital sinus anomalies. All fetuses underwent karyotyping and serial vesicocentesis for electrolytes, and those with PUV had favorable electrolyte values. Intervention was performed at a weight of 2000 g, with Apgar score of 5 and 7.[5] A 10-mm abdominal wall defect with minor omental herniation was present at the site of the trocar. The infant died of pulmonary hypoplasia on day 4 of life.

More recently, Martinez et al. reported fetal cystoscopic diode laser ablation of PUV in 20 fetuses at a mean gestational age of 18.1 weeks.[22] The median operative time was 24 minutes. Access to the urethra was obtained in 95% and normalization of amniotic fluid and bladder size occurred in 80%. In follow-up, termination of pregnancy occurred in 45%, 73% had "normal" renal function, and 27% had end-stage renal disease (ESRD) and were awaiting transplantation.

OUTCOMES

Holmes and colleagues reviewed the University of California San Francisco experience with fetal intervention for obstructive uropathy over 2 decades.[23] They evaluated 40 patients, and 36 fetuses underwent surgical intervention. Mean gestational age at intervention was 22.5 weeks. The fetuses underwent various in utero surgical procedures including cutaneous ureterostomies (one), fetal bladder marsupialization (two), in utero valve ablation (two), and placement of a vesicoamniotic catheter (nine). One patient who underwent valve ablation subsequently required a vesicoamniotic shunt for significant ascites. Another patient required multiple shunt placements as a result of malfunction or migration of the shunt. Before delivery, fetal demise occurred in 43%. One pregnancy was electively terminated because of significant pulmonary hypoplasia, and the remaining deaths resulted from prematurity

and respiratory failure. Long-term follow-up (mean 11.6 years) in five of eight living patients revealed that 63% had chronic renal insufficiency (mean serum creatinine, 2.5 mg/dL after 1 year of age). Two patients required renal transplantation. Five of the eight living patients underwent urinary diversion (vesicostomy or cutaneous ureterostomy) or augmentation cystoplasty. This study underscores the finding that intervention often does not prevent ESRD, despite "favorable" fetal renal function, and suggests that intervention may primarily assist in keeping the fetus viable to term.

Biard and colleagues reported their long-term outcomes in 7 of 18 boys with PUV treated by vesicoamniotic shunting.[24] Other diagnoses included urethral atresia (four) and prune belly syndrome (seven). These investigators followed their algorithm for antenatal evaluation including fetal karyotyping and serial vesicocentesis for electrolytes and management.[24] Parents requested shunting in three cases with poor predicted prognoses. Most cases (13 of 18) had good prognostic findings. The mean gestational age at first vesicocentesis was 19.8 weeks and at vesicoamniotic shunting was 21.9 weeks. Eight complications were associated with vesicoamniotic shunting including shunt displacement in five (requiring replacement in four), abdominal omental herniation in two, and premature rupture of membranes 4 days following shunt placement in one. Mean gestational age at delivery was 34.6 weeks. In boys with PUV, long-term renal function was acceptable (creatinine clearance >70 mL/minute) in three of seven. Mild renal insufficiency was defined as creatinine clearance <70 mL/minute not requiring renal replacement therapy and was found in three of seven. Only one of seven required renal transplantation at 10 years of age. Five patients voided spontaneously, one required catheterization, and one voided spontaneously and was also catheterized. In the overall group of children who underwent shunting, normal physical and cognitive development was noted in 78%.

In a recent retrospective case-controlled analysis of 111 fetuses comparing vesicoamniotic shunting to fetal cystoscopy/valve ablation and no intervention, both shunting and fetal cystoscopy improved survival at 6 months, and fetal cystoscopy was more likely to prevent impairment of renal function than was shunting.[25] A prospective randomized controlled trial comparing the effectiveness of these two interventions for severe lower urinary tract obstruction was recommended.

Initial Management of Patients With Posterior Urethral Valves

The newborn with PUV may have an abdominal mass (49%), failure to thrive (10%), urosepsis (8%), or urinary ascites (7%).[26] In most cases, antenatal sonography demonstrates bilateral hydroureteronephrosis and a distended bladder (Fig. 57.2). When the bladder is empty, one often feels or palpates a walnut-size, firm mass in the pelvis that corresponds to the trabeculated bladder muscle. In addition, dyspnea associated with pneumothorax or pneumomediastinum may be the initial sign of severe urethral obstruction.[27] A normal urinary stream is an infrequent finding.[26]

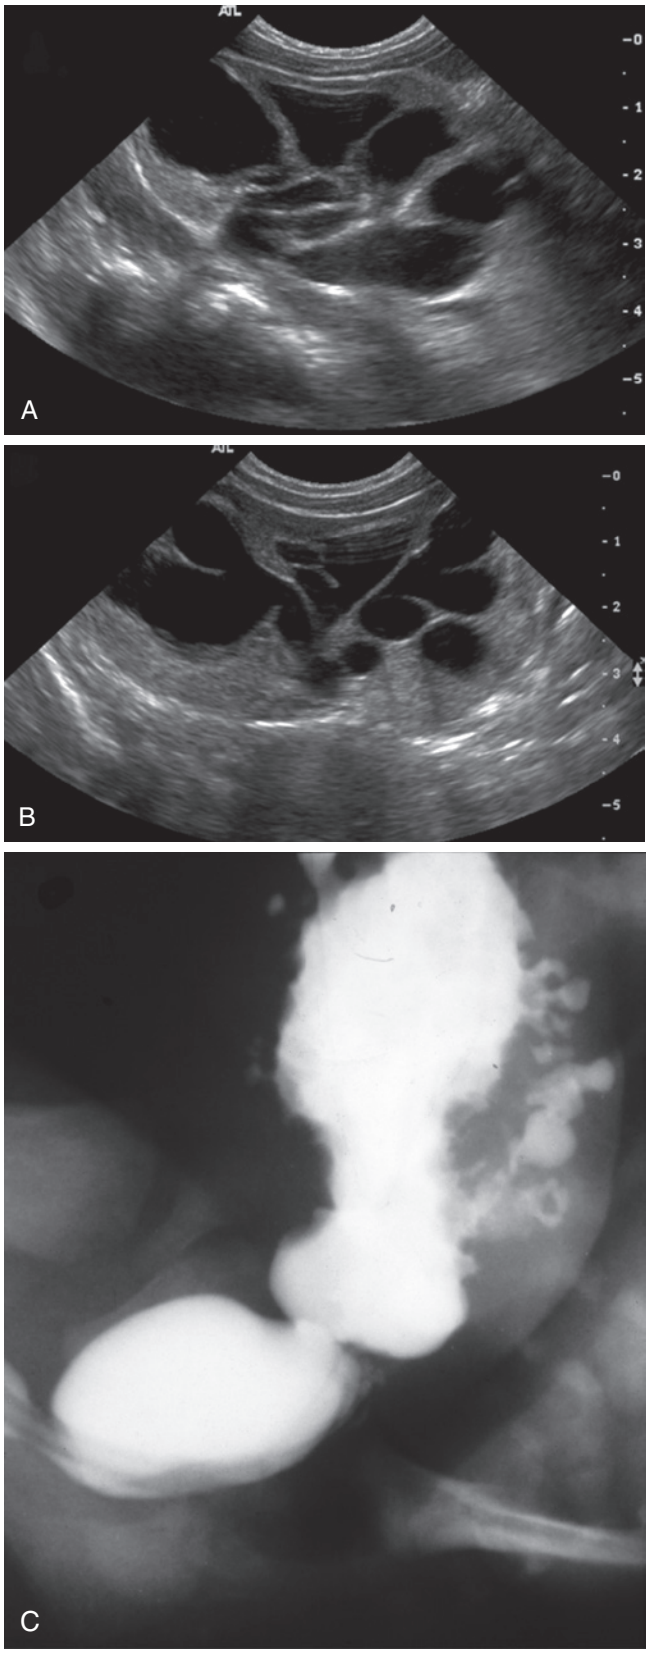

Figure 57.2 Renal ultrasound scan shows severe right hydronephrosis and hydroureter (A), severe left hydronephrosis (B), and voiding cystourethrogram demonstrating typical findings of type I posterior urethral valves (C).

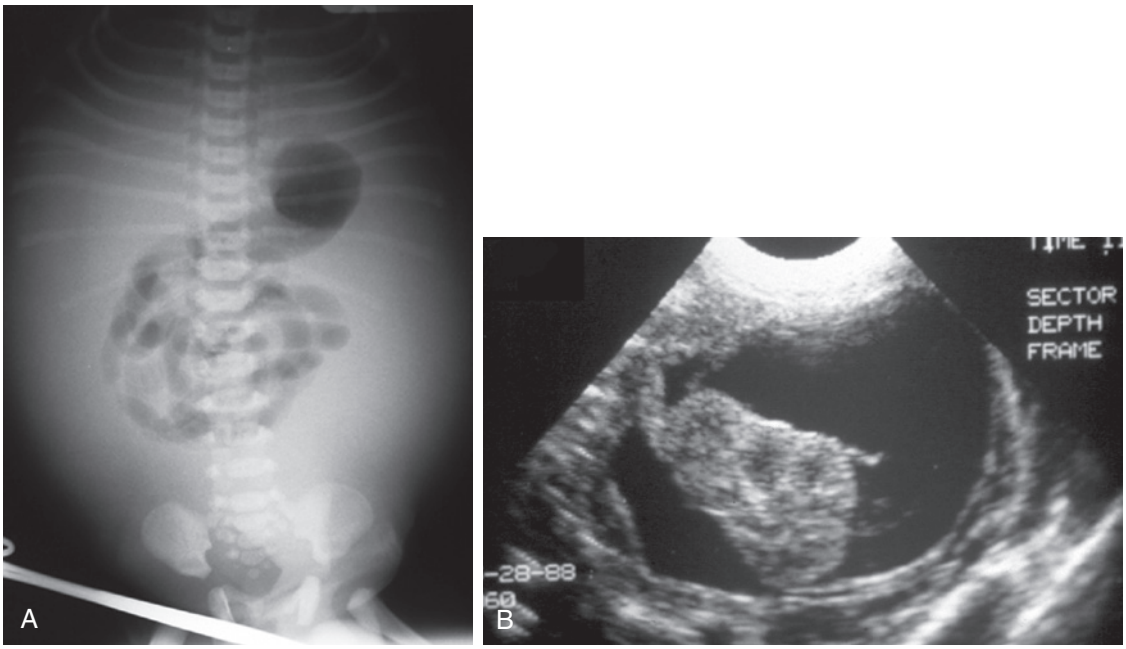

Figure 57.3 Newborn with an abdominal mass. A, Abdominal plain film shows the ground-glass appearance of abdominal ascites. B, Renal ultrasound scan demonstrates an extracapsular urinoma and complete decompression of the collecting system.

A voiding cystourethrogram (VCUG) should be obtained promptly to establish the correct diagnosis (see Fig. 57.2C). Sonography usually shows significant bilateral hydronephrosis with a thick bladder. Demonstration of the corticomedullary junction is a favorable prognostic sign for renal function. Conversely, echogenic kidneys, subcortical cysts, and failure to demonstrate the corticomedullary junction on the initial and follow-up ultrasound studies are unfavorable signs.[10,12,26]

Antenatal urinomas are thought to serve as a protective mechanism to reduce pressure-related impairment of renal function (Fig. 57.3). Patil and colleagues studied two groups of patients with PUV.[28] Group 1 had ascites with and without urinoma and no vesicoureteral reflux (VUR), and group 2 had urinoma formation alone (unilateral or bilateral) and bilateral VUR. Moderate renal failure was seen in the three boys with ascites alone, and mild renal failure was present in the three boys with urinoma and ascites. The investigators speculated that ascites without urinoma suggests bladder rupture and more severe renal damage. The three boys in group 2 with bilateral urinomas had normal glomerular filtration rates (GFRs), whereas the nine boys with unilateral urinomas showed impaired renal function on the side of the urinoma. These findings were confirmed in a more recent study of 89 boys with PUV, of whom nine had a urinoma.[29] The nadir creatinine (Cr) was significantly lower in boys with urinomas compared with unaffected boys, and none with a urinoma had ESRD or underwent renal transplantation.

Patil and colleagues hypothesized that if renal extravasation is extracapsular, it could have a protective effect on renal function, whereas if the extravasation is subcapsular, the renal parenchyma is compressed, thus possibly leading to the deleterious effects of a urinoma.[28] If the type of urinoma cannot be determined, this may explain the results of other studies that showed no association between renal function and urinoma formation.[30]

The initial treatment for neonates with suspected PUV is directed at decompressing the urinary tract with a small transurethral feeding tube. Attention is given to pulmonary function and fluid and electrolyte management. We recommend passing the catheter at the time of the first ultrasound scan immediately following birth. The catheter can be difficult to pass because of the dilated posterior urethra and the bladder neck hypertrophy. Sonography confirms the placement of the catheter within the bladder because a catheter that is coiled in the posterior urethra will cause the majority of urine to drain around the catheter. Similarly, if too much of the catheter is coiled in the bladder, the tip may extend distally through the external sphincter and provide some drainage of the bladder with continuous leakage around the catheter. Foley catheter use is discouraged because the balloon can obstruct the ureteral orifices when the thick-walled bladder is decompressed, or it can cause severe bladder spasm that can obstruct the intramural ureters. Although anuria can result from the noncompliant, hypertonic bladder wall and can lead to relative obstruction of the UVJ, mechanical occlusion can also be the source of anuria in some cases.[31]

A recent novel approach for temporary bladder decompression was described using a 6Fr 12-cm double J stent advanced over a guidewire.[32] In 30 patients, the mean peak serum Cr diminished from 2.23 mg/dL to 0.56 mg/dL, and the investigators also demonstrated that the stent drained the bladder significantly more efficiently than did either a feeding tube or Foley catheter.

Antibiotic prophylaxis is commonly prescribed. In the absence of suspected sepsis, ampicillin or cephalexin is administered at the time of catheter placement.[26] It is best to avoid nephrotoxic agents that may cause further tubular

dysfunction. Finally, neonatal circumcision should be recommended in these boys because it significantly reduces the risk of urinary tract infection (UTI).[33]

PRIMARY VALVE ABLATION

Infant urethral sounds should be passed to calibrate the urethra. The term newborn male urethra generally accepts an 8Fr endoscope. Dilation of the urethra to pass a larger instrument may lead to urethral trauma and stricture formation. Vigorous dilation may result in iatrogenic hypospadias due to splitting of the glans to the subcoronal level. Vesicostomy is the treatment alternative for the infant whose urethra is too small to accept an endoscope.[26]

Smith and colleagues reported valve ablation using the 6.9Fr cystoscope and the 3Fr Bugbee electrode in premature infants as small as 2500 g.[34] The coagulating current was used to ablate the valves. However, we advocate using a small Bugbee electrode using low cutting current. In older patients, the 11- or 13Fr Storz resectoscope can be used with the cutting current and the right-angle loop. In addition, the neodymium:yttrium-aluminum-garnet (Nd:YAG) or holmium:YAG laser may be used.[35,36] The Nd:YAG laser was successful in 16 of 20 patients, and four patients underwent repeat valve ablation.[35] In contrast, the holmium:YAG laser was reported to result in improved success in voiding after catheter removal, reduced need for repeat valve ablation, and a lower risk of urethral stricture compared with electrofulguration.[36]

Varying methods are used to ablate PUV. The valves should be incised at the 12-o'clock position and the lateral leaflets should be cut at the 5- and 7-o'clock positions.[37] Passing a cystoscope or resectoscope that is too large may result in urethral stricture.[38] Chertin and colleagues reported a series of 35 cases of valve ablation under fluoroscopic guidance using a 4Fr Fogarty balloon catheter filled with 0.5 mL of saline.[39] A postoperative VCUG revealed no residual valve in 34 of 35 patients (97%). Other methods include creation of a temporary perineal urethrostomy into which the cystoscope or resectoscope is passed or performance of the procedure in an antegrade fashion through a percutaneous cystostomy.[40]

A small feeding tube is left indwelling for 1 to 2 days, and a VCUG may be obtained at the time of catheter removal. If the VCUG is not obtained before discharge from the hospital, it should be obtained 2 to 4 weeks postoperatively to confirm satisfactory valve ablation. In addition, a renal sonogram assesses hydronephrosis and confirms satisfactory bladder emptying.

Another method to assess adequacy of valve ablation is the preoperative and postoperative urethral ratio.[41] This ratio is determined by measuring the diameter of the posterior urethra transversely at a point halfway between the bladder neck and the distal end of the membranous urethra and the diameter of the anterior urethra at the transverse diameter at the point of the maximum distention in the bulbar urethra. Measurements are most accurate on voiding films in which the catheter has been removed (Fig. 57.4). In one study,[41] the median urethral ratio before ablation was 8.6 (range 4–14.7) and that of normal age-matched controls was 2.6 (range 1.3–5.5). The postoperative urethral ratio was 3.1 (range 1.9–4). A second group of patients with a postoperative urethral ratio of 8 (range 5–15.5) after the first ablation underwent a second ablation with a final urethral ratio of 3.1 (range 2.9-6.4).[41] Valve ablation is successful in > 90% of patients. Long-term stricture formation is uncommon.[38]

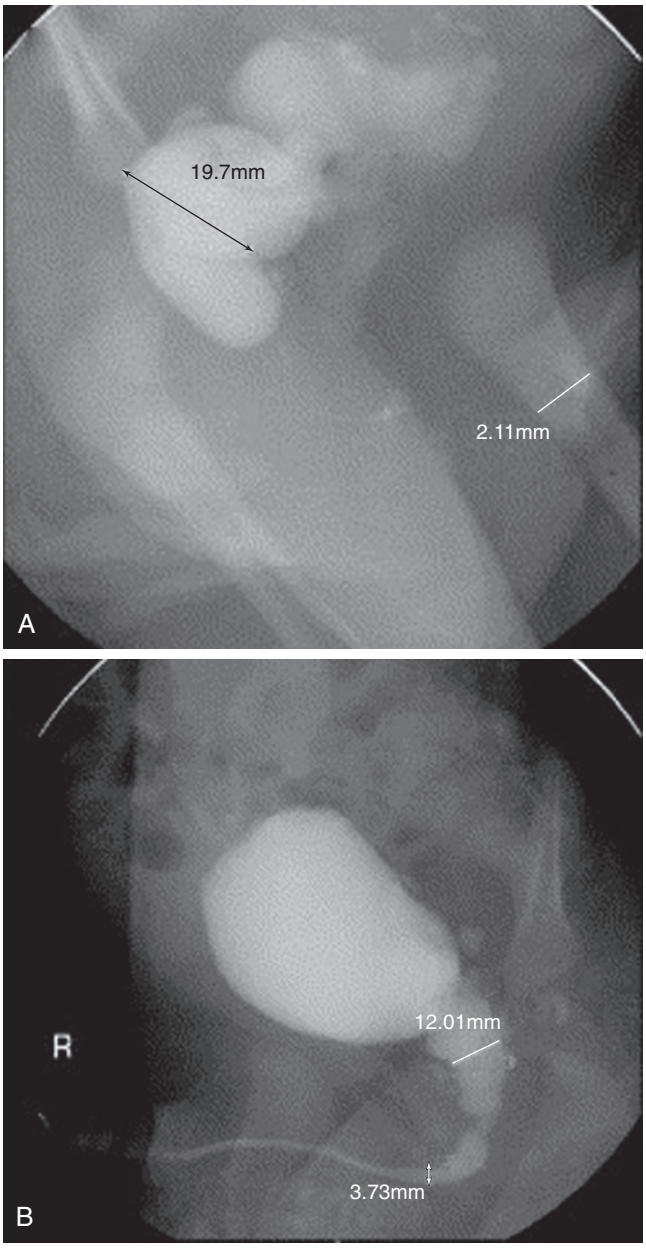

Figure 57.4 Posterior urethral measurements to determine the urethral ratio on a preoperative (A) and postoperative (B) voiding cystourethrogram. (With permission from Bani Hani O, Prelog K, Smith GHH. A method to assess posterior urethral valve ablation. *J Urol.* 2006;176:303-5.)

ALTERNATIVES TO VALVE ABLATION: CUTANEOUS VESICOSTOMY AND UPPER TRACT DIVERSION

An alternative to primary valve ablation is the creation of a temporary cutaneous vesicostomy.[42,43] A small transverse incision is made midway between the umbilicus and the pubic symphysis, and the dome of the bladder is brought

to the skin. If the anterior bladder wall rather than the dome is exteriorized, prolapse may occur. The vesicostomy should calibrate to 24–26Fr to avoid stenosis. In addition, daily dilation of the stoma with a plastic medicine dropper helps minimize contraction of the stoma. The vesicostomy drains into the diaper, and no urinary collection device is necessary.

Cutaneous vesicostomy has been shown to be as effective as valve ablation for initial therapy.[44] This form of management allows the bladder to cycle with voiding at low pressure through the stoma and does not reduce bladder capacity. A cutaneous vesicostomy should not be performed in the presence of active UTI because contraction of the bladder may occur. These babies should be maintained on antibiotic prophylaxis. In some cases, breakthrough febrile UTIs occur and vesicostomy closure is necessary.

In the past, proximal high diversion with cutaneous pyelostomy or cutaneous ureterostomy was advocated for neonates and infants with severe hydronephrosis and a persistently elevated creatinine concentration following catheter drainage.[26,45] Proximal diversion also provides the opportunity to perform renal biopsy, which may help predict the child's ultimate renal outcome. The problem with initial high bilateral proximal diversion is that urine is diverted away from the bladder, and this situation may result in a small contracted bladder that does not grow over time.[46]

In boys with PUV, UVJ obstruction usually occurs only during bladder filling and results from elevated intravesical pressure, rarely from obstruction secondary to detrusor hypertrophy. Furthermore, proximal high diversion therapy has not been shown to prevent ESRD because >85% of these patients have renal dysplasia.[47] In addition, by diverting the urine away from the bladder, regular cyclic vesical contraction may not occur and result in a smaller, less compliant bladder compared with vesicostomy.[46] Finally, cutaneous pyelostomies require placement of a diaper across the abdomen and flank, and even then the child's clothes may become wet. Consequently, this form of diversion generally is reserved for rare cases in which valve ablation or vesicostomy has failed to show improvement in upper urinary tract drainage or when urosepsis is secondary to pyonephrosis.[26,45]

An alternative form of upper urinary tract diversion is the Sober-en-T ureterostomy, in which the proximal ureter is exteriorized and the distal ureter is kept in continuity with the upper ureter with a proximal ureteroureterostomy.[48] The advantage of this approach is that it permits rapid decompression of the upper urinary tract while permitting urine to pass into the bladder. Fig. 57.5 shows a modification of the original Sober-en-T ureterostomy.

If cutaneous vesicostomy, ureterostomy, or pyelostomy is chosen as initial therapy, valve ablation should not be performed simultaneously because the urethra will remain dry, and urethral stricture formation is common (Fig. 57.6).[49] Another case illustrating the importance of choosing well-planned diversionary procedures and delaying primary valve resection is shown in Fig. 57.7.

CONTROVERSIES IN INITIAL MANAGEMENT OF POSTERIOR URETHRAL VALVES

The initial management of PUV is controversial. In 1997, Close and colleagues suggested that early valve ablation

Figure 57.5 A newborn underwent bilateral cutaneous pyelostomies and transurethral ablation of posterior urethral valves. Before upper tract reconstruction at age 4 years, a catheter could not be passed at the time of the voiding cystourethrogram. The cystogram through a cutaneous ureterostomy shows a complete proximal anterior urethral stricture requiring a perineal approach for reconstruction.

permitted recovery of the normal bladder appearance and function when the procedure was performed within the first month of life. In their patients, urinary diversion was deleterious to ultimate bladder function because of the absence of normal bladder cycling.[46] Patients who underwent diversion had reduced bladder compliance, which resulted in long-term bladder dysfunction. Delayed development of daytime urinary continence occurred in 80% of patients who underwent diversion procedures as opposed to 33% of those who underwent primary valve ablation. However, both groups developed similar degrees of renal dysfunction in the long term.[46]

Podesta and colleagues studied boys with PUV who underwent either vesicostomy and delayed valve ablation or primary valve ablation.[50] These investigators demonstrated that approximately 50% of the diverted group had detrusor overactivity, which was rarely observed in the primary ablation group. The primary ablation group also had a lower detrusor filling pressure at expected bladder capacity for age and improved detrusor compliance.

Although these groups advocated primary valve ablation, their observations on bladder function differed from the 1996 report of Smith and colleagues.[51] These investigators examined the long-term outcome of 100 patients treated with primary valve ablation (74%), vesicostomy (13%), or high diversion (90%). Overall, 13% developed ESRD by age 15 years. Treatment choice did not influence the age at which they developed ESRD. The incidence of chronic renal failure was 34% at age 10 years and 51% at age 20 years. Almost all patients had delayed development of daytime urinary continence; only 19% developed continence by age 5 years and 46% by age 10 years. Although formal urodynamic testing was performed in only 10 patients, only one patient was thought to need an augmentation cystoplasty.[51]

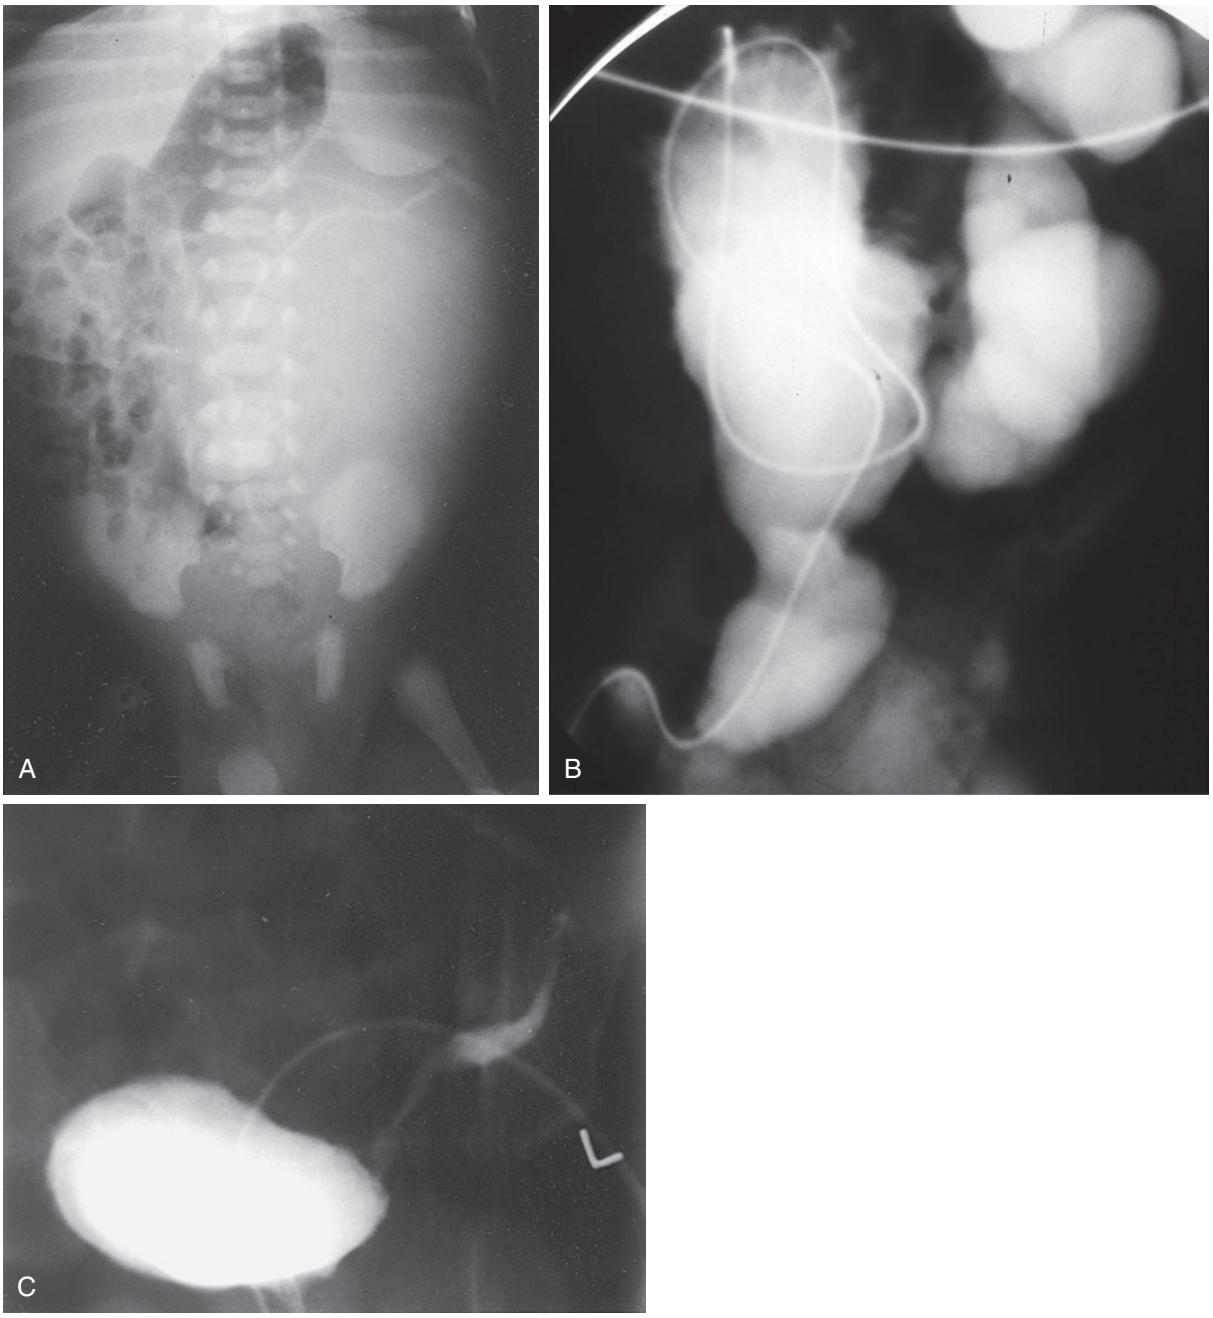

Figure 57.6 A newborn boy was noted prenatally to have left hydronephrosis and a distended bladder. A, Abdominal plain film shows a large left urinoma. B, Voiding cystourethrogram shows high-grade left vesicoureteral reflux and posterior urethral valves. His creatinine concentration was 0.5 mg/dL after 1 week of catheter drainage. During passage of the resectoscope, the glans split, creating a subcoronal hypospadias. Valve ablation proceeded and a left ureterostomy at the midureteral level was performed. Postoperatively, all his urine is noted from the left ureterostomy. Before urinary diversion at age 3 years, a renal scan demonstrates that the left kidney contributes 20% to the total renal function and a cystogram (C) shows reflux into a nondilated left distal ureter, mild trabeculation, and normal capacity for his age (150 mL). Left proximal ureterogram shows no obstruction. Takedown of the left ureterostomy with excision of the left distal ureter and ureteral reimplantation with a psoas hitch are performed. This case demonstrates several points: (1) Ureterostomy is not usually indicated for reflux; (2) ureterostomy should not be performed midureter when reimplantation will be required; (3) once the valve is resected, procedures should not be performed that completely divert urine from the bladder; and (4) care should be exercised when instrumenting the infant male urethra.

Kim and associates[52] compared the urodynamic findings in patients with PUV who underwent primary valve ablation, vesicostomy, or proximal diversion with pyelostomy or ureterostomy. When the urodynamic findings of end-filling detrusor pressure and bladder capacity were compared, no statistical difference was found in any of these groups. In fact, the vesical or proximal diversion groups had somewhat better urodynamic findings. The investigators concluded that the initial management of valve ablation or vesical or proximal diversion does not affect ultimate bladder function. However, adjunctive medical therapy in the treatment groups was difficult to assess.

A report of the long-term follow-up of bilateral high Sober-type urinary diversion in 36 patients with PUV who

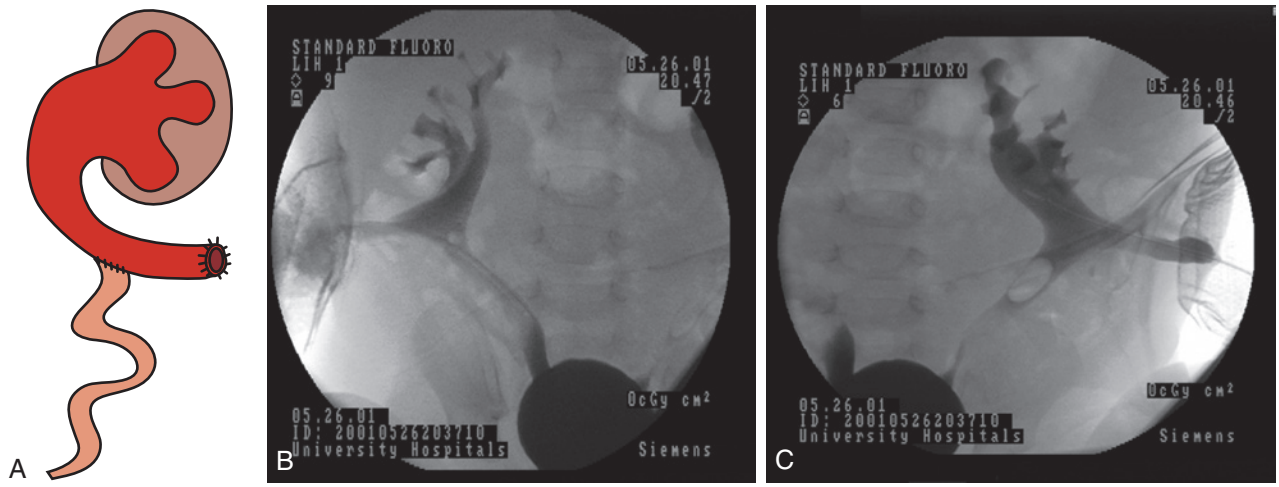

Figure 57.7 A, Sober-en-T ureterostomy decompresses the upper urinary tract and permits urine to pass into the bladder. The proximal ureter is divided below the lower pole of the kidney. The upper end is diverted to the skin. The lower end is anastomosed to the proximal ureter just below the renal pelvis, but not to the pelvis as originally described by Sober. Ureterograms showing the right (B) and left (C) kidneys 1 year after Sober Y-en T ureterostomies. (A, With permission from Liard A, Seguier-Lipszyc E, Mitrofanoff P. Temporary high diversion for posterior urethral valves. *J Urol.* 2000;164[1]:145-8.)

underwent urodynamic testing not only after diversion but also before and after ureterostomy closure showed well-preserved bladder capacity or compliance in 80% and 69%, respectively, and stable detrusor activity in 89%. An increase in bladder capacity was demonstrated in about a third of patients.[48]

Narasimhan and colleagues performed a prospective study of boys with PUV who underwent either primary ablation or vesicostomy.[53] These investigators analyzed the effect of the modality on renal function and somatic growth and whether the presence of VUR and an abnormal serum creatinine concentration affected somatic growth. At birth, body weight and length and serum creatinine concentrations were similar in the two groups, but the valve ablation group lagged behind the vesicostomy group at 3 and 6 months in weight and length measurements. The investigators concluded that treatment modality did not affect the outcome of renal function, because at 1 year the serum creatinine concentration decreased to 0.7 ng/dL in the valve ablation group and to 0.9 ng/dL in the vesicostomy group. Both groups showed delayed growth when compared with normal age-matched controls. Serum creatinine concentration >1.0 mg/dL and the presence of VUR were significantly associated with somatic growth delay by the end of the second year. Vesicostomy appeared to assist with catchup growth in weight and height by the end of the first 2 years of life.

With improved instrumentation, primary valve ablation is recommended as the initial treatment modality of choice when fulguration can be performed safely and when the patient has had improvement in upper tract dilatation with catheter drainage unless the neonate is ill and small. Circumcision is recommended, because it reduces the risk of UTI.[33] Antibiotic prophylaxis should be continued until the massive dilation of the upper urinary tract shows significant improvement, a process that may take several years.[26] In addition, if the child has VUR, prophylaxis should be continued until the reflux resolves spontaneously or is corrected surgically. Most patients benefit not only from long-term urologic management but also from nephrologic care initiated at birth.

Common problems include significant polyuria secondary to an inability of the kidneys to concentrate urine, metabolic acidosis (which may complicate somatic growth), renal insufficiency with hypocalcemia and hyperphosphatemia, and hypertension, as well as vitamin D deficiency and hyperparathyroidism.[54] If the patient remains clinically well with good somatic growth, periodic follow-up with sonography and evaluations of electrolytes, blood urea nitrogen, creatinine, urinalysis, and blood pressure will ensure satisfactory growth and development.

Prognosis Following Initial Therapy

The prognosis for satisfactory renal function may be predicted by several factors. A serum creatinine concentration >1 mg/dL 1 month following initial treatment or at 1 year of age is associated with late development of chronic renal insufficiency.[55] Other investigators concluded that the most significant prognostic factor for the future development of chronic renal failure is the GFR at 1 year of age, and the development of proteinuria portends a worse prognosis.[56] These investigators found no differences in age at diagnosis, initial management, VUR status, UTI, and hypertension in the development of chronic renal insufficiency, whereas sonographic observations may be useful in identifying patients who will develop renal insufficiency. The presence of the corticomedullary junction on renal sonography has been associated with a favorable outcome.[57] This radiologic finding may not be present on the initial ultrasound study but may become apparent during the first few months of life.

In another study, Duel and colleagues showed that 90% of boys with PUV who were followed for a mean of 8.5 years and who ultimately developed poor renal function had echogenic kidneys, whereas 46% of patients with good

renal function also had echogenic kidneys.[58] In addition, 60% of the patients with echogenic kidneys developed poor renal function compared with 13% of the patients with normal renal echogenicity. Increased cortical echogenicity and loss of corticomedullary differentiation were relatively insensitive predictors of eventual renal function in patients with PUV. These investigators found that the serum creatinine concentration following 4 days of catheterization was a more sensitive predictor of outcome in these boys.

Achieving diurnal continence by the age of 5 years also is recognized as a favorable feature.[59] Diurnal incontinence probably is related to detrusor instability and detrusor sphincter discoordination, which can result in elevated upper urinary tract pressures and gradual deterioration in renal function.

A controversial prognostic feature is the presence of a pressure pop-off mechanism, such as massive reflux into a nonfunctioning kidney (termed the *VURD syndrome* for valves, unilateral VUR, dysplasia), urinary ascites, or a large bladder diverticulum.[60,61] Although short-term studies suggested that these mechanisms may allow more normal renal development, Cuckow and colleagues reported that at 8–10 years of age, only 30% of boys with the VURD syndrome had a normal serum creatinine concentration.[62] In another retrospective study, Hoag et al. also found that VURD is not a favorable prognostic feature.[63] The finding that pop-off mechanisms may not always be protective was further supported by Patil and colleagues, who observed that ascites may result from bladder rupture, and GFR in those patients approaches the severe renal failure range.[28]

The detrimental or beneficial effects of VUR on renal function in patients with PUV remain controversial. Some investigators suggest that VUR in combination with high intravesical pressure contributes to deterioration of the upper urinary tract; others propose that VUR, especially when associated with the VURD syndrome, protects the upper urinary tract from high intravesical pressures. Hassan and colleagues reported that VUR in their 73 patients did not serve as a significant prognostic factor for renal function.[64] On the other hand, in a long-term study of 197 adults treated over a period of 50 years, Heikkila et al. found that bilateral VUR is often associated with poorly functioning kideys.[65] Persistent VUR with or without renal deterioration in the absence of UTI may indicate bladder dysfunction and the need for lower urinary tract evaluation.

Another adverse prognostic finding is renal parenchymal area <12 cm^2 on the first postnatal renal ultrasound, especially when the nadir serum Cr is 0.8 to 1.1 mg/dL.[66] Other adverse predictive factors include oligohydramnios, cortical cysts, and echogenic kidneys.[67] Whether antenatal diagnosis is beneficial is controversial.[68]

Vesicostomy Closure

The decision to close a cutaneous vesicostomy must be made carefully. If the patient has had breakthrough febrile UTIs, vesicostomy closure is important because it will reduce the risk of bacterial contamination. In other patients, this procedure may be necessary as a prerequisite to renal transplantation. In most cases, vesicostomy closure is performed after the upper urinary tract has stabilized and the child is large enough to undergo simultaneous valve ablation, generally between 6 months and 3 years.

Preoperatively, a VCUG should be obtained through the vesicostomy to assess the presence of VUR and to evaluate the bladder. In selected cases, urodynamic studies are helpful to assess bladder compliance.[69] Even if VUR is significant and the child is quite young, it is usually safe simply to close the vesicostomy and delay VUR correction until the child is older.

Following closure of the vesicostomy, the upper urinary tract should be monitored carefully to ascertain whether hydronephrosis is worsening and ensure that the child is emptying the bladder satisfactorily. In some cases, anticholinergic medication alone or with clean intermittent catheterization may be needed to improve compliance and bladder emptying. Alpha-blocker therapy may be effective in improving uroflowmetry and bladder emptying in some patients with PUV,[70,71] and Botox injection into the bladder neck is another treatment option.[72] Anticholinergic therapy might be beneficial in improving bladder function and protecting the upper urinary tract from elevated detrusor pressure.[73]

Vesicoureteral Reflux

Vesicoureteral reflux is present in approximately 50% of boys with PUV at presentation, with half bilateral and half unilateral. Following valve ablation, approximately 25% of patients show spontaneous VUR resolution and VUR may resolve as long as 3 years following initial treatment.[64] Antibiotic prophylaxis should be prescribed and assessment with cystography and upper tract imaging should be performed regularly. Hassan and colleagues showed that the rate of VUR resolution was related to the function of the involved kidney, with decreased resolution rates in the more poorly functioning renal units.[64]

Vesicoureteral reflux should be corrected if breakthrough UTIs occur or if it remains high grade. Although most pediatric urologists are adept at performing ureteral reimplantation surgery, reimplanting thick, dilated ureters into the abnormal valve bladder can be most challenging, and a 15–30% complication rate has been reported.[74]

Gearhart and colleagues studied dilated ureters from patients with PUV and demonstrated an increased ratio of collagen to smooth muscle.[75] This quantitative histologic finding was associated with less distensible ureters, which may predispose to failed ureteral reimplantation. In addition, Freedman and colleagues performed quantitative morphometry of 20-week gestational age bladders with PUV and demonstrated a significant increase in both the smooth muscle and collagen components.[76] Both of these observations show that the ureter and bladder can be suboptimal tissues for reconstruction despite the surgeon's best efforts and experience. For these reasons, endoscopic therapy with dextranomer/hyaluronic acid copolymer is an attractive alternative to open surgical intervention in some cases, but no long-term data in patients with PUV are available to support the efficacy of this approach.[77]

In boys with VUR and PUV, often the ureters are dilated and the bladder is thick-walled. Friedman and Hanna described a technique using a distal ureteral split-cuff nipple with a long

ureteral trough within the detrusor, often associated with a psoas hitch.[78] Results were quite favorable, and hydronephrosis was improved in 2/3 of the 45 megaureters.

In boys with the VURD syndrome, nephrectomy should be performed at some point.[50] The ureter should be removed, unless the bladder is small or poorly compliant, in which case ureterocystoplasty should be considered.[79] Following this procedure, the solitary kidney should be followed carefully for the development of hydronephrosis, because the pressure pop-off mechanism has been removed.[80] Narasimhan and colleagues demonstrated that when the contralateral kidney demonstrates evidence of renal scarring, renal function is more likely to be impaired.[81]

Bladder Dysfunction

Children with PUV have a spectrum of urodynamic findings. Favorable prognostic signs include pop-off mechanisms such as bladder diverticulum, patent urachus, and urinoma.[60,61] These pop-off mechanisms protect the bladder and assist in predicting bladder function. Kaefer and associates found that 71% of their patients had at least one pop-off mechanism, and 87% of these patients had favorable urodynamic findings such as satisfactory compliance and bladder capacity.[61] Only 55% of patients without a pop-off mechanism had favorable urodynamic findings. In the group who had no pop-off mechanism and unfavorable urodynamic findings, five of seven patients underwent augmentation cystoplasty.

Urinary incontinence in patients who have a history of PUV has several causes, including myogenic failure and overflow, uninhibited detrusor contractions, severe polyuria, high-pressure voiding secondary to incomplete valve resection with resultant outlet obstruction, stress urinary incontinence, and valve bladder syndrome (Fig. 57.8).[82,83] The term *valve bladder syndrome* refers to the bladder with poor detrusor compliance resulting from fibrosis secondary

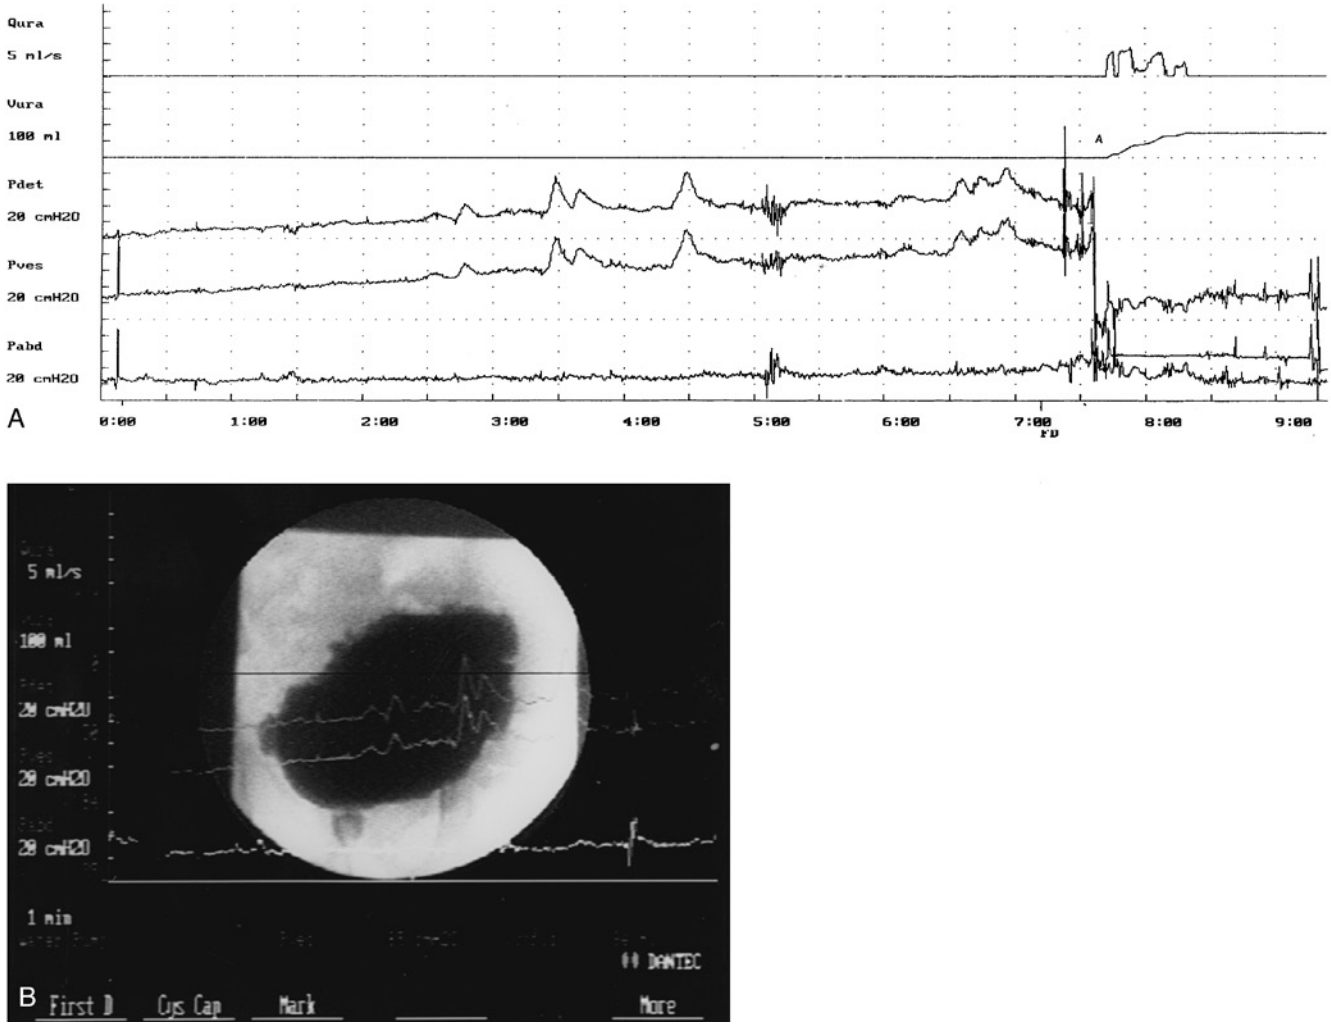

Figure 57.8 Urodynamic study of a 5-year-old boy with a history of posterior urethral valves resected at the age of 4 years. He has day and night incontinence and bilateral hydronephrosis evident on an ultrasound scan. A, Urodynamic tracing shows progressive loss of compliance with detrusor instability and no urinary flow with the urethral catheter in place. When the catheter is removed at A, the flow is weak and intermittent. B, The video portion of the study shows a trabeculated bladder with multiple diverticula and residual valve. Pabd, abdominal pressure; Pdet, detrusor pressure; Pves, total bladder pressure; Qura, uroflow rate; Vura, voided volume. (With permission from Horowitz M, Combs AJ, Shapiro E. Urodynamics in pediatric urology. In: Nitti VW, ed. Practical Urodynamics. Philadelphia: WB Saunders; 1998:262.)

to long-standing obstruction. This condition may cause secondary ureteral obstruction with worsening hydronephrosis if bladder pressure is >35 cm H_2O. The full valve bladder syndrome often is complicated by polyuria, which results from an inability of the chronically obstructed kidneys to concentrate urine. Polyuria results from nephrogenic diabetes insipidus caused by impaired medullary development with a paucity of collecting duct formation. This problem is common and may make it necessary for the child to void frequently to avoid upper urinary tract changes. Therefore, continence is difficult to achieve.

Initial therapy probably should consist of double or triple voiding. In addition, these patients usually require anticholinergic therapy and clean intermittent catheterization with or without augmentation cystoplasty.[83] Options include the usual segments of bowel, although these patients may then require bicarbonate supplementation unless stomach or ureter associated with a nonfunctioning kidney is used for augmentation.[79,84]

Koff and associates[85] evaluated the pathophysiology of the valve bladder syndrome. These investigators proposed that the cause of the valve bladder was chronic overdistention of the bladder during sleep as a result of polyuria, impaired bladder sensation, and residual urine. Because daytime decompression alone was insufficient, the investigators proposed nocturnal bladder emptying by placement of an indwelling catheter, intermittent nocturnal catheterization, or frequent nocturnal double voiding. Chronic hydronephrosis improved significantly or resolved completely in all patients. Serum creatinine concentrations improved in six of 18 patients, four of whom deteriorated and two of four of whom underwent renal transplantation.[85] In boys who resist overnight catheterization through the penis, a Mitrofanoff appendicovesicostomy may be performed.

Several distinguishable urodynamic patterns have been recognized in patients with PUV and vary depending on age (Fig. 57.9). Holmdahl and colleagues showed that the urodynamic pattern in infancy is characterized by hypercontractility and low bladder capacity.[86] During the first 3 years of life, the pattern changes with resolution of the hypercontractility to instability with emptying difficulties. Bladder emptying resulting from some degree of myogenic failure is again seen as a late, postpubertal problem.

Holmdahl and colleagues also studied bladder dysfunction before and after puberty.[87] In prepubertal patients, urodynamic features at presentation were again noted to be uniform with hypercontractility and diminished bladder capacities. The voiding pattern in early childhood was one of small, frequent voids during the day and no voids during sleep. Hypercontractility improved with age. After puberty, the bladders were found to be highly compliant, whereas instability and emptying difficulties remained unchanged. The bladder increased to a normal capacity in prepubertal boys, but mean bladder capacity was twice the normal size in postpubertal patients. Fifty percent of these dilated, decompensated bladders could not develop a sustained detrusor contraction. In these patients, a Valsalva maneuver was required to empty the bladder. The development of myogenic failure may be associated with polyuria. Because the urodynamic pattern changes during infancy, in early childhood, and before and after puberty, these patients should be followed carefully with periodic

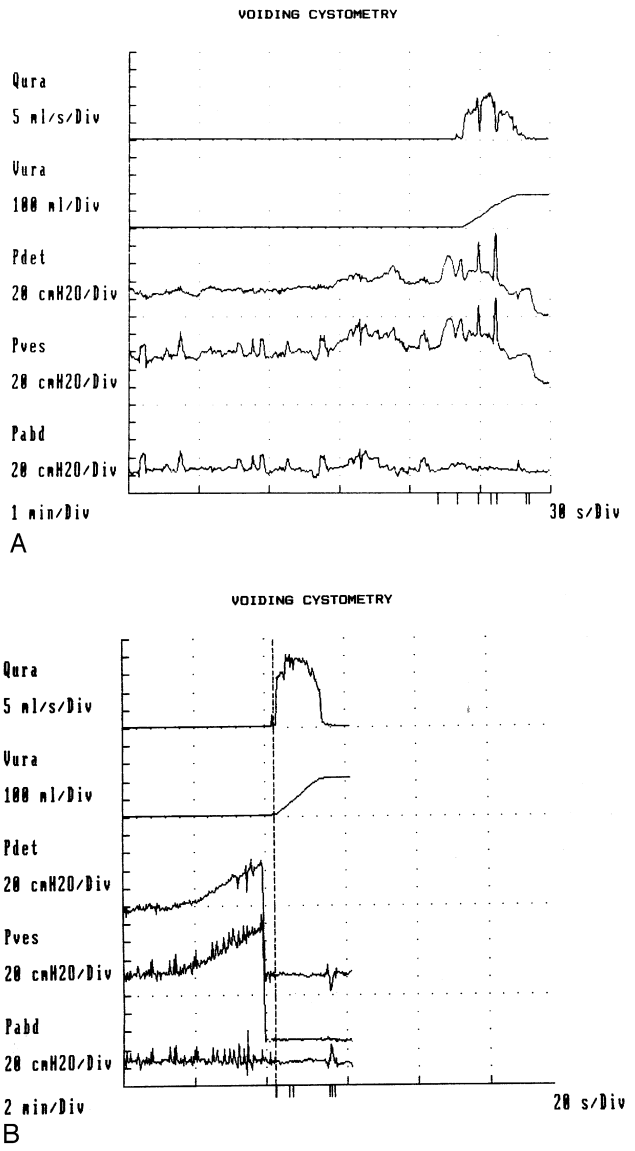

Figure 57.9 Urodynamic study of an 8-year-old boy with a history of posterior urethral valves who had a previous valve ablation. The child has persistent incontinence day and night. A, Tracing from the terminal portion of the urodynamic study demonstrating instability and impaired compliance (Pdet = 40 cm H_2O) before voiding. During voiding, with a 7Fr urethral catheter in place, a choppy flow pattern is noted with Qmax = 14.2 mL/second with 192 mL voided and no post-void residual. A significant component of the voiding pressure came from elevated pressure secondary to impaired compliance. B, Repeat study, with a faster fill, demonstrating a similar degree of impaired compliance (Pdet = 40 to 45 cm H_2O at capacity). The catheter was removed, and the patient voided with a Qmax of 20.7 mL/second with a normal-shaped flow curve. This study demonstrates the existence of bladder dysfunction; however, it is not secondary to persistent obstruction. Pabd, abdominal pressure; Pdet, detrusor pressure; Pves, total bladder pressure; Qura, uroflow rate; Vura, voided volume. (With permission from Horowitz M, Combs AJ, Shapiro E. Urodynamics in pediatric urology. In: Nitti VW, ed. Practical Urodynamics. Philadelphia: WB Saunders; 1998:263.)

videourodynamics to identify changes that may ultimately affect upper urinary tract function and drainage.[88]

Delayed Presentation of Posterior Urethral Valves

Bomalaski and colleagues described 47 patients, ages 5 to 35 years (mean 8 years), who were investigated for diurnal enuresis (60%), UTI (40%), and voiding pain (13%) and were found to have PUV.[89] Hydronephrosis was observed in 40% and VUR in 33%. Only 10% presented with a poor urinary stream, gross hematuria, and proteinuria. The serum Cr before valve ablation was elevated in 35%, whereas 10% had ESRD at presentation. These investigators noted that if the VCUG had been performed only in patients with an abnormal renal ultrasound scan or UTI, 30% of PUV would not have been diagnosed. Only one of those patients had an elevated serum creatinine, a finding supporting the notion that severity of signs and symptoms is significantly associated with renal impairment. The investigators recommended performing VCUG in boys >5 years old who have voiding complaints, especially associated with diurnal enuresis or UTI.

Schober and colleagues studied 70 boys (mean age 7.5 years; range 2–14 years) with delayed presentation of PUV who were undergoing valve ablation.[90] Dysfunctional voiding was the most common symptom, with nocturnal enuresis in 67% and urinary frequency in 60%. UTI occurred in 17%. Microhematuria was found in 30%, and mild age-corrected hypertension was noted in 17%. Serum creatinine concentrations were normal in all patients. Despite adequate valve resection, 63% of these patients had persistent dysfunctional voiding.

Ziylan and colleagues reported on 36 patients with PUV who were diagnosed at a mean age of 8.8 years (range 5–14 years).[91] The investigators compared the posttreatment urodynamic findings and renal function in the delayed presentation group (n = 20 with a mean age of 10.65 years at urodynamic evaluation) with age-matched controls who were children with PUV diagnosed and treated at <5 years of age (n = 19, mean age of 8.52 years). Abnormal urodynamic findings included detrusor overactivity in three (15%), significant postvoid residual in nine (45%), and an enlarged bladder capacity in nine (45%) patients. No significant difference was noted in bladder capacity, compliance, or post-void residual in the late presentation versus control group, whereas detrusor overactivity was significantly lower in the late presentation group. After approximately 5 years of follow-up, age-specific Cr levels were increased in 13 of 27 patients with late presentation, and seven (25.9%) of these patients developed ESRD. Renal function was significantly impaired in the late presenters compared with controls (48.1% versus 13.7%), with mean serum Cr levels of 2.17 and 1.03 mg/dL, respectively. Although renal function was significantly impaired in the patients with late presentation, the investigators reported a similar pattern of bladder dysfunctions in this older age group with PUV. In a recent meta-analysis, Hennus et al. reported that urodynamic abnormalities were found in 55% of children with PUV.[92]

Progression to End-stage Renal Disease and Renal Transplantation

Proteinuria results when the kidney has decreased functional reserve and in infancy is related to a worse prognosis.[56] To keep up with the child's growth, the functioning nephrons undergo hyperfiltration to attempt to maintain normal renal function. Excessive filtration leads to proteinuria and focal segmental glomerulosclerosis and renal failure. In a study of boys with PUV, proteinuria was present in 79% of patients with chronic renal failure compared with only 17% with normal renal function. One study suggested that angiotensin blockade may effectively control proteinuria and stabilize renal function in children with nondiabetic proteinuric kidney disease.[93]

Chronic renal failure affects puberty by influencing hypothalamic control of the onset and progression of pubertal growth and gonadarche, but puberty also affects chronic renal failure.[93] Pubertal acceleration of kidney dysfunction has been observed in VUR and PUV, whereas sex steroids alter kidney growth and function. Androgens are known to stimulate the renin-angiotensin II system by producing higher blood pressures in male patients. Androgens also promote normal and abnormal kidney growth and have been shown in animals to promote kidney damage.[94]

Holmdahl and Sillén[94] reported on long-term outcomes in patients with PUV who were 31–44 years old; these investigators focused on renal function, bladder function, and paternity. Of 19 male patients available for follow-up, 32% were uremic, 21% had moderate renal failure, and 47% had had no follow-up since adolescence. All patients were continent, although bladder dysfunction was reported in 40%, all of whom described detrusor weakness including weak urine stream, the need for double voiding, and urinary residual. Only five of 19 patients had experienced daytime continence at age 5 years. Infertility was associated with uremia. This study highlights the importance of long-term follow-up because of the risk of late renal impairment in 25–50%.[51] These investigators further noted that 50% of their patients who initially had favorable renal function and a low incidence of reflux had no clinical problems related to renal function.[95]

Tikkinen et al. studied the voiding habits of 68 adult men (median age 38.5 years) with a history of PUV and found that 32.4% had a bothersome lower urinary tract symptom, compared with 15.8% of controls.[96] In a larger cohort of patients from the same series, 23% had ESRD.[97]

Of all male patients with ESRD, 0.2% have a primary diagnosis of congenital obstructive uropathy.[98] Although transplantation before 5 years of age is thought to result in better somatic growth and neurologic development, bladder compliance and stability at >5 years of age is usually more favorable for transplantation.[44] Specific attention has focused on treating bladder dysfunction, because it influences the success of renal transplantation. Graft survival rates, patient survival rates, and serum Cr in boys with a history of PUV are now similar to those of patients without bladder outlet obstruction who require renal transplantation.[99] For example, DeFoor and colleagues reported their

experience between 1990 and 2000 with 10 patients with PUV, mean age 10 years, who underwent 13 renal transplants.[100] Although the mean follow-up in this report was only 3.9 years, cumulative allograft survival was 85% and 64% at 1 and 5 years, respectively. Nine of 10 patients had functioning living related donor transplants, and one patient lost three cadaveric transplants through chronic rejection. The mean serum creatinine concentration of patients with functioning grafts was 1.1 mg/dL. No grafts were lost to infection or bladder dysfunction. This study underscores the need for meticulous management of lower urinary tract dysfunction because prompt recognition and treatment of lower tract dysfunction result in successful graft function comparable to that of the general transplant population and obviate the need for augmentation cystoplasty in many cases.

Careful urodynamic evaluation and management of lower tract dysfunction with anticholinergic medication with or without intermittent catheterization ensure success in this selected group of patients. Most of these patients do not require bladder augmentation. If augmentation is required, it can be performed before renal transplantation and the start of long-term immunosuppression. However, some argue that augmentation should be delayed, since many valve bladders develop myogenic failure.[101] In addition, augmentation enterocystoplasty has been demonstrated to increase the risk of UTI following renal transplantation.[101,102] If bladder augmentation is needed after the transplant, one should proceed when the immunosuppressive regimen has been tapered.

Conclusions

The diagnosis and management of PUV continue to evolve with improved ultrasound technology and new techniques for fetal intervention. Advances in endoscopic instrumentation permit early surgical intervention for most neonates. Following initial treatment, recognition and prompt treatment of bladder dysfunction, including the valve bladder syndrome, optimizes the likelihood of preserving long-term renal function and furthers our knowledge of the underlying pathophysiology of bladder outlet obstruction. Bladder function in boys with PUV often changes over time. In patients with PUV and ESRD, renal transplantation is very effective.

Chapter 57 Questions

1. A male newborn is admitted with an antenatal diagnosis of bilateral hydroureteronephrosis, a distended bladder, and reduced amniotic fluid volume. The urologist should:
   a. Order a nephrology consult
   b. Insert a Foley catheter into the bladder
   c. Obtain a renal/bladder ultrasound
   d. Obtain a voiding cystourethrogram
   e. Insert a pediatric feeding tube into the bladder

2. A pregnant mother is diagnosed at 20 weeks' gestation with a male fetus with bilateral hydronephrosis, a distended bladder, and normal amniotic fluid volume. The next step is:
   a. Repeat fetal ultrasound in 4 weeks
   b. Perform a fetal karyotype
   c. Perform an amniocentesis
   d. Perform fetal vesicocentesis
   e. Refer for genetic counseling

3. A pregnant mother is diagnosed at 28 weeks' gestation with a male fetus with bilateral hydronephrosis, a distended bladder, and oligohydramnios. Fetal karyotype is 46,XY. Fetal vesicocentesis shows sodium 105 mEq/L, chloride 96 mEq/L, osmolality 216 mOsm/L, and β_2-microglobulin 3.6 mg/L. The next step is:
   a. Counsel patient for vesicoamniotic shunt
   b. Counsel patient that the baby probably will have renal failure
   c. Recommend fetal cystoscopic valve resection
   d. Perform repeat vesicocentesis in 2–3 days
   e. Observe with repeat ultrasound until delivery

4. A male newborn born at 34 weeks' gestation has suspected PUV. He is on a ventilator and has a right pneumothorax. A renal ultrasound demonstrates echogenic kidneys, severe bilateral hydroureteronephrosis, and a distended bladder. What conclusion can be drawn?
   a. This baby will have ESRD despite treatment
   b. Prognosis is uncertain based on this information
   c. Renal biopsy should be performed to determine treatment plan
   d. Upper urinary diversion will provide the best outcome
   e. Vesicostomy is recommended because the baby is too small for valve resection

5. A male term newborn with bilateral hydronephrosis is diagnosed with posterior urethral valves based on antenatal ultrasound, postnatal ultrasound, and voiding cystourethrogram. The appropriate treatment is:
   a. Placement of suprapubic tube by interventional radiology and schedule valve ablation when baby is stable
   b. Place on antibiotic prophylaxis and schedule for valve ablation after 52 weeks' gestation
   c. Perform cystoscopy, transurethral valve ablation, circumcision, and prescribe antibiotic prophylaxis
   d. Obtain follow-up renal/bladder ultrasound in 2 weeks
   e. Perform newborn circumcision to reduce the risk of urinary tract infection

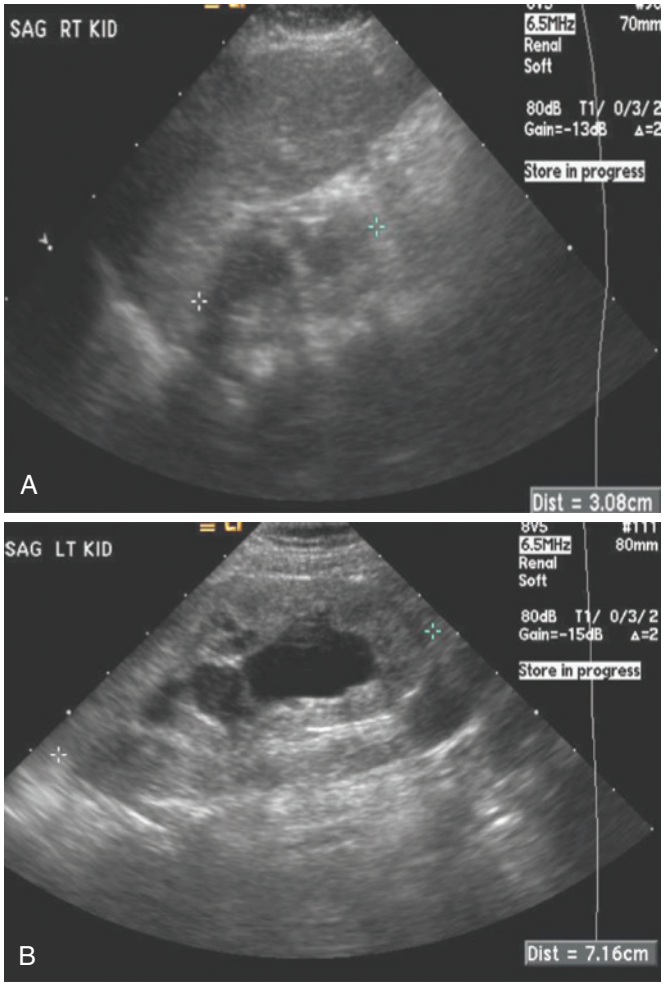
6. A newborn male with posterior urethral valves demonstrates grade V vesicoureteral reflux into the left kidney. A renal scan demonstrates nonfunction of the left kidney. What conclusion can be drawn?
   a. Left ureterostomy might preserve left renal function
   b. Left renal biopsy will predict whether the left kidney has potential function
   c. VURD syndrome (valves, unilateral reflux, dysplasia) is a protective factor for the upper urinary tract, and the patient's renal function should be normal
   d. When left nephrectomy is performed, left ureterocystoplasty should be considered
   e. Monitoring for proteinuria will determine prognosis

7. A term male newborn with posterior urethral valves is undergoing transurethral valve ablation. It is difficult to pass the pediatric cystoscope. What conclusion can be drawn?
   a. A circumcision should be performed to make it easier to pass the cystoscope
   b. The urethral meatus should be dilated gently with metal sounds
   c. A perineal urethrostomy should be performed to allow the cystoscope to be inserted
   d. A temporary vesicostomy should be performed
   e. The procedure should be delayed until the patient is older and the urethra is larger

8. A male newborn with posterior urethral valves has severe bilateral hydroureteronephrosis and a rising serum creatinine despite catheter drainage of the bladder. Bilateral cutaneous pyelostomies are being considered to maximize upper urinary tract drainage. This procedure would:
   a. Prevent ESRD if performed promptly
   b. Allow antegrade assessment of the ureters to determine whether there is ureterovesical junction obstruction
   c. Avoid the need for antimicrobial prophylaxis
   d. Increase the likelihood of a noncompliant bladder
   e. Facilitate total urinary tract reconstruction

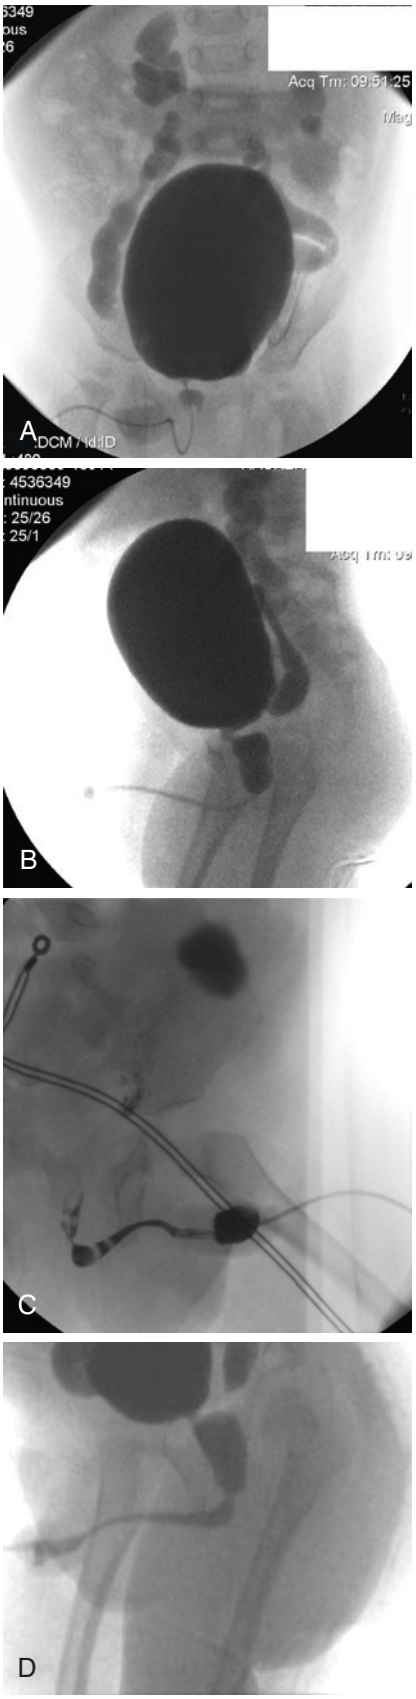
9. In delayed presentation of PUV, common symptoms and clinical studies include all of the following except:
   a. Abdominal pain
   b. Diurnal incontinence
   c. Urinary tract infection (UTI)
   d. Hydronephrosis
   e. Elevated serum Cr

10. A 15-year-old boy with treated PUV has ESRD and is being evaluated for living-related renal transplantation. What conclusion can be drawn?
    a. Augmentation enterocystoplasty should be performed before transplantation if the bladder capacity is less than 250 mL



b. He has an increased risk of UTI following transplantation
c. The 5- and 10-year graft survival is similar to that of patients without PUV
d. Performing an antirefluxing ureteral anastomosis has been shown to increase the likelihood of graft survival
e. Nephrectomy and ureterocystoplasty should be performed before transplantation

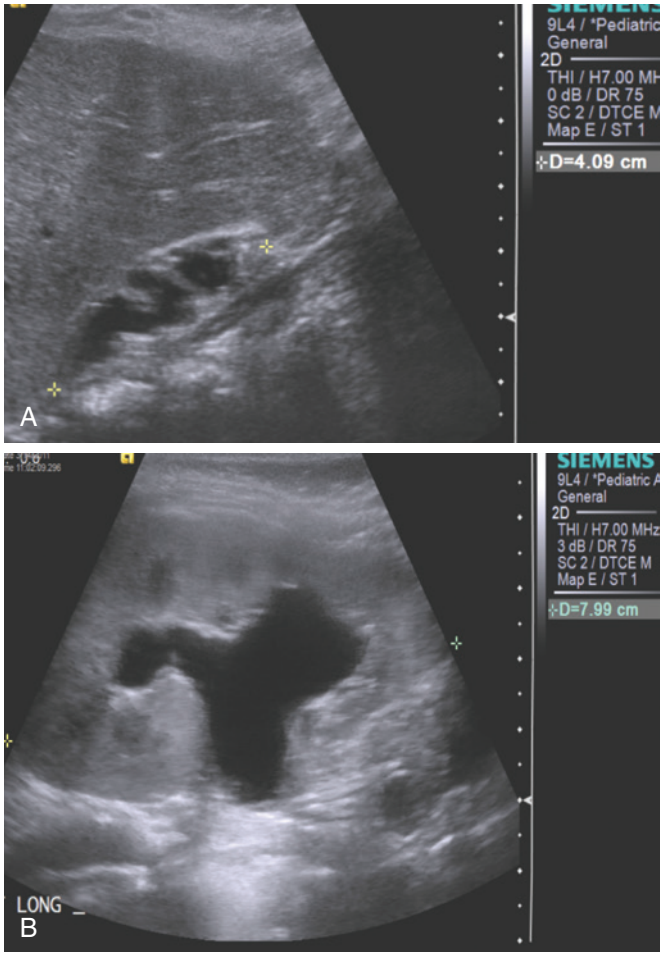
Case Studies



CASE 1

A 9-month-old boy has a history of prenatally diagnosed bilateral hydroureteronephrosis and oligohydramnios. Postnatally, he was found to have a small dysplastic right kidney, a left hydronephrotic kidney, bilateral grade V vesicoureteral reflux, and PUV. Transurethral incision of the valve leaflets was performed at 1 week of age. The serum creatinine decreased to 0.7 mg/dL. He subsequently had four episodes of pyelonephritis. The patient is uncircumcised.

Case Fig. 57.1 demonstrates the renal US. Case Fig. 57.2 demonstrates the voiding cystourethrogram.



Case Figure 57.1

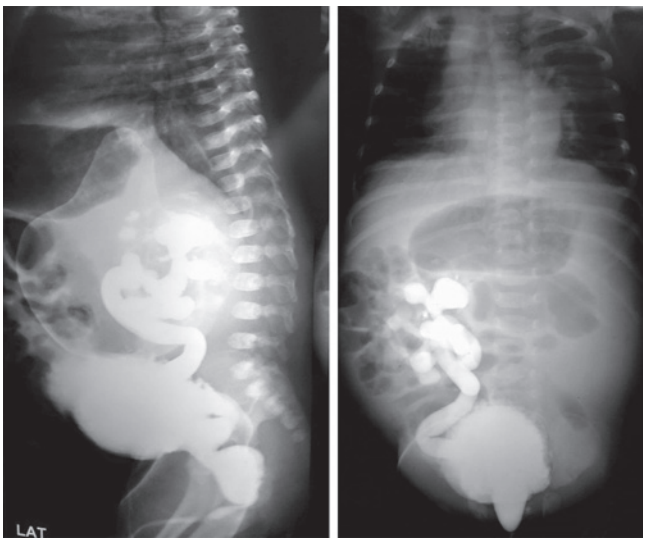
Case Figure 57.2

1. The radiologic studies demonstrate:
   a. Right reflux nephropathy, bilateral vesicoureteral reflux
   b. Right reflux nephropathy, bilateral vesicoureteral reflux, and a distal megalourethra
   c. Persistent PUV, bilateral vesicoureteral reflux, right reflux nephropathy, and a distal megalourethra
   d. Bilateral vesicoureteral reflux with bilateral ureterovesical junction obstruction
   e. Bilateral vesicoureteral reflux, right reflux nephropathy, left ureteropelvic junction obstruction, and distal megalourethra

2. The appropriate treatment is:
   a. Transurethral ablation of residual valve leaflets, bilateral subureteral injection of detranomer/hyaluronic acid, circumcision, antibiotic prophylaxis
   b. Transurethral ablation of residual valve leaflets, repair of distal megalourethra, circumcision, antibiotic prophylaxis
   c. Transurethral ablation of residual valve leaflets, repair of distal megalourethra, circumcision, bilateral ureteral reimplantation
   d. Transurethral ablation of residual valve leaflets, circumcision, left pyeloplasty, antibiotic prophylaxis
   e. Circumcision, antibiotic prophylaxis

Case Figure 57.3

At 6 years of age, the patient is not yet toilet trained. He is incontinent both day and night. His urine output is approximately 75 mL/hour. He has not had a UTI. VCUG shows persistent vesicoureteral reflux. Serum creatinine is 0.9 mg%. The renal US is in Case Fig. 57.3.



3. Which treatment option would *not* be appropriate?
   a. Daily alpha-blocker
   b. Timed voiding during the day
   c. Leaving a catheter in the bladder overnight
   d. Right nephrectomy, ureterocystoplasty, and left ureteral reimplantation
   e. Inject Botox into the bladder neck

CASE 2

A 6-month-old circumcised boy develops a febrile urinary tract infection. The renal/bladder US shows bilateral hydroureteronephrosis with thin right renal parenchyma, a small amount of fluid adjacent to the right kidney, and a distended trabeculated bladder. The VCUG is demonstrated in Case Fig. 57.4. Following bladder decompression, the serum Cr decreases from 1.5 mg% to 1.2 mg%. A renal scan demonstrates minimal function in the right kidney.

1. What is the appropriate treatment?
   a. Transurethral valve ablation, insertion of a drain adjacent to the right kidney, and antibiotic prophylaxis
   b. Transurethral valve ablation and antibiotic prophylaxis
   c. Cutaneous vesicostomy and antibiotic prophylaxis
   d. Transurethral valve ablation, right cutaneous ureterostomy, and antibiotic prophylaxis
   e. Bilateral cutaneous ureterostomies

Following transurethral valve ablation, at 4 1/2 years of age, the patient has diurnal and nocturnal incontinence. He recently developed a febrile UTI despite antibiotic prophylaxis. He is taking oxybutynin 4 mg TID. A renal ultrasound demonstrates moderate bilateral hydronephrosis

Case Figure 57.4

with thin parenchyma on the right side. Videourodynamics demonstrates a bladder capacity of 75 mL with an uninhibited bladder contraction at 50 mL. Serum Cr is 1.2 mg%.

2. What is the appropriate treatment?
   a. Right ureteral reimplantation
   b. Right-to-left transureteroureterostomy
   c. Change antibiotic prophylaxis
   d. Right nephrectomy and ureterocystoplasty
   e. Botox injection of bladder

The patient is now 12 years old and has a solitary left kidney with mild hydroureteronephrosis. The serum creatinine is 2.7 mg%. He has not had a UTI since age 5 years. Videourodynamics demonstrates a bladder capacity of 250 mL with mild trabeculation and bladder instability at 220 mL. He is being evaluated for living-related renal transplantation.

3. What conclusion can be drawn?
   a. He will need augmentation cystoplasty before renal transplantation
   b. His transplant is likely to fail early because of the history of posterior urethral valves
   c. An antireflux transplant ureteral anastomosis is likely to become obstructed
   d. He will have a significant risk of UTIs following transplantation and will require lifelong antibiotic prophylaxis
   e. The bladder instability probably will resolve in adolescence

Answers

1. **e.** In this case, the most likely diagnosis is posterior urethral valves (PUV), although prune belly syndrome and high-grade bilateral vesicoureteral reflux are other possibilities. A feeding tube should be inserted into the bladder for lower urinary tract decompression and to provide maximum decompression of the upper urinary tract. A Foley catheter is more difficult to pass, and the balloon can cause significant bladder spasm and even obstruct the ureters.
2. **a.** PUV is a likely diagnosis, but intervention such as an amniocentesis or vesicocentesis is unncessary at this time. The male fetus with oligohydramnios at this time is at greatest risk for neonatal complications such as pulmonary hypoplasia.
3. **d.** This fetus is at significant risk for pulmonary hypoplasia without treatment. The fetal urinary sodium, chloride, and osmolality are consistent with high-risk end-stage renal disease (ESRD), but the β_2-microglobulin is more favorable. Studies have demonstrated that serial vesicocentesis can provide a more accurate assessment of potential fetal renal function. Consequently, repeat vesicocentesis in 2–3 days should be performed, and if there are favorable indices, then fetal intervention should be considered.
4. **b.** Cortical cysts and prolonged oligohydramnios are adverse prognostic features in boys with PUV. However, echogenic kidneys at birth ultimately may have relatively normal renal function, and most babies with PUV have severe bilateral hydroureteronephrosis and a distended bladder. A pediatric feeding tube should be inserted and a follow-up renal ultrasound and VCUG should be performed to confirm the diagnosis of PUV.
5. **c.** The most appropriate initial therapy for the vast majority of boys with PUV is cystoscopy with transurethral valve ablation, assuming that the child can undergo anesthesia safely. It can even be performed in the NICU under sedation and caudal anesthesia. Circumcision has been demonstrated to reduce the risk of UTI in boys with PUV, and antibiotic prophylaxis with amoxicillin is beneficial in reducing the risk of UTI, even in the absence of VUR. Rarely is there a need for placement of a temporary suprapubic tube.
6. **d.** This child has the VURD syndrome. Usually the affected kidney is removed, and the ureter should be preserved for possible ureterocystoplasty to augment the bladder, rather than discarding the entire ureter. The kidney does not function, and ureterostomy will not improve function. Although early studies suggested that VURD syndrome was predictive of good long-term renal function, more recent studies with longer follow-up have demonstrated that many children ultimately have reduced renal function.
7. **b.** When the urethral meatus is too small for the cystoscope, forcing the cystoscope can result in a distal urethral (navicular) stricture. Gently passing increasing sizes of lubricated metal sounds should allow the cystoscope to pass without injuring the urethra. Although a circumcision is recommended, it will not make it easier to pass the cystoscope. A temporary vesicostomy is appropriate if the baby is very small.
8. **d.** One of the long-term risks of bilateral cutaneous ureterostomies is diverting all of the urine away from the bladder, which often results in a small, noncompliant bladder. For that reason, the Sober-en-T ureterostomy was developed, which allows urine to drain out through the flank as well as down the ureter into the bladder.
9. **a.** In boys over 5 years old diagnosed with PUV, the most common clinical presentation is dysfunctional voiding with diurnal incontinence urinary frequency, and nocturnal enuresis. Hydronephrosis, an elevated serum Cr, microhematuria, and hypertension also are common.
10. **c.** Renal transplantation is quite successful in patients with a history of PUV and has a graft success rate similar to patients without a history of PUV. Augmentation enterocystoplasty usually is delayed until after the transplant, but patients who undergo augmentation enterocystoplasty have a higher risk of UTI. Nephrectomy generally is unnecessary in patients with PUV.

CASE 1

1. **c.** The VCUG demonstrates persistent PUV with bilateral vesicoureteral reflux. Also, the distal urethra has a megalourethra (possible urethral diverticulum)

pattern. The renal ultrasound shows a 3.1-cm echogenic right kidney and a 7.2-cm left kidney with mild hydronephrosis. The small right kidney is indicative of reflux nephropathy with renal dysplasia.

2. **b.** This baby has evidence of persistent obstructive uropathy with a poorly functioning right kidney and a mildly hydronephrotic left kidney with significant residual bladder outlet obstruction. He needs to undergo transurethral ablation of residual valve to facilitate normal micturition. In addition, because of the UTI, he would benefit from circumcision and should receive antibiotic prophylaxis because of the bilateral vesicoureteral reflux. Repair of the distal megalourethra is an option.
3. **d.** The patient has evidence of a "valve bladder," with polyuria and persistent diurnal incontinence. All of the described treatment options might improve the patient's clinical condition. However, he is at significant risk for progressive renal deterioration. With the persistent severe right vesicoureteral reflux into a poorly functioning kidney and persistent left vesicoureteral reflux, following urodynamics, the most appropriate option would be to perform a right nephrectomy, ureterocystoplasty, and left ureteral reimplantation.

CASE 2

1. **b.** The VCUG shows classic posterior urethral valves with a trabeculated bladder and grade V right vesicoureteral reflux with intrarenal reflux and possibly perirenal urinary extravasation. The patient needs to undergo transurethral valve ablation. It is unlikely that cutaneous ureterostomies or a cutaneous vesicostomy will be beneficial. However, antibiotic prophylaxis should be prescribed because of the high-grade right vesicoureteral reflux.
2. **d.** The patient's UTI most probably is related to his right vesicoureteral reflux into a poorly functioning kidney. His bladder capacity is small, and he would benefit from augmentation cystoplasty, which can be performed utilizing the right ureter in conjunction with right nephrectomy. He might need to perform clean intermittent catheterization following this reconstructive procedure.
3. **e.** Long-term results of valve bladders suggest that they typically have bladder instability until puberty, at which time they become atonic. Consequently, it would be appropriate to proceed with renal transplantation.

Complications of Endoscopic Correction of Vesicoureteral Reflux
Surgical Complications of Laparoscopic/Robotic Reimplant
Surgical Complications of Megaureter Repair
Surgical Complications of Ureterocele Repair
Conclusions
Chapter 58 Questions and Answers

KEY POINTS

1. Open surgical correction of vesicoureteral reflux (VUR) remains the gold standard, with success rates >98% in most pediatric centers.
2. The primary goal of the treatment of VUR is to prevent pyelonephritis that may lead to reflux nephropathy with subsequent hypertension, poor somatic growth, renal insufficiency, and end-stage renal disease.
3. Despite aggressive medical and surgical management, reflux nephropathy accounts for 3% to 25% of cases of end-stage renal disease in children and 10% to 15% of cases of renal failure in adults.
4. Undiagnosed or underestimated bladder disease is a common cause of failed ureteral reimplants.
5. Important technical considerations for ureteral reimplantation include the following:
   - Adequate detrusor backing for the ureter in its submucosal tunnel
   - Preservation of the ureteral blood supply
   - Creation of a tension-free anastomosis
   - Adequate proximal and distal ureteral fixation
   - Adequate closure of the muscular hiatus
   - Placement of the hiatus posteriorly and medially in the immobile portion of the bladder
   - Avoidance of ureteral torsion, kinking, or J-hooking.
6. The most frequent cause of decreased urine output in the early postoperative period is mild ureteral obstruction secondary to transient edema. Additionally, dehydration resulting from preoperative fasting and supraphysiologic secretion of antidiuretic hormone in response to surgical stress may also contribute.
7. Late ureteral obstruction is most commonly the result of an error in surgical technique including mechanical obstruction or devascularization of the distal ureter.
8. Following surgical treatment of VUR, reflux may persist in the affected ureter or may occur in the contralateral ureter in approximately 2% and in 10–18% of patients, respectively.
9. Reported success rates with Dx/HA for the endoscopic treatment of VUR have been between 76% and 94% after a single injection.
10. Excisional tapering of a megaureter requires careful attention to ureteral blood supply during resection of the redundant ureter and closure of the tapered ureter. Injury to the blood supply may lead to devascularization, fistula, and urinary leakage.

The first successful attempt at surgical correction of vesicoureteral reflux (VUR) was reported by Hutch in 1952.[1] Since that time, multiple surgical, endoscopic, and minimally invasive techniques have been described. Open surgical correction remains the gold standard, with success rates of >98% in most pediatric centers.[2,3] While surgical results are excellent, most young children with reflux are managed medically, and older children with observation. Additionally, increasing numbers of children are managed with endoscopic techniques. Given multiple treatment options, it remains imperative that the urologist understand the potential risks and complications of each.

Nonsurgical Complications

Because primary VUR often resolves, the initial management is typically nonsurgical. Although it is impossible to predict which child will outgrow VUR, the disorder is most likely to resolve in younger children with lower grades of reflux.[4,5] The primary goal of the treatment of VUR, whether medical, surgical, or endoscopic, is to prevent pyelonephritis. Pyelonephritis may lead to reflux nephropathy with subsequent hypertension, poor somatic growth, renal insufficiency, and end-stage renal disease.

Antibiotic prophylaxis has proven effective in preventing urinary tract infection (UTI) in children with VUR.[6–8] Because reflux nephropathy may progress in patients with recurrent UTI, it is imperative to maintain sterile urine with daily antimicrobial prophylaxis.[9] The effectiveness of the use of continuous prophylactic antibiotics in preventing breakthrough UTI is well supported in the literature, especially for dilating grades of VUR.[10] Rates of breakthrough UTI in patients compliant with antibiotic treatment are reported to be as low as <5%.[7,11,12] Certainly, with longer periods of conservative management (5–10 years), the risk of UTI-related morbidity may increase. However, recent studies have brought into question whether continuous prophylactic antibiotics prevent breakthrough renal scarring and therefore affect eventual renal function.[7,13–15] Currently the management of VUR is controversial with no universal agreement. There are multiple factors affecting which treatment option is selected. Even daily antibiotic prophylaxis is called into question, with watchful waiting remaining a valid option.

Unfortunately, despite aggressive medical and surgical management of VUR, reflux nephropathy accounts for 3–25% of cases of end-stage renal disease in children and 10–15% of cases of renal failure in adults.[16–20] Reflux-related complications also increase the risk of pregnancy-related morbidity including UTI, pregnancy-related hypertension, and low birth weight.[21,22]

RISKS OF MEDICAL MANAGEMENT

Some uncertainty exists regarding the ideal antimicrobial prophylaxis for use in this population. The most commonly used antibiotics include sulfamethoxazole-trimethoprim, trimethoprim alone, nitrofurantoin, and amoxicillin for neonates and young infants, in daily doses one-fourth to one-half of treatment doses. Although side effects are lower than with treatment doses, adverse effects are reported.[23] Common side effects of sulfamethoxazole-trimethoprim including allergic skin reactions, nausea, vomiting, and diarrhea are reported in 15–22% of patients.[2] Uncommon adverse effects are neutropenia, thrombocytopenia, and photosensitivity reaction. Stevens-Johnson syndrome, although extremely rare, is the most serious side effect.

Nitrofurantoin suspension may cause gastric upset, nausea, vomiting, rash, and fever. Its foul taste may worsen compliance with treatment. Liver toxicity and interstitial pneumonitis are rare but are reported with the use of nitrofurantoin. The use of the macrocrystal preparation eliminates the foul taste, gastric upset, nausea, and vomiting.

Because fructose is used to prepare drug suspensions, children may be at increased risk of dental caries. As sulfa-based drugs and nitrofurantoin are hepatically metabolized they are contraindicated in children <2 months. For this reason, amoxicillin and cephalexin are used in the first 2 months of life. To date, no data suggest that the use of low-dose antibiotics for urinary prophylaxis is dangerous other than the concern for increased microbial resistance.[24]

Patient and family compliance with respect to daily prophylaxis and follow-up certainly affects successful prevention of pyelonephritis and reflux nephropathy. In a public health system model, compliance rates exceeded 90%.[11] The RIVUR study demonstrated a compliance rate of >75% for administering medications at least 75% of the time and >85% for administering medications at least 50% of the time.[7] However, >34% of patients with reflux in the United States are lost to follow-up.[25]

Current recommendations for patients with unresolved reflux after years of medical management vary, ranging from surgical correction of moderate-grade reflux after 4 years of observation[26] to complete discontinuance of antibiotic prophylaxis and clinical monitoring of patients after 6 or 7 years of age.[27] The American Urological Association (AUA) no longer automatically recommends surgical therapy for unresolved dilating VUR, but recommends escalating therapy for patients who experience breakthrough UTIs (either start daily prophylaxis or proceed with surgical or endoscopic therapy if the UTI occurs while on prophylaxis).[4] In female patients, ongoing VUR may increase the risk of pyelonephritis, especially during pregnancy and with sexual activity.[22,28,29] Therefore, surgical or endoscopic therapy may be warranted in some female patients regardless of VUR grade if the disorder does not resolve.

Bladder Dynamics and Vesicoureteral Reflux

Patients with voiding dysfunction often present with wetting, UTI, and VUR. Treatment of the underlying disease with a combination of bladder retraining, constipation treatment, anticholinergics, and biofeedback frequently eliminates incontinence, UTI, and at times VUR and thus obviates the need for surgical or endoscopic intervention. Normal voiding habits and normal bladder dynamics are essential for successful antireflux surgery. One of the most common problems with failed reimplants is undiagnosed or underestimated bladder disease. This error may have a significant effect on surgical and endoscopic outcomes and also increases the risk of postoperative UTIs. Most cases of

persistent postoperative reflux will likely resolve with the treatment of voiding dysfunction.[30]

Surgical Complications of Ureteral Reimplantation in the Nondilated Ureter

TECHNICAL CONSIDERATIONS

Many different techniques with similar success rates have been described for ureteral reimplantation. The technical aspects of these procedures are discussed elsewhere and are not reviewed here.[31–33] To ensure a successful result, several common principles of ureteral reimplantation must be followed. The most critical point is to provide adequate detrusor backing for the ureter in its submucosal tunnel. As advocated by Hendren,[34] an atraumatic no-touch technique should be employed to mobilize the ureter. Submucosal tunnel lengths should be four to five times the ureteral diameter. Other important technical considerations include the following:

1. Preservation of ureteral blood supply
2. Creation of a tension-free anastomosis
3. Adequate proximal and distal ureteral fixation
4. Adequate closure of the muscular hiatus
5. Placement of the hiatus posteriorly and medially, in the immobile portion of the bladder
6. Avoidance of ureteral torsion, kinking, or J-hooking.

POSTOPERATIVE EVALUATION AND IDENTIFICATION OF COMPLICATIONS

Complications of antireflux surgical procedures may be evident in the immediate postoperative period; however, many complications do not become evident until years after an assumed successful repair. Early complications of antireflux surgical procedures are symptomatic and clinically evident, whereas late complications are often asymptomatic. We typically obtain a renal and bladder ultrasound 4 weeks postoperatively to evaluate for hydronephrosis. Hydroureteronephrosis may be seen as a result of edema at the ureterovesical junction (UVJ) if the image is obtained <4 weeks after the procedure. If significant dilation is noted on the postoperative ultrasound, a diuretic renal scan is obtained to rule out significant obstruction.

We no longer routinely obtain postoperative voiding cystourethrograms (VCUGs) after uncomplicated reimplant procedures at our institution. Although this practice is supported by other surgeons,[35,36] the decision to obtain a postoperative VCUG should be based on the surgeon's experience and individual success rates. The AUA guidelines do not uniformly recommend postoperative VCUG after open surgical repair, but allow the clinical course to affect the final decision.[4] If a VCUG is obtained, it should be performed 3 to 4 months postoperatively to allow for resolution of edema or inflammation at the UVJ. Suppressive antibiotics are continued for 1–3 months postoperatively whether or not the patient had been on antibiotic prophylaxis preoperatively. Renal and bladder ultrasounds are obtained on a yearly basis for 3–4 years to screen for delayed complications of surgical treatment of VUR. Yearly blood pressure measurements and urinalysis are obtained to identify hypertension in children with renal scarring and UTI, respectively.

EARLY COMPLICATIONS

Low Urine Output

Low urine output may be a sign of several different complications of antireflux surgical procedures. The most frequent cause of decreased urine output (<1 mL/kg/hour) after ureteral reimplantation is mild ureteral obstruction secondary to transient edema at the UVJ. Mild dehydration secondary to preoperative fasting and supraphysiologic secretion of antidiuretic hormone in response to surgical stress also contribute to low urine output. This condition generally responds to fluid boluses (10 mL/kg lactated Ringer solution or 0.9% normal saline solution) and resolves ≤4 to 6 hours after the surgical procedure with no long-term sequelae. Dehydration may be avoided with vigorous intraoperative hydration to compensate for fasting and third-space losses.

Profound oliguria and anuria occur infrequently and most commonly in bilateral cases or after surgical correction of reflux in a solitary kidney. In both unilateral and bilateral obstruction, the patient may complain of abdominal or flank pain, nausea, and vomiting. Oliguria or anuria can be a sign of a technical error leading to ureteral obstruction or of severe ureteral or UVJ edema. It may be worsened by bladder spasm or obstruction of the orifices by the balloon of the urethral catheter. Treatment with anticholinergics and deflation of the catheter balloon or catheter removal are useful in differentiating between these factors. Overly aggressive fluid replacement with hypotonic solutions should be avoided because it may lead to hyponatremia. A renal and bladder ultrasound is useful if oliguria persists after volume replacement. Hydroureteronephrosis or urinary extravasation may be evident (Fig. 58.1). These findings may be confirmed with a diuretic renal scan (Fig. 58.2).

Decompression of the upper urinary tract with a temporary percutaneous nephrostomy tube with or without

Figure 58.1 Renal ultrasound scan 2 days after routine ureteral reimplantation shows moderate hydronephrosis. LT LONG KD, left longitudinal kidney.

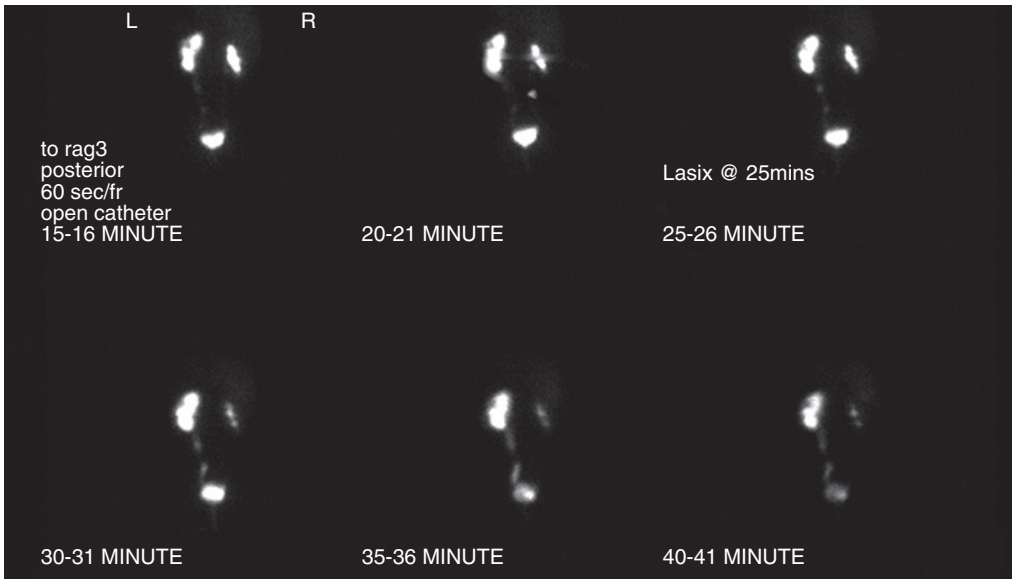

Figure 58.2 Diuretic renal scan confirms obstruction at the ureterovesical junction. This obstruction may be related to edema in the early postoperative period.

ureteral stenting is recommended in cases of ureteral obstruction. We agree with surgeons who advocate early stent internalization to avoid a "dry reimplant."[33] The ability to place a retrograde stent may be limited in the early postoperative period, particularly after a Cohen ureteroneocystostomy. Open retrograde stent placement may rarely become necessary if less invasive percutaneous techniques fail. Stents are generally left in place for 4 to 6 weeks to allow for resolution of edema at the UVJ. The ultimate outcome is usually that of a successful reimplantation. Once the stent is removed, urine output is monitored and serial renal ultrasounds are obtained. If hydroureteronephrosis persists, a diuretic renal scan is obtained and the patient is treated accordingly (see later). In our practice, ureters that are plicated or tapered and the ureter of a solitary kidney are routinely stented at the time of reimplantation.

Postoperative urinary extravasation is an uncommon problem and is usually related to inadequate closure of the detrusorotomy. This complication can be managed conservatively by replacing the urethral catheter for an additional 72 hours. Some surgeons routinely prefer to leave perivesical Penrose or Jackson-Pratt drains after reimplantation, although we have not found this approach to be necessary.

Infections and Voiding Dysfunction

Postoperative febrile UTI and urosepsis may occur after reimplantation. A preoperative urine culture is obtained 5 to 7 days before the surgical procedure. If results of the culture are positive and the patient is asymptomatic, the patient is treated with the appropriate antibiotics. If the patient is asymptomatic, the bladder is inspected cystoscopically to identify signs of inflammation before the incision is made. Inflammation may increase both the difficulty of the surgery and postoperative complications. If the preoperative culture grows unusual or resistant organisms or if a patient is symptomatic, urine culture should be repeated and results should be negative before the surgical procedure is performed. Generally, we postpone the operation to allow the inflammatory response to resolve.

The incidence of recurrent cystitis after successful reimplantation has been reported to be up to 39%, and ≤8% of patients have clinical pyelonephritis.[36–39] Voiding dysfunction may increase the risk of postoperative pyelonephritis after successful reimplantation and should be addressed. Parents should be forewarned of this complication because it may cause severe anxiety in the postoperative period.

Transient voiding dysfunction is common after intravesical ureteral reimplantation. Daytime urge incontinence, nocturnal enuresis, and bladder spasms may continue for several weeks and resolve as bladder inflammation resolves. Patients with significant bladder spasm or pain on urination may require anticholinergic therapy or phenazopyridine hydrochloride, respectively.

Postoperative urinary retention is rare following intravesical reimplantation. However, much concern and controversy exist regarding urinary retention after bilateral extravesical repair. The reported incidence of urinary retention after bilateral extravesical repair varies from 3.2% to >22%.[40–42] In the series reported by Fung and colleagues,[43] urinary retention persisted in 5.2% of their patients at 8 weeks postoperatively, and two patients had prolonged urinary retention and required temporary cutaneous vesicostomy and a catheterizable channel. Nerve-sparing techniques have been described because urinary retention is thought to be the result of neurapraxia related to detrusor nerve manipulation.[44] Using such modifications, the rate of immediate urinary retention was reported to be 2% with no long-term urinary retention or voiding dysfunction.

Following transvesical reimplant, hematuria is expected to persist for several weeks as the detrusor and mucosa heal and as spasms resolve. Meticulous closure of mucosal incisions minimizes this problem. Although rare, retrovesical hematoma may result in ureteral obstruction.[45] To avoid this complication, great care must be taken when the ureter is dissected, particularly in the retroperitoneum.

LATE COMPLICATIONS

Ureteral Obstruction

When prolonged ureteral obstruction occurs postoperatively or when obstruction is identified during routine follow-up, the cause is not typically related to transient edema, as is common in the early postoperative period. Late ureteral obstruction may be associated with abdominal or flank pain, nausea, vomiting, or UTI, or it may be completely asymptomatic.

Late ureteral obstruction is most commonly the result of an error in surgical technique (Fig. 58.3). The most common causes of obstruction are mechanical obstruction and devascularization of the distal ureter. Ureteral obstruction is rare, occurring in <2% of cases.[4,46] Although technical problems may become apparent early in the postoperative period, they are more commonly noted on radiographic examination in an asymptomatic patient. Often these changes are associated with significant loss of renal function.[47,48] It is unlikely that ureteral obstruction diagnosed early in the postoperative period that does not resolve spontaneously or after stent placement or obstruction diagnosed long after the surgical procedure will improve without reoperation.

The diagnosis of obstruction can be made with ultrasound or renal scan. A diuretic renal scan has the additional advantage of estimating the function of the affected kidney. Occasionally, an antegrade nephrostogram or Whitaker study may become necessary to differentiate persistent nonobstructive hydronephrosis from true obstruction (Fig. 58.4).

Devascularization of the distal ureteral segment may lead to ischemia and stricture. Devascularization may be avoided by gentle manipulation of the ureter and cautious use of electrocautery when the ureter is dissected from the detrusor hiatus. Torsion of the reimplanted ureter within the submucosal tunnel can also lead to obstruction. Placement of a traction suture at the ureteral meatus allows for gentler manipulation of the ureter. Additionally, this suture serves as a marker for proper orientation after mobilization of the ureter.

The submucosal tunnel should be created with care to ensure adequate width, length, and hemostasis. Bleeding from the submucosal tunnel can cause ureteral compression and early postoperative obstruction. The submucosal tunnel should allow the ureter to sit freely within it without compression. The distal ureter is anchored to the detrusor muscle with a long-lasting absorbable suture to prevent ureteral retraction. An additional suture may be used to secure the ureter to the detrusor muscle at the level of the hiatus to provide two-point fixation of the ureter at both ends of the submucosal tunnel. The ureter should be approximated to the bladder mucosa with a fine absorbable suture to prevent the uncommon complication of ureteral meatal obstruction.[49]

If the new ureteral hiatus is placed too far laterally on the mobile portion of the bladder, especially when one uses the Leadbetter-Politano technique or other suprahiatal techniques, intermittent ureteral obstruction caused by "J-hooking" and obstruction of the ureter as the bladder fills can result.[50] This diagnosis can be difficult to make because the complication manifests silently and requires upper urinary tract studies with the bladder empty and full. If the obstruction is mild and is identified with only significant bladder filling, these patients can be managed with frequent bladder emptying

Most patients with J-hooking require revisionary surgical procedures. This complication is related to redundancy in the ureter or lateral placement of the hiatus and therefore requires straightening and excision of the redundant ureter or movement of the ureteral hiatus medially onto the fixed portion of the posterior bladder wall.

Ureteral obstruction may also occur with a narrow neohiatus, a hiatal defect that is closed too tightly, or an acute angulation as the ureter enters the submucosal tunnel (commonly the result of a prominent lip of tissue at the detrusor hiatus). Kinking and narrowing may be avoided by incising some detrusor fibers at the inferior portion of the neohiatus to create a trough for the ureter.[33,51]

If the original hiatus is used, the defect must be closed carefully to ensure adequate mobility of the ureter within the detrusor portion of the tunnel. The hiatus should be left wide enough to allow passage of a tonsil clamp or similarly sized instrument adjacent to the ureter. In this manner, the hiatus is of sufficient caliber to prevent constriction but is narrow enough to prevent formation of a postoperative

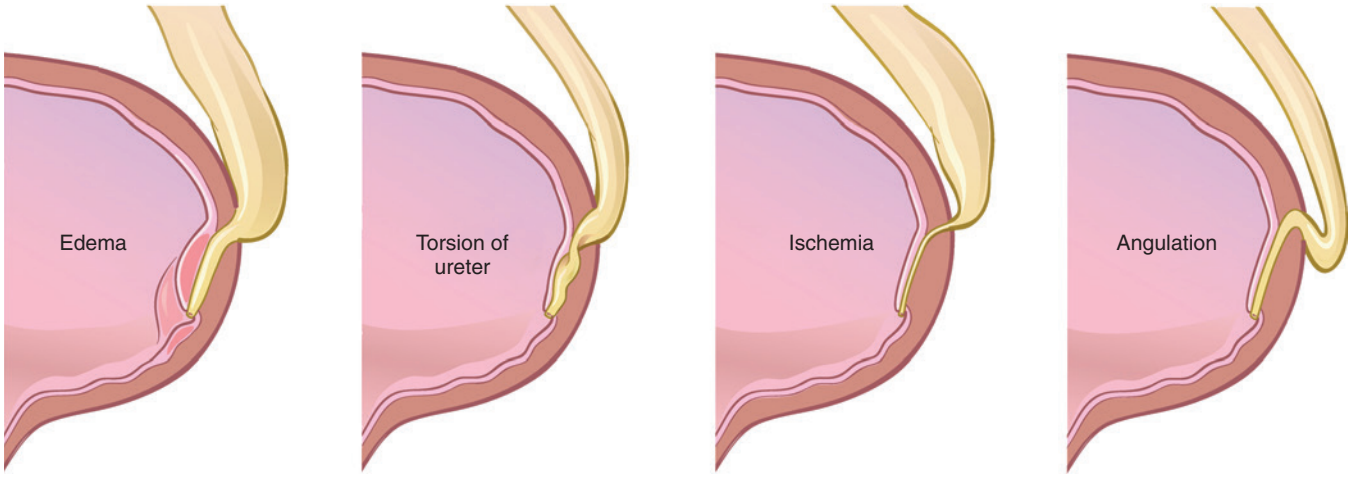

Figure 58.3 Various errors in technique may result in ureteral obstruction.

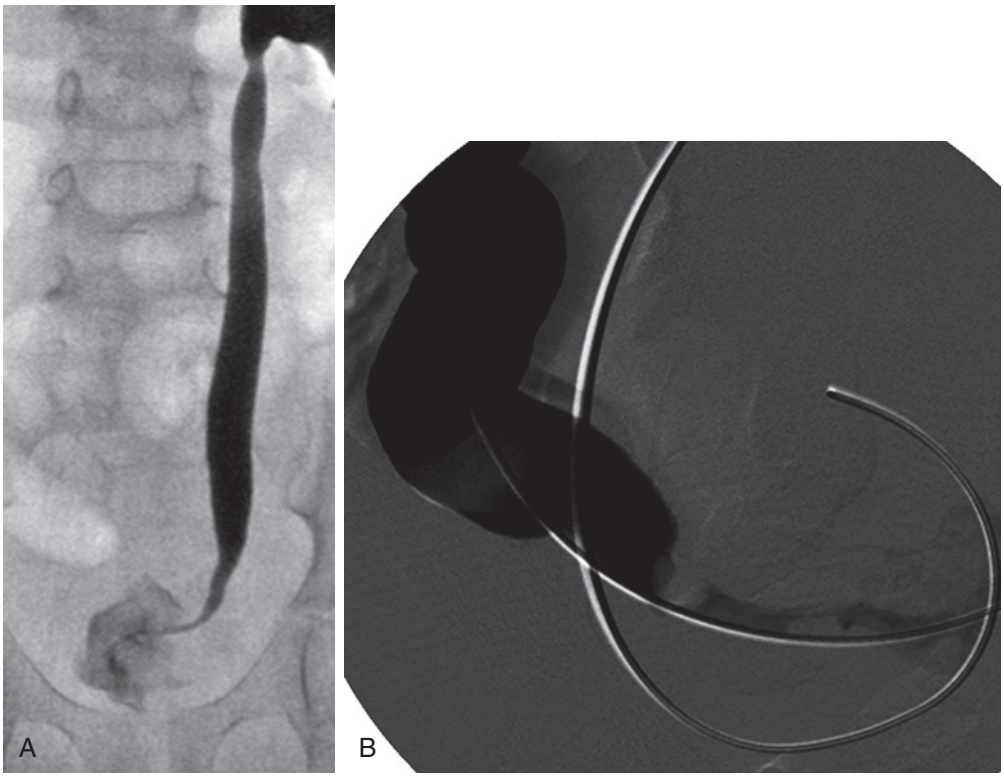

Figure 58.4 A, Antegrade nephrostogram shows narrowing at the ureterovesical junction. This condition was secondary to edema and resolved. B, Antegrade nephrostogram demonstrates massive dilation of the proximal ureter. The obstruction resulted from ischemia and required a tapered reimplant with a psoas hitch.

diverticulum. The incidence of postoperative diverticulum has been reported to be ≤17% following a Cohen reimplantation. Diverticula have been blamed for both recurrent reflux and postoperative obstruction.[52]

Care must be taken to pass the ureter under direct vision during transvesical procedures that require creation of a neohiatus, to avoid passage of the ureter into and out of the peritoneal cavity. Late ureteral obstruction has been attributed to adhesions within the transperitoneal course of the ureter, placement of the ureter through bowel segments, and placement of the ureter through the broad ligament.[47,53,54] Blunt dissection of the peritoneum off the posterior bladder wall and passage of a right angle through the neohiatus under direct vision should help prevent these complications.

In male patients, care must be taken to avoid injury to the vas deferens during transvesical mobilization of the ureter. Additionally, ureteral obstruction may occur if the hiatus is moved superiorly within the bladder and the ureter is not moved anterior to the vas, with resulting acute angulation.

POSTOPERATIVE REFLUX

Ipsilateral Reflux

Following surgical treatment of VUR, reflux may persist in the affected ureter or may occur in the contralateral ureter in approximately 2% and up to 32% of patients, respectively.[2,55] Significant evidence indicates that persistent reflux, identified on postoperative VCUG, may resolve without intervention because it may be caused by a transient voiding dysfunction and inflammation. Persistent postoperative VUR is reported to resolve spontaneously in 24% to 100% of cases.[55–61] Because the rate of postoperative resolution of persistent postoperative reflux is so high, our practice is to prescribe long-term prophylactic antibiotics for these patients. A repeat VCUG is delayed for approximately 1 year.

Persistent reflux is most commonly attributed to inadequate tunnel length, but it may also result from persistent inflammation at the submucosal tunnel (Fig. 58.5). An infrequent cause of postoperative reflux is the development of a ureterovesical fistula.[62,63] Formation of a ureterovesical fistula is attributed to entrapment and devascularization of the intravesical portion of the ureter with suture used to close the bladder mucosa. This complication can usually be recognized on cystoscopy and requires reoperation with resection of the ureter distal to the fistula with remobilization of the ureter and reimplantation with an appropriate tunnel. Bladder diverticulum at the hiatus may prevent adequate tunnel length and may result in persistent reflux.

Contralateral Reflux

The incidence of contralateral reflux after unilateral reimplantation has been reported to be between 0.6% and 32%, with more recent studies reporting an incidence of 10–18%.[54,64–68] Spontaneous resolution has been reported in 61–98% of cases with a minimum of 3 years of follow-up, and most investigators recommend observation while the patient is receiving prophylactic antibiotics as an initial

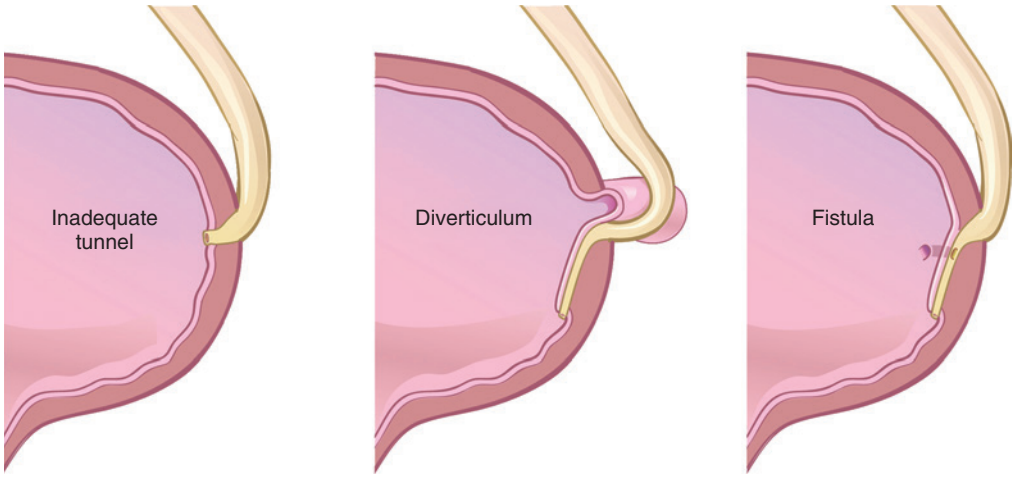

Figure 58.5 Potential technical errors that can result in persistent reflux.

treatment measure.[34,55,64,65,69] Additionally, treatment of voiding dysfunction, if present, with behavioral modification, medical therapy, or both is indicated during this period. In children with breakthrough UTIs, correction of postoperative reflux should be considered. Although most cases of postoperative contralateral reflux resolve spontaneously, this potential risk should be discussed preoperatively.

Several reasons have been proposed for the development of contralateral reflux. Warren and colleagues[55] suggested that patients with an abnormal shape or position of the ureter were at greatest risk. Other theories to explain contralateral VUR include operative trigonal distortion or a pop-off mechanism; however, these theories have been challenged.[67,70–74] In a review of 107 patients, Noe[75] identified two possible contributors to contralateral VUR: (1) age at initial operation, which correlates with a smaller number of cystograms and fewer opportunities to identify contralateral VUR; and (2) the presence of dysfunctional voiding. Additionally, low observed versus predicted bladder capacity may be associated with postoperative contralateral VUR.[68] On follow-up most postoperative contralateral VUR will resolve spontaneously with a benign clinical course.[68] While some believe it is not warranted, we tend to perform bilateral reimplants in any patient with a history of bilateral VUR even after unilateral spontaneous resolution.

MANAGING THE FAILED REIMPLANT

A reoperative surgical procedure after failed (persistent reflux or obstruction) ureteral reimplantation is often difficult and involves longer operative times. Surgical planes are challenging, and the risk of future complications related to devascularization and contralateral ureteral injury is increased. More aggressive extravesical mobilization and the use of a psoas hitch or a Boari flap are more likely to become necessary to prevent reflux successfully in repeat surgical procedures.

Patients whose initial reimplant fails should receive long-term antibiotic prophylaxis. Reevaluation of reflux should include renal and bladder ultrasound, VCUG, and diuretic renal scan. Additional studies including a Whitaker test may be necessary in cases of equivocal obstruction. We believe that all children with persistent reflux after reimplantation should undergo urodynamic evaluation.

In a child with postoperative obstruction, reoperation should be delayed for ≥3 to 6 months to allow the distal ureter to reestablish sufficient vascularity. Diversion with a percutaneous nephrostomy tube decompresses the collecting system and permits repeat investigation with a Whitaker test if necessary.

If the decision is made to reoperate on a child with persistent reflux or obstruction, the surgeon must individualize the management of each patient and be prepared with a variety of reconstructive options. Preoperative cystoscopy may aid in identifying a short mucosal tunnel, diverticulum, or fistula as the cause of persistent VUR. Retrograde ureteropyelography or intravenous urography can provide useful information about the severity of ischemic changes or angulation of the distal ureter if an antegrade study cannot be performed. Occasionally, the ureteral orifice may be completely obliterated by severe scarring.[47]

Various open procedures have been used for reoperative ureteral reimplantation including the Cohen, Leadbetter-Politano, Paquin, and a combined intravesical-extravesical approach, each with good results.[42,76–78] We have usually been able to mobilize the ureter adequately through the Pfannenstiel incision, although a vertical midline incision may also be employed for more exposure. The ureter must be carefully mobilized, to preserve all tissue surrounding the ureter. Sacrificing the gonadal vessels to improve the blood supply to the distal ureter is occasionally necessary and has been suggested by some surgeons. If the ureter is dilated >1 cm, it should be tapered to allow an adequate submucosal tunnel. A psoas hitch may be necessary when the ureter is short or when a longer tunnel for a tapered reimplant is necessary.[77,79] In rare cases, bowel interposition, transureteroureterostomy, or transureteropyelostomy may be necessary.[77,80] Alternatively, robotic/laparoscopic approaches have been shown to have similar success rates to open repair of failed previous antireflux surgery.[81,82] Percutaneous balloon dilation of UVJ strictures following reimplantation of the ureter has been described in a limited number of patients with favorable short-term outcomes.[83,84]

Dextranomer/hyaluronic acid (Dx/HA) has been used as an alternative to reoperation in patients with persistent postoperative VUR.[85–87] In each series, patients identified with postoperative VUR were initially observed. During the period of observation, Jung and colleagues[86] maintained patients on antibiotic prophylaxis and treated voiding dysfunction in those affected. Seventy to 80% of the renal units injected had complete resolution of reflux after one injection. A second injection was successful in two-thirds of the patients in the series by Jung and colleagues.[86] No complications resulting from injections were reported.

Complications of Endoscopic Correction of Vesicoureteral Reflux

Endoscopic therapy of VUR was first introduced in 1984.[88] This technique has become increasingly popular since the introduction of Dx/HA (Deflux, Q-Med Scandinavia), which was approved for use in the United States in 2001. Dx/HA is indicated for the treatment of grade II to IV VUR. The use of this agent is contraindicated in patients with active voiding dysfunction, UTI, ureters with associated Hutch diverticulum, ureteroceles, and nonfunctioning kidneys.[89] Success rates, defined as a lack of VUR on postoperative VCUG, after a single injection are reported to be between 76% and 94%.[90,91] However, these successes vary based on the experience of the endoscopist, the grade of reflux, the underlying bladder disease, and ureteral anomalies such as duplications and ectopia.[92–95] In duplicated systems, the success rate after one injection is reported to be approximately 70%.[96] The incidence of contralateral reflux following endoscopic injection with Dx/HA ranges from 4.5% to 12.5%.[91,97,98]

In cases of failed Dx/HA injection, the material appears to migrate away from the subureteric orifice or migrates to the extravesical space or along the periureteral sheath (Fig. 58.6). Although this issue is controversial, volume reduction may occur in time and may lead to failure.[89,99,100] In the meta-analysis by Elder and associates,[90,101] repeat therapy was successful in 68% of ureters, whereas Elmore and colleagues[100] reported a success rate in 89% of ureters undergoing second injections. The AUA guidelines recommend routine postoperative VCUG after endoscopic injection of bulking agents to ensure resolution of VUR.[4]

Open ureteral reimplantation after failed injection is more difficult than is a primary open reimplantation procedure and may be related to granuloma formation secondary to injection. In our practice, higher rates of obstruction have been noted after open reimplantation for failed injection therapy.[102] We therefore leave a ureteral stent in place in these children. In addition to persistence of reflux and new contralateral reflux, extravesical ureteral obstruction has also been reported (Fig. 58.7).[103] Salvage open and robotic extravesical approaches to persistent VUR after failed injection therapy have been described with some success.[82,104,105] Given the relatively recent introduction of injection therapy, it remains difficult to comment on long-term complications; however, the Swedish Reflux Study demonstrated a 20% rate of recurrent dilating reflux 2 years after initial Dx/HA injection.[106]

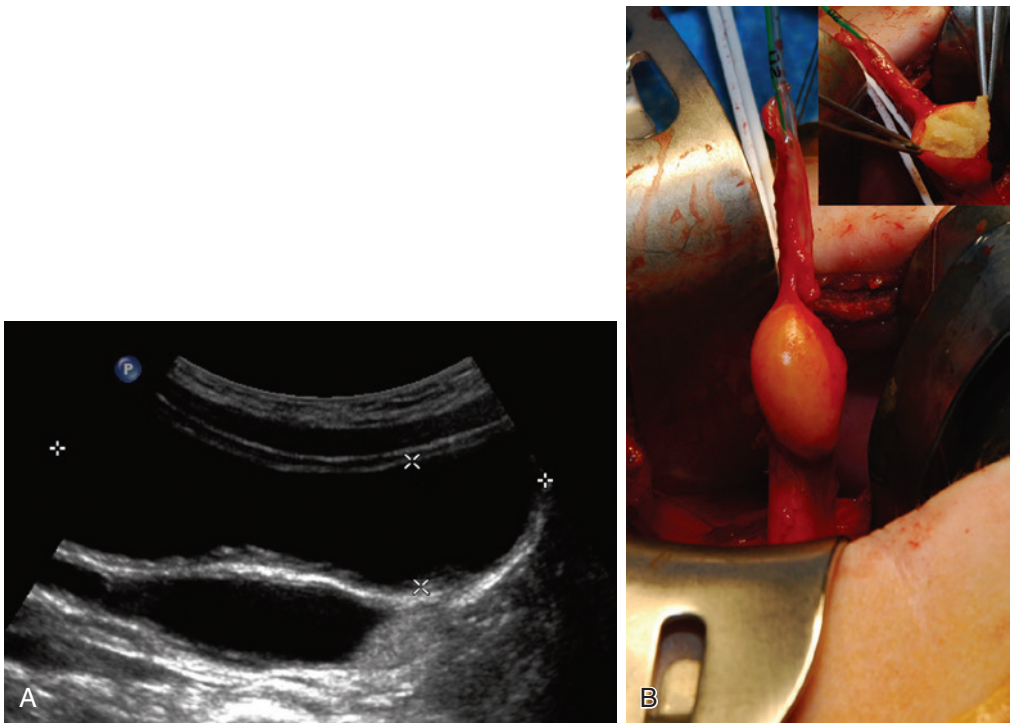

Figure 58.6 Migration of dextranomer/hyaluronic acid used in the treatment of vesicoureteral reflux. A, Hyperechoic material at the distal end of the ureter. B, Encapsulated migrated material consistent with ultrasound findings. The *inset* shows the granular makeup of dextranomer/hyaluronic acid.

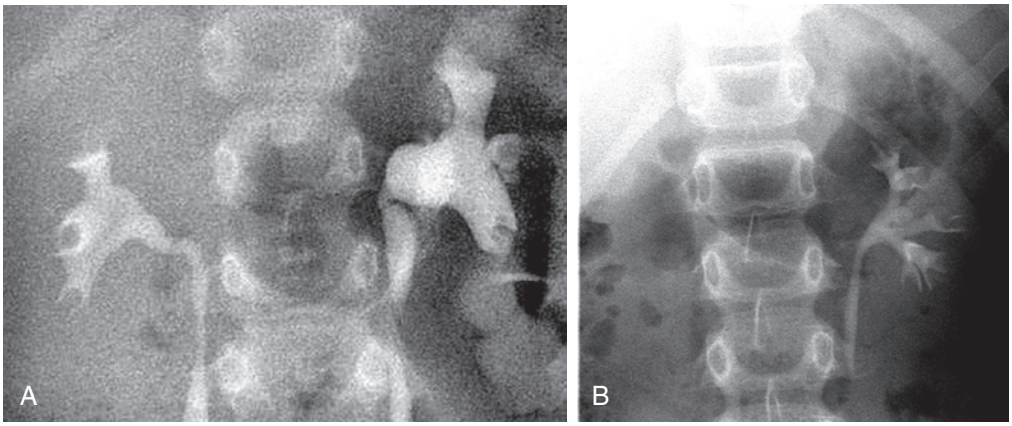

Figure 58.7 A, Preoperative voiding cystourethrograms with bilateral VUR after endoscopic therapy. B, Postoperative voiding cystourethrograms with resolution of right VUR and minimal improvement of left VUR. The dextranomer/hyaluronic acid "mound" was not sonographically identified on the left.

Surgical Complications of Laparoscopic/Robotic Reimplant

Both extravesical and transvesical laparoscopic and robotic ureteral reimplantation procedures have been described. The most common minimally invasive approach to VUR is the robotic-assisted laparoscopic extravesical ureteral reimplant.[107] Some significant series have reported success rates ranging from 77% to 100%.[82,105,108–110] Complication rates for robotic-assisted extravesical reimplantation are similar to the traditional open extravesical reimplantation, such as those for transient urinary retention (0–12%) and contralateral reflux (6–23%).[81,82,105,108–110] Pelvic plexus visualization has allowed for a nerve-sparing technique that is reported to decrease the rate of postoperative urinary retention and voiding dysfunction following bilateral extravesical robotic-assisted laparoscopic ureteral reimplantation.[110] The robotic approach has been expanded to ureters requiring tapering or dismembering and ureters with associated duplication and diverticula.[81,111,112] Complications unique to robotic surgery include potential conversion to an open procedure, longer surgery times,[108,109] intraperitoneal urine leak,[110] and intraabdominal organ injuries or ileus given the intraperitoneal approach.[82] Advantages may include shorter length of stay[81,107–109] and decreased narcotic use compared to open surgery.[109]

Surgical Complications of Megaureter Repair

Some controversy exists regarding the timing of megaureter repair. Today, many children with megaureters present as asymptomatic neonates referred for evaluation of antenatal hydroureteronephrosis.[113,114] Surgical treatment of the refluxing megaureter and of the nonrefluxing, nonobstructed megaureter is often unnecessary. Improvement in high-grade reflux occurs commonly in the first year of life.[2,4] The megaureter that is neither refluxing nor obstructed often maintains normal function and reverts to normal caliber in time.[115] Obstructed refluxing megaureters often require surgical intervention. However, the treatment of obstructed nonrefluxing megaureters remains controversial and can also include endoscopic management with stenting and early refluxing reimplants.[103,116–120]

Regardless of the timing or indications for megaureter repair, the procedure is technically challenging and carries a significantly greater risk of postoperative complications than in the case of a nondilated ureter.[121] Reconstruction of the megaureter may be achieved using an excisional technique described by Hendren[122] or by one of the imbricating methods, most commonly those described by Starr[123] and Kalicinski and colleagues.[124]

Excisional tapering of a megaureter requires careful attention to ureteral blood supply during resection of the redundant ureter and closure of the tapered ureter. Injury to the vascular supply of the ureter may lead to devascularization, obstruction, fistula, and urinary leakage. Inherent ureteral characteristics such as increased collagen and altered smooth muscle of the distal ureter may also contribute to surgical failure.[121,125,126] Reported success rates for excisional tapering range from 74% to 90%.[127–131]

Tapering should be performed when a submucosal tunnel long enough to fulfill the 5:1 rule of tunnel length to ureteral diameter cannot be achieved. Hendren's series[122] remains the largest reported, and the complications are well detailed.[115,127] Of 160 patients with primary and secondary megaureter, 14 had transient obstruction requiring percutaneous nephrostomy tubes, 11 had obstruction requiring reoperation, and eight had postoperative reflux, for an overall success rate of 88%.

Success rates for imbricated techniques are slightly better and are reported to be 93–95%, with lower rates of vascular injury when compared with excisional techniques.[117,124,125,130,132] The slightly better success rates in the imbricated group may be a consequence of selection bias because plication was limited to ureters with smaller diameters in some studies.[125] Persistent reflux, seen in both the Kalicinski and Starr techniques, is most likely the result of failure of reimplantation rather than failure to narrow the ureter. The plicated ureter is bulky, a characteristic that renders creation of a submucosal tunnel more difficult.[133] One of the greatest advantages of folding and plication

techniques is that these procedures can be performed on moderately dilated ureters entirely intravesically.

Patients in whom megaureter repair has failed and patients with iatrogenic megaureter secondary to obstruction after ureteral reimplantation must be carefully evaluated for factors contributing to treatment failure such as voiding dysfunction or poor bladder compliance. Patients with new or persistent VUR after megaureter repair should be given prophylactic antibiotics because reflux may resolve with observation.

In cases of obstruction, a percutaneous nephrostomy tube should be placed. Occasionally, the obstruction resolves with diminishing edema. Upper urinary tract drainage with the nephrostomy tube allows for antegrade radiographic examinations, Whitaker tests, and time for healing before a corrective surgical procedure is attempted. Altered ureteral histologic features may limit the ureter's capacity for proper peristalsis. As in any reimplantation procedure, bladder dynamics must be examined. In some cases clean intermittent catheterization, anticholinergics, or frequent bladder emptying may become necessary.

Surgical Complications of Ureterocele Repair

A *ureterocele* is a cystic dilation of the terminal ureter within the bladder, urethra, or both that creates diagnostic and therapeutic dilemmas once it is identified. Management of ureterocele varies and depends on the presence of obstruction, reflux, and incontinence, as well as the function of the affected kidney or renal moiety. Ureteroceles occur most commonly in white patients and are four to six times more frequent in girls than in boys.[134] Ectopic ureteroceles are four times more common than are intravesical ureteroceles.[135]

Today, ureteroceles are more likely to be diagnosed based on prenatal ultrasonography rather than on UTI. Hydronephrosis and dysplasia of the upper pole moiety are commonly associated with a ureterocele.[133] Rarely, ureteroceles may manifest with bladder outlet obstruction because ectopic ureteroceles can prolapse. Ureteroceles found in adults are usually intravesical and are associated with a single collecting system. Adult ureteroceles may be acquired rather than congenital, as in children. Function of the affected kidney is less likely to be impaired in an adult.[136]

The diagnosis of ureterocele may be difficult. A ureterocele may be collapsed and thus not visible on an ultrasound scan if the bladder is overfilled. If the bladder is underfilled, a large ureterocele may fill the entire bladder and give the impression of a partially filled bladder. A VCUG should be obtained to evaluate for VUR in association with the ureterocele. Reflux to the ipsilateral lower pole occurs in approximately 50% of cases, and contralateral reflux occurs in approximately 25%. This complication is likely the result of distortion of the bladder base by the ureterocele.[137] Occasionally, a ureterocele may evert during VCUG and resemble a diverticulum. Nuclear renal scans are useful to evaluate the function of the moiety associated with the ureterocele and that of other moieties. Poorly functioning moieties may not be worth salvaging.

Once the ureterocele has been radiographically evaluated, treatments range from endoscopic decompression to complex reconstruction.[138] Nonoperative management has also been advocated in cases involving nonobstructed duplex systems with relatively good preservation of renal function, associated multicystic dysplastic moieties, or completely nonfunctioning upper pole moieties.[139] Additionally, watchful waiting may have a role in cases of prenatally detected ureteroceles without bladder outlet obstruction, ipsilateral lower moiety obstruction, and ipsilateral lower moiety VUR less than grade IV.[140]

It is beyond the scope of this chapter to discuss each of the different management techniques; however, the complications encountered are directly related to the treatment options selected. Endoscopic incision or puncture is simple and minimally invasive. It typically requires a short anesthetic regimen and usually can be performed as an outpatient procedure. The procedure has been reported to offer definitive therapy in ≤93% of patients with intravesical ureteroceles.[141,142] No consensus exists on the effectiveness of technique for treating ectopic ureteroceles; however, the watering can technique of endoscopic puncture may lead to less de novo VUR compared to endoscopic incision.[143] Although it may not be curative, incision may relieve obstruction of both the involved and uninvolved moieties and may thus prevent further loss of function and UTI.

If incision does not result in a cure, it allows the delay of definitive treatment until the child has grown. Additionally, the decompressed system may be easier to reconstruct.[144–146] Other investigators have argued that this approach may commit the child to future lower urinary tract reconstruction.[147] Despite controversy, investigators agree that endoscopic puncture of an ectopic ureterocele is indicated for patients with uncontrolled sepsis, azotemia, and bladder outlet obstruction. New reflux may be created in 28–47% of patients as a consequence of ureterocele incision or puncture, and the procedure may fail to decompress the involved moiety in 10–25% of cases.[137,141–143] Postoperatively, the ureterocele may prolapse and urinary retention may occur in ≤10% of patients.[146]

The traditional upper urinary tract approach for ureteroceles associated with a duplicated collecting system and minimal function of the upper pole segment is partial nephrectomy with subtotal removal of the upper pole ureter and ureterocele aspiration. This approach seems to be decreasing with the widespread acceptance of ureterocele incision. Complications of upper pole heminephrectomy include inadvertent ligation of branch vessels to the lower pole resulting in devascularization. Additionally, traction on the lower pole of the kidney may lead to intimal injury and thrombosis of lower pole vessels. Consequently, significant atrophy of the lower pole occurs in 7–10% of cases.[148,149] Careful handling and the use of topical papaverine (30 mg/mL) to prevent vasospasm minimize this complication. Additional complications include prolonged urine leak as a result of entrance into the lower pole collecting system, hemorrhage, and new-onset lower pole VUR.

Complete reconstruction of the ureterocele includes partial nephrectomy, excision of the ureterocele, and reimplantation of the lower pole ureter in patients with a nonfunctioning upper pole or ureterocelectomy and a common sheath reimplant with or without tapering in patients with preservable function in the upper pole.

Ureteral reimplantation associated with a ureterocele is more difficult than is uncomplicated reimplantation and is associated with higher failure rates. To increase the chance of success, our recommendation is to create the tunnel for reimplantation above the area of ureterocele excision. This technique allows normal muscle backing for the reimplanted ureter and precludes working in the area of the reconstructed bladder base or marsupialized ureterocele. Success rates for reimplantation of single system ureteroceles can approach those of uncomplicated reimplantation procedures.

Other potential complications of ureterocele excision include bladder neck injury, urinary incontinence, bladder diverticulum, vesicovaginal fistula, and urethrocutaneous fistula. These complications may be avoided with careful dissection of the posterior wall of the ureterocele from the bladder with approximation of the bladder musculature. The surgeon must be meticulous in any dissection near the bladder neck. Following excision of the ureterocele it is imperative to be certain there is no residual lip of tissue distally that may result in bladder outlet obstruction.

Robotic approaches have been described for partial nephrectomy in children with duplicated collecting systems, and early studies demonstrate similar complication rates to those of open surgery.[150–152]

Conclusions

Ureteral reimplantation of a normal-caliber ureter into a normal bladder can be accomplished successfully with minimal complications. Newer endoscopic techniques are also successful and have few associated complications; long-term effectiveness of endoscopic techniques is unknown. Robotic approaches to ureteral reimplantation approach similar effectiveness and complication rates. Successful outcomes depend on thorough preoperative evaluation of bladder dynamics and meticulous surgical technique. Careful postoperative evaluation allows early recognition and treatment of the uncommon complications.

Chapter 58 Questions

1. What should be considered in the use of prophylactic antibiotics for patients with vesicoureteral reflux?
   a. Prophylactic antibiotics decrease the rate of febrile urinary tract infections
   b. Prophylactic antibiotics decrease the rate of new renal scarring
   c. Prophylactic antibiotics are recommended in all patients with vesicoureteral reflux
   d. Sulfa-based antibiotics can be given during the first 2 months of life
   e. Nitrofurantoin can be given during the first 2 months of life

2. What does successful ureteral reimplantation require?
   a. A submucosal tunnel length two times the diameter of the ureter
   b. No need for ureteral fixation (proximally or distally) within the mucosal tunnel
   c. Preservation of the ureteral blood supply
   d. Placement of the hiatus posterior and lateral in the bladder with an adequate J-shaped curve to the submucosal tunnel
   e. Minimal closure of the muscular hiatus

3. Which of the following statements about postoperative contralateral vesicoureteral reflux is true?
   a. It occurs only after robotic-assisted laparoscopic extravesical ureteral reimplantation
   b. It never occurs after endoscopic therapy
   c. It occurs more frequently in older patients
   d. It often resolves spontaneously
   e. It requires immediate surgical correction

4. Which of the following statements about surgical therapy for megaureter is true?
   a. All megaureters eventually require operation
   b. Excisional tapering and imbrication demonstrate the same complication rates
   c. It always requires careful attention to the vascular supply of the distal ureter
   d. Persistent vesicoureteral reflux after megaureter reimplantation never spontaneously resolves
   e. Voiding dysfunction does not play a role in persistent vesicoureteral reflux after megaureter reimplantation

5. Robotic-assisted laparoscopic extravesical ureteral reimplantation can be considered for which of the following patients?
   a. 8-year-old female with bilateral grade IV vesicoureteral reflux and associated febrile urinary tract infections
   b. 5-year-old male with a refluxing megaureter and associated febrile urinary tract infections that may require tapering
   c. 3-year-old female with left lower pole grade III vesicoureteral reflux and associated febrile urinary tract infections
   d. 10-year-old female with persistent grade II vesicoureteral reflux and associated febrile urinary tract infections after failed injection therapy
   e. All of the above

6. Which of the following statements regarding ureteroceles is true?
   a. It is common to have hydronephrosis and dysplasia of the associated lower pole moiety
   b. There is a low likelihood of reflux in the ipsilateral lower pole
   c. All ureteroceles require operative intervention
   d. Ureteral reimplantation with an associated ureterocele has higher failure rates and is more difficult
   e. Tunnel creation for reimplantation should be made over the area of ureterocele excision

7. Complications unique to robotic-assisted laparoscopic ureteral reimplantation include all of the following, EXCEPT:
   a. Longer surgery times
   b. Intraperitoneal urine leak
   c. Ileus
   d. Postoperative urinary retention
   e. Intraabdominal organ injury

8. Success of endoscopic injection of bulking agents depends on all of the following, EXCEPT:
   a. Experience of the endoscopist
   b. Grade of reflux
   c. Associated voiding dysfunction
   d. Duplicated systems
   e. Number of prior urinary tract infections

9. Which of the following statements for management of postoperative obstruction following surgical correction of reflux is true?
   a. Reoperation should be performed immediately upon identification
   b. Only open revision is recommended (not endoscopic or robotic)
   c. Late ureteral obstruction is most commonly the result of an error in surgical technique
   d. Ureteral obstruction is always symptomatic
   e. Symptomatic ureteral obstruction should initially be managed with endoscopic retrograde placement of a ureteral stent

10. Treatment options for vesicoureteral reflux include:
    a. Watchful waiting
    b. Prophylactic antibiotics
    c. Ureteral reimplantation (open or robotic-assisted laparoscopic)
    d. Endoscopic injection of bulking agents
    e. All of the above

Case Studies

CASE 1

A 3-year-old girl presents with a history of left grade III vesicoureteral reflux and resolved right grade II vesicoureteral reflux with recurrent febrile urinary tract infections requiring hospitalization and intravenous antibiotics while compliant on prophylactic antibiotics.

1. What intervention would you not recommend at this point?
   a. Open left intravesical vesicoureteral reimplantation
   b. Open bilateral intravesical vesicoureteral reimplantation
   c. Bilateral robotic-assisted laparoscopic extravesical ureteral reimplantation
   d. Bilateral endoscopic injection therapy
   e. Investigation for associated dysfunctional voiding

The parents are interested in correction of the VUR, and she undergoes a bilateral Cohen ureteral reimplantation without ureteral stent placement. The next morning she is noted to have low urine output and decreased oral intake, but denies flank pain, nausea, or emesis. Creatinine is stable.

2. What is the most appropriate intervention at this time?
   a. Observation
   b. Increased intravenous fluids
   c. Renal bladder ultrasound
   d. Diuretic renal scan
   e. Cystoscopy and retrograde bilateral ureteral stent placement

With aggressive fluid administration her oliguria resolves and oral intake improves. She is discharged on postoperative day two on prophylactic antibiotics. On her postoperative follow-up at 1 month, renal bladder ultrasound does not demonstrate any hydroureteronephrosis and her prophylactic antibiotics are stopped 3 months after surgery. She presents 12 months after surgery, with recurrent episodes of pyelonephritis.

3. What is the most appropriate intervention at this time?
   a. Restart prophylactic antibiotics
   b. Repeat renal bladder ultrasound
   c. Repeat voiding cystourethrogram
   d. Investigate for dysfunctional voiding
   e. All of the above

CASE 2

A 5-year-old girl with a history of bilateral, grade II VUR diagnosed after an episode of pyelonephritis when she was 2 years old underwent bilateral endoscopic therapy with dextranomer/hyaluronic acid (Dx/HA) after several febrile urinary tract infections while on antibiotic prophylaxis. She was discharged on the day of surgery and was maintained on prophylactic antibiotics. A voiding cystourethrogram performed 3 months after the procedure demonstrated persistent grade II, bilateral VUR, and she was maintained on prophylactic antibiotics. She continued to have recurrent febrile urinary tract infections while on prophylactic antibiotics postprocedure.

1. What do the AUA guidelines state regarding postprocedure voiding cystourethrograms?
   a. Postoperative voiding cystography may be performed following open ureteral reimplantation
   b. Postoperative voiding cystography must be performed following open ureteral reimplantation
   c. Postoperative voiding cystography following endoscopic injection of bulking agent is recommended
   d. Postoperative voiding cystography must be performed following robotic-assisted laparoscopic ureteral reimplantation
   e. a and c

2. What are the treatment options for failed injection therapy for VUR treatment?
   a. Salvage open ureteral reimplantation
   b. Salvage robotic ureteral reimplantation
   c. Repeat injection
   d. Evaluation for voiding dysfunction
   e. All of the above

3. For whom is the use of Dx/HA contraindicated?
   a. Patients with grade IV vesicoureteral reflux
   b. Patients with bilateral vesicoureteral reflux
   c. Patients with failed open reimplantation
   d. Patients with active voiding dysfunction
   e. Patients with duplicated systems

Answers

1. **a.** Antibiotic prophylaxis has proven effective in preventing urinary tract infection (UTI) in children with vesicoureteral reflux (VUR). Because reflux nephropathy may progress in patients with recurrent UTI, it is imperative to maintain sterile urine with daily antimicrobial prophylaxis. The effectiveness of the use of continuous prophylactic antibiotics in preventing breakthrough UTI is well supported in the literature, especially for dilating grades of VUR. Rates of breakthrough UTI in patients compliant with antibiotic treatment are reported to be as low as <5%. Certainly, with longer periods of conservative management (5–10 years), the risk of UTI-related morbidity may increase. However, recent studies have brought into question whether continuous prophylactic antibiotics prevent breakthrough renal scarring and therefore affect eventual renal function. Currently the management of VUR is controversial with no universal agreement. There are multiple factors effecting which treatment option is selected. Even daily antibiotic prophylaxis is called into question, with watchful waiting remaining a valid option. Sulfa-based drugs and nitrofurantoin are contraindicated in children <2 months old because these drugs are hepatically metabolized. For this reason, amoxicillin and cephalexin are used in the first 2 months of life.

2. **c.** Successful reimplantation requires preservation of the ureteral blood supply, a submucosal tunnel four or five times the diameter of the ureter, proximal and distal ureteral fixation of the ureter within the mucosal tunnel, placement of the hiatus posterior and medial in the immobile portion of the bladder, and a muscular hiatus sufficiently wide for the ureter but not wide enough to allow for a diverticulum.
3. **d.** Contralateral reflux often resolves spontaneously and should be monitored without any need for immediate revision surgery. Prophylactic antibiotics are usually administered until the reflux resolves. Contralateral vesicoureteral reflux (VUR) may be related to trigonal distortion, young age at initial operation, which correlates with fewer cystograms and fewer opportunities to identify contralateral VUR, the presence of dysfunctional voiding, and bladder capacity. It may occur after open, robotic, and endoscopic correction.
4. **c.** Surgical treatment of the refluxing megaureter and of the nonrefluxing, nonobstructed megaureter is often unnecessary because improvement occurs commonly in the first year of life. When surgery is necessary, it is imperative to maintain the vascular supply of the distal ureter. Megaureters may be tapered or plicated at the time of reimplantation. Success rates for imbricated techniques are slightly better and are reported to be 93–95%, with lower rates of vascular injury when compared with excisional techniques. The slightly better success rates in the imbricated group may be a consequence of selection bias because plication was limited to ureters with smaller diameters in some studies. Patients in whom megaureter repair has failed and patients with iatrogenic megaureter secondary to obstruction after ureteral reimplantation must be carefully evaluated for factors contributing to treatment failure such as voiding dysfunction or poor bladder compliance. Patients with new or persistent VUR after megaureter repair should be given prophylactic antibiotics because reflux may resolve with observation.
5. **e.** Pelvic plexus visualization has allowed for a nerve-sparing technique that is reported to decrease the rate of postoperative urinary retention and voiding dysfunction following bilateral extravesical robotic-assisted laparoscopic ureteral reimplantation. The robotic approach has been expanded to ureters requiring tapering or dismembering and ureters with associated duplication and diverticula. Salvage open and robotic extravesical approaches to persistent VUR after failed injection therapy have been described with some success. Robotic/laparoscopic approaches have been shown to have similar success rates to open repair of failed previous antireflux surgery.
6. **d.** Hydronephrosis and dysplasia of the upper pole moiety are commonly associated with a ureterocele. Reflux to the ipsilateral lower pole occurs in approximately 50% of cases, and contralateral reflux occurs in approximately 25%. This complication is likely the result of distortion of the bladder base by the ureterocele. Nonoperative management has also been advocated in cases involving nonobstructed duplex systems with relatively good preservation of renal function, associated multicystic dysplastic moieties, or completely nonfunctioning upper pole moieties. Ureteral reimplantation associated with a ureterocele is more difficult than is uncomplicated reimplantation and is associated with higher failure rates. To increase the chance of success, our recommendation is to create the tunnel for reimplantation above the area of ureterocele excision. This technique allows normal muscle backing for the reimplanted ureter and precludes working in the area of the reconstructed bladder base or marsupialized ureterocele.
7. **d.** Complication rates for robotic-assisted extravesical reimplantation are similar to those of traditional open extravesical reimplantation, such as those for transient urinary retention (0–12%) and contralateral reflux (6–23%). Pelvic plexus visualization has allowed for a nerve-sparing technique that is reported to decrease the rate of postoperative urinary retention and voiding dysfunction following bilateral extravesical robotic-assisted laparoscopic ureteral reimplantation. Complications unique to robotic surgery include potential conversion to an open procedure, longer surgery times, intraperitoneal urine leak, and intraabdominal organ injuries or ileus given the intraperitoneal approach. Advantages may include shorter length of stay and decreased narcotic use compared to open surgery.
8. **e.** Success rates, defined as a lack of VUR on postoperative VCUG, after a single injection are reported to be between 76% and 94%. However, these successes vary based on the experience of the endoscopist, the grade of reflux, the underlying bladder disease, and ureteral anomalies such as duplications and ectopia. In duplicated systems, the success rate after one injection is reported to be approximately 70%.
9. **c.** Late ureteral obstruction is most commonly the result of an error in surgical technique. The most common causes of obstruction are mechanical obstruction and devascularization of the distal ureter. In a child with postoperative obstruction, reoperation should be delayed for ≥3– 6 months to allow the distal ureter to reestablish sufficient vascularity. Robotic/laparoscopic approaches have been shown to have similar success rates to open repair of failed previous antireflux surgery. Percutaneous balloon dilation of ureterovesical junction strictures following reimplantation of the ureter has been described in a limited number of patients with favorable short-term outcomes. Late ureteral obstruction may be associated with abdominal or flank pain, nausea, vomiting, or UTI or it may be completely asymptomatic. Decompression of the upper urinary tract with a temporary percutaneous nephrostomy tube with or without ureteral stenting is recommended in cases of ureteral obstruction. The ability to place a retrograde stent may be limited in the early postoperative period, particularly after a Cohen ureteroneocystostomy. Open retrograde stent placement may rarely become necessary if less invasive percutaneous techniques fail.
10. **e.** The first successful attempt at surgical correction of VUR was reported by Hutch in 1952. Since that time, multiple surgical, endoscopic, and minimally invasive techniques have been described. Open surgical correction

remains the gold standard, with success rates of >98% in most pediatric centers. While surgical results are excellent, most young children with reflux are managed medically, and older children with observation. Additionally, increasing numbers of children are managed with endoscopic techniques. Given multiple treatment options, it remains imperative that the urologist understand the potential risks and complications of each.

CASE 1

1. **a.** Many approaches to correcting vesicoureteral reflux exist: open, robotic, and endoscopic. All may be appropriate in the select patient. Postoperative contralateral reflux has been associated with young age at initial operation, which correlates with a smaller number of cystograms and fewer opportunities to identify contralateral VUR. While some believe it is not warranted, we tend to perform bilateral reimplants in any patient with a history of bilateral VUR even after unilateral spontaneous resolution. Patients with voiding dysfunction often present with wetting, UTI, and VUR. Treatment of the underlying disease with a combination of bladder retraining, treatment of constipation, anticholinergic therapy, and biofeedback frequently eliminates incontinence, UTI, and at times VUR and thus obviates the need for surgical or endoscopic intervention. Normal voiding habits and normal bladder dynamics are essential for successful antireflux surgery.
2. **b.** The most common cause of decreased urine output (<1 mL/kg/hr) after ureteral reimplantation is mild ureteral obstruction resulting from transient edema at the UVJ. Mild dehydration from preoperative fasting and supraphysiologic secretion of antidiuretic hormone in response to surgical stress also contribute to low urine output. This condition generally responds to fluid boluses (10 mL/kg lactated Ringer solution or 0.9% normal saline solution) and resolves 4–6 hours after the surgical procedure with no long-term sequelae. Dehydration may be avoided with vigorous intraoperative hydration (e.g., 40–50 mL/kg during the case) to compensate for fasting and third-space losses. A renal and bladder ultrasound is useful if oliguria persists after volume replacement. Hydroureteronephrosis or urinary extravasation may be evident. These findings may be confirmed with a diuretic renal scan. The ability to place a retrograde stent may be limited in the early postoperative period, particularly after a Cohen ureteroneocystostomy.
3. **e.** The incidence of recurrent cystitis after successful reimplantation has been reported to be up to 39%, and <8% of patients have clinical pyelonephritis. This patient's episodes of pyelonephritis may be due to voiding dysfunction, persistent VUR, or obstruction and should be investigated. Voiding dysfunction may increase the risk of postoperative pyelonephritis after successful reimplantation and should be addressed. The AUA guidelines do not uniformly recommend postoperative VCUG after open surgical repair, but allow the clinical course and family preference to affect the final decision. If a VCUG is obtained, it should be performed 3–4 months postoperatively to allow for resolution of edema or inflammation of the submucosal tunnel. Late ureteral obstruction may be associated with abdominal or flank pain, nausea, vomiting, or UTI, or it may be completely asymptomatic. The diagnosis of obstruction can be made with ultrasound or renal scan.

CASE 2

1. **a.** The AUA guidelines state that (as an option) postoperative cystography may be performed following open ureteral reimplantation and (as a recommendation) that postoperative voiding cystography following endoscopic injection of bulking agents is recommended. There are not yet published recommendations on routine use of postoperative voiding cystourethrogram following robotic correction of reflux.
2. **e.** The use of Dx/HA is contraindicated in patients with dysfunctional voiding as it is associated with persistent VUR. Repeat injection has been reported to have a success rate of 68–89%. Open ureteral reimplantation after failed injection is more difficult than is a primary open reimplantation procedure and may be related to granuloma formation secondary to injection. Salvage open and robotic extravesical approaches to persistent VUR after failed injection therapy have been described with some success.
3. **d.** The use of Dx/HA is contraindicated for patients with Hutch diverticula, active voiding dysfunction, urinary tract infections, nonfunctional kidneys, or ureteroceles.

Chapter 59 Questions and Answers

KEY POINTS

1. Continence can be achieved in 71–74% of children following the MSRE regimen (exstrophy closure at birth, epispadias repair at 6–12 months, and bladder neck reconstruction as well as an antireflux procedure at 5–6 years). Other repairs (complete primary repair and the Kelly repair) have been offered, long-term outcomes show continence rates of 20%.
2. The success of bladder exstrophy closure depends on the newborn's bladder template size and condition, a tension-free closure, free egress of urine, secure placement of suprapubic tubes and stents, wound care, avoidance of infection, and excellent pain and movement control.
3. The complications of any primary closure include infections, wound dehiscence, bladder prolapse, and urethral outlet obstruction.
4. Diligent care and pampering as well as the liberal use of an indwelling, tunneled epidural catheter, analgesics, antispasmodics, and tranquilizers will provide for a calm, pain-free postoperative course with proper immobilization.
5. Although various anatomic approaches to osteotomy have been implemented, the combined anterior innominate and vertical iliac technique is preferred because of its technical practicality, comparable outcomes, and long-term success.
6. The most common complications of epispadias repair are urethrocutaneous fistulas, urethral strictures, loss of penile skin, and persistent dorsal chordee. However, loss of glans or corpora can occur.
7. Modified Young-Dees-Leadbetter bladder neck reconstruction and ureteral reimplantations (transtrigonal or cephalotrigonal) are performed at 5–6 years of age when the child wants to be dry, will participate in postoperative voiding training, and has a bladder capacity of ≥100 mL and stable urodynamics.
8. Complications of bladder neck reconstruction include difficulty with urinating, persistent incontinence, the development of hydronephrosis due to bladder outlet obstruction, and the formation of calculi.
9. Most patients with failed exstrophy reconstruction require augmentation cystoplasty or continent urinary diversion to provide prolonged stability in the upper urinary tract and continence.
10. Long-term considerations include the appearance of the external genitalia, male fertility, introital difficulties, uterine prolapse, and malignant disease.

The surgical management of classic bladder exstrophy remains a challenge to the pediatric urologist and pediatric surgeon. Multiple reconstructive approaches exist to repair classic bladder exstrophy. The modern staged repair approach to closure of bladder exstrophy (MSRE) has provided excellent long-term successful results.[1–3] This method of treatment consists of bladder, posterior urethral, abdominal wall, and pubic closure in the newborn period, if the newborn is robust with an excellent bladder template. Pelvic osteotomies are performed as needed. Concomitant epispadias repair can be performed in very selected cases, but only by experienced exstrophy surgeons. In most cases, the epispadias repair is performed when the patient is 6–12 months old. This repair precedes bladder neck reconstruction. By adding outlet resistance, epispadias repair facilitates bladder growth to an adequate capacity for bladder neck reconstruction. Along with ureteral reimplantation, bladder neck reconstruction is usually performed at 5–6 years of age when the patient has achieved satisfactory bladder capacity, wants to be dry, and will comply with an intense postoperative voiding regimen. This chapter identifies the complications of all current forms of exstrophy and epispadias treatment and highlights methods to avoid many of these problems.

The modern era of exstrophy reconstruction began in the early 1970s when Jeffs and colleagues[4] and Cendron[5] introduced a staged approach to functional closure of bladder exstrophy. Formerly, this treatment regimen consisted of bladder closure, later bladder neck reconstruction, and finally epispadias repair. However, since the middle to late 1980s with MSRE, reconstructive procedures have evolved and have been altered such that exstrophy closure is performed as a newborn, epispadias repair is performed at 6–12 months of age, and bladder neck reconstruction is undertaken at 5–6 years of age.

The success of the MSRE approach has been quite encouraging. In specialist centers, continence is achieved in 71–74% of children.[6–8] In a series of 67 patients treated at the Johns Hopkins Hospital in Baltimore by a single surgeon and followed up for ≥5 years, 70% achieved continence (daytime and nighttime) and 80% achieved social continence (dry for ≥3-hour intervals).[6] Additionally, we have had excellent success with MSRE done outside of our institution with referral for continence procedure. Eighty-three percent (57 of 68) of patients referred were continent via urethra without a need for augmentation or for clean intermittent catheterization (CIC).[9]

This review of complications associated with classic bladder exstrophy and epispadias includes the experience of 213 patients who have been seen and treated at the Johns Hopkins Hospital between 1988 and 2004 by Gearhart and colleagues.[6] These patients, as well as those referred either for exstrophy complications or after initial closure for epispadias repair or bladder neck reconstruction, form the substance of this chapter.

To achieve a successful treatment result by way of functional closure, the needs of each child with bladder exstrophy must be carefully considered at birth. Numerous factors determine the surgical success of bladder exstrophy closure, including the newborn's bladder template size and condition, tension-free closure, free egress of urine, secure placement of suprapubic tubes and stents, wound care, avoidance of infection, movement, and prevention of raised intraabdominal pressure that occurs with straining, coughing, and postoperative ileus.[10–12]

Bladder size and functional capacity of the detrusor muscle are important factors in the ultimate outcome of closure. It is imperative not to confuse apparent bladder size with potential bladder capacity; true bladder size can be accurately assessed only while the patient is under anesthesia. Although the bladder may appear small on preliminary examination, an examination while the patient is under anesthesia may reveal a bladder with suitable capacity that indents easily when it is depressed by a gloved finger.

If the initial bladder capacity after successful closure is estimated to be ≥5 mL, one can expect the bladder to develop adequate size and capacity over time. However, repeated irritation or trauma not only produces a bladder that is unsuitable for closure, but also hinders subsequent bladder growth. In addition, a small fibrotic bladder patch without elasticity or contractility may not be appropriate for primary closure. Other conditions that prevent successful primary closure include ectopic bowel, severe upper tract changes, and significant hamartomatous polyps.

In some neonates with small bladder templates, it may be prudent to wait until the child is 4 to 6 months of age, to allow the child and the bladder to grow, and then undertake closure with epispadias repair under testosterone stimulation, rather than risk a failed closure in the newborn period.[13] Conversely, many patients with small bladders do undergo closure, and some obtain a volume that can yield a satisfactory dry interval after bladder neck reconstruction. In addition, a small bladder that is successfully closed can be subsequently used as a template for ureteral reimplantation and bladder augmentation if adequate bladder capacity is not eventually attained.

The main complications of primary bladder exstrophy closure are complete wound dehiscence (Fig. 59.1), bladder prolapse (Fig. 59.2), and urethral outlet obstruction (Fig. 59.3). Other resultant complications of bladder closure include bladder and renal calculi. In some repairs, such as the complete primary repair of exstrophy (CPRE), glans and corpora loss has been reported. In addition, vesicocutaneous fistula has also been reported by Massanyi et al.[14] This often is a subtle sign of a failed closure as the pubis is often separated and the bladder assumes a very superficial position where it is easy for fistulization to occur. This occurrence must be carefully evaluated as reclosure is oftentimes required.[14] With the modern treatment of bladder exstrophy, the incidence of all the aforementioned complications has declined significantly. These complications and methods to avoid them are discussed in the following sections on initial bladder closure, epispadias repair, bladder neck reconstruction, and long-term considerations.

Initial Bladder Closure

OVERVIEW

The technique for primary bladder closure that has been previously described and diagrammed is to close the bladder template, bladder neck, and proximal posterior urethra well up onto the shaft of the penis in a secure manner

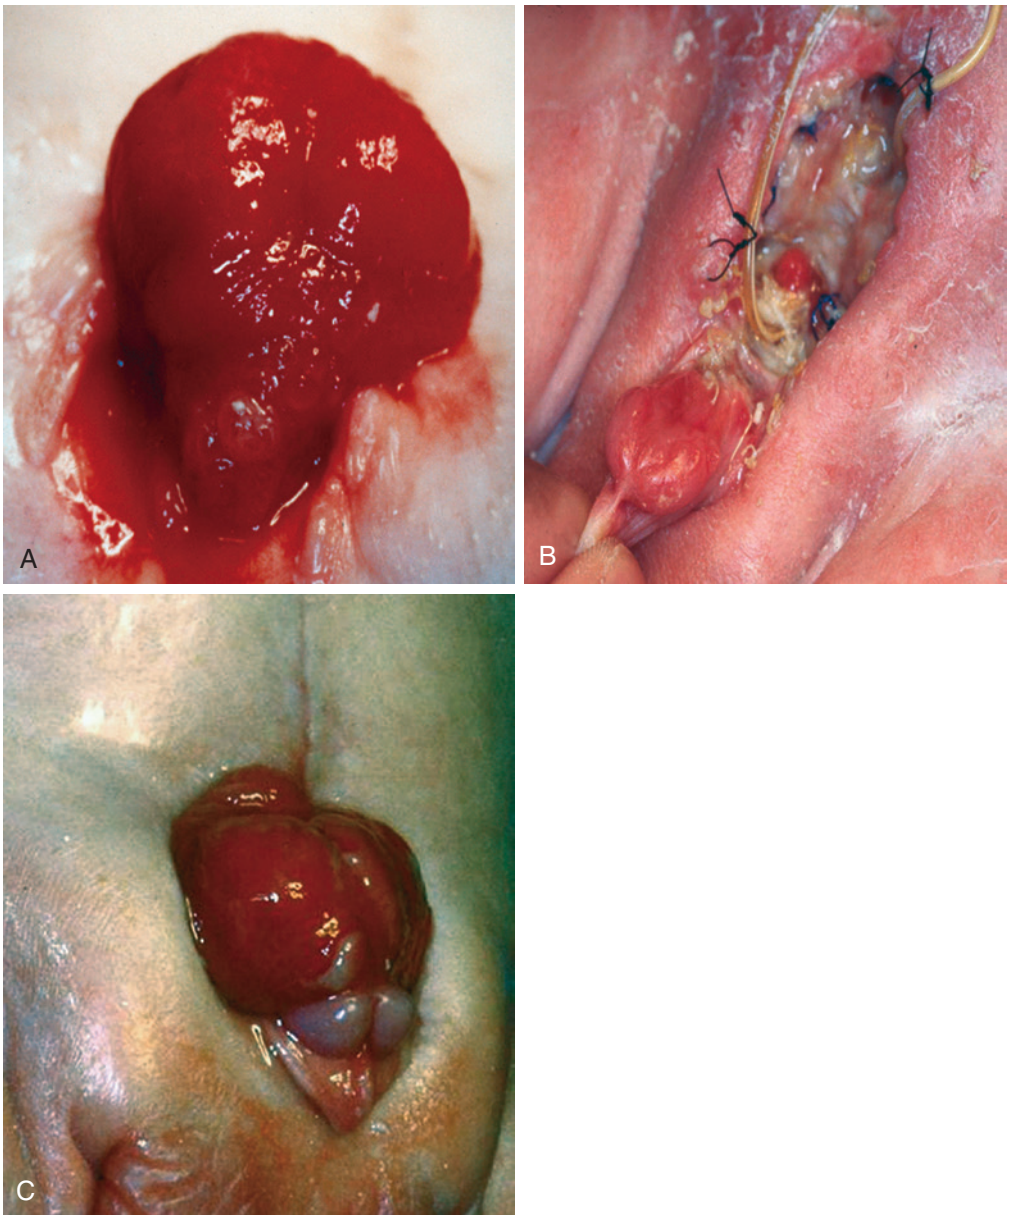

Figure 59.1 A, Complete bladder dehiscence in a 2-month-old girl whose primary exstrophy closure was performed at 2 days without osteotomy. B, Bladder dehiscence with early granulation tissue following initial exstrophy closure with insufficient mobilization of the vesicourethral unit. C, Bladder dehiscence from the lower end of the midline abdominal incision in a boy with loss of penile skin.

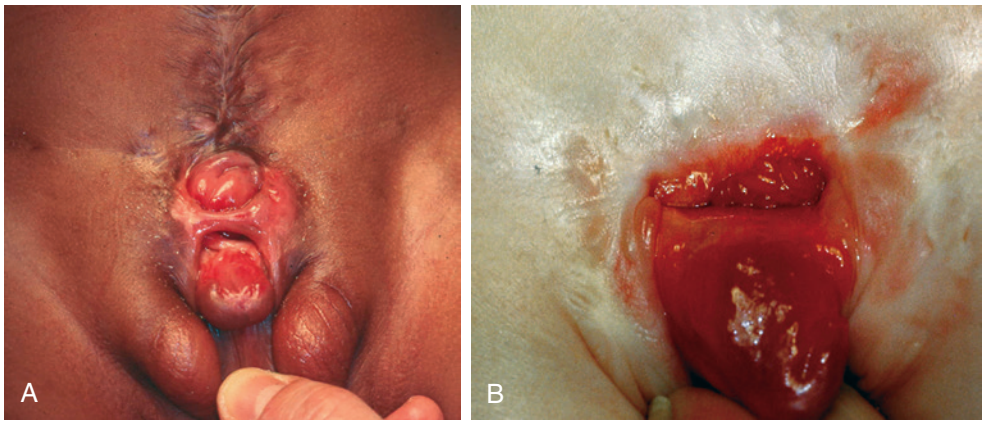
to allow free egress of urine.[1] In very selected cases, this technique can be combined with formal epispadias repair in patients who have a generous bladder template, an adequately sized penis, and a deep urethral groove. However, this complex procedure should only be performed by surgeons experienced in treating bladder exstrophy. Regardless of the chosen method, free egress of urine during healing is essential.

To prepare the newborn infant for later bladder neck repair in an attempt to achieve continence, the bladder, bladder neck, and posterior urethra must be placed well within the pelvis. This placement allows the bladder to drain under a well-closed pubic arch and for the pelvic floor musculature to aid in eventual continence by compressing the urethra to interrupt the urinary stream. In addition, ultimate tailoring of the bladder neck in a "funnel" manner and suspension of the vesicourethral angle are more readily accomplished when the bladder and bladder neck are located deep in the pelvis. These later maneuvers are distinctly more difficult when the bladder is superficial and is covered merely by skin or attenuated fascia and when continued mobility of tissue between the pubic bones exists.

The distance from the anal verge to the umbilicus is significantly shortened in exstrophy. Therefore deeper structures are crowded into a smaller space. Positioning these structures into the deep pelvis can be accomplished only by radical mobilization of the urogenital diaphragm and medial aspects of the pubic bone down to the level of the levator hiatus. This maneuver allows the posterior urethra and bladder to be placed deeper into the pelvis and to exit



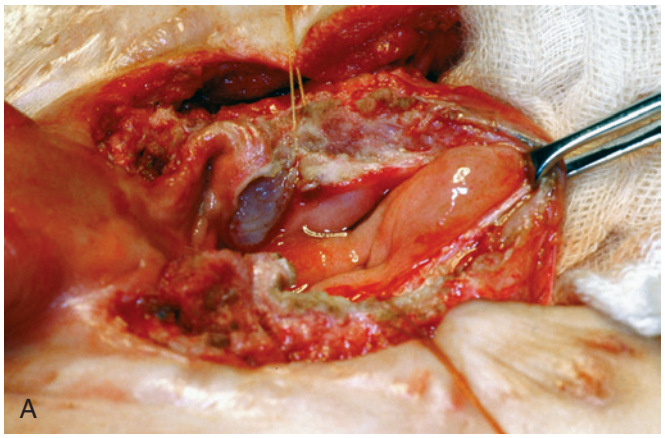


Figure 59.2 A, Bladder prolapse seen in a 2-year-old female after adoption. Note the prominence of the cystoscopic light source through the skin consistent with fascial dehiscence. B, Minor bladder prolapse that developed within 3 months in a 16-month-old boy who underwent exstrophy closure at 3 days without osteotomy. Reclosure was performed with epispadias repair and osteotomy at 18 months.

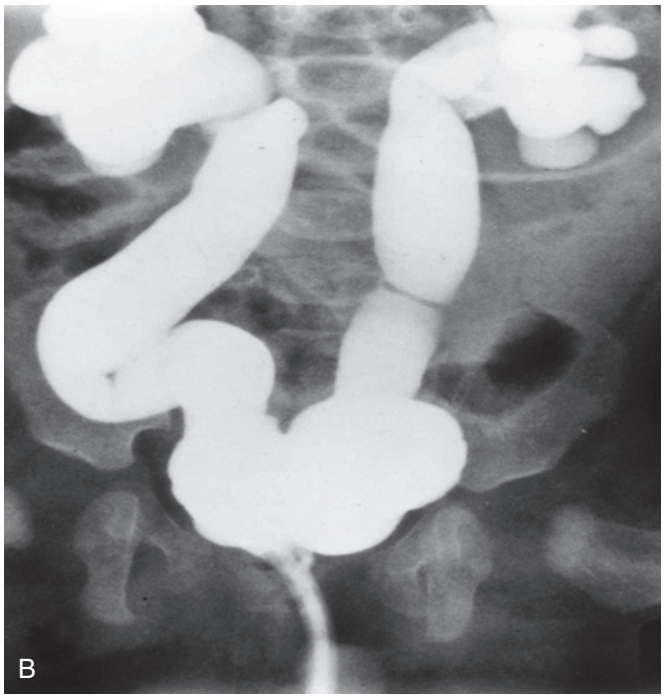

Figure 59.3 A, Dense urethral stricture following initial exstrophy closure using paraexstrophy skin flaps with a thickened bladder and posterior urethra. B, Resultant bladder and upper urinary tract decompensation.

the pelvis more posteriorly. At the same time, sectioning of the suspensory ligament and anterior attachments of the penis helps correct dorsal chordee and allows the penis to gain length and to lie in a more dependent position.

Formerly, paraexstrophy skin flaps were used to lengthen the urethra and to allow the bladder neck to recede into the pelvis. However, with the modern techniques of epispadias repair, including modified Cantwell–Ransley repair, this procedure is performed only rarely. In our practice, paraexstrophy skin flaps are only used if the verumontanum is located distal on the shaft of the penis near the glans; in this situation, the foreshortened urethral plate makes placing the posterior urethra and bladder deep into the pelvis impossible. These flaps are constructed with great care and are monitored carefully for the first several months after closure.

COMPLICATIONS

The previously discussed bladder and posterior urethra closure is easily accomplished when it is performed with a sterile field and with tissues that could be brought into apposition without tension and immobilized during the healing period. Infection, tension, and movement, along with an indwelling urethral catheter, can cause wound separation and exposure of deeper holding sutures that can result in subsequent minor or major degrees of bladder prolapse or even complete dehiscence.

Infection

To limit the potential for infection, the bladder should be closed as soon after birth as possible. From birth until the time of bladder closure, the bladder should be protected with a nonadherent plastic film such as plastic (Saran) wrap to prevent petroleum jelly, gauze, umbilical clamps, or the diaper itself from denuding the mucosa and removing the epithelium and natural surface antibodies. The bladder surface should be irrigated at each diaper change with sterile saline solution at body temperature. All efforts should be made to minimize diaper rash and ammonia burns that occur in this area from contamination with urea-splitting organisms. The umbilical stump should be tied with a silk suture below the umbilical clamp and the clamp removed to protect the bladder template.

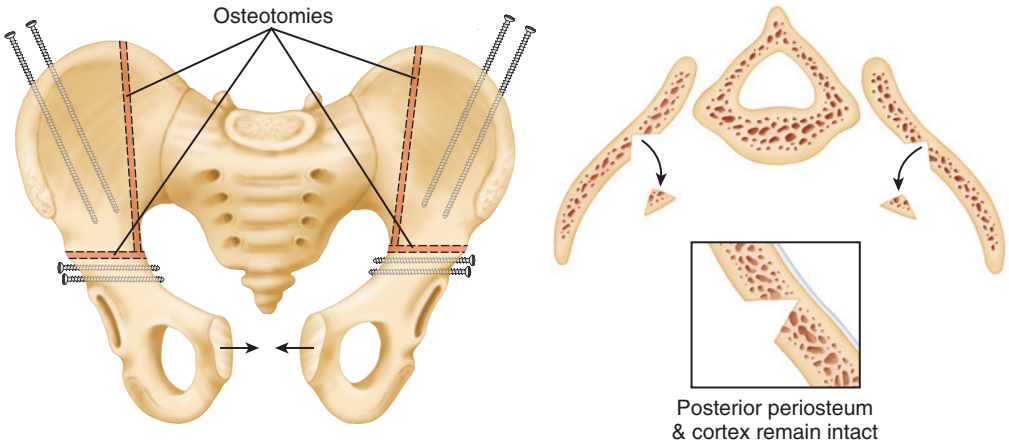

Figure 59.4 Combined anterior innominate and vertical iliac osteotomy and pin placement with preservation of posterior periosteum and cortex.

At the time of initial closure, antibiotics (typically ampicillin and gentamicin) are given preoperatively and are continued for 10 to 14 days postoperatively, with subsequent transition to oral prophylactic antibiotics. Antibiotics remain an essential adjunct to successful bladder closure because exstrophic bladders and the surrounding tissues inevitably become contaminated. The administration of antibiotic therapy is an attempt to convert the contaminated area into a clean surgical wound. In addition, the local area is thoroughly washed and cleansed with povidone-iodine, and the bladder and its interstices are liberally soaked.

The patient is prepared from the nipples to the knees anteriorly and from the base of the scapula down to the popliteal fossa posteriorly. The entire area is then draped into the operative field. This method allows access to the posterior body while manipulating the pelvic ring to bring the pubic bones together and to the orthopedic fixating device should an osteotomy be performed. Finally, gauze or an adhesive surgical dressing is inserted into the patient's anus to prevent stool contamination during the procedure.

Wound Tension and Mobility

Wound tension and mobility also contribute to wound dehiscence. These situations are prevented by firm anterior fixation of both sides of the pubis, whether or not an osteotomy is performed. After the induction of anesthesia, the patient is examined to reapproximate the pubic diastasis, and the elasticity of the pubis is noted. As long as the pubic bones can be easily coapted without tension, closure is performed without osteotomy. This situation typically occurs when the pubic diastasis is ≤4 cm, and particularly when the newborn undergoes the closure procedure in ≤72 hours. If the diastasis is >4 cm or if any uncertainty exists about the mobility of the pubic bones, an osteotomy is warranted. Those patients with a very large bladder template and a wide pubic diastasis stand to benefit the most from successful closure, and a bilateral osteotomy will help protect the closure and ensure an excellent result. Osteotomy reduces tension on the midline wound closure and is most beneficial in those patients who do not undergo delayed closure, reclosure after initial failure, or those newborns with a large size bladder template with wide diastasis.

Our experience with combined anterior innominate and vertical iliac osteotomy in >100 patients led us to adopt this procedure because of decreased blood loss and operating time (Fig. 59.4).[15] When the operation is performed using this position, the anterior apposition is achieved without flattening the pelvis and thus without drawing the penis inferiorly under the pubic closure. Therefore penile length is enhanced rather than decreased by the osteotomy procedure.

Movement during healing often results in excessive moisture, eventual infection, and subsequent dehiscence. Fixation of the wound is vital for initial healing. A three-part plan is recommended to obviate the problem:

1. An attempt is made to coapt the pubic bones with a horizontal mattress suture tied on the outside of the closure. When this is accomplished, another heavy suture can be easily placed in the lower rectus fascia at the junction of the rectus fascia onto the top of the pubic bone, which is now closer to the midline. The pubic stitch must be of very large caliber, usually number 2 nylon, to give the initial strength required for closure. The same caliber suture is also used in an interrupted fashion above the pubic closure in the lower rectus fascia. As shown by biomechanical testing by Sussman and associates,[16] number 2 nylon suture provides the best load-to-failure ratio among several methods of pubic approximation using various commonly employed suture materials. However, all approaches are weak compared with the intact pelvis.
2. Patients who undergo a closure procedure without pelvic osteotomy are kept in modified Bryant's traction for 4 weeks to complete pelvic ring closure and pubic healing. Patients who undergo combined anterior innominate and vertical iliac osteotomies are kept in an external fixating device and modified Buck's traction for 4 weeks in primary closures and 6 weeks in secondary closures (Fig. 59.5). Plaster casting, mummy wrapping, and other maneuvers have been used by other surgeons but are not recommended because these methods are less effective and are associated with significant complications (Fig. 59.6).[10,17] In a series of 86 failed closures in patients referred to the Johns Hopkins Hospital for definitive treatment, these alternative measures were associated with failure of the closure in a majority of cases because they provided insufficient immobilization.[17]

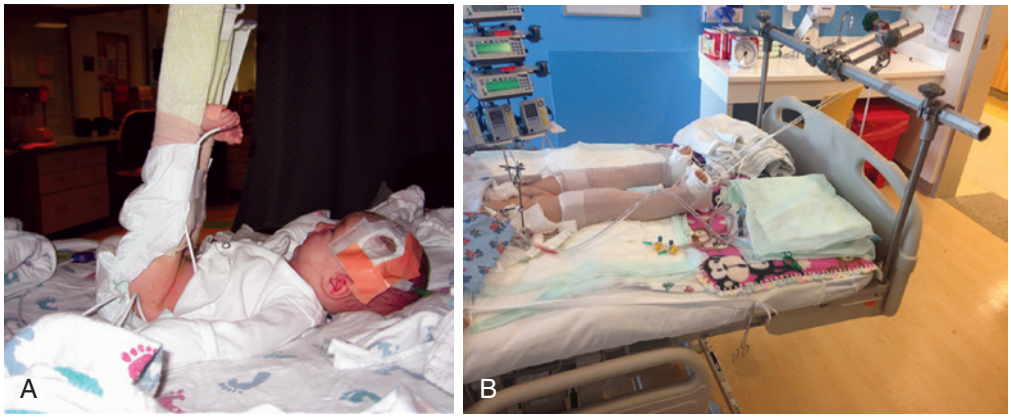

Figure 59.5 Adequate postoperative pelvic and lower extremity immobilization. A, No osteotomy: modified Bryant's traction for 4 weeks. B, With osteotomy: Buck's traction and external fixator for 4 weeks (6 weeks in secondary closures).

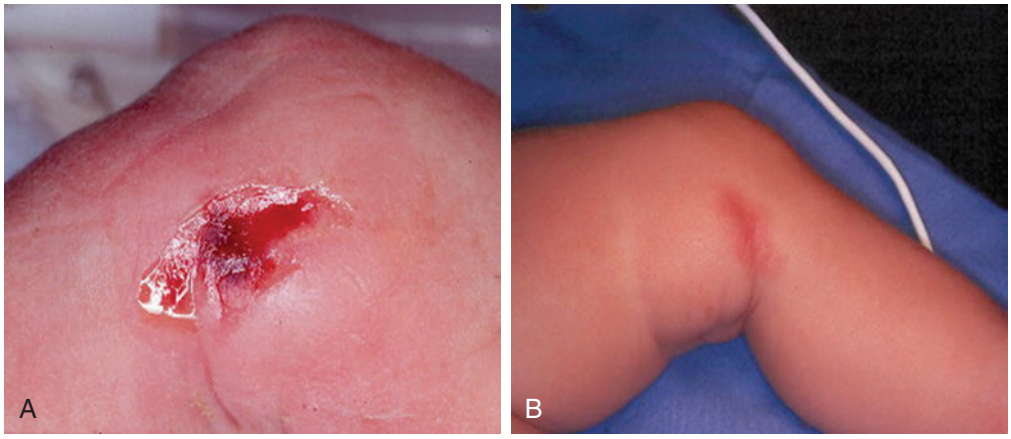

Figure 59.6 Complications of mummy wrap. A, Pressure sore on the medial knee after wrap removal. B, Persistent scar after 3 months.

3. The child's muscular activity, incisional pain, and bladder spasms must be controlled to permit wound fixation. In our unit these goals are achieved through collaboration with our pediatric anesthesia colleagues who place a tunneled epidural catheter, which is left indwelling after closure. This epidural catheter, along with supplemental intravenous narcotics, diazepam, and anticholinergics, keeps the child still and obviates pain. This treatment necessitates a team approach with physicians, nurses, parents, and members of the pediatric pain service who pamper the child to ensure that pain, frustration, hunger, and muscle and bladder spasms do not produce undue or prolonged activity that defeats attempts to prevent wound mobility.

Mothers are encouraged to nurse and cuddle their babies while these infants are in traction and to assist the nursing staff when the children appear agitated. When the mother is not present during the postoperative healing phase, recorded tapes of fetal heart sounds are often used to simulate the intrauterine environment. Through diligent care and pampering as well as the liberal use of the continuous caudal epidural catheters, analgesics, antispasmodics, and tranquilizers, the goal of providing a calm, pain-free postoperative course with proper immobilization may be reached.

Osteotomy Complications

We believe in performing pelvic osteotomies as indicated because 90% of children referred to our institution following partial or complete bladder dehiscence do not have an osteotomy or adequate lower extremity immobilization.[17,18] Controlled fracture of the pelvis allows the pubic rami to be approximated in the midline and thereby permits the bladder to be placed in a more physiologic position. Although various anatomic approaches to osteotomy have been implemented, we favor the combined anterior innominate and vertical iliac technique because of its technical practicality and equivalent or improved outcomes.[19,20]

In a series reported by Baird et al.[15] of 68 patients who underwent combined anterior innominate and vertical iliac osteotomies, no episodes of osteomyelitis and only one external fixator pin site infection occurred. The complete absence of osteomyelitis in this modern series is probably the result of the use of broad-spectrum antibiotic coverage as well as the meticulous pin site care given by the nursing staff at our institution. With careful attention to wound care, even superficial pin site infections are rare.

Another complication of the osteotomy procedure described in some older series is partial femoral nerve palsy.[19] We have since changed our practice such that currently, after fixator placement, we do not tighten the device until

≥7 days after the primary surgical procedure. The external fixating device is then rotated medially to help ensure complete pubic bone apposition. With this modification, we have observed only two partial femoral nerve palsies in our last 100 patients, and both completely resolved.[15]

Undue blood loss has not been a problem with pelvic osteotomy, even in very young patients. Nevertheless, osteotomy wounds do ooze fairly frequently until clot formation inside the osteotomy is adequate. In some patients who have undergone failed closure and who need repeat pelvic osteotomy, blood loss can be more extensive and some patients may require transfusion. Nonetheless, the added benefit of closure performed with repeat pelvic osteotomy is worth the slight increase in operative blood loss.[20]

The return of pubic diastasis occurs in all patients, especially in young infants in whom the pelvic bones are not as strong. However, the diastasis is less than the initial defect, and when patients undergo bladder neck reconstruction, the residual diastasis is narrow and a firm intrasymphyseal bar is easily palpated. This observation underscores the importance of adequate fixation and solid closure of the pubis to allow a strong intrasymphyseal bar to form. Although it is not sufficient to prevent ultimate recurrence of some degree of pubic diastasis, this union is essential during the immediate postoperative period of wound closure and healing. This point was aptly demonstrated in the report by Baird et al.[15] who noted that none of the patients with classic bladder exstrophy who underwent a combined osteotomy developed bladder prolapse or wound dehiscence.

Bladder Outlet Obstruction

When paraexstrophy skin flaps are used, urethral stricture can occur where the flaps join in the midline or to the bladder neck. These strictures have generally been treated successfully with dilation alone and only a few have required operative revision. However, several patients referred to our institution developed severe stricture at this location that resulted in massive hydronephrosis and reflux; these patients generally required multiple procedures to correct this problem.

In a review by Gearhart and associates,[21] 31 of 78 patients (40%) who had undergone paraexstrophy skin flap procedures with initial bladder exstrophy closure developed strictures. Various maneuvers were employed to correct these problems including direct vision urethrotomy in 12 cases, urethral dilation in four cases, open revision in three cases, and full-thickness grafts in five cases. The other seven patients had such complex strictures that they required continent diversion (five), colon diversion (one), or cutaneous ureterostomy (one). The last two patients had undergone vesicostomy for their strictures elsewhere before they were referred to our institution.

Despite the decreased use of paraexstrophy skin flaps, they are a viable approach when the urethral plate is very short. This will allow positioning of the bladder in the deep pelvis behind the pubic closure by lengthening the urethral plate. The use of paraexstrophy skin flaps demands special attention to design, careful placement, and avoidance of urinary drainage catheters through the urethra. Indwelling catheters through the urethra can cause ischemia leading to the aforementioned complications. When paraexstrophy skin flaps are used, careful follow-up, especially in the immediate 4–6 postoperative months, is mandatory to avoid complicating strictures and their sequelae.

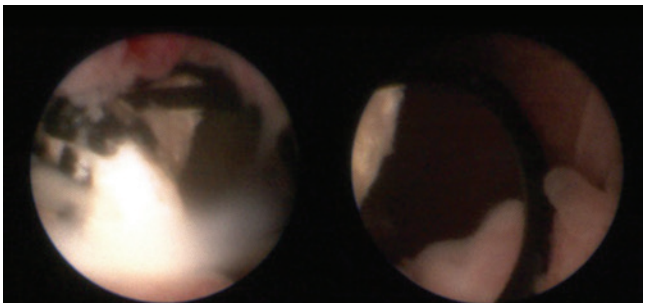

Figure 59.7 Erosion of the intrapubic stitch seen with two views cystoscopically prior to epispadias repair with associated stone.

We have also seen severe urethral strictures after CPRE, as described by Grady and Mitchell,[22,23] and after the Kelly repair[24] using radical soft tissue mobilization.[23,24] In many of the patients undergoing these repairs, urethral closures associated with stricture formation occurred. Whether these complications resulted from ischemic damage of the urethral plate or technical error is unclear. However, severe strictures can be seen after both the CPRE repair and the Kelly repair.[25,26]

Another outlet complication of primary closure is erosion of the intrapubic stitch into the posterior urethra during the healing process (Fig. 59.7). This complication can manifest as urinary tract infection a few months after primary closure, increasingly dry diapers in the 2 or 3 months after closure, or high residual urine volumes in the postoperative state after healing has occurred but before removal of the suprapubic tube. Immediate cystoscopy should be performed to rule out any form of obstruction if hydronephrosis is seen on a postoperative ultrasound scan, if a urinary tract infection occurs, if high residuals arise after healing is completed, or if diapers seem dryer.

An intrapubic stitch that has eroded into the posterior urethra >4 months after the operation can easily be removed through a small suprapubic incision. When this complication occurs in the immediate postoperative state, we typically leave the suprapubic tube in place for 2–3 months and then remove the stitch through a small suprapubic incision. Although this complication is rare, it led us to use AlloDerm (collagen matrix) as an extra level of soft tissue between the intrapubic stitch and the posterior urethra routinely with our exstrophy closures. With this modification, no stitch erosions into the posterior urethra have occurred; however, we have seen one erosion of an intrapubic metal bar in the posterior urethra after reclosure with osteotomy, which was successfully treated with debridement, multiple tissue layer interpositon, and wound vacuum placement.

Penile Complications

Most penile complications have been seen in CPRE and the Kelly radical soft tissue mobilization procedure. Loss of the glans, loss of one or both corpora, and loss of the entire urethral plate have been reported (Fig. 59.8).[25–27] In a recently reported series, of 55 males referred for treatment after CPRE, 13 patients had major penile soft tissue loss.[28] Whether these disastrous complications are the result of damage to the terminal arteries of the penis or injury to the

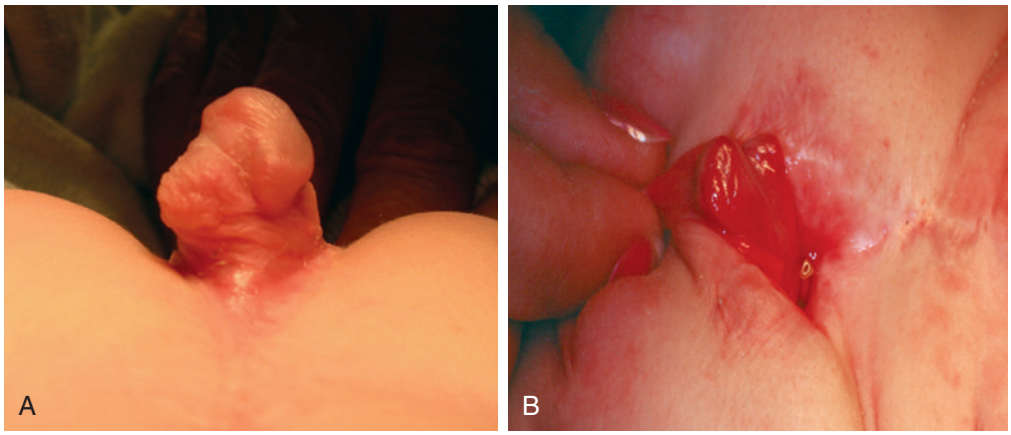

Figure 59.8 A, Loss of left hemiglans following complete primary repair of exstrophy. B, Loss of right hemiglans and distal corpora.

bulbar artery as it exits into the corpus spongiosum from the common penile artery is unclear. In addition, excess venous congestion of these tissues from overzealous pubic closure could be implicated. If congestion occurs after pubic closure, the intrapubic stitch should be removed and replaced more cephalad on the pubic rami. Whatever the cause, this operation carries significant risks and should be performed only by experienced surgeons.

Other Complications

Penile lengthening procedures must not be taken lightly because brisk bleeding can occur during mobilization of the prostatic plate in the male patient and can lead to damage to the corpus cavernosa or spongiosum. Care must be taken during dissection over the corporal bodies, especially between the lower edge of the urogenital diaphragm and the urethral plate on top of the corpora cavernosa. In some referred patients, corporal damage was so severe that it resulted in the inability to achieve erection in the corpus on one side. If this condition is not corrected, it will permanently interfere with erections and sexual function.

Hypertension remains a major concern in patients undergoing primary closure. This problem can be eliminated by ureteral intubation begun at the time of closure and maintained for 10–14 days postoperatively. Bladder drainage is accomplished with a suprapubic Malecot catheter. However, if the ureteral tubes are draining well and the child will be in traction for 4–6 weeks, we frequently do not remove the stents until healing is complete.

A commonly seen complication of ureteral intubation is blockage of the small ureteral stents. Normally, these stents are 3.5 to 5Fr pediatric feeding tubes that have a small perforation at the end. These tubes are easily clogged by debris or small blood clots, and we simply incise the end of the tube to make one large hole that is easier for irrigation. These stents are secured to the suprapubic tube at the skin line with Steri-Strips to keep them in position and to prevent inadvertent removal. The stents and the suprapubic tube are irrigated at regular intervals to insure patency.

LATE POSTOPERATIVE STATE

To prevent complications after the period of immobilization, external fixation, and healing, the adequacy of the bladder outlet should be tested before discharge. After the ureteral stents are removed, a renal ultrasound is obtained to rule out hydronephrosis. The suprapubic tube is then clamped and residual urine volumes are measured over a few days via gravity drainage. If the residual urine volumes are consistently low, the suprapubic tube is removed. A sample for urine culture is always sent from the bladder through the suprapubic tube before its removal to ensure that the bladder urine is sterile. If the residual urine volumes are high, cystoscopy is mandated to look for a stricture or erosion of the intrapubic stitch into the posterior urethra.

Patients are administered long-term suppressive antibiotics postoperatively, and the effectiveness of these drugs is monitored by monthly urine cultures. Renal and bladder ultrasounds are obtained 6 weeks after discharge and again at 4 months. This monitoring ensures that the upper urinary tract drains appropriately and that obstruction or reflux is not causing any undue change in the upper urinary tract.

Treatment of the newborn with bladder exstrophy is a significant undertaking that requires a high-quality team of neonatologists, pediatricians, pediatric anesthesiologists, nurses, pediatric orthopedists, and surgeons. To protect against and manage complications, a concentrated team effort should be organized so that the child can be adequately prepared for a formal continence procedure at a later date.

INCONTINENT INTERVAL

Although patients who underwent successful newborn exstrophy closure may appear free of obvious complications, detailed follow-up is required for early detection of impending problems. Normal bladder closure converts a child with exstrophy into one with complete epispadias and incontinence. When epispadias repair is combined with bladder closure in the newborn period, the child remains incontinent and follow-up is the same. Ultrasound scans are repeated at regular intervals during the 2–3 years after closure to detect any upper urinary tract changes that can result from obstruction, reflux, or infection. Children who develop a significant dry interval early on must be carefully monitored for outlet obstruction.

CONCLUSION

The ability of functional closure of bladder exstrophy to yield a 70–80% continence rate with preservation of renal

function was documented by several series.[3,6–8,12,29] However, the success of initial bladder closure most significantly affects the eventual ability to achieve continence through spontaneous voiding without the use of clean intermittent catheterization. After one failed bladder exstrophy closure, the chance of achieving adequate capacity for bladder neck reconstruction is reduced to 68%,[30] and the chance of attaining ultimate dryness after bladder neck reconstruction is only 30%.[31] After two failed exstrophy closures, only 40% of patients achieve enough bladder capacity for bladder neck reconstruction and only 20% overall achieve continence; 80% of these patients require intermittent catheterization and bladder augmentation.[10] Thus, after two or more failed exstrophy closures, only 20% of patients are continent and voiding through the urethra. This underscores the need for successful primary closure and illustrates the need for closure to be performed at specialized centers of excellence.

Epispadias Repair

OVERVIEW

Many surgical techniques have been described for reconstruction of the penis and urethra in patients with classic bladder exstrophy. Four key concerns must be addressed to ensure a functional and cosmetically acceptable penis:

1. Dorsal chordee
2. Urethral reconstruction
3. Glandular reconstruction
4. Penile skin closure.

Historically, most epispadias repairs borrow heavily from Cantwell's original description in 1895.[28] Although these early pioneering steps in penile reconstruction were used, devascularization of the urethral closure occurred and led to the abandonment of this approach. Young modified Cantwell's technique by leaving the urethral plate attached to one corpus and transposing this plate ventrally.[32]

Although some penile lengthening can be achieved with release of chordee during the initial bladder closure, it is often necessary to perform penile elongation with release of chordee at the time of epispadias repair in patients with bladder exstrophy. All remnants of the suspensory ligaments and residual scar tissue must be excised, and further dissection of the corpus cavernosa from the inferior pubic ramus is often required. Lengthening of the urethral groove is also essential. Regardless of whether paraexstrophy skin flaps were used at the time of bladder closure, further lengthening is needed. The urethral plate must be completely dissected from the corporal bodies both proximally to the bladder and distally toward the glans to achieve maximal penile length. However, the urethral plate is left attached to the distal centimeter of the glans and the Ransley mesentary to preserve blood supply.

Furthermore, to release dorsal chordee, one can lengthen the dorsomedial aspect of the corpora by incision and anastomosis of the corpora and by placement of dermal graft to allow lengthening of the distal aspect of the corpora. Ransley and colleagues[33] introduced this concept of releasing dorsal chordee by incision and anastomosis of the dorsomedial aspect of the corpora over the urethra and ventral meatotomy at the distal end of the glans and thus moving the urethra to a more anatomic position. Various authors have reported success with the Cantwell–Ransley repair and modifications thereof.[34–38]

Urethral reconstruction is an important aspect of external genital reconstruction in patients with bladder exstrophy. This procedure can be accomplished by several methods. In the late 1980s, we began to use the Cantwell–Ransley repair exclusively for the repair of epispadias in patients with bladder exstrophy or epispadias. We reported on our success with long-term experience with this procedure.[34] In our variation of the Cantwell–Ransley repair, the urethral plate is mobilized almost completely from the glans penis to a location above the prostate and is transferred to the ventrum of the penis under the separated corpora. Mitchell and Bagli[39] reported a technique of complete disassembly of the corpora from the urethral plate in an attempt to lengthen the penis and to correct dorsal chordee. Unfortunately, 30–70% of these patients are left with hypospadiac meatus requiring hypospadias repair.[39–41]

Historically, bladder neck reconstruction was performed before urethral or penile reconstruction. However, the finding of a significant increase in bladder capacity after epispadias repair in those patients with small bladder capacity prompted a change in our management program in the late 1980s. In a review of patients with small bladders after initial closure that were deemed inadequate for satisfactory bladder neck repair, we noted a mean increase of 55 mL after only 22 months following urethroplasty for epispadias.[42] These patients subsequently underwent successful bladder neck reconstruction. At present, construction of a neourethra, penile lengthening, and dorsal chordee release are performed between 6 and 10 months of age. Because most boys with bladder exstrophy have a small, widened penis and a shortage of available skin, all our patients undergo testosterone stimulation before urethroplasty and penile reconstruction.

COMPLICATIONS

The most common complication of epispadias repair is a urethrocutaneous fistula. In a series of 129 Cantwell–Ransley repairs by Baird et al. of the Johns Hopkins Hospital,[34] fistulas developed in the immediate postoperative period in 16% of patients with bladder exstrophy and in 13% of patients with complete epispadias. In 5 of 18 patients, the fistulas closed spontaneously in the first few postoperative months. The other 13 patients underwent a separate procedure to close the fistulas.

Fistulas in this group of patients all uniformly appeared at the base of the penis, where the urethra comes up proximally between the corporal bodies and then goes under the pubic bone. Initially, we thought that this location would be the most common area of fistula formation when paraexstrophy skin flaps were used. However, fistulas occurred more often in patients with an intact urethral plate. In all patients, whether paraexstrophy skin flaps were used or not, fistulas occurred at the base of the penis. Currently, while performing epispadias repair, we harvest and de-epithelialize the inner aspect of the ventral foreskin or use the tunica vaginalis as a soft tissue flap to cover the urethral repair at the base of the corporal bodies before it dives under the

corpora to the level of the prostate. Our hope is that adding this extra layer of soft tissue will further reduce the incidence of fistula.

Although the most common complication of epispadias repair is urethrocutaneous fistula, in a series of 129 Cantwell–Ransley repairs, nine cases of urethral stricture occurred, all at the proximal anastomosis.[34] One of these strictures responded quite well to direct vision internal urethrotomy. Other techniques included urethral dilation and intermittent catheterization, free full-thickness skin grafts, and buccal grafts. Currently, we use a buccal mucosa graft to replace the urethra instead of a full-thickness skin graft; therefore the incidence of stricture formation should decrease in time.

Another complication of epispadias repair is loss of penile skin. As mentioned previously, these patients have a preexisting paucity of skin, and testosterone is used to increase the vascularity and availability of local penile skin. In the previously mentioned series by Baird et al.,[34] 15 patients had minimal separation of dorsal skin that granulated without incidence. No instances of substantial skin or glans loss have been observed in our entire experience with the Cantwell–Ransley repair.

Another epispadias repair procedure is complete penile disassembly, as described by Mitchell and Bagli in 1996.[39] The fistula rate reported with this repair was 18% in a small published series.[43] Some of the most worrisome complications of epispadias repair have been observed with this approach. Loss of the glans, loss of the corpora, and loss of the urethral plate were reported in a combined series by Husmann and Gearhart.[27] In addition, data by Purves and Gearhart showed similar risks with the Kelly radical soft tissue mobilization technique.[26] These serious complications point to the risks of this procedure, especially when it is performed by a surgeon who does not routinely operate on delicate, infant tissues, because they can doom the ability of the child to undergo later bladder neck repair and further reconstruction.

Dorsal chordee can persist after epispadias repair. In the review of 129 patients with the Cantwell–Ransley repair, most patients had penises that were straight or deflected downward, but many of these patients were still quite young.[34] Patients >18 years old who engage in satisfactory sexual intercourse state that their penises are quite acceptable, both functionally and cosmetically. Whether simple rotation of the corpora is adequate or whether corporal incision and anastomosis are required is a judgment call at the time of the surgical procedure. Whether these patients require further penile straightening as they achieve sexual maturity is unknown, but they certainly will require prolonged follow-up.

Our experience with older children finds that mobilization of the urethral plate and corporal rotation are inadequate to correct the chordee completely. Incision and anastomosis of the corporal bodies or dermal grafts are required to achieve penile straightness in these older patients. With current methods of epispadias repair, the urethra is straight under the corporal bodies. The urethra obtains a more anatomic and straighter course and is supported dorsally by the more normally placed corporal bodies. This issue has become increasingly important because, should intermittent catheterization be needed in the future, an easily catheterized urethra may obviate the need for a continent urinary stoma. More than 100 patients have undergone cystourethroscopy or urethral catheterization and a smooth urethral tube that is easy to negotiate was present in all patients.

Bladder Neck Reconstruction

OVERVIEW

Bladder neck reconstruction is usually performed at the age of 4–5 years when the child is mature enough to want to be dry and participate in a postoperative voiding training program. Bladder capacity is measured with a gravity cystogram obtained while the child is under anesthesia. If the bladder capacity is ≥85 mL, bladder neck reconstruction can be considered.[10] Because all patients with bladder exstrophy have vesicoureteral reflux, an antireflux procedure is required at the time of bladder neck repair. One common problem that we have seen in multiple patients is bladder neck reconstruction performed when the child is 2–3 years of age. At that time, the child has no interest or need to be continent and these operations are doomed to failure.

Some repairs such as the CPRE and the Kelly repair have been purported to decrease the number of operations and to obviate the need for bladder neck reconstruction. In a series by Grady and associates,[44] 72% of female patients and 86% of male patients who underwent CPRE required bladder neck reconstruction, as did 80% of patients in another series by Borer and colleagues.[45] Recent series have shown that the vast majority of patients will require bladder neck reconstruction after CPRE.[46,47]

At the time of initial bladder neck repair, an attempt is made to obtain continence by creating a long, narrow bladder neck and an elongated posterior urethra in the modified Young-Dees-Leadbetter manner.[48] The reflux is corrected by transtrigonal or cephalotrigonal reimplants, which are also necessary to move the ureters away from the bladder neck repair so that trigonal tissue can be used to create the bladder neck. In the past, the classic Cohen transtrigonal procedure was used exclusively.[49] However, when the ureters lie low and laterally on the bladder floor, our preference is a more cephalic course for the ureters that involves using the same hiatus but constructing a submucosal tunnel in the cephalad position.[50] This procedure brings the ureteral meatus from each ureter together near the midline of the bladder. This approach works quite well with ureters positioned onto the upper aspect of the trigone and away from the newly reconstructed bladder neck.

Outlet pressure and continence length can be measured by intraoperative urethral pressure profilometry, and resistance of the bladder neck is measured after bladder closure. Our research indicates that urethral closure pressure of 70 to 100 cm H_2O over a length of 2.5 cm is necessary to achieve a successful outcome.[51] Finally, a Marshall-Marchetti-Krantz bladder neck suspension is performed to further increase the continence and urethral closure pressure further.[52] This repair must be allowed to heal for 3 weeks without indwelling urethral stents and with a suprapubic tube to drain the urine before voiding trials begin.

Numerous factors account for a successful outcome after bladder neck repair. Leadbetter[48] considered the length of

the bladder neck to be the most significant factor contributing to continence. Therefore, we follow his recommendation and construct the bladder neck approximately 2.5–3 cm in length.[48] In addition, bilateral pelvic osteotomies performed at the time of initial closure permit placement of the urethra in the pelvic ring. This maneuver allows for the levator ani and puborectalis muscles to aid in voluntary urinary control. A bladder neck suspension aids in preventing static and stress incontinence. The effectiveness of bladder neck suspension has been demonstrated intraoperatively using urethral pressure profilometry.[51]

The mechanism for achieving urinary continence must not compromise renal function. Both intravenous pyelography and ultrasound studies have been used to evaluate the upper urinary tract in our patients following bladder neck reconstruction. In a series of 189 patients treated by a single surgeon at our institution from primary closure through bladder neck reconstruction, 67 male patients were identified who had a minimum of 5-year follow-up. Of these, only one patient developed hydronephrosis after bladder neck reconstruction, and that complication was corrected with reoperative surgical repair.[6] All of our patients and parents undergo an intensive voiding improvement program prior to bladder neck reconstruction including not only the urologist, but also senior clinical nurses and child psychologists to ensure patient readiness.

COMPLICATIONS

Complications of bladder neck reconstruction do occur and include the following:

1. Difficulty with urinating after bladder neck repair
2. Persistent incontinence
3. Development of hydronephrosis.

In the previously mentioned series of 67 bladder neck reconstructions with long-term follow-up, difficulty with urination developed in 20% of patients postoperatively.[6] All these patients learned to void except a single patient, who required long-term intermittent catheterization for continence.

Obstruction to the flow of urine occurring at the end of the 3-week healing period may be managed by continued suprapubic drainage, gentle dilation of the urethra with passage of an indwelling urethral catheter, or intermittent self-catheterization. As an initial step, an 8Fr Foley catheter is placed while the patient is under anesthesia; the surgeon uses a pediatric cystoscope and guidewire during catheterization, and the catheter is left in place for 3–5 days. After removal of the catheter, voiding usually occurs. If difficulty persists, an extended period of catheter drainage is employed before another voiding trial is attempted.

As indicated from the results of our study, urinary continence with a long-term dry interval does not occur immediately after bladder neck reconstruction and can take ≤2 years to achieve. In our series, the interval between bladder neck reconstruction and urinary continence ranged between 4 and 23 months, with a mean time of 14 months.[6] Nighttime dryness varies but can also take ≤2 years to obtain. Most patients have dry intervals of 3 hours within the first year. During the second year, a few additional patients achieve successful continence. However, if they are still not dry for 3 hours during the day after the second year, bladder neck reconstruction has failed.

The bladder must also adjust to a new environment and new constraints. In addition, and probably more important, the patient must learn for the first time to recognize bladder filling and must be able to initiate voluntary detrusor contractions. With cooperation and time, urinary continence can be achieved in 71–74% of patients who have had a successful initial closure operation.[6]

If stress incontinence or dribbling is present 3–4 weeks after bladder neck reconstruction, the chance of obtaining adequate control is almost nonexistent. As noted, some patients gain continence with time, usually by increasing their bladder capacity and dry interval rather than by achieving better closure of their outlet. In male patients, growth of the prostate was formerly thought to help produce control of voiding. However, research by Gearhart and colleagues[53] showed that the prostate probably contributes little to the eventual attainment of continence.

Continuous postoperative dribbling typically indicates that further intervention will be required. Although the injection of substances (e.g., bovine collagen and dextranomer/hyaluronic acid [Deflux]) into the bladder neck after modified Young-Dees-Leadbetter bladder neck reconstruction is simple and safe, and although this approach has been used to try to improve continence, the success rate is approximately 45%.[54,55] Unfortunately, this procedure is typically not sufficient to create continence and should be used only as an adjunct to bladder neck reconstruction.

Bladder neck reconstruction can be repeated a second time if it fails. However, bladder capacity must be superb and urodynamic studies must reveal a stable bladder with absence of uninhibited contractions. In a series by Gearhart and colleagues,[56] only 50% of patients with failed prior bladder neck reconstruction were candidates for reoperative surgical procedures. In this highly selected group, continence rates (dry day and night) were approximately 85% after the reoperative bladder neck repair. All these patients had excellent bladder capacity (>100 mL) and stable function demonstrated on urodynamic examination before the reoperation.

Hydronephrosis can persist after bladder neck reconstruction and reimplantation. Careful follow-up to provide frequent evaluation of the upper urinary tract must be undertaken to prevent this complication. If hydronephrosis occurs and a small bladder capacity persists, bladder augmentation can be performed to protect the urinary tract and to achieve improved continence. In a review by Surer and colleagues,[57] 91 patients whose bladder exstrophy reconstruction failed required either bladder augmentation or continent urinary diversion. Of these patients, 62 had undergone previous bladder neck reconstruction but remained incontinent because of small bladders that did not grow after bladder neck reconstruction. None of these patients had reflux after their failed bladder neck procedures.

Treatment options in this group of patients include the following:

1. Placement of an artificial urinary sphincter and bladder augmentation
2. Reoperative bladder neck repair

3. Bladder augmentation with or without continent abdominal stoma
4. Continent stoma along with bladder augmentation and bladder neck transection or replacement.

The prospect of reoperation around the bladder neck after earlier failed surgical procedures makes the artificial sphincter and reoperative bladder neck procedures less attractive. However, in a bladder without reflux, the bladder neck can usually be transected safely and the bladder used as a template for augmentation and continent stoma construction.

In a series of 35 patients with bladder exstrophy who had multiple treatment failures, when the bladder capacity was >50 mL, reimplantation of the ureters into the bladder template and stoma creation were usually possible.[58] In these patients, when the bladder capacity was <50 mL, a continent stoma was implanted in the taenia of the bowel used for reconstruction and the ureters were reimplanted into the bladder template. In some cases, bladder capacity after treatment failure was so small that the entire bladder was replaced and the stoma channel was implanted into the neobladder. No major complications occurred in this group of patients. Therefore we believe that in patients with failed exstrophy reconstruction, augmentation cystoplasty or continent urinary diversion provides prolonged stability in the upper urinary tract and continence, and this approach has proved a successful alternative to urinary diversion.

Finally, stones can form in the urinary tract after bladder neck repair. In a series of 67 bladder neck repairs, bladder stones developed in seven patients and renal stones in one patient.[6] Most of these patients had difficulty with urinating after bladder neck repair and required prolonged suprapubic drainage. Thus, proper hydration and tube removal as soon as possible may aid in decreasing stone formation after bladder neck repair.

Long-Term Considerations

PENILE APPEARANCE

Most patients in our series had not reached adulthood and therefore may ultimately develop problems that occur in older patients. Some older patients seen at Johns Hopkins Hospital have problems pertaining to their exstrophy repair. Most of these young adults handle their problems well. However, the most severe problems are encountered in patients who underwent urinary diversion previously.

Certainly, penile shape and size are problems for some of these patients. Although many patients make good and imaginative use of their phallus, others voice concerns about its short and broad appearance. In addition, certain patients complain of residual chordee. Some patients have been counseled and learned to live with their problems and others have undergone surgical treatment with neophallus creation, depending on their emotional and penile status.

The penile lengthening procedure, as described by Johnston,[59] can be performed in adulthood to achieve a more dependent penile position, especially in the patient who has undergone previous urinary diversion. Sometimes, these patients can obtain greater length (usually ≈1 inch) by a repeat penile lengthening procedure, which must be carefully performed. Persistent dorsal curvature can also be corrected by dermal grafts used as corporal substitutions, which can be especially helpful in achieving a straight penile length when disproportion exists in size and length of the corporal bodies.

In an article by Mathews and colleagues from our institution,[60] the use of subcutaneously placed tissue expanders was found to be of great benefit in adults and adolescents with a history of bladder exstrophy. Penile skin can be stretched, and a considerable amount of new penile skin can be achieved in this manner. All remaining remnants of the suspensory ligaments and scars are radically excised and the penis is covered again with the newly generated penile skin. This procedure has been especially helpful in patients who have lost skin on one side of the penis or who have an overall paucity of skin secondary to surgical procedures in infancy and childhood.

PENILE AND INTROITAL DIFFICULTIES

Another problem encountered in older patients is ejaculatory dysfunction. Again, many patients who underwent previous urinary diversion may have a seminal fistula located in the mons area at the base of the penis. Ben-Chaim and associates[61] measured seminal volumes in 16 patients who were voiding through the urethra and found that 10 reported an ejaculatory volume of a few millimeters, three ejaculated only drops, and three had no ejaculations. Overall, patients with a history of bladder exstrophy ejaculate only small amounts compared with their physiologically normal contemporaries.

In adolescent female patients, the anterior location of the vaginal introitus can cause difficulty with sexual intercourse. A relaxing incision can often be made to facilitate intromission. Great care must be taken, however, because uterine prolapse has been reported after these procedures. These patients typically have short and wide vaginas, similar to the penises seen in male bladder exstrophy, and the cervix is very near the vaginal introitus. In girls who have not had an osteotomy, when one opens the vaginal introitus to make it suitable for sexual intercourse, the uterus sometimes descends, even in virginal female patients. In this case, we perform abdominal sacral colpopexy using a synthetic sling to allow sexual intercourse and pregnancy.

Many patients present with a bifid clitoris and a less than ideal appearance of the mons and surrounding area. Both uterine prolapse and an unsuitable appearance of the external genitalia appear to be less common in those patients who underwent osteotomy in the newborn period. When the pubic bones have been brought together in proper apposition, a mons-like appearance above the genitalia is created that facilitates subsequent feminizing genitoplasty without tension. Many of these female patients want a more cosmetic appearance to this area at puberty. Skin flaps and tissues expanders have been used in this area with great success.

FERTILITY AND PREGNANCY

Reconstruction of the male genitalia and preservation of fertility were not primary objectives in the early surgical

management of bladder exstrophy. Many accounts of pregnancy in female patients and impregnation by male patients with bladder exstrophy have been reported. In a review by Shapiro and associates[62] of 2500 patients who had undergone exstrophy and epispadias repair, 38 male patients had fathered children and 131 female patients had given birth. Ejaculatory fertility is rare in patients with a history of bladder exstrophy. However, in our database of >890 patients with bladder exstrophy who we have treated and followed up, we have had 18 patients deliver healthy babies with in vitro technology, and so far none of the newborns has had bladder exstrophy. In an article by Mathewset al.,[63] sexual function and pregnancy were normal in a selected group of female patients.

Libido in patients who have undergone bladder exstrophy repair remains high. The erectile mechanism in patients who underwent epispadias repair appeared intact in >90% of patients in our series who had erections following epispadias repair.[64] In a series of adult patients with long-term follow-up, all the women had normal and regular menstrual periods.[61] All these women had serious long-term relationships and were sexually active. Most experienced orgasm.

As mentioned previously, surgical complications include cervical and uterine prolapse. These young women must be informed of the likelihood of uterine and cervical prolapse even after one pregnancy. Birth by cesarean section is mandatory for women who have undergone closure and bladder neck repair or continent urinary diversion, to alleviate stress on the pelvic floor and to avoid trauma to the surgically reconstructed lower genitourinary tract.

MALIGNANT DISEASE

Most reported malignant diseases have occurred in patients with exstrophies that were left unclosed.[65] The most common tumor is adenocarcinoma, often resembling colonic malignant disease on immunohistochemical staining.[66] Investigators have suggested that rests of ectopic colonic epithelium serve as the origin of these adenocarcinomas.[67,68] Published case reports and other sources found rhabdomyosarcomas in three patients with bladder exstrophy.[69,70]

The inherent malignant potential of the closed exstrophic bladder has not been determined because long-term follow-up of a large cohort of patients with bladder exstrophy without urinary tract infections, obstruction, or chronic irritation has not been published. In an article by Novak and colleagues,[71] polyps associated with bladder exstrophy were evaluated pathologically and were found to be either fibrotic or edematous. Cystitis glandularis was often described, typically in polyps removed from bladders undergoing secondary exstrophy closures. Although no dysplasia was noted, cystitis glandularis is associated with adenocarcinoma of the bladder, and we believe these patients warrant surveillance with routine urine cytologic and cystoscopic examination as they enter adult life. We must be prudent and maintain a high index of suspicion until long-term studies become available.

Adenocarcinoma of the colon adjacent to the ureterointestinal anastomosis in ureterosigmoidostomy as well as in trigonocolonic diversion has been reported.[72,73] Gittes[74] calculated the long-term risk of developing a malignant tumor in the ureterosigmoidostomy at approximately 5%. In a study of patients who had a ureterosigmoidostomy for >15 years, the risk was found to be 11%.[75] In this study the risk of developing malignant tumors at the ureterocolonic anastomosis by 36 years of age was 11%. However, a more recent study with >30 year follow-up found only one malignancy in 13 patients with ureterosigmoidostomies still intact.[76] Although these types of urinary diversions are not commonly performed in North America at this time, we still see one to two patients a year with rectal cancer secondary to ureterosigmoidostomy. Thus, any patient who has a ureterosigmoidostomy should have an annual colonoscopy.

SOCIAL ADJUSTMENTS

Studies have shown that these patients are relatively normal and well-adjusted with good psychological integration and a positive attitude toward life.[61,77] However, the exstrophy-epispadias complex may be associated with an increased risk of anxiety disorders.[78] A recurring theme in all these patients is concern about penile length and chordee. The main objective of surgical intervention in bladder exstrophy repair is to enable these patients to achieve normal social interactions with their families and communities. With continuing excellent results of MSRE, it is gratifying that great progress has been made toward the realization of this goal.

Conclusions

This review of the complications of all methods of modern treatment of bladder exstrophy emphasizes the complexity of reconstruction of the bladder exstrophy spectrum. In experienced hands, the surgical results of primary bladder closure, epispadias repair, and bladder neck reconstruction are quite acceptable. A review of MSRE by Baird and Gearhart demonstrated that a secure abdominal wall closure, urinary continence, preservation of the upper urinary tract, and a cosmetically acceptable penis can be achieved in patients with a successful primary closure and in a reasonably high percentage of patients with an unsuccessful primary closure.[6] Similarly, in a review by Gearhart and associates,[58] all 35 patients in whom bladder exstrophy reconstruction failed were doing well following bladder augmentation or continent stoma. Therefore, although complications such as dehiscence, deterioration of renal function, and fistula do occur, with careful attention to surgical detail and frequent follow-up, these patients can have a normal childhood and can become contributing members of society.

Acknowledgment

This chapter is dedicated to the memory of Robert Douglas Jeffs, MD, FRCS(Can) (1924–2006), Emeritus Professor of Pediatric Urology at the Johns Hopkins Hospital in Baltimore, a respected teacher, colleague, and friend.

Chapter 59 Questions

1. All of the following should be routinely used for closure of an exstrophic bladder, except:
   a. Combined anterior innominate and vertical iliac osteotomy for reclosure of failed primary closure
   b. Radical mobilization of the bladder from the pelvic floor musculature
   c. Ureteral stent and suprapubic tube drainage
   d. Continuous, postoperative traction via Buck's or Bryant's traction
   e. Paraexstrophy skin flaps for urethral lengthening

2. At what point can an eroded intrapubic stitch be safely removed?
   a. 1 month
   b. 2 months
   c. 3 months
   d. 4 months
   e. >1 yr

3. Which of the following is the most appropriate style and size of suture for an intrapubic stitch?
   a. #0 polypropylene
   b. #2 polydioxanone
   c. #2 nylon
   d. #2 polypropylene
   e. #0 silk

4. Penile tissue loss is associated more commonly with which type of surgery?
   a. Modern stage repair of exstrophy
   b. Modified Cantwell–Ransley epispadias repair
   c. Bladder neck reconstruction
   d. Complete primary repair of exstrophy
   e. Augmentation cystoplasty

5. After primary repair of exstrophy, routine use of which imaging modality for postoperative monitoring of the urinary tract is advised?
   a. Renal ultrasound
   b. Voiding cystourethrogram
   c. Nuclear medicine scan
   d. a and b
   e. All of the above

6. What bladder capacity is generally considered adequate for using at least some part of the bladder as part of a continence procedure?
   a. 100 mL
   b. 10 mL
   c. 20 mL
   d. 30 mL
   e. 50 mL

7. At what point should continence surgery be considered?
   a. The child is at least 5 years of age
   b. The patient and parents have had excellent preoperative counseling regarding bladder neck reconstruction
   c. The child has expressed interest in being dry
   d. All of the above
   e. None of the above

8. Which of the following can be used for achieving additional penile length after puberty?
   a. Penile lengthening with skin release and division of the suspensory ligaments
   b. Penis transplant
   c. Neophallus creation with radial forearm flap
   d. Penile prosthesis implantation alone
   e. a and c

9. Which of the following is a concerning finding on follow-up after successful primary repair of exstrophy?
   a. Persistent urine leakage from the epispadias
   b. Asymptomatic bacteriuria found on bagged urine culture
   c. Reflux seen on cystogram
   d. Prolonged dry interval
   e. No hydronephrosis noted on ultrasound

10. If large residuals are obtained from the suprapubic tube after primary repair, the first step in evaluation should be:
    a. Cystoscopy
    b. Renal ultrasound
    c. Voiding cystourethrogram
    d. Percutaneous nephrostomy tube placements
    e. Immediate surgical exploration of the urethral closure

Case Studies

CASE 1

A 3-year-old boy is referred to your practice after recent adoption from China. He had closure in his home country near birth with posterior iliac osteotomies. Upon examination, a small vesicocutaneous fistula is seen above the epispadias.

1. After newborn exstrophy closure, appropriate immobilization of the pelvis is important for which of the following reasons?
   1. To keep the pelvis rotated medially
   2. To keep shearing forces from distracting the pubic closure laterally
   3. To take tension off the midline closure
   4. To keep the lower extremities in the midline
   5. To keep the pelvis flat on the bed
      a. 1 and 3
      b. 2 and 4
      c. 1, 2, and 3
      d. 3 and 5
      e. All of the above

2. When the initial exstrophy closure fails with complete dehiscence, what is the most appropriate next step?
   a. Immediate reclosure with pelvic osteotomy, even if previously performed

b. Place the child in immediate modified Bryant's traction with Buck's skin traction
c. Cover the bladder with moist gauze and reclose in 6 weeks
d. Perform a cutaneous vesicostomy
e. Allow healing for 4 to 6 months and then reclose with pelvic osteotomy and proper immobilization for 6 weeks

3. The most appropriate next step in management is:
a. Operative intervention with closure of fistula
b. Closure of fistula with concomittent epispadias repair to improve bladder growth
c. Immediate reclosure with bilateral iliac and innominate osteotomies
d. Exam under anesthesia and cystoscopy
e. Observation until appropriate for continence procedure

CASE 2

A 10-month-old boy presents to your clinic with his parents for second opinion of bladder exstrophy. He has a history of failed exstrophy repair at birth without osteotomy, followed by revision of closure with anterior innominate osteotomy at 2 weeks of age.

1. Which of the following physical exam findings would be concerning for failed closure?
a. Pink tissue visible at the base of the epispadias that becomes more prominent with crying
b. A low umbilicoplasty
c. A palpable bladder
d. A right-sided inguinal hernia
e. A short, wide penis

2. After successful reclosure with concomitant epispadias repair, which option(s) should routine follow-up include? (Select all the correct answers)
a. At least yearly renal ultrasound
b. Voiding cystourethrogram
c. Nuclear medicine renal scan
d. Yearly operative cystoscopy and cystogram
e. Yearly basic metabolic panel

3. The patient now presents at 10 years of age with his parents greatly desiring to be continent of urine. Before proceeding to surgical correction of incontinence all of the following should play roles in the treatment plan except:
a. Prior failed closures
b. An assessment of willingness of patient and parents to adhere to rigorous treatment plans by physicians, experienced nursing, and child psychologist
c. Penile length
d. Bladder capacity
e. Constipation

Answers

1. **e**. Though previously used for lengthening of the posterior urethra routinely, the risk of posterior urethral stricture is too high to recommend routine use. Use in select cases where the verumontanum lies in close proximity to the glans is advised, and careful attention to using full thickness flaps with minimal manipulation with forceps is mandated.
2. **d.** After 4 months the osteotomies have adequately healed to keep the pelvis in place, and a strong intrapubic bar has developed, negating the need for continued apposition of the pubic tubercles with a stitch.
3. **c.** #2 nylon suture provides the best load-to-failure ratio among several methods of pubic approximation using various commonly employed suture materials.
4. **d.** Significant penile tissue loss has been seen most commonly with complete primary repair of exstrophy (CPRE). Penile loss is also seen with primary exstrophy repair without osteotomy due to vascular congestion at the pubic closure.
5. **a.** Routine use of ultrasound is indicated to follow for upper tract changes. Other imaging modalities should be employed if upper tract changes are noted, and tailored to the patient's clinical status, but should not be used as routine follow-up imaging.
6. **a.** Bladder capacity around 50 mL is adequate for use of the bladder as part of a continence procedure, typically for ureteral reimplantation with augmentation and catheterizable channel implanted into the augment. Less than this volume makes reimplantation with adequate tunnel length difficult to impossible.
7. **d.** Continence procedure is a significant undertaking for both the exstrophy patient and surgeon. This requires willingness on the part of the parents and patient for timed voiding, cathing regimens, etc.
8. **e.** Both radical dissection of the penis and neophallus should be considered and tailored to the individual placement. Though inflatable penile prosthesis (IPP) placement is necessary with neophallus, IPP alone will further shorten the exstrophic penis. Though penile transplant is under investigation by several centers, it is not currently considered for exstrophy patients.
9. **d.** When bladder outlet obstruction is suspected, a renal and bladder ultrasound should be performed immediately to assess for hydronephrosis and/or an enlarged bladder.
10. **a.** If large residuals are encountered after closure and removal of traction and ureteral stents, posterior urethral stricture must be considered. This can be due to a variety of causes, and cystoscopy allows for the most direct way to evaluate. Treatment can then be determined from the etiology seen on cystoscopy.

CASE 1

1. **e.** Proper immobilization provides for medial rotation of the pelvis, reduces lateral distraction and tension, and keeps the lower extremities midline and the pelvis flat. Patients who are closed without pelvic osteotomy are kept in external fixation with modified Bryant's traction for 4 weeks; those with osteotomies are kept in external fixation and modified Buck's traction for 4 weeks in primary closures and 6 weeks in secondary closures.
2. **e.** When initial exstrophy closure is complicated by complete dehiscence, it is prudent to wait until the

infant is 4–6 months of age, allowing both the child and the bladder to grow, and then undertake reclosure with bilateral pelvic osteotomies. At this time epispadias repair also may be performed under testosterone stimulation in many male patients.

3. **d.** When a vesicocutaneous fistula is found after primary closure, one should have a high index of suspicion for failed closure with fascial dehiscence. The most appropriate step would be to evaluate the child's anatomy under anesthesia with an attempt for cystogram to check capacity/growth since birth. Careful attention should be paid during cystoscopy for position of the bladder, especially with visualization of the cystoscopy light through the skin. Given the high likelihood of failed closure and re-diastasis, one should be prepared for reclosure only once the examination under anesthesia and cystoscopy confirm the diagnosis.

CASE 2

1. **a.** This scenario represents prolapse of the bladder into the urethra with abdominal straining. This is due to failure of the fascial and pelvic closure allowing the bladder to be too anterior in the pelvis, thus creating hypermobility with abdominal pressure. A palpable bladder would make one concerned for outlet obstruction. Though inguinal canals should be explored, and repaired at closure, a recurrent hernia does not indicate a failed repair.
2. **a and d.** Monitoring of the upper tracts for deterioration should be done with renal ultrasound to evaluate for signs of obstruction that can be intervened upon before changes in creatinine may be seen. Also, operative cystoscopy and cystogram are done to evaluate for bladder growth, vesicoureteric reflux (which is common), bladder quality, and urethral quality for both immediate management (antibiotic prophylaxis for reflux) and future surgical planning/parent and patient counseling.
3. **c.** Though penile length is a problem for male exstrophy patients, continence procedures will not change length and thus do not play a role in readiness for such operations. Failed closures and bladder capacity help the surgeon to decide the appropriateness of bladder neck reconstruction versus diversion procedures, and need for augmentation. Voiding programs with rigorous assessment of bowel voiding habits should be done prior to undergoing any continence surgery.

Chapter 60 Questions and Answers

KEY POINTS

1. Hypospadias repair requires meticulous attention to detail, especially with regard to tissue handling and the creation of local tissue flaps.
2. When operating for complex hypospadias the surgeon must have a variety of techniques available to be able to tailor the operation to the needs of the patient.
3. When necessary, staging of the hypospadias operation may provide adequate time for graft healing and chordee corrections, thus facilitating more effective urethroplasty at a second stage.
4. Use of a barrier layer with local tissue is crucial for reinforcing the urethroplasty and for preventing the formation of fistulas.
5. When evaluating a hypospadias complication, the surgeon should be careful to address all factors that may have contributed to the complication and not just the complication in isolation.
6. In a boy with a complication, the surgeon must be willing to completely revise the repair if other treatments would leave the patient less than satisfied or at high risk for a second, later complication caused by correction of the initial complication.

Duckett tabulated his experiences with hypospadias repair to coin the term *hypospadiology*.[1] His intent was to highlight the complex interplay of both art and science that results in a successful hypospadias repair. Since the first modern descriptions of hypospadias repair in the mid-19th century, the surgical management of this defect has undergone a remarkable evolution to improve functional outcomes and minimize complications.[2]

Despite continued advances, successful penile reconstruction for hypospadias repair remains one of the most challenging areas within the field of pediatric and reconstructive urology. A combination of factors threatens to compromise even the most meticulous repair. The structures are delicate and the healing process is dependent upon neovascularization in spite of surgical reconstruction. Postoperative edema, the risk of infection, the inherent variability in the healing process, and the potential for patient harm by early catheter removal creates a complex environment with risk for failure.

A rigid surgical approach to the spectrum of hypospadias will be uniformly successful in this environment of complex penile reconstruction. Nevertheless, it is important for anyone who undertakes this type of surgical procedure to have a thorough understanding of the potential pitfalls in the workup, surgical management, and postoperative care of these patients. This chapter discusses the approach to prevention and management of hypospadias complications with reference to commonly used techniques.

Prevention of Complications

Hypospadias repair is complex and should be performed by pediatric urologists that have undergone specific training and have sufficient experience.[3] Expertise is not achieved at the completion of a fellowship alone, but this training combined with increasing surgical volume significantly improves outcomes. In a study following a single surgeon's experience, the complication rates in 231 consecutive patients over a 5-year period were examined, beginning immediately post fellowship. The investigators demonstrated a significant decrease in urethrocutaneous fistula development each successive year following training.[4] Similar studies have directly correlated less experience and surgical volume with increased risks of complication development.[5,6]

The best treatment of hypospadias complications is through prevention. Penile reconstruction is a complex art form that requires a complex blend of experience, the ability to utilize a wide variety of techniques dependent upon the unique presentation, and safe handling technique. In spite of meticulous technique, patient factors such as wound healing and tissue ischemia can result in complication development. An understanding of the technical factors predisposing patients to failure aids in their prevention. We therefore begin our discussion with a specific emphasis on the workup, surgical technique, and perioperative care of these patients.

PREOPERATIVE EVALUATION

Timing of Repair

To facilitate a successful repair the ideal age for hypospadias repair must be identified by balancing the adverse psychological effects of surgery, the anesthetic risk to the child, and the degree of penile growth. Genital awareness begins to occur around 18 months of age and progresses with increasing age.[7] Several investigators reported that patients undergoing earlier repair (usually <12 months of age) experienced less anxiety and had improved psychosexual outcomes when compared with older children undergoing hypospadias repair.[8,9] Patients operated on at a younger age may also experience fewer complications, a finding that reinforces the need for early correction.[9] We counsel all parents that at 6 months of age anesthesia risks are equal to those of older children and adults, allowing hypospadias repair to be performed as an outpatient. Based on these studies, the American Academy of Pediatrics Section on Urology suggested that the optimal time for hypospadias repair is between 6 and 12 months of age.[10]

Parents often raise questions about the safety of anesthesia exposure in young children. Data in animal models suggest varying degrees of neurotoxicity in response to agents commonly utilized for general anesthesia.[11] These studies are difficult to replicate in human subjects but longitudinal analysis of children exposed to anesthesia (general vs regional block) resulted in no detectable neurodevelopmental delays at 2 years of age.[12] Although far from conclusive, it appears that there are no consequences of a single anesthesia exposure at short-term follow-up.[13]

History and Physical Examination

The initial evaluation of patients presenting for hypospadias repair requires a careful history and physical examination. In the patient without previous surgery, the history is directed toward identification of coexistent anomalies that could affect surgical care. The inquiry should focus on a history of prior urinary tract infections (UTIs), voiding dysfunction, and any associated medical diseases that may complicate care, such as asthma or a bleeding diathesis.

Patients with a history of other global systemic anomalies should be considered for evaluation with a screening ultrasound for the presence of associated urinary tract abnormalities.[14] The physical examination focuses on staging the phenotype to assess the degree of severity. This includes the degree of chordee, the location of the urethral meatus, the quality of the urethral plate, and the amount of skin for reconstruction.[15] These factors play a significant role in the surgical planning process and potentially increase the risk for complication development. Finally, patients with unilateral or bilateral undescended testes, perineal hypospadias, or ambiguous genitalia must undergo additional workup to rule out a disorder of sexual differentiation, which occurs much more frequently in this setting.[16–19]

A glans size of 14 mm or less at the time of surgical repair has been associated with increased risk for complication occurrence.[20] Preoperative testosterone can be given to increase glans width and penile length.[21,22] Whether this decreases the postoperative complication rate remains controversial, but given the risk associated with a smaller glans, increasing its width has potential benefits.[23,24] Our practice is to administer intramuscular testosterone in the setting of a small glans (14 mm) at 6 and 3 weeks prior to planned surgical intervention.

Surgical planning continues after the induction of anesthesia. Following antiseptic preparation of the genitalia and administration of intravenous antibiotics, the genitalia are carefully examined again to classify the hypospadias phenotype and to determine the surgical approach. We do not find it necessary to perform routine cystoscopy except in cases of severe proximal hypospadias or salvage operations. Prostatic utricles occur in >10% of patients, more frequently in proximal hypospadias, and therefore cystoscopic examination may be useful in these particular situations to facilitate catheter insertion.[25] Alternatively, catheter placement over a wire typically results in successful catheter insertion in the setting of a prostatic utricle.

Options for regional block include caudal vs penile blockade. There has been some recent focus upon the potential for increased complication rates for patients undergoing caudal blockade, although this remains controversial.[26,27] When administered a second dose at the completion of the procedure can prolong the period of blockade.[28,29] At our institution we prefer caudal anesthesia when a block is administered for hypospadias repair.

OPERATIVE TECHNIQUE

The patient is placed in the supine position after the anesthesia block is performed. A glans holding stich is placed. The urethra is evaluated with a catheter or sound to determine the caliber of the opening and the quality of the

overlying skin, which can be hypoplastic, requiring repair in spite of appearing intact. A circumcision incision is then made and the penis is degloved. The initial step in treatment of penile chordee (orthoplasty) is excision of all chordee tissue to the level of the penoscrotal junction. The adequacy of resection can be assessed with saline injection[30] or pharamocologically induced erection.[31] This step is crucial as inadequate assessment and undertreatment of chordee can result in significant morbidity and poses a complex surgical problem.

Chordee release often results in migration of urethral meatus to a more proximal location. Although several hundred techniques have been described in the literature, urethroplasty techniques can be broadly categorized as those using flaps of local genital skin, those using flaps or grafts of preputial or extragenital tissue, and urethral tubularization. In a survey of pediatric urologists, the tubularized incised plate technique was utilized >90% of the time for distal hypospadias repairs and 80% of the time for midshaft repairs.[32] Numerous techniques are available for the management of proximal or complex hypospadias, and selection of approach is beyond the scope of this chapter. The use of hair-bearing skin is discouraged because it renders the neourethra susceptible to stone formation and recurrent UTIs.

Surgical technique is as important a factor for outcomes as surgical approach. Gentle tissue handling prevents crush injury and preserves blood supply to tissues, which is crucial to complication prevention. Ischemia results in fibrosis and contraction of tissues, predisposes patients to infection, and potentiates the breakdown of suture lines. Tissue trauma can be minimized by the use of fine forceps, skin hooks, and stay sutures. Intraoperative magnification facilitates this process and helps to identify the delicate blood supply of flaps. Flaps must be mobilized generously to minimize tension on suture lines and to prevent ischemia. Subcuticular neourethral approximation with epithelial inversion has been shown to decrease complications when compared with full-thickness approximation.[33,34] For urethroplasty we prefer a fine absorbable monofilament such as polydioxanone (PDS), polyglactin (Vicryl), or polytrimethylene carbonate (Maxon). Next, the use of multiple tissue layers is vital in the reduction of complications. Dartos interposition flaps increasing the vascularized layers above the repair reduce fistula formation after tubularized incised plate repair (Fig. 60.1).[35]

Finally, careful hemostasis should be maintained with the judicious use of pinpoint cautery and a compressive bioocclusive dressing (Fig. 60.2). This dressing can be formed from an adhesive membrane such as Tegaderm, which is applied circumferentially from the level of the glans to the penoscrotal junction. The glans must be included in the dressing to avoid excessive swelling. Care must be taken to prevent a constricting ring at the proximal extent of the dressing. Alternatively, we also use a sandwich dressing, which works in a similar fashion by restricting the penis toward the body for the first 72 hours post surgery.

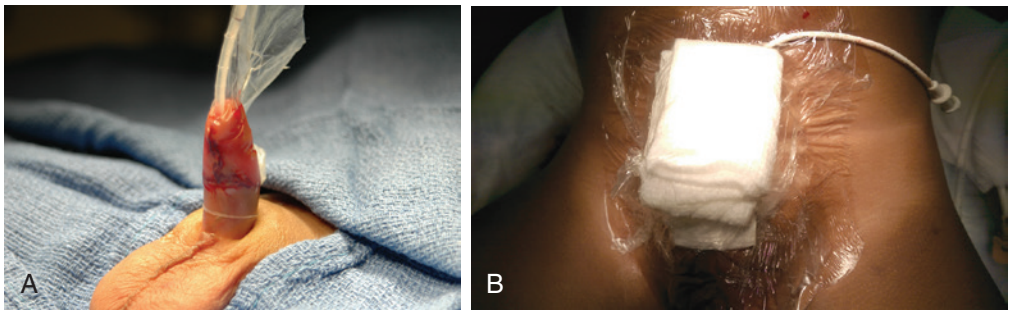

Figure 60.2 Dressing for hypospadias repair. A, Transparent adherent dressing (Tagaderm) is applied from the glans to the level of the penoscrotal junction, with care taken to prevent a constricting band at the proximal extent. A 6 or 8Fr silicone urethral stent is sutured to the glans to allow free passage of urine. B, Sandwich dressing compressing the penis against the body with a loose fitting Tagaderm overlying a Telfa gauze. The urethral catheter can be sutured in place for prolonged diversion or secured temporarily until the dressing is removed.

POSTOPERATIVE CARE

Good postoperative care is essential. An excellent surgical repair can be inadvertently compromised with poor management. Options for methods of urinary diversion, dressings, and perioperative medication administration have varied greatly throughout the history of hypospadias management. Options for urinary diversion include urethral stents, urethral catheters, and suprapubic tubes or a combination thereof and are intended to minimize stress to the urethroplasty in the immediate postoperative period. Particularly for complicated repairs, urethral diversion has been shown to decrease rates of meatal stenosis and urethrocutaneous fistula development.[36,37] Catheters must be well secured before the patient leaves the operating room, and indwelling duration ranges from 1 to 3 weeks.

Regional block via either a caudal regional block or a circumferential penile block reduces narcotic requirement both in the operating room and the immediate postoperative period.[38] As mentioned above, some reports suggest an increased risk of complications when caudal block is used, but this remains controversial and we routinely use caudal blocks at our institution.[26] The effect can be improved when blocks are performed prior to and just after the procedure.[28,29] In addition, ketorolac (0.5 mg/kg), given as a single dose 30 minutes before the conclusion of the procedure, is a safe and effective adjunctive pain medication that is associated with less emesis than are opioid analgesics.[38,39]

Postoperatively, bladder spasm is common after urethroplasty and can result in high-pressure voiding around stents and catheters, placing undue stress on the urethroplasty. This can be alleviated with an anticholinergic agent such as oxybutynin, which is started in the postoperative period and continued until 24 hours before removal of the urethral stent. Perioperative antibiotics are routine practice, and prophylactic antibiotics during the postoperative catheterization period have been shown to reduce postoperative complicated UTI and thus potentially to decrease overall fistula and stenosis rates.[40–42]

Management of Complications

EARLY POSTOPERATIVE COMPLICATIONS

Ischemia

Tissue ischemia occurs to some degree with all reconstructions performed for hypospadias and is responsible for most of the complications that occur. Ischemia potentiates edema and infection, delays wound healing, and promotes fibrosis. Common techniques in urethroplasty employ either the transfer of tissue island flaps that are dependent upon a delicate blood supply or grafts that must rely on the quality of the vasculature of the recipient tissue bed. These tissues are at risk for ischemic changes that can lead to tissue breakdown, which can result in the formation of a urethrocutaneous fistula or stricture. In a similar fashion, ischemia of flaps used for skin coverage, particularly in the setting of large deficits, can lead to necrosis, eschar formation, and wound contraction (Fig. 60.3). Advances in technique have decreased the incidence of this complication in our experience. A ventral penile incision that extends to the penoscrotal junction frees the dorsal skin and increases exposure of the vascular pedicle. Holding sutures place tension on the flap, further identifying the vascular pedicle to ensure preservation during dissection.

Thoughtful operative technique can usually prevent ischemic complications by minimizing postoperative edema or hematoma formation. Flaps must be harvested with adequate blood supply and without tension. High-powered visual magnification with loupes aids in pedicle identification and preservation, while gentle retraction with holding sutures minimizes tissue trauma. Ideally, poor tissue perfusion is discovered during the procedure, though this is often not the case. Tissue edges that blanch when sutured indicate excessive tension and should be taken down and reapproximated. Despite meticulous technique, ischemia to the penile skin may not become apparent until after removal of the dressing. Treatment is initially conservative with liberal application of petroleum jelly. Necrosis of skin flaps is usually partial, as long as a healthy layer of dartos tissue is present. The eschar will necrose and the defect will gradually re-epithelialize. If a clearly demarcated edge exists, debridement of the eschar can be considered. Grafting and revision surgical procedures are rarely necessary and are reserved for wound contraction that results in chordee.

Bleeding and Hematoma

A wound hematoma can occur even with meticulous intraoperative hemostasis, though a compressive dressing typically limits its progression. In its most severe form, the mass effect of blood may distort tissue planes and interfere with perfusion of tissue flaps or prevent graft uptake.[43] A large hematoma can also result in skin separation or act as a nidus for infection, and resorption of the blood can result in inflammation, scarring, and fibrosis. A wound

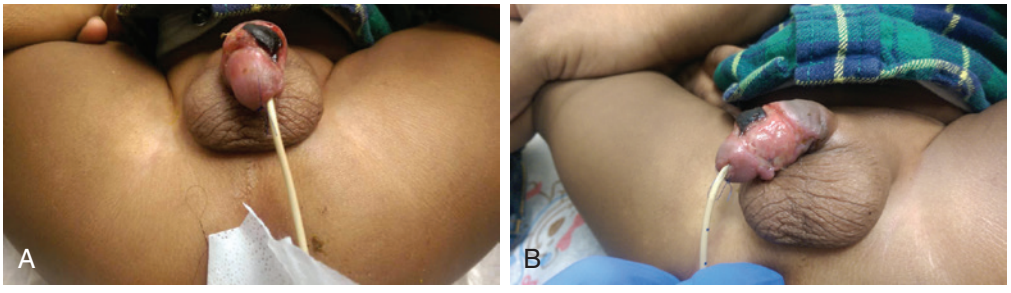

Figure 60.3 Example of eschar formation on penile shaft skin after transfer of dorsal inner preputial island flap transfer to compensate for lack of ventral shaft skin. Black area represents remaining eschar, which will slough with time. A supple underlying layer of dartos allows re-epithelialization.

hematoma increases risk for complications such as fistula, stricture, and recurrent chordee.

Hematoma management depends on its size and the time at which it is noted. A delicate balance is achieved between adequate hemostasis during the procedure and maintaining tissue perfusion. If a significant hematoma is present during the procedure at skin closure or with dressing placement, the skin should be opened, the clot evacuated, and the precise source of bleeding identified and controlled. In a patient with a large hematoma discovered early in the postoperative period, consideration should be given toward returning to the operating room for evacuation of the hematoma and placement of a drain, particularly if the surgeon believes that the hematoma may affect flap survival. Alternatively, reinforcement of the compression dressing in the setting of a nonexpanding hematoma can be performed with minimal consequence to the repair. Smaller hematomas rarely cause long-term problems and can usually be managed conservatively.

Wound Infection

Because of the superb blood supply of the genital structures, severe infections rarely occur after hypospadias repair. Nevertheless, poorly perfused flaps, skin grafts, and traumatized tissue can develop localized infections, secondary to gram-positive skin flora. These organisms predominate cultures of perimeatal tissues performed at the time of the surgical procedure.[44]

UTIs can also occur in the postoperative period. Typical urinary tract pathogens represent the etiology for most infections and some suggest that perioperative antimicrobial therapy combined with daily prophylaxis until after catheter removal decreases the risk for infectious complications.[45] This finding coincides with our practice of administering prophylaxis to our patients until all catheters are removed. When infections do occur, aggressive management is important to prevent inflammation, which can delay wound healing and predispose to fistula or stricture formation. Delayed UTI suggests poor urinary drainage and should raise concern for urethral diverticulum, meatal stenosis, and/or urethral stricture. Stent encrustation is a possibility in the setting of a proteus infection, although this typically isn't evident until the time of stent removal. If the stent isn't easily removed in the office then removal in a controlled setting under general anesthesia is warranted.

Superficial wound infections typically respond to oral antibiotics directed at gram-positive organisms. Escalating infection in spite of appropriate antibiotic therapy warrants inpatient admission for IV antibiotic administration for multidrug-resistant organisms. Wound cultures and urine cultures should be obtained when appropriate to guide antibiotic therapy. We find that UTI in the setting of a well-positioned and draining catheter is rare.

Wound Separation

The origin of separation of the penile shaft skin is multifactorial, with infection, ischemia, edema, and hematoma formation all potentially playing a role. When this occurs conservative management with liberal application of petroleum jelly to the defect allows closure by secondary intention with minimal morbidity, as long as supple dartos tissue is present. Attempts at suture placement are not recommended as these may require anesthesia and may exacerbate edema or inflammation. If wound disruption occurs several days postoperatively and is associated with excessive edema, the surgeon must entertain the possibility of a wound infection or urine extravasation.

LATE POSTOPERATIVE COMPLICATIONS

While outcomes for hypospadias repair are generally favorable, particularly for distal repairs, increasing intention is being given toward the need for long-term follow-up, particularly for proximal repairs where the complication rate can approach 60%.[46–48] Follow-up that does not extend into puberty underestimates our complication rate, in spite of what appears to be a successful outcome.[49,50] Standardization and extension of our follow-up protocols is vital and will allow us to ensure that we are achieving good outcomes for these boys not only in the immediate postoperative period but for their lifetime.[51]

Urethrocutaneous Fistula

Urethrocutaneous fistula is the most commonly reported major complication of hypospadias repair and increases in frequency with the increasing severity of hypospadias.[52] The incidence of fistula has decreased with the improvement in operative techniques.[53] An incidence of <10% for distal hypospadias repair is now to be expected.[49,52,54]

The development of fistula is a multifactorial phenomenon. As mentioned earlier, ischemia, edema, infection, and hematoma may contribute to improper healing of the neourethra. Distal urethral obstruction from meatal stenosis or urethral stricture results in high urethral pressures during voiding, placing undue stress proximally on the suture line. Technical factors such as overlapping suture lines, inadequate inversion of the epithelium, or use of poorly absorbable suture material play a role.[55] Finally, the severity of hypospadias plays perhaps the largest role in fistula formation.[20,56,57]

Management of urethral fistula depends on the number, size, location, and time interval from the surgical procedure. A urine leak usually becomes apparent with the generation of multiple urinary streams, and most are noticed within the first 2 years of surgical repair.[49,50,58] A fistula can be singular, with a patient presenting with two or multiple streams. Urine can be completely diverted out of the fistula site or as a fraction extending from the native urethra and the fistula. Finally, a pinpoint fistula can be more subtle in presentation, with a drop of urine during or after urination. In our experience, we have also observed children who present in a delayed fashion at toilet training, when the urinary stream is more likely to be consistently observed.

Small fistulas noted in the immediate postoperative period without concomitant inflammation or meatal stenosis may spontaneously close on their own or with the aid of catheter insertion.[59] Although this may be the case, the vast majority of urethrocutaneous fistulas require surgical repair, which is delayed until at least 6–12 months after the initial hypospadias repair to allow proper wound healing. This delay allows ingrowth and establishment of the vascular supply and resolution of inflammation and edema, maximizing the potential for success.

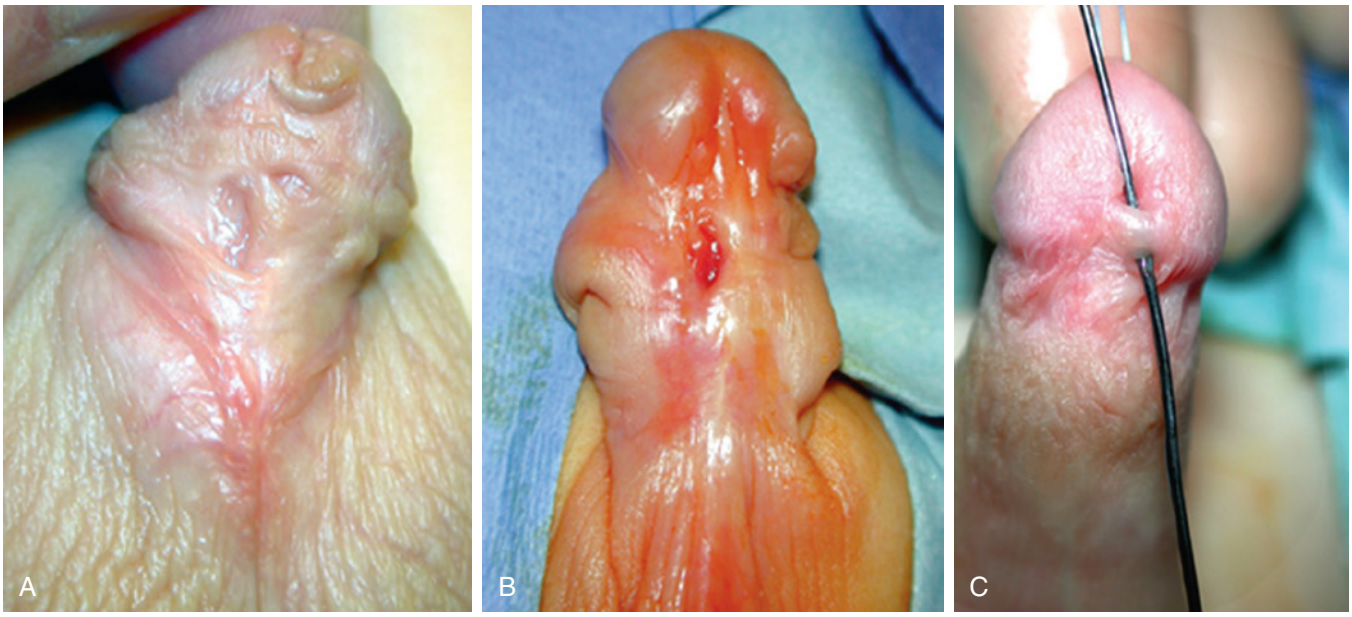

Figure 60.4 These children have large urethrocutaneous fistulas (A, B, C). C, Probe in a urethral fistula.

The first step in management of complications demands a careful evaluation to rule out any additional anomalies, such as persistent chordee, urethral stricture, and/or diverticula. The surgical approach is dictated by these findings, as well as by the size and location of the fistula. Intraoperatively, it is important to calibrate the urethra distal to the fistula with an 8 to 12Fr bougie à boule to ensure adequate caliber (Fig. 60.4). If any question remains about the anatomy a cystoscopy should be performed. The penile shaft must be evaluated for the presence of other unrecognized fistulas. The fistula tract can be cannulated with a lacrimal probe to determine the site of entrance into the urethra. In our hands a urethral catheter inserted to inject saline to perform a "stress test" will readily identify fistula tracts not visualized on examination.

Small-caliber fistulas on the penile shaft proximal to the coronal margin can potentially be closed primarily.[60] Prolene holding stitches are placed through the epithelialized tract, which is then excised in an elliptical fashion down to the urethra. The site is then closed primarily in a subepithelial fashion, and multiple overlapping layers are placed to prevent recurrence. Larger fistulas may require coverage with a trap-door or island flap of penile shaft skin. In general, better results have been achieved when a second layer or flap coverage in an offset fashion is utilized.[33,43,60] Skin coverage can be obtained by several methods to avoid overlap of urethral and skin suture lines (Fig. 60.5).

Fistulas at the coronal margin can prove to be more challenging. While it is tempting to perform excision and primary closure, a fistula at this site often represents a pathologic narrowing that requires takedown and revision of the distal urethroplasty. Failure to do so results in a high risk of failure.

Despite a well-performed repair, fistulas recur about 20% of the time.[3,61] This recurrence rate may be lessened with interposition of multiple well-vascularized nonepithelialized layers between the urethral closure and the skin. Redundant dartos tissue, if present, or a scrotal-based tunica vaginalis flap[62–64] may also be used. Scrotal dartos tissue has been used in a similar fashion.[65] A de-epithelialized flap repair is another technique that has shown promise.[60] There is no need to divert the urine for simple repairs, but for larger repairs we routinely divert the urine for 7 to 10 days.[60,66,67] Finally, in cases of severe fistula formation with a lack of local tissue for skin flaps, buccal mucosa grafts have been used with some success.[68] For challenging cases, particularly those with a history of multiple prior repairs with poor local skin and having undergone a buccal mucosa graft, we have had success with the Cecil modification to promote graft healing and additional vascular supply.[69] Release of the penile shaft from the scrotum after 12 months of healing typically reveals a supple urethroplasty and ample tissue for tension-free shaft skin coverage.

Urethral Stricture

Urethral stricture is the second most frequently reported complication of hypospadias repair, with rates varying according to urethroplasty technique and length.[70,71] These strictures tend to form at anastomotic suture lines, such as the urethral meatus or the proximal anastomosis of the native and reconstructed urethra. The clinical picture can vary, with strictures presenting with complaints of a diminished force of urine stream, stranguria, urinary retention, or urinary tract infection. Alternatively, some physicians note anomalous uroflow rates on routine follow-up after toilet training.

Several factors increase the risk of postoperative stricture. Improper urethroplasty technique, such as primary tubularization of a narrow urethral plate when an onlay may be indicated, can result in a conduit of insufficient caliber, place tension on suture lines, and narrow the anastomosis. Tissue ischemia, trauma, or infection can result in inflammation and concentric scarring of the lumen. In tubularized pedicle flaps, a stricture may be functional, secondary to a redundant neourethra kinking at the proximal anastomosis. It is best to characterize the stricture via

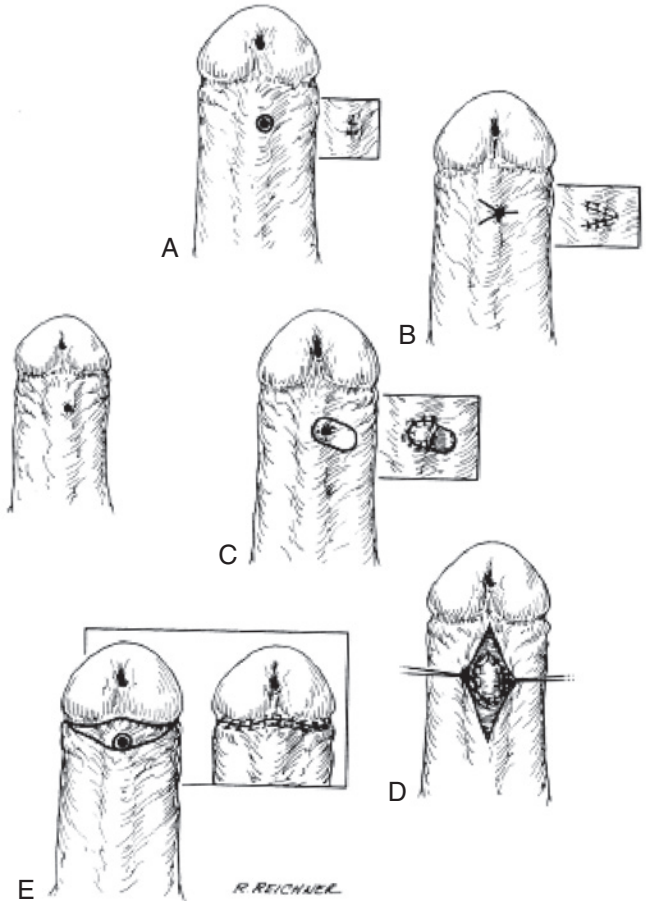

Figure 60.5 Techniques of fistula repair after hypospadias correction. A, Excision and primary closure. B, Y-V skin advancement after excision and closure of the fistula. C, Trap-door flap of penile skin. D, Full-thickness patch graft. E, A small coronal fistula is excised and penile shaft skin is advanced to cover the defect. Chicago: Year Book; 1990.)

cystoscopy while the patient is under anesthesia to carefully delineate the length, caliber, and location of the stricture and to evaluate for any additional complications.

Initial management depends upon the severity of the stricture. For short strictures causing minimal symptoms, a single try at urethral dilation or endoscopic treatment is appropriate. In most cases, however, this will not provide a long-term solution. Direct visual internal urethrotomy in adult strictures has low success rates and risks worsening the stricture by generating worsening inflammation and scar.[72] Success rates for small strictures (<1 cm), even when done in conjunction with intermittent catheterization, are poor, with only approximately 20% of patients exhibiting a normal flow rate 2 years post incision.[71] These investigators reported success rates of 72% (onlay urethroplasty) and 63% (urethral plate urethroplasty) for strictures, suggesting that this approach may have some utility in these patients. The outcome may be better for short anastomotic strictures when conservative treatment is initiated ≤3 months after operation, although in our experience conservative management is rarely successful in these patients.[70]

Strictures not responding to conservative management or those with extensive disease at diagnosis require revision urethroplasty.[73] The surgeon must be prepared to harvest a local skin flap or buccal mucosa as there will likely be significant tissue loss at the site of the stricture. Attempts at repeated dilation or urethrotomy in these patients are usually not successful and should be discouraged because of the possibility of worsening the existing fibrosis.[74]

Urethral Diverticulum

Symptoms of urethral diverticula include weak urinary stream, post-void dribbling, UTI, and occasionally hematuria. The patient or caregiver may notice ballooning of the penile shaft during voiding (Fig. 60.6) or report the need to "milk" residual urine from the penile urethra. Diverticula occur more commonly in patients with onlay flaps, two-stage repairs, and with more proximal repairs.[75] This is in part due to lack of urethral reinforcement by a lack of corpus spongiosum tissue, which is absent or hypoplastic as part of the hypospadias complex. More often meatal stenosis or urethral stricture increases voiding pressures, causing dilation of the reconstructed urethra, resulting in a urethral diverticulum.[76] To achieve a successful repair the intraoperative approach must rule out distal urethral obstruction, with cystoscopy an important adjunct to define any uncertainties in the anatomy.

A small, localized saccular diverticulum can typically be excised and reduced in a longitudinal fashion, returning the urethral lumen to a uniform caliber. The more commonly encountered extensive megalourethra has traditionally been repaired by excision of redundant diverticular tissue, urethral closure, and multi-layered reinforcement before skin closure.[77] The redundant tissue is usually elastic, well vascularized, and lined with urothelium, making it an ideal candidate for repair of associated fistulas and distal strictures.[76] Various flap techniques have been employed to reconfigure redundant diverticular tissue for this purpose (Fig. 60.7).[78] Urethral plication in an extraurethral fashion is an alternative technique that does not violate the urethral plane.[79] As mentioned previously, interposition of a tunica vaginalis flap or dartos between the urethral closure and the skin is standard practice to reinforce the anastomosis and improve wound healing. Any repair beyond a simple excision should involve urine diversion for at least 7 days.

Meatal Complications

Characterizing meatal stenosis is difficult as definitions vary considerably across studies.[80] Technical aspects increasing the risk of stenosis include excessive extension of glans incisions and distal narrowing with glansplasty technique. Prolonged indwelling stent posturethroplasty may decrease the risk of stenosis development.[36] In the postoperative period the meatus should calibrate to a size no less than 8Fr. A narrowed meatus with symptoms of stranguria, deflected stream, poor uroflow, or urinary retention would suggest a clinically relevant stenosis that would warrant repair. Occasionally a stenotic meatus can be managed conservatively with meatal dilation with a sound and topical betamethasone cream.[81] Repeated dilation after hypospadias repair is not necessary as a routine practice to decrease rates of stenosis but may be indicated when the meatus appears small in the early postoperative period, and may be diagnostic of

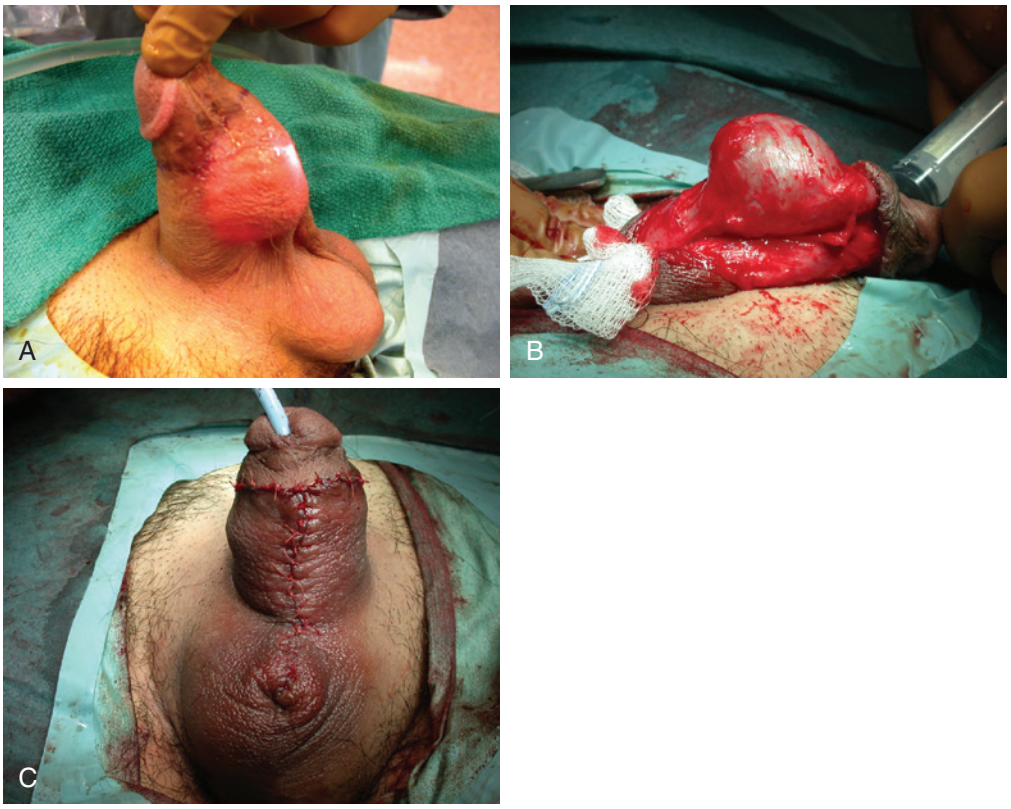

Figure 60.6 Urethral diverticulum in a pubertal boy after onlay hypospadias repair. A, The diverticulum highlighted with a cystoscope present within the defect. The defect is clearly seen in B after penile degloving. A satisfactory cosmetic result can be seen after closure of the diverticulum (C).

subclinical stenosis.[82] When the stenosis is refractory to dilation, a dorsal midline meatotomy can achieve patency in some cases.[83] Alternatively, an onlay utilizing a ventral penile flap can be successful in the absence of lichen sclerosis.[84] If these fail then revision glansplasty may be required and caution must be taken as there is often loss of glans tissue limiting the ability to achieve a cosmetic glans closure, necessitating a coronal meatus creation.

Meatal retrusion occurs when there is too much tension on the distal urethra or the glansplasty has broken down.[85] Meatal retrusion in part is due to improper surgical repair, resulting in an immobile urethra that retracts with penile growth, or a meatus that is noncompliant results in retrusion of the neourethra to its original position. The consequences of this complication are predominantly cosmetic rather than functional. However, if significant splaying or deflection of the stream occurs, revision of the meatus may be considered.[86]

Balanitis xerotica obilaterans (BXO) or lichen sclerosis is a chronic inflammatory dermatosis that can occur after hypospadias repair. Clinical presentation can vary and includes meatal stenosis or progression into the urethra, causing stricture. The initial course of treatment includes topical steroids (betamethasone 0.05%).[87] Unfortunately if conservative measures fail, surgical resection of all diseased tissue and reconstruction with buccal mucosa is required, often necessitating multiple reconstructive procedures.[88,89]

Persistent Chordee

Persistent chordee is an unfortunate complication of hypospadias repair that can have severe consequences from both a urinary and sexual function standpoint. Residual curvature may worsen as boys advance through puberty and undergo exponential penile growth.[90] Persistent or recurrent chordee occurs when the surgeon underestimates the intraoperative erection or fails to repair the curvature completely.[91] Improper technique can also result in extensive urethral scarring, which can tether the penis ventrally.

Residual chordee can be corrected but requires a systematic approach. Parents should be counseled that several procedures may be required. The first stage focuses on assessing the degree and source of chordee. We begin by assessing the ventral shaft skin and length of the urethra. Artificial erection after degloving will determine if the chordee is secondary to skin deficiency, urethral tethering, or corporal disproportion. If chordee persists after this procedure, elevation of the urethral plate down to the bulbar urethra if necessary has been shown to be another effective treatment (Fig. 60.8).[92] If bow-stringing of the urethra remains after mobilization, we divide the neourethra at the point of maximal curvature. If chordee remains, we proceed with corporoplasty designed to lengthen the ventrum of the penis with either dermal or tunica vaginalis grafting. We then move skin and dartos to provide a suitable bed for a subsequent free graft. The second stage of the repair involves placement of the buccal mucosa graft 12 months later, followed by urethroplasty at the third stage, again 12 months later. Shaft skin closure can be performed at that time but we often perform a Cecil modification during the third stage, which provides supple tissue for skin closure at the fourth stage.[69]

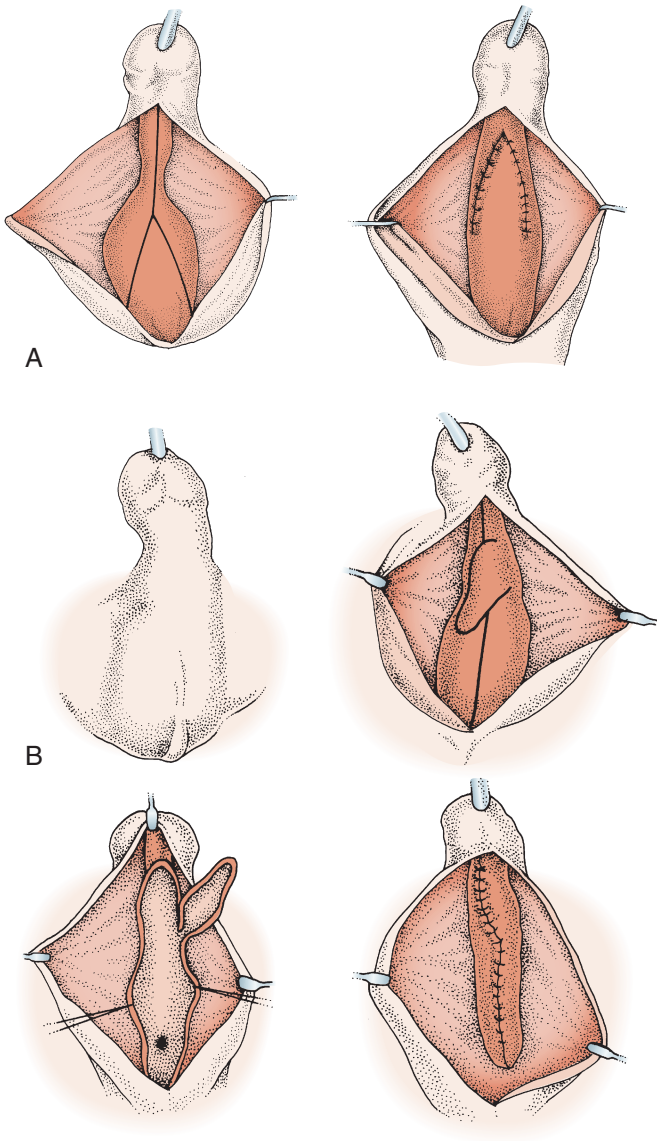

Figure 60.7 Use of diverticular tissue to correct distal stenosis. A, Repair of urethral diverticulum with distal stricture using Y-V plasty. B, Repair of urethral diverticulum with distal stricture using rotation flap.

Other Urethral Problems

If hair-bearing skin is used for the hypospadias repair, the patient may eventually experience protrusion from the meatus. This complication usually occurs after multiple-stage procedures or complex reoperations in which a paucity of non–hair-bearing skin is available but gets incorporated out of necessity. Hair in the urethral lumen occasionally acts as a nidus for stone formation or recurrent UTIs. Laser ablation has shown some initial success.[93,94] Stone debris can be endoscopically removed in the majority of cases. In severe cases with recurrent stones or UTIs, the affected area is excised and repaired with a buccal mucosa graft or a local penile shaft skin flap, if available.

Recurrent UTIs should prompt evaluation for urethral diverticulum or stricture. Occasionally, a voiding cystourethrogram demonstrates an enlarged prostatic utricle, which can promote urinary stasis, acting as a reservoir for bacteria. If no other source of infection can be found in these patients, consideration should be given to either excision or fulguration of the utricle.[25]

Psychological Consequences

In addition to surgical and functional concerns, studies in children, adults, and parents have identified psychological concerns with hypospadias repair. In a study of 6- to 10-year-old patients, behavior problems and poorer school performance was more likely in patients that underwent hypospadias repair when compared with age-matched controls.[95] In a series of adults who underwent hypospadias correction at an average age of 5 years, 38% had limited or no sexual experience (mean age, 27 years).[96] Overall, these patients tended to have fewer sexual partners and were older when they began sexual activity. Comparison of patient and parental expectations with those of the surgeon reveals a discrepancy that leads to an element of decisional regret.[97]

In general, adult patients with a history of hypospadias repair do not manifest major psychological problems. However, they tend to be less satisfied with penile appearance, have more inhibitions in seeking sexual contacts, as a result of embarrassment, and have a more negative genital appraisal. These patients tend to manifest more anxiety, hostility, and lower self-esteem, some of which may be ameliorated by operating at an earlier age.[98]

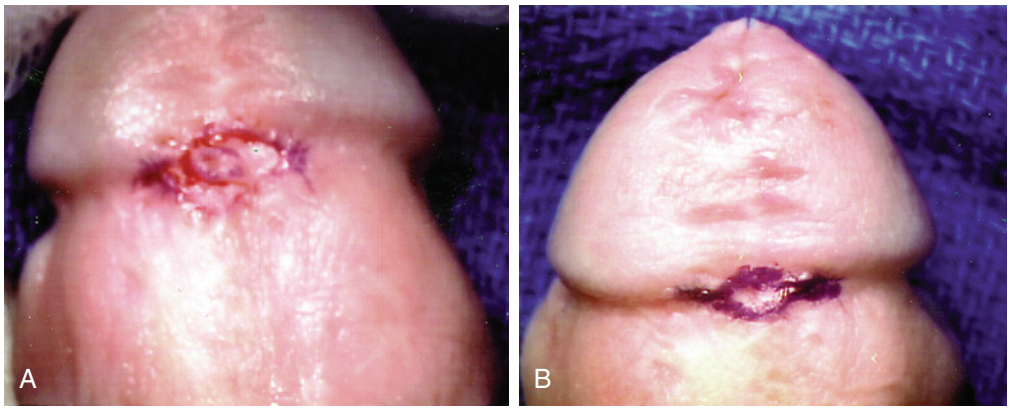

Figure 60.8 Fistula located at the coronal margin. Urehtral meatus was located within the distal glans and is without stenosis and the distal urethra calibrates normally to 8Fr.

Complex Hypospadias

Management of hypospadias complications depends on the complexity of the problem. Some boys can be managed with a single intervention, resulting in a cosmetically pleasing, functional outcome. With each successive procedure, however, the penis becomes more scarred and less tissue is available for reconstruction, and hence the complication rate increases with each successive repair.[99] A small percentage of patients undergo multiple unsuccessful repairs and are left with persistent, unresolved complications that result in significant morbidity that is often worse than the original congenital defect. To reiterate the importance of long-term follow-up and identification of these complications, Devine reasoned that "once complications have occurred in hypospadias repairs, the surgeon has a tendency to attempt small operations, hoping to convert failure with a minimum of effort. This generally makes matters worse. In these cases, extensive resection of scarring, major shifts of tissues and meticulous reconstruction will usually be found necessary to transform a difficult problem into a therapeutic success."[100] The approach to complex hypospadias reconstruction should include a full assessment of the number and degree of complications present, resection of all diseased tissue, and an aggressive surgical strategy in which the potential for success is maximized.

Salvage hypospadias for a focal issue (fistula, diverticulum) in the absence of chordee is ideally performed using a local skin flap that can be utilized as an onlay flap or for multi-layer vascular flaps.[99,101] We typically take this approach when redundant penile shaft skin is present from the original repair. When this is not the case, options are limited and tissue must be harvested from extra genital sites. Single stage repairs with full-thickness skin grafts had some initial success but significant complications such as graft shrinkage and stricture limited use of these grafts.[102] Bladder mucosal grafts have a reported overall complication rate of 40%, also limiting their use.[103] Complications related to the neomeatus have been the major drawback of bladder mucosal grafts, as prolapse can result in a cauliflower-type deformity in up to 38% of patients.[104,105]

Buccal mucosa is now the graft of choice in complex urethra reconstruction.[106–108] This tissue is ideally suited for urethral reconstruction because it is well adapted to contact with both fluid and air, readily neovascularizes, is hairless, minimally contracts, and causes little morbidity at the donor site. Because of its elasticity and good tensile strength, buccal mucosa can be used as an onlay graft, an inlay graft, or a tube graft and can be used to reconstruct the urethra in a single or multi-stage fashion. Long-term observation into puberty shows that the buccal graft is pliable and will not contract with age, an important aspect of management as we aim to avoid ventral chordee as a result of a tethered uretha.[109]

There are several key technical points when harvesting a buccal mucosa graft.[110] The graft should be outlined 10% larger than the needed surface area to allow for graft contraction as it incorporates. Closure of the donor site is controversial, and it remains unclear as to whether there is any benefit to such closure.[111,112] Although both are viable options for reconstruction, a labial graft appears to have fewer complications compared to the inner-cheek buccal mucosa.[113,114] For longer defects in complex cases or in older children, buccal mucosa can be used because it allows for a larger graft size. Alternatively, multiple sites can be combined to maximize tissue harvest. Strict attention to defatting and removing all nonmucosal tissue is important to allow neovascularization. The graft is then fenestrated with an 18G needle and placed in saline until the recipient site is prepared. Alternatively, one can prepare the recipient site first. A deep, long incision is made ventrally from the urethra through the glans to the site of the intended neomeatus.[115] The graft is then secured at multiple sites over the length of the graft, and quilting sutures are placed throughout the width of the graft to prevent hematoma formation, which can impede uptake. When performing a staged operation, the graft needs at least 6 months to heal before proceeding with urethroplasty and skin closure. We typically wait 12 months until to the next stage in reconstruction.

Conclusions

The surgical repair of hypospadias remains one of the biggest challenges in surgery. Although improvements in technique, instrumentation, and perioperative care have improved results, we still must deal with complications. By understanding the factors involved in failure of the repair, the surgeon can develop a logical and step-wise approach to repair to maximize the potential for success.

Chapter 60 Questions

1. What is the most common complication of hypospadias repair?
   a. Urethral diverticulum
   b. Urethrocutaneous fistula
   c. Meatal stenosis
   d. Urethral stricture
   e. Urinary tract infection

2. Urethral diverticulum is more likely to occur with the following hypospadias repair:
   a. Tubularized incised plate (TIP)
   b. Thiersch Duplay
   c. Island onlay flap
   d. Meatal advancement glanduloplasty (MAGPI)
   e. Mathieu repair

3. What is the recommended age to perform a hypospadias repair?
   a. <3 months
   b. >18 years
   c. Just prior to puberty (<13 years)
   d. 6–12 months of age
   e. Once a patient enters puberty, i.e., exhibits Tanner V characteristics

4. Which of the following risk factors increase(s) the risk of developing a complication?
   a. Small glans size (<14 mm)
   b. Proximal hypospadias
   c. Undescended testis
   d. All of the above
   e. a and b only

5. Which of the following are key aspects of the surgical approach to prevent complications?
   a. Meticulous, atraumatic handling of tissues
   b. Subepithelial urethroplasty closure
   c. Utilization of fine, absorbable sutures for urethroplasty
   d. Multiple layers of well-vascularized closure
   e. All of the above

6. When ischemia results in eschar formation of shaft skin the following action should be taken:
   a. Complete resection of eschar
   b. Application of full-thickness skin graft to ischemic area
   c. Conservative management with application of petroleum jelly to allow healing by secondary intent
   d. Reapplication of dressing
   e. Sterile Betadine soaks until the eschar sloughs

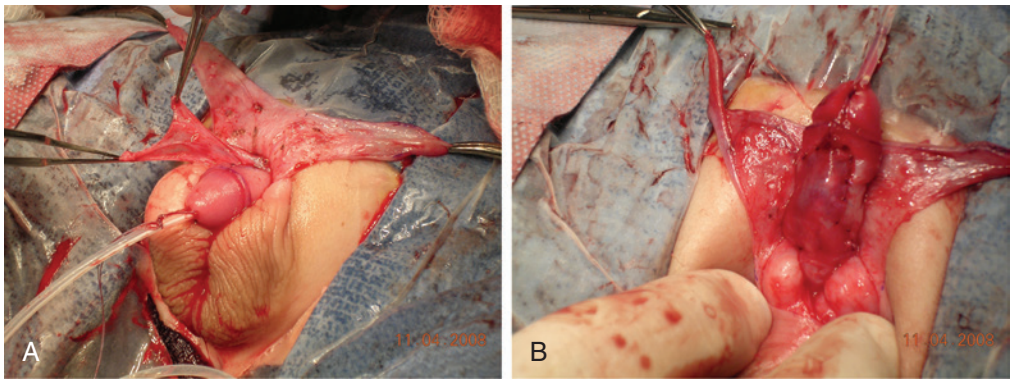
7. When a complication is noted, the repair should be performed:
   a. Immediately regardless of the time since surgery
   b. At least 2 weeks from the initial procedure
   c. At least 6–12 months after the initial repair
   d. At the time the child enters puberty
   e. When the patient begins to toilet train

8. Urethrocutaneous fistula is most likely to present with the following:
   a. In conjunction with a urethral diverticulum
   b. With multiple urinary streams
   c. With a urinary traction infection
   d. With distal repairs only
   e. Much less frequently than a urethral stricture

9. The most definitive approach to a 2-cm urethral stricture after hypospadias repair includes:
   a. Direct visual internal urethrotomy alone
   b. Direct visual internal urethrotomy in conjunction with clean intermittent catheterization
   c. Urethral dilation with indwelling urethral catheter
   d. Revision of urethroplasty with local flaps or buccal mucosa
   e. Creation of a perineal urethrostomy

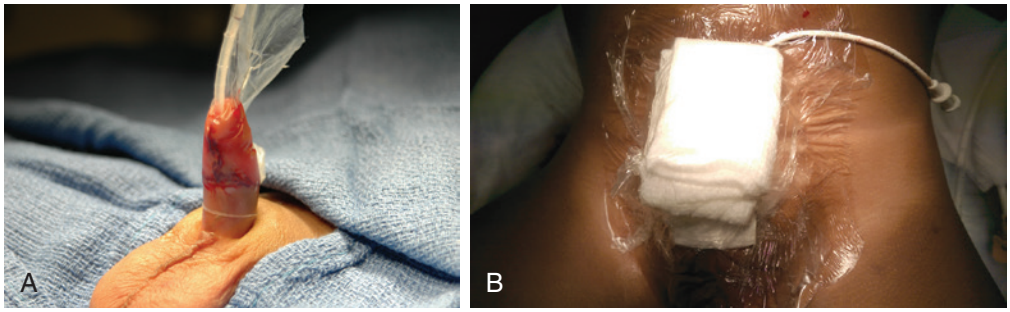
10. Ideal management of recurrent chordee and a tethered urethra in a patient with a history of a previous hypospadias repair includes:
    a. A staged approach in which the first stage addresses the chordee with corporal grafting with subsequent second stage urethral closure
    b. A single stage repair with dorsal plication
    c. A single stage repair with ventral fairy cuts and urethral mobilization
    d. A single stage repair with corporal grafting and closure
    e. A long tubularized incised plate repair with fairy cuts on the ventral corpora

Case Studies



CASE 1

A 30-month-old boy underwent a subcoronal hypospadias repair via a Thiersch Duplay technique at the age of 8 months. He is now undergoing potty training and the parents report a recent history of two urinary streams, the second of which appears to be coming from the original site of the urethral meatus (Case Fig. 60.1).



1. Which approach would you take to repair the hypospadias?
   a. Primary repair with excision of the fistula with multiple layer closure and urethral diversion
   b. Primary repair with excision of the fistula with multiple layer closure and no urethral diversion
   c. Placement of urethral catheter for 1 month and reassessment
   d. Redo hypospadias repair
   e. Placement of suprapubic tube for urinary diversion for 2 months for healing by secondary intent

Alternatively the fistula is located in a similar location but is more extensive (Case Fig. 60.2).

2. What treatment options would you offer at this time?
   a. Primary repair with excision of the fistula with multiple layer closure and urethral diversion
   b. Primary repair with excision of the fistula with multiple layer closure and no urethral diversion

Case Figure 60.1

Case Figure 60.2

Case Figure 60.3

c. Placement of urethral catheter for 1 month and reassessment
d. Redo hypospadias repair
e. Placement of suprapubic tube for urinary diversion for 2 months for healing by secondary intent

On postoperative day #1 after redo hypospadias repair the family calls with a complaint of blood in the diaper. They send a picture (Case Fig. 60.3).

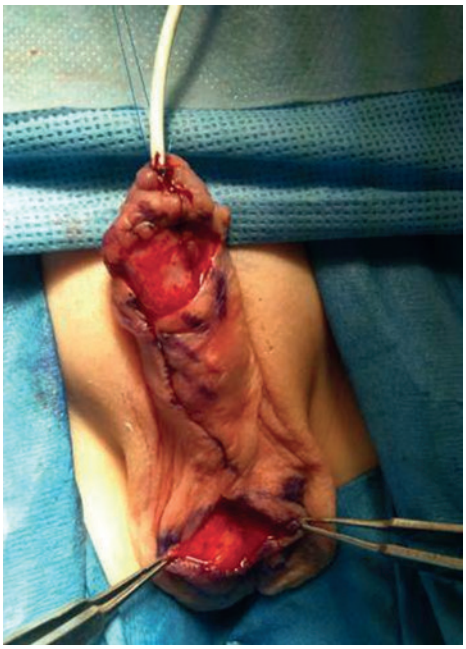
3. What is the next best course of action?
   a. Remove the dressing and replace it with another compression dressing
   b. Return to the operating room for clot evacuation and replacement of dressing
   c. Observation
   d. Reinforce the dressing
   e. Admit to the hospital with full hematology workup

CASE 2

A 6-year-old boy presents to your office with concerns about penile pain and a urinary stream that is directed in a backward direction. He has a history of a previous proximal hypospadias repair at 1 year of age, performed in a single stage. You take him to the operating room and perform a cystoscopy, exam under anesthesia, and artificial erection after penile degloving. After penile degloving the urethral meatus is located at the proximal penile shaft with loss of the distal urethra and significant ventral curvature (>30 degrees) (Case Fig. 60.4).

1. What is your next step in management?
   a. Proceed with single stage hypospadias repair with urethral mobilization, ventral fairy cuts, and distal interposition tube
   b. Proceed with first stage of two-stage repair
   c. Multi-staged repair with the first step correcting ventral curvature with corporal grafting
   d. Dorsal plication in the ventral midline
   e. Dorsal plication via the Nesbit technique

Twelve months later you take the boy for his second-stage repair. At this point he has healed well with no residual penile curvature. The urethral meatus is located at the penoscrotal junction.



Case Figure 60.4

2. What is your approach?
   a. Harvest a flap from redundant penile shaft skin as an interposition tube to replace the distal urethra
   b. Harvest of a buccal mucosa graft as an interposition tube to replace the distal urethra in a single stage
   c. Harvest of buccal mucosa graft as a dorsal inlay with a planned third-stage procedure, at which time the distal urethroplasty is performed
   d. Utilization of a dermal graft as an interposition tube for the distal urethra replacement
   e. Leave the meatus at the penoscrotal junction until the patient enters puberty

At the time of the second stage procedure with urethroplasty you notice that there is a lack of ventral tissue for secondary coverage and skin closure.

When closing the buccal mucosa graft at the time of the third stage of the repair the lack of penile shaft skin prevents tension-free closure of the shaft skin. The picture below reveals an island of distal shaft skin that is unable to be closed at that time (Case Fig. 60.5).

3. What are your options at this point?
   a. Z-plasty technique to maximize skin coverage
   b. Full-thickness skin graft to replace defect
   c. Rotational scrotal flap to ventral shaft skin
   d. Cecil modification repair
   e. Split-thickness skin graft from the gluteal region to replace the defect

Case Figure 60.5

Answers

1. **b.** Urethrocutaneous fistula occurs in up to 10% of hypospadias repairs.
2. **c.** Island onlay flap is an approach that is more likely to result in a urethral diverticulum. It is also more likely to occur in a staged repair in which a long urethroplasty is performed.
3. **d.** Six to 12 months of age is the ideal age to perform a hypospadias repair based on the American Academy of Pediatrics' guidelines. This is before genital awareness occurs and at a stage when anesthetic risk is minimized.
4. **e.** The severity of hypospadias and smaller glans has been shown to result in higher rates of complications.
5. **e.** All of the above.
6. **c.** Conservative management with application of petroleum jelly will allow for healing via secondary intent, which rarely results in graft contraction.
7. **c.** At least 6–12 months after the initial repair. This allows the reconstructed tissue to heal, particularly the establishment of neovascularization, which maximizes success rates for further surgical intervention.
8. **b.** This occurs particularly around the age of potty training when the urinary stream is more likely to be observed.
9. **d.** A long stricture is less likely to respond to conservative management, and definitive repair involves revision of the urethra.
10. **a.** The association of a previous repair, persistent chordee >30 degrees is complex, and higher failure rates are observed when chordee and urethroplasty are addressed in the same procedure.

CASE 1

1. **b.** Primary repair by excision of the fistula tract with closure at the level of the urethra with multiple

layer closure with dartos and consideration of tunica vaginalis. Urinary diversion is optional but in a small fistula with an acceptable glans closure diversion can be omitted.

2. **d.** In this situation the fistula tract is close to the urethral meatus and there is limited surrounding tissue to allow multi-layer closure of the defect. The surgeon must calibrate the meatus to ensure patency and to ensure that no additional complications are present. Urethral diversion would be recommended in this situation given the location and increased risk of a secondary complication.
3. **c.** There is some evidence of bleeding but it is limited and is well controlled with the compression dressing. Removal of the dressing could potentially exacerbate the degree of bleeding. There is no indication for surgical exploration in the absence of uncontrollable bleeding in the immediate postoperative period. This is an acceptable amount of postoperative bleeding; workup for a bleeding diathesis is not necessary.

CASE 2

1. **c.** In the presence of severe curvature (>30 degrees) we find that corporoplasty is the best approach to correct curvature. The first step must ensure that the curvature has been corrected.
2. **c.** In our hands and in this particular setting of a complex redo hypospadias, buccal graft uptake is dependent upon a well-vascularized dartos layer that acts as a bed for receiving the graft. Simultaneous corporoplasty and buccal mucosa grafting increases failure rate, hence increasing the risk of recurrent ventral curvature.
3. **d.** In our hands we have had great success with the Cecil modification in the setting of ventral skin deficiency and redo hypospadias repair. By suturing the distal shaft defect into the mirror-image, diamond-shaped defect in the scrotum, neovascularization via the underlying dartos softens the shaft skin, allowing tension-free closure 12 months after the third stage. The shaft skin has already been maximized and additional Z-plasty incisions are not likely to increase skin coverage. Rotational scrotal flaps will place hair-bearing skin on the penile shaft, which is an unfavorable approach (Case Fig. 60.6).

   Closure of the penile defect into the scrotal defect with an interposed area of closed shaft skin (marked by hemostat in the picture) fosters growth of the dartos layer, which allows release and subsequent skin closure 12 months later.

61 Complications of Surgery for Disorders of Sex Development

JASON M. WILSON and LAURENCE BASKIN

CHAPTER OUTLINE

Overvirilization
Vaginal Agenesis and Vaginoplasty
Undervirilization and Gonadal Abnormalities
Conclusions
Chapter 61 Questions and Answers

KEY POINTS

1. The newborn with a disorder of sex development (DSD) must be evaluated for salt-wasting adrenal hyperplasia.
2. An assembled team of multidisciplinary experts should be assigned the task of educating and treating patients with DSD and their families.
3. Surgical procedures must be undertaken cautiously with knowledge of the accumulated and growing body of data, stressing functional and psychosexual adjustment outcomes.

Disorders of sex development (DSDs) can be defined by congenital conditions in which development of chromosomal, gonadal, or anatomic sex is atypical. These abnormalities comprise a myriad of disorders as illustrated in Table 61.1.[1] Debate has centered on the timing of genital surgery and on whether surgical treatment should be delayed until such time as the patient can be involved in the surgical decision-making process. Surgical procedures in patients with 46,XX DSD are most commonly encountered and have traditionally been performed early in life to avoid potential psychological stressors involved in rearing the child. The difficulty in the objective assessment of perceived psychological complications associated with genital ambiguity contributes to a lack of culturally adjusted, control-matched data that may help in solidifying the medical consensus in regard to management.

Discussion shall proceed under the assumption that patients in whom surgical treatment is deemed necessary have met and undergone evaluation and counseling with an assembled gender assignment team composed of chosen, experienced individuals in the fields of endocrinology, pediatric urology or surgery, psychology, social work, and genetics or dysmorphology. The purpose of such a team is to inform the legal guardians thoroughly of all available options including expectant management and the current state of and expected outcome in each area of reconstruction considered. Particular attention should also be given to discussion of psychosexual outcomes data or lack thereof. In patients who require surgical treatment, the surgeon has the responsibility to outline the surgical sequence and subsequent consequences from infancy to adulthood. Only surgeons with specific expertise in the care of these patients and specific training in the surgical treatment of DSDs should undertake these procedures.

For the purpose of discussion, it is useful to categorize patients in whom surgical treatment is necessary into three general groups:

1. Overvirilization
2. Vaginal agenesis
3. Undervirilization and gonadal abnormalities.

Each category is discussed in turn in this chapter.

Overvirilization

The most common cause of overvirilization is congenital adrenal hyperplasia (CAH), and 21-hydroxylase is responsible for 90% of cases. Surgical treatment for the clitoris should be considered only in cases of severe virilization (Prader III, IV, and V) and should be performed in conjunction, when appropriate, with repair of the common urogenital sinus. Parents now appear to be less inclined to choose surgical treatment for children with less severe clitoromegaly.[1] The only known function of the clitoris is in contribution to sexual pleasure.[2–3] Because orgasmic function and erectile sensation may be disturbed by clitoral surgery, the surgical procedure should be anatomically based to preserve erectile function and the innervation of the clitoris. Further delineation of neurovascular anatomy has allowed a more direct and conscious approach when clitoral surgery is necessary, to preserve the neural architecture important in the sensory aspect of sexual pleasure.[4–6]

Nerve density is lacking in the 12-o'clock position in contrast to the densely innervated 11- and 1-o'clock positions in respect to dorsal nerve distribution. In one report, cavernous nerves were noted to perforate the tunica albuginea

Table 61.1 Classification of Disorders of Sex Development

Sex Chromosome DSDs	46,XY DSDs	46,XX DSDs
A. 45,X (Turner's syndrome and variants)	A. Disorders of gonadal (testicular) development 1. Complete gonadal dysgenesis (Swyer's syndrome) 2. Partial gonadal dysgenesis 3. Gonadal regression 4. Ovotesticular DSDs	A. Disorders of gonadal (ovarian) development 1. Ovotesticular DSDs 2. Testicular DSDs (e.g., SRY+, dup 5OX9) 3. Gonadal dysgenesis
B. 47,XXY (Klinefelter's syndrome and variants)	B. Disorders in androgen synthesis or action 1. Androgen biosynthesis defect (e.g., 17-hydroxysteroid dehydrogenase deficiency, 5α-reductase deficiency, StAR mutations) 2. Defect in androgen action (e.g., CAIS, PAIS) 3. LH receptor defects (e.g., Leydig cell hypoplasia, aplasia) 4. Disorders of AMH and AMH receptor (persistent Müllerian duct syndrome)	B. Androgen excess 1. Fetal (e.g., 21-hydroxylase deficiency, 11-hydroxylase deficiency) 2. Fetoplacental (aromatase deficiency, POR) 3. Maternal (e.g., luteoma, exogenous)
C. 45,X/46,XY (mixed gonadal dysgenesis, ovotesticular DSD)	C. Other (e.g., severe hypospadias, cloacal exstrophy)	C. Other (e.g., cloacal exstrophy, vaginal atresia, MURCS, other syndromes)
D. 46,XX/46,XY (chimeric, ovotesticular DSDs)		

AMH, antiMüllerian hormone; CAIS, complete androgen insensitivity syndrome; DSDs, disorders of sex development; LH, luteinizing hormone; MURCS, Müllerian, renal, cervicothoracic somite abnormalities; PAIS, partial androgen insensitivity syndrome; POR, cytochrome P-450 oxidoreductase, StAR, steroidogenic acute regulatory protein

of the dorsal clitoral bodies near the crus.[6] The nerve distribution suggested by this study seems to correlate with reported areas of sensitivity and ease of orgasm as demonstrated by Schober and associates.[7] Despite evolving understanding of the neurovascular anatomy of the clitoris, it remains difficult to predict what types of surgical procedure will irrevocably alter clitoral sensation and sexual pleasure. Investigators have suggested that any type of clitoral surgery significantly alters sensation. Crouch and colleagues[8] reported that five of six women who had undergone feminizing genitoplasty had abnormal sensation results in response to temperature and vibration. One of the patients had undergone surgical treatment within 1 year of the study and conceivably had benefited from improved surgical techniques.[8] This finding demonstrates a typical situation in that it is often difficult to determine exactly what type of surgical procedure has been performed and whether newer techniques will impart preserved neurovascularity. Yang and colleagues reported on 51 patients who had undergone nerve-sparing ventral clitoroplasty (NSVC) performed by a single surgeon between 1996 and 2005 and concluded that the technique maintained neurovascular integrity of the glans clitoris. Limited data regarding sensitivity threshold were reported, likely secondary to a mean age of 6.8 years. Capillary refill was normal in 49 of 49 tested. Ten patients over 5 years of age were appropriate for sensitivity testing, which the authors interpreted as normal; however, there was no age-matched cohort without surgery with whom to compare. Two patients reportedly underwent preoperative and postoperative testing without significant differences in sensation thresholds.[9] In a related publication, Poppas et al. present findings from immunohistochemical staining of the reduced corporal tissue after NSVC by a single surgeon in 27 patients. They conclude that NSVC optimizes preservation of dorsal nerves.[10] It seems apparent that modern techniques more efficiently preserve neurovascular tissue, but without large series of patients that have undergone NSVC compared with age-matched controls and, perhaps more importantly, a number of patients old enough to undergo preoperative and postoperative sensory thresholds, it remains unclear how this effects psychosexual adjustment.

Two case reports in the literature noted that the preservation of dorsal and ventral neurovascular bundles while preserving the glans during reduction clitoroplasty imparted no difficulty in achieving orgasm or perceived decreased clitoral sensation. These surgical techniques were suggested as reproducible operations in children.[11–12] Thus, emphasis is on functional outcome rather than on strictly cosmetic appearance. Clinical trials in which success is judged solely on an acceptable aesthetic result are conspicuously insufficient and ignore the potential loss of psychosexual adjustment. It is also unreasonable to assume that preservation of neurovascular anatomic features will result in "normal" development and a gratifying sexual life. Investigators generally believe that surgical procedures performed for cosmetic reasons in the first year of life relieve parental distress and improve attachment between the child and the parents.[1]

The current recommendation is that surgical treatment, when necessary, be performed between the ages of 3 and 12 months. Evidence on the establishment of functional anatomy is inadequate to abandon the practice of early separation of the vagina and urethra.[1] The rationale for early reconstruction is based on guidelines on the timing of genital surgery from the American Academy of Pediatrics, the beneficial effects of estrogen on tissue in early infancy, anecdotally reported and experienced difficulty in performing feminizing surgery in adolescent and adult patients, and the avoidance of potential complications from the connection between the urinary tract and the peritoneum through

the fallopian tubes.[1] It is anticipated that surgical reconstruction in infancy will need to be refined at puberty.[1]

Although it is considered acceptable to undertake surgical correction of the common urogenital sinus at an early age, one must be aware and accepting of the likelihood of further surgical intervention in adolescence. Fourteen girls who had early surgical procedures were reassessed near adolescence and were found to have abundant fibrosis and scarring.[13] Another series reported the need for further surgical procedures in 43 of 44 similarly treated young girls with CAH to correct poor cosmesis or to correct introital stenosis.[14] It is currently unknown whether newer surgical techniques will lessen the need for surgical treatment later in life.

Several studies suggested that urogenital sinus mobilization, when possible, may decrease the risk of vaginal stenosis, especially if this procedure is performed early in life. These findings led to the further application and refinement of partial urogenital mobilization in feminizing surgery for the patient with CAH.[15–18] Encouraging early results based on position and caliber of vaginal introitus require longer follow-up to clarify further whether improved technique and early surgical treatment obviate the need for revisions in pubertal female patients. In a forthcoming publication, Stites and colleagues review toilet training success in 66 patients undergoing vaginoplasty for CAH-related urogenital sinus (UGS). Median age at time of surgery was 17 months. Techniques for vaginoplasty were flap vaginoplasty (41), total urogenital sinus mobilization (10), pull-through (nine), partial urogenital sinus mobilization (three), pull-through with partial mobilization of urogenital sinus (two), and cut-back (one). Sixty-four of 66 achieved continence without further surgery, though 11 required behavioral modification with or without pharmacotherapy and treatment for constipation. Two patients that had undergone total urogenital sinus mobilization (TUM) required urethral bulking to achieve continence. TUM requires dissection anterior to urethra and may extend proximal to pubourethral ligaments, presumably interfering with continence mechanism and may inherently impart a higher risk of incontinence.[19a] The current trend toward delayed operative intervention paralleled by the continued refinement of early surgical technique may produce enlightening outcomes data on psychological, physiologic, and anatomic function in these differently managed groups of patients.

Vaginal Agenesis and Vaginoplasty

An absent or inadequate vagina (with rare exceptions) requires a vaginoplasty performed in adolescence when the patient is psychologically motivated and a full partner in the procedure. No one technique has been universally successful; self-dilation, skin substitution, and bowel vaginoplasty each has specific advantages and disadvantages.

Considering a low vaginal confluence, the most popularly employed technique of vaginoplasty is skin substitution of the posterior vagina through an omega flap. The omega flap is a modification of the perineal skin flap proposed and developed by Fortunoff et al.[19b] Twenty-eight patients with a salt-losing form of CAH underwent posterior flap vaginoplasty between 1997 and 2001. Twenty-six of these patients had a low vaginal confluence. The age of these patients ranged from 5 months to 17 years, and follow-up was between 1 and 4 years. Nine patients had undergone previous surgical procedures but none had had prior vaginoplasty. None of the patients required further surgical treatment of vaginal stenosis or inadequate caliber, although two patients were undergoing continued vaginal dilation without reported difficulty.[20]

Jenak and colleagues[21] described the use of a narrow-based (omega) perineal skin flap to create a widened introitus. Four of the six patients had CAH, and follow-up ranged from 1 to 9 months. The mean vaginal calibration in four patients was 10.5 Hegar.[21] The initial cosmetic results noted in these two reports were encouraging, but long-term follow-up is needed to determine the functional capacity imparted in early versus late surgical vaginoplasty.

Another technique described, requiring 1.5–2 cm of urethral length, combines urogenital sinus mobilization with creation of urogenital sinus flaps. These urogenital sinus flaps can be posteromedially rotated to form a posterior vagina that is mucosa lined and thus obviate the need for a perineal skin flap. The group reported a mean follow-up of 2.5 years without vaginal stenosis or the need for vaginal dilation. The age range was 3 months to 13 years and CAH was present in seven of the 11 patients. Most of these procedures were accomplished with a perineal approach (eight of 11).[22] A major concern is whether the vagina will undergo stenosis or fibrosis that will increase the possibility of painful or unpleasant penetrative sexual intercourse in the future. Because assessment of successful results should incorporate both the feasibility and the quality of sexual intercourse, continuing methods of evaluating the quality of sexual life must be developed.

High vaginal confluence is generally considered to be >3 cm.[15] From a surgical standpoint, a high vaginal confluence indicates a position near or proximal to the urethral sphincter and the need for a vaginal pull-through procedure.[23–24] The likelihood of encountering this anatomic feature in a patient with CAH is 5%.[25] Vaginal pull-through requires separation of the vagina from the urethra and increases the probability of complications such as urethral stricture, urethrovaginal fistula, and urinary incontinence.

Hendren and Atala[23] reported the results of 16 female patients with high vaginal confluence and CAH who had undergone repair procedures using the described technique for pull-through with superior and inferior U-flaps and partially mobilized labia majora between 1962 and 1993. At the time of the report, nine of 16 women were adults and six of the nine were sexually active (five of six with heterosexual preference and one of six with bisexual orientation). One woman had given birth to a child by cesarean section, and at the time this was the first reported birth after a pull-through operation for high vaginal confluence.

In 1994, Donahoe and Gustafson[26] advocated a one-stage repair for patients at an early age and cited a high incidence of vaginal stenosis with the two-staged pull-through procedure. Three older patients aged 2, 3.2, and 9.2 years required the use of posterior buttock flaps. Three younger children aged 8, 8, and 12 months did not require

such flaps, and vaginoplasty was undertaken with the use of local tissue and a posterior, perineal skin flap. Follow-up at 6 weeks with endoscopic and anesthetic-aided examination and follow-up at 5 to 17 months indicated no fistulas and an adequate introital caliber. These investigators noted the importance of long-term follow-up to detect delayed vaginal stenosis. They also noted that injury to the urethra was of particular concern.[26]

A posterior approach as described by Pena and colleagues[27] included division of the rectum and creation of a diverting colostomy. Subsequently, Rink and associates[28] described a posterior prone approach in which the rectum was retracted and division avoided. Eight patients aged 6 months to 25 years underwent the procedure. Four had ambiguous genitalia and the other half had a pure urogenital sinus anomaly. Follow-up ranged from 6 months to 5 years and one patient was sexually active. These investigators noted greater mobility of tissue and no increased technical difficulty in the younger patients. One of the older patients required ongoing vaginal dilation for mild vaginal stenosis and a teenaged patient had an asymptomatic urethrovaginal fistula noted during cystoscopic examination.[28]

True vaginal agenesis is a rare condition consisting of primary amenorrhea and an intact hypothalamic-pituitary-gonadal axis in a genotypically and phenotypically normal female patient. Numerous techniques are described, dating as far back as 1817, when Dupuytren described creation of a pouch that could epithelialize without the use of a mold, to create a vagina in place of its absence or in place of a small vaginal dimple.[29] Technique has evolved with a common goal: creation of a functional vaginal vault in concordance with the desire of the patient, who accepts the ongoing need for self-dilation and commits to that regimen.

Nonsurgical dilation was first described by Frank in 1938.[30] Subsequently, the technique was described as successful and easier to perform using the patient's weight instead of digital pressure, especially when patients had no history of earlier surgical procedures and were motivated by an active sexual relationship.[30–34] Vaginal creation has been successful in 43% to 91% of patients by using the technique as described by Frank and further modified by Ingram.[35] In these patients, success is determined by the presence of a vagina that allows satisfactory penetrative sexual intercourse. Ingram's modification and initial report[35] involved 12 women with primary vaginal agenesis, and 62.5% of a total of 24 women (12 of whom had vaginal stenosis) reported comfortable sexual intercourse after 4 to 6 months of progressive dilation.

Surgical management of vaginal agenesis (Figs. 61.1 and 61.2) can be broken down into three categories:

1. Creation of space between bladder and rectum and use of mold and covering
2. Vulvovaginoplasty using skin flaps
3. Bowel segment vaginoplasty.

The primary advantage at the time of inception of the first-described use of a mold in a created perineal space was avoidance of the peritoneum. Different coverings have been used with variable success, including peritoneum, split-thickness skin grafts (STSG), bladder mucosa, amnion, and peritoneofascial flaps.[36–39]

Figure 61.1 Gross photograph of the introitus of a female patient with vaginal agenesis.

Figure 61.2 Magnetic resonance image of a female patient with complete vaginal agenesis. Note the dilated uterus with retained menstrual fluid.

Buccal mucosa was reported for use in vaginoplasty in 2003. Two different groups described the use of buccal mucosa free grafts of similar sizes for neovaginal creation in women with vaginal agenesis; the average age at time of operation in the two groups was 21.75 years. Both groups used similar technique in that a perineal space was created between the rectum and bladder, the graft size was increased by several small incisions ("meshing"), and grafts were placed within the neovaginal cavity such that the epithelial side was in contact with a subsequently placed vaginal mold or stent that remained in place for a period of time sufficient to aid in graft vascularization and epithelial proliferation. Follow-up was 15 to 18 months, at which time the authors had reported successful, regular intercourse and no occurrences of oral contracture or vaginal stenosis. Both groups suggested regular use of the vaginal mold or stent, with discontinuation of use only during times of regular intercourse, and both groups reported closure of the donor site with absorbable suture.[40,41] In 2014, Grimsby and Baker reviewed the literature and reported the senior author's experience with vaginal reconstruction and autologous buccal mucosa. Their series included 42 patients with CAH (n = 13), vaginal agenesis (n = 13), cloaca/UGS (n = 7), 46,XY (n = 6), cancer (n = 2), and Hircshsprung's disease (n = 1). In seven patients requiring total neovagina creation, two had had prior vaginoplasty. Immediate complications included urethral injury, recognized and repaired at time of surgery, and one dislodged vaginal stent that required another anesthetic for replacement of the stent. There were two patients that required revision: vaginal synechiae in one and vaginal foreshortening in the other. Five of the seven patients reported successful sexual activity, and two were not yet sexually active. Fourteen patients required distal vaginal augmentation, nine of whom had undergone primary repair of UGS. They describe mobilization of the UGS, urethroplasty, and autologous buccal mucosa used to bridge the gap between the vagina and perineum. No acute complications were reported. Three of 14 patients required revision for vaginal stenosis, and two of 14 developed oral contracture because of scarring at the donor site, with one of the two requiring further oral surgery. Donor sites were not reapproximated in any of the patients in this series. Buccal grafts were also used for successful treatment in cases of vaginal stenosis after primary vaginoplasty and some in whom vaginal stenosis repairs had failed. Stenotic areas were incised, and the tissue gaps were filled with buccal mucosa grafts. Three of 12 patients required revision for recurrence of stenosis, and one required oral surgery for oral contracture. With this publication, the authors illuminate the versatility of buccal mucosa free grafts for use in primary vaginoplasty and other types of vaginal reconstruction, while advising the need for long-term studies documenting outcomes in sexual function and health, reproduction, growth and growth characteristics of grafted epithelium, and direct comparison to other techniques.[42] Thirty-two women aged 17 to 39 years underwent surgical creation of vagina using a mold and STSG harvested from gluteus or thigh.[37] On postoperative day 7, the mold was removed to allow determination of STSG take, and it was then used continuously for 3 months. After time, it was possible to use the mold for 1 hour per week to avoid shrinkage. In judging the success of the procedure, these investigators used several criteria: STSG take, presence and degree of pseudomucinous metaplasia and associated sensitivity, vaginal dimensions and variation over time, and characteristics of sexual relationships. No regrafting was needed, and the rate of complete STSG take was 90.6%. Average vaginal dimensions were 10 cm in length and 4 cm in diameter. Twenty-seven of 32 (84.3%) women reported normal sexual activity with good sensitivity, and five did not engage in sexual intercourse. The rate of complications was 9.3% for partial take of STSG and 6.2% for partial vaginal stricture. One patient had total vaginal stricture. Success in outcome depended on mold management adherence or regular sexual activity.[37]

Long-term outcome in this type of reconstruction is directly related to the patient's motivation and willingness to comply with postoperative management and the desire for or presence of sexual intercourse.[43] An extensive retrospective review of 201 cases was reported in 1996.[44a] A modified Abbe-McIndoe procedure was performed in all cases with an average patient age of 20.5 years. In most cases, the impetus for performing reconstruction was the patient's desire to engage in sexual relationships. Follow-up was from 3 to 16 years, and the investigators reported low morbidity and high success rates. In this review, 156 women completed a sexual satisfaction questionnaire; 112 (71.8%) reported their sexual life as good or satisfactory, considering the presence of lubrication and the absence of dyspareunia, and some within this group noted insufficient vaginal lubrication. Reported complications were low and included graft site infection (5.5%), graft infection (4%), and rectal perforation (1%). The investigators recommended that surgical reconstruction be delayed until regular sexual intercourse is anticipated or desired by the patient.

The use of skin in vulvovaginoplasty has been described by several surgeons, with modern approaches derived from those described by Fliegner Jr.[44b], Fortunoff[19b], Williams[45a], and Donahoe and Hendren[45b]. Use of local skin in creation of a distal vagina in the case of a severely masculinized female patient with whom the decision has been made for reconstruction often requires more than a perineal skin flap. A proximal vaginal confluence increases the concern for incontinence and vaginal stenosis after reconstruction. Hendren and Donahoe[46a] described the creation of lateral and anterior walls of the distal vagina by using bilateral, medially rotated buttock flaps. Passerini-Glazel[46b] described the use of local skin for creation of distal vagina, advocated this technique for patients with proximal and distal vaginal confluence, and suggested that the procedure could be used at any age.

The use of musculocutaneous flaps is avoided in this patient population secondary to the considerable bulk of such flaps. The use of tissue expansion in the labia minora can create hairless, abundant, elastic, and well-vascularized flaps for creation of the distal vagina.[47] Donahoe and Gustafson[26] noted in 1994 that in patients presenting for vaginal exteriorization as part of a two-staged procedure, the use of bilateral rotated buttock flaps was necessary. In management of infants with a proximal vaginal confluence, no additional skin was needed for a posterior perineal-based flap and an anterior subphallic skin flap.[26] Based on the experience and comparison between the two techniques, the investigators recommended early, one-stage

reconstruction and emphasized the mobility of tissue and the use of labia minora and majora flaps for anterior and lateral introitus construction.[26]

Long-term follow-up in patients undergoing Passerini-Glazel feminizing genitoplasty demonstrated a significant difference in incidence of vaginal stenosis between two groups of patients. The first group, who had undergone the surgical procedure at a mean age of 2 years, was noted to have a 45% (10 of 22) incidence of vaginal stenosis. The incidence of vaginal stenosis was 25% (six of 24) in the group who underwent the procedure at a mean age of 14 years and who had a history of other surgical procedures performed at younger ages. The overall incidence of vaginal stenosis was noted to be 35%.[48]

When multiple approaches and the timing of surgical treatment are taken into consideration, the incidence of vaginal stenosis ranges from 11% to 94%. The decision to perform early reconstructive surgery should include the expectation for minor surgical procedures (i.e., introitoplasty) near the adolescent period.[13,14,23,49,50] Repair of vaginal stenosis should be undertaken at puberty when estrogen levels are high, to facilitate healing and to decrease the likelihood of recurrence.

Bowel segment vaginoplasty was initially described by Baldwin in 1904 and was subsequently avoided because of complications including several deaths.[29] The use of bowel to create a functional vagina has been associated with long-term complications unique to the use of a colonic segment such as the reported occurrence of diversion colitis associated with mucus discharge and bleeding.[51] Other complications or unwanted long-term associations include enteric segment prolapse, stenosis, and the long-term need for daily use of absorbent liners or douching for copious mucoid discharge.

Parsons and associates[52] reviewed 28 patients who had undergone colovaginoplasty and identified the following postoperative complications: introital stenosis (four), mucosal prolapse (four), partial small bowel obstruction (two), perineal hematoma (two), wound infection (two), and vaginal prolapse (one). The complication rate was 50%. The mean follow-up period was 6.2 years, and the patients in the review believed that adolescence was an appropriate time to undergo the procedure. Despite the high complication rate, long-term patency and cosmesis were not affected and 15 of 16 adult patients were sexually active.[52]

Hendren and Atala[53] reported on a large volume of patients who had undergone bowel segment vaginoplasty for various conditions. The most common complication was mucosal prolapse, occurring in 16 of 65 patients. The prolapse was easily repaired with a simple trimming, and the investigators believed that technical changes to avoid this minor complication would predispose the patient to more serious complications such as stenosis or bowel segment retraction. Recommendations from this report included early reconstruction to avoid the psychological ramifications of an absent vagina and daily douching with normal saline solution to prevent the accumulation of foul-smelling mucoid concretions.[53]

A published review of sigmoid vaginoplasty performed at a mean patient age of 16.8 years in 14 female patients with congenital vaginal agenesis indicated that the procedure provided a cosmetically suitable, self-lubricating vagina without the need for routine dilation, although daily irrigation and dilation were implemented for 8 weeks postoperatively. The psychosexual status of these patients was reported as acceptable, and no complaints of dyspareunia were reported. The patient population in the study was unique in that they had all presented at the inception of marriage arrangements. This finding indicates that the successful results were associated with older patients motivated, presumably, by the prospect of an active sexual life. Mean follow-up was 4.1 years.[54]

A review of the literature suggests that very few patients with CAH require the use of an enteric segment for construction of a functional vagina. In deciding whether to proceed with early as opposed to delayed reconstruction, one must weigh the potential psychological aspects of an absent vagina throughout childhood and early adolescence against the reported complications of vaginal stenosis and chronic discharge. Once again, evidence-based literature to help in establishing an algorithmic approach to decision making in this type of reconstruction is conspicuously lacking, and it is of utmost importance to consider each patient individually and to incorporate anatomic, physiologic, and psychosexual facets of personal development into the decision-making process. Family counseling and education with a multidisciplinary team approach are crucial.

Undervirilization and Gonadal Abnormalities

The undervirilized newborn with a DSD should be approached in the same manner as previously described, with a multidisciplinary approach in an experienced medical center. The historically described emergency status of the newborn with ambiguous genitalia has been challenged, and referral to an experienced center is always possible after the workup has ruled out true emergencies such as salt-wasting adrenal hyperplasia. 46,XY DSD is characterized by a spectrum of medical conditions including hypospadias, genetic syndromes, androgen receptor abnormalities, defects in androgen biosynthesis, and gonadal abnormalities. A specific diagnosis is identified in 50% of children with 46,XY DSD, in contrast to those children with 46,XX DSD.[1] Assuming that each patient has been carefully evaluated with full family participation and education, surgical treatment can proceed appropriately after consideration of factors including fertility, sexual function, degree of in utero exposure to androgens, psychosexuality, and culture.

In the case of a DSD associated with hypospadias, standard techniques for surgical repair such as chordee correction, urethral reconstruction, and the judicious use of testosterone supplementation apply.[1] An animal model of penile growth subsequent to testosterone stimulation indicated that the early use of synthetic androgen to achieve a more normal penis in childhood may ultimately result in the absence of further growth during puberty and result in a significantly smaller phallus.[55] Therefore, caution should be exercised when testosterone supplementation is considered.

The magnitude and complexity of phalloplasty in adulthood should be taken into account during the initial counseling period if successful gender assignment depends on this procedure.[56] At times this may affect the balance of

gender assignment. Patients must not be given unrealistic expectations about penile reconstruction, including the use of tissue engineering. No evidence indicates that prophylactic removal of asymptomatic discordant structures, such as a utriculus or Müllerian remnants, is required, although future symptoms may indicate surgical removal.

In a review including 57 patients over 20 years who were undergoing masculinizing genitoplasty, only two patients required excision of a utriculus. In this review, 77% of patients had severe penoscrotal hypospadias and 33% had perineal hypospadias.[57] Technique-specific, long-term outcome data are not sufficient to determine whether refinement in surgical technique will decrease the incidence of long-term complications. One-stage techniques may offer superior cosmetic and functional outcomes without the potential psychological trauma of repeated genital surgery.

Miller and Grant[58] reported on 19 patients in whom staged procedures had been performed for severe hypospadias. Only seven patients reported satisfactory ejaculation, and 15 reported satisfactory erection and orgasm. A questionnaire completed by 22 men aged 18 to 26 years in whom surgical treatment had been performed in childhood for hypospadias (severe, 11) identified penile size as a cause of dissatisfaction.[59] Age-matched controls showed no significant differences in sexual behavior, and a slightly higher rate of dissatisfaction was reported in the surgical group (40.9% vs 34.2%).

Using the described modern surgical techniques involving inner preputial skin, Chertin and colleagues[57] performed masculinizing genitoplasty in 39 patients at a median age of 1.8 years. With a median follow-up of 6 years, 10 patients required further surgical procedures for urethral breakdown (three), urethrocutaneous fistula (five), and excision of utriculus (two).

Lam and associates[60] reported on the outcome in 27 male patients who had undergone two-stage repair of hypospadias in infancy for congenitally located meatus at midshaft or more proximally. Five patients had a DSD and hypospadias. Additional surgical treatment had been necessary in five patients for excision of diverticulum, in three patients for fistula, and in four with minor urethral strictures. Forty percent of patients experienced spraying of the urinary stream but were able to stand and urinate. Nine of 20 patients who were able to ejaculate reported the need to "milk" the ejaculate. All patients reported satisfaction with genitourinary function, and 23 of 27 were happy with their penile appearance.[60]

When considering masculinizing genitoplasty for the patient with a DSD, one must be mindful of potential complications of Müllerian remnants and dysgenetic gonadal tissue. Utricular manifestations may include chronic urinary dribbling, recurrent urinary tract infection, and multiple failed attempts at hypospadias repair. Desantel and colleagues[61] found a high risk of infertility in patients undergoing surgical treatment for symptomatic utricles. This condition was thought to be either secondary to abnormal anatomic insertion of ejaculatory ducts or vas deferens or caused by operative injury.

The severity of hypospadias or micropenis should not be considered when one determines the sex of rearing in the patient without an androgen receptor defect. Current data do not support the amputation of sexually sensitive and functional but small male phallic structures.[56,62,63] Another review of patients with micropenis noted that either male or female gender assignment was possible, and no patients sought gender reassignment. The investigators noted a higher complication rate in feminizing surgery and a higher rate of dissatisfaction with external genital appearance and concluded that male gender assignment was preferable.[64]

In management of the patient with a DSD, removal of gender-discordant structures is generally directed by symptoms or risk of malignant disease. Specifically, varying degrees of gonadal dysgenesis may be present and may necessitate surveillance or removal of this tissue. This situation is encountered in the patient with a DSD and Y chromosomal material. Several gene mutations that have been identified and documented are associated with DSDs and a propensity toward gonadal malignant disease.[1,65]

Historically, gonadal biopsy and excision were performed using laparotomy. More recent trends support the use of laparoscopy for diagnosis, biopsy, and excision of aberrant or discordant structures.[66–69] Standard laparoscopic techniques apply, and three-port placement is sufficient for surgical procedures in the pelvis. Bladder drainage increases visualization and reduces the chance of injury during laparoscopic pelvic surgical procedures, particularly in the patient weighing <15 kg.

The testes in patients with complete androgen insensitivity syndrome and in those with partial androgen insensitivity syndrome who are raised as girls should be removed to prevent malignant disease in adulthood.[1] The availability of estrogen replacement therapy allows for the option of early removal of testes at the time of diagnosis. This approach also takes care of the associated risks of hernia, psychological problems with the presence of testes, and malignancy. Parental choice allows deferment of treatment until adolescence, because the earliest reported malignancy in complete androgen insensitivity syndrome occurred at 14 years of age.[1]

The streak gonad in a patient with mixed gonadal dysgenesis who is raised as a boy should be removed laparoscopically (or by laparotomy) in early childhood.[1] Bilateral gonadectomy is performed in early childhood in girls (bilateral streak gonads) with gonadal dysgenesis and Y chromosome material. In patients with androgen biosynthetic defects who are raised as girls, gonadectomy should be undertaken before puberty. A scrotal testis in patients with gonadal dysgenesis is at risk for malignant disease.

Current recommendations are testicular biopsy at puberty to seek signs of the premalignant lesion termed *carcinoma in situ* or *undifferentiated intratubular germ cell neoplasia*. If results of the biopsy are positive, the option is sperm banking before treatment with local low-dose radiation therapy, which is curative.[1] Surgical management of DSDs should also consider options that will facilitate the chances of fertility. In patients with a symptomatic utriculus, removal is best undertaken laparoscopically to increase the chance of preserving continuity of the vasa deferentia.

Patients with bilateral ovotestes are potentially fertile from functional ovarian tissue.[1] Separation of ovarian and testicular tissue can be technically difficult and should be undertaken, if possible, in early life. Four-fifths of ovotestes will demonstrate tissue that is adjacent and clearly demarcated in an end-to-end fashion.[70]

Conclusions

Growing numbers of specialty trained and experienced physicians, advocacy and support groups, and well-informed patients and families herald a future for the child with a DSD that is free of stigma and abounds with the opportunity for a life of choice. It is quite clear that technical advances have decreased the number of surgical procedures and complications associated with DSDs. The possibility of delaying surgical treatment when it is not immediately necessary will perhaps provide the community with a patient population that is older and more involved in the treatment decision-making process. This would provide the community with a control population to illuminate the areas of neuroanatomic and psychosexual functioning further. For example, we may learn that, regardless of age at surgical reconstruction, the patient with a DSD is more likely to have difficulty in adjusting.

Education and further clinical trials undoubtedly will clarify this issue in the future, particularly with emphasis on all facets of outcome, including an extrapolation of the previously held notion that successful outcome was based on appearance and the ability to engage in conventional sexual intercourse. Expanding models of sexuality will aid in defining a reproducible measure of sexual function and psychological well-being. Critical factors should remain well within the foreground during discussions with family and health-care providers: preservation of fertility, preservation of sexually sensitive tissue, measures and metrics for determining successful outcome, cultural and societal factors, and the time-honored, sage admonition – *primum non nocere*.

Chapter 61 Questions

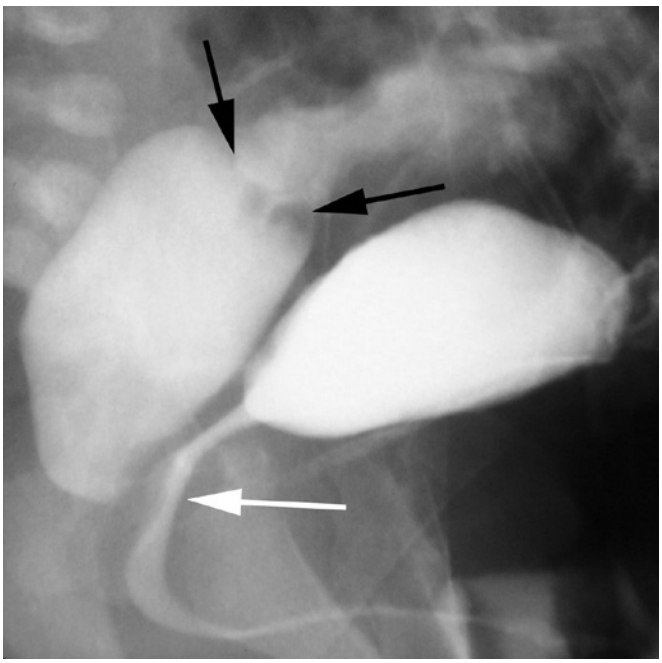
1. You are asked to see a newborn with atypical genitalia (Case Fig. 61.1). The term infant was born by vaginal delivery and has good Apgar scores. The infant is ready to be discharged from the hospital. What is the best diagnostic study?
   a. MRI
   b. Sonogram
   c. Genitogram
   d. CT scan
   e. Laparoscopy

2. After sending a sample for a chromosome analysis, what is the most important test?
   a. Complete blood cell (CBC) count
   b. Serum testosterone
   c. 17-OH progesterone
   d. Electrolytes
   e. Androstenedione

3. A voiding cystourethrogram (VCUG) is shown in Case Fig. 61.2. What do the *black arrows* denote?
   a. Utricle
   b. Fistula
   c. Rectum
   d. Cervix
   e. Introitus

4. What does the *white arrow* in Case Fig. 61.2 denote?
   a. A high confluence
   b. A low to middle confluence
   c. The vagina
   d. The urethra
   e. The rectum

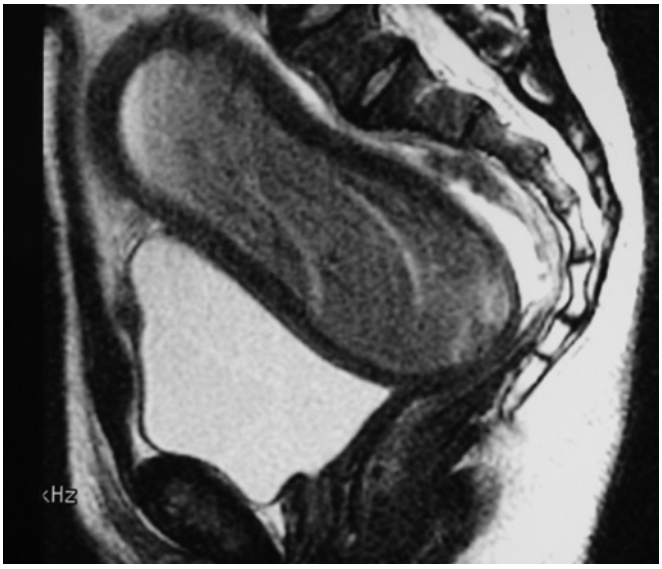
5. After surgical repair, what likely outcome should the family be counseled about?
   a. The need for examination and revision when the child is a teenager
   b. Loss of sexual function
   c. Gender dysphoria
   d. Infertility
   e. Cancer



6. A 12-year-girl complains of cyclic abdominal pain lasting for 5 days and returning each month. Physical examination reveals a pelvic mass and no vaginal opening but a normal introitus (Case Fig. 61.3). What is the best test to determine the diagnosis?
   a. MRI
   b. Sonogram
   c. Genitogram
   d. Serum testosterone
   e. Serum levels of FSH and LH

7. An MRI of the abdomen and pelvis is obtained (Case Fig. 61.4). What organ is absent in the MRI study?
   a. Kidney
   b. Uterus
   c. Ovary
   d. Vagina
   e. Clitoris

8. A patient with similar findings of vaginal agenesis but no uterus has complete androgen insensitivity syndrome. What is this patient at risk for?
   a. Gender dysphoria
   b. Gonadoblastoma
   c. Wilms' tumor
   d. Cervical cancer
   e. Aneurysm



Case Figure 61.1

Case Figure 61.2

Case Figure 61.3

Case Figure 61.4

9. A 6-month-old, XY boy with severe hypospadias responds to testosterone stimulation with phallic growth. At the time of surgery, it is difficult to pass a tube into the bladder. What is the most likely reason?
   a. Urethral stenosis
   b. A utricle
   c. Rectal fistula
   d. High bladder neck
   e. Inaccurate diagnosis

10. Patients undergoing repair of severe hypospadias are at risk for what condition?
    a. Fistula
    b. Urethral diverticulum
    c. Urethral stenosis
    d. Chordee
    e. All the above

Case Studies

CASE 1

1. A newborn presents with atypical genitalia shown in Case Fig. 61.1. Gonads are not palpable. The initial most important diagnostic test is:
   a. Karyotype
   b. Pelvic sonogram
   c. Electrolytes
   d. 17-OH progesterone

2. The diagnosis of 21-hydroxylase deficiency is made in the same patient. What is the next step in deciding surgical reconstruction?
   a. MRI
   b. Genitogram
   c. Laparoscopy
   d. Exam under anesthesia

3. The genitogram shows a high urogenital sinus, and the patient undergoes a partial urogenital sinus mobilization with nerve-sparing clitoroplasty. What is the most common complication after surgery?
   a. Urinary tract infection
   b. Unsatisfactory sexual function
   c. Distal vaginal stenosis
   d. Lack of orgasm

CASE 2

A baby with Prader V congenital adrenal hyperplasia (CAH) and high urogenital sinus undergoes a total urogenital mobilization and reduction clitoroplasty (Case Fig. 61.2).

1. What are possible complications from injuring the dorsal nerve of the clitoris during genitoplasty?
   a. Decreased glans sensation
   b. Decreased erectile dysfunction
   c. Decreased sexual arousal
   d. All the above

2. What is the best use of excess tissue from the common urogenital sinus?
   a. Anterior vaginal wall reconstruction
   b. Posterior vaginal wall reconstruction
   c. Labia majora reconstruction
   d. Labia minora reconstruction

3. Reduction of the glans clitoris to maximize sensation should be performed on the:
   a. Ventral aspect
   b. Dorsal aspect
   c. Lateral aspect
   d. At the coronal glans margin

Answers

1. **b.** The most practical choice is a sonogram. In the newborn period, ultrasound can document the presence of a uterus in patients with congenital adrenal

hyperplasia, which is the most common diagnosis for patients with disorders of sex development. The other studies also can do this but are invasive or require anesthesia or irradiation.
2. **d.** For patients with possible congenital adrenal hyperplasia, it is critical to rule out a salt-losing form, which can be life threatening.
3. **d.** The black arrows point to the top of the vagina or the cervix (which is seen as an impression) in this patient with congenital adrenal hyperplasia.
4. **b.** The white arrow denotes the confluence of the urethra and vagina. If the confluence were close to the bladder neck, it would be considered high. In this case, it is middle to low, which has ramifications for the type of surgery.
5. **a.** Patients undergoing surgery for congenital adrenal hyperplasia often require at least an examination under anesthesia as they go through puberty to rule out vaginal stenosis at the introitus.
6. **a.** The diagnosis of vaginal agenesis is best made by MRI.
7. **d**. The enlarged uterus is clearly seen on MRI along with absence of the vaginal canal, which is consistent with vaginal agenesis. Patients with vaginal agenesis also may have an absent kidney (Mayer-Rokitansky-Kuster-Hauser [MRKH] syndrome), but the MRI cut does not include the area of the kidneys for evaluation.
8. **b**. The patient with complete androgen insensitivity syndrome is at risk for cancer in the intraabdominal gonads, which should be removed at or before puberty.
9. **b.** A prostatic utricle is more likely in patients with severe hypospadias.
10. **e.** Patients undergoing repair of severe hypospadias are at risk for all of the conditions and require long-term follow-up.

CASE 1

1. **c.** In a newborn with atypical genitalia and nonpalpable gonads the most common diagnosis is congenital adrenal hyperplasia. The workup includes all of the answers but initially it is important to check electrolytes to rule out salt wasting, thereby avoiding an adrenal crisis.
2. **b.** A genitogram will determine the level of confluence of the urethra and vagina and the length of the common urogenital channel. This will allow a determination of whether this is a high versus low confluence, thereby helping to plan both the type and length of reconstruction.
3. **c.** The most common complication after repair of a high urogenital sinus is distal vaginal stenosis. Therefore these patients need a careful exam before puberty and counseling that an additional procedure may be required to correct the distal stenosis at that time.

CASE 2

1. **d.** All the above. The dorsal nerve of the clitoris innervates the glans and skin of the clitoris affecting all aspects of sexual function.
2. **a.** Excess common urogenital sinus tissue is best used for reconstruction of the anterior vaginal wall by splitting sinus on the dorsal aspect and flipping the excess sinus tissue 180 degrees to anastomose to the anterior vaginal wall.
3. **a.** The dorsal nerve of the clitoris enters the glans clitoris on the dorsal aspect with the sparsest innervation being on the ventral aspect of the glans; hence if reduction clitoroplasty is indicated it should be performed on ventral aspect.

62 Complications of Pediatric Urinary Diversions and Bladder Augmentation

DOUGLAS A. HUSMANN

CHAPTER OUTLINE

The Goals of Congenital Urologic Diversions and Urinary Reconstruction
Complications Following Temporizing Urinary Diversions of Infancy and Childhood
Cutaneous Pyelostomy, Ureterostomy, and Noncontinent Vesicostomy
Complications Following Definitive Urologic Reconstruction in Childhood
Lethal Complications Following Urologic Reconstruction in Childhood
Neoplasia
Spontaneous Bladder Perforations
Preservation of Renal Function Following Urinary Conduits and Bladder Reconstruction
Surgical Complications
Bladder and Renal Calculi
Need for Secondary Augmentations
Small Bowel Obstruction
Stomal Revision of Urinary Conduits or Revision of Catheterizable Limb
Medical Complications Following Bladder Augmentation or Urinary Diversion
Chronic Bacteriuria
Metabolic Sequalae
Hyperchloremic Metabolic Acidosis–induced Osteoporosis or Growth Retardation
Fecal Incontinence
Prothrombin Deficiency
B_{12} Deficiency
Bladder Augmentations Not Using the Gastroenteric Segments
Autoaugmentation-detrusor Myomectomy
Ureterocystoplasty
Incontinent Ileovesicostomy (Ileal Chimney)
Pregnancy Following Bladder Augmentation and Urinary Diversion
Patient Selection
Chapter 62 Questions and Answers

KEY POINTS

1. In infants (<1 year of age) with obstruction of the urinary tract, long term usage of a percutaneous nephrostomy or suprapubic tube is associated with a 40% complication rate. If temporary drainage for over six months is required, the surgical creation of tubeless urinary diversion via either a cutaneous pyelostomy, ureterostomy or vesicostomy are preferred.
2. The incidence of bladder cancer is increased in all children with a congenitally abnormal bladder with a incidence of approximately 1% per decade of life. This risk is not significantly increased in patients undergoing a ileal or colonic bladder augmentation, approximately 1.5% per decade post augmentation.
3. Spontaneous perforation of an augmented bladder has reported mortality incidence of 25% and most often occurs due to patient non-compliance with intermittent catheterization.
4. The use of urinary conduits is associated with 80% incidence of new onset of renal scarring during a 20 year observation period. The risk of renal scarring is directly related to the development of either stomal stenosis or ureteroenteric stenosis.
5. The use of a tunneled enteric anastomosis has twice the risk of developing a ureteroenteric stricture (1% per ureter per year) compared to a flush ureteral enteric anastomosis (0.5 % per ureter per year).
6. The use of high volume (>240 mL) daily bladder irrigations has been documented to decrease the risk of bladder calculi formation following a enteric bladder augmentation by 5 fold.
7. In patients with ≥2 recurrent bladder calculi following a bladder augmentation 30% of patients will develop a third stone within five year observation study period. Metabolic abnormalities will be found in 90% of these patients however, neither successful treatment of the metabolic anomaly nor, the use of indwelling mucolytic agents have been found to decrease this risk.
8. Stomal revisions of continent catheterizable limbs are two times more frequent following formation of a Monti catheterizable stoma compared to a appendicovesicostomy.
9. Approximately 10% of patients where the ileum, or ileal cecal junction was used for urologic reconstruction purposes will develop low B_{12} levels by the fifteenth post-operative year.

The Goals of Congenital Urologic Diversions and Urinary Reconstruction

The goals of congenital urologic reconstructive surgery are fourfold: preservation of life, preservation of renal function, creation or preservation of urinary continence, and creation or preservation of sexual function. There is one proviso in the clinical application of these four goals: At no time should one of the lesser goals trump those that go before it.

Complications Following Temporizing Urinary Diversions of Infancy and Childhood

CUTANEOUS PYELOSTOMY, URETEROSTOMY, AND NONCONTINENT VESICOSTOMY

Unlike adults where prolonged drainage of the urinary tract system can be safely performed by percutaneous nephrostomy or suprapubic cystostomy tubes, attempted management of infants by continued percutaneous access is associated with a 40% incidence of complications.[1,2] Specifically, frequent tube dislodgment, urinoma, or obstruction will occur in 15%; infectious complications, pyelonephritis, cystitis or urosepsis in 15%; and bleeding complications, retroperitoneal hemorrhage, or chronic anemia with the need for transfusion due to low-volume but persistent blood loss in 10%.[1,2] Due to the frequency of these complications the surgeon should consider the use of tubeless diversions, such as cutaneous pyelostomies, ureterostomies, or vesicostomy, in any infant where definitive reconstruction is to be delayed for greater than 6 months. Classically, cutaneous pyelostomy or ureterostomies are performed in infants presenting with an infected obstructive ureter(s), bladder hypoplasia/agenesis, or as a palliative procedure in infants with large nonresectable pelvic tumors. Cutaneous pelvic or ureteral stenosis will occur as a postoperative complication in 10–15% of these cases and recurrent pyelonephritis in 20%.[3,4] When pyelonephritis does occur it is usually associated with either a cutaneous stenosis or a poorly functioning kidney associated with urinary stasis. In these latter patients, resolution of the recurrent infections is best treated by nephrectomy.[3,4]

A cutaneous noncontinent vesicostomy is a temporary urinary diversion used to decompress the bladder and upper tracts in the presence of bladder outlet obstruction. It is classically indicated for the following conditions: (1) in infants with posterior urethral valves where the urethra is too small for endoscopic instruments; (2) in patients with neurogenic bladders, cloacal anomalies, or imperforate anus where urethral catheterization is difficult; (3) in patients with common cloacal or imperforate anus where urethral–rectal fistulas have resulted in metabolic abnormalities or repeated urinary tract infections (UTIs); and (4) in infants where parenteral noncompliance with medical directives is a concern.[5–8] Revision of the vesicostomy due to either stenosis or prolapse will be necessary for 10% of infants.[3,5,7–9] Although this is an excellent form of temporary urinary diversion in neonates, its use becomes more problematic after 3 years of age. Specifically, with maturation, the bladder changes from predominantly an intraabdominal to a pelvic organ. The relative change in position will result in the need to significantly mobilize the bladder to reach the skin level and be associated with increased tension on the vesicocutaneous anastomosis resulting in a significantly increased risk of vesicocutaneous stricture formation in the older child or adult. As the child matures attempts to cover the stoma with diapers, protective clothing, or a collection bag become increasingly problematic with the stoma location usually being cephalad to the areas covered by protective clothing. The stoma is also in a highly mobile area, associated with multiple skin folds, which significantly hinders the patient's ability to maintain a stomal collection bag. The inability to successfully contain the urine results in problems with skin irritation, breakdown, need for frequent clothing changes, and a decrease in the societal acceptance of the malodorous patient. Take down of a cutaneous vesicostomy is therefore commonly pursued between 1 and 2 years of age.[8]

Complications Following Definitive Urologic Reconstruction in Childhood

Management of patients with spina bifida and bladder exstrophy has played a major role in the development of reconstructive urology. Children suffering from these anomalies were initially at risk for chronic UTIs, pyelonephritis, end-stage renal failure, and death.[10–13] If they did survive to adulthood, they faced the social stigma and psychological trauma associated with chronic urinary incontinence.[14,15] Physicians empathetic to these children's dilemma began to seek ways to surgically intervene in the 19th century, usually with abysmal results.[10,11] A significant technical leap forward occurred in the 1950s with the concurrent development of broad-spectrum antibiotics and the ileal conduit.[16] For approximately 3 decades the use of urinary conduits (either ileal or colonic) and ureterosigmoidostomy reigned supreme. During the 20–30 years of their heyday, physicians slowly came to realize their association with metabolic derangements, renal lithiasis, chronic pyelonephritis, advancing renal insufficiency, and, in the case of ureterosigmoidostomy, malignancy.[17–26] The death knell for these procedures as the predominant surgical reconstructive methods for congenital urologic anomalies occurred in the late 1970s when multiple publications revealed the operations were associated with either a significant risk for renal deterioration and/or malignancy and recommended these operations be abandoned in children.[17–20]

Reconstructive efforts were subsequently refocused in the direction of bladder augmentation and continent urinary reservoirs. It was believed that the use of bladder augmentations or urinary reservoirs – procedures that are liberated from the fecal, urinary slurry and relatively free from the risk of stomal stenosis, parastomal hernias, and ureteroenteric strictures – would be associated with a significant decrease in morbidity and mortality.

Currently, bladder augmentations or continent urinary reservoirs are reserved for use in patients with either a congenitally or surgically absent bladder, sustained detrusor overactivity, i.e., detrusor pressures, ≥40 cm H_20, or poor detrusor compliance, i.e., end fill detrusor volume/end fill detrusor pressures of <20 mL/cm of H_20. Patients with sustained detrusor overactivity or poor detrusor compliance are already associated with or clinically at risk for upper tract renal deterioration and urinary incontinence. They are considered for this procedure only after they have been proven to be recalcitrant to intermittent catheterization and anticholinergic medications and after failing or refusing intravesical injections of onabotulinumtoxin A.[5]

Unlike urinary diversion for the management of malignancy, the success and complications of urinary reconstruction in children are measured by long-term outcomes.[15,27–31] Currently, the lifetime risk for needing an additional surgical intervention to treat complications arising from a bladder augmentation, continent urinary reservoir, or urinary conduit in childhood is >50%.[28,31,32] This incidence does vary from study to study based on the length of follow-up, the type of operation performed, the use of concurrent bladder outlet obstructive procedures, the presence of continent abdominal stomas, and the patient's ability to comply with medical directives. In this regard, this chapter will focus not on the immediate postoperative complications but rather on the long-term consequences found upon decades of follow-up.

Lethal Complications Following Urologic Reconstruction in Childhood

NEOPLASIA

The development of a malignant tumor within a urinary reservoir or augmented bladder is based on the type of bowel used, the length of time from surgery, the concurrent use of immunosuppressives, and the etiology for primary bladder dysfunction.[26,29] It is noteworthy that the overall risk for development of a bladder malignancy is increased in all patients with a primary congenital bladder dysfunction.[26,29] The incidence of bladder cancer development within this population is approximately 1% per decade.[26,29] This risk is not significantly increased if these patients undergo an ileal or a colonic bladder augmentation; reported incidence following these procedures is approximately 1.5% per decade.[26,29] This risk is, however, approximately tripled to 2.8% per decade for patients undergoing a gastric augment and is increased approximately fivefold, i.e., 5% per decade, following a ureterosigmoidostomy.[25,26,33,34] Two specific patient populations appear to be at an increased risk for tumor development following a bladder augmentation; specifically, patients who have undergone a gastric augment and patients with an augmentation who are on immunosuppressives.[26,33,34] Both of these patient populations appear to have between a two- and threefold increased risk for cancer development compared to patients with a primary congenital bladder dysfunction.[26,29,33]

The question that arises is, should patients with congenital bladder dysfunction treated by bladder augmentation be routinely screened by annual endoscopy and cytology? We currently do not believe data exist that can support this recommendation.[28] Specifically, the World Health Organization recommends annual cancer screening be performed when the four following criteria are met: (1) cancer has a high prevalence within a well-defined patient population; (2) cancer routinely presents at a low treatable stage; (3) screening tests are available that are safe, inexpensive, reliable, and reproducible with high specificity and sensitivity; and (4) the screening test must allow the cancer to be diagnosed at a low treatable stage and result in an improved patient prognosis.[26,29,30]

Currently, epidemiologic and pathologic findings reveal tumors arising within a congenitally dysfunctional bladder cannot meet these criteria. Specifically, 5–7.5% of patients with congenital bladder dysfunction with or without an augment will develop a bladder cancer by the sixth decade of life, a 1–1.5% risk of malignancy per decade. Approximately 80% of these patients will present with locally advanced disease or nodal metastasis at the time of diagnosis, with a cancer-specific mortality of 80% at 18 months following the diagnosis.[26,29,30]

Pathologic evaluations inevitably reveal unique morphologic, immunohistochemical, and genetic tumor alterations that are associated with rapid tumor growth, i.e., brisk mitotic activity, lymphovascular invasion, tumor necrosis, and a high incidence of invasion into or through the bladder or bowel muscle at the time of diagnosis.[26,29,30] Indeed, in support of the findings reviewed above are five cases of malignancy that arose within an augmented bladder where routine cystoscopic evaluations had been normal 4–18 months prior to the development of an invasive malignancy that eventually proved to be fatal.[26,29,30]

In essence low-stage medically or surgically curative bladder cancer can rarely be detected by annual screening endoscopic and cytologic studies. Indeed, it is our belief that the costs of these studies far outweigh the prevalence of the disease and have no proven benefit in diagnosing early-stage and curable tumors.[26,29,30]

SPONTANEOUS BLADDER PERFORATIONS

This complication is associated with significant patient morbidity with a reported mortality incidence of approximately 25%.[28,35–38] Spontaneous bladder perforations may occur at any time ranging from the first postoperative year to more than 30 years following the augmentation.[28,35–38] Their incidence varies from 2% to 10% and is related to the findings of post augment, high leak point pressures, compliance with intermittent catheterization, and length of follow-up.[28,35–38]

Diagnosis of a spontaneous rupture of the augment can be problematic due to the large number of patients with impaired sensation that have undergone this procedure, e.g., patients with spina bifida or spinal cord injury. Patients with decreased sensation will frequently present with vague symptomatology, such as malaise and nausea, with or without associated diaphragmatic irritative symptoms, i.e., persistent hiccups or shoulder pain. Without interventional treatment patients will usually progress to complaints of vomiting, fever, abdominal pain with or without abdominal distention, and physical findings consistent with peritoneal irritation.[38–40] From a urologic standpoint, the differential diagnosis will be small bowel obstruction, severe

Table 62.1 Comparison of Renal Deterioration Following Bladder Augmentation With and Without Bladder Neck Reconstruction and Creation of a Continent Abdominal Stoma

Patient Categories	% of Patients With BladderCalculi	% of Patients With Kidney Stones	% With Renal Scarring or Loss of One Kidney	% With ≥Stage 3 Chronic Renal Failure	Median Length of Follow-up Since Augmentation
Bladder augmentation with bladder neck reconstruction or sling and continent stoma N = 134	22% (29/134)	16% (22/134)	31% (41/134)	11% (15/134)	14 years (10–45 years)
Bladder augmentation without bladder neck reconstruction catheterization through urethra N = 39	18% (7/39)	5% (2/39)	43% (17/39)	36% (14/39)	15 years (10–38 yrs)
Statistical Evaluation p =	0.617	0.070	0.130	0.000278	

cystitis-pouchitis, or ruptured viscus, pouch, or augment. The diagnostic test of choice is an abdominal and pelvic CT without contrast followed by a CT cystogram.[38,39]

Although case reports of successfully managing spontaneous bladder perforation by nonoperative measures, that is, larger bore urethral catheter drainage, intravenous antibiotics, and serial physical examinations, have been reported, the physician should remember the 25% mortality rate associated with this diagnosis.[41,42]

Radiographic or physical findings of extruded bladder calculi outside of the augment, the presence of omentum or small bowel within the bladder lumen, progressive peritoneal irritation, and/or hemostatic instability should prompt an immediate abdominal exploration. Surgery will require irrigation of the peritoneal cavity, repair of the bladder rupture, and consideration for externalization of the ventriculo-peritoneal shunt, if one is present.[41,42]

Preservation of Renal Function Following Urinary Conduits and Bladder Reconstruction

Following preservation of life, maintenance of renal function is one of the key metrics to appraise the worth of a genitourinary reconstructive procedure. Imperative in assessing long-term renal function following diversion or augmentation is the known decrease of glomerular filtration rate (GFR) that occurs with aging. Routine studies on the aging kidney have shown the GFR on average decreases 0.4–0.5 mL/min/BSA between the ages of 20 and 50 years and then decreases by 1.0 mL/min/BSA after the age of 50.[43,44] With these facts in mind, most authorities define an abnormal decline in renal function after urologic reconstruction as: (1) a decrease in GFR of >10 mL/min/BSA during a 10-year follow-up interval,[40,41] (2) the development of new renal scars, or (3) the onset of stage 3 renal failure (<60 mL/min/BSA).[24,28,43–45] The development of stage 3 or higher renal failure is especially concerning, due to the increased risk of cardiovascular death related to renal failure. For example, there is a 20% increased risk of cardiovascular death for patients in stage 3 renal failure and a 60% increased risk of cardiovascular death related to stage 5 renal failure.[28,45–47]

It is our belief that any assessment of current reconstructive techniques must be compared to those of the past. From this point of view, we should remember that ureterosigmoidostomy is associated with a 70% incidence of deterioration of the upper tracts, defined as the development of new renal scarring, during a median follow-up interval of 15 years.[17,48,49] Ileal conduits performed in childhood have an 80% incidence of new renal scarring during a median follow-up of 20 years.[4,18,19,24,50,51] Nonrefluxing colon conduits using a submucosal tunneled ureteroenteric anastomosis, and freely refluxing colon conduits, are associated with a 45% and 24% incidence of new renal scarring, respectively, during median follow-up intervals of 15 years.[20–24,52] The difference in the incidence of renal scarring between the nonrefluxing and refluxing colonic conduits is directly related to the development of ureteral strictures within the submucosal ureteral enteric tunnels. It is notable that tunneled submucosal ureteral enteric anastomoses are associated with a 1% incidence of ureteral enteric strictures per ureter per year. In contrast, a flush, freely refluxing ureteroenteric anastomosis has a 0.5% risk of developing a ureteroenteric stricture per year.[50–53] The more favorable results for renal preservation by colonic conduits over ileal conduits appear to be directly related to the decreased risk of stomal stenosis in colon conduits.[11,21–24] In fact, deterioration of the upper tracts following urinary conduit diversion has been found to be directly related to the development of an obstruction arising as a consequence of stomal stenosis, ureteroenteric anastomotic strictures, parastomal hernias, and/or the development of obstructive renal-ureteral calculi.[11,54] It is compounded by the concurrent medical problems of diabetes mellitus and/or hypertension.[55]

The question that arises is how well do bladder augmentations preserve renal function? In this regard we believe two dichotomous patient categories need to be compared: individuals undergoing bladder augmentation with a simultaneous bladder outlet procedure and continent abdominal stoma versus patients with a bladder augmentation catheterizing per urethra. The comparison between these two different patient populations is imperative due to the reportedly two- to fivefold increased risk of complications in patients undergoing a bladder neck procedure, augmentation, and continent abdominal stoma compared to individuals with a bladder augmentation catheterizing through the urethra.[28,31,43,54,56,57]

The comparison of how well these two different procedures have preserved renal function within our patient population is depicted in Table 62.1. It is concerning to see that renal scarring occurred in 31% (41/134) of our patients undergoing a bladder augmentation with simultaneous

bladder outlet procedure and creation of a continent catheterizable stoma and in 43% (17/39) of our patients undergoing a bladder augmentation and catheterizing per urethra, respectively, during a median follow-up of 14–15 years. Indeed, the incidence of renal deterioration following an augmentation is no different from the 24–45% incidence of renal scarring following colon conduit diversion during a median of 15 years of follow-up.[20–24,52] Perhaps the most telling fact regarding why renal scarring developed following augmentation is the finding that 67% (39/58) of our patients who developed renal scarring did so after they were documented to be noncompliant with intermittent catheterization. Noncompliance is defined as a ≥3-month period where the patient catheterized three times or fewer per day.[28] The finding that significantly more patients had stage 3 or higher renal failure when catheterizing per urethra compared to abdominal stoma is intriguing (36%: 14/39 vs 11%: 15/134, respectively, p = 0.000278). This finding suggests the degree of noncompliance was higher in the individuals catheterizing through the urethra. In this regard, it is noteworthy that >80% of our patients in both patient categories were adults confined to a wheelchair and that both patient populations displayed a high incidence of obesity, with a BMI of ≥30 seen in approximately 40% of our patients in both groups (41%: 16/39 and 39%: 54/134, respectively). Moribund obesity (BMI >40) was noted in 8% of both groups (8%: 3/39 and 8%: 11/134, respectively). Interestingly, although not evaluated in our study cohort, other investigators have documented that the degree of obesity found in this patient population is significantly correlated with the patient's intellectual disability.[58–61] By reviewing our data and the existing literature, we hypothesize that the degree of noncompliance with intermittent catheterization is lessened by the use of a catheterizable abdominal stoma. Indeed, we believe that the combination of limited mobility, obesity, and decreased intellectual acuity makes management of these patients by a continent stoma both attractive and problematic. It is attractive because the abdominal stoma makes the catheterization easier, but problematic in that obesity has been found to be significantly associated with the risk of stomal stenosis, stomal retraction, and difficulty with catheterization.[62]

We also believe it is imperative to point out that long-term follow-up of this patient population reveals that the majority of patients did not manifest their noncompliance with catheterization until their late teens, twenties, and even thirties, decades after their surgical procedure.[28] Whether this increase in noncompliance is due to the greater independence of the patient from their caregivers, the increased frequency of risk-taking activities common in adulthood (i.e., drug and alcohol use), or the difficulty that may accompany catheterization and the slow but steady increase in obesity that occurs with aging, is open to conjecture.

Surgical Complications

BLADDER AND RENAL CALCULI

Bladder stone formation following urologic reconstruction is directly related to the type of augmentation performed, the use of a continent catheterizable abdominal stoma, patient compliance with medical directives, and length of follow-up.[28,31,37] Of note is that the incidence of bladder stones following augmentation has significantly decreased over the past 2–3 decades. For example, in the early 1980s 50% of the individuals undergoing an ileal or colonic bladder augmentation developed a bladder calculi within 5 years of the augmentation, and 50% of the patients that developed a bladder stone had a recurrent bladder stone within 5 years.[28,31,54,56,63] The metabolic composition of these stones was found to be struvite, i.e., infectious, in etiology in 70% of cases. Thirty percent of the bladder stones were, however, composed of metabolic active components, e.g., calcium phosphate or calcium oxalate.[64] Stone analysis usually revealed that the calcium salts had precipitated around a mucous core, with approximately 85% of the stones concurrently having positive bacterial cultures.[63,64] The finding of metabolically active calcium phosphate stones within a bladder augment is not surprising, based on the high alkalinity of the urine following either augmentation or creation of a continent urinary reservoir with ileum or colon. Specifically, alkaline urine is invariably present due to ammonium chloride absorption and bicarbonate secretion from the bowel wall. Compounding the problem of an elevated pH are the low levels of urinary citrate, a known urinary inhibitor of stone formation. Hypocitraturia is invariably present and directly related to the presence of chronic bacteriuria, with the vast majority of bacteria actively catabolizing citrate. The combination of elevated urinary pH, retained mucus serving as a nidus for crystallization, chronic bacteriuria, and low urinary citrate creates the perfect environment for the precipitation of calcium salts.[65]

Over the past 3 decades, significant strides have been made in decreasing the incidence of stone formation following augmentation or continent urinary diversion.[28,56,63,66] The decrease in the incidence of stone formation has been achieved predominantly by irrigation of the bladder with a minimum of 250 mL of water or saline solution on a daily basis. Use of high-volume daily irrigations coupled with a minimum of four times daily catheterization schedule has been documented to decrease the incidence of chronic bacteriuria, symptomatic UTIs, and bladder stones.[28] Currently, if patients are compliant with high-volume daily bladder irrigations, approximately 10% of the patients will develop a bladder stone by the tenth postsurgical year.[27,28,31,54,56,63,64,67,68]

Although high-volume bladder irrigations have helped to reduce bladder stone formation, it is far from a panacea.[28,31] In patients presenting with a second bladder stone, despite high-volume irrigation, 30% will have a third recurrent bladder stone within 5 years. Metabolic evaluations of patients with recurrent bladder stones will reveal hypocitraturia in >90% of individuals. In addition to the almost ubiquitously found hypocitraturia, either coexisting low 24-hour urinary volumes (<1600 mL) hypercalciura or hyperoxaluria will concurrently be found in one-third of the patients. Although treatment of metabolic abnormalities has been documented to decrease renal calculi, it is controversial if treatment of underlying metabolic abnormalities will reduce the incidence of recurrent bladder calculi.[28,72,73] In fact, in our experience with patients with recurrent bladder calculi and a coexisting identifiable metabolic abnormality, correction of the metabolic abnormality did not significantly decrease the risk of recurrent bladder stone formation compared to the controls.[28]

Once we recognized that treatment of the underlying metabolic abnormalities was not reducing the incidence of recurrent bladder stones, we attempted to decrease recurrent stone formation using mucolytic agents, such as 20% *N*-acetylcysteine or 10–20% urea instilled in the bladder at night along with high-volume bladder irrigation.[28,66,74,75] It was our hope that the addition of mucolytics would enhance dissolution of the mucous nidus and decrease the incidence of recurrent stone formation. Unfortunately, in a clinical trial comparing the use of high-volume bladder irrigation alone compared with high-volume bladder irrigation with the use of indwelling mucolytics overnight, we found no difference in stone formation between the two groups (30% at 5 years).[28] In essence, in patients who experience recalcitrant bladder stone formation following augmentation, we have found that neither treatment of the underlying metabolic abnormality nor the use of mucolytic agents decreased the frequency of recurrent stones over high-volume bladder irrigation alone.[28] This latter finding has been confirmed in a double-blind placebo-controlled study by N'Dow and associates.[76] These authors found that neither *N*-acetylcysteine nor ranitidine, an H_2 blocker that reduces mucus secretion, was found to be of any benefit over placebo alone in the prevention of recurrent bladder calculi.[74,76]

The question arises as to what to do with this difficult patient population. Currently, in patients of ours who are forming recurrent bladder stones, we will, in addition to the high-volume bladder irrigations (250 mL per day), use a 60-mL solution of 20% acetylcysteine placed into the bladder at night. In patients with concurrent hypocitraturia, we will also correct their urinary citrate levels.[28,57,66,74,77] We would caution that we have absolutely no clinical documentation that this treatment will substantially decrease the risk of additional stones, and this treatment regimen is done as an empiric trial.

During our 20-year follow-up of patients with an ileal or colonic bladder augmentation, we have found that approximately 15% of patients will develop a renal stone, with a median time to stone development post augmentation of 16 years (see Table 62.1).[26,28,76,78] Stone analysis will reveal the renal calculi to be of infectious etiology, i.e., struvite, in 40% of cases. The struvite calculi will invariably be associated with a urease-splitting organism colonizing the upper tract. In these circumstances assessment for vesicoureteral reflux may be merited, and it is our unsubstantiated belief that free reflux of mucus into the collecting system results in a high risk of stone recurrence. Consideration for repair of the reflux, if found, should be given. Interestingly, the majority of renal stones within this patient population are associated with metabolic abnormalities such as hyperoxaluria, hypocitraturia, hyperuricosuria, and hypercalciura.[78] The induction of hyperoxaluria, hypocitraturia, and hyperuricosuria are believed to arise as a consequence of a shortened bowel with rapid bowel transit time, saponification of calcium to fatty stools, chronic bacteriuria, and metabolic acidosis. The level of hyperoxaluria can also be affected if chronic antibiotic suppression is used resulting in loss of *Oxalobacter formigenes* the gut flora that metabolizes intestinal oxalate. Hypercalciuria classically arises in patients with a known neuropathy due to impaired mobility, or mobilization of calcium phosphate from bony stores to buffer the metabolic acidosis induced by the augment.[13,28,50,65,69–71,78]

NEED FOR SECONDARY AUGMENTATIONS

The need for a repeat or secondary augmentation has been reported to be necessary for 5–10% of patients.[31,37] The need for re-augmentation usually comes to attention due to the findings of either persistent or new onset of urinary incontinence or hydronephrosis. The need to re-augment is confirmed by urodynamic evaluation.[31,37] Urodynamic findings will reveal either impaired compliance or resumption of bladder/bowel contractions. The findings of impaired compliance are believed to be due to an inadequate-sized initial bladder augmentation, vascular impairment of the augment resulting in its fibrosis, or the inherent native characteristics of the augmenting segment.[11,79] Regarding the inherent characteristics of the augmenting segment both the stomach and sigmoid colon have been found to be problematic.[4,51,80] Specifically, ileal or ascending colon augments have been shown to improve their compliance and subsequently increase the bladder capacity on serial postoperative urodynamic studies over the first 3–5 years post augmentation. In contrast, gastric augments exhibit little to no improvement in compliance following the initial postoperative urodynamic evaluation, i.e., no serial improvement in compliance. The problem with sigmoid augmentation relates to its ability to redevelop strong autonomic contractions despite its detubularization at the time of augmentation. The resumption of high-pressure sigmoid mass contractions is associated with upper tract deterioration, urinary incontinence, and spontaneous bladder perforations. These clinical findings strongly suggest that close long-term observation of patients undergoing augmentation with gastric or sigmoid segments is necessary, especially if these procedures are combined with a bladder outlet procedure.[31,38]

SMALL BOWEL OBSTRUCTION

The need for hospitalization to manage small bowel obstruction is dependent upon the length of follow-up. During the first 2 decades post augmentation, hospitalization will be required in 10–15% of patients, with exploratory laparotomy required in 5%.[27,31,37,81] Of note is that patients requiring exploration for a small bowel obstruction will frequently be found to have an internal hernia with the small bowl volvulus intricately involving the vascular pedicle to the augment or continent stoma. Damage to the blood supply to the augment or stoma is, therefore, a distinct concern at the time of surgery.[27,31,37,81]

STOMAL REVISION OF URINARY CONDUITS OR REVISION OF CATHETERIZABLE LIMB

The incidence of stomal complications in both urinary conduits and catheterizable limbs is directly related to the surgeon's experience, the patient's body mass index, and the length of follow-up.[24,71,82–88] Regarding urinary conduits, stomal, midloop stenosis or parastomal hernias will occur in up to 40% of ileal conduits and 15% of colon conduits by the tenth postoperative year.[24,51,89] As noted previously, these complications are frequently related to deterioration of the upper tracts, and routine evaluation for their presence should be an integral part of the patient's follow-up. If obstruction of the stomal outlet is found it should be

immediately addressed by either long-term radiologic intervention with interval stenting of the kidneys and conduit, or surgical revision.[32,82,83,85,90]

Approximately 75% of children undergoing a bladder augmentation will have the simultaneous performance of a continent catheterizable stoma. The continent stoma is classically performed to either aid the child in his/her ability to catheterize from a wheelchair, to decrease the discomfort of catheterizing through the urethra, to prevent problems with catheterization through a reconstructed bladder neck, or due to surgical closure of the bladder neck. Catheterizable channels are performed using either the principles of the Mitrofanoff procedure, e.g., appendovesicostomy, Montie-Yang tubes, or tapered ileal tubes with a reinforced ileocecal valve.[32,71,82–88] Postoperative complications with stomal leakage of urine are reported to occur in 5–10% of the patients. Incontinence secondary to a faulty valve may be treated with either a bulking agent or revision of the anastomosis. However, if on urodynamic evaluation urinary incontinence is found to be due to persistent elevations in storage pressures or recurrent mass contractions of the augmented bladder, re-augmentation of the bladder, not stomal revision, will be necessary. On occasion we have seen the delayed onset of stomal-site urinary incontinence develop years to decades following the surgical procedure. The late onset of stomal incontinence is frequently due to the development of obesity, with successful weight loss resulting in the patient regaining urinary continence. Alternatively, we have also seen the delayed onset of incontinence secondary to development of a false passage within the catheterizable limb that will require surgical revision.[71,85–88] Difficulty with catheterization of the continent limb will be reported in 20% of the patients managed by appendicovesicostomy and Montie-Yang procedures, and in 10% of patients with a tapered ileal channel, by their tenth postoperative year. Unfortunately, we have seen this complication continue to increase with time, especially in patients who gain significant weight as they mature, with difficulty with catheterization reported to occur in up to 50% of the patients by the third postoperative decade.[32,51,71,85–88] Difficulty with catheterization may arise secondary to either stenosis at the cutaneous or midfascial levels, kinking of the stoma channel, or creation of a false passage or diverticulum within the catheterizable limb. Approximately 50% of the patients may be managed by use of an L-shaped stent at night time. Unfortunately, it will not work in all patients, and approximately 50% of patients will require a formal revision or creation of a new channel.[45,51,80,86,88,89,91]

Medical Complications Following Bladder Augmentation or Urinary Diversion

CHRONIC BACTERIURIA

In patients undergoing bladder augmentation or continent urinary reservoir formed with ileum or colon, we have found the incidence of asymptomatic bacteriuria to range between 45% and 85% in routinely obtained urine cultures.[26,28,86] Interestingly, we have found the incidence of asymptomatic bacteriuria and symptomatic UTIs to be directly related to both the volume of fluid used for daily bladder irrigations and the patient's compliance with physician recommendations.[28] Specifically, daily bladder irrigations of ≥240 mL along with a minimum of four times per day catheterization is associated with a significant reduction in the incidence of asymptomatic bacteriuria and symptomatic UTIs.[28]

Whether the presence of chronic bacteriuria is associated with a decrease in renal function is controversial. The majority of clinical studies have found that chronic bacteriuria is not associated with an elevation in antibacterial serum titer antibodies or markers for systemic inflammation. Therefore treatment is currently not recommended.[43,44]

METABOLIC SEQUALAE

The metabolic consequence of hyperchloremic metabolic acidosis arises as a result of urine contacting the ileal-colonic epithelium. Due to the enteric epithelium's functional nature, it will absorb ammonium chloride and, to a lesser extent, secrete bicarbonate. The frequency of this complication is related predominantly to the length of bowel incorporated into the reconstruction, urinary dwell time, and the patient's renal function.[43] With these three factors in mind, it is not surprising the incidence of this disorder is greatly dependent upon the type of reconstruction performed. Specifically, the reported incidence of hyperchloremic metabolic acidosis that requires treatment (serum bicarbonate <21 mEq/mL or chloride >110 mEq/dL) will occur in approximately 50% of the patients following ureterosigmoidostomy, in 20% of patients with an ileal or colonic augmentation, Indiana pouches or ileal neobladder, and in 10% of patients with an ileal or colonic conduit.[11,17,45,50,51,82,92] Treatment of the metabolic acidosis is with either potassium citrate or sodium bicarbonate therapy. To prevent bony demineralization that may arise secondary to the chronic metabolic acidosis, the addition of a daily multivitamin and mineral supplementation to enhance vitamin D and calcium intake may be considered.

It is noteworthy that in a patient whose GFR <45 mL/min/BSA (stage 3B renal failure), renal function will be unable to compensate for the excess endogenous acid load induced by the absorption of ammonium chloride caused by inserting a ileal or colon segment into a urinary reservoir. The resultant hyperchloremic metabolic acidosis and hyperfiltration injury from excess urinary absorption by the bowel segment may, hypothetically, hasten renal failure in this subset of patients. Due to this sequela, urinary conduits are preferred in patients whose GFR ≤50 mL/min/BSA.[43,93]

Of particular note when we are discussing metabolic sequalae of bladder augmentation are the complications found following a gastric cystoplasty. The conceptual foundations of why a gastric augment should be used for urologic reconstruction are based on four major points: (1) Patients with renal failure (stage 3B or higher) would be spared the increased risk of metabolic acidosis and accelerated renal failure by using a segment of bowel that is non-absorptive in nature and associated with acidic loss, i.e., HCl secretion by gastric epithelium into the urine. (2) Use of the gastric augment was recommended in patients where bowel transient time was already compromised due to inadequate length, e.g., cloacal exstrophy. Gastric augments were recommended in this patient population to

reduce the risk of the short gut syndrome and fecal incontinence. (3) Use of a gastric augment decreases the risk of recurrent UTIs in immunosuppressed patients. In this situation, the acidotic secretion from the gastric segment would make the bladder unsuitable for bacterial colonization. Subsequently, this would decrease the risk of symptomatic UTIs and reduce the incidence of pyelonephritic stimulated transplant rejection episodes. (4) It was also hypothesized that the stomach wall, because of its well-defined mucosal and muscular components, would provide a better technical environment for a tunneled anastomosis, reducing complications related to reimplantation of the ureter or continent catheterizable channel.[57,81,94]

Despite its hypothetical advantages, the clinical use of gastric cystoplasty was found to be associated with a multitude of complications.[81] Specifically, one-third of the patients undergoing this type of augmentation complained of hematuria-dysuria syndrome, i.e., bladder irritation secondary to hypergastrinemia and HCl secretion.[51,57,94,95] The symptomatology of the hematuria dysuria syndrome can, at least, be partially combated by the use of H_2 blockers and proton pump inhibitors. Unfortunately, these symptoms cannot all be resolved with pharmacologic therapy, and approximately 15% of patients, i.e., approximately half of the patients with this syndrome, will undergo resection of the gastric augment as a consequence of refractory symptomatology.[51,96] Five percent of gastrocystoplasty patients will also develop episodic hypochloremic, hypokalemic metabolic alkalosis.[4] This metabolic abnormality is usually stimulated by a state of dehydration and is associated with life-threatening cardiac arrhythmia and sudden death.[57] In addition to the aforementioned complications, 1–2% of patients will develop the dumping syndrome, resulting in a significant decrease in gastric-bowel transit times. This complication, if it occurs in a patient with an already foreshortened gut, can be devastating.[4,51,57,96] Not to overstate the problems arising with gastrocystoplasty, the physician should also be aware that this procedure is associated with a two- to threefold increased risk of neoplasia.[26,29,33] Due to the multitude of long-term complications found following gastrocystoplasty this procedure has been largely abandoned from the surgical armamentarium.[51,57]

HYPERCHLOREMIC METABOLIC ACIDOSIS–INDUCED OSTEOPOROSIS OR GROWTH RETARDATION

Chronic untreated hyperchloremic metabolic acidosis may on rare occasions be associated with hypocalcemia. Specifically, metabolic acidosis results in a decreased reabsorption of renal calcium and a subsequent increase in osteoclastic bone activity to balance serum calcium levels.[50,92] Combine the homeostatic calcium problem with possible malabsorption of vitamin D and dietary calcium due to steatorrhea arising from a shortened gut and it would appear that this population could be at high risk for osteoporosis and growth retardation. Interestingly, multiple large series, evaluating patients for the onset of osteoporosis or growth retardation, have revealed this to be a rare complication, presumably due to the physician's tendency to treat the underlying hyperchloremic metabolic acidosis before the onset of bony abnormalities.[43,92]

FECAL INCONTINENCE

Complications arising from the functional loss of the bowel used for urologic reconstruction are related to both the type and length of the bowel used and are highly dependent upon proper patient selection. This complication is, in general, more common when the urologic reconstruction involves the use of the ileocecal junction or large volumes of ileum (>200 cm). Use of the ileocecal junction or large amounts of ileum for urologic reconstructive purposes should not be done in patients with a previously foreshortened gut or a history of loose stools, fecal incontinence, or inflammatory bowel disease, and it is relatively contraindicated with a history of radiation enteritis.[32] Provided the physician correctly selects the patients, loose stools following urologic reconstruction, even with the removal of the ileocecal valve, will be found in <3% of patients.[32] If this complication does arise it is usually correctable with cholestyramine 4–8 g twice daily. If cholestyramine is not successful the use of gastrointestinal motility inhibitors, such as loperamide (i.e., Imodium), may be considered.[32,92] It is imperative that we stress that assessment of the patient regarding fecal continence and stool habits before urologic reconstruction is necessary to decrease the frequency of this complication. In the absence of appropriate patient selection, fecal incontinence has been reported to be as high as 20% following formation of ileocecal urinary reservoirs and ileal neobladders.[32,43,50,57]

PROTHROMBIN DEFICIENCY

Fat absorption and subsequent absorption of the fat-soluble vitamins A, D, E, and K depend heavily on the emulsification of dietary fat by bile salts. It is noteworthy that 95% of bile salts are absorbed in the preterminal and terminal ileum. Loss of ileal length results in a larger percent of bile salts reaching the colon, where they will act as a direct mucosal irritant and induce diarrhea. As more bile salts are lost, dietary fat malabsorption occurs, resulting in steatorrhea and, subsequently, the malabsorption of the fat-soluble vitamins. Deficiency of vitamin K, a necessary factor in blood coagulation, is often subtle and not clinically apparent until a major surgical procedure or traumatic injury occurs. It is therefore suggested that all patients scheduled to undergo a major procedure with a history of ileal resection or loss of ileal continuity undergo a prothrombin evaluation with correction of any identifiable anomaly prior to surgical intervention.[50,92]

B_{12} DEFICIENCY

Classically, low serum B_{12} levels will begin to show up 3–5 years post surgical reconstruction; however, due to high storage levels within the body, they may take up to 15 years to become manifest.[82,97,98] Specifically, B_{12} is bound to an intrinsic factor secreted by the parietal cells within the stomach. It forms a soluble complex that reacts with the B_{12} receptor protein within the ileal epithelial cells. B_{12} deficiency following urologic reconstruction has been found to be associated with any type of urologic surgery using any segment of ileum, i.e., ileal augmentations, ileal neobladders, ileocecal reservoirs, and ileal conduits.[97] Approximately 8–10% of patients for whom ileum is used for

reconstructive purposes will develop low serum B_{12} levels by 10–15 years of follow-up. The vast majority of patients will be able to correct the defect by increasing ingestion of B_{12} or multivitamins.[82,97,98] Long-term follow-up of this patient is mandatory to verify that oral supplementation remains successful; if not, parenteral treatment will become necessary.[97] It is noteworthy that failure to identify or correct this anomaly may be associated with peripheral neuropathy, dementia, accelerated atherosclerosis due to elevated levels of homocysteine, and megaloblastic anemia.[99,100]

Bladder Augmentations Not Using the Gastroenteric Segments

AUTOAUGMENTATION-DETRUSOR MYOMECTOMY

Autoaugmentation, also known as detrusor myomectomy, is an operation where the detrusor muscle is resected off the dome of the bladder to create a large low-pressure bladder diverticulum. It is an alternative augmentation, using native bladder mucosa as opposed to secretory gastrointestinal epithelium. Classically the operation is used only in patients with mild bladder noncompliance (>20 mL/cm H_20). At its best it results in only mild-to-moderate improvement in bladder compliance. The procedure is associated with significant problems with bladder emptying with approximately 25% of the patients needing to perform intermittent catheterization to prevent recurrent symptomatic UTIs, and 50% will eventually require an enteric augmentation due to persistent high detrusor pressures or urinary incontinence.[57,101]

URETEROCYSTOPLASTY

Ureterocystoplasty hypothetically should be the ideal augment. It is naturally lined by native urothelium and is free from metabolic disturbance and mucus production. Classically this procedure utilizes a preexisting dilated ureter for augmentation and involves a concurrent ipsilateral nephrectomy if the dilated ureter is associated with a nonfunctional kidney, or transureteroureterostomy if the ipsilateral kidney is functional in nature. Preoperative urodynamics is essential in the assessment of patients when considering this procedure. In individuals with mild bladder noncompliance (>20 mL/cm H_20) this operation's success approaches 100%. However, 75% of patients will require intermittent catheterization to prevent recurrent symptomatic UTIs.[101,102] In contrast, in poorly compliant systems (≤20 mL/cm H_20), success is <20% with greater than 80% of patients requiring re-augmentation due to persistent high bladder pressures with continued urinary incontinence or upper tract deterioration.[51,101,102]

INCONTINENT ILEOVESICOSTOMY (ILEAL CHIMNEY)

This operation is considered in children with inadequate bladder emptying and low BMI and is seen as an option of last resort. It is usually performed in severely mentally and physically compromised patients where intermittent catheterization, an indwelling suprapubic tube, or urethral catheter is not feasible.[103] This operation attaches a short portion of the ileum to the dome of the bladder allowing the patient to wear a stomal appliance bag for collection of the urine. Although short-term follow-up has been favorable, long-term follow-up evaluations have revealed multiple complications, with upper tract deterioration due to urinary stasis and stone formation found in 60% of patients at 10 years.[103,104]

Pregnancy Following Bladder Augmentation and Urinary Diversion

In patients who have undergone a bladder augmentation or urinary reservoir formation and become pregnant, the incidence of symptomatic UTIs that will require treatment during pregnancy will approach 50%. Increased urinary incontinence either through stoma or urethra will occur in 40%. Symptomatic upper tract obstruction requiring intervention will occur in 10%, and preeclampsia in 10%. In patients who have had a bladder neck reconstructive procedure and became incontinent with pregnancy, persistent postpartum urinary incontinence will result in the need for surgical intervention in 20%. Deterioration in renal function occurs only rarely and is usually associated with a pre-pregnancy creatinine of >1.2 mg/dL. It is noteworthy that 30% of patients that have a pre-pregnancy serum creatinine of >2.2 mg/dL have a permanently documented decrease in postpartum renal function.[57,105,106]

Women with a history of bladder augmentation and a bladder neck procedure are considered for cesarean section to prevent ischemic injury and pressure necrosis of the bladder neck and urethral continence mechanism during vaginal delivery. It should be noted that, although this is the standard recommendation, vaginal delivery has been proven to be a safe alternative in some of these individuals.[57,105,106]

Patient Selection

Although the complications we have reviewed following childhood reconstructive urologic procedures are myriad, the physician must weigh their occurrence against the quality-of-life improvements, in both self-image and self-esteem, noted by the vast majority of these patients following surgical reconstruction.[14,15] Assessment of the individual's intellectual and physical capability, as well as his or her ability to comply with medical directives, refrain from high-risk habits (i.e., alcohol and illicit drug abuse), and maintain long-term follow-up visits, is critical to long-term success. Indeed, it must be stressed that appropriate preoperative evaluation and patient selection are the key factors for a triumphant reconstructive procedure.

Chapter 62 Questions

1. A 32-week-old premature boy is born with posterior urethral valves. He is in the operative room for endoscopic incision of his valves. However, the cystoscope is too large for the urethra. The next step is:
   a. Urethral dilation
   b. Place indwelling Foley catheter, wait 1 month, and reattempt endoscopy
   c. Percutaneous suprapubic tube placement
   d. Vesicostomy
   e. Perineal urethrostomy with valve ablation

2. A 5-kg 2-month-old boy with a history of a high imperforate anus is initially managed with a diverting colostomy. He is referred for evaluation of recurrent urinary tract infections (UTIs) and metabolic acidosis (HCO_3 of 18 mEq/mL). Evaluation reveals grade 3 bilateral vesicoureteral reflux, post-void residual urines of >100 mL, a urethral rectal fistula, and a tethered spinal cord. The next step is:
   a. Intermittent catheterization
   b. Vesicostomy
   c. Release of tethered cord
   d. Rectal pull through procedure with ligation of fistula
   e. Bilateral ureteral reimplantation

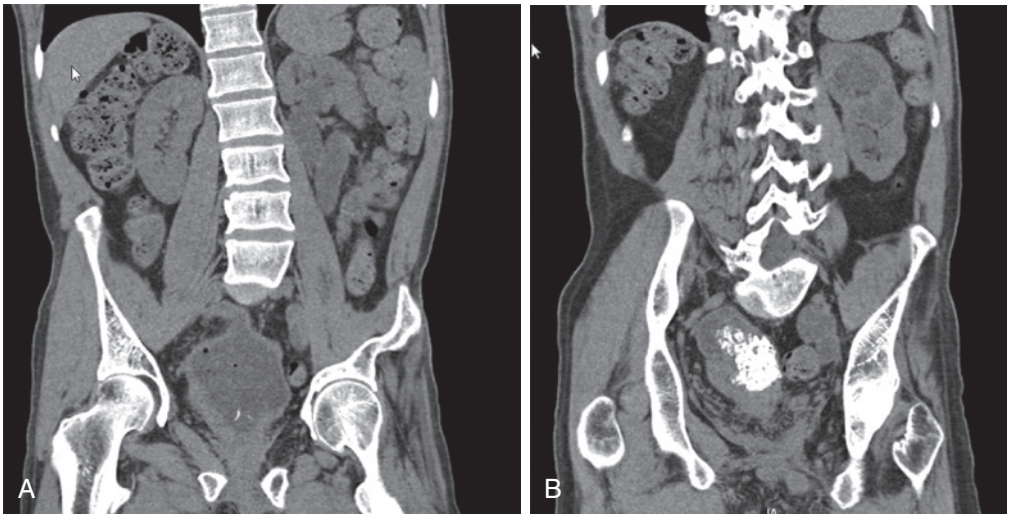
3. The bladder augmentation that is at the highest risk for developing a bladder cancer is:
   a. Ileal
   b. Gastric
   c. Ileocecal
   d. Sigmoid
   e. Ureterocystoplasty

4. An 18-year-old man with T-6 paraplegia underwent an ileal bladder augmentation and appendicovesicostomy 3 years ago. He presents with a history of anorexia, fatigue, lethargy, malaise, and chronic hiccups for the past week. The next test is:
   a. Urine culture
   b. Chest x-ray
   c. Cystogram
   d. CT of the abdomen and pelvis followed by CT cystogram
   e. CT urogram

5. The most common reason for deterioration in renal function following a bladder augmentation is:
   a. Obesity
   b. Bladder stones
   c. Noncompliance with intermittent catheterization
   d. Persistent elevations in detrusor pressures post augmentation
   e. Vesicoureteral reflux

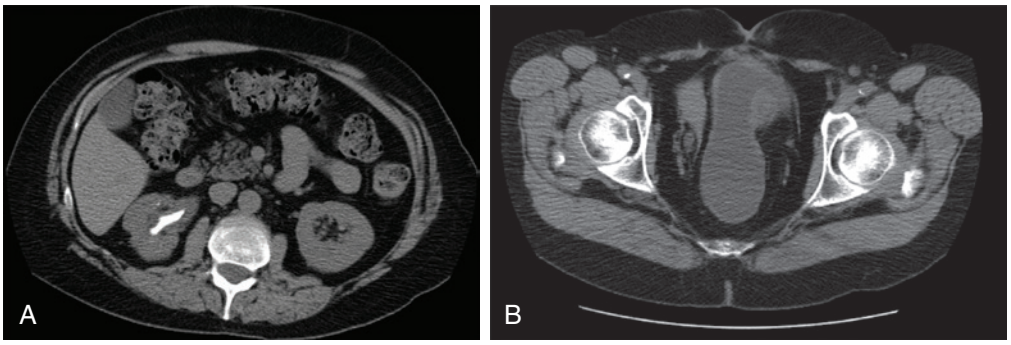
6. The decrease in the incidence of bladder stone formation following bladder augmentation from 50% in the 1980s to 10% in the 2010s is due to the use of:
   a. Mucolytic agents
   b. Potassium citrate
   c. Chronic antibiotics
   d. High-volume bladder irrigation
   e. Routine use of continent abdominal stomas

7. The majority of renal stones that develop in patients following a bladder augmentation are due to:
   a. Short-bowel syndrome
   b. Chronic antibiotic suppression
   c. Reflux of mucus into the upper tracts
   d. Proteus colonization of the upper tracts
   e. The development of bladder calculi



8. A 14-year-old boy with spina bifida underwent a bladder neck reconstruction, sigmoid bladder augmentation, and appendicovesicostomy 5 years ago. He complains of new onset of stomal urinary incontinence over the past month. He was empirically given a trial of antibiotics without improvement. Urine cultures are currently sterile. The next step is:
   a. Cystoscopy
   b. Urodynamic evaluation
   c. Renal and bladder ultrasound
   d. MRI of the lumbar sacral spinal canal
   e. CT scan of the abdomen and pelvis

9. A 12-year-old boy with a history of embryonal rhabdomyosarcoma of the prostate underwent a cystoprostatectomy and detubularized ascending colon pouch formation with a tapered ileal limb (Indiana pouch) 8 years ago. He now presents with an osteosarcoma of the iliac crest. Prior to extirpative surgery he should undergo:
   a. Platelet count
   b. A bleeding time
   c. Prothrombin time
   d. Partial thromboplastin time
   e. Serum lactate dyhydrogenase (LDH)



10. A relative indication for cesarean section post urologic reconstruction is:
    a. Ureterocystoplasty
    b. Continent ileocecal reservoir
    c. Sigmoid bladder augmentation with appendicovesicostomy
    d. Ileal bladder augmentation with reconstruction of bladder neck and appendicovesicostomy
    e. Presence of an artificial urinary sphincter at the bladder neck

Case Studies

1. A 21-year-old male with a history of spina bifida has been lost to follow-up for the past 5 years. His status is post bladder neck ligation, ileal bladder augmentation, and appendicovesicostomy 12 years ago. He complains of new onset of incontinence per stoma and multiple symptomatic febrile UTIs over the past year. CT scan without contrast is shown in Case Fig. 62.1. The next step is:
   a. MAG 3 diuretic renal scan
   b. Cystostogram
   c. Cystoscopy
   d. Percutaneous nephrostomy
   e. Percutaneous suprapubic tube placement

Case Figure 62.1

Case Figure 62.2

2. A 57-year-old woman with a history of classical bladder exstrophy underwent a staged bladder reconstruction, eventually becoming continent following a sigmoid colon bladder augmentation, bilateral Cohen cross-trigonal ureteral reimplantations, and bladder neck reconstruction. She presents for her annual follow-up evaluation with complaints of right flank and pelvic pain. CT images without contrast are shown in Case Fig. 62.2. The next step is:
   a. Dimercaptosuccinic acid (DMSA) renal scan
   b. Cystoscopy
   c. Ureteroscopy with laser lithotripsy
   d. Percutaneous nephrolithotomy
   e. MAG 3 diuretic renal scan

Answers

1. **d.** In newborn boys with posterior urethra valves urethral catheterization, classically with a 5- to 8Fr pediatric feeding tube, is initially used to decompress the upper tracts. Placement of a feeding tube over a Foley catheter is preferred to prevent inadvertent blowing up of the Foley balloon in the urethra thereby preventing urethral injury. The temporary placement of the pediatric feeding tube allows electrolyte stabilization of the infant and will passively dilate up the urethra to allow for endoscopic placement of instruments. If at the time of attempted endoscopic incision of the posterior urethral valves the endoscopic instrument does not fit, the next step is cutaneous vesicostomy. Percutaneous placement of a suprapubic tube in infants should be done as a temporary procedure if the physician is unable to place a urethral catheter at birth. In a child with posterior urethral valves whose bladder is distended into the abdominal cavity, placement should always be done under ultrasound guidance to prevent injury to the surrounding organs, i.e., bowel. Although perineal urethrostomy and valve ablation is an alternative approach, it does place the infant at risk for urethral stricture with maturation and veiscostomy with delayed valve resection is a safer approach.
2. **b.** Imperforate anus is associated with six major urologic anomalies: (1) renal agenesis, (2) vesicoureteral reflux, (3) rectal-urethral or vesical fistulas, (4) neurogenic bladder secondary to a tethered cord or partial sacral agenesis, (5) cryptorchidism, and (6) erectile dysfunction. Infants with imperforate anus and rectal-urethral fistulas will frequently present with recurrent UTIs and/or metabolic acidosis from urine absorption by the colonic epithelium. In infants too small to undergo a complex posterior sagittal repair (i.e., <10 kg), a temporary vesicostomy will relieve both symptoms. In this child with a concurrent neurogenic

bladder secondary to a tethered cord, the vesicostomy will also temporarily treat the bladder dysfunction reducing the risk of upper tract deterioration. Release of the tethered cord will be necessary; however, it may or may not improve bladder function and would not relieve the recurrent UTIs related to the rectal-urethral fistula. Intermittent catheterization would be highly problematic with the rectal-urethal fistula, the catheter frequently either hanging up at the fistula site or passing through the fistula into the rectum. Vesicoureteral reimplantation is not recommended in a infant due to technical problems and would not resolve the metabolic acidosis or recurrent bacteriuria.

3. **b.** The two patient categories that are at the highest risk for developing a cancer after an augmentation are patients who were augmented with the stomach, and individuals undergoing an augmentation that are on immunosuppression. These two patient populations are at a two- to threefold increased risk for developing a malignancy, a risk of approximately 3% per decade post augment.
4. **d.** The majority of bladder augments are performed in patients with a diminished sensation. In this patient population an abdominal mishap, such as appendicitis, severe pouchitis (infection of the augmented bladder), or perforation of a bladder augmentation may present with vague constitutional and abdominal complaints. Missed diagnosis of a perforated viscus or augment within these patients can be catastrophic with a reported mortality rate of 25%. Diagnosis of an intraabdominal mishap must be ruled out during their presentation. The best test is an abdominal and pelvic CT without contrast followed by a CT cystogram. The combination of these tests has a diagnostic accuracy rate of >95% for finding clinically significant intraabdominal pathology.
5. **c.** Noncompliance with intermittent catheterization is the most common etiologic cause for both bladder perforation (85%) and upper tract deterioration (67%). Obesity, although not the most common cause for renal deterioration, has been found to be related to noncompliance with catheterization, especially in wheelchair-bound patients. Presumably these patients are often noncompliant with catheterization due to difficulty with transferring from their wheelchair to perform the catheterization. Noncompliance with catheterization in obese, wheelchair-bound patients appears to be lessened by the creation of a continent abdominal stoma. Unfortunately complications with continent abdominal stomas such as stomal stenosis and false passages have also been found to correlate with obesity. This makes creation of a continent stoma in the obese patient population a very mixed bag of blessings and woes. Deterioration of renal function is only rarely caused by persistent elevations in detrusor pressures following augmentation. Deterioration of renal function has not been found to correlate with the presence of bladder calculi.
6. **d.** High-volume irrigation of the bladder augment performed daily has been associated with a decreased incidence of bladder stone formation, decreased frequency of bacterial colonization of the bladder, and decreased incidence of symptomatic urinary stone formation. The use of chronic antibiotic suppression, potassium citrate, or mucolytic agents has not been proven to be of any benefit in the prevention of bladder stones post augmentation. The use of continent abdominal stomas is actually associated with a increased risk for bladder stone formation.
7. **a.** Short-bowel syndrome is classically associated with loss of the ileal length, especially the terminal 15–25 cm. Short-bowel syndrome is a phenomenon that occurs due to the rapid transit of bile salts, a necessary component for the metabolism of dietary fats. The majority (95%) of bile salts are resorbed in the preterminal and terminal ileum. When this region of ileum is lost, excess bile salts will enter the colon. Bile salts have a direct cathartic effect on colonic mucosa accelerating bowel transit time resulting in the loss of bile salts in the feces. Loss of bile salts results in excess fat within the intestinal lumen, i.e., steatorrhea. Under normal circumstances dietary calcium is bound to oxalate within the stool; however, in the presence of excess stool fat calcium will preferentially be bound to the fat, a process called saponification. This makes dietary oxalate more available for absorption. Excess systemic oxalate is excreted in the urine resulting in hyperoxaluria and increased risk of metabolic calculi. If the short-bowel syndrome results in excess stool loss, the high bicarbonate content of stool can result in metabolic acidosis. In turn this results in calcium phosphate absorption from boney stores in an effort to buffer the system pH, further compounding the risk of metabolic induced stones due to hypercalciuria arising from bone resorption. In general, following a bladder augmentation, 60% of upper tract stones are found to be metabolically active calculi due to one of the aforementioned abnormalities. The likelihood of metabolic stones can be further potentiated by the use of chronic antibiotics; antibiotic usage results in the loss of *Oxalobacter formigenes*, the gut flora that metabolizes intestinal oxalate. Although vesicoureteral reflux with reflux of mucus into the upper tracts and chronic infection from bladder calculi can absolutely play a role in upper tract stones, they are not the predominant etiology of renal calculi following bladder augmentation.
8. **c.** New onset of urinary incontinence following a bladder augmentation is usually secondary to a UTI, and a urine culture with appropriate treatment or an empiric trial of antibiotics is the initial first step. If incontinence persists, the differential diagnosis includes, bladder stone, resumption of bowel activity, bladder malignancy resulting in irritation and overactivity of the augment, false passage of the continent stoma, or the onset of obesity impacting the vesical leak point pressure. The most common etiology after infection is the development of a bladder stone. A renal bladder ultrasound with or without kidney, ureters, and bladder x-rays is therefore the next step. Although a complete workup with a renal bladder ultrasound, urodynamic evaluation, and cystoscopy may be pursued, the initial step is with the noninvasive ultrasound. Ultrasound preferred over a CT scan due to cost benefit. It should be noted that sigmoid bladder augments are the most likely to have resumption of intrinsic bowel contractions even with detubularization of the bowel and would be mandated in this patient if no

bladder stone, false passage, or malignancy is found. It would be extremely rare for a tethered spinal cord to present with new onset of incontinence post augmentation. Following a bladder augmentation, the augmentation will dampen out the detrusor overactivity classically found with a tethered cord. Symptoms of a tethered cord post augmentation are classically related to alterations in lower-limb functionality.

9. **c.** Abnormal absorption of all fat-soluble vitamins (A, D, E, and K) can occur with loss of the preterminal and terminal ileum. The decrease in vitamin K can be subtle and may only become manifest with uncontrollable bleeding following trauma or major surgery. Vitamin K deficiency is diagnosed by an elevation in prothrombin time. Partial thromboplastin time, bleeding time, and platelet counts will all be normal. It is recommended that all patients where ileum was used as a part of their urologic reconstruction should undergo a prothrombin time assessment prior to any major surgery. Serum LDH is used in the evaluation of hemolytic anemia and is not indicated in this patient.
10. **d.** Women with a history of bladder augmentation and a bladder neck procedure are considered for cesarean section to prevent ischemic injury and pressure necrosis of the bladder neck and urethral continence mechanism during vaginal delivery. Cesarean section is not indicated following a ureterocystoplasty, continent ileocecal reservoir, or bladder augmentation not involving a bladder neck reconstruction or closure. Interestingly, although cesarean sections are recommended following bladder neck reconstruction. No indications for a cesarean section exist directly related to a prior placement of an artificial urinary sphincter at the bladder neck. Multiple vaginal deliveries have successfully occurred in this patient population without sequalae.

CASE STUDIES

1. **c.** In this patient, who has been lost to follow-up, the history of recurrent UTIs and new onset of urinary incontinence is most commonly due to bladder stones. CT scan documents the presence of multiple bladder stones along with left hydroureteronephrosis. These findings are highly concerning for the development of noncompliance with routine intermittent catheterization. The first step should be endoscopic evaluation of the pouch. This will confirm the presence of bladder calculi and rule out the presence of a concurrent invasive bladder tumor. The hydroureteronephrosis could be due to the presence of vesicoureteral reflux, edema at the ureterovesical junction due to multiple bladder stones, or the concurrent development of a tumor associated with chronic bladder calculi that is invasive at the sight of the left trigone. If cystoscopy confirms the absence of tumor, removal of the stones by either an endoscopic or open approach is the next step. Evaluation for the etiology of hydroureteronephrosis should be delayed until after the stones have been removed. The hydroureteronephrosis will almost invariably resolve and was secondary to inflammation either causing obstruction of the ureterovesical junction or vesicoureteral reflux.
2. **b.** CT images show both right renal calculi and a filling defect within the bladder. Cystoscopy with biopsy of the mass is the next step. This patient had a highly aggressive adenocarcinoma of the augment wall. She was treated with percutaneous nephrolithotomy and 1 week later underwent a radical cystectomy and colon conduit urinary diversion. No assessment of renal function was performed, due to the need to preserve renal function to enable the chemotherapy required by the majority of these patients. Despite cystectomy with clear surgical margins and negative lymph nodes, she developed metastatic disease within 6 months. Chemotherapy and radiation therapy failed to halt the rapidly progressive disease and she died 15 months post surgery. Although she initially presented with organ-confined disease, 80% of patients will present with locally advanced disease or nodal metastasis at the time of diagnosis, with a cancer-specific mortality of 80% at 18 months following the diagnosis.

  urethral-vesical, after robot-assisted radical prostatectomy, 335

Anastomotic stricture
after orthotopic neobladder diversion, 509, 511*f*
after radical retropubic prostatectomy, 454–455
ureteroileal, 491–492
Ancillary procedures, in nephrolithiasis, 594
Anderson-Hynes dismembered pyeloplasty, 587
Androgen insensitivity syndrome, 663
Anemia
in chronic kidney disease, 48
postoperative apnea and, 582–583
preoperative, 34
radical cystectomy and, 441
Anesthesia. *See also* General anesthesia; Regional anesthesia.
ASA physical status classification system of, 60–61
for children, 584–585
complications of, in urologic surgery, 58–81
during combined spinal/epidural anesthesia, 69–70
during epidural anesthesia, 69
during general anesthesia, 63–67
local anesthetic systemic toxicity as, 70
preoperative assessment of, 60–62
during regional anesthesia, 67–71
during spinal anesthesia, 68–69
spinal hematoma as, 70–71
induction of, in children, 582
intraoperative management of, 63–67
in nephrolithiasis, 594
neurocognitive development and, 585
pulmonary complications of, 14
safety of, 60
technique for, 61–62
patient-specific risk stratification, 61
procedure-specific indications, 61–62
total intravenous, for postoperative nausea and vomiting, 67
for transurethral resection of bladder tumors, 258–259
Aneurysm, abdominal aortic, after extracorporeal shock wave lithotripsy, 302
Angioembolization, preoperative, for renal tissue ablation, 238–239
Angiography
in arteriovenous fistula, 476, 477*f*
for partial nephrectomy, 357–358, 359*f*
in transplant renal artery stenosis, 474, 474*f*
Angiomax. *See* Bivalirudin.
Angiomyolipomas (AMLs), during pregnancy, 190
Antegrade endopyelotomy, 288
Antegrade nephroureterogram, for ureteral injury, 161, 161*f*
Antegrade ureteral stents
complications of, 225
indications for, 219
Anterior urethral injuries, 172–174, 172*f*, 174*f*
Antibiotic-impregnated prostheses, 559–560
"Antibiotic stewardship", 90
Antibiotics
for orthotopic neobladder diversion, 507
perioperative, for pediatric patient, 584
prophylactic, 86
for endocarditis, 26
for posterior urethral valves, 613–614
for radical retropubic prostatectomy, 451
recent use of, urinary tract infection risk and, 9
resistance, in infectious complications of urologic surgery, 90
Anticholinergics, for local toxicity, from bacille Calmette-Guérin, 228
Anticoagulation, 39*t*–40*t*
for hypercoagulable state, 43*t*
perioperative, in renal transplantation, 470
for pulmonary embolism, 18
for thromboembolic disease, 44
during vascular repair, 118–119
Antiemetic medications, for postoperative nausea and vomiting, 66
Antimicrobial prophylaxis
for infectious complications of ureteroscopic surgery, 283
for infectious complications of urologic surgery, 83*t*
before ureteroscopic surgery, 277
Antiphospholipid syndrome, 42
Antiplatelet medications, 39*t*
Antireflux surgery. *See also* Ureteral reimplantation.
complications of, 623–633
Antithrombin III deficiency, 41
Anuria, after ureteral reimplantation, 625
Anxiety, in pediatric patient, 581–582
Aortic aneurysm, abdominal, after extracorporeal shock wave lithotripsy, 302
Aortic injuries, 120–121
Aortic stenosis (AS)
aortic valve intervention for, 26
postoperative management of, 26–27
APC resistance, 42
Apixaban, 40*t*
Apnea
postoperative, in pediatric patient, 582–583
sleep, in radical retropubic prostatectomy, 446
Appendicovesicostomy (APV), 605
Appendix, in continent cutaneous diversion, 499
Argatroban, 39*t*
Argon beam coagulator, 315, 315*t*
Argus adjustable male sling, 538–539
Arixtra. *See* Fondaparinux.
Arrhythmias, 27
after extracorporeal shock wave lithotripsy, 302
postoperative, 27
preoperative, 27
Arterial clamping, for bleeding, in partial nephrectomy, 404
Arterial complications, in lymphadenectomy, 425, 428*f*
Arterial injuries, 120–121
management of, 120–121
Arteriovenous fistula, 289
after renal transplantation, 476, 477*f*
in vascular injuries, 120
Arthralgias, from bacille Calmette-Guérin, 230
Arthritis, from bacille Calmette-Guérin, 230
Artificial urinary sphincter (AUS), 536–537, 537*f*
complications of, 536*t*
delayed and long-term complications in, 541–542
infection and erosion, 541–542
mechanical malfunction causing, 542
recurrent incontinence, 542
urethral atrophy, 542
urinary retention, 542, 543*f*
early postoperative complications of, 540–541
erosion in, 540
hematoma in, 540
infection in, 540
retention in, 540
Artificial urinary sphincter (AUS) *(Continued)*
intraoperative complications of, 539–540
bleeding in, 539
corporal injury in, 539
device injury in, 539–540
urethral injury in, 539
Ascites, chylous
after retroperitoneal lymph-node dissection, 421–422, 422*f*
complications related to kidney exposure and, 355–356
Aspiration, for hydrocele, 577
Aspiration pneumonia, 16
Aspiration pneumonitis, 64
Aspirin
benefits of, 30
preoperative, 38. *See also* Acetylsalicylic acid.
Asthma, in pediatric patients, 583
Asymptomatic bacteriuria
defined, 188
during pregnancy, implications of, 188
Atelectasis, 16
Atrial fibrillation, 27, 31, 38, 62
Atrial natriuretic peptide (ANP), 54
AUA guidelines, 85
AUA Quality registry (AQUA), 94
Augmentation, bladder, 665–673, 668*t*. *See also* Bladder augmentation.
acidosis after, 520–521
anastomotic leak after, 517, 517*f*
bacteriuria after, 518–519
bowel dysfunction after, 521
carcinoma after, 520
complications of, 516–522
long-term, 518–522
short-term, 517–518
incontinence after, 521–522
indications for, 516
medical complications following, 671–673
not using gastro-enteric segments, 673
perforation after, 520
pregnancy after, 522, 673
stones after, 519–520, 519*f*
urinary tract infection after, 518–519
Augmentation cystoplasty, 605
Augmentation enterocystoplasty, for urge urinary incontinence, 525–526
AUS. *See* Artificial urinary sphincter.
Autoaugmentation-detrusor myomectomy, 673
Autonomic hyperreflexia, 65
Autotransplant, renal, 466
Avulsion injuries, 116
Aztreonam, for prostate biopsy complications, 216

B

B12 deficiency, after urinary diversion, 672–673
Bacille Calmette-Guérin, 226–227
arthralgic complications of, 230
continuing therapy and maintenance with, 230
contraindications to, 231
granulomatous complications of, 229–230
infectious toxicity of, 228–229
inflammation from, 230
inflammatory toxicity of, 228
local toxicity of, 227–228
low-dose, 227
overview of complications of, 227–228, 227*t*
purified protein derivative conversion and, 230–231
strains of, 227
systemic absorption of, prevention of, 229

Bacille Calmette-Guérin-refractory disease, gemcitabine for, 235
Bacteriology, of ileal conduit, 493
Bacteriuria
  after bladder augmentation, 518–519
  asymptomatic
    defined, 188
    implications during pregnancy of, 188, 188*t*
Balanitis xerotica obliterans (BXO), 547–548, 547*f*, 654
Balanoposthitis, granulomatous, from bacille Calmette-Guérin, 229
Bare metal stent, as antiplatelet management, 24*t*
Benign prostatic hyperplasia (BPH)
  complications of endoscopic procedures for, 265–274
    intraoperative, 266–270
    perioperative, 266*t*
    postoperative, 266*t*, 270–273
    treatment initiation challenges as, 269–270
  obesity and, 181
Beta blockers, for cardiac complications, 30
Bioethics, 590
Biopsy, of prostate, 247–248
Biopsy-related infection, flow chart of steps for prevention and evaluation of, 216*f*
Bipolar current, 314–315
Bivalirudin, 39*t*
Bladder
  calculi, after urologic reconstruction, 669–670
  decompression of, for posterior urethral valves, 613
  diffuse carcinoma in situ of, 259–260
  dysfunction of, posterior urethral valves and, 619–621, 619*f*–620*f*
  injury to, 268–269
    during robot-assisted radical prostatectomy, 330
    during stress urinary incontinence surgery, 528–529
  neurogenic, surgery for, 516–522
  perforation of
    after bladder augmentation, 520
    spontaneous, 667–668
    during transurethral resection of bladder tumors, 262–263
Bladder augmentation, 665–673, 668*t*
  acidosis after, 520–521
  anastomotic leak after, 517, 517*f*
  bacteriuria after, 518–519
  bladder perforation after, 520
  bowel dysfunction after, 521
  carcinoma after, 520
  complications of, 516–522
    long-term, 518–522
    short-term, 517–518
  incontinence after, 521–522
  indications for, 516
  medical complications following, 671–673
  not using gastro-enteric segments, 673
  pregnancy after, 522, 673
  stones after, 519–520, 519*f*
  urinary tract infection after, 518–519
Bladder cancer
  Charlson Index score in, 10
  intravesical therapy for, 226. *See also* Intravesical therapy.
  obesity and, 5–6, 181
  radical cystectomy for, 433
  robotic cystectomy for, 371
Bladder capacity, for bladder neck reconstruction, 643
Bladder contracture
  after pelvic radiation therapy, 208–209, 208*f*–210*f*
  from bacille Calmette-Guérin, 230
  from mitomycin C, 233
Bladder diverticulum
  after ureteral reimplantation, 628, 629*f*
  tumor in, 260
Bladder dynamics, vesicoureteral reflux and, 624–625
Bladder exstrophy, classic
  bladder neck reconstruction in, 643–645
  cancer after, 646
  epispadias repair in, 642–643
  fertility and pregnancy after, 645–646
  initial bladder closure in, 635–642
    bladder outlet obstruction after, 640, 640*f*
    complications of, 637–641
    immobilization in, 639, 639*f*
    incontinent interval after, 641
    infection after, 637–638
    late postoperative state in, 641
    overview of, 635–637
    penile complications of, 640–641, 641*f*
    wound tension and mobility after, 638–639, 638*f*
  long-term considerations in, 645–646
  modern staged repair approach to, 635
  with pelvic osteotomy, 639
  penile and introital difficulties after, 645
  penile appearance after, 645
  social adjustment after, 646
Bladder flap, Boari, 463–464, 463*f*–464*f*
Bladder mucosal grafts, 656
Bladder neck contracture
  after cryosurgical ablation, 253
    etiology and pathogenesis of, 253
    incidence of, 253
    management of, 253
  after endoscopic BPH procedures, 272–273, 272*f*
  after radical retropubic prostatectomy, 454–455
Bladder neck reconstruction, for bladder exstrophy, 643–645
Bladder outlet obstruction
  after bladder exstrophy, 640, 640*f*
  after male slings, 543, 544*f*
  after stress urinary incontinence surgery, 529–530
Bladder prolapse, complication of primary bladder exstrophy, 635, 637*f*
Bladder reconstruction
  preservation of renal function following, 668–669
  urinary leak following, 154–155
    definition and diagnosis of, 154
    incidence and differential of, 155
    management of, 155–157, 156*f*
    prevention of, 155
    risk factors of, 155
    symptoms of, 154–155
Bladder spasms, ureteroscopic surgery and, 284
Bladder surgery, in children, 602–605
  appendicovesicostomy in, 605
  augmentation cystoplasty in, 605
  ureteroneocystostomy in, 602–604, 603*t*
  ureteroureterostomy in, 604–605
Bladder trauma, 170–171
Bladder tumors
  on anterior surface, 260
  in diverticula, 260
  at dome, 260
  involving ureteral orifice, 260
Bladder tumors *(Continued)*
  at lateral wall, 260
  during pregnancy, 191
  transurethral resection of, 256–264. *See also* Transurethral resection of bladder tumors.

  after hypospadias repair, 650–651
  in artificial urinary sphincter, 539
  circumcision and, 585
  as complication of ablation
    after RFA, 241, 241*f*
    in cryoablation, 242–243
    managing, 244–245
    in microwave ablation, 243
  endoscopic BPH procedures
    intraoperative, 266–267
    postoperative, 270
  from hypogastric veins injuries, 122
  increased, 36–38
  intraoperative, 41
    management approach to, 117*f*
  in male slings, 540
  in minimally invasive pyeloplasty, 363, 365–366
  during nephrectomy, 388–390
  in nephrostomy tubes, 223–224, 224*f*
  in partial nephrectomy, 356–358, 356*f*–358*f*, 403–405, 404*f*–405*f*
    delayed, 405
  prostate biopsy complications and, 213
  in radical cystectomy, 439
  during radical retropubic prostatectomy, 447–449, 448*f*–449*f*
  in renal transplantation, 470–471
  from renal vein injuries, 122
  in robot-assisted radical prostatectomy
    intraoperative, 331–332, 332*f*
    postoperative, 334–335, 335*f*
  in robot-assisted surgery, 322–323
  during robotic pelvic floor reconstruction, 343–344
  during stress urinary incontinence surgery, 527–533, 528*f*
  in uremia, 36
  ureteral, ureteroscopic surgery and, 280–281
  ureteroscopic surgery and, 284
  in vascular complications, initial management of, 116–118, 117*f*
Bleomycin, chemotherapy, pulmonary complications of, 19–20
Blood component abnormalities, hematologic complications and, 34–36
Blood donation, autologous, in radical retropubic prostatectomy, 447
Blood loss, osteotomy complications, after bladder exstrophy, 640
Blood supply, of ureter, 159, 160*f*
Blue-light cystoscopy, for carcinoma in situ, 259–260
Boari bladder flap (BBF), 167, 167*f*, 463–464, 463*f*–464*f*
  minimally invasive, postoperative complications of, 368
Body mass index (BMI), 3–4, 4*f*, 178, 179*t*. *See also* Obesity.
Bone anchored sling, 537
Bone-anchoring techniques, in stress urinary incontinence, 525
Bone marrow, granulomatous reactions of, from bacille Calmette-Guérin, 230
Bone scans, for prostate, 248
Botulinum toxin A
  complications of, 533–534
  for urge urinary incontinence, 526

Bougie à boule, urethral calibration with, 548
Bowel
  for conduit urinary diversion
    complications of, 483
    length of, 480, 481*f*
    selection of, 479–480
  preoperative preparation of, 103
  reoperation for, 130
  strangulation of, 130
Bowel complication(s)
  after continent cutaneous diversion, 497–498
  after orthotopic neobladder, 508–509, 508*f*
  ileus as, 126–127
  internal hernia as, 130
  intraabdominal abscess as, 129
  management of, 126–131
  Ogilvie's syndrome as, 131
  vesicoenteric fistula as, 129
Bowel dysfunction, after bladder augmentation, 521
Bowel injury, 128, 128*f*
  kidney exposure, complications related to, 355
  during robot-assisted radical prostatectomy, 333
  during stress urinary incontinence surgery, 529
Bowel obstruction, 127, 127*t*, 129–131, 130*f*
  after orthotopic neobladder diversion, 508, 508*f*
  volvulus as, 131
Bowel perforations, after extracorporeal shock wave lithotripsy, 303
Bowel preparation, 127–128
  for conduit urinary diversion, 479
  for orthotopic neobladder diversion, 507
  in pediatric patients, 583
  for radical cystectomy, 436
  use of, prostate biopsy complications and, 216
Bowel segment vaginoplasty, 662
BPH. *See* Benign prostatic hyperplasia.
Brachial plexus, common positioning nerve injuries, 310*t*
Brachial plexus injury, 108
  nephrectomy, patient positioning, complications related to, 353
Bradyarrhythmias, postoperative, 27
Breathing exercises, deep, for pulmonary complications, 15
Bronchospasm
  during general anesthesia, 64
  postoperative, 15
Buccal mucosa, 661
Buccal mucosa graft
  for hypospadias repair, 656
  for ureteroplasty, 464–465
Buccal mucosal graft ureteroplasty, minimally invasive
  intraoperative complications of, 364
  postoperative complications of, 368
Budd-Chiari syndrome, 393–394
Bupivacaine, toxic doses of, 70
Burch colposuspension, for stress urinary incontinence, 524, 524*t*
Bypass, cardiopulmonary, in nephrectomy, 395

Dexamethasone, for postoperative nausea and vomiting, 66
Dexamethasone suppression test (DST), for Cushing's syndrome, 412
Dextranomer/hyaluronic acid (Dx/HA), for vesicoureteral reflux, 592, 630
Diabetes mellitus
  in children, 583
  in chronic kidney disease, 48
  control, preoperative, 203
  prosthetic surgery, infection from, 558
  urinary tract infection risk and, 9
Diagnostic laparoscopy, in children, 605–606
Diaphragm, injury to, during nephrectomy, 392
Diaphragmatic tears, during laparoscopy, 19
Difficult airway
  during general anesthesia, 64
  obesity and, 63
Diffuse carcinoma in situ, of bladder, 259–260
Dilutional anemia, pregnancy and, 184
Dilutional coagulopathy, 38
Dipyridamole, 39*t*
Direct coupling, 314*f*
Direct suture ligature, for repair of cut renal vessels, 404, 404*f*
Direct thrombin inhibitors, 39*t*–40*t*
Dismembered pyeloplasty, for ureteral injury, 164, 165*f*
Disorders of sex development (DSD)
  classification of, 658*t*
  complications of surgery for, 657–664
  of overvirilization, 657–659
  of undervirilization and gonadal abnormalities, 662–663
  vaginal agenesis and vaginoplasty and, 659–662, 660*f*
Disorders of sexual differentiation (DSD), 590
Dissection, instruments for, 113
Disseminated intravascular coagulation (DIC), 36–37
Distal ureteral repair, for ureteral injury, 163*f*, 167
Diuresis, postobstructive, 53–55, 54*t*
Diverticulum
  bladder
    after ureteral reimplantation, 628, 629*f*
    tumors in, 260
  urethral, after hypospadias repair, 653, 654*f*–655*f*
Donor nephrectomy, 360
Dorsal lithotomy position, in ureteroscopic surgery, 277
Dorsal nerve of penis, deep, 73
Dorsal penile nerve block, 73
Dorsal venous complex, in radical retropubic prostatectomy, 447, 448*f*–449*f*
Double-barreled wet colostomy (DBWC), 493
"Double J" stents (DJS), 219
Down syndrome, in children, 583
Doxorubicin, 234–235
  toxicity of, 235*t*
Drainage, of UUT obstruction, 218
Dressings, scrotal, 569, 569*f*
Drug eluting stent
  as antiplatelet management, 24*t*
  preoperative, 23
  thrombosis in, 23–24
Drug intoxication, after urinary diversion, 57
Dual antiplatelet therapy (DAPT), preoperative, for drug eluting stent, 23
Duodenum, injury to, during nephrectomy, 391
Duplex ultrasound, for partial nephrectomy, 357–358, 358*f*
Dysfibrinogenemia, 36
Dyspareunia, after stress urinary incontinence surgery, 533

E

"Early failure," in vasectomy, 571
Effient. *See* Prasugrel.
Ejaculation, failure of, in lymphadenectomy, 420, 420*f*–421*f*
Ejaculatory dysfunction, in bladder exstrophy, 645
Elderly patient, nephrectomy for, 396

Electrocardiography, of acute MI, 24, 25*f*
Electrocautery, 313
Electrolyte
  considerations
    after urinary diversion, 55
    in chronic kidney disease, 48–49
  gastrointestinal transport of water and, 55
Electrolyte disturbances, in children, 588–589
Electroporation, irreversible, 244
Electrosurgery, in laparoscopy, 313–316, 314*f*, 315*t*
Eliquis. *See* Apixaban.
Embolectomy, for vascular injuries, 118
Embolism
  gas
    in pediatric laparoscopy, 599–600
    during robot-assisted radical prostatectomy, 330
  pulmonary, 18, 43–45, 297. *See also* Pulmonary embolism.
    after renal transplantation, 475–476
    after robot-assisted surgery, 322–323
    radical retropubic prostatectomy after, 451
Embolization, in vascular injuries, 119–120
Embolization syndrome, 389
Emergency surgery, timing and risk of, 22, 22*t*
Emesis. *See also* Nausea and vomiting.
  postoperative, in pediatric patient, 588
Emphysema, subcutaneous. *See also* Subcutaneous emphysema.
  during laparoscopy, 80
  in pediatric laparoscopy, 599
  during robot-assisted radical prostatectomy, 329–330
Encephalopathy, hyperammonemic, in TUR syndrome, 52
Encrustation, stent, 222
Endo-GIA (endoscopic gastrointestinal anastomosis), 317
Endopelvic fascia, in radical retropubic prostatectomy, 447–448, 448*f*
Endopyelotomy, antegrade, 288
Endoscopic correction, of vesicoureteral reflux, 592
Endoscopic gastrointestinal anastomosis (Endo-GIA), 317
Endoscopic repair, for ureteral injury, 163–164, 163*f*
Endoscopic surgery
  pediatric, complications of, 591–597
    cystoscopic interventions in, 591–592
    nephrolithiasis in, 593–597
  radiation exposure during, 593
Endoscopy
  flexible, for pouch stones, 500, 500*f*
  of posterior urethral injuries, complications of, 550
  ureteroscopic surgery and, 279
Endotracheal intubation, in laparoscopy, 77
Endoureterotomy, for ureteral strictures, 501
Endovascular instruments, 114
Enhanced recovery, after surgery strategies, 374*t*
Enoxaparin, 39*t*
Enoxaparin prophylaxis, in robotic cystectomy, 380–381
Enterobacteriaceae, 88
Enterocutaneous fistula, 382, 512, 513*f*
Ephedrine, for cardiovascular stability, 71
Epididymal fibrosis, ischemic, from vasoepididymostomy, 576
Epididymal injury
  after hydrocelectomy, 577
  after spermatocelectomy, 578
Epididymis
  anatomy of, 568
  surgical complications of, 567–579
Epididymo-orchitis, granulomatous, from bacille Calmette-Guérin, 229
Epidural anesthesia
  combined with spinal anesthesia, 69–70
  complications during, 69
  laparoscopy under, 78
Epidural blood patch, for postdural puncture headache, 68
Epigastric artery, injury to, inferior, during robot-assisted radical prostatectomy, 330
Epirubicin, 234–235
Epispadias repair, complications of, 634–646
Eptifibatide, 39*t*
Erectile dysfunction
  after cryoablation, 249–251
  after endoscopic BPH procedures, 273
  after radical retropubic prostatectomy, 452
  complications of surgery for, 556–566
  etiology and pathogenesis of, 250
  incidence of, 249–250, 249*t*–250*t*
  from internal urethrotomy, 550
  management of, 250–251
  obesity and, 6, 181–182
  penile prosthesis for. *See also* Penile prosthesis.
    antibiotic-impregnated, 559–560
    crural perforation and, 561, 562*f*
    erosion of, 561
    infection of, 558–560, 558*f*, 558*t*
    mechanical malfunction of, 560–561, 560*t*
    penile necrosis after, 562
    for Peyronie's disease, 562–566, 566*t*
    supersonic transporter deformity after, 561–562
    surgery for, 556–558
    types of, 556, 557*b*, 557*f*
  from posterior urethral reconstruction, 552
  as prostate biopsy complications, 213*t*, 214–215
  from tissue transfer reconstruction, 553–554
Erosion
  in artificial urinary sphincter, 540–542
  male incontinence and, 541–542
  in male slings, 542–543, 543*f*
  stent, 221–222
Erythrocytosis, 34–35
Erythromycin, for paralytic ileus, 435
Erythropoietin, preoperative, in radical retropubic prostatectomy, 447
Escherichia coli, of prostate biopsy complications, 214
Esophageal trauma, 64
Ethics, pediatric patient and, 590
European Society for Clinical Nutrition and Metabolism (ESPEN) guidelines, for nutritional status, 203
Evisceration, wound, 104
Exstrophy, complications of, 634–646
External genitalia, 174–176
  penile amputation and, 174–175, 175*f*
  penile fractures and, 174, 175*f*
  testicular trauma and, 175–176, 176*f*
External sphincter, preservation of, in radical retropubic prostatectomy, 454
External urinary catheter, removal of, for urologic procedures, 84*t*
Extracorporeal shock wave lithotripsy (ESWL)
  arrhythmias after, 302
  complications of, 299–306
  diabetes risk from, 305
  fertility effects of, 305
Extracorporeal shock wave lithotripsy (ESWL) *(Continued)*
  gastrointestinal injury from, 303
  hematoma after, 299–301, 300*f*
  hepatic injury from, 303
  hypertension from, 303–304, 304*t*
  muscle damage from, 303
  obesity and, 6, 182
  pancreatic injury from, 303
  potential long-term complications of, 305
  pulmonary contusion from, 303
  renal insufficiency after, 304–305
  sepsis after, 301–302
  splenic injury from, 303
  steinstrasse after, 301, 301*f*
  urinary fistula after, 303
  vascular injury from, 302
Extraserosal tunnel (T-limb), in continent cutaneous diversion, 499
Extraureteral stone fragment migration, 291, 292*f*
Extravasation, 290–291, 290*f*
  in retrograde urethrography, 548, 548*f*
  urinary, in renal transplantation, 471, 471*f*

F

Factor deficiencies, 35–36, 36*t*
Factor V deficiency, 35
Factor V Leiden, 42
Factor VII deficiency, 35
Factor VIII deficiency, 35
Factor X deficiency, inherited, 35
Factor Xa inhibitor, 40*t*
  perioperative, 31
Factor XI deficiency, 35
Factor XII deficiency, 36
Failure, of ureteroscopic surgery, 281–283
Failure mode and effects analysis (FMEA), for quality improvement strategies, 97
False urethral passage, 268
Fascial dehiscence
  after robotic cystectomy, 381
  in radical cystectomy, 439
Fasciocutaneous flap
  for urethral stricture, 205
  for urethrocutaneous fistula, 197, 197*f*
Fasting, preoperative, for pediatric patient, 583–584, 583*t*
Fecal incontinence, after urinary diversion, 672
Female to male gender confirmation surgery, complications of, 196–199
  meatal stenosis after, 199, 199*f*
  persistent vaginal cavity after, 198–199, 199*f*
  urethral stricture after, 196–198, 198*f*
  urethrocutaneous fistula after, 196–198, 197*f*
Feminizing genitoplasty, 657–658
Femoral nerve injury
  positioning-related, 108–109, 109*f*
  in radical cystectomy, 441
  during robot-assisted radical prostatectomy, 334
Fentanyl, for postoperative pain, 75
Fertility
  after bladder exstrophy, 645–646
  effects of extracorporeal shock wave lithotripsy to, 305
Fetal monitoring, perioperative, for urologic surgery, 192–193, 192*b*
Fever, in sepsis, 89
Fibrin, as hemostatic agents, 115*t*
Fibrinogen deficiency, 36
Fibrinogenolysis, primary, 37

Fibrinolysis, primary, 37
Fibroepithelial polyps, causing obstruction, in ureteropelvic junction, 160, 161*f*
Fine needle aspiration (FNA), for sperm extraction, 575
Fistula
  arteriovenous, after renal transplantation, 476, 477*f*
  to bowel, 129
  enterocutaneous, 382, 512
  formation, after vasectomy, 571
  nephropleural, after percutaneous nephrolithotomy, 19
  in orthotopic neobladder diversion, 512–513, 512*f*–513*f*
  urinary. *See also* Urinary fistula.
    after extracorporeal shock wave lithotripsy, 303
    after stress urinary incontinence surgery, 533
    as bowel complications, 127*t*
    intestinal, 144–146, 145*f*
    management of, 132–146, 133*f*
    ureteral, 141–144, 142*b*, 144*f*
    urethrovaginal, 139–141, 140*t*
    vesicovaginal, 133–139, 133*f*, 135*b*–136*b*, 135*f*, 136*t*, 137*f*–138*f*
  vesicoenteric, 129
Fixed male sling, 537–538
Flank incision, pleural injury during, 19
Flank position
  cardiopulmonary system and, 385
  technique for, 107, 107*f*
Flap, Boari bladder, 463–464, 463*f*–464*f*
Fluid
  administration of, for bowel obstruction, 130
  extravasation of. *See* Extravasation.
  overload of, 297
Fluid and electrolyte considerations, in chronic kidney disease, 48–49
Fluid resuscitation, in infectious complications of urologic surgery, 88
Fluoroquinolone, 85
  for prostate biopsy complications, 216
Focal cryoablation, complication rates in, 247
Fogarty thromboembolectomy catheter, 114
Foley catheter, loss of, after radical retropubic prostatectomy, 451
Fondaparinux, 39*t*
Foot drop, 309
Forceps, vascular, 113
Fosfomycin, 190
Fowler-Stephens orchiopexy, 606
Fragmentation, stent, 222
Fragmin. *See* Dalteparin.
Freer instrument, in partial nephrectomy, 404, 404*f*
Fructose, for vesicoureteral reflux, 624
Functional capacity, 23, 23*t*
Furosemide, for TUR syndrome, 53

G

Gas embolism, 19
  in pediatric laparoscopy, 599–600
  during robot-assisted radical prostatectomy, 330
Gastric mucosa, for urinary diversion, 55
Gastro-enteric segments, bladder augmentations not using, 673
Gastrocystoplasty, 521
Gastrointestinal complications, in lymphadenectomy, 425–426
Gastrointestinal injury, from extracorporeal shock wave lithotripsy, 303
Gastrointestinal tract, water and electrolyte transport in, 55
Gelatin, as hemostatic agents, 115*t*
Gemcitabine, 235–236
  toxicity of, 235*t*
Gender confirmation surgery, management of complications of, 195–201
General anesthesia
  complications during, 63–67
  laparoscopy under, 77–78
  pneumoperitoneum under, 76–77
  positioning-related complications of, 67
Genitofemoral nerve, injury to, during orchidopexy, 587
Genitoplasty
  feminizing, 657–658
  masculinizing, 663
Genitourinary surgery, complications in irradiated pelvis of, 202–210
Genitourinary toxicity, from mitomycin C, 232
Glans hyperemia, after penile revascularization, 562
Glans tissue, excision of, circumcision and, 585
Glomerular filtration rate (GFR), 48
  during pregnancy, 184
Glutaraldehyde-based, hemostatic agents, 115*t*
Gluteal compartment syndrome, rhabdomyolysis and, 353
Glycine, in irrigating solution, 257–258
Glycoprotein IIb/IIIa receptor antagonist, 39*t*
Glycopyrrolate, for intraoperative penile erection, 74
Goldblatt kidney, 170
Gonadal abnormalities, 662–663
Gonadal artery, 388
Graft harvest, for open surgical procedures, 553, 553*f*
Graft perfusion, poor, in renal transplantation, 470
Graft rejection, after renal transplantation, 476–477
Grafts, for urethral stricture, 205
Granulomas, sperm, 571
Granulomatous complications, of bacille Calmette-Guérin, 229–230
Groin surgery, in children, 605–608
  diagnostic laparoscopy in, 605–606
  laparoscopic
    inguinal hernia repair in, 607–608
    orchiopexy in, 606–607, 606*t*
    varicocelectomy in, 607, 607*t*
Growth retardation, after urinary diversion, 672
Guideline directed medical therapy (GDMT), for myocardial infarction, 25
Guideline Focused Update on Duration of Dual Antiplatelet Therapy in Patients with Coronary Artery Disease, 24
Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery, 21
Guideline recommendations, for cystoscopy, 83–85
Guidewire, in ureteroscopic surgery, 277
  hydrophilic, 277
Gum chewing, for postoperative ileus, 436
Gynecologic surgery, iatrogenic ureteral injuries in, 142

H

Haloperidol, for postoperative nausea and vomiting, 67
Harmonic scalpel, 315
Hasson technique, in robot-assisted radical prostatectomy, 329
Headache, postdural puncture, 68
Heart failure, obesity and, 62
Hematologic complications
  anticoagulation and, 38–41
  blood component abnormalities and, 34–36
  increased bleeding and, 36–38
  increased coagulation, 41–45
  intraoperative bleeding, 41
  preoperative evaluation for, 32–34
  preoperative hematologic assessment and management of, 32–46
Hematoma. *See also* Bleeding/hemorrhage.
  after extracorporeal shock wave lithotripsy, 299–301, 300*f*
  after hypospadias repair, 650–651
  after nephrectomy, 390
  after renal transplantation, 473, 474*f*
  after vasectomy reversal, 576
  in artificial urinary sphincter, 540
  in male slings, 540–541
  from Micro-TESE, 575
  in minimally invasive pyeloplasty, 365–366
  pelvic, 119
  retroperitoneal, 119
  scrotal, postoperative, 568*t*, 569, 569*f*
  spinal, 70–71
  wound, 101
Hematuria
  after renal transplantation, 473
  from bacille Calmette-Guérin, 228
  in nephrostomy tubes, 223–224, 224*f*
  of prostate biopsy complications, 213*t*
Hematuria-dysuria syndrome, 521
Hemoglobin, preoperative, 34
  in irradiated patient, 203
Hemophilia A, 35
Hemophilia B, 35
Hemorrhage, 287–290. *See also* Bleeding/hemorrhage.
  after hypospadias repair, 650–651
  in artificial urinary sphincter, 539
  circumcision and, 585
  as complication of ablation
    after RFA, 241, 241*f*
    in cryoablation, 242–243
    managing, 244–245
    in microwave ablation, 243
  endoscopic BPH procedures
    intraoperative, 266–267
    postoperative, 270
  from hypogastric veins injuries, 122
  increased, 36–38
  intraoperative, 41
    management approach to, 117*f*
  in male slings, 540
  in minimally invasive pyeloplasty, 363, 365–366
  during nephrectomy, 388–390
  in nephrostomy tubes, 223–224, 224*f*
  in partial nephrectomy, 356–358, 356*f*–358*f*, 403–405, 404*f*–405*f*
    delayed, 405
  prostate biopsy complications and, 213
  in radical cystectomy, 439
  during radical retropubic prostatectomy, 447–449, 448*f*–449*f*
  in renal transplantation, 470–471
  from renal vein injuries, 122
  in robot-assisted radical prostatectomy
    intraoperative, 331–332, 332*f*
    postoperative, 334–335, 335*f*
  in robot-assisted surgery, 322–323
  during robotic pelvic floor reconstruction, 343–344

Hemorrhage *(Continued)*
during stress urinary incontinence surgery, 527–533, 528*f*
in uremia, 36
ureteral, ureteroscopic surgery and, 280–281
ureteroscopic surgery and, 284
in vascular complications, initial management of, 116–118, 117*f*
Hemostatic agents, for vascular complications, 114, 115*t*
Hemothorax, 17–18
Heparin, 39*t*
complications of, 44
preoperative, 41
for pulmonary embolism, 18
in radical cystectomy, 440
for thromboembolic disease, 44
during vascular repair, 118
Hepatic blood flow, during laparoscopy, 77
Hepatic injury, during extracorporeal shock wave lithotripsy, 303
Hepatitis, granulomatous, from bacille Calmette-Guérin, 229
Hepatobiliary injury, kidney exposure, complications related to, 355
Hernia
after partial orchiectomy, 579
in bowel mesentery, 130
inguinal, after radical retropubic prostatectomy, 455
parastomal, 484–485, 485*f*, 503–504
port site
after robot-assisted radical prostatectomy, 337
after robotic pelvic floor reconstruction, 342–343
Hernia repair, for pediatric patient, 587
High-grade ureteral injury, ureteroscopic surgery and, 281
Host factors, impact of, 2–11
Hurria, Arti, 373
Hyaluronic acid, for vesicoureteral reflux, 592
Hydrocele, 576
after scrotal surgery, 568*t*
after varicocelectomy, 573
aspiration for, 577
recurrence of, 577
sclerotherapy for, 577
treatment option techniques for, 577
Hydrocelectomy, 577
complications after, 577, 577*f*
Hydrodisplacement, for renal tissue ablation, 239, 239*f*
Hydronephrosis, 161–162
as complications in bladder exstrophy, 644
physiologic, of pregnancy, 185
on renal ultrasound, 471–472, 472*f*
ureteral stent for, 222
Hydropneumothorax, after supracostal percutaneous nephrolithotomy, 19
Hydrothorax, 18
Hyperacute rejection, after renal transplantation, 477
Hyperaldosteronism, 412, 416–417
Hyperammonemic encephalopathy, in TUR syndrome, 52
Hyperbaric oxygenation, for radiation-induced stricture surgery, 203
Hyperchloremic metabolic acidosis, metabolic sequelae of, 671
Hypercoagulable state, 41–43, 42*t*
anticoagulants for, 43*t*
evaluating the, 42–43
management of, 43
physiology of, 41–42
Hyperinsulinemia
cancer and, 178–179
urolithiasis and, 182
Hyperkalemia, in chronic kidney disease, 49
Hyperkalemic cardiac arrest, 65
Hyperkeratosis, 487
Hyperreactive airway, during general anesthesia, 64
Hypertension
in chronic kidney disease, 48
from extracorporeal shock wave lithotripsy, 303–304, 304*t*
obesity and, 62–63
Hyperthermia, malignant, 66
Hypertrophic cardiomyopathy (HCM)
interventions for, 26
postoperative management of, 27
Hypervolemia, in TUR syndrome, 48
Hypogastric artery, 121
Hypogastric vein injuries, 122
Hypomagnesemia, after urinary diversion, 57
Hyponatremia
in chronic kidney disease, 49–50, 50*t*
pediatric patient at risk for, 589
in TUR syndrome, 50*t*
Hypospadias, 555
DSDs with, 662
Hypospadias repair
bleeding and hematoma after, 650–651
in complex hypospadias, 656
complications of, 647–656
early, 650–651
late, 651–656
prevention of, 648–650
ischemia after, 650, 650*f*
meatal complications after, 653–654
operative technique for, 648–649, 649*f*
persistent chordee after, 654, 655*f*
postoperative care in, 649*f*, 650
preoperative evaluation for, 648
psychological consequences of, 655
timing of, 648
urethral diverticulum after, 653, 654*f*–655*f*
urethral stricture after, 652–653
urethrocutaneous fistula after, 651–652, 652*f*–653*f*
wound infection after, 651
wound separation after, 651
Hypothermia, 297
for pediatric patients, 585
perioperative, 65

Minor vascular injuries, during laparoscopy, 311–312
Mitomycin C, 232–233, 233*f*–234*f*
toxicity of, 232*t*
Mitral stenosis (MS), interventions for, 26
Mobility, after bladder exstrophy, 638–639
Mobilization, early, for pulmonary complications, 15
Monopolar electrosurgery, 313
Monopolar *versus* bipolar electrocautery, for transurethral resection of bladder tumors, 261
Morcellator injury, of bladder, 268–269
Morphine, for postoperative pain, 75
Mortality
of prostate biopsy complications, 215
in scrotal surgery, 571
MRI. *See* Magnetic resonance imaging.
MRI fusion biopsy, for salvage prostate ablation, 247–248
Multi-segment ureteral strictures, for ureteral injury, 163*f*, 167
Multidrug resistant (MDR), 90
Multiple vessels, in renal transplantation, 470
Mummy wrap, complications of, 639*f*
Muscle damage, from extracorporeal shock wave lithotripsy, 303
Musculocutaneous flaps, 661–662
Myelosuppression, from mitomycin C, 232–233
Myocardial infarction (MI)
acute, ECG manifestations of, 24, 25*f*
classification of, 24
management of, 25
postoperative, 23–24
Third Universal Definition of, 24
Myopathy, in malignant hyperthermia, 66

N

Na^+/K^+ ATPase, 55
Narcotics, for postoperative pain, 75
Nasogastric decompression
for ileus, 127
for radical cystectomy, 436
Nasogastric tube, for pulmonary complications, 15
National Nosocomial Infection Surveillance (NNIS) risk index, 103
National quality registries, for complications, 94
National Surgical Quality Improvement Program (NSQIP), 94
Nausea and vomiting
postoperative, 66–67
in pediatric patient, 588
propofol total intravenous anesthesia for, 67
vascular injuries and, 116
Necrosis
circumcision and, 585
penile, 73–74
Needle holders, vascular, 113–114
Neoadjuvant androgen deprivation therapy (NADT), cryoablation and, 248
Neobladder, orthotopic. *See also* Orthotopic neobladder.
bowel complications in, 508–509, 508*f*
complications of, 505–515
contraindications to, 506–507, 506*t*
fistulas in, 512–513, 512*f*–513*f*
patient selection for, 506–507
pelvic tumor recurrence with, 514–515
rupture of, 515
surgical complications in, 507–515
ureterointestinal anastomotic complications in, 509–511, 511*f*
urethral anastomotic complications in, 509
urethral tumor recurrence with, 514–515
urinary tract colonization and pyelonephritis after, 511–512
urolithiasis after, 511
voiding dysfunction after, 513–514, 514*f*
Neobladder-enteric fistula, 512, 513*f*
Neobladder-vaginal fistula, 512, 512*f*
Neonates, posterior urethral valves in, 613
Neoplasia, after urologic reconstruction, 667
Neostigmine
for colonic pseudo-obstruction, 437–438
for Ogilvie' s syndrome, 131
Neourethra, stricture of, 200
Neovaginal fistula, after male to female gender confirmation surgery, 200

Neovaginal prolapse, after male to female gender confirmation surgery, 201
Neovaginal stenosis, after male to female gender confirmation surgery, 199*f*, 200–201
Nephrectomy
  adrenal-sparing, 392
  cardiopulmonary considerations in, 385
  complications of, 349–361, 384–396
    bowel injury, 355
    chylous ascites, 355–356
    hepatobiliary injury, 355
    in kidney exposure, 353–356
    nerve injuries, 353
    pancreatic injury, 355
    in patient positioning, 352–353
    pleural injury, 355
    rhabdomyolysis, 353
    spleen injury, 355
    vascular injury, 354–355
  cytoreductive, 395
  donor, 360, 395–396
  in elderly, 396
  general medico-renal considerations of, 385
  hematoma after, 390
  hemorrhage during, 388–390
  incisions for
    anterior, 387*f*
    flank, 387, 387*f*
    lumbodorsal, 388
    thoracoabdominal, 387–388
  infection after, 392–393
  injury to nearby organs during, 390–392
    to adrenal glands, 392
    to colon, 392
    to diaphragm, 392
    to duodenum, 391
    to liver, 391–392, 391*f*
    to pancreas, 390–391
    to spleen, 390
    to stomach, 392
  intraoperative complications of, 388–392
  for locally recurrent disease, 395
  obesity and, 180–181
    technical considerations in, 180–181
  partial, 356–361
    bleeding, 356–358, 356*f*–358*f*
    complications of, 403–409
      bleeding as, 403–405, 404*f*–405*f*
      infarct as, 405, 406*f*
      positive margin as, 403, 403*f*–404*f*
      renal functions and, 408–409
      reoperation as, 409
      urine leak as, 405–408, 407*f*
    elective, 397–398
    general complications of, 400–403
    incisions for, 398, 400*f*–402*f*
    laparoscopic, 350–351, 398
    open, 401–403
    operative planning of, 351–352, 352*f*, 398–399, 399*f*–401*f*
    preoperative considerations for, 397–398
    procedural complications of, 352–356
    renal function, 359–360
    tumor and, 398
    urinary leak associated with, 148–151
      definition and diagnosis of, 148
      incidence and differential of, 148–149, 149*f*
      prevention of, 149–150
      risk factors of, 149
      symptoms of, 148
      treatment of, 150–151, 150*f*
    urine leak, 358–359
  patient preparation for, 385

Nephrectomy *(Continued)*
  preoperative considerations in, 350–352, 385
  preoperative embolization in, 388–389, 389*f*
  procedure-specific considerations, 356–361
  in renal tissue ablation, 237
  simple, 360–361
  site verification in, 385–386, 386*t*
  surgical approach to, 385–388
  total and partial, 601–602
  tumor thrombus and, 393–395, 393*f*–394*f*
  urologic considerations in, 385
  vessel dissection in, 389–390
Nephrocutaneous fistula, 293
Nephrolithiasis, 593–597
  general considerations for, 593–594
    ancillary procedures/anesthesia in, 594
    radiation in, 593–594
    residual fragments in, 594
  goals of therapy for, 593
  percutaneous nephrolithotomy for, 595–597
  ureteroscopy for, 594–595, 595*f*
    characteristics, outcomes, and complications of, 596*t*
Nephrolithotomy
  percutaneous, 593, 595–597
    complications after, 596*t*
    pulmonary complications of, 19
Nephrometry score, 398
Nephron-sparing techniques, 237
Nephropathy
  allograft, chronic, 477
  obstructive, pathophysiology of, 53–54
  salt-wasting, post-obstructive diuresis from, 54
Nephropexy, 464
Nephropleural fistula, after percutaneous nephrolithotomy, 19
Nephrostogram, of ureteral obstruction, 627, 628*f*
Nephrostomy
  for hydropneumothorax, 19
  percutaneous, for steinstrasse, 301
Nephrostomy tubes
  complications of, 223–225
    hemorrhage, hematuria/clot colic as, 223–224, 224*f*
    intraabdominal organs, injury to, 224
    pleural, 223, 223*f*
    prone positioning, 223
    tumor seeding as, 224–225
    urine leak/renal pelvic perforation as, 224
    UTI/sepsis as, 223
  indications for, 219
Nerve blocks
  for pediatric patient, 589
  peripheral, laparoscopy under, 78
  in urology, 71–74
Nerve injury
  in cryoablation, 243
  during laparoscopy, 309
  positioning-related, 67, 106–111
    femoral, 108–109, 109*f*
    from lithotomy position, 109–110, 110*f*
    lower extremity, 108
    robotic surgery, 110–111
    upper extremity, 106–108, 107*f*
  in radical cystectomy, 441–442
  during robot-assisted radical prostatectomy, 334
Nerve palsy, partial femoral, osteotomy complications, after bladder exstrophy, 639–640

Neuralgia, after inguinal surgery, 587
Neuraxial anesthesia, 68
Neurocognitive development, anesthesia and, 585
Neuromuscular injury, after stress urinary incontinence surgery, 532
Neuropathies
  nephrectomy, patient positioning, complications related to, 353
  in RFA, 241
Neuropraxia, after lithotomy positioning, 551
Neuropraxic injury, nephrectomy, patient positioning, complications related to, 353
Neurovascular bundle, in radical retropubic prostatectomy, 452
Nitrofurantoin, pregnancy and, 189
Nitrofurantoin suspension, for vesicoureteral reflux, 624
Nitrous oxide, in laparoscopy, 77–78
No-scalpel vasectomy, 570
Noncontinent vesicostomy, urinary diversions of infancy and childhood, 666
Noncontrast CT (NCCT), before ureteroscopic surgery, 276
Nonpalpable testes
  diagnostic laparoscopy in, 605
  laparoscopic orchiopexy in, 606
NonST segment acute coronary syndrome (NSTE-ACS), 24–25
Nonsteroidal antiinflammatory drugs (NSAIDs)
  for inflammatory toxicity, from bacille Calmette-Guérin, 228
  for postoperative pain, 75
Nonsurgical dilation, 660
Normal clotting cascade, 33*f*
Nosocomial pneumonia, 16
Nutrition, preoperative management of, 7–8
Nutritional Risk Classification, or Nutritional Risk Screening 2002, 203
Nutritional status, optimization of, 203
Nutritional status assessment, 7, 8*t*

O

Obesity, 3–6, 62–63
  benign prostatic hyperplasia and, 6
  bladder cancer and, 5–6, 181
  central, 4
  in children, 583
  comorbidities associated with, 62–63
  cystectomy and, 5–6
  difficult airway and, 63

  impact of, on urologic conditions, 182*t*
  kidney cancer and, 5, 180–181
  in laparoscopy, 309
  lower urinary tract symptoms and, 6, 181
  malignant urologic disease and, 178–179
  nephrectomy and, 180–181
  partial nephrectomy and, 180–181
  peripheral, 4
  physiologic changes of, 62
  preoperative considerations for, 63
  prevalence of, 178, 179*f*
  prostate cancer and, 4–5
  radical prostatectomy and prostate cancer and, 179–180
  strategies for anesthesia and pain management in, 63
  stress urinary incontinence and, 6
  urolithiasis and, 6, 182
  urologic cancer and, 4
  urologic surgery in, 178–182
    condition-specific considerations for, 178–182

Obstruction
inadequate relief of, in ureteral stent, 222
in male slings, 543, 544*f*
Obstructive sleep apnea (OSA), 62–63
obese patients with preoperative diagnosis of, 63
obesity and, 62
postoperative management for, 17
postoperative pain management of, 76
preoperative considerations for, 63
strategies for anesthesia and pain management in, 63
Obturator nerve injury, after robot-assisted radical prostatectomy, 336
Obturator nerve injury, in radical cystectomy, 441
Obturator reflex, 74
Ofloxacin, with bacille Calmette-Guérin, 228
Ogilvie's syndrome, 131
Oliguria, after robot-assisted radical prostatectomy, 334–335
Omega flap, in vaginoplasty, 659
Open radical cystectomy (ORC), complication rates for, 371
Open surgical procedures, complications of, 551–555
excision and primary anastomosis for posterior disruptions and, 552–553, 552*f*
excision and primary anastomosis for proximal anterior strictures and, 553
flap reconstruction and, 554, 554*f*–555*f*
graft harvest and, 553
graft reconstruction and, 554–555
patient positioning and, 551
suprapubic tube placement and, 551
tissue transfer reconstruction and, 553–554
Open urologic surgery, pulmonary complications of, 19
Operative planning, for robotic upper urinary tract reconstruction, 362–363
Opioids. *See* Narcotics.
Oral aminocaproic acid, after transurethral resection of bladder tumors, 262
Oral anticoagulants, 40*t*
ORC. *See* Open radical cystectomy.
Orchidopexy, for pediatric patient, 586–587
failure of, 586–587
Orchiectomy
postoperative hematoma in, 569
radical, partial, and simple, 578–579
Orchiopexy, laparoscopic, in children, 606–607, 606*t*
Orgasm, change in, after radical retropubic prostatectomy, 455
Orthotopic neobladder
bowel complications in, 508–509, 508*f*
complications of, 505–515
contraindications to, 506–507, 506*t*
fistulas in, 512–513, 512*f*–513*f*
patient selection for, 506–507
pelvic tumor recurrence with, 514–515
rupture of, 515
surgical complications in, 507–515
ureterointestinal anastomotic complications in, 509–511, 511*f*
urethral anastomotic complications in, 509
urethral tumor recurrence with, 514–515
urinary tract colonization and pyelonephritis after, 511–512
urolithiasis after, 511
voiding dysfunction after, 513–514, 514*f*
Osseus complications, of male slings, 544, 544*f*
Osteoporosis, hyperchloremic metabolic acidosis-induced, 672
Osteotomy complications, after bladder exstrophy, 639–640
Overvirilization, 657–659
Oxidized regenerated cellulose, as hemostatic agents, 115*t*
Oxygenation, hyperbaric, for radiation-induced stricture surgery, 203

Robot-assisted radical prostatectomy *(Continued)*
    late postoperative, 337–338
    in positioning, 328–329
  extraperitoneal approach, 329
  impotence after, 338
  incontinence after, 337–338
  lymphocele after, 336
  nerve injury during, 334
  port site hernia after, 337
  preoperative considerations in, 327–331
  thromboembolic complications after, 337
  transperitoneal approach, 329
  ureteral injury during, 334, 334*f*
  urethral-vesical anastomotic leak after, 335
  urinary tract infection after, 336
  visceral injury during, 332–334, 333*f*
  wound infection after, 336–337
Robot-assisted renal surgery, 350
Robot-assisted surgery
  patient positioning in, 320–323, 320*f*–321*f*
  patient preparation for, 319
  patient selection for, 319
  pneumoperitoneum, effects of, 323
  special considerations in, 319–325
  system failure in, 324–325
  team approach in, 320
  team communication in, 323–324
Robotic-assisted laparoscopic pyeloplasty, 601
Robotic-assisted laparoscopic ureteral reimplantation (RALUR), 603, 603*t*
Robotic-assisted laparoscopic ureteroureterostomy (RALUU), 604
Robotic-assisted surgical techniques, obesity and, 180
Robotic cystectomy
  anastomotic leak after, 382
  complications of, 370–382
    factors associated with, 372–373
    intraoperative, 374–380
    postoperative, and management, 380–382
    review of perioperative and postoperative, 371–373
  developing space of Retzius and prostate dissection, 377
  enterocutaneous fistula after, 382
  ileus after, 382
  issues unique to female, 378, 379*f*
  lymphocele after, 381
  open, radical cystectomy *versus*, 371–372
  operative equipment and setup of, 373–374
  patient selection of, 373
  perioperative pathways of, 373
  perioperative preparation of, 373–374
  posterior dissection and pedicles of, 376–377, 376*f*
  safety checklist, 375*t*
  ureteral dissection after, 374–376
  venous thromboembolism after, 380–381
  wound infection/fascial dehiscence after, 381
Robotic pelvic floor reconstruction
  complications of, 339–348
  intraoperative complications of, 343–346, 343*b*
    bowel, 343
    hemorrhagic, 343–344, 345*f*
    urological, 344–346
    vaginal, 346
  patient positioning for, 341–343
  postoperative complications of, 346–348, 346*b*
    bowel, 347
    de novo incontinence in, 348
    infectious, 346–347
Robotic pelvic floor reconstruction *(Continued)*
    related to synthetic mesh, 347–348
    thromboembolic, 347
  preoperative considerations in, 340–341, 340*t*
  surgical set up for, 341–343
Robotic radical cystectomy, 443–444
Robotic surgeries
  bleeding in, 118
  injuries related to positioning for, 110–111
  pediatric, complications of, 598–608
Robotic system failure, 324–325
Robotic upper urinary tract reconstruction, 362–369
Root cause analysis (RCA), for quality improvement strategies, 96, 96*f*
Ropivacaine, toxic doses of, 70

S

Sacral neuromodulation
  complications of, 534, 534*t*
  for urge urinary incontinence, 525–526
Sacral promontory vascular anatomy, 345*f*
Safety wire, in ureteroscopic surgery, 278, 278*f*
Salicylates, 39*t*
Saline
  for hyponatremia in TUR syndrome, 50
  as irrigant, 257
  for irrigation, in ureteroscopic surgery, 279
  for post-obstructive diuresis, 55
Salt-wasting nephropathy, post-obstructive diuresis from, 55
Salvage prostate ablation, 247–248
  imaging and other tests for staging in, 248
Salvage prostatectomy, 455–456
Scar formation, from sperm extraction, 575
Sciatic nerve
  common positioning nerve injuries, 310*t*
  positioning-related injury to, 109
Scleral edema, nephrectomy, patient positioning, complications related to, 353
Sclerotherapy, for hydrocele, 577
Scope, damage and durability of, in ureteroscopic surgery, 282–283
Scrotal arteries, 568
Scrotal dressings, 569, 569*f*
Scrotal injuries, nephrectomy, patient positioning, complications related to, 353
Scrotal skin, for urethral reconstruction, 554, 555*f*
Scrotal surgery, complications of, 567–579
  anatomy for, 567–568
  common, 569
  general considerations in, 568–569, 568*t*
Scrotal varicocele, adolescent, 607
Scrotal vein, 568
Scrotum
  anatomy of, 567–568
  blood supply to, 568
Secondary augmentations, need for, 670
Selective factor Xa inhibitors, 39*t*
Sensorium, altered, after urinary diversion, 57
Sensory blockade, 68
Sepsis, 89–90, 89*t*. *See also* Infection.
  after extracorporeal shock wave lithotripsy, 301–302
  bacille Calmette-Guérin and, 228
  in nephrostomy tubes, 223
  in ureteral stents, 220
  ureteroscopic surgery and, 283–284
Septic shock, 89*t*
Serapin, 41–42
Seroma, 100–101, 100*f*

Sex development, disorders of
classification of, 658*t*
complications of surgery for, 657–664
of overvirilization, 657–659
of undervirilization and gonadal abnormalities, 662–663
vaginal agenesis and vaginoplasty and, 659–662, 660*f*
Sex hormones, obesity and, 179
Sexual dysfunction, after stress urinary incontinence surgery, 533
Shivering, perioperative, 65
Shock-wave lithotripsy, for urologic procedures, 84*t*
ShockPulse lithotripter, 595–597
Shoulder pain, postoperative, 81
Shunts
infection of, after bladder augmentation, 517–518
vesicoamniotic, for posterior urethral valves, 610
Sickle cell anemia, in children, 583
Sigmoid vaginoplasty, 662
Sildenafil, after radical retropubic prostatectomy, 453
Simple cystourethroscopy, for urologic procedures, 84*t*
Simple nephrectomy, 360–361
Simple orchiectomy, 578–579
procedure of, 579
"Single J" stents, 219
Skin, separation, in radical cystectomy, 439
Sleep apnea, in radical retropubic prostatectomy, 446
Sling incision, for bladder outlet obstruction, 530, 530*f*
Small bowel obstruction
after urologic reconstruction, 670
in radical cystectomy, 437
Small intestine
damage of, in radiofrequency ablation, 241
injury to, in cryoablation, 243
Smead-Jones closure, 106
Sodium, absorption of, after urinary diversion, 55
Solute transport, after urinary diversion, 55
Sonographic techniques, fetal, in posterior urethral valves, 610
Sorbitol, in irrigating solution, 257–258
Space of Marseille, 377, 378*f*
Sperm extraction procedures, 574–575
complications after, 575
techniques in, 574–575, 574*f*
Sperm granulomas, 571
Spermatic cord block, 568–569
Spermatocele, 577–578, 578*f*
recurrence of, 578
Spermatocelectomy, 577–578
complications after, 578
procedure techniques, 578, 578*f*
Spina bifida, latex use and, 584
Spinal anesthesia
combined with epidural anesthesia, 69–70
complications during, 68–69
laparoscopy under, 78
Spinal cord injury, autonomic hyperreflexia with, 65
Spinal hematoma, 70–71
Spirometry, for pulmonary complications, 15
Splanchnic blood flow, during laparoscopy, 77
Spleen injury
from extracorporeal shock wave lithotripsy, 303
kidney exposure, complications related to, 355
during nephrectomy, 390
Split-thickness skin grafts (STSG), in vaginoplasty, 660
Spontaneous bladder perforations, 667–668
Staphylococcus aureus, 88
Statin therapy, perioperative, 30
Statistical process control (SPC), for quality improvement strategies, 95–96, 96*f*
Steinstrasse, after extracorporeal shock wave lithotripsy, 301, 301*f*
Stenosis, in vascular injuries, 120
Stensen's duct, injury to, graft harvest and, 553, 553*f*
Stent
ureteral
antegrade
complications of, 225
indications for, 219
complications of, 219–223
migration as, 221, 221*f*
periureteral fluid collection in, 220–221, 220*f*
symptoms of, 219–220
urinary tract infection/sepsis as, 220
wire-related, 221
hydronephrosis in, 222
in minimally invasive pyeloplasty, 363
obstruction of, 366
morbidity in, 219–220
retrograde, indications for, 219
in ureteral fistula, 143
for ureteral strictures, 501
urethral, complications of, 550–551
urinary diversion, 489
Stoma
for conduit urinary diversion
complications of, 483–488, 484*f*
maturation of, 487, 487*f*–489*f*
parastomal hernia or prolapse, 484–485, 485*f*
reconstruction of, 487–488, 489*f*–490*f*
site of, 480–482, 481*f*
stenosis of, 486–488, 486*f*–487*f*
for continent cutaneous diversion
hernia of, 503–504
stenosis in, 501–502
Stomach
injury to, during nephrectomy, 392
for urinary diversion, 55–56, 56*t*
Stomal varices, in conduit urinary diversion, 493
Stone retrieval basket, failure of, in ureteroscopic surgery, 282
Stones
after bladder augmentation, 519–520, 519*f*
after bladder neck repair, 645
in ileal conduits, 482–483
pouch, in continent cutaneous diversion, 499–500, 499*f*–500*f*
Stress urinary incontinence (SUI), 523–524, 536
after endoscopic BPH procedures, 271
obesity and, 6
surgery for, 524–525
bladder injury during, 528–529
bleeding during, 527–533, 528*f*
cystoscopy in, 529
neuromuscular injury after, 532
pain after, 532–533
postoperative complications of, 529–533
sexual dysfunction after, 533
ureteral injury during, 529
urethral injury during, 528
urinary tract erosion after, 531, 532*f*
urinary tract injury during, 528–529
vaginal exposure after, 531, 531*f*
voiding dysfunction and urinary retention after, 529–531, 530*f*
Stricture
in minimally invasive pyeloplasty, 366
in minimally invasive ureteral reimplantation, 367
Stridor, postoperative, in pediatric patient, 588
Subarachnoid injection, inadvertent, 69
Subcutaneous emphysema
during laparoscopy, 80
in pediatric laparoscopy, 599
during robot-assisted radical prostatectomy, 329–330
Sulfamethoxazole-trimethoprim, for vesicoureteral reflux, 624
Superficial dorsal penile vein thrombosis, after varicocelectomy, 573–574
Superior mesenteric artery injury, 121
during laparoscopy, 313
Supersonic transporter deformity, in penile prosthesis surgery, 561–562
Supracostal percutaneous nephrolithotomy, 19
Suprapubic tube (SPT)
after endoscopic BPH procedures, 272
placement, complications in, 551
for urethral stricture, 197
Supraventricular tachycardias (SVT), 27, 29*f*
Surgeon, in vascular complications, 115–116
Surgery, robot-assisted
patient positioning in, 320–323, 320*f*–321*f*
patient preparation for, 319
patient selection for, 319
pneumoperitoneum, effects of, 323
special considerations in, 319–325
system failure in, 324–325
team approach in, 320
team communication in, 323–324
Surgical antimicrobial prophylaxis, in infectious complications of urologic surgery, 83
Surgical Care Improvement Project (SCIP), 85
Surgical-site infection, 82–83, 86–87, 101–104. *See also* Infection, surgical-site.
antimicrobial prophylaxis against, 103–104
definition of, 101–102, 102*f*
diagnosis and management of, 104
microbiology of, 103, 103*t*
in pediatric patient, 588
prevention of, 103–104
risk stratification for, 102–103, 102*t*
Suture selection and technique, wound dehiscence and, 105–106
Suturing, in laparoscopic pyeloplasty, 363
Sympathetic block, 68
Syndrome of inappropriate secretion antidiuretic hormone (SIADH), 50–51

T

Tachycardia, postoperative, 27
Tampon
in ureteral fistula, 143
in vesicovaginal fistula, 134–135
Tamsulosin, for stent morbidity, 220
Teflon graft, 119
Tension pneumothorax, after laparoscopy, 80
Terbutaline, intraoperative penile erection, 74
Testicle, surgical complications of, 567–579
Testicular artery, 568
injury/ligation, 571
Testicular atrophy, 587
after partial orchiectomy, 579
after varicocelectomy, 573
from vasectomy reversal, 576
from vasoepididymostomy, 576
Testicular biopsy, 663
Testicular cancer, orchidopexy and, 586–587

Testicular injuries, nephrectomy, patient positioning, complications related to, 353
Testicular retraction, 586–587
Testicular surgery, in children, 605–608
  diagnostic laparoscopy in, 605–606
  laparoscopic
    inguinal hernia repair in, 607–608
    orchiopexy in, 606–607, 606*t*
    varicocelectomy in, 607, 607*t*
Testicular trauma, 175–176, 176*f*
Testicular volume, decreased, from Micro-TESE, 575
Testis, nonpalpable, 605–606
The International Robotic Cystectomy Consortium (IRCC), 373
Thermal ablation, 237
Thermal damage, after prostate tissue ablation, 249
Thienopyridines, 39*t*
Thiotepa, 234
  toxicity of, 234*t*
Third Universal Definition, of myocardial infarction, 24
Thoracic segmental artery injuries, 121
Thrombectomy, vena cava, 394*f*
Thrombin, as hemostatic agents, 115*t*
Thrombin inhibitors, perioperative, 31
Thrombocytopenia, 35
Thrombocytosis, 35
Thromboembolic events, prevention of, in ureteroscopic surgery, 277
Thromboembolism, venous. *See* Venous thromboembolism.
Thrombolytic therapy, for pulmonary embolism, 18
Thrombomodulins, 41–42
Thrombosis
  deep vein, 475–476. *See also* Venous thrombosis.
  with hypercoagulable state, 41
  renal artery, transplant, 475
  renal vein, 475
  in vascular injuries, 119–120
Thrombus, inferior vena cava tumor, 122–125, 123*f*–124*f*
Thunderbeat device, 315
Ticlid. *See* Ticlopidine.
Ticlopidine, 39*t*
Time-sensitive procedure, timing and risk of, 22, 22*t*
Tinzaparin, 39*t*
Tirofiban, 39*t*
Tissue adhesive, in open partial nephrectomy, 407
Tissue slough, after cryoablation, 251–252
  etiology and pathogenesis of, 251–252
  incidence of, 251
  management of, 252
Tissue transfer reconstruction, open surgical procedures and, 553–554
TMP-SMX, 85
Tobacco use, wound healing and, 203
Total intravenous anesthesia (TIVA), 61
Total nephrectomy, in children, 601–602
Total urogenital sinus mobilization (TUM), 659
Tramadol, for postoperative pain, 75
Tranexamic acid, hemostatic agents, 115*t*
Transabdominal approach, to rectourethral fistula, 208
Transanal approach, to rectourethral fistula, 207–208
Transcatheter aortic valve replacement (TAVR), indications for, 26
Transection injuries, 116
Transfusion, complications of, 34*t*
Transient ischemic attack, ureteroscopic surgery and, 284
Transient neurologic syndrome, 68–69
Transient voiding dysfunction, 626
Transitional cell carcinoma, nephrectomy for, 396
Transobturator sling, 537–538
Transperineal approach, to rectourethral fistula, 208
Transperineal biopsy, 215
Transplantation, renal, complications of, 469–477. *See also* Renal transplantation.
Transrectal prostate biopsy, for urologic procedures, 84*t*
Transrectal ultrasound guided biopsies (TRUS-bx), 212
Transrectal ultrasound (TRUS), for cryosurgical ablation, 248
Transsphincteric approach, to rectourethral fistula, 207
Transureteroureterostomy (TUU), 465
  minimally invasive, postoperative complications of, 368
Transurethral resection of bladder tumors (TURBT), 256–264
  anesthesia for, 258–259
  cautery artifact in, reducing, 261
  complications of, 261–264
    infection as, 263
    instrument introduction as, problems of, 261–262
    intravesical chemotherapy after, 264
    morbidity and mortality as, overall, 261
    postoperative bleeding as, 262
    trainee participation on, effect of, 264
    TUR syndrome as, 263
    urinary retention as, 263–264
  general considerations in, 257
  irrigating solution in, 257–258
  laser for, 261
  for muscle invasive bladder cancer, radical, 261
  obturator reflex during, 74
  patient positioning in, 258–259, 259*t*
  patient preparation for, 258
  preoperative evaluation before, 258
  resection in, 259, 259*f*, 260*t*
  restaging, 260–261
  surgical approach to, 259–261
  surgical instrumentation for, 257, 257*t*
Transurethral resection prostate (TURP)
  biopsy, 213
  TUR syndrome as. *See* Transurethral resection (TUR) syndrome.
Transurethral resection (TUR) syndrome, 51–53, 267–268
  after transurethral resection of bladder tumors, 263
  etiology of, 51
  evaluation of, 51, 51*b*
  management of, 51
  mechanism of, 51–52
  presentation of, 51–53
  risk factors for, 52, 52*b*
  symptoms of, 53*t*
Transvaginal mesh exposure, for stress urinary incontinence, 525
Trauma, urologic, during delivery, 194
Traumatic injuries, complications related to, management of, 169–176
  bladder, 170–171
  external genitalia, 174–176
    penile amputations and, 174–175, 175*f*
    penile fractures and, 174, 175*f*
    testicular trauma and, 175–176, 176*f*
Traumatic injuries, complications related to, management of *(Continued)*
  renal, 169–170
  ureteral, 170, 171*f*
  urethral, 171–174
    anterior, 172–174, 172*f*, 174*f*
    posterior, 171–172, 172*f*
Trimethoprim/sulfamethoxazole (TMP-SMX), pregnancy and, 190
Trocar injury, in robot-assisted radical prostatectomy, 329
Trocar placement, 312*b*
True vaginal agenesis, 660
Tube dislodgment, 223
Tubeless percutaneous renal surgery, 288
Tumor seeding, 292–293
  in nephrostomy tubes, 224–225
Tumor thrombus, nephrectomy and, 393–395, 393*f*–394*f*
Tumor(s)
  bladder. *See* Bladder tumors.
  carcinoid, in ileal conduits, 483
  inferior vena cava, thrombus, 122–125, 123*f*–124*f*
  recurrence of, with orthotopic neobladder
    pelvic, 514–515
    urethral, 514–515
  urologic, during pregnancy, 190–191

during radical retropubic prostatectomy, 450
repair, timing of, 162
during robot-assisted radical prostatectomy, 334, 334*f*
during robotic pelvic floor reconstruction, 344–346
strategies for, management of, 162–168, 163*f*
distal ureteral repair for, 163*f*, 167
endoscopic repair for, 163–164, 163*f*
long-length ureteral repair for, 163*f*, 167
mid-ureteral repair for, 163*f*, 165–167, 166*f*–167*f*
Ureteral injury *(Continued)*
multi-segment ureteral stricture for, 163*f*, 167
proximal ureteral repair for, 163*f*, 164–165, 165*f*
during stress urinary incontinence surgery, 529
Ureteral obstruction
after renal transplantation, 471–472, 472*f*
after ureteral reimplantation, 627–628, 627*f*–628*f*
bilateral mid, from vascular grafts, 159–160, 161*f*
in radical cystectomy, 438
Ureteral orifices
injury to, 268–269
tumor involving, 260
Ureteral reconstruction
minimally invasive, 363–364
urinary leak in, 157
Ureteral reconstructive surgery
complications of, 458–468
diagnosis in, 460–461
postoperative stenting and drainage, 467–468
preoperative planning in, 460–461, 460*f*
surgical anatomy in, 459, 459*f*
surgical considerations in, 461, 461*f*
surgical management in, 461–468
tenets of, 461*b*
ureteral stricture after, 468
urine leakage after, 468
Ureteral reimplantation
complications of, 625–630
early, 625–626
identification of, 625
late, 627–628
postoperative evaluation of, 625
contralateral reflux after, 628–629
failed management of, 629–630
infections after, 626
low urine output after, 625–626, 625*f*–626*f*
minimally invasive, postoperative complications of, 367
postoperative reflux after, 628–629
reflux after, 629*f*
technical considerations in, 625
ureteral obstruction after, 627–628, 627*f*–628*f*
ureterocele associated with, 633
voiding dysfunction after, 626
Ureteral stents
antegrade
complications of, 225
indications of, 219
complications of, 219–223
migration as, 221, 221*f*
periureteral fluid collection in, 220–221, 220*f*
symptoms of, 219–220
urinary tract infection/sepsis as, 220
wire-related, 221
encrustation, 222
erosion, 221–222
fragmentation, 222
hydronephrosis in, 222
metal, 222–223
in minimally invasive pyeloplasty, 363
obstruction of, 366
morbidity in, 219–220
retained, 222
retrograde, indications for, 219
in ureteroscopic surgery, 279, 279*f*, 284
retained and encrusted, 285
Ureteral stones, ureteroscopic surgery for, 276
Ureteral stricture
after ureteral reconstructive surgery, 468
detection of, 284–285
distal, balloon dilation of, 163*f*, 164
endoscopic management of, 285
high mid, Boari flap pyelovesicostomy for, 165
multi-segment, 167
short segment, endoscopic repair for, 163
ureteroscopic surgery and, 284–285
in ureteroscopy, 595
Ureteral stricture obstruction, diagnosis of, 245
Ureteral surgery, lower, in children, 602–605
appendicovesicostomy in, 605
augmentation cystoplasty in, 605
ureteroneocystostomy in, 602–604, 603*t*
ureteroureterostomy in, 604–605
Ureteral trauma, 170, 171*f*
Ureteral tumors, during pregnancy, 191
Ureteroarterial fistulae (UAF), 142
Ureterocalicostomy, minimally invasive, postoperative complications of, 368
Ureterocele
puncture of, 591–592
repair, surgical complications of, 632–633
ureteral reimplantation associated with, 633
Ureterocystoplasty, bladder augmentation and, 673
Ureteroenteric anastomotic stricture, 466–467
Ureteroenteric fistula, 142
Ureteroenteric stricture, 510, 511*f*
Ureteroileal stenosis, in continent cutaneous diversion, 500–501, 501*f*
Ureterointestinal anastomosis, in conduit urinary diversion
complications of, 488–492
refluxing *versus* nonrefluxing, 492–493
Ureterointestinal anastomotic complications, in orthotopic neobladder diversion, 509–511, 511*f*
Ureterolysis, 467
minimally invasive
intraoperative complications of, 364
postoperative complications of, 366–367
Ureteroneocystostomy, 462, 602–604
Ureteropelvic junction obstruction (UPJO), 587
diagnosis of, 245
fibroepithelial polyps causing, 160, 161*f*
Ureteroplasty, buccal mucosa graft for, 464–465
Ureteroscope, entry of, in ureteroscopic surgery, 278–279, 279*f*
Ureteroscopic surgery
complications of, 275–285
cardiopulmonary, 284
early postoperative, 283–284, 283*t*
infectious, 283–284
intraoperative, 279–283, 279*t*, 280*f*
late postoperative, 284–285, 284*t*
contraindications to, 276
cystoscopy and initial upper urinary tract access in, 277
endoscopy in, 279*f*
entry of the ureteroscope in, 278–279, 279*f*
instrument failure in, 282–283
maintaining access in, 277–278
negotiating the obstruction in, 277, 278*f*
patient positioning in, 277
patient selection for, 276
perioperative preparation for, 277
preoperative assessment for, 276
preparation for, 276–277
technique for, 277–279

Ureteroscopy (URS), 193
  for nephrolithiasis, 593–595, 595*f*
    characteristics, outcomes, and complications of, 596*t*
    radiation exposure in, 593–594
  for urologic procedures, 84*t*
Ureterostomy
  cutaneous, for posterior urethral valves, 615, 616*f*–617*f*
  urinary diversions of infancy and childhood, 666
Ureteroureterostomy, 461–462, 462*f*, 604–605
  minimally invasive, 363–364, 367–368
  for ureteral injury, 165, 166*f*
Ureterovaginal fistulae, 142–143
Ureterovesical fistula, after ureteral reimplantation, 628
Ureterovesical junction (UVJ), 625
Ureters
  assessment of, in posterior urethral valves, 610
  duplex, in conduit urinary diversion, 493
Urethra
  anatomy of, 196, 196*f*
  anterior, ischemic stenosis of, 552
  neophallus, meatal stenosis of, 199, 199*f*
Urethral anastomotic complications, in orthotopic neobladder diversion, 509
Urethral atrophy, in artificial urinary sphincter, 542
Urethral bulking agents, in stress urinary incontinence surgery, 533
Urethral carcinomas, during pregnancy, 191
Urethral contrast imaging, complications of, 548
Urethral dilation, complications of, 549
Urethral diverticulum, after hypospadias repair, 653, 654*f*–655*f*
Urethral injuries
  from artificial urinary sphincter, 539
  posterior, complications of endoscopic treatment for, 550
  during stress urinary incontinence surgery, 528
Urethral outlet obstruction, complication of primary bladder exstrophy, 635, 637*f*
Urethral perforation, from urethral dilation, 549
Urethral ratio, in posterior urethral valves, 614, 614*f*
Urethral reconstruction, complications of, 546–555
Urethral stents, complications of, 550–551
Urethral stricture
  after cryosurgical ablation, 253
    etiology and pathogenesis of, 253
    incidence of, 253
    management of, 253
  after endoscopic BPH procedures, 271–272, 272*f*
  after epispadias repair, 643
  after female to male gender confirmation surgery, 196–198, 198*f*
  after hypospadias repair, 652–653
  after pelvic radiation therapy, 204–205, 205*f*
Urethral stricture disease
  complications of, 546–548, 547*f*
    balanitis xerotica obliterans as, 547–548, 547*f*
  diagnostic procedures for, complications of, 548–549, 548*f*–549*f*
  from primary realignment, 550
Urethral trauma, 171–174
  anterior, 172–174, 172*f*, 174*f*
  posterior, 171–172, 172*f*
Urethral tumor recurrence, with orthotopic neobladder diversion, 514–515
Urethral valves, posterior, 609–622. *See also* Posterior urethral valve.
Urethral-vesical anastomotic leak, after robot-assisted radical prostatectomy, 335
Urethrocutaneous fistula
  after epispadias repair, 642
  after female to male gender confirmation surgery, 196–198, 197*f*
  after hypospadias repair, 651–652, 652*f*–653*f*
  circumcision and, 585
Urethrography, retrograde, complications of, 548
Urethrolysis, for bladder outlet obstruction, 530
Urethroplasty, 550
  for epispadias in bladder exstrophy, 642
  for hypospadias repair, 649, 649*f*
  in irradiated pelvis, 205
  for urethral stricture, 197–198, 198*f*
  urinary incontinence after, 205
Urethroscopy, complications of, 548
Urethrostomy, for urethral stricture, 198
Urethrotomy, internal, complications of, 549–550
Urethrovaginal fistula, 133*f*, 139–141
  causes of, 140*t*
  diagnosis of, 140
  etiology of, 139–140
  management of, 140–141
  presentation of, 140
Urge urinary incontinence (UUI), 524
  after endoscopic BPH procedures, 271
  surgery for, 525–526
Urgent procedure, timing and risk of, 22, 22*t*
Urinalysis, for pediatric patients, 582
Urinary conduits
  preservation of renal function following, 668–669
  stomal revision of, 670–671
Urinary diversion
  complications of, 433–444
  conduit, 478–493. *See also* Conduit urinary diversion.
  congenital, goals of, 666
  continent cutaneous, 495. *See also* Continent cutaneous diversion.
  medical complications following, 671–673
  metabolic complications of, 55–57
  pediatric, complications of, 665–673
  pregnancy following, 673
  robotic cystectomy with, 378–380, 379*f*
  suprapubic, 207
  urinary leak following, 154–155
    definition and diagnosis of, 154
    incidence and differential of, 155
    management of, 155–157, 156*f*
    prevention of, 155
    risk factors of, 155
    symptoms of, 154–155
Urinary extravasation, in renal transplantation, 471, 471*f*
Urinary fistula. *See also specific types*.
  after extracorporeal shock wave lithotripsy, 303
  after stress urinary incontinence surgery, 533
  as bowel complications, 127*t*
  intestinal, 144–146, 145*f*
  management of, 132–146, 133*f*
  ureteral, 141–144, 142*b*, 144*f*
  urethrovaginal, 139–141, 140*t*
  vesicovaginal, 133–139, 133*f*, 135*b*–136*b*, 135*f*, 136*t*, 137*f*–138*f*. *See also* Vesicovaginal fistula.
Urinary free cortisol (UFC) level, for Cushing's syndrome, 412
Urinary incontinence, 523. *See also* Incontinence.
  after endoscopic BPH procedures, 271, 271*f*
  after urethroplasty, 205
  in posterior urethral valve, 592
Urinary leak
  after radical retropubic prostatectomy, 450–451
  associated with partial nephrectomy, 148–151
    definition and diagnosis of, 148
    incidence and differential of, 148–149, 149*f*
    prevention of, 149–150
    risk factors of, 149
    symptoms of, 148
    treatment of, 150–151, 150*f*
  associated with radical prostatectomy, 151–154
    definition and diagnosis of, 151–152
    incidence and differential of, 152
    prevention of, 152–153
    risk factors of, 152
    symptoms of, 152
    treatment of, 153–154, 153*f*
  categories of, 147–148
  following miscellaneous procedures, 157–158
    in pyeloplasty, 157–158
    in ureteral reconstruction, 157
  following urinary diversions and bladder reconstruction, 154–155
    definition and diagnosis of, 154
    incidence and differential of, 155
    management of, 155–157, 156*f*
    prevention of, 155
    risk factors of, 155
    symptoms of, 154–155
  intraperitoneal, 148
  management of, 147–158
  in minimally invasive pyeloplasty, 365–366
  in minimally invasive ureteral reimplantation, 367
  from pyeloplasty, 587–588
Urinary obstruction
  correction of, post-obstructive diuresis after, 53
  presentation of, 54
Urinary reconstruction, goals of, 666
Urinary reservoirs, continent, 667
Urinary retention
  acute, 214
  after artificial urinary sphincter
    as delayed and long-term complications, 542, 543*f*
    as early postoperative complications, 540
  after cryoablation, 251
    etiology and pathogenesis of, 251
    incidence of, 251
    management of, 251
  after male slings, 541
  after stress urinary incontinence surgery, 529–531
  after transurethral resection of bladder tumors, 263–264
  after ureteral reimplantation, 626
  as prostate biopsy complications, 213*t*
Urinary sphincter, artificial, for female stress urinary incontinence, 525
Urinary tract
  colonization of, after orthotopic neobladder diversion, 511–512
  decompression of, for posterior urethral valves, 615

Urinary tract *(Continued)*
diversion, for posterior urethral valves, 615, 616*f*–617*f*
erosion of, after stress urinary incontinence surgery, 531, 532*f*
injury to, during stress urinary incontinence, 528–529
lower, symptoms of, associated with obesity and, 6
obstruction of, urinary tract infection risk and, 9
surgical decompression of, 219
upper, carcinoma in, nephrectomy for, 396
Urinary tract infection (UTI), 8–9
after bladder augmentation, 518–519
after continent cutaneous diversion, 497
after endoscopic BPH procedures, 270
after robot-assisted radical prostatectomy, 336
after ureteral reimplantation, 624
complicated, 8–9
in infectious complications of urologic surgery, 82–83
during pregnancy, 188–190
epidemiology and risk factors of, 188
implications of, 188, 188*t*
management of, 189–190, 189*t*
from pyeloplasty, 587
radical retropubic prostatectomy after, 451
in ureteral stents, 220
Urinary tract injury
as complication of ablation
in cryoablation, 243
managing, 245
in microwave ablation, 243
with RFA, 240–241, 241*f*
during robotic pelvic floor reconstruction, 344
Urinary tract reconstruction, robotic upper, 362–369
intraoperative complications of, 363
minimally invasive
Boari flap in, 368
buccal mucosal graft ureteroplasty in, 364, 368
ileal ureter in, 368
pyeloplasty in, 363, 365–366, 365*t*
renal autotransplantation in, 364–365
transureteroureterostomy in, 368–369
ureteral reconstruction and, 363–364
ureteral reimplantation in, 367
ureterocalicostomy in, 368
ureterolysis in, 364, 366–367
ureteroureterostomy in, 367–368
operative planning for, 362–363
postoperative complications of, 365–369
preoperative considerations for, 362–365
Urine, fetal, 610
Urine leak, 476
in ablation, 245
after continent cutaneous diversion, 496–497
after ureteral reconstructive surgery, 468
in nephrostomy tubes, 224
partial nephrectomy and, 358–359, 405–408, 407*f*
in radical cystectomy, 438
Urine loss, after radical retropubic prostatectomy, 455
Urine output, low, after ureteral reimplantation, 625–626, 625*f*–626*f*
Urinoma, 162
antenatal, in posterior urethral valves, 613, 613*f*
in minimally invasive pyeloplasty, 365–366
Urodynamic study, for urologic procedures, 84*t*, 85
Urodynamic testing, for male incontinence, 536
Urogenital sinus flap, in vaginoplasty, 659
Urogenital sinus mobilization, 659
Urolithiasis
after orthotopic neobladder diversion, 511
obesity and, 6
during pregnancy, 185–187
complications of, 187–188
diagnosis of, 185–186, 186*f*–187*f*
epidemiology of, 185
etiology of, 185
management of, 186–187, 187*f*
Urologic cancer, obesity and, 4
Urologic disease
malignant, obesity and, 178–179
during pregnancy, 185–191
Urologic imaging, for ureteral injury, 161
Urologic malignant diseases, 4–6
Urologic reconstruction, complications following
definitive, 666–667
lethal, 667–668
Urologic surgery
infectious complications of, 82–91
antibiotics resistance, 90
antimicrobial prophylaxis in, 82–86, 83*t*
endourologic procedures, 83–85, 84*t*
heart valves, prostheses, special consideration in, 86, 86*t*
open, laparoscopic, and robotic, 85–86
C. difficile colitis, 90
management of, 86–90
intraabdominal infections, 87–88
postoperative urinary tract infections, 88–89
sepsis, early recognition and treatment, 89–90, 89*t*
surgical site infections, 86–87
special considerations, 91
inflatable penile prostheses, 91
prostate biopsy, 91
metabolic complications of, 47–57
in pregnant patient, 183–194
endoscopic, 193
ethical considerations for, 185
open *versus* laparoscopic approaches to, 192–193
perioperative fetal monitoring in, 192–193, 192*b*
surgical considerations for, 191–193, 192*b*
surgical positioning in, 192
rhabdomyolysis after, 353
UroLume stent, 550–551
Urosepsis, 8–9, 296
Urosepsis, after ureteral reimplantation, 626
Urothelial carcinoma, of upper urinary tract, ureteroscopic surgery for, 276
URS. *See* Ureteroscopy.

V

Vaginal agenesis, 659–662, 660*f*
Vaginal cavity, persistent, after female to male gender confirmation surgery, 198–199, 199*f*
Vaginal confluence, high, 659
Vaginal exposure, after stress urinary incontinence surgery, 531, 531*f*
Vaginal prolapse, after stress urinary incontinence surgery, 533
Vaginal surgery, for urologic procedures, 84*t*
Vaginoplasty, 659–662, 660*f*
Valrubicin, 234–235
Valve ablation, primary, of posterior urethral valves, 614, 614*f*
Valve bladder syndrome, 619–620
Valvular heart disease, 26–27
Vanillylmandelic acid (VMA) testing, for pheochromocytoma, 413
Varicocele, 572–574
persistence or recurrence, after varicocelectomy, 573
repair techniques, 572
Varicocelectomy, 572–574
complications after, 572–574
indications for repair in, 572
laparoscopic, in children, 607, 607*t*
laparoscopic approach to, 572
microsurgical inguinal approach to, 572
microsurgical open approach to, 572
microsurgical subinguinal approach to, 572, 573*f*
open retroperitoneal approach to, 572
Vas deferens
injury to
after hydrocelectomy, 577
during inguinal surgery, 587
surgical complications of, 567–579
Vascular clamps, 113–114
Vascular complications
causes of, 114–116, 114*f*
in lymphadenectomy, 422–423, 423*f*
management of, in urology, 112–125
instruments and supplies, 113–114
Vascular control and repair, instruments for, 113–114
Vascular grafts, bilateral mid ureteral obstruction from, 159–160, 161*f*
Vascular injuries, 311
causes and prevention of, 114–116
complications of, 119–120
definitive operative management of, 118–119
from extracorporeal shock wave lithotripsy, 302
identification of, 116
kidney exposure, complications related to, 354–355
during lymph node dissection, 378
specific cases of, 120–125
types of, 116
Vascular repairs, general principles of, 118–119
Vasectomy, 570–571
complications after, 570–571
failure, 571
long-term considerations in, 571
no-scalpel, 570
pre-vasectomy consultation for, 570
procedure techniques, 570
Vasectomy reversal, 575–576
complications after, 576
procedure techniques in, 575–576
Vasoepididymostomy, 575–576
Vasovasostomy, 575–576
Vasovenous fistula, 571
Vein grafting, in Peyronie's disease, 564–565
Vena cava thrombectomy, 394*f*
Venous anomalies, in lymphadenectomy, 424–425, 425*f*
Venous complications, in lymphadenectomy, 423–424
Venous injuries, 121–122
Venous return, after robot-assisted radical prostatectomy, 334–335
Venous thromboembolic events
after robot-assisted radical prostatectomy, 337
ureteroscopic surgery and, 284

Venous thromboembolism (VTE), 18, 38
after radical cystectomy, 440, 440*t*
after radical retropubic prostatectomy, 451
after renal transplantation, 475–476
after robotic cystectomy, 380–381
after robotic pelvic floor reconstruction, 347
robotic pelvic surgery and, 322–323
Venous thrombosis
after extracorporeal shock wave lithotripsy, 302
deep, 43–45, 297
after renal transplantation, 475–476
AUA prophylaxis, 45, 45*t*
in lymphadenectomy, 432
radical retropubic prostatectomy after, 451
risk factors for, 380*t*
Ventricular tachycardia (VT), 27
Ventriculoperitoneal (VP) shunt infection, after bladder augmentation, 517–518
Veress needle, in robot-assisted radical prostatectomy, 329
Veress needle access, 120
Veress placement, 310*b*
Verumontanum, 271, 271*f*
Vesicoamniotic shunts, for posterior urethral valves, 610
Vesicocentesis, for posterior urethral valves, 610
Vesicoenteric fistula, 129
Vesicopsoas hitch, 462–463
Vesicostomy, for posterior urethral valves
closure, 618
cutaneous, 614–615, 616*f*–617*f*
Vesicoureteral reflux (VUR)
bladder dynamics and, 624–625
in children, 602
endoscopic correction of, 592, 630, 630*f*–631*f*
nonsurgical complications of, 624
posterior urethral valves and, 618–619
risks of medical management of, 624
Vesicourethropexy, for stress urinary incontinence, 524, 524*t*
Vesicovaginal fistula (VVF), 133–139, 133*f*, 137*f*, 139*f*
classification of, 136*t*
diagnosis of, 134–135, 135*b*, 135*f*
etiology of, 133–134, 133*f*
Vesicovaginal fistula (VVF) *(Continued)*
management of, 136–139, 136*b*
pathophysiology of, 134
presentation of, 134
prevention of, 135–136
Video urodynamics, for stress urinary incontinence, 534.*e*3–534.*e*4
Virtue® sling, 538
Visceral artery injuries, 121
Visceral injuries, during laparoscopy, 317–318
Visceral organ injuries, in pediatric laparoscopy, 599
Vitamin B_{12} deficiency
after bladder augmentation, 521
after conduit urinary diversion, 483
Vitamin K antagonists, 31, 40*t*
Vitamin K-related disorders, 37–38
Voiding
dysfunction of
after orthotopic neobladder diversion, 513–514, 514*f*
after stress urinary incontinence surgery, 529–531
after ureteral reimplantation, 626
in vesicovaginal fistula, 134
Voiding cystourethrograms (VCUGs), after uncomplicated reimplant, 625
Volume depletion, in infectious complications of urologic surgery, 88
Vomiting. *See* Nausea and vomiting.
von Willebrand's disease (VWD), 35
Vulvovaginoplasty, use of skin in, 661
VURD syndrome, 618

W

Warfarin, 40*t*
complications of, 44
preoperative, 40
for thromboembolic disease, 44
Water
gastrointestinal transport of, 55
sterile, as irrigating solution, 257
transport of, after urinary diversion, 55
Weight loss, preoperative, before radical prostatectomy, 180
Well's criteria, for pulmonary embolism, 44, 44*t*
Wire-related complications, in ureteral stents, 221
Wolff-Parkinson-White syndrome, 27, 28*f*
Wong-Baker FACES Pain Rating Scale, 589, 589*f*
Wound closure
layered *versus* mass, 106, 106*f*
in pelvic radiation, 204, 204*b*
Wound complication(s), 100*f*
hematoma as, 101
infection as. *See* Wound infection.
seroma as, 100–101
surgical-site infection as, 101–104
Wound dehiscence, 104–106
clinical features of, 104–105
complication of primary bladder exstrophy, 635, 636*f*
layered *versus* mass closure and, 106, 106*f*
pathogenesis of, 104–105, 105*t*
risk factors associated with, 105*t*
suture selection and technique for, 105–106
Wound healing, radiation for, 202–203
Wound hematomas, 101
Wound infection. *See also* Infection, surgical-site.
after hypospadias repair, 651
after robot-assisted radical prostatectomy, 336–337
after robotic cystectomy, 381
in radical cystectomy, 438–439
radical retropubic prostatectomy after, 451
Wound separation, after hypospadias repair, 651
Wound seroma, 100–101
Wound tension, after bladder exstrophy, 638–639
Wrong-site surgery, 385–386, 386*t*

X

X-ray, of steinstrasse, 301, 301*f*
Xarelto. *See* Rivaroxaban.

Y

York Mason approach, for rectourethral fistula, 207, 207*f*

ClinicalKey®

Fast answers and trusted evidence

Drive better outcomes with a clinical search engine that makes it easier to find and apply relevant knowledge.

Fast

Anticipates your query, recognizing concepts and offering shortcuts

Complete

Draws relevant answers from a wide range of current, comprehensive content across 30+ medical and surgical specialties

Convenient

Accessible at the patient's bedside or on the go, making it easy to discover, share, and apply content anywhere

Trusted

Content from Elsevier, the name healthcare professionals worldwide rely on
