Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

Surgery is never perfect, but that should not stop a surgeon's pursuit of perfection.

In many ways, this is the nature of a surgical career – continually refining one's approach and technique through observation, trial and error, and experience. In doing so, excellent outcomes can be achieved with any operation, and when complications arise, early recognition and proper management can allow expeditious recovery.

Optimizing surgical outcomes can be viewed as a lifelong exercise for the surgeon, but for the individual patient, only one outcome matters. Although it is easy for the busy surgeon to consider any operation as routine, it is essential to view each procedure, no matter how routine, as important and carrying potentially life-altering results for the patient. The balance between confidence and neglect is narrow for surgeons, and humility serves the surgeon well in recognizing that no matter how good or experienced the surgeon is, complications are inevitable. Even the operation that appears to go well, in an otherwise healthy patient, can result in complication.

When planning an operation, consideration of unique host factors predisposing the patient to complication is essential. With increasing experience, the surgeon will recognize those cases in which surgery is ill advised. Too often, early in a surgeon's career, complications arise through poor patient selection or preparation, or inadequate attention to risk factors in planning the procedure. Patients with underlying cardiopulmonary compromise, diabetes, coagulopathy, or morbid obesity should be considered at highest risk of complications delaying or preventing recovery. In particular, obese patients carry both the risk of complications due to underlying medical disease and those related to the increased technical difficulty of the procedure. Likewise, re-operative procedures can carry unique technical challenges and risks. When starting out, recognition of these challenges, and consideration of referral to a surgeon experienced with those types of patients, can save a great deal of anguish for surgeon and patient.

While caution is essential, surgeons must also be willing to take on challenging cases when patients are in absolute need of care. Careful preoperative assessment, operative planning, consultation when appropriate, and adherence to fundamental surgical principles allow the best opportunity for a good outcome. When confronted with a complication, the surgeon must refrain from efforts to minimize the problem and use a judicious approach to determine the right course.

First and foremost, complications take a tremendous emotional and physical toll on our patients, and surgeons must remember this when confronted with a complication. For the patient, the process of surgery is one in which control is given completely to the surgeon. The uncertainty of outcome, the loss of control, and the fear of mortality are tremendously stressful for the patient even in the setting of an uncomplicated surgery. When complications arise, these stresses are magnified and patients and their families are often confused, depressed, or angry. Demonstration of sincere empathy and sympathy are critically important. Careful, calm, and comprehensive communication are essential to enable them to understand the nature of the complication, its probable causes and outcomes, and concerns going forward. Specific benchmarks for improvement can allow the patient and family a structured process to mentally cope with the situation. Patients with complications often fear the surgeon will abandon them, and reassurance can go a long way toward maintaining a good relationship.

Physical concerns in the setting of complications relate to the patient's ability to tolerate the stresses and the relative risk of prolonged hospitalization. In patients with preexisting comorbid conditions, careful attention to management of underlying disease processes, particularly those influencing recovery, will help in avoiding secondary complications. Maintaining nutrition, preventing infection, and carefully monitoring fluids and electrolytes are fundamental surgical principles that directly affect recovery from most procedures, but that can easily be forgotten in the heat of stressful complication. Although not all patients recover from complications, the surgeon's primary goal must be to optimize the patient's condition to maximize the patient's odds of recovery.

The balance between action and inaction is a difficult one for surgeons. An underlying desire to make a complication go away often leads to a hasty decision to act quickly through reoperation or intervention. Although sometimes indicated, quick decisions to intervene often result in worsening of the problem or development of secondary complications. At the time of complication, careful diagnostic evaluation to fully understand its nature and extent are critically important before any action is taken. Although stressful for both the patient and the surgeon, sometimes waiting it out is the best course of action.

Over the years, *Complications of Urologic Surgery: Diagnosis, Prevention, and Management* has become a text popular among those in training and those in practice, largely due to its ability to provide information relevant to day-to-day practice. It has been translated in multiple languages, creating access for urologists around the world. In this fifth edition of the text, we have expanded the title to include "Diagnosis", recognizing that the early identification of complications is as important as their management. We have additionally made the content more contemporary, by removing references to operations rarely performed in modern practice, and adding a number of chapters dedicated to complications unique to the emerging standard of minimally invasive surgery and specific procedures commonly employing laparoscopy or robotic-assisted laparoscopy. Recognizing that robotic-assisted surgery is growing in utilization, but remains underutilized, due to cost, around the world, we have retained detailed discussion of

the conventional procedures commonly performed in urologic practice, expanding upon the diversity of authors to allow a broad perspective to approach. Finally, for trainees, we have added a new study guide with questions and case presentations to test knowledge and inspire questions in mastering the content of the text. It is our sincere hope that the text will remain a popular, frequently utilized source of information for practicing urologists around the globe.

Samir S. Taneja, MD

Ojas Shah, MD

We would like to dedicate this book to the many who have so greatly influenced our lives and careers.

To our parents, Vidya Sagar and Sudesh Taneja, and Dinker and Aruna Shah, for setting an example and encouraging us to relentlessly pursue excellence in our education and professional life.

To our mentors, Jean deKernion, Robert Smith, Richard Ehrlich, Dean Assimos, and Herbert Lepor, for teaching us the science and craft of surgery and supporting us in failure or success.

To our families, Uma, Sorab, and Sabina Taneja, and Rupa, Siena, Devon, and Mira Shah, for their patience, love and support in allowing us to pursue the distractions of our academic life.

And, most importantly, to our many patients whose care has taught us so much, whose needs have inspired persistence and innovation, and whose gratitude has motivated us to carry on each day.

Table of Contents

SECTION I PREOPERATIVE ASSESSMENT AND PERIOPERATIVE MANAGEMENT

1 *Impact of Host Factors and Comorbid Conditions,* 2
KATHLEEN F. MCGINLEY and STEPHEN J. FREEDLAND

2 *Preoperative Pulmonary Assessment and Management of Pulmonary Complications,* 12
JAMES S. WYSOCK

3 *Preoperative Cardiac Assessment and Management of Perioperative Cardiac Complications,* 21
ALAN SHAH

4 *Preoperative Hematologic Assessment and Management of Hematologic Complications,* 32
BRENTON ARMSTRONG, SAMIR S. TANEJA, and OJAS SHAH

5 *Metabolic Complications of Urologic Surgery,* 47
KEVIN HEINSIMER and MICHAEL O. KOCH

6 *Anesthetic Complications in Urologic Surgery,* 58
GEORGE T. VAIDA and SUDHEER K. JAIN

7 *Infectious Complications of Urologic Surgery,* 82
MARC A. BJURLIN

8 *Classification of Complications and Assessment of Quality of Care,* 92
MARK D. TYSON and DAVID F. PENSON

SECTION II COMMON SURGICAL CONSIDERATIONS

9 *Complications of the Incision and Patient Positioning,* 99
BORIS GERSHMAN, MATTHEW K. TOLLEFSON, STEPHEN A. BOORJIAN, and BRADLEY C. LEIBOVICH

10 *Management of Vascular Complications in Urology,* 112
SCOTT LUNDY and VENKATESH KRISHNAMURTHI

11 *Management of Bowel Complications,* 126
BROCK O'NEIL and SAM S. CHANG

12 *Management of Urinary Fistula,* 132
DANIEL S. HOFFMAN, TEMITOPE L. RUDE, and BENJAMIN M. BRUCKER

13 *Management of Urine Leak,* 147
MOHAMMED HASEEBUDDIN and ROBERT G. UZZO

14 *Management of Ureteral Injury,* 159
RYAN S. HSI and MARSHALL L. STOLLER

15 *Management of Complications Related to Traumatic Injuries,* 169
ALLEN MOREY and TIMOTHY TAUSCH

SECTION III SURGICAL SCENARIOS PREDISPOSING TO COMPLICATION

16 *Urologic Surgery in the Obese,* 178
SCOTT C. JOHNSON and NORM D. SMITH

17 *Urologic Surgery in the Pregnant Patient,* 183
VERNON M. PAIS JR and LAEL REINSTATLER

18 *Management of Complications of Gender Confirmation Surgery,* 195
KIRANPREET K. KHURANA, AARON C. WEINBERG, JAMIE P. LEVINE, and LEE C. ZHAO

19 *Complications of Genitourinary Surgery in the Irradiated Pelvis,* 202
KARL COUTINHO and CHRIS M. GONZALEZ

SECTION IV COMPLICATIONS OF AMBULATORY UROLOGIC PROCEDURES

20 *Prostate Biopsy Complications,* 212
MEENAKSHI DAVULURI and STACY LOEB

21 *Complications of Upper Tract Drainage,* 218
ZITA FICKO and ELIAS S. HYAMS

22 *Complications of Intravesical Therapy,* 226
HASAN DANI and SAMIR S. TANEJA

23 *Complications of Renal Tissue Ablation,* 237
NOAH E. CANVASSER, ILIA S. ZELTSER, and JEFFREY A. CADEDDU

24 *Complications of Prostate Cryosurgical Ablation,* 246
RAJAN RAMANATHAN, AHMED ELSHAFEI, and J. STEPHEN JONES

SECTION V COMPLICATIONS OF ENDOUROLOGIC PROCEDURES

25 *Complications of Transurethral Resection of Bladder Tumors,* 256
ERIC A. SINGER, AMY N. LUCKENBAUGH, and GANESH S. PALAPATTU

26 *Complications of Endoscopic Procedures for Benign Prostatic Hyperplasia,* 265
TRACY MARIEN, MUSTAFA KADIHASANOGLU, and NICOLE L. MILLER

27 *Complications of Ureteroscopic Surgery,* 275
JUSTIN B. ZIEMBA and BRIAN R. MATLAGA

28 *Complications of Percutaneous Renal Surgery,* 286
DANIEL WOLLIN and OJAS SHAH

29 *Complications of Extracorporeal Shock Wave Lithotripsy,* 299
NADYA E. YORK and JAMES E. LINGEMAN

SECTION VI COMPLICATIONS OF LAPAROSCOPIC/ROBOTIC PROCEDURES

30 *Special Considerations in Laparoscopy,* 308
MATTHEW D. GRIMES, BRETT A. JOHNSON, and STEPHEN Y. NAKADA

31 *Special Considerations in Robot-Assisted Surgery,* 319
STEVEN V. KHEYFETS and CHANDRU P. SUNDARAM

32 *Complications of Robotic-Assisted Laparoscopic Radical Prostatectomy,* 326
ALON Y. MASS and SAMIR S. TANEJA

33 *Complications of Robotic Pelvic Floor Reconstruction,* 339
NIRIT ROSENBLUM and DOMINIQUE MALACARNE

34 *Complications of Laparoscopic/Robotic Nephrectomy and Partial Nephrectomy,* 349
MARC A. BJURLIN and SAMIR S. TANEJA

35 *Complications of Robotic Upper Urinary Tract Reconstruction,* 362
LEE C. ZHAO, KIRANPREET K. KHURANA, and MICHAEL D. STIFELMAN

36 *Complications of Robotic Cystectomy,* 370
ANGELA B. SMITH, JEFFREY W. NIX, and RAJ S. PRUTHI

SECTION VII COMPLICATIONS OF EXTIRPATIVE SURGERY

37 *Complications of Nephrectomy,* 384
THENAPPAN CHANDRASEKAR, MARC A. DALL'ERA, and CHRISTOPHER P. EVANS

38 *Complications of Open Partial Nephrectomy,* 397
MARC A. BJURLIN and SAMIR S. TANEJA

39 *Complications of Adrenal Surgery,* 410
MICHAEL DANESHVAR and GENNADY BRATSLAVSKY

40 *Complications of Lymphadenectomy,* 419
DMITRY VOLKIN and WILLIAM C. HUANG

41 *Complications of Radical Cystectomy and Urinary Diversion,* 433
JAMES M. MCKIERNAN and CHRISTOPHER B. ANDERSON

42 *Complications of Radical Retropubic Prostatectomy,* 445
JAMES S. WYSOCK, SAMIR S. TANEJA, and HERBERT LEPOR

SECTION VIII COMPLICATIONS OF RECONSTRUCTIVE SURGERY

43 *Complications of Ureteral Reconstructive Surgery,* 458
MITCHELL HUMPHREYS and SEAN MCADAMS

44 *Complications of Renal Transplantation,* 469
NICHOLAS G. COWAN, JEFFREY L. VEALE, and H. ALBIN GRITSCH

45 *Complications of Conduit Urinary Diversion,* 478
ALEXANDER P. KENIGSBERG, JAMIE A. KANOFSKY, and SAMIR S. TANEJA

46 *Complications of Continent Cutaneous Diversion,* 494
EILA C. SKINNER and DIMITAR ZLATEV

47 *Complications of Orthotopic Neobladder,* 505
SANJAY G. PATEL and MICHAEL S. COOKSON

48 *Complications of Bladder Augmentation and Surgery for Neurogenic Bladder,* 516
HIMANSHU AGGARWAL, CATHERINE J. HARRIS, and GARY E. LEMACK

49 *Complications of Female Incontinence Surgery,* 523
LEAH CHILES and ERIC S. ROVNER

50 *Complications of Surgery for Male Incontinence,* 535
TEMITOPE L. RUDE, DANIEL HOFFMAN, and VICTOR W. NITTI

51 *Complications of Urethral Reconstruction,* 546
JOEL GELMAN and ERIC S. WISENBAUGH

52 *Complications of Surgery for Erectile Dysfunction and Peyronie's Disease,* 556
BOBBY B. NAJARI and JOHN P. MULHALL

53 *Complications of Surgery of the Testicle, Vas Deferens, Epididymis, and Scrotum,* 567
JAMES WREN and ROBERT BRANNIGAN

SECTION IX COMPLICATIONS OF PEDIATRIC UROLOGIC SURGERY

54 *Special Considerations in the Pediatric Patient,* 581
MADELINE J. CANCIAN and ANTHONY A. CALDAMONE

55 *Complications of Pediatric Endoscopic Surgery,* 591
DAVID I. CHU, PASQUALE CASALE, and GREGORY E. TASIAN

56 *Complications of Pediatric Laparoscopic and Robotic Surgery,* 598
DAVID I. CHU and ASEEM R. SHUKLA

57 *Complications of Surgery for Posterior Urethral Valves,* 609
ELLEN SHAPIRO and JACK S. ELDER

58 *Complications of Ureteral Reimplantation, Antireflux Surgery, and Megaureter Repair,* 623
JESSICA T. CASEY, ROSALIA MISSERI, and RICHARD C. RINK

59 *Complications of Exstrophy and Epispadias Repair,* 634
PETER P. STUHLDREHER and JOHN P. GEARHART

60 *Complications of Hypospadias Repair,* 647
CHRISTOPHER J. LONG and DOUGLAS A. CANNING

61 *Complications of Surgery for Disorders of Sex Development,* 657
JASON M. WILSON and LAURENCE BASKIN

62 *Complications of Pediatric Urinary Diversions and Bladder Augmentation,* 665
DOUGLAS A. HUSMANN

Index, 675

List of Contributors

Himanshu Aggarwal, MD, MS
Assistant Professor of Urology, Division of Female Pelvic Medicine and Reconstructive Surgery, Department of Urology, University of Alabama, Montgomery, AL, USA
Complications of Bladder Augmentation and Surgery for Neurogenic Bladder

Christopher B. Anderson, MD, MPH
Assistant Professor, Columbia University Medical Center, Department of Urology, New York, NY, USA
Complications of Radical Cystectomy and Urinary Diversion

Brenton Armstrong, MD
Resident, Department of Urology, New York University Langone Medical Center, New York, NY, USA
Preoperative Hematologic Assessment and Management of Hematologic Complications

Laurence Baskin, MD
Professor and Chief, Pediatric Urology, University of California–San Francisco Benioff Children's Hospitals, San Francisco and Oakland, CA, USA
Complications of Surgery for Disorders of Sex Development

Erectile Dysfunction
Stress Urinary Incontinence
Urolithiasis
Malnutrition
Nutritional Status Assessment
Preoperative Management of Malnutrition
Infection and Urosepsis
Quantifying Comorbidity
Conclusion
Chapter 1 Questions and Answers

KEY POINTS

1. With increasing life expectancy in the general population, the prevalence of comorbid conditions such as obesity, heart disease, and diabetes has increased to alarming proportions.
2. Awareness of comorbidities allows the urologist to institute the proper measures to control preexisting diseases to optimize the overall health status of the individual patient, maximize the likelihood of a good outcome, and minimize the risk of a complication.
3. Obesity can directly influence surgical outcome because of certain proposed biologic linkages with urologic malignant diseases.
4. Nutritional status is a key clinical parameter demanding thorough evaluation in the surgical patient to prevent nutrition-related complications.
5. Given that certain host factors predispose the urologic patient to complicated infection, it is necessary to determine the need for antimicrobial prophylaxis preoperatively and to prevent the occurrence of systemic septicemia.

Every urologist would prefer that any patient who has a consultation for a urologic disease would be solely afflicted with the disease for which he or she seeks medical attention, that every surgical patient would be healthy enough to tolerate the proposed surgical intervention to treat the condition, and that complications would occur with only miniscule probability. Unfortunately, this situation is far removed from reality and certainly is becoming less common in current clinical practice in which medical histories, physical examinations, preoperative laboratory examinations, and imaging scans are likely to reveal coexisting medical problems in the urologic patient.

In the present era, with life expectancy ever increasing, the prevalence of comorbid conditions such as obesity, heart disease, and diabetes, which affect urologic diseases and their clinical outcome following management, has congruently reached alarming proportions in the general population. Whether driven by improved medical science, rapid technologic advancement, or an effect of natural selection, men and women are living longer (Fig. 1.1). The medical community recognizes special considerations for elderly patients, and most of these considerations are brought about by medical conditions that are diagnosed in later life and progress with advancing age. In urologic disease entities such as erectile dysfunction in men, pelvic floor disorders in women, and urologic malignant diseases such as prostate and bladder cancer, the predisposition and clinical effects related to advanced age have direct biologic implications for the urologic condition. Moreover, because most of these disease entities are diagnosed in the more mature stages of life, the probability of preexisting medical conditions in these patients at the time of consultation is high.

Notwithstanding the effect of age on comorbid medical conditions in the urologic patient, the past decades have also seen a dramatic rise in the prevalence of disease entities closely linked to harmful lifestyle choices such as smoking and alcohol consumption, unhealthy diets, lack of physical activity, and intravenous drug abuse. These lifestyle choices adversely affect patients of all ages who may seek urologic consultation and who may present with detrimental comorbidities such as childhood obesity, juvenile diabetes, chronic obstructive pulmonary disease, liver disease, and human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS).

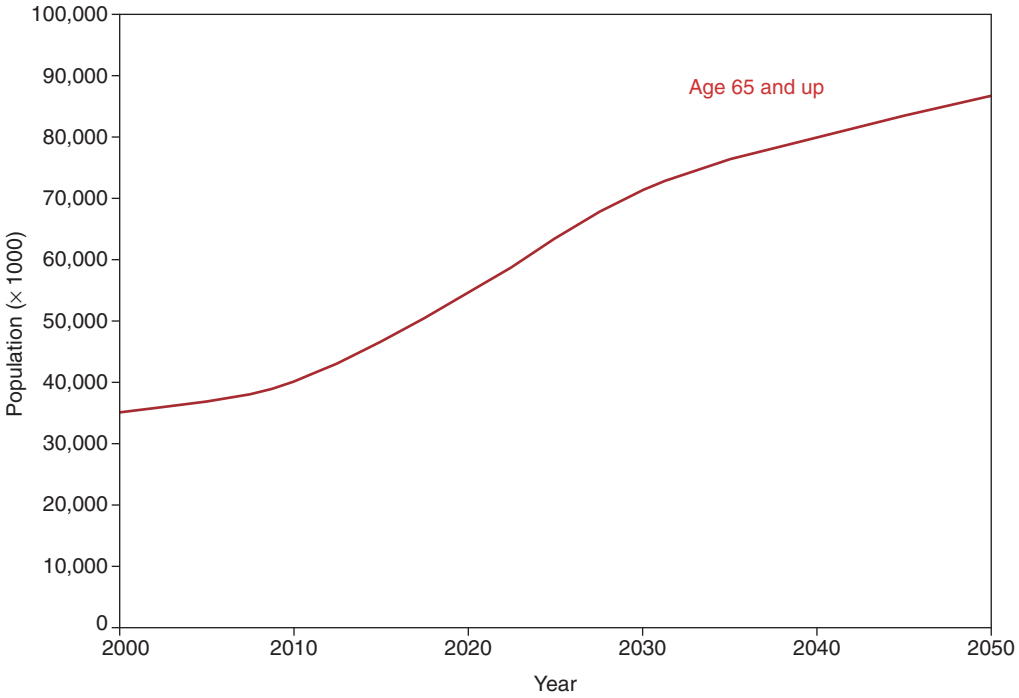

Figure 1.1 Projected population of the United States for adults ≥65 years old (2000–2050). Based on data from the United States Census Bureau (http://www.census.gov/ipc/www/usinterimproj/).

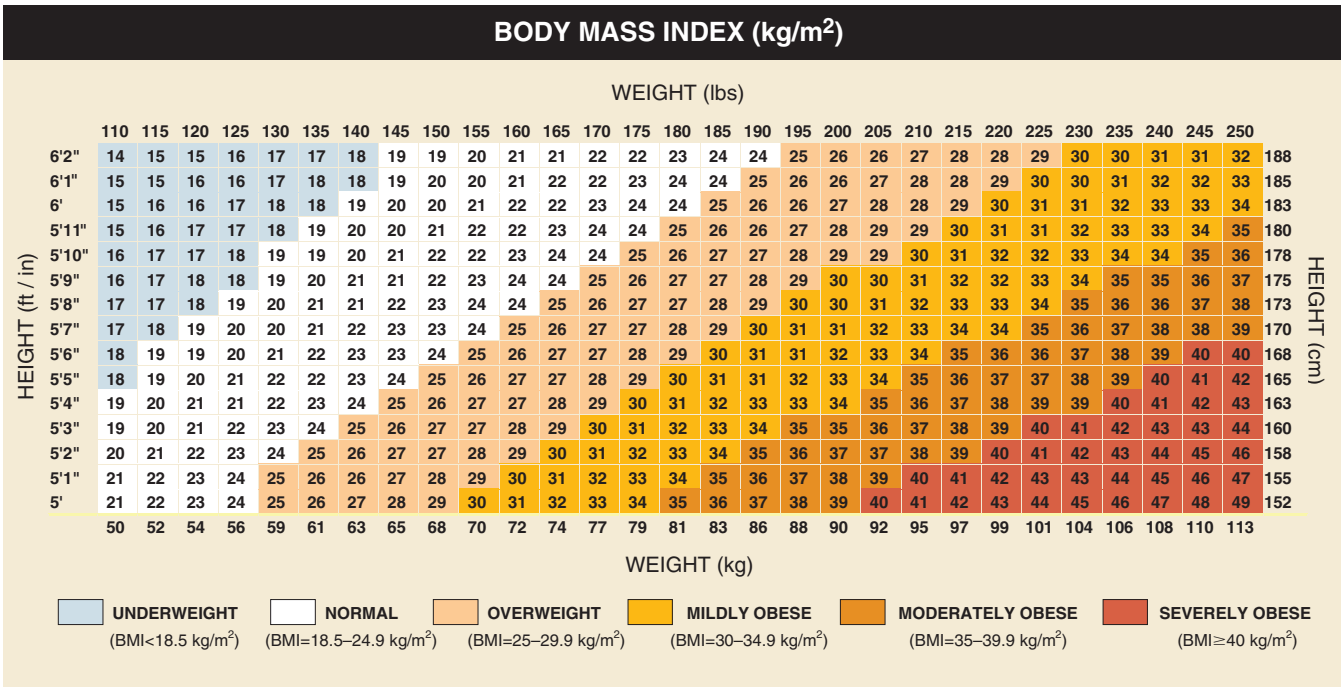
Although biologic links to known urologic diseases may be less apparent, the overall outcome and incidence of complications following surgical intervention are directly affected by coexisting health problems. Indeed, assessing the urologic patient for preexisting comorbidities is of critical importance because host factors play an important role in postoperative complications. Awareness of comorbidities allows the urologist to institute the proper measures to control preexisting diseases to optimize the overall health status of the individual patient, maximize the likelihood of a good outcome, and minimize the risk of a complication. The urologist also can assess the need for ancillary examinations for a more comprehensive evaluation of comorbid conditions more accurately and can determine the need for intraoperative monitoring and specialized intensive postsurgical care. More importantly, comprehensive knowledge of all concurrent illnesses in the urologic patient aids the urologist in deciding whether surgical intervention is the optimal treatment option or whether conservative management may be the best therapeutic alternative.



To serve as an introduction to the succeeding chapters in this section, we tackle host factors that significantly affect the occurrence of nonurologic complications following urologic surgery. We provide an overview of comorbidities in the urologic patient and highlight current prevalent disease entities that influence outcome following definitive surgical management. Comorbidities to which whole chapters are devoted, such as those pertaining to cardiovascular, pulmonary, hematologic, and anesthetic complications, are discussed only briefly here, to leave room for a more detailed discussion of topics of special interest such as obesity that are of major interest in the field of contemporary urology. We also provide insight into clinical tools such as useful comorbidity indices and scoring systems that aim to quantify the severity of comorbidities and predict posttreatment morbidity and mortality.

Obesity

The importance of nutritional status to surgical outcomes and the deleterious effects of obesity are of significant interest in the field of urology. Interest has centered on obesity for two main reasons: First, the prevalence of obesity has been growing at epidemic proportions worldwide,[1] and second scientific evidence suggests a relationship between obesity and multiple urologic conditions including benign prostatic hyperplasia (BPH),[2] urologic malignant diseases, incontinence, erectile dysfunction, and stone disease, to name a few.[3]

Most of the leading causes of death in the United States are linked to obesity, including heart disease, cancer, stroke, and diabetes.[4] Viewed as a growing national health crisis, obesity is the second leading cause of preventable death;[5] obesity not only results in a potentially avoidable toll in human lives but also incurs a substantial cost in health expenditure for the country.[6] Affecting over one-third of all adults in the United States,[7] obesity is further associated with various comorbidities, such as hypertension, sleep apnea, cholecystolithiasis, osteoarthritis, and depression, that may aggravate the overall health status of the overweight or obese patient and may contribute to surgical complications.[8] Childhood obesity is also on the rise and could have undesirable consequences for children and adolescents undergoing pediatric urologic procedures.[9]

Obesity is defined as an excess accumulation of adipose tissue in the body; however, functionally, *overweight* and *obese* are labels used to denote ranges of weight that are in

Figure 1.2 Estimates of body mass index using measured height and weight.

excess of what is generally considered healthy for the given height of a person. Because of its simplicity, body mass index (BMI) is a widely accepted method to assess for obesity. BMI is calculated by dividing the weight (in kilograms) of an individual by the height (in meters) squared.[10] Fig. 1.2 illustrates the standard weight status categories associated with BMI range for adults. Although other anthropometric measurements such as skinfold thickness and midarm circumference may be used for more accurate estimation of body fat, these measurements are not routinely recorded in clinical practice and are of limited availability for retrospective studies.[10]

Fat distribution may also be an important determinant of obesity because individuals with high BMI who have upper body fat distribution (android) have been shown to be at greater risk for comorbidities such as cardiovascular disease, cerebrovascular disease, and hypertension compared with men and women who have lower body fat distribution (gynecoid).[11] Newer studies found better accuracy in gauging obesity with the use of waist circumference and waist-to-hip ratios; however, these parameters are more cumbersome to measure compared with BMI.[12] *Central obesity* correlates with visceral fat accumulation in the abdomen and is diagnosed when the waist-to-hip ratio exceeds 1.0 in men and 0.9 in women. This condition is in contrast to *peripheral obesity*, in which fat accumulation occurs subcutaneously in the gluteofemoral region. However, the distinction is clinically important because central obesity imparts a significantly higher risk of insulin resistance and type 2 diabetes, blood lipid disorders, hypertension, and heart disease compared with peripheral obesity.[13]

The medical consequences of obesity result in part from increased secretion of pathogenic macromolecules from enlarged adipose cells. Increased release of fatty acids from fat cells that are stored in the liver or muscle results in the insulin-resistant state that is commonly seen in obesity. Diabetes ensues as the mounting insulin resistance overwhelms the secretory response of the pancreas.[14] Bioactive cytokines, particularly interleukin-6, released from adipocytes promote the proinflammatory state that is characteristic of obesity. Secretion of prothrombin activator inhibitor-1 from adipose cells, coupled with impaired endothelial function, plays a key role in the hypercoagulable state of obesity and ultimately increases the risk of cardiovascular disease, stroke, and hypertension in obesity. This prothrombotic state is further aggravated directly by increased estrogen levels and is complicated indirectly by decreased antiangiogenic cytokines such as adiponectin.[15] The overall effect of these multiple pathologic consequences of increased fat stores is the risk of shortened life expectancy.[16]

OBESITY AND UROLOGIC MALIGNANT DISEASES

Investigations since the late 1980s have sparked keen interest in the link between obesity and urologic cancer, especially for prostate adenocarcinoma and kidney cancer.[17] Investigators have hypothesized that diet and obesity affect the underlying biologic mechanisms that ultimately lead to carcinogenesis, including promotion of angiogenesis and mitogenesis, increased cellular proliferation, impairment of immune response, increased exposure to oxidative damage by free radicals, and promotion of a proinflammatory state.[18] Obesity can directly influence surgical outcome as a result of these proposed biologic linkages with urologic malignant diseases.

Prostate Cancer

Because obese men with prostate cancer have lower serum prostate-specific antigen (PSA) levels relative to men of normal weight,[19,20] and because physical assessment of the

prostate through digital rectal examination is hindered by adiposity, detection of prostate cancer among men with a high BMI may be delayed. Performing a transrectal ultrasound–guided biopsy to establish a tissue diagnosis of prostate cancer can also be more technically difficult in obese men, and because of prostatic enlargement, some cancers may be missed by undersampling.[19] After histopathologic confirmation of prostate cancer, the patient may opt for surgical treatment, but urologists may be reluctant to operate on morbidly obese patients for several reasons. The anesthetic risks pertaining to adequacy of ventilatory support and difficulty in fluid monitoring[21] are further complicated by the increased incidence of comorbid conditions such as hypertension, heart disease, stroke, and diabetes.[14]

If the urologist does perform surgery, adiposity can be a physical hindrance that may curtail adequate exposure of the surgical field, particularly when a retropubic approach is planned for access to the prostate. Among men undergoing an open retropubic prostatectomy, increasing BMI is associated with increasing operative time and increasing intraoperative blood loss.[22] For these reasons, some urologists have advocated that perineal prostatectomy or a robotic-assisted laparoscopic prostatectomy should be favored over an open retropubic approach for treatment of obese men with prostate cancer. However, a study by Fitzsimons and associates[23] suggested that both perineal and open retropubic approaches have comparable outcomes in terms of estimated blood loss and operative time for obese patients. In contrast, Ellimoottil and colleagues[24] found lower transfusion rates among 9108 obese men undergoing robotic-assisted laparoscopic prostatectomy versus an open retropubic approach; however, no difference in perioperative complications between the groups was identified. In a matched pair analysis including 255 patients, Beyer et al.[25] reported lower blood loss, transfusion rates, and fewer 30-day complications among obese men undergoing a robotic-assisted laparoscopic prostatectomy as compared to those undergoing an open retropubic prostatectomy.

Beyond technical issues, obesity may also influence the oncologic outcome among men undergoing radical prostatectomy. First, earlier studies found an increased incidence of positive surgical margins and capsular incision among men with higher BMIs.[26,27] Similarly, men with higher BMIs present with higher-grade tumors and more advance pathologic stages of disease.[28] On postsurgical follow-up, men with an elevated BMI ($\geq 30\ kg/m^2$) are at significantly increased risk of biochemical recurrence relative to men with a lower BMI, as denoted by an elevated postoperative PSA test result (>0.2 ng/mL or two values at 0.2 ng/mL).[26,29,30] More ominously, increased body weight was found to be associated with an increased risk of death from prostate cancer in a large, prospectively studied population.[31] Thus, obesity may well exert a biologic effect on prostate cancer that promotes aggressiveness and disease progression. However, in terms of health-related quality of life after radical prostatectomy, prospective studies have so far failed to demonstrate large differences between mildly obese men and men of normal weight.[32–35] For a more detailed review of obesity and prostate cancer, we recommend the article by Allott and Freedland in *European Urology*.[36]

Kidney Cancer

Obesity, particularly in women, has been shown to be associated with renal cell carcinoma (RCC).[31,37] A high BMI was found to be a strong risk factor for RCC; several underlying mechanisms were suspected, including higher insulin and estrogen levels, hypertension, hypercholesterolemia, and impaired host immune response.[38] Boeing and colleagues[39] examined determinants such as smoking, diet, occupational hazards, beverage consumption, medications, and obesity in a case-control cohort of 277 patients with RCC and 286 matched controls and found that specific dietary patterns associated with obesity, such as consumption of fatty foods and meat products, may explain the higher incidence of RCC in industrialized countries relative to developing countries.[39] Indeed, in a large retrospective study involving 363,992 men, investigators from the National Institutes of Health found that obese men, especially those with a history of tobacco use and elevated systolic blood pressures, have an increased long-term risk for RCC.[40]

As in prostate cancer, open surgical procedures for RCC can be technically difficult in patients with severe adiposity. Thus, wide interest exists in prescribing minimally invasive procedures for obese patients because these approaches have been found to be safe and effective for this subset of patients.[41–43] While BMI was found to be a significant risk factor for major postoperative complications in patients treated with laparoscopic surgery for RCC,[44] more recent literature evaluating robotic-assisted laparoscopic procedures have found no association between obesity and complication rates.[45,46] Finally, with regard to clinical outcome and cancer-specific mortality, overweight and obese patients have a higher risk of death from kidney cancer relative to patients of normal weight.[31]

Bladder Cancer

Compared with prostate and renal cancer, published reports of relationships between bladder cancer and obesity are scarce. In 1994, an epidemiologic study of 514 patients with bladder cancer found that beyond the well-known link with smoking, obesity was also a significant risk factor for bladder cancer.[47] This was substantiated in a recent case control study, in which patients with metabolic syndrome were at a twofold higher risk of bladder cancer.[48] However, a large prospective study of nearly 1 million people found no link between BMI and bladder cancer mortality.[31] With regard to diet, reports on the association between high fat intake and bladder cancer have been conflicting.[49,50]

With respect to surgical outcome for radical cystectomy, abundant reports show not only that obesity contributes to the technical challenge of the operation but also that higher BMI increases the risk of perioperative complications. In a retrospective analysis of 304 consecutive patients who underwent radical cystectomy and urinary diversion for bladder cancer, increased BMI was independently associated with higher estimated blood loss.[51] This finding was later confirmed in a cohort of 498 patients; the investigators concluded that, along with greater blood loss, an increased BMI was also independently associated with prolonged operative time and increased rate of complications.[52] In limited robotic cystectomy case series, increasing BMI

was not associated with prolonged operative times or increased blood loss, though it was associated with an increased rate of 90-day re-admission.[53,54]

OBESITY AND BENIGN UROLOGIC CONDITIONS

Several nonmalignant urologic conditions are also unfavorably affected by an increased BMI and morbid obesity.

Benign Prostatic Hyperplasia and Lower Urinary Tract Symptoms

Obesity is a known risk factor for lower urinary tract symptoms (LUTS) and BPH. Indeed, a large-scale, cross-sectional study from the Prostate Study Group of the Austrian Society for Urology found a link between BPH and obesity.[55] The relationship between obesity and LUTS was further confirmed in a report from Johns Hopkins University in Baltimore on 2797 men from the Third National Health and Nutrition Examination Survey.[56] In another confirmatory study, BPH was found to be associated with increased serum insulin levels and abdominal obesity as opposed to BMI itself.[57] The biologic link between obesity and BPH likely has its origin in the association of obesity with hyperinsulinemia and the status of insulin as a direct prostate growth factor.[58]

Erectile Dysfunction

Obesity, particularly central obesity, is a known predictor of erectile dysfunction in men.[59] Both atherosclerosis and diabetes mellitus, which are associated with obesity, play significant roles in the development of erectile dysfunction. Although the underlying cause for erectile dysfunction is thought to be multifactorial, investigators have suggested that obesity increases the risk of erectile dysfunction of vascular origin as a result of the development of chronic vascular disease.[60] Obesity is also known to increase the risk of diabetes. The microvascular complications characteristic of diabetes exert deleterious effects on erectile tissue similar to the pathologic features of diabetic nephropathy, retinopathy, and gastroparesis.[61] Furthermore, weight loss is the only known lifestyle intervention that can improve erectile dysfunction.[62]

Stress Urinary Incontinence

Pelvic floor weakness leading to stress urinary incontinence (SUI) in women is aggravated by increased intraabdominal pressure and is closely associated with truncal obesity. A report examined the association of bladder function with smoking, food consumption, and obesity in 6424 women with SUI and found a strong relationship between SUI and obesity.[63] These findings were confirmed in a questionnaire-based study conducted in Norway involving 27,936 women.[64] The proposed underlying mechanism for the association between high BMI and incontinence is that a high BMI leads to increased intravesical pressures and thus lowers the differential between the detrusor pressure and leak point pressure such that incontinence is more likely to occur.[65] With regard to the perioperative effect of obesity in surgical treatment of SUI, a study involving 250 women who underwent retropubic anti-incontinence procedures revealed that operative time was significantly longer for obese women; however, blood loss and major perioperative complications were similar across BMI groups.[66]

Urolithiasis

Urinary stone formation has been linked to obesity, as illustrated by a report on 527 calcium oxalate stone formers wherein an increased BMI was strongly associated with an elevated risk of stone formation for both men and women.[67] However, a retrospective study of 5492 stone formers revealed that the association between obesity and stone formation was significant only in women.[68] In a study conducted at Duke University, the major metabolic abnormalities found in obese stone formers that were possible contributors to recurrent stone formation were hypocitraturia, gouty diathesis, and hyperuricosuria.[69] An inverse association between pH and body weight suggests that production of excessively acidic urine promotes uric acid nephrolithiasis in obese stone formers.[70]

With respect to urologic procedures to treat stone disease, obesity adversely affects outcome following extracorporeal shock wave lithotripsy (ESWL). In a report examining clinical and radiologic variables associated with poor outcome after ESWL, along with obesity, pelvic ureteral stones, stones >10 mm, and obstruction were independent predictors of unsuccessful outcome.[71] Thus, because of the probability of treatment failure, obese patients, particularly those with a skin-to-stone distance of >10 cm, may be better served by endourologic procedures than by ESWL.[72,73]

Malnutrition

At the opposite end of the nutritional spectrum from overnutrition and obesity is malnutrition. With regard to the surgical patient, malnutrition has been associated with an increased incidence of nosocomial infection, poor wound healing, an increased length of hospital stay, multiorgan dysfunction, and mortality.[74] Various scientific investigations have demonstrated that deterioration of nutritional status has an invariably deleterious effect on surgical outcome. As early as 1932, Cuthbertson reported the association of impaired wound healing with negative nitrogen balance in trauma patients.[75] A more recent prospective study conducted in a cohort of patients who did not have cancer used four clinical parameters to predict perioperative morbidity:

1. Percentage of ideal body weight
2. Preoperative percentage of weight loss
3. Arm muscle circumference
4. Serum albumin.

Results of the study revealed that patients with at least one abnormal clinical parameter had a significant increase in the incidence of major complications and in length of hospital stay relative to patients with normal preoperative parameters.[76] Not only has malnutrition per se been implicated in surgical complications but also certain types of nutrient deficiency, protein malnutrition in particular, may lead to more severe postoperative problems. Relative to protein-calorie malnutrition, which is characterized by a lack of both proteins and carbohydrates, severe protein malnutrition leads to low serum albumin concentration,

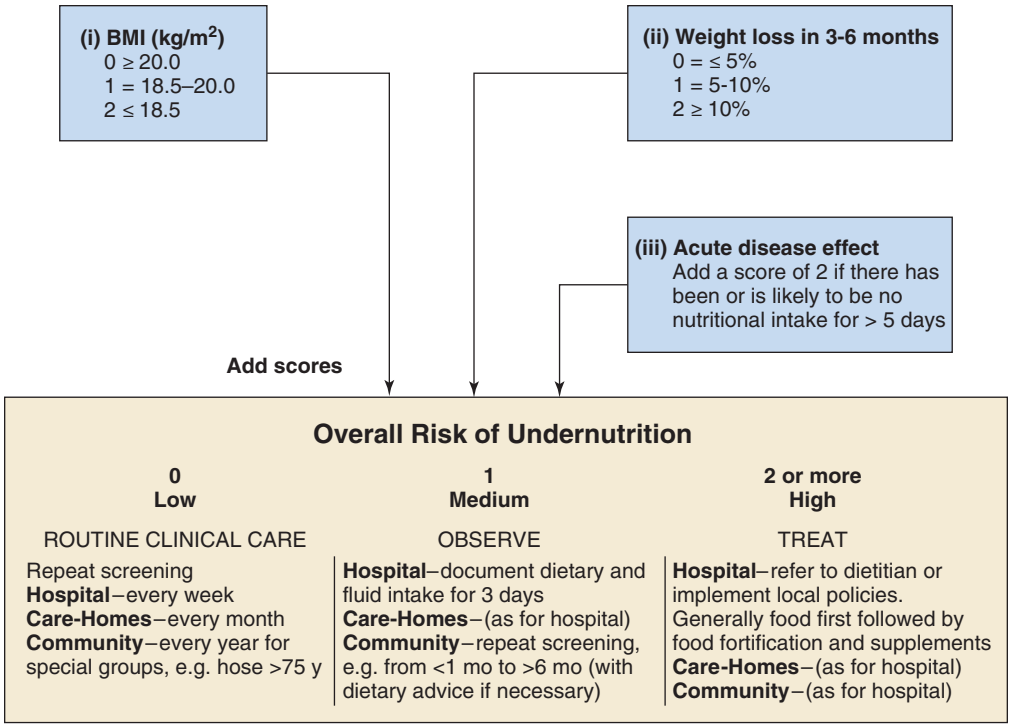

Figure 1.3 Malnutrition Universal Screening Tool. (With permission from Kondrup J, Allison SP, Elia M, Vellas B, Plauth M. ESPEN guidelines for nutrition screening 2002. Clinical nutrition (Edinburgh, Scotland). 2003;22(4):415-21.)

edema, and a high prevalence of acute infections.[77] Thus, it is evident that nutritional status is a key clinical parameter demanding thorough evaluation in the surgical patient to prevent nutrition-related complications.

Nutritional Status Assessment

Traditionally, clinicians relied on anthropometric measurements, which they compared with tables providing ideal weight-for-height estimates to evaluate the nutritional status of patients.[78] Clinicians also determined body mass composition determinants such as lean body mass based on limb skinfold or circumference measurements and used these variables as indicators for adequacy of nutrition. However, problems pertaining to the precision of anthropometric measurements, wide intra-observer and inter-observer variations, and the lack of reliable reference standards have challenged the validity of these methods in ascertaining nutritional health of the surgical patient.[74] These issues surrounding the traditional methods of screening for malnutrition led to an interest in studying serum markers for more accurate determination of preoperative nutritional competence. However, the use of serum markers to diagnose malnutrition is fraught with inaccuracy, as the most commonly used serum markers, albumin and prealbumin, are affected by multiple conditions other than malnutrition, including inflammation, liver disease, and kidney disease.

In the absence of reliable serum markers to judge nutritional status and challenges applying anthropometric measurements, the next best option for nutritional assessment may be screening tools such as the Malnutrition Universal Screening Tool (MUST)[79] or the NRS 2002.[79,80] MUST was designed to be used in the community and factors in BMI, weight loss, and acute disease effect, with referral to a dietitian recommended for a score ≥2 (Fig. 1.3). The NRS 2002, validated for in-hospital use, provides an initial screening based upon a BMI <20.5, recent weight loss, reduced dietary intake, and the presence of severe illness (Tables 1.1 and 1.2). During an inpatient hospitalization, nutritional plans are advised for patients with NRS-2002 scores of ≥3.

An evolving tool for preoperative assessment with bearing upon nutritional status is sarcopenia, a condition characterized by progressive and generalized loss of skeletal muscle mass and strength.[81] Sarcopenia is commonly measured by assessing psoas muscle density and total psoas area on preoperative CT scan.[82] Sarcopenia has been correlated with major postoperative complications in women following radical cystectomy[83] and with infectious complications in both men and women undergoing radical cystectomy.[84] While interesting and objective, measurement of total psoas area and psoas muscle density has not yet transitioned from retrospective research to mainstream clinical practice.

Preoperative Management of Malnutrition

While preoperative nutritional support has been found to improve surgical outcomes in other specialties, limited data exist in the urologic literature. Pilot studies with immunonutrition among bladder cancer patients undergoing radical cystectomy reveal an association of immunonutrition with decreased postoperative complications, including infections and paralytic ileus.[85,86] Larger studies are anticipated.

Applying data from other surgical fields, preoperative nutritional support may be useful for patients with severe malnutrition. In a study of 1085 abdominal surgery patients, patients with a NRS 2002 assessment score of ≥5 who received preoperative enteral or parenteral nutrition had fewer postoperative complications and a shorter length of stay as compared to those patients with severe malnutrition who did not receive preoperative nutritional supplementation.[87] When possible, enteral feeding, rather than parenteral, should be provided, as enteral nutrition is associated with fewer infectious complications and better glycemic control.[88] Among patients with mild-to-moderate malnutrition, there is no proven benefit to preoperative nutritional supplementation.[87,89] In a systematic review and meta-analysis of preoperative nutrition among patients undergoing gastrointestinal surgery, no differences in overall complications, infectious complications, or length of stay were identified among patients receiving preoperative liquid oral supplements as compared to those receiving usual care or dietary advice.[90]

Table 1.1 Initial Screening

1	Is BMI <20.5?	Yes	No
2	Has the patient lost weight within the last 3 months?		
3	Has the patient had a reduced dietary intake in the last week?		
4	Is the patient severely ill? (e.g., in intensive therapy?)		

Yes: If the answer is 'Yes' to any question, the screening in Table 1.2 is performed.
No: If the answer is 'No' to all questions, the patient is re-screened at weekly intervals. If the patient, e.g., is scheduled for a major operation, a preventive nutritional care plan is considered to avoid the associated risk status.

Infection and Urosepsis

Although community-acquired urinary tract infections (UTIs) are very common and are considered relatively easy to treat, complicated UTIs such as those acquired in the hospital setting are a legitimate cause for concern in urology. The term *complicated UTI* connotes infections brought about by a functional or anatomic abnormality in the urinary

Table 1.2 Final Screening

Impaired Nutritional Status		**Severity of Disease (≈ Increase in Requirements)**	
Absent Score 0	Normal nutritional status	Absent Score 0	Normal nutritional requirements
Mild Score 1	Wt loss >5% in 3 mths or food intake below 50–75% of normal requirement in preceding week	Mild Score 1	Hip fracture* Chronic patients, in particular with acute complications: cirrhosis*, COPD*. *Chronic hemodialysis, diabetes, oncology*
Moderate Score 2	Wt loss >5% in 2 mths or BMI 18.5–20.5 + impaired general condition or food intake 25–60% of normal requirement in preceding week	Moderate Score 2	Major abdominal surgery* Stroke* *Severe pnuemonia, hematologic malignancy*
Severe Score 3	Wt loss >5% in 1 mnth (>15% in 3 mths) or BMI <18.5 plus impaired general condition or food intake 0–25% of normal requirement in preceding week	Severe Score 3	Head injury* Bone marrow transplantation* *Intensive care patients (APACHE >10)*
Score	+	Score	= Total Score
Age	If ≥70 years: add 1 to total score above	= age-adjusted total score	

Score ≥3: the patient is nutritionally at risk, and a nutritional care plan is initiated.
Score <3: weekly screening of the patient. If the patient, e.g., is scheduled for a major operation, a preventive nutritional care plan is considered to avoid the associated risk status.

NES 2002 is based on an interpretation of available randomized clinical trials.
*indicates that a trial directly supports the categorization of patients with that diagnosis.
Diagnoses shown in *italics* are based on the prototypes given below.
Nutritional risk is defined by the present nutritional status and risk of impairment of present status, due to increased requirements caused by stream metabolism of the clinical condition.
A nutritional care plan is indicated in all patients who are (1) severely undernourished (score = 3), or (2) severely ill (score = 3), or (3) moderately undernourished + mildly ill (score 2+1), or (4) mildly undernourished + moderately ill (score 1 + 2).
Prototypes for severity of disease
Score = 1: a patient with chronic disease, admitted to hospital due to complications. The patient is weak but out of bed regularly. Protein requirement is increased but can be covered by oral diet or supplements in most cases.
Score = 2: a patient confined to bed due to illness, e.g., following major abdominal surgery. Protein requirement is substantially increased but can be covered, although artificial feeding is required in many cases.
Score = 3: a patient in intensive care with assisted ventilation, etc. Protein requirement is increased and cannot be covered even by artificial feeding. Protein breakdown and nitrogen loss can be significantly attenuated.
(With permission from Kondrup J, Allison SP, Elia M, Vellas B, Plauth M. ESPEN guidelines for nutrition screening 2002. Clinical nutrition (Edinburgh, Scotland). 2003;22(4):415-21.)

tract, but it may also be used to indicate an infection that occurs in a patient with altered defense mechanisms.[91] When an infection previously localized to the urinary tract enters the bloodstream and causes a systemic infection, urosepsis ensues.

Judicious use of prophylactic antibiotics in surgical procedures has served to minimize the incidence of these preventable yet potentially lethal complications in urologic practice.[92] However, the rising incidence of antimicrobial resistance, especially of gram-positive pathogens such as methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococci (VRE), can lead to treatment failure and life-threatening sepsis.[93] Moreover, the increasing numbers of patients who are immunocompromised either by an underlying disease (e.g., HIV/AIDS) or through concurrent medical therapy (e.g., steroids, chemotherapy)[94] also lead to greater infection risk. These risk factors are particularly relevant when surgery entails instrumentation and manipulation of the urinary tract. Given that certain host factors predispose the urologic patient to complicated infection, it is necessary to determine the need for antimicrobial prophylaxis preoperatively and to prevent the occurrence of systemic septicemia.

Both demographic factors and medical conditions play a role in susceptibility to complicated UTI. Advanced age in a patient should alert the urologist to the possible presence of UTI. The prevalence of UTI increases with age and reaches approximately 3.6% in men ≥70 years old and 7% in women ≥50 years old.[95] As previously discussed, nutritional imbalances leading to obesity and malnutrition could impair cellular immunity and thereby predispose patients to UTI. Preexisting local or systemic infections intuitively are associated with complicated UTI.

Recent antimicrobial use has been linked to complicated UTI, possibly through two mechanisms: (1) antibiotic therapy fails, and the initial infection, either systemic or local, progresses to complicated UTI or frank urosepsis; or (2) antibiotics used to eliminate competing pathogens promote the growth of resistant strains and lead to infection with a more virulent strain.[96] Diabetes mellitus not only increases the incidence of UTI in adults but also contributes to a complicated course despite antibiotic prophylaxis and treatment. This situation is the result of defects in the secretion of urinary cytokines and increased adherence of microorganisms to the uroepithelial cells in diabetic patients.[97]

Not surprisingly, many urologic and medical renal conditions are associated with an increased incidence of complicated UTIs and urosepsis. One of the most consistent contributors to complicated UTI is obstruction of the urinary tract.[98] This underlying mechanism encompasses the following: intrinsic disorders of the kidney, renal pelvis, and ureters (e.g., congenital anomalies including vesicoureteral reflux, renal or ureteral calculi, neoplasms, strictures); extrinsic abnormalities of the upper urinary tract (e.g., aberrant vessels, retroperitoneal hematomas or fibrosis, nonurologic neoplasms); and disorders of the bladder and bladder neck (e.g., BPH, prostate and bladder cancer, cystolithiasis, bladder neck contracture) and urethra (e.g., valves, strictures). Functional impairment of the bladder, as seen in spastic or atonic neurogenic bladders, may have the same consequences as conditions causing physical obstruction.[99] Renal diseases, whether unilateral, bilateral, or segmental, may also complicate UTI and include conditions such as azotemia, polycystic kidney disease, and papillary necrosis, as well as nephropathies brought about by abuse of analgesics such as nonsteroidal antiinflammatory drugs.[100]

Immunosuppressed urologic patients present a unique problem with regard to susceptibility to complicated UTI. Whether impairment of immunologic response was brought about iatrogenically (e.g., patients with cancer who are undergoing chemotherapy, transplant recipients receiving steroids) or was the result of a disease process (e.g., HIV/AIDS, persistent neutropenia or granulocytopenia),[94] avid use of broad-spectrum antibiotics not only for common infections but also for opportunistic organisms should be considered by the urologist for an optimal clinical outcome. Finally, urologic instrumentation leads to an increased probability of introducing microorganisms into an otherwise sterile urinary tract and thus predisposes patients to infections. The same principle applies to urologic procedures in which foreign bodies are purposefully left in the human body (e.g., ureteral stents, penile prostheses).[101] Although intended to elicit only a minimal inflammatory response, any foreign body can serve as a nidus of infection and must be removed promptly when it is determined to be the source of infection or when its presence in the body contributes to a complicated UTI.

Quantifying Comorbidity

In medicine, *comorbidity* is defined as the effect of all other pathologic conditions an individual patient may have other than the primary disease of interest. The very nature of comorbidities, as secondary or lesser diseases of interest, has led to some indifference among practicing clinicians and research investigators regarding the significance of these illnesses in treatment decision making and survival outcomes. Because of the significant correlation between advanced age and increased prevalence of preexisting comorbidities at the time of surgery, physicians have traditionally used age as a surrogate for the effects of concurrent medical conditions, especially in elderly urologic patients.[102] Although no one can discount the value of age in treatment decisions, the use of age as a strict criterion that may deny appropriate curative therapy to healthy older patients is unacceptable and may even have litigious consequences.

The impact of comorbidities is substantial in the field of urology, particularly in urologic oncology. An analysis of 34,294 newly diagnosed cases of cancer in patients from the Netherlands Eindhoven cancer registry showed that, aside from lung cancer (58%) and stomach cancer (53%), the crude prevalence of comorbidities was highest in malignant diseases of the kidney (54%), bladder (53%), and prostate (51%).[103] In terms of prognosis, Post and colleagues[104] acknowledged that comorbidity was the most important prognostic factor for 3-year survival in a population-based study of 1337 patients with localized prostate cancer. In a series of 1023 consecutive radical nephrectomies and nephron-sparing surgical procedures for RCC in Dresden, Germany, comorbidities were closely associated with overall morbidity and mortality.[105] With regard to treatment-related side effects, both peripheral vascular disease and

diabetes have been shown to be significant risk factors for development of impotence following external beam radiation for prostate cancer as well as for gastrointestinal and genitourinary toxicities.[106] Thus, comorbidities can affect almost all aspects of urologic disease but most importantly the incidence of posttreatment morbidity and all-cause death.

Up until the late 1980s, the effects of comorbidities were largely unquantifiable and subjective. As a result, certain beliefs and attitudes in clinical practice were based mostly on anecdotal data rather than on appropriate evidence-based information. The need for methods to quantify the effects of comorbidities led to the development of comorbidity scoring systems, which are gaining utility for both research and clinical purposes.

The most extensively studied and most commonly used comorbidity scoring scheme in medicine is the *Charlson Index score*.[107] Dr. Mary E. Charlson, a clinical epidemiologist and methodologist who was interested in improving clinical outcome in both medical and surgical patients, first published the index in 1987 at Cornell University in Ithaca, New York. The Charlson Index is a list of 19 pathologic conditions (Table 1.3). Based on the proportional hazards regression model that Charlson constructed from clinical data, each condition is assigned a weight from 1 to 6. The Charlson Index score is the sum of the weights for all concurrent diseases aside from the primary disease of interest. Thus, for example, in men with prostate cancer, although cancer is generally assigned a score of 2, in this case, men are assigned no points for prostate cancer because it is the primary index disease. In a cohort of 685 patients with breast cancer in the original study, the Charlson Index score showed a strong association of a 2.3-fold increase in the 10-year risk of mortality per 1-point increment in the comorbidity level.

Table 1.3 Weighted Index of Comorbidity [Defined by the Charlson Index]

Assigned Weights for Diseases	Conditions
1	Myocardial infarct Congestive heart failure Peripheral vascular disease Cerebrovascular disease Dementia Chronic pulmonary disease Connective tissue disease Ulcer disease Mild liver disease Diabetes
2	Hemiplegia Moderate or severe renal disease Diabetes with end organ damage Any tumor Leukemia Lymphoma
3	Moderate or severe liver disease
6	Metastatic solid tumor AIDS

Assigned weights for each condition that a patient has. The total equals the score. Example: chronic pulmonary (1) and lymphoma (2) = total score (3).

(With permission from Charlson ME, Pompei P, Ales K, MacKenzie CR. A new method of classifying prognostic comorbidity in longitudinal studies: development and validation. J Chronic Dis. 1987;40:373-83.)

The Charlson Index score provides a simple means to quantify the effect of comorbid illnesses, incorporate the severity of a particular disease (diabetes without complications versus diabetes with end-organ damage), and account for the aggregate effect of multiple concurrent disease processes on clinical outcome, most often mortality. In prostate cancer research, the Charlson Index score has been extensively evaluated as a predictor of both cause-specific mortality and all-cause mortality. Albertsen and colleagues[108] showed that the Charlson Index score provided significant predictive information on cancer-specific and all-cause survival independent of age, Gleason score, or clinical stage in a cohort of 451 patients with Jewett-Whitmore stage A1-B prostate cancer treated with hormonal ablation. In 2002, a competing risk analysis of 751 men who underwent radical prostatectomy for clinically localized prostate cancer at the Mayo Clinic in Rochester, Minnesota, showed that, whereas the Gleason score emerged as the only significant predictor of prostate cancer–specific mortality, both the Charlson Index score and the Gleason score were predictive of overall mortality.[109] Comparable results were reported by other groups who performed similar analyses using Charlson Index scores in prostate cancer outcome studies.[104,110,111] With recent efforts to minimize the overtreatment of men with prostate cancer, the Charlson Index has a critical predictive role. In a retrospective study of 1482 men with nonmetastatic prostate cancer diagnosed from 1997 to 2004, each point increase in Charlson score was associated with a twofold increase in hazard of nonprostate mortality. After stratification by tumor risk, prostate cancer mortality was rare among low-risk and intermediate-risk groups, leading to the recommendation that men with the highest Charlson scores should consider conservative management of low-risk and intermediate-risk tumors.[112,113] In a larger study of 140,553 men aged ≥ 66 years with early-stage prostate cancer who were diagnosed between 1991 and 2007 from the Surveillance, Epidemiology, and End Results-Medicare database, men with Charlson scores ≥ 3 were found to garner no survival benefit from aggressive treatment.[114]

The clinical utility of the Charlson Index score extends to other urologic diseases as well. With regard to bladder cancer, the Charlson Index score was evaluated in predicting adverse pathologic characteristics, cancer-specific death, and overall survival following radical cystectomy.[115] Logistic regression revealed that the Charlson Index score was independently associated with an increased risk of extravesical disease. Cox regression models further revealed that the index was significantly associated with decreased cancer-specific survival. In 302 men undergoing transurethral resection of the prostate (TURP) or simple prostatectomy for BPH, the Charlson Index score correlated with 5-year mortality.[116] Thus, even for nononcologic urologic operations, comorbidity indices have demonstrated power for predicting mortality following surgery.

Other indices of comorbidity are available but have not been as broadly used as the Charlson Index. Three prime examples are the Index of Co-Existent Disease (ICED),[117] the Kaplan-Feinstein Index (KFI),[118] and the Cumulative Illness Rating Scale (CIRS).[119] Similar to the Charlson Index, the

ICED, KFI, and CIRS are designed to measure the impact of concurrent diseases on prognosis. Because of the lack of definitive head-to-head comparisons of the various comorbidity assessments, no clear-cut evidence exists to establish the advantage of one scale over the other.[120] In fact, in a study in which Charlson Index scores were shown to be predictive of 5-year mortality following TURP for BPH, similar analysis using the KFI and ICED demonstrated comparable predictive power.[116]

Conclusion

It is the ultimate goal of every urologist to provide the best possible care for the urologic patient. The projected surge in life expectancy in the new millennium translates into an analogous increase in urologic patients who will potentially present with various comorbid diseases. These patients will require thorough evaluation including the addressing of associated comorbidities to obtain an excellent outcome. The impact of host factors and comorbidities cannot be taken lightly because more and more scientific evidence points to associations of these pretreatment parameters with a heightened risk for undesirable posttreatment complications. In particular, obesity, which is associated with other significant comorbidities and has been found to affect both the urologic disease process and consequent complications, must be investigated comprehensively. Furthermore, adequate assessment of nutritional status to ensure sufficient nutritional support in the surgical patient is also warranted.

Patients with host factors that predispose them to infections may require prophylactic antibiotic coverage and must be closely monitored to anticipate the need for further antimicrobial treatment to prevent urosepsis. Finally, various comorbidity scoring systems are being investigated for their clinical value and may further provide urologists and other clinicians with more accurate predictive models for assessing the risk of complications among patients with urologic diseases. As subsequent chapters in this book delve into more organ-specific, urologic disease–specific, or procedure-specific complications, we encourage the readers to make every effort in taking a broad, encompassing approach when evaluating urologic patients by diligently considering the effects of comorbid conditions in each individual person.

Chapter 1 Questions

1. By 2050, the estimated population of the United States ≥65 years of age will be:
   a. 25 million
   b. 42 million
   c. 67 million
   d. 88 million
   e. 110 million

2. Obesity is associated with increased rates of:
   a. Erectile dysfunction
   b. Stress urinary incontinence
   c. Kidney cancer
   d. Uric acid nephrolithiasis
   e. All of the above

3. What is the calculated BMI of a patient who is 6'0" tall and weighs 221 pounds?
   a. 24.3
   b. 27.8
   c. 30.2
   d. 33.2
   e. 38.6

4. Compared to men of normal weight, obese men have:
   a. Lower PSA levels
   b. Lower PCA3 levels
   c. Lower % free PSA levels
   d. Higher PSA levels
   e. Higher PCA3 levels

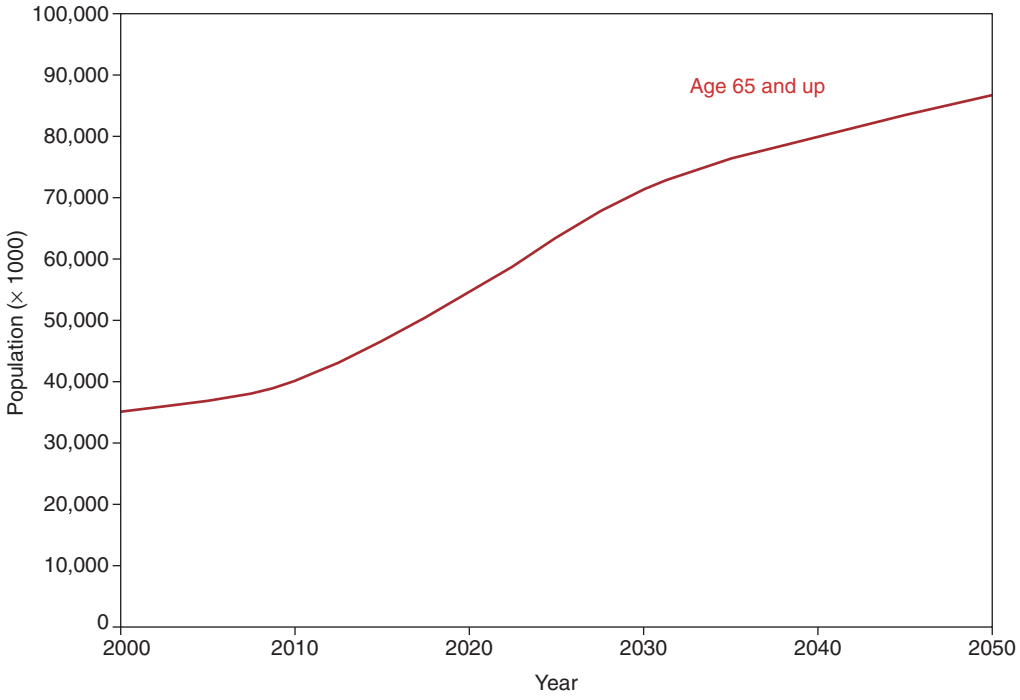
5. A validated tool that may be used for the assessment of inpatient nutritional status is:
   a. NRS 2002
   b. MUST
   c. MMSE
   d. Albumin
   e. Prealbumin

6. A 79-year-old male with muscle invasive bladder cancer is scheduled to undergo a radical cystectomy. He has a history of chronic obstructive pulmonary disease, congestive heart failure, obesity, and obstructive sleep apnea. What is his Charlson comorbidity score?
   a. 1
   b. 2
   c. 3
   d. 4
   e. 5

7. Which of the following statements regarding prostate cancer and obesity is *incorrect*?
   a. Obese men with prostate cancer have lower serum prostate-specific antigen levels relative to men of normal weight
   b. Among men undergoing an open retropubic prostatectomy, increasing BMI is associated with increasing operative time and increasing intraoperative blood loss
   c. Mildly obese men undergoing radical prostatectomy have worse health-related quality of life postoperatively than men of normal weight
   d. Men with higher BMIs present with higher-grade tumors and more advance pathologic stages
   e. Increased body weight was found to be associated with an increased risk of death from prostate cancer in a large, prospectively studied population[31]

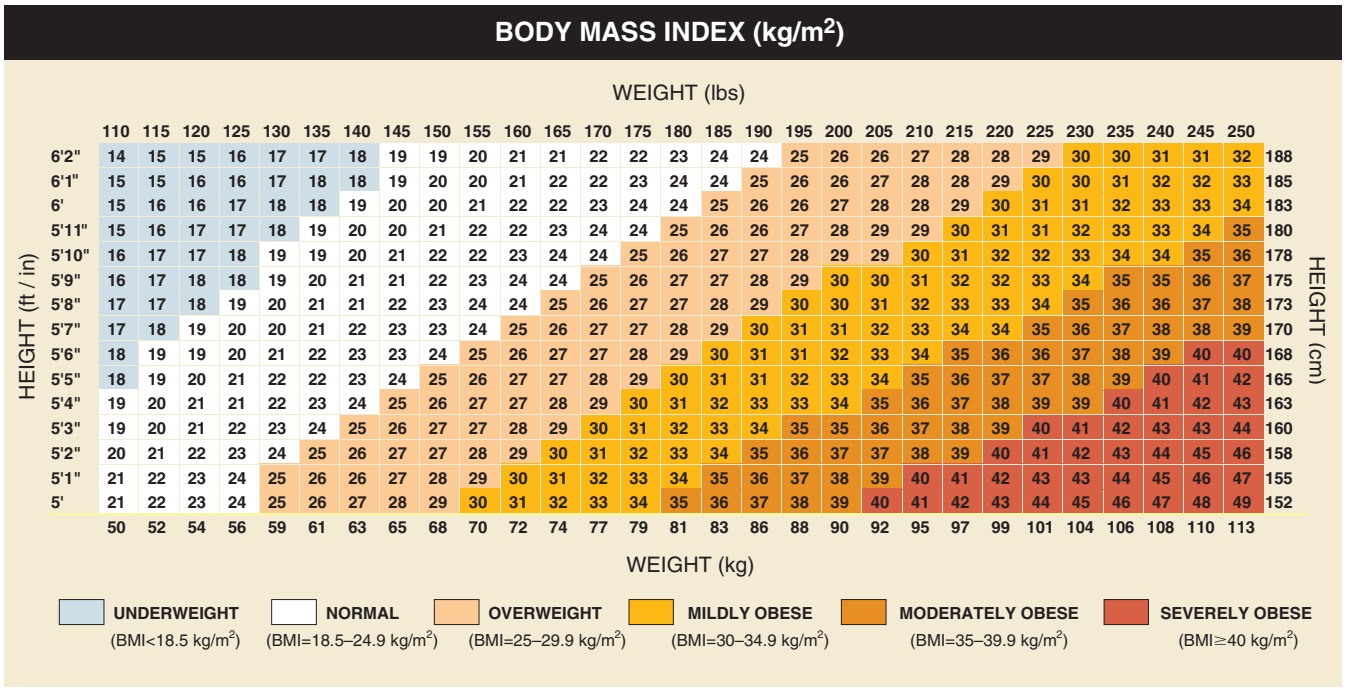
8. A 67-year-old male just underwent emergent stent placement for a 7 mm proximal right ureteral calculus with associated hydronephrosis, a fever of 101.7°F (38.7°C), and a blood pressure of 86/57. Risk factors in his history that increase his risk for urosepsis include:
   a. Ongoing cisplatin and etoposide chemotherapy for treatment of small cell lung cancer
   b. An indwelling Foley catheter for a recent episode of acute urinary retention
   c. Prednisone taper following a recent diagnosis of herpes zoster ophthalmicus
   d. Obstructing urolithiasis
   e. All of the above

9. In urologic diseases, comorbidity indices have demonstrated power for predicting mortality among patients undergoing:
   a. RPLD for testis cancer
   b. InterStim placement for refractory urinary urgency/frequency
   c. Transobturator sling placement for stress urinary incontinence
   d. Transurethral resection of the prostate for BPH
   e. Percutaneous nephrolithotomy for nephrolithiasis



10. The most important prognostic factor for 3-year survival among men with localized prostate cancer is:
    a. Gleason score
    b. PSA doubling time
    c. Comorbidities
    d. Clinical stage
    e. Interval of time between initial treatment and biochemical recurrence

Answers



1. **d.** According to the US Census Bureau, and as illustrated in Case Fig. 1.1, the US population ≥65 years of age is exponentially growing and is estimated to reach approximately 88.5 million by 2050.
2. **e.** In Dr. Mydlo's article "The impact of obesity in urology," he reviewed that obesity is a risk factor for stress urinary incontinence, erectile dysfunction, infertility, renal cell carcinoma, and renal calculi.
3. **c.** Using the formula BMI = Weight (in kilograms)/height (in meters) squared, 100 kg/(1.82 m)^2 = 30.2. Alternatively, using Case Fig. 1.2, a man who is 6'0" tall and weighs 220 pounds has a BMI of 30, falling within the mildly obese group.
4. **a.** In Baillargeon's population-based study of 2779 men without prostate cancer, mean PSA decreased in

a linear fashion with an increase in BMI category, from 1.01 ng/mL in normal-weight men to 0.69 ng/mL in obese men, after adjusting for race/ethnicity and age.

5. **a.** The NRS 2002 is a predictive, validated assessment tool for screening of undernutrition in hospitalized patients. In contrast, the Malnutrition Universal Screening Tool (MUST) is used to detect undernutrition among community-dwelling adults. While widely used as assessments for nutritional status, albumin and prealbumin are affected by many disease processes, including liver disease, kidney disease, and acute inflammation and are therefore unreliable for monitoring nutritional status.
6. **b.** The patient receives 1 point each for his diagnoses of chronic obstructive pulmonary disease and congestive heart failure. As his bladder cancer is our primary disease of interest, the patient receives no points for that diagnosis.
7. **c.** Thus far, prospective studies have failed to demonstrate large differences in postoperative health-related quality of life between mildly obese men and men of normal weight.
8. **e.** One of the most consistent contributors to complicated urinary tract infections is obstruction of the urinary tract, including obstruction due to ureteral calculi. Indwelling catheters are associated with an increased risk of urosepsis. Patients on chemotherapy or immunosuppression due to steroids are also at increased risk for urosepsis.
9. **d.** In Krousel-Wood et al.'s study of 302 men undergoing transurethral resection of the prostate (TURP) or simple prostatectomy for BPH, the Charlson Index score correlated with 5-year mortality.
10. **c.** Post and colleagues found that comorbidity was the most important prognostic factor for 3-year survival in a population-based study of 1337 patients with localized prostate cancer.

Chapter 2 Questions and Answers

KEY POINTS

1. Accurate preoperative identification of patients at risk for developing postoperative pulmonary complications optimizes preoperative testing and ideally minimizes occurrence of postoperative complications.
2. Risk factors for respiratory complications stem from patient-related factors as well as from procedure-related factors including surgical site, duration of surgery, and type of anesthesia. Procedure-related factors carry the highest risk for postoperative pulmonary complications.
3. Urologists should identify and inform patients who smoke of the associated risk factors for pulmonary complications as well as for urothelial cancer. Cigarette smoking cessation should be 4 weeks or more prior to surgery to begin to provide benefit.
4. Multiple new preoperative risk calculators are available to assist in assessing risk stratification. The most important patient-related risk factor is age, increasing significantly over the age of 50.
5. Recommendations for patients undergoing major urologic procedures include intermittent pneumatic compression, use of graduated compression stockings, early and frequent ambulation, in addition to pharmacologic venous thromboembolism (VTE) prophylaxis when possible.

Multiple studies evaluating complications following noncardiac surgery demonstrate that postoperative pulmonary complications (PPCs) occur at similar frequency and result in similar rates of morbidity and mortality as cardiovascular complications.[1,2] The reported rates of PPCs range from 5% to 40%, dependent upon procedure risk, with PPC-associated mortality risks ranging from 10% to 25%.[3–7] Data from the National Surgical Quality Improvement Program (NSQIP) demonstrate that PPCs are the most costly of postoperative complications and result in the longest hospital length of stay.[8]

Although there is no exact definition of what constitutes a PPC, most literature includes conditions such as atelectasis, infection (pneumonia, bronchitis), respiratory failure

requiring prolonged mechanic respiratory support, acute respiratory distress syndrome (ARDS), and hypoxemia.[7,9] For the purposes of this chapter, we have also included discussion regarding pulmonary embolism and additional surgical complications such as pneumothorax. The economic impact of PPCs has been estimated to account for 3.4 billion dollars in health care costs in the United States.[10] Ultimately, prevention of PPC requires careful assessment of risk factors, both from patient characteristics and procedure-associated factors. Proper identification of these risk factors aids development of strategies to prevent these complications.

Preoperative Pulmonary Assessment

Identifying the primary risk factors associated with PPCs assists with accurate risk stratification prior to surgery and informs strategies to reduce morbidity and mortality. Pulmonary risks factors stem from two sources, preexisting patient characteristics as well as procedure-associated factors.

PATIENT FACTORS

Identifying factors that predispose to the development of PPC requires an understanding of the principal patient-related risk factors as well as an understanding of the degree of risk associated with these factors. The American College of Physicians (ACP) provides guidelines for assessing PPC risk factors for noncardiopulmonary surgery. These guidelines stem from a systematic review of the existing literature performed by Smetana and colleagues.[1,2] This work, published in 2006, remains the largest evidence-based source of information regarding PPC. From these data, the primary patient-related factors associated with increased risk of PPCs and are detailed in Table 2.1.

The most important patient-related risk factors found by this review are patient age and presence of an increased American Society of Anesthesiologist's (ASA) score.[1,11] Age confers an increasing level of risk for PPC for each decade over 50. Ultimately, as age increases beyond 80, the odds ratio increases to 5.63 as compared to patients younger than 50. Given that the population requiring major urologic surgery is often in this age range, this risk factor becomes especially pertinent to consider during urologic preoperative evaluation.[12,13]

The existence of chronic lung diseases such as chronic obstructive pulmonary disease (COPD) warrants special consideration when assessing PPC risk. In fact, the presence of chronic lung disease represents the most common risk factor identified by Smetana and colleagues. However, the degree of this risk factor varies widely upon the degree of pulmonary impairment. Consequently, the presence of preoperative congestive heart failure (CHF) confers a higher risk for PPC than COPD (OR 2.93 vs 2.36, respectively).

Additional significant risk factors for PPC include active cigarette use and decreased overall functional dependence. More recently, data regarding obstructive sleep apnea (OSA) indicate that OSA confers an increased risk for immediate airway management complications as well as for PPC.[14–16]

Table 2.1 Primary Patient Related Risk Factors From the American College of Physicians Guideline

Risk Factor	Odds Ratio for PPC	95% Confidence Interval
Age		
50–59	1.50	1.31–1.71
60–69	2.09	1.65–2.64
70–79	3.04	2.11–4.39
≥80	5.63	4.63–6.85
ASA Score ≥2	4.87	3.34–7.10
Congestive heart failure	2.93	1.02–8.03
Total functional dependence	2.51	1.99–3.15
COPD	2.36	1.90–2.93
Cigarette use	1.40	1.17–1.69

COPD, chronic obstructive pulmonary disease; PPC, postoperative pulmonary complication

(Adapted from Smetana GW, Lawrence VA, Cornell JE, American College of Physicians. Preoperative pulmonary risk stratification for noncardiothoracic surgery: systematic review for the American College of Physicians. Ann Intern Med. 2006;144(8):581-95.)

Patients should thus be screened for signs and symptoms of OSA prior to undergoing anesthesia. Several tools for assessing for OSA have been published and assist with assessing level of OSA risk.[17,18]

Interestingly, this systematic review did not find strong evidence demonstrating an increased risk of pulmonary complications amongst patients with obesity and controlled asthma, findings corroborated by additional studies.[3,19] However, obesity remains a risk factor for development of venous thromboembolic complications including pulmonary embolism and thus remains an important patient factor clinicians should consider when assessing risk.

While the ACP guideline provides a necessary evidence-based framework for assessing risk for PPC, the data have not been systematically updated for nearly 10 years. More recent data indicate that additional risk factors include respiratory infections within 1 month prior to surgery, diabetes, preoperative hypoxemia, and preoperative anemia.[3,4,20–22] Currently, prospective studies are under way to improve PPC definition and identify more accurate risk factors.[23]

Given that most patients requiring urologic intervention are over the age of 50, and many patients undergoing procedures associated with urothelial carcinoma have a history of significant tobacco use, the risk of PPC in this patient cohort warrants special attention. Prior exposure to bleomycin presents an additional urologic-specific patient risk factor that will be discussed in more detail later in the chapter.

CIGARETTE SMOKING

When considering patient-related factors, cigarette smoking warrants additional commentary. Smoking tobacco is a well-known risk factor for cardiac, vascular, infectious, and respiratory complications.[24–27] Many PPCs occur at a higher rate in smokers, conferring an increased risk with an odds

ratio of 1.4 to 4.3.[6,28] Tobacco smoking confers additional risk for urologic malignancies, increasing the risk of renal cell carcinoma and urothelial carcinoma, and continued tobacco use is associated with disease progression and recurrence.[29–34]

In their prospective study of 200 patients undergoing coronary artery bypass surgery, Warner and associates demonstrated that patients who had stopped smoking ≥8 weeks preoperatively had a significantly lower risk of pulmonary complications than did patients who were active smokers (14.5% vs 33%).[35] Moreover, patients who had stopped smoking for >6 months had pulmonary complication rates similar to those patients who had never smoked (11.1% vs 11.9%). Surprisingly, patients who had quit smoking <8 weeks preoperatively experienced more untoward pulmonary events than did active smokers (57% vs 33%). This appears to be due to increased airway reactivity and sputum production that occur in the initial period after smoking cessation.[9] Recent studies have corroborated these findings, indicating that smoking cessation ultimately benefits patients but requires 4 to 6 weeks to provide benefit.[36–38]

Given the important role cigarette smoking plays both in the pathophysiology of urologic malignancies and on the risk of PPC as well as other major postoperative complications, the urologist is in a unique position to intervene and provide guidance on smoking cessation. In addition, observational studies indicate that patients may be more receptive to quitting during the perioperative period.[39,40] A recent prospective study within a urology clinic demonstrated the efficacy of this approach.[41]

Patients who smoke should be identified preoperatively. The duration and amount of smoking should be quantified. These patients should be informed that smoking increases the perioperative risk and also that quitting can decrease this risk. Preoperative abstinence should be recommended for a minimum period of 4–6 weeks prior to surgery.

PROCEDURE FACTORS

Procedure-related factors associated with risks for PPC are displayed in Table 2.2 and are adapted from the ACP guideline.[1,2] In terms of risk assessment, procedure relegated factors represent the most significant predictors for development of PPC.

Table 2.2 Primary Procedure Related Risk Factors (American College of Physicians Guideline)

Risk Factor	Odds Ratio for PPC	95% Confidence Interval
Surgical site		
Aortic	6.90	2.74–17.3
Thoracic	4.24	2.89–6.23
Any abdominal	3.01	2.43–3.72
Upper abdominal	2.91	2.35–3.60
Emergency surgery	2.21	1.57–3.11
Surgery >3 hours	2.26	1.47–3.47

PPC, postoperative pulmonary complication
(Adapted from Smetana GW, Lawrence VA, Cornell JE, American College of Physicians. Preoperative pulmonary risk stratification for noncardiothoracic surgery: systematic review for the American College of Physicians. Ann Intern Med. 2006;144(8):581-95.)

Surgical Approach and Anatomic Considerations

Special consideration should be paid toward surgical anatomic location. While certain surgical sites (aortic, thoracic, neurologic) are not common in urologic procedures, it is important to note that abdominal surgical location confers an odds ratio of 3.01 and thus is a critical factor to be considered as risk factor for PPC. Regardless of proximity to the diaphragm, surgical trauma to the abdomen impacts respiratory function. Abdominal incisions decrease lung volumes in a restrictive pattern, resulting in reduction in vital capacity of 50–60% and functional residual capacity by approximately 30%.[42,43] Incisional pain limits respiratory motion, often subconsciously, promoting development of atelectasis and pleural effusions. Manipulation of the intestines during transperitoneal dissection can result in phrenic nerve stimulation, which further impairs normal respiratory function.[9,44]

Urologic procedures that involve, or are in close proximity to, the diaphragm represent a high-risk group. This category includes surgical approaches utilizing flank, subcostal, and thoraco-abdominal incisions. Additionally, minimally invasive renal surgery, upper retroperitoneal dissection, and percutaneous renal access present anatomic risk to the pulmonary space. Proximity to the diaphragm and pleural cavity may result in both obvious and discrete injury to the diaphragm and entry into pleural space. While these injuries are often recognized and managed intraoperatively, opportunity for occult injury should still be considered and postoperative assessment should address this risk.

Additional procedure-related factors include prolonged surgical time (>3 hours) and emergent procedures.[1,2]

Anesthesia

Evidence also supports that general anesthesia represents an independent risk factor for PPC. Induction of general anesthesia results in an immediate development of atelectasis due to collapse of lung tissue, ventilation-perfusion mismatch, creation of respiratory dead-space, hypoxemia, and decreased surfactant function.[9] Narcotics, sedatives, and other centrally acting drugs may depress respiratory drive and further increase risk for PPC.

PREOPERATIVE PATIENT EVALUATION

The evaluation of preoperative pulmonary risk begins with a detailed history and physical examination. Patients with a smoking history should be identified and efforts included to quantify duration and amount of smoking. A history of chronic lung disease should also be identified. A recent history of an upper respiratory infection, including influenza, should also be identified. A thorough pulmonary evaluation such as exercise intolerance, chronic cough, sputum production, previous pulmonary surgery, previous chemotherapy (see later), dyspnea at rest or on exertion, wheezing, rales, cyanosis, or weakness or debilitation assist in identifying patients at risk. Evaluation for signs of sleep apnea may also help with risk stratification.[17]

A chest radiograph should be obtained in all patients with any of the above risk factors or over the age of 50. However, clear evidence supporting a benefit from obtaining routine chest radiographs does not currently exist.

Evidence indicates that preoperative pulmonary function testing (PFT) does not accurately predict PPC, and consequently these tests are overused.[45,46] Debate continues regarding the value of PFT. The ACP systematic review concluded that PFT is reasonable for patients with COPD or asthma in whom clinical evaluation is unclear and in patients with unexplained dyspnea or exercise intolerance.[2,47]

As preoperative hypoalbuminemia predicts PPC, recognition of patients with severe malnourishment should be identified, and it is reasonable to recommend preoperative nutritional supplementation.[48,49]

Several risk calculators have been developed to provide quantitative assessment for pulmonary risk and are available online.[50–53] One example is the ARISCAT risk score, which was developed and validated from European surgical databases and uses five risk factors to predict risk of PPC.[3,54] This is shown in Table 2.1. Implementation of these risk calculators offers numerical risk evaluations that may assist with clinical decision making.

Preoperative Strategies

Once a patient is identified as having a higher risk for PPC, several strategies may be employed to decrease that risk. As stated above, urologists should instruct and guide current smokers to stop smoking and provide tools and referrals for patients that are willing to attempt cessation.

Patients with chronic lung disease who do not appear to be in optimal status should have surgery deferred until their pulmonary status has been medically optimized. Patients with a history of asthma should also be assessed for how well their asthma is controlled. At the time of surgery these patients should be free of wheezing and should use beta-agonist inhalers prior to intubation and during the perioperative period. Any signs of a recent upper respiratory infection, even for patients without a history of lung impairment, should prompt further workup and delay in surgical timing until recovery from respiratory infection is complete.

Preoperative pulmonary physical therapy has been shown to reduce postoperative atelectasis and hospital stay in patients undergoing cardiac surgery.[55–57] Preoperative teaching with incentive spirometry for all patients undergoing elective abdominal surgery results in improved understanding of the techniques and perioperative use.[58] It is our practice to provide this teaching and to reinforce incentive spirometry in the perioperative period.

Postoperative Strategies

The strategy for postoperative pulmonary rehabilitation differs from preoperative approaches in that postoperative tactics apply to every patient, regardless of preoperative risk level. These strategies focus on maneuvers aimed to counteract the surgical and anesthesia impairments on respiratory function. Adequate pain control and lung expansion through incentive spirometry (IS), coughing, and early ambulation comprise the cornerstone of such strategies.

INCENTIVE SPIROMETRY AND DEEP BREATHING EXERCISES

While a few small trials demonstrate that utilizing postoperative IS and deep breathing exercises (DBE) reduces PPC and length of stay,[58–60] a recent Cochrane review found no evidence that IS prevented PPC.[61] The authors concluded that the evidence for this conclusion is of low quality and that higher quality trials are needed to evaluate the efficacy of IS.

It remains our practice to employ incentive spirometry in both the immediate postoperative and perioperative period.

EARLY MOBILIZATION

Facilitating early ambulation improves fluid mobilization and increases respiratory utilization. While very few studies provide guidance on the impact of mobilization, one study demonstrated an increase in PPC for each additional day of delay in mobilization following abdominal surgery.[62] It remains our practice to encourage ambulation and routinely employ the assistance of physical therapists for patients that require assistance.

PAIN CONTROL

Adequate pain control ameliorates the pulmonary functional depression induced by surgical incisions and assists with early ambulation. However, use of opioid efficacy is limited by subsequent depression of the respiratory drive. Epidural anesthesia has been associated with fewer PPCs, including in patients with COPD undergoing abdominal surgery.[63,64] Intercostal nerve blockade may also help reduce PPC in patients undergoing subcostal or upper abdominal incisions.[65] For patients with risk factors for PPC, consideration of epidural anesthesia or intercostal nerve block should be considered when applicable.

NASOGASTRIC TUBE

Routine use of postoperative nasogastric tube (NGT) increases PPC including pneumonia and atelectasis, although on Cochrane review this trend was insignificant ($p = 0.07$).[66,67] We do not recommend routine postoperative NGT and employ this only in situations when worsening postoperative nausea, distention, or bilious vomiting develop due to postoperative ileus.

Bronchospasm

Bronchospasm in the postoperative setting may occur due to histamine release from perioperative medications, aspiration, and exacerbation of underlying pulmonary disease such as asthma or COPD. Management rests upon the identification of an underlying cause and treating it appropriately. Removal of offending drugs or allergens and addressing asthma or COPD with inhaled bronchodilators

represent first-line strategies.[68] For refractory cases, consider employing systemic steroids.

Atelectasis

Atelectasis commonly occurs following abdominal surgery, affecting patients in all ranges.[69,70] A consequence of surgical and anesthetic effects, atelectasis develops when dependent airways collapse, ultimately leading to changes in the compliance of lung tissue, decreased ventilation in these regions, and reduced movement of airway secretions.[71,72–74] These changes result in decreased oxygen exchange and increase respiratory effort and hypoxemia. In younger healthy patients, these changes may result in little to no clinical effect but may significantly alter the clinical course for patients with impaired lung function or comorbidities such as CHF.

Atelectasis develops in the early postoperative course with symptoms of hypoxemia typically becoming apparent approximately 48–60 hours following surgery and continuing for several days.[75,76] Hypoxemia that develops earlier than this time course (i.e., in the postanesthesia recovery unit) should prompt urgent investigation into alternative PPC including pneumothorax, upper airway edema, and anesthesia effects. Atelectasis in the postoperative setting is most commonly nonobstructive in nature and typically results from loss of contact between the parietal and visceral pleurae or compression of the lower and middle lobes, often due to pleural effusion.[77]

Within the appropriate clinical time course, atelectasis should be suspected when findings such as tachypnea, dyspnea, and hypoxemia are noted. Patients should be assessed for abundant sputum production and secretions, evident as rhonchi on auscultation or frequent productive cough. Obtaining a chest radiograph or chest computed tomography (CT) often confirms the diagnosis.[78]

Management of atelectasis through methods to reverse the process of lung volume collapse can prevent further PPC.[79] Strategies for managing atelectasis differ depending upon the level of airway secretions. For those without abundant secretions, implementation of supplemental oxygen, DBE, and IS remains the mainstay of initial management. Patients without secretions that remain hypoxic and with continued increased respiratory effort may benefit from positive airway pressure (CPAP). Squadrone et al. reported results of a randomized multicenter controlled trial of CPAP versus supplemental oxygen alone and demonstrated a decrease in intubation, pneumonia, and sepsis for patients receiving CPAP.[80] For patients with significant secretions, frequent chest physiotherapy and suctioning (nasogastric if the patient is not able to expectorate) should be implemented. In patients who fail to improve with these methods, consider pulmonary consultation for consideration of possible bronchoscopy and other techniques aimed to improve secretion clearance.[81,82]

Pleural Effusion

Limited data suggest that pleural effusion detected on chest radiograph occurs in up to 49% of patients' surgery when evaluated between 48 to 72 hours following abdominal surgery.[83] Pleural effusion appears to occur more commonly following upper abdominal surgery. Management of effusion is primarily conservative, as most of effusions resolve spontaneously. Pulmonary toilet with DBE and IS as well as early and frequent ambulation may serve to hasten resolution.

In the setting of persistent effusion or clinical concern, diagnostic evaluation of an effusion requires thoracentesis.[84] Thoracentesis can be performed at the bedside, and analysis can help establish diagnoses including malignancy, empyema, chylothorax, urinothorax, hemothorax, and infection.[85]

Postoperative Pneumonia

The incidence of postoperative pneumonia ranges from 1.5% to 50%, depending on a wide array of conditions including type of anesthesia, surgical details, and patient risk factors.[86,87] Postoperative pneumonia can present similarly to other conditions, such as atelectasis, pulmonary edema, and pulmonary embolism.[88] However, postoperative pneumonia requires accurate diagnosis as it is associated with mortality rates from 1.5% to 10%.[87,89]

Postoperative pneumonia should be considered in patients with fevers, increased white blood cell count, and chest imaging demonstrating new onset pulmonary infiltrates. Clinical symptoms of fever, tachypnea, dyspnea, and hypoxemia typically develop within the first five postoperative days.[90,91] Risk factors such as COPD, altered lung defenses, and active smoking should increase clinical suspicion.

Successful management of postoperative pneumonia requires accurate pathogen identification and appropriate antibiotics.[92] These infections, primarily nosocomial in origin, frequently result from resistant organisms, although multiple organisms may be identified. One study demonstrated that the most common pathogens were gram-negative bacteria (e.g., *Pseudomonas aeruginosa, Klebsiella pneumoniae, Acinetobacter* species), *Staphylococcus aureus,* and *Streptococcus pneumoniae.*[90] Prolonged intubation and exposure to antibiotics as well as COPD may increase risk for pneumonia due to organisms such as *Pseudomonas aeruginosa, Acinetobacter,* or methicillin-resistant *S. aureus* (MRSA).[93–96] Postoperative treatment requires accurate collection of respiratory culture and prompt empiric antibiotics.

Aspiration pneumonia during the postoperative period may result in patients with risk factors for decreased protection of their airways. These include neurologic disorders, impaired cough reflex, impaired mental status following surgery leading to dysfunctional swallowing, and postoperative vomiting. Introduction of gastric fluids or particulate matter into the lower airways may stimulate an inflammatory response and subsequent chemical pneumonitis, bacterial infection, or mechanical obstruction.[97–99]

Chemical pneumonitis occurs quickly after aspiration of gastric contents and may lead to dyspnea and respiratory distress.[100] Clinical symptoms include abrupt dyspnea, cyanosis, severe hypoxemia, and infiltrates on chest imaging. The inflammatory response may rapidly progress to acute respiratory distress syndrome (ARDS) and lead to respiratory failure.[101] As ARDS develops, inflammation of

the lung parenchyma results in systemic release of inflammatory mediators and frequently results in multisystem organ failure.[102] Treatment of ARDS involves mechanical ventilation, treatment of underlying causes, supportive care, and antibiotic coverage if indicated.

Gupta and colleagues have developed and validated a risk calculator for predicting postoperative pneumonia. This tool is available for free download at surgicalriskcalculator.com.[53]

Postoperative Management for Patients With Obstructive Sleep Apnea

More than half of patients with clinically important obstructive sleep apnea (OSA) present for surgery without formal diagnosis of OSA.[103,104] As the prevalence of obesity continues to rise, the rates of undiagnosed OSA in surgical patients will likely continue to increase.[105] As a result of the large number of patients that are undiagnosed, heightened vigilance for postoperative complications in patients with risk factors for OSA, such as obesity, should be considered.

Hypoventilation, periods of central apnea and upper airway obstruction combine to lead to rapid hypoxemia for patients with OSA. Consequently, careful monitoring of blood oxygen saturation both in the postanesthesia recovery unit, and also during postoperative hospital stays, is prudent. Patients who use CPAP at home should resume as soon as possible following surgery.[106,107] The evidence does not demonstrate a clear benefit for initiating CPAP in patients with OSA who have not used this preoperatively unless these patients are at high risk for PPC.[80] For patients demonstrating hypoxemia or hypoventilation following surgery, implementation of CPAP should be considered on an individual basis.

Complications Involving the Pleural Space

Injury involving the pleural cavity can occur during abdominal surgery, although risk is highest during surgery in the upper abdomen or upper retroperitoneum. These injuries occur both during open and laparoscopic procedures. Oftentimes violation of the pleural space is noted intraoperatively and should be suspected during laparoscopic surgery when excessive diaphragm motion, or billowing, is noted.[108] During open procedures, bubbling noted in the operative field may indicate an occult violation of the diaphragm and pleural cavity. Occult injuries should be considered when hypoxemia or dyspnea is discovered in the postanesthesia recovery unit. However, clinical manifestation of pleural space injury is variable, ranging from an asymptomatic small apical pneumothorax to a large tension pneumothorax that may lead to hemodynamic instability.

PNEUMOTHORAX

Gas may enter the pleural cavity through several routes. These range from patent congenital diaphragm defects to direct injuries to the diaphragm, chest wall, or via musculofascial planes of the diaphragm and mediastinum during insufflation with carbon dioxide (CO_2).[109,110] The volume of gas that enters the pleural cavity determines the degree of pneumothorax (PTX). Small amounts of gas often do not increase the pressure in the pleural cavity above atmospheric pressure, and thus clinical symptoms may not develop. Often these PTX are detected on chest radiograph and do not demonstrate mediastinal shift or represent clinically significant entities.[111] As the amount of gas increases, the pressure in the affected pleural space increases above atmospheric pressure, eventually compressing the ipsilateral lung. Mediastinal shift to the contralateral hemithorax and flattening of the ipsilateral hemidiaphragm are classically noted on radiograph.

Reported rates of PTX following urologic surgeries range from 0.6% to 25%.[112–116] The rates for PTX following laparoscopic surgeries appear lower (0.6% to 8.5%).[112,114–116]

Management of PTX begins with clinical suspicion. When noted intraoperatively, the anesthesiologist should be informed to confirm hemodynamic and respiratory stability. Once established, repair of diaphragm injury should be performed using running, absorbable suture. Prior to closure of this suture, a red rubber catheter can be introduced into the pleural space with its distal end submerged under water or saline. The anesthesiologist then ventilates the patient in order to evacuate gas from the pleural space via the catheter until no further bubbles are noted from the red rubber catheter. The catheter is removed when the diaphragm suture is tied down.[117] This approach can be performed with equal effectiveness for both open and laparoscopic procedures and is necessary when repairing diaphragmatic incisions used during thoraco-abdominal approaches. In the case of a diaphragmatic excision due to malignancy, successful mesh replacement of the diaphragmatic defect secured with nonabsorbable sutures has been reported.[117]

Despite the low rates of these injuries, clinical suspicion for occult injury should remain. Postoperative hypoxemia or dyspnea should be investigated with chest radiography. If central venous catheterization was performed for intraoperative fluid management, postoperative chest radiography should be performed. Routine use of postoperative chest imaging may identify small PTX without clinical sequelae.[111] These can be safely managed conservatively and followed with serial chest radiograph. In the event that a large PTX is noted, management with a tube thoracostomy is recommended.

CHYLOTHORAX

Chyle accumulation within the pleural space is a rare complication. Case reports describe chylothorax following retroperitoneal surgeries; however, these occur in conjunction with chylous ascites and subsequent communication into the pleural space.[116,118] Management includes diagnosis through thoracentesis and treatment of the underlying lymph leakage. Successful pleural space drainage and sclerotherapy have been reported.[118]

HEMOTHORAX

Accumulation of blood within the pleural space following urologic surgery is also a rare complication, with only a few

case reports available. Abreu et al. report one case (0.08%) in their review of 1129 patients undergoing laparoscopic urologic surgery.[116] In this case, an intercostal artery was injured, and repair required emergent open thoracotomy. Additional case reports describe hemothorax following laparoscopic pyeloplasty, laparoscopic cryoablation of renal masses, and percutaneous nephrolithotomy.[119–121] Management requires identification of the bleeding source and possible tube thoracostomy.

HYDROTHORAX

Iatrogenic instillation of irrigation fluid into the pleural space may result in hydrothorax. Hydrothorax has been reported as a complication following percutaneous nephrolithotomy.[122,123] Supracostal percutaneous nephrolithotomy may result in higher risk than standard approaches.[122] Management may require tube thoracostomy. For additional discussion of hydrothorax, please refer to the section below regarding percutaneous nephrolithotomy.

Pulmonary Embolism

Pulmonary embolism (PE) results from venous thromboembolism (VTE) and is a potentially fatal pulmonary complication. Prior to use of VTE prophylaxis, studies estimated the incidence of deep vein thrombosis (DVT) in hospitalized patients to range between 10% and 80%, with fatal PE ranging from 0.1% to 7% in patients undergoing elective surgery.[124] While DVT prophylaxis has decreased these rates, VTE and PE remain serious postoperative complications.

Risk for postoperative patients varies depending upon multiple factors.[124–127] Significant risk factors include age, prior VTE, history of malignancy, obesity, and hypercoaguable state (e.g., Factor V Leiden) as well as medical comorbidities. The American College of Chest Physicians provides guidelines to risk stratify surgical patients.[128] Many urologic procedures fall into the moderate risk or higher categories.

Strategies for prevention of VTE aim to decrease risk of subsequent PE. Nonpharmacologic approaches employ frequent, early ambulation, compression stocking, and pneumatic compression devices and may be sufficient for patients who are very low or low risk. In patients who are moderate or higher risk, including pharmacologic prophylaxis is preferred. Pharmacologic prevention must be balanced with potential for bleeding complications in the perioperative period. Options for pharmacologic prevention include unfractionated heparin, low-molecular-weight heparin, fondaparinux, and novel oral antithrombotic agents (e.g., rivaroxaban, dabigatran, apixaban). Regional and spinal anesthesia should be considered for higher risk patients undergoing lower abdominal or pelvic urologic procedures as these have been associated with a decreased risk of PE when compared with general anesthesia.[129]

The clinical presentation of PE is varied and nonspecific. Patients may be asymptomatic but may also experience sudden shock and death.[130] The most common symptoms of PE, according to two large prospective studies, are dyspnea (73%), pleuritic chest pain (44%), cough (37%), orthopnea (28%), calf/thigh pain/swelling (44%), wheezing (21%), and hemoptysis (13%).[130] Despite these clinical indicators, patients with large PE may report mild or no symptoms.[130–132] The most common clinical signs include tachypnea (54%), calf/thigh swelling/edema/erythema (47%), tachycardia (24%), and rarely fever (3%). Unfortunately, given the nonspecific nature of this clinical presentation, the sensitivity and specificity for PE on clinical evaluation are 85% and 51%, respectively.[133]

Clinical suspicion for PE in the postoperative phase prompts urgent investigation. Multiple clinical calculators may assist with stratifying patients to empiric therapy.[134–136] For the majority of patients with suspicion for PE, the preferred diagnostic study is a computed tomographic pulmonary angiogram (CTPA).[130,137] For patients unable to undergo CTPA, ventilation/perfusion (V/Q) scan remains a sensitive but poorly specific test that can be obtained. In addition, lower extremity duplex ultrasound should be obtained to assess for presence of DVT, and, if found, anticoagulation should be initiated.

Once clinical evaluation confirms suspicion for DVT or PE, empiric anticoagulation should be promptly initiated. In postoperative patients anticoagulation may result in bleeding. Absolute contraindications to heparin therapy are active bleeding, severe bleeding diathesis, a platelet count $\leq 20{,}000/mm^3$, neurosurgical or ocular surgical procedures performed within the past 10 days, or intracranial bleeding within the past 10 days.[138] In essence these contraindications to anticoagulation serve as indications for placement of an IVC filter. Consideration may also be given to placement of an IVC filter in the setting of recurrent PE while therapeutic on anticoagulation or when bleeding risk outweighs risk of DVT or PE such as poor cardiopulmonary reserve.

If PE embolism results in hemodynamic instability, more aggressive treatment with thrombolytic therapy is indicated. Thrombolytic therapy should also be considered when patients are at high risk of bleeding from systemic anticoagulation or if systemic anticoagulation fails. Finally, for hemodynamically unstable patients who are not candidates for thrombolytic therapy, embolectomy via either catheter-based approaches or open surgical approaches may be warranted.

It is our practice to administer unfractionated heparin preoperatively (5000 units subcutaneously administered prior to surgery) and throughout the perioperative period for all patients undergoing pelvic surgery for urologic malignancy. This practice is also applied to patients undergoing retroperitoneal oncologic surgery when bleeding risk is deemed acceptable.

Air Embolism

Introduction of insoluble gas into the vasculature system is a rare but dangerous event. Amongst urologic procedures, laparoscopic procedures carry the highest risk for this complication.[139–142] Gas may gain entry into open vasculature via any vascular invasion, surgical or traumatic, within the pleural or peritoneal cavity as well as through endoscopic approaches. Venous air emboli have been reported following retrograde pyelogram, transurethral resection of the prostate, percutaneous nephrostomy tube placement,

and percutaneous nephrolithotomy as well as open radical prostatectomy and laparoscopic prostatectomy.[143–150] Additionally, case reports describe gas embolism following sexual intercourse, autoerotic exercises, and following urethral insufflation.[151–155]

Air or gas embolism occurs when insoluble gas enters an open venous or arterial channel with sufficient pressure differential to allow for gas entry into the vascular system. Gas emboli should be considered in appropriate clinical situations (trauma, laparoscopic surgery, neurosurgery, central venous catheterization) when patients experience sudden onset respiratory distress or neurologic decompensation. However, there are no clear clinical indicators to differentiate gas emboli from other potential complications including pulmonary emboli, myocardial infarction, stroke, and other acute adverse events.

When gas emboli are suspected, the optimal diagnostic test is transthoracic echocardiography (TTE) followed by CTPA.[156,157] When the diagnosis is suspected, patients should be immediately positioned into left lateral decubitus position (Durant's maneuver) or Trendelenburg for suspected venous emboli or supine for suspected arterial emboli. These positioning maneuvers aim to contain the gas emboli.[158] Once the diagnosis has been confirmed, management options range from hyperbaric oxygen, manual aspiration of air from the right ventricle via central venous catheter, or, as a last resort, chest compressions.[159–162]

Pulmonary Complications of Open and Laparoscopic Urologic Surgery

Pleural space violation during surgical procedures in the flank and upper abdomen may occur due to the fact that the pleura extends down to the 11th rib in the posterior axillary line and to just below the 12th rib in the area of the vertebral column.[163] At times, pleural space entry is planned for flank or thoraco-abdominal incision. In addition, upper pole renal tumors have been reported involving or invading the diaphragm.[117,164] As noted above, upper abdominal and flank surgical procedures are associated with a risk of pleural injury and pneumothorax.[165,166] Modifications of the traditional flank incision, such as the supra-11th mini-flank incision, help to prevent pleural injury during open surgical procedures of the kidney.[167]

Pleurotomies recognized intraoperatively during open and laparoscopic surgical procedures can usually be repaired without difficulty or sequelae.[113] A 12Fr rubber catheter is initially placed through the defect and into the pleural cavity, and the pleura is closed with absorbable suture in a running pattern. The lung is then expanded with positive pressure ventilation by the anesthesiologist, removing the remaining gas within the pleural cavity through the end of the catheter. Once all gas has been expelled, the catheter is removed, and the running suture is tied while the lung remains expanded.

Suspected diaphragmatic tears during laparoscopy should be repaired primarily, if possible. Depending on the severity of the injury and the clinical status of the patient, these repairs can be performed either immediately or when the primary operation has been completed. Delaying repair until after specimen extraction may provide better visualization of the injury; however, unstable patients require immediate attention to this complication. If repair can be delayed, then it is advised to decrease the pneumoperitoneum to 10 mm Hg to limit the extent of any present pneumothorax, to facilitate patient ventilation, and to allow for tension-free anastomosis.[168] A thoracostomy tube is indicated for pleural hemorrhage, lung injury, or inability to primarily close the diaphragm.[115]

It is our practice to obtain routine postoperative chest radiograph, although this is up to surgeon discretion. Several studies recommend that postoperative chest radiographs are obtained following cases involving central line placement, intraoperative diaphragm injury, postoperative respiratory distress, or abnormal postoperative clinical findings.[169,170]

Pulmonary Complications of Percutaneous Nephrolithotomy

Pulmonary injuries following percutaneous nephrolithotomy (PCNL) occur during the percutaneous access. Pleural complication rates have been reported to range from 2.3% to 23%, depending on the definition of injury.[171–175]

Rates of PPC are higher with the supracostal PCNL, with a reported 16-fold greater risk of pleural injury when access is above the 12th rib.[176,177] While an infracostal approach is associated with fewer PPC, a supracostal puncture improves stone access and clearance for certain situations (e.g., scoliosis, upper calyx stone).[178] Supracostal punctures should be performed using C-arm fluoroscopic guidance and following maximal exhalation.[179,180] In addition, utilization of an adequately sized working sheath and maintaining low pressure saline irrigation minimize entry of gas and fluid into the pleural space.[176]

The incidence of pulmonary complications that necessitate surgical intervention after a supra-12th rib approach ranges from 3% to 23%.[179,181] Intraoperative placement of an 8 to 10Fr loop nephrostomy tube into the pleural space under fluoroscopic guidance for significant hydropneumothorax following supracostal PCNL may obviate the need for a traditional thoracostomy tube insertion.[182] Traditional thoracostomy tube placement is recommended for when parenchymal injury is suspected or significant drainage of fluid or blood is required.

Nephropleural fistula is a rare pulmonary complication of PCNL and may present as urinothorax. Rates of nephropleural fistula range from 2.3% for supra-12th rib approaches to 6.3% for supra-11th rib access.[183] Management involves collecting system decompression with ureteral stent and concomitant thoracostomy tube. Refractory cases may require decortication with pleural sclerosis.

Patients With Prior Bleomycin Chemotherapy

Men with a history of testicular cancer may have been exposed to chemotherapy regimens including bleomycin, an antibiotic with antineoplastic activity. Often, men with

poor-risk or intermediate-risk testicular cancer are subjected to bleomycin.

Patients exposed to bleomycin are at risk for developing bleomycin-related toxicities, which include interstitial pneumonitis (bleomycin-induced pneumonitis [BIP]). The pathophysiology of this toxicity is multifactorial and is related to cumulative bleomycin exposure, age, thoracic radiation, renal insufficiency, tobacco use, and exposure to high oxygen concentration.[184] Pulmonary fibrosis can develop in 2–40% of those who develop BIP.[185] Symptoms of BIP include cough, dyspnea on exertion, and fever. These symptoms often begin gradually but may manifest as late as 6 months following discontinuation of therapy. In some cases, symptoms progress to worsening respiratory failure.[186]

Patients with a history of bleomycin exposure should undergo pulmonary function testing prior to elective surgical procedures. Management of these patients requires careful perioperative fluid managements and minimization of exposure to high concentration oxygen.[187,188]

Conclusion

Postoperative pulmonary complications occur at a similar frequency and result in similar rates of morbidity and mortality as cardiovascular complications. The most important patient-related factor that should be considered by the urologist when assessing preoperative risk is patient age, although COPD, CHF, and cigarette smoking also increase risk. Many urologic procedures involve risk for PPC, and thus elevated vigilance in the perioperative period is recommended. Venous thromboembolism prophylaxis should be utilized whenever possible.

Chapter 2 Questions

1. Which of the following patient characteristics has not been shown to confer an increased risk of postoperative pulmonary complications?
   a. Chronic lung disease
   b. Age over 50
   c. Obesity
   d. Cigarette smoking
   e. Congestive heart failure

2. Which of the following risk factors is the most important when considering risk for development of postoperative pulmonary complications?
   a. Chronic obstructive pulmonary disease
   b. Surgical site
   c. Surgical time
   d. Preoperative anemia
   e. General anesthesia

3. Evidence suggests that cigarette smokers who quit 1 week prior to surgery appear to experience an increased risk for postoperative pulmonary complications (PPCs) due to which of the following mechanisms?
   a. Elevated carbon monoxide levels
   b. Elevated nicotine levels
   c. Increased airway reactivity
   d. Increased sputum production
   e. All of the above

4. Which of the following postoperative interventions may increase risk of postoperative pulmonary complications?
   a. Nasogastric tube
   b. Epidural anesthesia
   c. Deep breathing exercises
   d. Intercostal nerve block
   e. Chest physical therapy

5. A healthy 49-year-old male underwent a right robotic partial nephrectomy. The patient is noted to be awake, alert, and comfortable with normal heart rate and blood pressure. However, PACU oxygen saturation is noted to be 89% on room air, which improves to 94% on 2 L nasal cannula oxygen. He reports a productive cough and mild dyspnea. Which of the following conditions is least likely the cause of his hypoxemia?
   a. Pneumothorax
   b. Atelectasis
   c. Pulmonary embolism
   d. Airway edema
   e. Bronchospasm

6. When venous air embolism is suspected, which of the following maneuvers should be performed first?
   a. Closed-chest cardiac massage
   b. Air aspiration via central venous catheter
   c. Position the patient in left lateral decubitus position
   d. Position patient in sitting position
   e. Position the patient in a supine position

7. Which of the following mechanisms is most likely responsible for hemothorax after percutaneous cryoablation of the kidney?
   a. Direct contact of the "ice ball" with the posterior surface of the diaphragm
   b. Inadvertent laceration of the superior epigastric artery
   c. A secondary consequence of postprocedure atelectasis
   d. Injury to the phrenic or subcostal arteries that run along the lower border of the 12th rib
   e. All of the above

8. During a left-sided robotic partial nephrectomy, the diaphragm is noted to billow with each ventilation. Which of the following features necessitates insertion of a tube thoracostomy?
   a. Intraoperative inspection reveals injury to the lung parenchyma
   b. Intraoperative inspection reveals 2 cm laceration of the diaphragm
   c. Irrigation fluid is noted within the pleural space via diaphragmatic injury
   d. Intraoperative inspection reveals 6 cm laceration of the diaphragm
   e. None of the above

9. A 45-year-old male presents with fever, dyspnea, tachycardia, and urinothorax following supra-12th rib PCNL for a staghorn stone. Which of the following procedures should be initially considered in the management of this complication?
   a. Tube thoracostomy
   b. Pleurodesis
   c. Left ureteral stent insertion
   d. A and C
   e. All of the above

10. A 65-year-old woman with a history of diabetes and a BMI of 38 undergoes an uncomplicated cystocele repair. She is noted to be hypoxic in the postanesthesia care unit. She otherwise has no symptoms and the remainder of her clinical evaluation is unremarkable, and a chest radiograph is normal. Which of the following interventions should be initially be considered?
    a. CT chest with IV contrast
    b. Supplemental oxygen and continued pulse oximetry
    c. Continuous positive airway pressure (CPAP)
    d. Empiric anticoagulation
    e. Chest physical therapy

Answers

1. **c.** Evidence does not demonstrate an increase in pulmonary complications associated with obesity. Obesity does confer an increased risk in venous thromboembolic complications such as deep vein thrombosis, which may lead to pulmonary embolism and is thus a critical risk factor requiring clinical assessment.

2. **b.** The most important individual risk factor for postoperative pulmonary complication is the surgical site and location. High-risk surgical procedures present significant risk for complications even in young and healthy patients. Special consideration should be taken for surgical approaches involving, or near, the diaphragm.
3. **e.** The pathophysiology on lung function in the first 2 weeks following smoking cessation involves elevated carbon monoxide and nicotine levels that decline within the first week. Airway reactivity also begins to reduce after 1 week of cessation. Sputum volume increased in the initial 2 weeks following cessation and begins a steady decline over the next 6 weeks.
4. **a.** Nasogastric tube placement as a routine postoperative procedure has been widely employed to speed recovery of bowel function, decrease risk to GI anastomoses, and decrease risk of ileus. Several studies have demonstrated increased PPC associated with nasogastric tube (NGT) use; however, a Cochrane review demonstrated an insignificant increase in PPC associated with routine NGT use ($p = 0.07$).
5. **b.** Patients who develop acute postoperative hypoxemia are more likely experiencing an acute postoperative pulmonary complication and should be evaluated accordingly. Postoperative atelectasis typically develops on postoperative days 2–4.
6. **c.** Durant's maneuver should be performed immediately when venous air embolism is suspected. This position aims to trap the gas embolus into the right ventricle and decrease risk of passage further into the pulmonary vasculature. Alternatively, the patient can be put in a left lateral decubitis position with the head down or in Trendelenburg position. Patients with suspected arterial gas emboli should be placed in the supine position.
7. **d.** Injury to the phrenic or subcostal arteries during percutaneous procedures may result in hemorrhage through the probe tract and into the pleural space. Pleural effusions or atelectasis is commonly an exudate, and "ice ball" contact with the diaphragm frequently results in transudates, which are nonblood effusions.
8. **a.** Intraoperative diaphragmatic injuries or pleurotomies should be suspected when the "floppy diaphragm" is noted. Attempts should be made to primarily close these injuries intraoperatively, either after completion of resection or prior, depending on the clinical situation. There is no size limitation to primary closure of the pleurotomy. Tube thoracostomy is necessary when injury to lung parenchyma is noted, the pleurotomy cannot be closed primarily, or significant hemorrhage is noted in the pleural space. Fluid in the pleural space can be evacuated safely with suction or via a catheter placed into the pleural space.
9. **d.** Nephropleural fistula is a rare complication of percutaneous nephrolithotomy (PCNL) and occurs more frequently following supra-12th rib access. Use of low-pressure saline irrigation and a large percutaneous sheath may help decrease the likelihood of this complication. Initial management includes tube thoracostomy and collecting system decompression with ureteral stent. In refractory cases, pleurodesis may be necessary.
10. **b.** The rate of undiagnosed obstructive sleep apnea has been steadily increasing and mirrors rising rates of obesity. Patients with obstructive sleep apnea are prone to rapid desaturation and upper airway obstruction, which may manifest itself in the postanesthesia recovery unit. Current guidelines include preoperative screening for obstructive sleep apnea and close monitoring of those with clinical signs and symptoms. CPAP appears to be useful for patients who are using this at home and should be implemented in patients with suspected obstructive sleep apnea and signs of dyspnea, respiratory effort, or hypoxemia that does not respond to supplemental oxygen.

Chapter 3 Questions and Answers

KEY POINTS

1. A careful history and physical examination may identify underlying cardiac disease.
2. Patients with coronary artery stenting should have close coordination between the cardiology consultant and surgical team in order to determine appropriate antiplatelet therapy management.
3. Patients with decompensated congestive heart failure have an increased operative risk and should be medically optimized prior to surgery.
4. Patients with valvular heart disease should be evaluated for changes in their clinical status. Transvalvular aortic valve replacement is an option available for severe aortic stenosis in certain patients.
5. Patients with unstable cardiac arrhythmias should be treated prior to surgery.
6. A wide variety of cardiac implantable electronic devices are available. An appropriate prescription for perioperative management of the device should be established prior to surgery.
7. Patients with pulmonary hypertension should be managed by experts perioperatively.

Introduction

Careful perioperative evaluation of a patient undergoing surgery combines clinical assessment with current clinical practice guidelines (CPG). The CPGs translate scientific evidence into guidelines that standardize cardiovascular care. These guidelines assess the strength and quality of evidence using evidence-based methodologies[1]. Defining the patient's perioperative risk in the context of CPGs and communicating this with the patient, surgeon, anesthesiologist, and other caregivers is essential. Using this approach, the patient and surgical team can understand the perioperative cardiovascular risk in the context of the anticipated surgery.

In 2014, the Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery was updated[2]. This guideline combined with other disease specific CPGs and statements provide the reference for this chapter.

Timing and Surgical Risk

It is important for the cardiology consultant to understand the timing and risk of a surgery. An *emergency* surgery is required within six hours when life or limb is threatened. An *urgent* procedure will need to be performed within 6 to 24 hours. This will allow for a limited evaluation and optimization of the patient's risk factors. A *time-sensitive* procedure, >1 week to 6 weeks, will allow for evaluation and management of a patient in order to avoid potential complications. An elective procedure can be delayed for up to one year[2] (Table 3.1).

A *low risk procedure* is when the combined surgical patient characteristics have a <1% risk of major adverse cardiac event (MACE) of death or myocardial infarction (MI). A ≥1% MACE is considered an elevated risk procedure[2].

Table 3.1 Timing of Surgery

Definition	Time
Emergency	<6hours
Urgent	6-24 hours
Time-Sensitive	1-6 weeks
Elective	Up to 1 year

Evaluating the Patient and Risk Stratification

Defining the patient's clinical risk factors is the first step in risk assessment. Clinical risk factors include: coronary artery disease (CAD), congestive heart failure (CHF), valvular heart disease (VHD), arrhythmia and conduction disorders, cardiovascular implantable electronic devices (CIED), and pulmonary vascular disease.

The 2014 ACC/AHA Perioperative Clinical Practice Guideline outlines a stepwise approach for perioperative cardiac assessment for CAD[2] (Fig. 3.1). For emergent surgeries, the patient should proceed directly to the operating room. In elective or time sensitive procedures, patients with acute coronary syndromes (ACS), symptomatic arrhythmias, new exacerbation of CHF, or symptomatic valvular disease should be managed according to the appropriate CPG prior to surgery.

For patients who are otherwise stable, there are several risk stratification tools available to estimate the perioperative risk. The Revised Cardiac Risk Index (RCRI) incorporates high-risk surgery (intraperitoneal, intrathoracic, or suprainguinal vascular), history of ischemic heart disease, history of CHF, history of cerebrovascular disease, history of diabetes requiring preoperative insulin, and preoperative creatinine ≥ 2 mg/dl to establish a perioperative risk[3]. The rates of complication in patients with 0, 1, 2, or ≥3 risk factors are 0.4%, 0.9%, 7%, and 11% respectively. The American College of Surgeons NSQIP MICA risk prediction

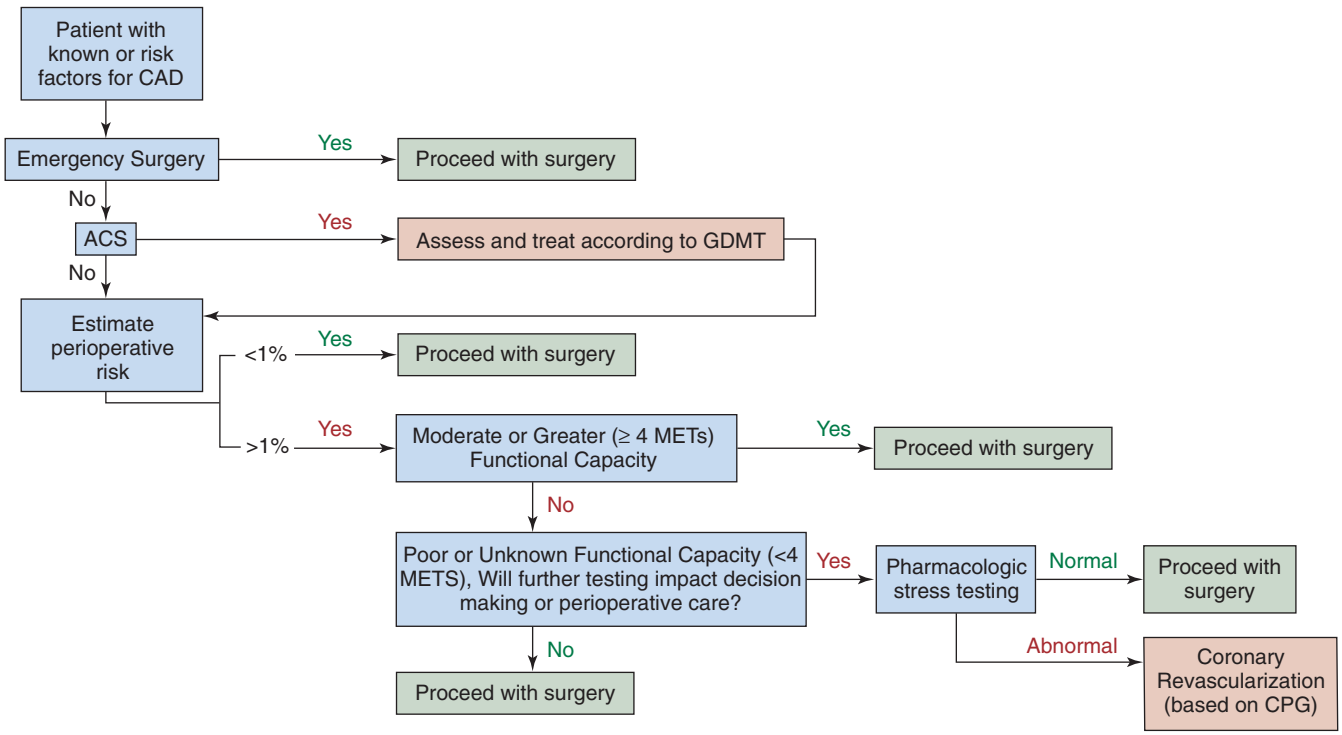

Figure 3.1 Approach to Perioperative Assessment of CAD. CAD, coronary artery disease; ACS, acute coronary syndrome; GDMT, guideline-directed medical therapy; MET, metabolic equivalents; CPG, clinical practice guidelines. (Modified from Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol. 2014;64:e77-e137.)

rule incorporates different surgical sites and predicts the risks for cardiac arrest or myocardial infarction (MI) (http://www.surgicalriskcalculator.com/miorcardiacarrest)[4]. The American College of Surgeons NSQIP Surgical risk calculator uses the current procedural terminology code along with 21 specific patient variables (http://riskcalculator.facs.org/)[5].

Patients with a perioperative risk < 1% can usually proceed to surgery without any further risk stratification. Patients with a perioperative risk ≥ 1% should have an assessment of their functional capacity. Functional capacity is expressed in terms of metabolic equivalents (METs). One MET is the resting oxygen consumption for a 70 kg, 40-year-old male. An excellent functional capacity, defined as > 10 METs, includes strenuous sports such as singles tennis or basketball. Good functional capacity, 7-10 METs, includes activities such as jogging. Moderate functional capacity, 4-6 METs, includes heavy housework, climbing a flight of stairs, walking up a hill, or walking for 4 miles per hour (mph) on a level surface. Examples of poor functional capacity, ≤4 METs, include walking at 2-3 mph or light housework (Table 3.2). Patients who have a moderate or excellent functional capacity can proceed with surgery without any further testing. Patients with an unknown or poor functional capacity undergoing high-risk surgery may require further cardiac testing if the results will change management. Patients with a poor exercise tolerance have a higher incidence of perioperative complications[6].

Table 3.2 Estimated Energy Requirements for Various Activities

	Can you …		Can you …
1 MET	Take care of yourself?	4 METs	Climb a flight of stairs or walk up a hill?
	Eat, dress, or use the toilet?		Walk on level ground at 4 mph (6.4 kph)?
	Walk indoors around the house?		Run a short distance?
	Walk a block or 2 on level ground at 2–3 mph (3.2–4.8 kph)?		Do heavy work around the house such as scrubbing floors or lifting or moving heavy furniture?
4 METs	Do light work around the house like dusting or washing dishes?		Participate in moderate recreational activities like golfing, bowling, dancing, playing doubles tennis, or throwing a baseball or football?
		>10 METs	Participate in strenuous sports like swimming, singles tennis, football, basketball, or skiing?

kph, kilometers per hour; MET, metabolic equivalent; mph, miles per hour. (Modified from Hlatky MA, Boineau RE, Higgenbotham MB, et al. A brief self-administered questionnaire to determine functional capacity (the Duke Activity Status Index). Am J Cardiol. 1989;64:651-654.)

Coronary Artery Disease

PREOPERATIVE

A MI that occurred within six months of planned noncardiac surgery is considered recent[2]. Data shows that the rates of postoperative MI decreased as the length of time from the cardiac event to surgery increased[7]. Surgery should take place at least 60 days after the last cardiac event[2]. Furthermore, the patient's age also plays an important role. Patients over 55 years of age have a greater prevalence of cardiac risk factors which increases their overall risk for MACE[2]. Patients over the age of 65 have an increased risk of acute ischemic stroke undergoing noncardiac surgery[8].

Routine revascularization prior to noncardiac surgery to reduce perioperative cardiac events is not recommended[2]. The Coronary-Artery Revascularization before Elective Major Vascular Surgery trial demonstrated that revascularization before elective major vascular surgery does not improve long-term survival[9]. Furthermore, there was no significant reduction in MACE postoperatively. In this trial, patients with clinically significant, stable coronary disease were randomized to undergo coronary revascularization or medical therapy. Patients were carefully screened and those with coronary artery disease not amenable to revascularization, ≥ 50% stenosis of the left main coronary artery, left ventricular ejection fraction <20%, and severe aortic stenosis (AS) were excluded.

Indications for revascularization prior to surgery include: high risk coronary anatomy such as left main disease, unstable angina, MI, or arrhythmias that are ischemic in origin. Patients who require revascularization prior to surgery should be treated according to the CPG for coronary artery bypass grafting (CABG)[10] or percutaneous intervention (PCI)[11].

In patients who underwent a drug eluting stent (DES) who now require surgery, the decision to continue aspirin or dual antiplatelet therapy (DAPT) should be individualized. DAPT includes an aspirin and a $P2Y_{12}$ platelet receptor-inhibitor, which includes clopidogrel, prasugrel, and ticagrelor. Non-operative risk factors for DES thrombosis include: premature discontinuation of DAPT, diabetes, renal failure, low ejection fraction, advanced age, and procedural characteristics. These include type of DES, bifurcation and ostial lesions, long stent length, multiple stents, overlapping stents, small-diameter vessels and suboptimal results such as coronary dissection or under expansion[12]. In the operative setting, multiple factors such as coronary vasospasm, activation of inflammatory pathways, increase in catecholamine secretion, reduction in tissue plasminogen activator, and increased platelet activation and shear stress may also lead to acute stent thrombosis.

In the nonoperative setting, the rates of stent thrombosis with newer-generation DES is low[13]. Several trials have shown that there was no significant difference in the rates of stent thrombosis in patients treated with 3 to 6 months of DAPT as compared to patients treated with longer durations[13]. In the operative setting, studies showed that the risk of stent thrombosis is greater when the surgery is performed soon after stent implantation. The risk of thrombosis was 3.5% within 6 weeks of stent (BMS and first generation DES stents- sirolimus and paclitaxel) implantation and 1% at 6

Table 3.3 Antiplatelet Management in Patients With PCI

Balloon Angioplasty	Delay surgery for at least 14 days (Class I)
BMS stent	<30 days, Delay surgery for at least 30 days, continue ASA (Class I) ≥30 days, Proceed with surgery
DES stent	<3 months, Delay surgery 3-6 months, Proceed based on risk vs. benefits (Class IIb) >6 months, Proceed with surgery (Class I)

PCI, percutaneous coronary intervention; BMS, bare metal stent; DES, drug eluting stent; ASA, aspirin.

(Adapted from Figure 6 Levine GN, Bates ER, Bittl JA, et al. 2016 ACC/AHA Guideline Focused Update on Duration of Dual Antiplatelet Therapy in Patients with Coronary Artery Disease: A Report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. J Am Coll Cardiol. 2016;68:1082-1115.)

and 24 months[14]. In a meta-analysis of 839 patients with DES, 2.3% had stent thrombosis within six months of implantation, 1.7% within 6 to 12 months, and 0.86% >12 months after implantation[15].

The 2016 ACC/AHA Guideline Focused Update on Duration of Dual Antiplatelet Therapy in Patients with Coronary Artery Disease has updated the recommendations of DAPT perioperatively[13]. The decision on timing of surgery and DAPT therapy involve the type of surgery, risk of delaying the surgery, risk of stent thrombosis and ischemia, and the risk of bleeding. In situations where noncardiac surgery needs to be performed urgently, balloon angioplasty may be required and surgery should be postponed for at least 14 days[2]. Patients who had recent BMS stent implantation, surgery should be delayed for at least 30 days. Patients with DES placed within the first 3 months should have their surgery delayed. Proceeding with surgery within the first 3 to 6 months may be considered if the risk of delaying surgery is greater than the risk of stent thrombosis (Class IIb).[13] Patients with DES implanted ≥ 6 months can proceed with surgery (Class I)[13] (Table 3.3).

In those situations where discontinuation of $P2Y_{12}$ platelet receptor-inhibitor therapy is required, aspirin should be continued if surgically feasible. The risk of bleeding with DAPT therapy is most likely to be higher than aspirin alone or no antiplatelet therapy but the degree of increase is currently unclear[2]. Clopidogrel[16] and ticagrelor[17] should be stopped 5 days prior to surgery, and prasugrel should be stopped 7 days prior to surgery[18]. Restarting $P2Y_{12}$ platelet receptor-inhibitor therapy should be done as soon as the patient is surgically stable[2].

POSTOPERATIVE

Perioperative MI is a common complication of major noncardiac surgery. A perioperative MI increases the risk of cardiac morbidity and mortality[19,20]. Myocardial infarction can be diagnosed based on clinical symptoms, electrocardiographic (ECG) findings, measurement of biomarkers, and imaging. The Third Universal Definition of an MI is defined as detection of a rise and/or fall of cardiac biomarkers with at least one value above the 99th percentile upper reference limit and with at least one of the following: 1) symptoms of ischemia; 2) new or presumed new significant ST-segment-T-wave changes or new left bundle branch block (LBBB); 3) development of pathological Q waves in the ECG; 4) imaging evidence of new loss of viable myocardium or new regional wall motion abnormality; and, 5) identification of an intra-coronary thrombus by angiography or autopsy[21].

Patients with a perioperative MI and myocardial injury that do not fulfill the Third Universal Definition of a MI[21] have a worse short and long-term outcome[19,20,22]. Myocardial infarction is classified in five categories. A spontaneous MI (Type 1) is due to atherosclerotic plaque rupture resulting in intraluminal thrombus[21]. A Type 2 MI is due to an ischemic imbalance. Myocardial injury with necrosis occurs when the demand for myocardial oxygen is greater than the supply. Cardiac death due to myocardial infarction is classified as Type 3. Type 4 and 5 are related to peri-procedural injury in the setting of PCI or CABG respectively. While most perioperative MIs are usually Type 2, clinicians should be vigilant for Type 1 MIs.

Biomarkers of cardiac necrosis include cardiac troponin (T or I) or the MB fraction of creatinine kinase. It is important to distinguish between a rise and/or fall of biomarkers from a chronic elevation. Blood samples should be drawn on first assessment and then repeated 3-6 hours later. The measurement of troponin levels is recommended in the setting of signs or symptoms suggestive of myocardial ischemia or MI (CIass I)[2]. The routine use of biomarkers in patients without signs or symptoms suggestive of myocardial ischemia or MI is not recommended (Class III).

ECG manifestations of acute MI (Figs. 3.2 and 3.3) are defined as: 1) new ST elevation at the J point in 2 continuous leads with the cut-point ≥1 mm in all leads other than leads V2-V3. These leads require ≥ 2 mm in men ≥40 years, ≥ 2.5 mm in men <40 years, or ≥ 1.5 mm in women[21]. In patients with a concern for left circumflex ischemia, leads can be positioned in the left posterior axillary line (V7), left mid-scapular line (V8), and the left paraspinal border (V9). In patients with a suspected inferior or right ventricular infarction, leads can be placed in the right V3 and V4 positions. In addition, ST depression in ≥2 precordial leads (V1–V4) may indicate transmural posterior injury. Multilead ST depression with coexistent ST elevation in lead aVR has been described in patients with left main or proximal left anterior descending artery occlusion[23]. In addition, patients may also present with a new LBBB. In those patients with an existing LBBB, the Sgarbossa criteria can be used: 1) ST-elevation ≥1 mm and concordant with QRS complex (5 points); 2) ST segment depression ≥ 1 mm in lead V1, V2 or V3 (3 points); and, 3) ST-elevation ≥ 5 mm and discordant with QRS complex (2 points). A score of more than 3 points has a 98% specificity[24].

With the exception of a true posterior myocardial infarction, the absence of persistent ST-elevation is suggestive of non-ST segment acute coronary syndrome (NSTE-ACS). These patients can be categorized on the basis of elevated cardiac biomarkers. Patients with elevated cardiac biomarkers in the appropriate clinical context are considered to have non-ST segment myocardial infarction (NSTEMI). ECG changes such as ST depression, transient ST elevation, and/or prominent T-wave inversions may be present but are

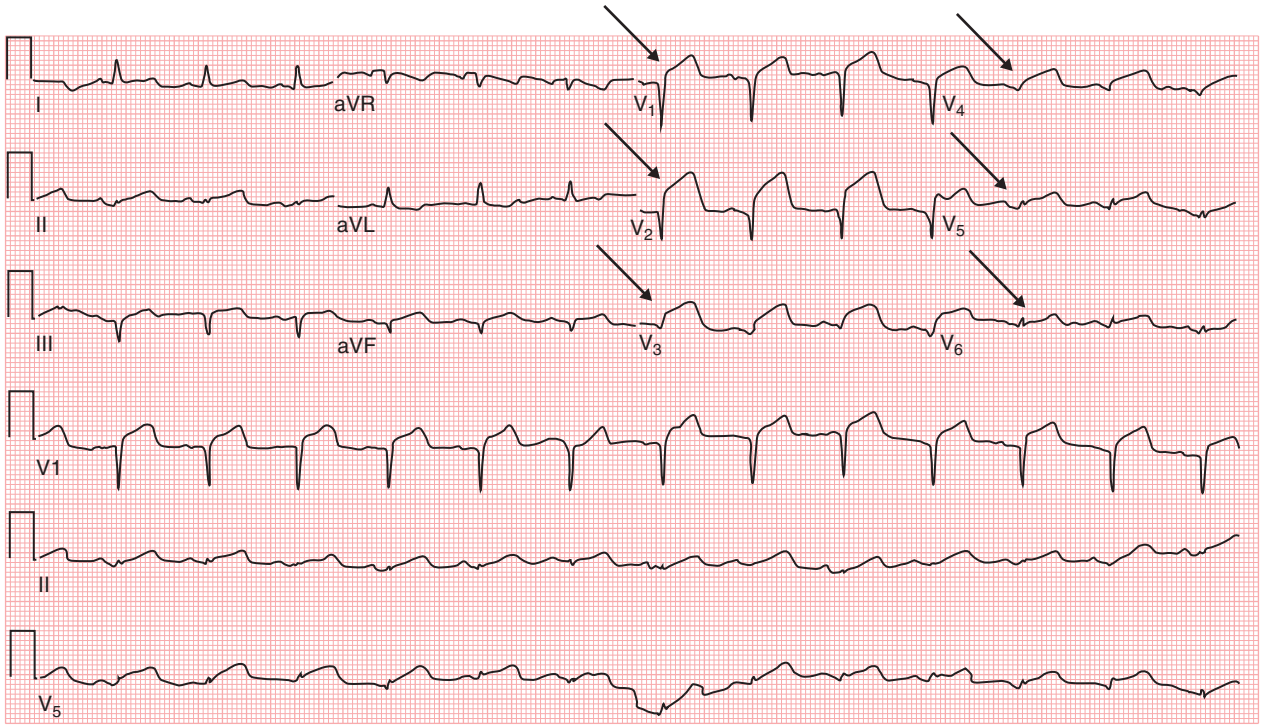

Figure 3.2 Anterior wall myocardial infarction, arrows pointing to ST elevations.

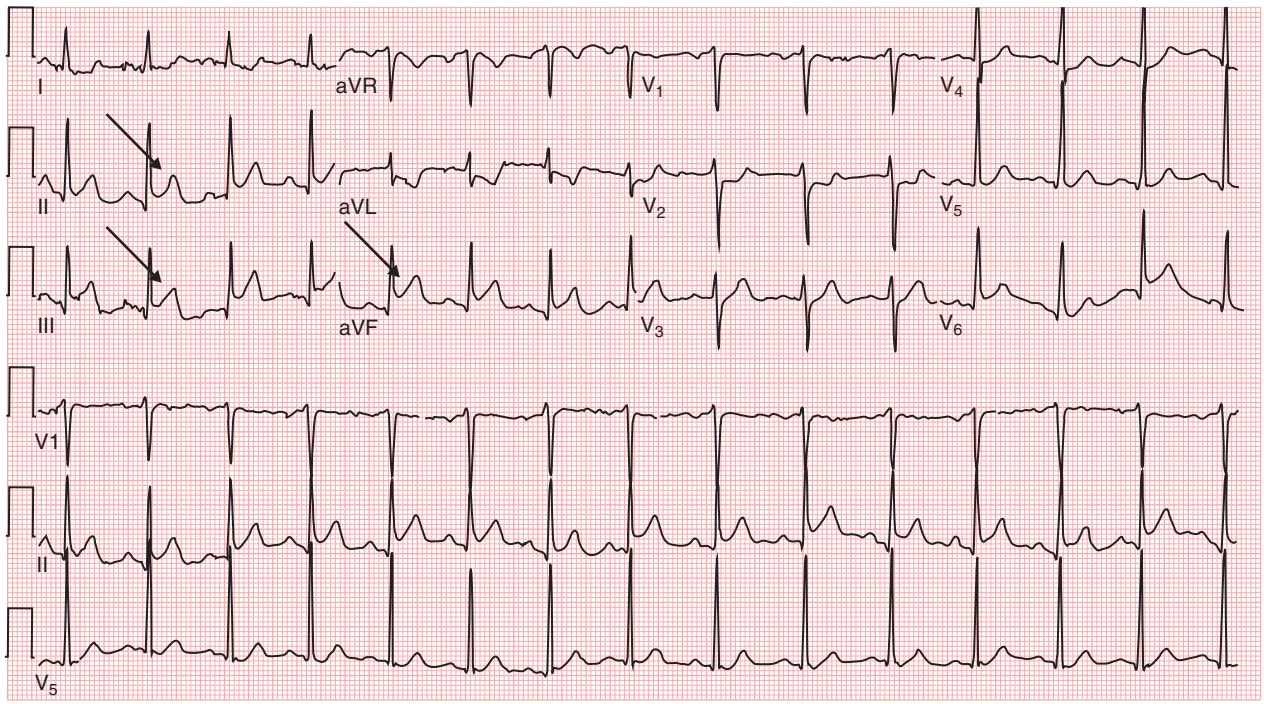

Figure 3.3 Inferior wall myocardial infarction, arrows pointing to ST elevations.

not required for a diagnosis of NSTEMI. Patients with clinical symptoms but with no elevations in cardiac biomarkers are considered to have unstable angina (UA)[25].

Currently, there is little data on the management of myocardial infarction and injury in the post-operative setting. In patients who fulfill the diagnostic criteria for an acute MI, immediate consultation with a cardiologist, cardiac catheterization laboratory, and surgical team should be done in order to facilitate immediate revascularization when possible. These patients should receive guideline-directed medical therapy (GDMT) according to the AHA Guideline for the Management of ST-Elevation Myocardial Infarction[26]. Patients who develop NSTE-ACS following noncardiac surgery should receive GDMT with limitations imposed by the specific surgical procedure and the severity of the NSTE-ACS[25].

Congestive Heart Failure

PREOPERATIVE

Heart failure is a diverse clinical syndrome due to any structural or functional impairment of left ventricular filling or ejection of blood[27]. Patients with heart failure can have a reduced left ventricular ejection fraction, <40%, (HFrEF), or a heart failure with preserved left ventricular ejection fraction, >50%, (HFpEF)[27]. Common symptoms include fatigue, orthopnea, shortness of breath either at rest or exertion, dyspnea, tachypnea, cough, lower extremity edema, increasing abdominal girth or discomfort, and loss of appetite. Prior to surgery, the presence of pulmonary or systemic congestion should be determined. Patients with pulmonary congestion may have rales, dullness to percussion, or diminished breath sounds. However typical lung exam findings may be absent in patients with elevated left ventricular filling pressures due to compensatory changes in lymphatic and perivascular tissue. The presence of increased jugular venous pressure (JVP) has a good sensitivity (70%) and specificity (79%) for estimating an increased left ventricular filling pressure[28]. Patients with decompensated CHF should be treated according to GDMT for heart failure[27]. A two-dimensional echocardiogram should be performed in patients who have newly diagnosed heart failure, develop a significant clinical change, or receive treatment that affects cardiac function.

POSTOPERATIVE

Patients with active or stable heart failure have an increased risk for perioperative morbidity and mortality[2,29]. The presence of a severely decreased, <30%, left ventricular ejection fraction, is an independent risk factor in perioperative outcome and increased long-term mortality in patients undergoing elevated-risk noncardiac surgery[30].

There is limited data on the use of pulmonary artery catheters perioperatively. The routine use of pulmonary artery catheters perioperatively is not recommended[2]. They may be considered in patients who are unable to have medical conditions that may affect hemodynamics corrected prior to surgery[2]. According to the 2013 ACCF/AHA Guideline for the Management of Heart Failure, pulmonary artery catheters should be used in those patients who have respiratory compromise or impaired perfusion that cannot be adequately assessed clinically (Class I)[27].

Valvular Heart Disease

PREOPERATIVE

Since the progression of VHD may be slow, patients may not exhibit symptoms due to a gradual decrease in their daily activities. A detailed examination may reveal signs of severe VHD. Echocardiography is recommended in patients with suspected moderate or greater degree of stenosis or regurgitation who have not had an echocardiogram within one year or who exhibit a change in their clinical status on examination[31]. In patients who meet the criteria for treatment of the valvular disease, intervention prior to elective surgery is indicated[31].

Patients who have severe AS should be evaluated for a change in their clinical symptoms. The Class I recommendations for aortic valve intervention include: 1) symptomatic patients; 2) asymptomatic patients with severe AS with a LVEF <50%; and, 3) patients with severe AS who are undergoing other cardiac surgery[31]. Options for treatment include surgical aortic valve replacement (SAVR), transcatheter aortic valve replacement (TAVR), and balloon valvuloplasty. Current indications for TAVR include patients who have a prohibitive surgical risk and a predicted post-TAVR survival of >12 months. Balloon aortic valvuloplasty may be considered as a bridge to SVAR or TAVR in those patients who require emergent or urgent surgery (Class IIb)[31].

Patients with severe mitral stenosis (MS) should also be evaluated prior to surgery. Class I indications for intervention include patients who are symptomatic. Patients with suitable anatomy can undergo a percutaneous mitral balloon commissurotomy.

Patients with chronic aortic insufficiency and chronic mitral insufficiency should be managed according to the Guidelines for Management of Patients with Valvular Heart Disease[31].

Patients with hypertrophic cardiomyopathy (HCM) have unexplained asymmetric pattern of hypertrophy associated with non-dilated ventricular chambers in the absence of a cardiac or systemic disorder that could explain the hypertrophy[32]. Based on echocardiography, HCM is defined by an end-diastolic wall thickness ≥ 1.5 cm in any myocardial segment accompanied by a normal wall thickness in the other segments. The complex pathophysiology of HCM includes: left-ventricular outflow tract (LVOT) obstruction, diastolic dysfunction, myocardial ischemia, autonomic dysfunction, mitral regurgitation, and atrial and ventricular arrhythmias. Patients may have an implantable cardiac defibrillator (ICD) if there is a history of cardiac arrest, ventricular fibrillation, or hemodynamically significant ventricular tachycardia[32]. There are no large trials examining perioperative risk. However, retrospective data suggests that patients with HCM have an increased operative risk. In one study with 227 patients with HCM, the presence of HCM tripled the risk of perioperative MI and death[33].

Except in highest risk patients, prophylactic antibiotics are not recommended for patients with VHD undergoing genitourinary (GU) procedures (Class III)[34]. Antibiotic therapy may be reasonable prior to elective cystoscopy or other urinary tract procedures in patients who are at highest risk for endocarditis with an enterococci urinary tract infection or colonization (Class IIb)[34]. Highest risk patients include: 1) prosthetic cardiac valve; 2) previous infective endocarditis; 3) congenital heart disease (CHD)- unrepaired cyanotic disease, completely repaired CHD with prosthetic material or device during the first six months, repaired CHD with residual defects; and, 4) cardiac transplantation recipients who develop cardiac valvulopathy. If they require urgent procedures, treatment with an antimicrobial effective against enterococci may also be reasonable (Class IIb)[34].

POSTOPERATIVE

Patients with AS have a fixed obstruction to forward blood flow. During anesthesia, a decrease in vascular resistance

results in hypotension due to an inability to increase cardiac output. This results in an ischemic cascade due to a decrease in coronary perfusion resulting in a further decline in cardiac output. Atrial arrhythmias in the setting of severe AS also lead to hypotension due to the loss of atrial contractility. Patients with severe symptomatic AS undergoing nonemergent procedures had a 2.1% 30-day mortality compared to 1% in patients without severe AS[35]. In addition, there is an increased frequency of postoperative MI. In emergent and urgent noncardiac surgery, patients with severe AS had a 5.9% mortality[36].

In patients with MS, tachycardia, either sinus tachycardia or atrial arrhythmias, should be avoided. A rapid ventricular rate will lead to a decrease in diastolic filling time leading to an increase in left atrial pressure, resulting in pulmonary edema. In addition, judicious use of intravenous fluids should be used perioperatively to avoid pulmonary edema.

Perioperatively, in patients with aortic or mitral insufficiency, adequate preload should be maintained and significantly elevated blood pressures should be avoided.

In patients with HCM, the effects of anesthesia, perioperative volume loss, arterial vasodilatation, and tachycardia may increase the degree of LVOT obstruction resulting in decreased cardiac output. In addition, increased contractility, such as the use of inotropic agents, will also increase the degree of LVOT obstruction. Maneuvers to improve hypotension include intravenous fluids and beta-blockers. Drugs that increase systemic vascular resistance without increasing heart rate or contractility, such as phenylephrine and vasopressin, can also be used[37]. Perioperative atrial fibrillation may also lead to hemodynamic compromise due to the loss of atrial kick. Pharmacologic or direct current cardioversion may be required.

Arrhythmias

PREOPERATIVE

Patients may have supraventricular or ventricular arrhythmias. Patients with unstable atrial or ventricular arrhythmias should be referred to a cardiologist prior to surgery.

Supraventricular tachycardias (SVT) are a group of arrhythmias with atrial and/or ventricular rates above 100 beats per minute (bpm) with a mechanism that occurs at or above the bundle of His[38]. This definition excludes atrial fibrillation. Patients with SVT may present with palpitations, panic or anxiety, neck pulsations, lightheadedness, or syncope. Patients may have hemodynamic instability due to the presence of a SVT regardless of the ventricular rate[39]. Patients may be managed medically or undergo catheter-based ablation.

Atrial fibrillation involves uncoordinated atrial activation resulting in an ineffective atrial contraction. ECG manifestations include: 1) irregular atrial activity, 2) absence of distinct P waves; and, 3) irregular R-R intervals[40]. Atrial fibrillation can be paroxysmal, persistent, or permanent. Paroxysmal atrial fibrillation terminates spontaneously or with intervention within seven days of onset. Episodes may occur with variable frequency. Persistent atrial fibrillation is continuous atrial fibrillation that is longer than seven days but less than 12 months. Permanent atrial fibrillation is characterized when the patient or physician has decided to defer further attempts to maintain sinus rhythm[40]. Patients may be treated with beta-blockers, non-dihydropyridine calcium channel blockers, or antiarrhythmic medications. In addition, patients should be treated with anti-thrombotic therapy in order to prevent thromboembolism. For patients with a CHA_2DS_2-Vasc score (congestive heart failure, hypertension, age ≥ 75 years [2 points], diabetes mellitus, prior stroke or TIA or thromboembolism [2 points], vascular disease, age 65 to 74 years, female sex), ≥1 oral anticoagulation is recommended[40]. Options for anticoagulation include aspirin, warfarin, and target-specific oral anticoagulants. These include a direct thrombin inhibitor, dabigatran, and direct factor Xa inhibitors, rivaroxaban, apixaban, and edoxaban. There is limited data on bridging with low molecular weight heparin (LMWH) or unfractionated heparin[40]. There is also limited data on the management of direct thrombin and factor Xa inhibitors perioperatively. The timing of cessation of and resumption of therapeutic coagulation should be guided by the individual risks and benefits.

Patients may have an SVT due to an accessory pathway. Wolff-Parkinson-White (WPW) syndrome is characterized by patients who have SVT and ventricular pre-excitation on ECG, short PR and delta wave (Fig. 3.4). Patients may also have an accessory pathway that is not evident on the 12-lead ECG (concealed accessory pathway)[38].

Patients with ventricular tachycardia (VT) should be evaluated by a cardiologist in order to determine whether the patient is stable and an appropriate surgical candidate.

POSTOPERATIVE

Patients who develop tachycardia postoperatively should have a 12-lead ECG. An ECG that reveals a wide complex tachycardia may either have VT or SVT with abnormal conduction. SVT with abnormal conduction may occur in the setting of existing bundle branch block or intraventricular conduction defect, aberrant conduction due to tachycardia, electrolyte and metabolic disorders, conduction over an accessory pathway, paced rhythm, or artifact[38]. It is important to differentiate SVT from VT since the administration of diltiazem or verapamil may result in hemodynamic instability in the setting of VT or atrial fibrillation with pre-excitation. Patients with pre-excitation who develop arrhythmias postoperatively should be managed in consultation with a cardiologist.

Class I recommendations for acute treatment of patients with SVT include vagal maneuvers, adenosine (Fig. 3.5), and synchronized cardioversion for hemodynamically unstable SVT or when pharmacologic therapy is contraindicated[38].

Patients who develop complex ventricular ectopy such as ventricular tachycardia should be evaluated for myocardial ischemia, electrolyte abnormalities, or adverse effects from medications.

Bradyarrhythmias postoperatively may be due to sleep apnea, electrolyte abnormalities, myocardial ischemia, medications, or due to increased vagal tone factors such as pain[2].

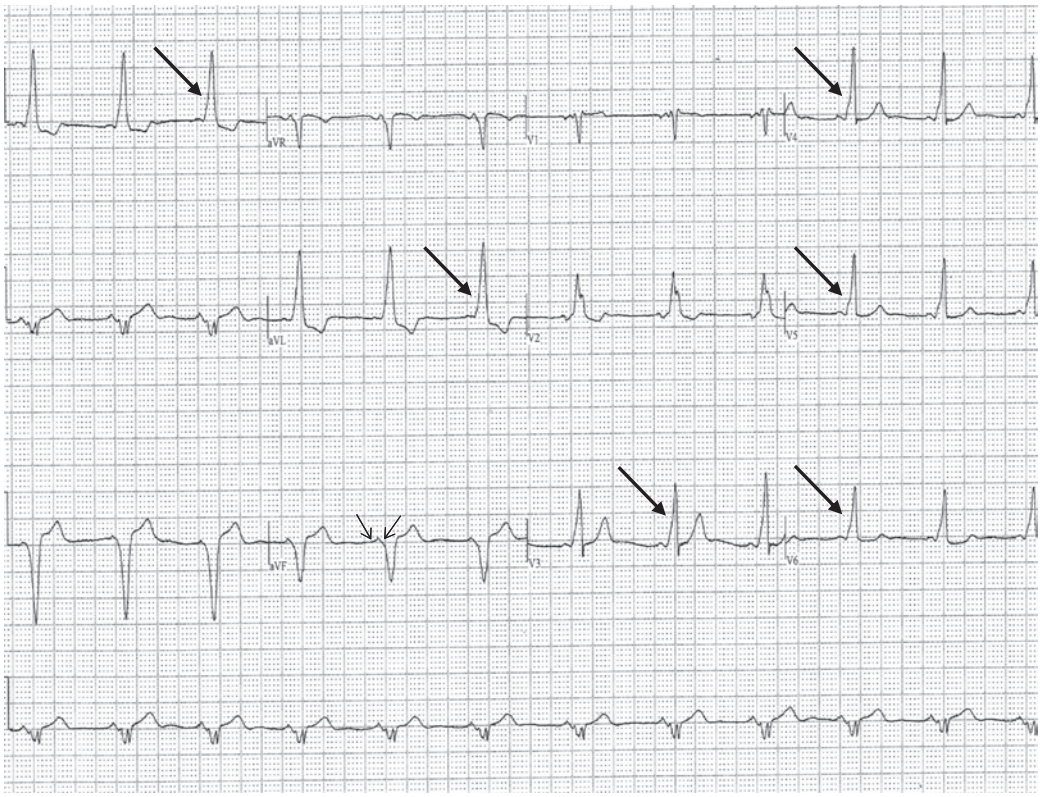

Figure 3.4 Pre-excitation in patient with WPW Syndrome, closed arrows=delta waves, Open arrows=short PR interval.

Cardiovascular Implantable Electronic Devices

PREOPERATIVE

There are a wide variety of CIEDs available. Communication between the CIED and surgical teams is required to develop an individualized treatment plan.

Device interaction is generally electrical interference from nonphysiologic electrical sources, such as electrocautery, or rarely direct damage to the generator or leads[41]. In patients undergoing monopolar surgery, inhibition of pacing and inappropriate activation of anti-tachycardia therapies may occur. Patients who have an inhibition of pacing may experience hemodynamic instability. In patients with ICDs, over-sensing results in inhibition of pacing and inappropriate ICD therapy. This includes both anti-tachycardic pacing therapy and ICD shocks. Uncommonly, electrical reset of the pulse generator, permanent damage or failure of the pulse generator, and damage to the lead-myocardial interface may occur[41].

Prior to surgery, the CIED team should be notified of the type of procedure, anatomic location, use of monopolar electrosurgery, other sources of electromagnetic interference (EMI), surgical venue, post-procedural recovery, and any unusual surgical circumstances. The CIED team will communicate the history of the device, pacemaker (PPM) dependency, and the appropriate perioperative CIED recommendations. Patients with pacemakers are recommended to have the device evaluated every 3 to 12 months, and patients with ICD and cardiac resynchronization therapy defibrillators (CRT-D) every 3 to 6 months either in person or by remote interrogation[42]. Patients who have had a change in their clinical condition should have their devices reevaluated prior to surgery. Devices near Elective Replacement Time may be unreliable and the generator should be changed prior to surgery.

In general, electrosurgery applied below the umbilicus is unlikely to cause pacemaker or ICD/CRT-D interference as compared to above the umbilicus. The greatest risk of over-sensing occurs when the anatomical surgical site and placement of the return electrode occurs across the CIED and/or leads[41]. In order to minimize the effects on the CIED, patients undergoing TURP should have placement of the return pads on the buttock or thigh. Patients who are pacemaker dependent, asynchronous pacing by programming or placement of a magnet over the pulse generator may be required for most procedures above the umbilicus. Inactivation of ICD detection is recommended for all procedures using monopolar electrosurgery above the umbilicus. Intraoperatively external defibrillation equipment should be available. It is important to note that application of a magnet over an ICD will not protect the patient from EMI inhibition of pacing. Changing the pacing mode will require reprogramming of the ICD. All patients should have plethysmographic or arterial pressure monitoring during the procedure since electrocautery may interfere with electrocardiographic monitoring and interpretation of the patient's underlying rhythm[41].

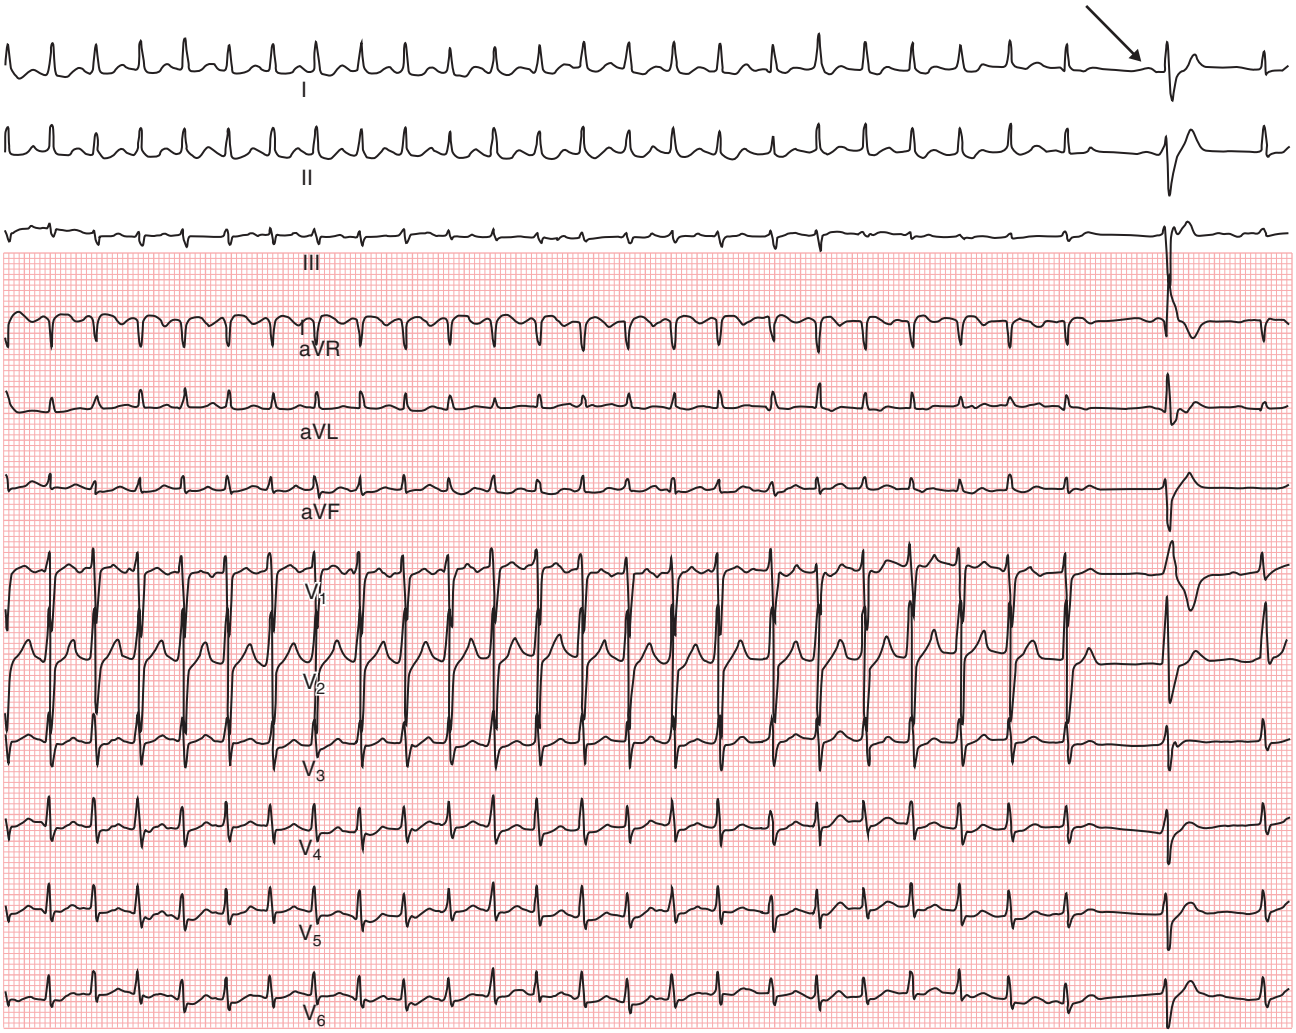

Figure 3.5 Narrow complex PSVT, arrow points to P wave and conversion to normal sinus rhythm after administration of adenosine.

POSTOPERATIVE

Postoperatively, patients with an ICD should have continuous cardiac monitoring until a member of the CIED team reevaluates the ICD and confirms that the appropriate preoperative settings are restored. This is essential since patients with ICDs are considered to be at risk for ventricular arrhythmias perioperatively[41]. Postoperative assessment of the PPM will depend on the operative environment. Patients who have intraoperative reprogramming, unexpected hemodynamic change, emergent surgery above the umbilicus, procedures that have a possibility of affecting device function, or who are unable to logistically have the device evaluated within one month should have the device evaluated prior to transfer from a cardiac telemetry environment[41]. Unless there was a change in the patient's clinical status perioperatively, patients undergoing transurethral resection of the prostate do not need additional CIED evaluation. Patients who require lithotripsy should have their device evaluated within 1 month unless there was a clinical change during the procedure[41]. Patients undergoing monopolar electrosurgery with no unexpected perioperative complications should have their device evaluated within the month either in person or by remote telemetry[41].

Pulmonary Hypertension

PREOPERATIVE

Pulmonary hypertension is defined by the presence of mean pulmonary artery pressure (mPAP) ≥25 mmHg assessed by right heart catheterization[43]. The classification of pulmonary hypertension is based on groups of patients with similar pathological findings, hemodynamic profiles, and management strategies. Patients can be classified as: group 1, pulmonary arterial hypertension (PAH), mPAP≥25 mm Hg with normal pulmonary artery occlusion pressure ≤15 mm Hg and pulmonary vascular resistance above 3 wood units in the absence of pulmonary parenchymal or thromboembolic disease; group 2, pulmonary hypertension due to left heart disease; group 3, pulmonary hypertension due to lung diseases and/or hypoxia; group 4, chronic thromboembolic pulmonary hypertension; and group 5, pulmonary hypertension with unclear or multifactorial mechanisms (Box 3.1)[44].

In observational studies, patients with PAH have an increased morbidity and mortality[2]. Risk factors include urgency of surgery, severity of pulmonary hypertension,

Box 3.1 Classification of Pulmonary Hypertension*

1. Pulmonary arterial hypertension
   - 1.1 Idiopathic PAH
   - 1.2 Heritable PAH
     - 1.2.1 BMPR2

   - 2.2 Left ventricular diastolic dysfunction
   - 2.3 Valvular disease
   - 2.4 Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
3. PH due to lung diseases and/or hypoxia
   - 3.1 Chronic obstructive pulmonary disease
   - 3.2 Interstitial lung disease
   - 3.3 Other pulmonary diseases with mixed restrictive and obstructive pattern
   - 3.4 Sleep-disordered breathing
   - 3.5 Alveolar hypoventilation disorders
   - 3.6 Chronic exposure to high altitude
   - 3.7 Developmental lung diseases
4. Chronic thromboembolic PH
5. PH with unclear multifactorial mechanisms
   - 5.1 Hematologic disorders: chronic hemolytic anemia, myeloproliferative disorders, splenectomy
   - 5.2 Systemic disorders: sarcoidosis, pulmonary histiocytosis, lymphangioleiomyomatosis
   - 5.3 Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
   - 5.4 Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure, segmental PH

BMPR 2, bone morphogenetic protein receptor type 2; CAV1, caveolin-1; ENG, endoglin; HIV, human immunodeficiency virus; PAH, pulmonary arterial hypertension; PH, pulmonary hypertension

*5th World Symposium on Pulmonary Hypertension, Nice, France, February 27 to March 1, 2013

(Adapted from Simonneau G, Gatzoulis MA, Adatia et al. Updated clinical classification of pulmonary hypertension. J Am Coll Cardiol. 2013; 62 (Suppl 25): D34-D41.)

degree of RV dysfunction, and surgery in a center without expertise in pulmonary hypertension[2]. Given the complex nature of PAH, patients should be managed at a PAH center of excellence[45]. Preoperatively, patients should have a thorough cardiac evaluation and optimization prior to surgery. Signs and symptoms of deterioration may include changes in functional status, presence of elevated jugular venous pressure, congestive heart failure, hypoxia, or syncope. In addition, the patient's pulmonary hypertension medications and the possibility of additional pulmonary hypertension specific medications should be made available prior to surgery[46].

POSTOPERATIVE

Postoperative management requires close coordination between the surgeon and PAH team. Postoperative complications may include respiratory failure, cardiac arrhythmias, congestive heart failure, renal insufficiency, sepsis, hepatic dysfunction, hypertension, cardiac ischemia and stroke[46].

Perioperative Medical Interventions

Several classes of drugs including beta blockers, statin therapy, alpha agonists, angiotensin-converting enzyme (ACE) inhibitors, and antiplatelet therapy have been studied perioperatively. In addition, the use of anticoagulants is also discussed briefly.

Studies have shown that perioperative beta blockers can reduce perioperative cardiac events but were associated with an increased risk of stroke, hypotension and bradycardia[2,47,48]. Given this, it is not recommended to start beta-blocker therapy on the day of surgery (Class III)[2]. The current guidelines recommend continuing beta-blockade for patients who are on beta-blockers chronically (Class I). Beta-blockers can be started on those patients who have 3 or more risk factors, such diabetes, renal insufficiency, cerebrovascular accident, heart failure, coronary artery disease, and in patients who are at intermediate-or high-risk for myocardial ischemia (Class IIb)[2]. The beta-blocker should be started 2 to 7 days prior to surgery.

Patients on chronic statin therapy should have them continued perioperatively (Class I)[2]. Alpha-2 agonists, such as clonidine, are not recommended in patients undergoing noncardiac surgery[2,49]. ACE inhibitors may be continued perioperatively, and if they are held prior to surgery, they should be restarted when the patient is stable[2].

The benefits of aspirin in non-stented patients undergoing surgery is uncertain. In patients with cerebrovascular disease or increased risk of CAD with no history of coronary stenting, it may be reasonable to continue daily aspirin therapy, where the benefits of decreasing potential cardiovascular events outweigh the risks of perioperative bleeding (Class IIb)[2]. Given data that suggests that aspirin was associated with a higher risk of bleeding and did not reduce the risk of myocardial infarction, the initiation or continuation of aspirin is not recommended in patients undergoing elective noncardiac noncarotid surgery unless the risk of ischemic events outweighs the risks of surgical bleeding (Class III)[2,50].

For patients with mechanical mitral valve or mechanical aortic valve with one additional risk factor such as atrial fibrillation, prior thromboembolism, left ventricular dysfunction, older-generation prosthetic aortic valve, or hypercoagulable state, bridging anticoagulation may be appropriate when the risk of surgical bleeding is more than minimal (Class I)[31]. In patients with mechanical valves undergoing minor procedures, continuation of

therapeutic anticoagulation is recommended (Class I)[31]. Patients with mechanical aortic valves and no other risk factors for thrombosis, temporary cessation of vitamin K antagonists without bridging can be done as long as the interruption is brief (Class I)[31]. Factor Xa inhibitors and direct thrombin inhibitors are not indicated for mechanical valves.

In patients with atrial fibrillation, the 2014 AHA/ACC/HRS Guideline for the Management of Patients with Atrial Fibrillation does not provide specific perioperative recommendations but recommends an individualized approach[40].

No guidelines are available for factor Xa inhibitors and direct thrombin inhibitors perioperatively. In patients with normal renal function undergoing elective procedures, it is suggested to discontinue the anticoagulant ≥ 48 hours[2]. In patients on dabigatran requiring urgent reversal, idarucizumab is now available to completely reverse the anticoagulant effects[51]. For patients on vitamin K antagonists, options include fresh frozen plasma, prothrombin complex concentrates, and vitamin K. Vitamin K is not routinely recommended due to the delay in both action and return to a target therapeutic level. As of this writing, there are no approved reversal agents for factor Xa inhibitors.

Chapter 3 Questions

1. An 85-year-old male with a past medical history significant for diabetes mellitus, COPD, osteoarthritis, hypertension, and hyperlipidemia is scheduled for a radical nephrectomy. He is unable to walk more than a 1/2 block due to dyspnea. He is referred for further cardiac evaluation. The next appropriate step is:
   a. Schedule the patient for surgery
   b. Refer for cardiac catheterization
   c. Schedule pharmacologic stress test
   d. Start beta blocker on day of surgery and proceed with surgery
   e. Pulmonary consultation

2. 70-year-old female with no prior history and an excellent exercise tolerance develops chest pain postoperatively after a laparoscopic partial nephrectomy. Her ECG prior to surgery was normal. On your arrival to the recovery room, the patient develops chest pain and then ventricular tachycardia. The most likely diagnosis is:
   a. Atypical chest pain due to endotracheal intubation
   b. Pulmonary embolism
   c. Acute myocardial infarction
   d. Pneumothorax
   e. Incisional pain

3. An 80-year-old male with a past medical history significant for diabetes mellitus, hypertension, and hyperlipidemia is referred for cardiac evaluation. He reports exertional dyspnea which began six months ago. He denies any chest pressure or syncope. On examination, his blood pressure is 110/80 mm Hg with the resting pulse 95 bpm. He has a 3/6 systolic crescendo murmur best heard at the base and radiates to the carotid arteries. The next appropriate diagnostic test is:
   a. An echocardiogram to evaluate for mitral regurgitation
   b. An echocardiogram to evaluate for hypertrophic cardiomyopathy
   c. No further testing is warranted
   d. An echocardiogram to evaluate for aortic stenosis
   e. Exercise stress test to assess functional capacity

4. 77-year-old female with a past medical history significant for hypertension, diabetes mellitus and peripheral arterial disease develops atrial fibrillation in the recovery room. Her blood pressure is 120/70 mm Hg with a pulse of 80 bpm. She has no evidence of JVD. Heart exam is significant for an irregularly irregular pulse with a 3/6 systolic murmur at the apex. The appropriate intervention is:
   a. Start intravenous beta blocker
   b. Check CBC, electrolytes and TSH
   c. Start an intravenous diltiazem drip
   d. Emergent electrical cardioversion
   e. Intravenous amiodarone

5. The same patient remains in atrial fibrillation with ventricular rates in the 70s. Her echocardiogram shows a normal left ventricle ejection fraction with mitral valve prolapse and severe mitral regurgitation. She has been stable with no signs of surgical bleeding. Her renal function is normal. She is now ready for discharge. The next appropriate step is:
   a. Start aspirin
   b. Start therapeutic enoxaparin and transition to warfarin
   c. Start dabigatran
   d. Start rivaroxaban
   e. Start apixaban

6. You are called to the bedside for a patient who has increasing hypotension postoperatively. The patient has a history of hypertrophic cardiomyopathy with an ICD. Prior to your arrival the patient was started on intravenous dobutamine. The patient then developed atrial fibrillation. His blood pressure is 80/60 mm Hg and telemetry shows atrial fibrillation with ventricular rate of 120. His 02% is 90%. Appropriate interventions include all the following except:
   a. Emergent cardioversion
   b. 1L bolus of normal saline
   c. Increase the dosage of dobutamine
   d. Intravenous beta blockers
   e. Pain control

7. An 80-year-old man was admitted for urgent surgery. Patient reports a recent episode of syncope and increasing chest pain. An echocardiogram shows a normal left ventricular ejection fraction and severe aortic stenosis with an aortic valve area of 0.7 cm^2. Prior to surgery, you would recommend:
   a. No intervention and can proceed with surgery
   b. Surgical aortic valve replacement
   c. Transcatheter aortic valve replacement
   d. Balloon aortic valvuloplasty
   e. CT scan of the aorta to evaluate for aortic dissection

8. A 70-year-old female underwent drug eluting stent to her left anterior descending artery for unstable angina 8 months ago. Post-procedure, she developed hematuria and was found to have renal cancer. Her current medications include aspirin and clopidogrel. Appropriate perioperative recommendations include:
   a. Schedule surgery for next week
   b. Delay surgery for six weeks, stop clopidogrel two weeks prior to surgery and continue an aspirin
   c. Delay surgery for six months and discontinue both aspirin and clopidogrel
   d. Stop clopidogrel five days before surgery,continue an aspirin, and proceed with surgery
   e. Change clopidogrel to prasugrel

9. A 60-year-old male with a past medical history significant for a nonischemic cardiomyopathy with ejection fraction of 25%, hypertension, diabetes mellitus, and an ICD is scheduled for surgery. He has a good exercise tolerance with no recent chest pain or shortness of breath. His last ICD interrogation was two months ago and showed no events. His physical exam is significant for blood pressure 120/70 mm Hg, resting pulse of

60 bpm. He has no JVD. His lungs were clear to auscultation. He had a 2/6 holosystolic murmur at the apex. He had no lower extremity edema. His medications include carvedilol, lisinopril, furosemide, spironolactone, and an aspirin. Appropriate recommendations include:
   a. Refer patient for evaluation of coronary ischemia
   b. Proceed with surgery with recommendations from his electrophysiologist
   c. Schedule cardiac catheterization
   d. Increase diuretics
   e. Repeat echocardiogram

10. The same patient on the day of surgery reports having a syncopal episode two days prior to surgery. He denied any chest pain, shortness of breath, palpitations. Appropriate recommendations include:
   a. Proceed with surgery
   b. Cancel patient and refer for outpatient evaluation with his electrophysiologist
   c. Send to emergency room for evaluation with his electrophysiologist
   d. Send to emergency room for evaluation for cardiac catheterization
   e. Reschedule the surgery for the following week

Answers

1. **c.** Given his symptoms and we are unable to assess his exercise tolerance, he should have a pharmacologic stress test prior to surgery due to his risk factors and symptoms.
2. **c.** Given the presence of chest pain and ventricular tachycardia, this is suggestive of an acute myocardial infarction.
3. **d.** The physical exam suggests aortic stenosis and in the presence of symptoms and a significant murmur an echocardiogram is indicated.
4. **b.** Given the patient is hemodynamically stable, a work-up to evaluate a reversible cause is appropriate at this time.
5. **b.** Given her CHA2DS2-Vasc=6 (1 for hypertension, 2 for age>75, 1 for diabetes, 1 for female, and 1 for peripheral arterial disease), she should have therapeutic anticoagulation. Since she has severe valvular disease, she is not a candidate for dabigatran, rivaroxaban, or apixaban.
6. **c.** The patient has hypertrophic cardiomyopathy and increasing inotropic support will result in further outflow obstruction resulting in hypotension.
7. **d.** Given the patient needs urgent surgery, a balloon aortic valvuloplasty is an appropriate bridge to surgery.
8. **d.** The patient had revascularization more than six months ago. Given her need for surgery, it is reasonable to proceed with surgery while on an aspirin. Her clopidogrel should be stopped five days prior to surgery.
9. **b.** While the patient has a severely reduced ejection fraction, he does not have any signs of decompensated congestive heart failure or recent ICD events. Therefore, a repeat echocardiogram is not indicated. He should have appropriate recommendations for the management of his ICD perioperatively.
10. **c.** Given the patient had a syncopal event, he should be referred to the emergency room for further cardiac evaluation of his ICD. He does not have any symptoms of acute coronary ischemia.

4 Preoperative Hematologic Assessment and Management of Hematologic Complications

BRENTON ARMSTRONG, SAMIR S. TANEJA, and OJAS SHAH

CHAPTER OUTLINE

Preoperative Evaluation
Abnormalities of Blood Components
Red Blood Cells
Platelets
von Willebrand's Disease
Hemophilia A and B
Rare Inherited Factor Deficiencies
Disorders of Increased Bleeding
Renal Failure
Disseminated Intravascular Coagulation
Primary Fibrinolysis
Vitamin K–related Disorders
Massive Transfusion Syndrome
Anticoagulated Patient
Antiplatelet Therapy
Anticoagulation Therapy
Management of Intraoperative Bleeding
Problems of Increased Coagulation
Hypercoagulable State
Physiology
Evaluating the Hypercoagulable Patient
Management
Deep Venous Thrombosis and Pulmonary Embolism
Management
Conclusion
Chapter 4 Questions and Answers

KEY POINTS

1. Although routine preoperative coagulation defect screening is not shown to be cost-effective, it is commonly used in patients at risk of significant bleeding during a planned procedure.
2. Anemia can affect surgical outcomes and should be corrected whenever possible before elective surgical procedures.
3. Urologists must become familiar with the ever-expanding number of anticoagulation medications for the safe perioperative management of their patients.
4. Individuals undergoing elective surgical procedures should discontinue the use of aspirin, clopidogrel, or nonsteroidal antiinflammatory drugs (NSAIDs) a full 7 to 10 days preoperatively to allow normalization of platelet function.
5. In patients with drug-eluting coronary stents, or specific indications for anticoagulation, the risk of stopping anticoagulation should be weighed against the risk of intraoperative bleeding, depending on the planned procedure.
6. Patients with abnormal preoperative partial thromboplastin time (PTT) value and no history of anticoagulation should undergo careful evaluation for clotting factor deficiency.
7. In patients with certain risk factors for a hypercoagulable state, and in patients at risk for venous thrombosis, evaluation for factor deficiency or lupus anticoagulant is indicated.
8. The risk factors for venous thrombosis can be thought of in the context of Virchow's triad for the pathophysiology of thrombus formation (stasis, hypercoagulability, and intimal injury).
9. Venous thromboembolism (VTE) prophylaxis recommendations should be risk adjusted.

Preoperative Evaluation

When evaluating patients for potential hematologic complications before any urologic surgical procedure, the most important first steps are thorough history taking and physical examination. The clinician taking the patient's history should pay specific attention to the following: any personal or family history of known bleeding disorder; a history of prolonged bleeding after trauma, surgery, or dental procedure; a history of liver disease, malabsorption, or malnutrition; and recent use of anticoagulants. Physical findings suggestive of coagulopathy include petechiae, ecchymosis, hematomas, purpura, and the stigmata of acquired disease, such as liver failure or uremia.

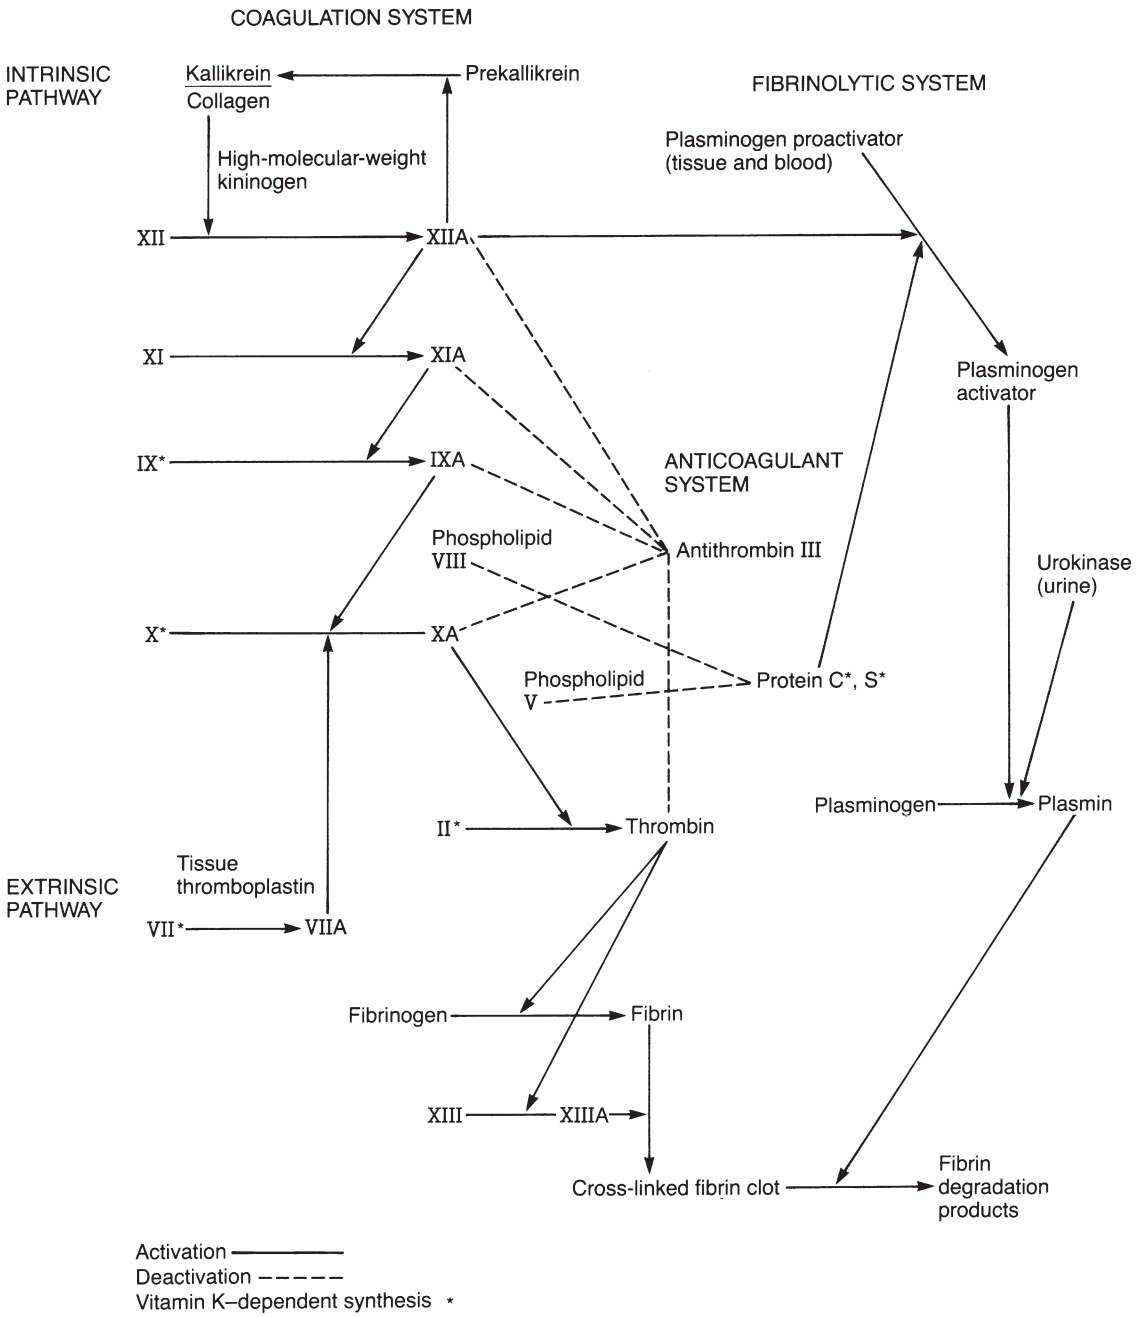

Figure 4.1 Normal clotting cascade.

Bleeding symptoms in the patient or in a member of the patient's family should prompt a laboratory evaluation. In addition, routine laboratory screening tests are often performed in asymptomatic patients, including complete blood count, platelet count, prothrombin time (PT), and activated partial thromboplastin time (aPTT). The PT measures the activity of the extrinsic clotting system, and the aPTT measures the intrinsic clotting system (Fig. 4.1). Measurement of the bleeding time is used to identify patients with possible platelet dysfunction. Further laboratory evaluation is unnecessary unless history, physical examination, or routine laboratory tests reveal an abnormality.

In obtaining preoperative screening PT, aPTT, and platelet count, surgeons attempt to identify asymptomatic patients at increased risk for intraoperative or postoperative hemorrhage. The evaluation of symptomatic patients is not considered screening. Most patients experiencing significant perioperative bleeding, however, would not be identified by preoperative screening measures because most bleeding episodes are the result of surgical technique rather

than of intrinsic coagulopathy. The risk of preexisting coagulopathy, in the absence of historical symptoms and signs of bleeding, is extremely low.

Multiple studies have evaluated the cost-effectiveness of baseline preoperative screening and, collectively, these studies recommended that preoperative screening for coagulopathy is unnecessary and should not be performed in the absence of clinical findings suggestive of an increased bleeding risk.[1–5] Preoperative testing should always be performed in all patients in whom adequate clinical assessment is not possible. The elimination of routine screening based on these criteria would reduce the total number of preoperative tests of coagulation by approximately 50%.[2] The limitations of coagulation testing are well known. Coagulation tests have been shown to have limited sensitivity and positive predictive value for bleeding episodes. Abnormal values may have little clinical significance or represent false positives and do not correlate with volume of blood loss or need for transfusion.[5]

These data do not support the use of routine preoperative screening coagulation tests in asymptomatic patients,[2–5] but despite these recommendations physicians continue to obtain routine PT, aPTT, and platelet count on all patients undergoing major extirpative or reconstructive procedures in which significant blood loss is possible.

Table 4.1 Complications of Transfusions per Unit Transfused

Complications	Frequency
REACTION	
Febrile nonhemolytic	1-4/100
Allergic	1-4/100
Delayed hemolysis	1/1000
Transfusion-related acute lung injury	1/5000
Acute hemolysis	1/12,000
Fatal hemolytic	1/100,000
Anaphylaxis	1/150,000
Alloimmunization (RBC)	1/100
Alloimmunization (HLA)	1/10
INFECTION	
Hepatitis B	1/220,000
Hepatitis C	1/1,800,000
HIV-1, -2	1/2,300,000
HTLV-1, -2	1/2,993,000
Malaria	1/4,000,000
RARE	
Allosensitization (RBC)	1/100
Allosensitization (HLA)	1/10
Graft-versus-host disease	Rare

HIV, human immunodeficiency virus; HLA, human leukocyte antigen; RBC, red blood cell; HTLV, human T lymphotropic virus

Abnormalities of Blood Components

RED BLOOD CELLS

Anemia detected in routine preoperative screening should be evaluated with regard to its functional significance and origin. Typically, a preferred preoperative hemoglobin level is >10 g/dL. Although lower intraoperative hemoglobin levels can generally be tolerated by most patients, these values are associated with an increased risk of morbidity and mortality. Additionally, anemia may reflect a previously unsuspected coexisting disease process that could have a significant effect on the perioperative course. Because anemia can be a primary disorder or can occur secondary to other systemic processes, a careful history and physical examination are essential and can provide extensive information about the underlying cause.[6]

Initial diagnostic studies should include reticulocyte count, mean corpuscular volume (MCV), examination of the peripheral blood smear, and a fecal occult blood test.[6] Many urologic conditions can be associated with anemia, including malignancy and chronic renal failure. Iron deficiency anemia has been associated with states of renal cell carcinoma. Direct involvement of the bone marrow by cancer may result in myelofibrosis and subsequent anemia, most often seen in metastatic prostate cancer.[7] Radiation therapy can lead to bone marrow suppression or vitamin B_{12} deficiency secondary to radiation ileitis.[8] The use of gastrointestinal segments in the urinary tract is associated with known metabolic derangements including vitamin B_{12} deficiency with utilization of the ileum. The body has about 3 years of vitamin B_{12} stores, after which the patient can develop megaloblastic anemia.[9] Many chemotherapeutic agents can cause myelosuppression. Commonly used antibiotics in urology, such as nitrofurantoin, sulfa compounds, and quinolones, can produce hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency. Hemolytic anemia has also been reported in association with renal cell carcinoma and seminoma.[10,11] Finally, hematuria itself can cause anemia if it is chronic or severe.

Understanding the cause of the anemia can dictate the appropriate perioperative course of action to minimize operative morbidity. For patients with an uncorrectable underlying cause of anemia who are judged to be at risk for functional compromise, therapy consists of transfusion. In patients who are undergoing surgical procedures that are deemed elective, it is advisable to proceed after correcting the underlying cause of anemia preoperatively and thereby avoiding transfusion. Preoperative transfusions should ideally be performed 24 hours in advance to allow regeneration of 2,3-diphosphoglycerate, which shifts the oxygen dissociation curve to increase oxygen availability to the tissues. Transfusions incur a potential risk of morbidity, including hemolytic reactions, allergic reactions, and transmission of viral diseases (Table 4.1).[12]

Erythrocytosis, a hematocrit level significantly higher than normal, increases blood viscosity and decreases oxygen transport. Erythrocytosis can significantly increase surgical morbidity and mortality, particularly related to thromboembolic complications. This increase in red blood cell (RBC) mass can be primary, as in polycythemia vera, or secondary. Common causes of secondary erythrocytosis are hypoxic states or paraneoplastic syndromes (as seen in

renal cell carcinoma and Wilms' tumor) likely resulting in increased production of erythropoietin. Patients with polycythemia vera should undergo preoperative phlebotomy to lower hematocrit levels to <45% to reduce the risk of thromboembolic complications. In patients with secondary erythrocytosis, the hematocrit should be lowered to <50%.[13,14]

PLATELETS

Normal platelet count can vary greatly among healthy individuals; a platelet count >50,000 is usually adequate for surgical hemostasis. Thrombocytopenia results from decreased production of platelets (radiation, primary marrow disorders, alcohol, drugs), increased peripheral destruction (autoimmune disease, disseminated intravascular coagulation [DIC], sepsis, drugs), sequestration (splenomegaly), or extracorporeal platelet loss (exsanguination). Initial therapy should consist of treating the underlying cause; if this is not possible then the next step is platelet transfusion. One unit of platelets can be expected to raise the platelet count by 5000 to 10,000/mm^3.

Thrombocytosis can be caused by myeloproliferative disorders and is associated with increased risk of both thrombotic and bleeding complications. Secondary or reactive thrombocytosis leads to an elevation of total number of platelets with normal function caused by underlying inflammation or infection. Patients with reactive thrombocytosis are not at increased risk of thrombotic events and do not require anticoagulation.[15]

Inherited defects of platelet function are rare genetic disorders that result in altered platelet function or morphology, most commonly involving deficiency of glycoprotein mediators that regulate aggregation or adhesions of platelets. Treatment or prevention of bleeding frequently requires platelet transfusion.[16]

Acquired intrinsic platelet dysfunction is most commonly due to medications that affect platelet function, but can also be caused by liver disease, uremia, hypothyroidism, and cardiopulmonary bypass. For acquired defects not related to medication, treatment is directed at the underlying cause.

VON WILLEBRAND'S DISEASE

von Willebrand's disease (vWD) is the most common inherited bleeding disorder and is a result of dysfunction or deficiency of von Willebrand Factor. vWD is a plasma protein that mediates platelet adhesion and binds to and stabilizes coagulation factor VIII in the circulation. The disease is transmitted in both an autosomal dominant and recessive fashion and affects both men and women. Symptoms are primarily related to platelet dysfunction and are usually manifested in late childhood. Symptoms most commonly include easy bruising and bleeding at skin sites or mucus membranes. Although spontaneous bleeding may be mild, serious gastrointestinal bleeding can occur. Treatment is preferably with cryoprecipitate and desmopressin (DDAVP), which induces endothelial release of vWD and coagulation factor VIII. Desmopressin can result in hyponatremia; very young or elderly patients are at highest risk for this side effect.[17]

HEMOPHILIA A AND B

Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) are extremely rare inherited disorders. Both deficiencies are typically inherited as a recessive X-linked trait and affect males almost exclusively. The underlying pathophysiology behind both diseases is based on the insufficient generation of thrombin by the factor VIIIa/IXa complex.

Hemophilia A occurs in 1 in 5000–7000 male births.[18,19] The aPTT is prolonged, whereas PT, fibrinogen level, and platelet count are normal. In severe deficiency, spontaneous bleeding may occur, whereas patients with moderate disease may only have excessive traumatic bleeding. The diagnosis is established by demonstrating a reduction in factor VIII activity. Patients with minor bleeding can generally be treated with factor levels that are 25–30% of normal; surgical patients generally require target levels that reach 75–100% of normal activity. Many different factor VIII preparations can be given; the half-life of factor VIII is 8 to 12 hours, and many administrations may be required to maintain a steady state. Most patients require 2 to 3 weeks of postoperative hematologic support to allow sufficient wound healing and scar formation.[16]

Hemophilia B, also known as Christmas disease, clinically resembles hemophilia A, but is less common with an incidence of 1 in 30,000 male births.[18,19] Replacement therapy with factor IX, as in hemophilia A, is recommended.

RARE INHERITED FACTOR DEFICIENCIES

Other factor deficiencies are much less common, and not all are associated with coagulopathies. The presentation and management of these disorders are outlined in Table 4.2. In general, these patients may present with ecchymosis, hematoma, or delayed traumatic bleeding.

Prothrombin deficiency is a very rare autosomal recessive disorder manifested by prolonged PT and variably prolonged aPTT. Prothrombin is usually converted to its active form thrombin (coagulation factor II) leading to fibrin formation. Maintenance of >15% of normal levels should be adequate for surgery and can be achieved with fresh frozen plasma (FFP).

Factor V deficiency, also called parahemophilia, is also a very rare disorder in which the PT and aPTT are prolonged. Approximately 25% of normal activity can be maintained for surgery by treatment with FFP.

Factor VII deficiency is uncommon and is inherited as an autosomal gene with intermediate penetrance. The PT is prolonged and the aPTT is normal. Replacement is achieved by transfusing plasma or factor VII replacement.

Inherited factor X deficiency is autosomal recessive. Maintenance of levels >40% of normal may be achieved with plasma transfusion in preparation for surgery.

Factor XI deficiency is an uncommon disorder inherited in an autosomal dominant fashion. A higher frequency of this deficiency is noted in the Ashkenazi Jewish population. These patients may not have bleeding histories but often present with epistaxis. Severe bleeding may occur with trauma or major surgery. Patients can successfully undergo urologic surgical procedures with adequate FFP therapy.

Table 4.2 Laboratory Findings and Treatment of Factor Deficiencies

Deficient Factor	PT	aPTT	TT	Bleeding Time	Replacement Factor
I	↑	↑	↑	↑, N	FFP, cryoprecipitate
II	↑	↑	N	N	FFP, factor IX concentrate
III*					
IV*					
V	↑	↑	N	N	FFP
VII	↑	N	N	N	FFP, factor IX concentrate
VIII	N	↑	N	N	cryoprecipitate, factor VIII concentrate
IX	N	↑	N	N	FFP, factor IX concentrate
X	↑	↑	N	N	FFP, factor IX concentrate
XI	N	↑	N	N	FFP
XII	N	↑	N	N	
XIII	N	N	N	N	FFP
vWF	N	↑	N	↑	FFP, cryoprecipitate

aPTT, activated partial thromboplastin time; FFP, fresh frozen plasma; N, normal time; PT, prothrombin time; TT, thrombin time; vWF, von Willebrand's factor; ↑, prolongation

*Deficiency affecting coagulation is unknown

(Adapted from Wilner ML, Rosove MH. Hematologic complications. In: Smith RB, Ehrlich RE, editors. Complications of Urologic Surgery: Prevention and Management. 2nd ed. Philadelphia: WB Saunders; 1990:441-52.)

Factor XII deficiency is not usually associated with bleeding manifestations, although the aPTT is prolonged. Therapy is not needed for this deficiency. Factor XII stabilizes fibrin into a covalent network, and in factor XII deficiency coagulation studies are normal except fibrin stability. Abnormal clot solubility and specific factor XII assay establish the diagnosis, and transfusion of FFP is sufficient for hemostasis.

Fibrinogen deficiency, or dysfibrinogenemia, is uncommon, and FFP or cryoprecipitate may be given to maintain a level of fibrinogen adequate for normal hemostasis.[20]

Disorders of Increased Bleeding

Coagulation and bleeding abnormalities are among the major problems encountered in the surgical or critically ill patient. Although most of these patients have no intrinsic abnormalities of hemostasis, either their underlying disease or the therapy of the disease may produce clinically significant bleeding problems. The urologist must be able to recognize these abnormalities quickly and address them before significant problems arise. Failure to do so may result in an increase in morbidity and mortality in the acutely ill patient or the surgical patient. In this section, we discuss the major critical disorders that may lead to increased bleeding.

RENAL FAILURE

Uremia can cause a coagulopathic state that can place patients in renal failure at risk for severe hemorrhage. The main hemostatic defect is complex and multifactorial but is primarily the result of impaired platelet function, which can manifest as an elevated bleeding time in laboratory testing. Investigations of the hemorrhagic tendency associated with uremia have mostly been performed in patients with chronic renal failure, and whether these findings can be extrapolated to acute renal failure is unclear.[21]

Uremic bleeding is mainly the result of impaired platelet–vessel wall interaction. Observed changes that are thought to contribute to this dysfunction include increased prostacyclin and nitric oxide production by the endothelium, abnormalities in vWF, and biochemical and functional platelet abnormalities.[22,23]

Anemia, often associated with renal failure, also plays a role in platelet dysfunction. Correction of anemia in uremic patients has been shown to improve or correct the prolongation of bleeding time. Improvement in coagulation studies was seen when the hematocrit was increased to 27–32% by transfusion of packed red blood cells or by stimulation of erythropoiesis with recombinant human erythropoietin.[24–27] Anemia related bleeding diathesis is not exclusive to uremia and can be found in anemia from other etiologies.[28]

The finding that acquired platelet dysfunction is partially corrected by hemodialysis suggests that accumulation of uremic toxins in the blood may contribute to the observed effects. Despite the hemorrhagic tendency, activation of coagulation has been demonstrated in uremic patients and is more prominent in those who are being treated with hemodialysis. The safest treatment to relieve uremic bleeding is administration of desmopressin (DDAVP), but its effect is often short-lived. High-dose intravenous (IV) conjugated estrogens can significantly improve the bleeding time and have a longer duration of action in most uremic patients.[29–32]

DISSEMINATED INTRAVASCULAR COAGULATION

DIC is a clinicopathologic syndrome characterized by systemic activation of the coagulation system. Of all acute causes of coagulopathy, it is potentially the most life-threatening. DIC is not a single entity, but rather the end product of a variety of underlying disorders, most commonly bacterial sepsis and malignancy in the urologic patient.[33–36]

Central to the pathogenesis of DIC is the unregulated and excessive generation of thrombin.[34] Normally, the cumulative effect of clot production, clot dissolution (fibrinolysis), and inhibition of clot activation is to produce a steady-state equilibrium of hemostasis. In DIC, excess thrombin is generated, resulting in the inappropriate activation of fibrinolysis and the shifting of the steady state to excessive clot dissolution. A secondary result is that fibrin thrombi are formed in the microvasculature, and platelets and RBCs are trapped and consumed. As the cycle continues, platelets, fibrinogen, and other clotting factors are consumed beyond the body's ability to compensate, and excessive bleeding ensues. It

should be clear from this description that DIC is initially a thrombotic process with secondary hemorrhage occurring only when platelets and clotting factors are sufficiently consumed and depleted. Approximately 10% of patients with DIC present with only thrombotic manifestations.[36]

Patients in whom DIC is suspected generally present with diffuse bleeding from several sites, petechiae or ecchymosis, hypoxemia, hypotension, or oliguria. In acute DIC, laboratory evaluation demonstrates variable degrees of thrombocytopenia, hypofibrinogenemia, and prolongation of PT and aPTT. Assays for fibrin split products (FSPs), fibrin degradation products (FDPs), or the D-dimer fragments of fibrin are generally markedly elevated. The D-dimer assay is theoretically more specific for DIC because this fragment is produced by the action of plasmin on polymerized fibrin.[37,38] Patients with malignant disease often have chronic, compensated DIC in which bleeding is minimal in the steady state, and these patients often present with normal PT/PTT, platelet, and fibrinogen test results. Patients in this subset demonstrate an elevation of FDPs, FSPs, or D-dimer. These patients are also at increased risk for significant bleeding following an insult resulting in activation of their clotting system, such as relatively minor surgical procedures.[36,39]

The diagnosis of DIC relies heavily on laboratory results, but overall the clinical picture must be considered. Of all the laboratory findings, thrombocytopenia, hypofibrinogenemia, and D-dimer fragments appear to be the most sensitive in making a laboratory diagnosis.[36–39] In addition to the coagulation abnormalities, microangiopathic hemolytic anemia is present with fragmented RBCs (schistocytes) on the peripheral blood smear.[36]

The primary management strategy in patients with DIC consists of aggressive basic supportive measures and prompt treatment of the underlying process causing the DIC.[33,36,40] When this is not possible, treatment of the underlying disease accentuates the DIC, or the DIC is progressing despite appropriate treatment of the underlying process, the general approach is to support the patient's hemostatic system with the transfusion of FFP, cryoprecipitate, or platelets.[36] The idea that this approach will add to the consumption coagulopathy has never been clinically proven. If hemorrhage is excessive, replacement with packed RBCs is advised. Use of heparin in DIC is controversial. Therapeutic heparin can be considered if thrombosis is the predominate manifestation and there is no significant bleeding that may be exacerbated by anticoagulation.[38,41]

PRIMARY FIBRINOLYSIS

Primary fibrinolysis is a condition in which the fibrinolytic pathway is activated independent of the activation of coagulation resulting in the pathologic degradation of fibrinogen and fibrin by plasmin. Fibrinolysis is associated with advanced and often metastatic prostate cancer and portends a very poor prognosis, even if significant bleeding is not present.[42,43] In patients with metastatic carcinoma, the tumor cells are presumed to release a substance that directly activates fibrinolysis.[35]

Patients do not typically present with gross bleeding but are at significant risk for hemorrhage resulting from hypofibrinogenemia. Marked thrombocytopenia should raise the suspicion of the development of DIC. The major laboratory discriminant between primary fibrinogenolysis and DIC is a normal level of D-dimer. Once active bleeding develops, it is very difficult to distinguish the two entities because fibrin is generated through the action of thrombin and lysis of fibrin produces D-dimer.[35]

Unlike in DIC, the treatment of choice of primary fibrinogenolysis is the use of antifibrinolytic agents, such as ε-aminocaproic acid or tranexamic acid.[35,42,44] Transfusion support with cryoprecipitate may also be given for severe hypofibrinogenemia. If DIC has developed, the use of antifibrinolytic agents in the absence of systemic anticoagulation (heparin) is contraindicated because of the risk of increased microvascular thrombosis. The best approach in individuals with primary hyperfibrinogenolysis secondary to malignant disease is often aggressive treatment of the underlying malignant condition. Caution should be used in balancing chemotherapy-related bone-marrow suppression with bleeding complications resulting from fibrinogenolysis.

VITAMIN K–RELATED DISORDERS

Liver disease and vitamin K deficiency are common causes of abnormal coagulation test results and clinical coagulopathy. The pathophysiology of these disorders is the decreased production of vitamin K–dependent clotting factors (factors II, VII, IX, X), protein C, and protein S. The liver is the major source of all coagulation proteins except factor VIII and vWF. Liver disorders may also produce abnormalities in fibrinolysis.[37,38] Primary vitamin K deficiency is extremely rare in healthy people. A wide variety of animal and plant sources can provide sufficient vitamin K, and the bacterial flora in the intestine is able to synthesize a significant portion of the required dietary vitamin K. Vitamin K is fat soluble, and therefore adequate bile salt circulation is necessary for absorption.

Vitamin K deficiencies can result from a wide range of conditions. These include, but are not limited to, the following:

1. Newborns, owing to poor transfer of vitamin K by the placenta and lack of vitamin K synthesis in the initially sterile intestine
2. Severe malnutrition or total parenteral nutrition
3. Extrahepatic biliary obstruction
4. Intestinal malabsorption syndromes
5. Broad-spectrum antibiotic use.

The liver also synthesizes factor V, which plays a critical role in fibrin generation. Significant impairment of hepatic synthetic function may result in the decreased production of any of these clotting factors despite normal vitamin K status.

Patients with liver disease or vitamin K deficiency initially have isolated prolongation of the PT resulting from a depletion of factor VII without any signs of clinically significant bleeding. Factor VII has the shortest half-life (6–10 hours) of the coagulation factors. In more severe deficiencies, the PTT can also be elevated because of depletion of factors II, IX, and X. A marked reduction in fibrinogen solely on the basis of decreased synthesis is an ominous sign and suggests very severe liver disease. Patients with long-standing liver disease develop portal hypertension, which may result in splenic pooling of platelets. A valuable assessment of

liver synthetic function is the measurement of albumin or cholesterol.

In a patient with vitamin K deficiency and no evidence of active bleeding, observation with repletion of vitamin K is indicated. Vitamin K may be administered orally, subcutaneously, intramuscularly, or intravenously. Subcutaneous injection is not favored due to variable response and absorption. The fastest route is intravenous injection (1 mg/day), but this carries a risk of anaphylaxis and therefore should be done slowly and in a monitored setting.[45] Oral vitamin k is given at a dose of 5–10 mg/day; improvement is usually seen within 24 hours.[46]

The response to vitamin K may be poor in the presence of liver disease. Patients who fail to respond to vitamin K, who demonstrate increasing abnormalities of PT or PTT, or who are to undergo an invasive procedure may be treated with FFP infusions. Given the short half-life of factor VII, aggressive support with FFP every 6 hours in the perioperative period is generally necessary to produce sustained correction in clotting.[47]

MASSIVE TRANSFUSION SYNDROME

Massive transfusion syndrome results from the replacement of total body blood volume in less than 24 hours without the concomitant transfusion of platelets and FFP, usually in the setting of trauma.[48] This situation leads to dilutional coagulopathy because stored RBCs contain no viable platelets and are usually deficient in coagulation factors. This dilution results in a clinical and laboratory picture resembling DIC.[48] This diagnosis should be suspected in any patient who presents with bleeding, prolonged PT, prolonged PTT, and thrombocytopenia after receiving >5 units of blood. The key element in making the diagnosis is the transfusion history.

Treatment of this disorder is accomplished by replenishment of clotting factors and platelets through administration of FFP and platelet transfusions. The best treatment is prevention by transfusion of 1 unit of FFP and platelets for every 5 units of packed RBCs given. In individuals with continued or excessive blood loss, empirical treatment with FFP or platelets may be advisable. In the absence of uncontrolled or continued bleeding, it is acceptable to hold the use of FFP and platelets unless they are clinically indicated for postoperative bleeding.[48]

Anticoagulated Patient

Patients receiving chronic anticoagulation therapy who require a urologic procedure represent a challenge to the urologist. Perioperative management of these patients should be aimed at minimizing both surgical and medical risks. To accomplish this goal, the urologist must have an understanding of the indication for anticoagulation therapy, the consequence of withholding the therapy, and the pharmacologic mechanism of action of the particular anticoagulation medication.[42] Perioperative management of anticoagulation or antiplatelet therapy should be determined by the patient and a therapeutic team made up of the urologist, anesthesiologist, cardiologist and primary care physician. The number of available antiplatelet and anticoagulant agents has increased significantly over the last few years. The following tables will provide an overview of the available medications (see Tables 4.3–4.5).

The most common indications for chronic anticoagulation include venous thromboembolism (VTE), mechanical prosthetic heart valves, chronic atrial fibrillation, and coronary stents, particularly drug-eluting stents (DES). Discussion of VTE is addressed later in this chapter. Mechanical prosthetic heart valves require anticoagulation secondary to the risk of thrombotic complications, including systemic embolization and occlusive thrombosis. Patients with atrial fibrillation require anticoagulation because of a six times higher rate of stroke.[42]

ANTIPLATELET THERAPY

The most commonly encountered antiplatelet medications include aspirin (ASA) and the $P2Y_{12}$ receptor blocking agents (e.g., clopidogrel and prasugrel). See Table 4.3 for an overview of antiplatelet medications. These drugs are used for secondary prevention in patients with cerebrovascular, coronary, and peripheral vascular disease. Antiplatelet medications are also used after percutaneous coronary intervention (PCI) with placement of endovascular stent to prevent stent thrombosis.

ASA exerts its anticoagulant effect by irreversibly inhibiting platelet cyclooxygenase 1 (COX-1), which inhibits thromboxane A production and reduces platelet aggregation. This effect is irreversible and lasts for the life of the platelet, which is approximately 7 to 10 days. Therefore patients taking ASA who are undergoing an elective procedure should discontinue ASA for approximately 7–10 days before the procedure.[49] The most common side effects of aspirin are gastrointestinal and can manifest as minor dyspepsia or major gastritis, ulcers, and bleeding.

The thienopyridines or $P2Y_{12}$ receptor blockers target an integral ADP receptor on the surface of platelets. The thienopyridines include ticlopidine, clopidogrel, and prasugrel (Table 4.4). This potent irreversible blockade prevents ADP-induced platelet aggregation. The thienopyridines can also cause gastrointestinal side effects, but also major hematologic complications (neutropenia, thrombocytopenia, and thrombotic thrombocyptopenic purpura). These major effects usually manifest within the first 3 months of initiation of these medications. $P2Y_{12}$ receptor blockers should be stopped 5–7 days prior to a procedure to reduce the risk of bleeding.[49,50]

Percutaneous coronary intervention is now very common in treatment of obstructive coronary artery disease. During PCI either bare metal stents (BMS) or DES are often placed. Dual antiplatelet therapy (DAPT) with ASA and a $P2Y_{12}$ receptor blocker are used to decrease risk of stent thrombosis. Risk of stent thrombosis in the perioperative period is highest in the first 4–6 weeks after stent implantation. DES decrease the risk of re-stenosis but have longer periods of increased risk for in-stent thrombosis. The American College of Cardiology (ACC) and the American Heart Association (AHA) task force created practice guidelines in 2014 for perioperative cardiovascular management of patients undergoing noncardiac surgery. Elective noncardiac surgery should be delayed 14 days after PCI with balloon angioplasty (no stent placement), 30 days for BMS

Table 4.3 Antiplatelet Medications

Class	Drugs	Mechanism of Action	Common Indications	Dose	Side Effects
Salicylates	Acetylsalicylic acid (Aspirin)	Irreversible platelet COX-1 inhibition	Secondary prevention in patients with cerebrovascular, coronary, and peripheral vascular disease	75–325 mg PO daily	GI (dyspepsia, gastritis, ulcers, bleeding), hepatic and renal toxicity in overdose
Thienopyridines	Clopidogrel (Plavix), Ticlopidine (Ticlid), Prasugrel (Effient)	Irreversibly blocks platelet ADP receptor ($P2Y_{12}$ receptor) leading to disruption of platelet aggregation	Secondary prevention in cerebrovascular, coronary, and peripheral vascular disease (in combination with ASA) to prevent post cardiac and peripheral stent thrombosis or in cases of unstable angina	Clopidogrel 75 mg PO daily (commonly started with loading dose)	GI thrombocytopenia TTP
Dipyridamole	Aggrenox (combination extended-release dipyridamole and low-dose Aspirin)	PDEi causing increased intracellular platelet cAMP leading to platelet inhibition	Stroke prevention in patients with history of TIA	200 mg dipyridamole – 25 mg ASA PO twice daily	GI, headaches, facial flushing, dizziness, hypotension
Glycoprotein IIb/IIIa receptor antagonist	Abciximab (ReoPro), Eptifibatide (Integrillin), Tirofiban (Aggrastat)	Targets the glycoprotein IIb/IIIa receptor on surface of platelets limiting aggregation	Patients with acute myocardial infarction or planned percutaneous intervention tirofiban/eptifibatide – high-risk patient with unstable angina	Intravenous bolus followed by infusion	Immune-mediated thrombocytopenia

ASA, aspirin; TTP, thrombotic thrombocytopenic purpura; TIA, transient ischemic attack; PDEi, phosphodiesterase inhibitor; cAMP, cyclic adenosine monophosphate; PO, per os; GI, gastrointestinal; ADP, adenosine diphosphate

(Adapted from Braunwald E, Bonow RO, editors. Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine. 9th ed. Philadelphia: Saunders; 2012. 1961)

Table 4.4 Parenteral Anticoagulants

Class	Drugs	Administration	Mechanism of Action	Common Indications	Side Effects
Heparin	Heparin	Intravenous or subcutaneous	Activation and enhancement of antithrombin activity	Acute coronary syndrome, atrial fibrillation, prevention and treatment of venous thromboembolism, treatment of pulmonary embolus	Elevation of transaminases, HIT, osteoporosis
Low-molecular-weight-heparin	Enoxaparin (Lovenox), dalteparin (Fragmin), tinzaparin (Innohep)	Subcutaneous injection	Activation of antithrombin causing inhibition of factor Xa	Similar to heparin	HIT, osteoporosis
Selective factor Xa inhibitors	Fondaparinux (Arixtra)	Subcutaneous injection	Catalyzes inhibition of factor Xa by antithrombin	Similar to heparin, appears to be effective in treating HIT	Bleeding
Direct thrombin inhibitors	Bivalirudin (Angiomax), argatroban	Intravenous or subcutaneous	Bind directly to thrombin to block substrate interaction	Similar to heparin, treatment of HIT	Back pain, nausea, headache, and hypotension

HIT, heparin induced thrombocytopenia

(With permission from Braunwald E, Bonow RO, editors. Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine. 9th ed. Philadelphia: Saunders; 2012. 1961)

implantation, and 365 days after placement of a DES. Elective noncardiac surgery can be considered after 180 days if the risk of surgical delay is greater than the risk of ischemia or stent thrombosis. In patients undergoing urgent noncardiac surgery during the first 4–6 weeks after stent implantation (BMS or DES), DAPT should be continued if the risk of bleeding is not too great. If the bleeding risk is deemed too high, then ASA should be continued if possible and the $PG2Y_{12}$ platelet receptor inhibitor should be restarted as soon as possible. The benefit of aspirin use in prevention of perioperative ischemic complications in a patient without previous cardiac stenting is unclear. The continuation of aspirin in a patient with a high-risk coronary artery disease or cerebrovascular disease with no history of coronary stenting may be reasonable if the risks of an ischemic event outweigh the risks of bleeding.[51]

The American Urologic Association (AUA) and the International Consultation on Urological Diseases (ICUD) released a 2014 review paper covering anticoagulation and antiplatelet therapy in urologic practices. Some of the urology-specific recommendations regarding antiplatelet medication will be listed below. Patients with cardiac risk

Table 4.5 Oral Anticoagulants

Class	Drugs	Mechanism of Action	Common Indications	Side Effects	Half-Life (Hours)
Vitamin K antagonist	Warfarin (Coumadin)	Interferes with synthesis of vitamin K–dependent clotting factors	Stroke prevention in patients with atrial fibrillation, prevention of thrombotic or thromboembolic events in patients with prosthetic heart valves, prevention and treatment of deep venous thrombosis	Skin necrosis	36–42
Factor Xa inhibitor	Rivaroxaban (Xarelto), apixaban (Eliquis)	Reversible inhibition of active site of factor Xa	Stroke prevention in patients with nonvalvular atrial fibrillation, prevention and treatment of deep venous thrombosis	Gastrointestinal bleeding	9–14
Direct thrombin inhibitor	Dabigatran etexilate (Pradaxa)	Reversible inhibition of active site of factor IIa (thrombin)	Stroke prevention in patients with nonvalvular atrial fibrillation		12–17

(Adapted from Braunwald E, Bonow RO, editors. Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine. 9th ed. Philadelphia: Saunders; 2012. 1961)

factors on low-dose aspirin by itself can continue the medication in the perioperative period without increased risk of bleeding. Patients taking low-dose aspirin without any specific indication can hold their aspirin for an elective procedure until directed to restart by the surgical team. Prostate biopsy can be performed safely on a patient taking low-dose aspirin, but with an increased risk of minor bleeding. In general, the continuation of aspirin for urologic procedures in the perioperative period is associated with a minor risk of increased bleeding without major consequences and is not associated with an increased risk of transfusion. Transurethral resection of the prostate, shockwave lithotripsy, and percutaneous renal surgery are probable exceptions to this rule.[52]

ANTICOAGULATION THERAPY

Full-dose or therapeutic anticoagulation can be achieved with vitamin K antagonists (warfarin) or the novel oral anticoagulants (NOACs), which include direct thrombin inhibitors and factor Xa inhibitors. These medications are used to prevent thrombotic and thromboembolic events in high-risk patients and in treatment or prevention of deep venous thrombosis. Again, perioperative choices for the management of anticoagulation should be made in conjunction with other providers and must weigh the risks of bleeding against the risk of a thrombotic event.

Warfarin exerts its anticoagulant effect by inhibiting vitamin K–dependent procoagulation factors II, VII, IX, and X and anticoagulant proteins C and S. Warfarin's effect usually occurs 2–3 days after initiation of therapy because of the prolonged half-life of the different procoagulant factors; factor II has the longest half-life (72 hours). In the past, the PT was used to measure the effect of warfarin, but because of variability in PT measurements the INR (international normalized ratio) is currently used. Most procedures can be performed safely when the INR is 1.4 or less. Warfarin is used in patients with prosthetic heart valves, atrial fibrillation, and a history of stroke as well as in preventing recurrent myocardial infarction and death in patients with an acute myocardial infarction.[53] However, the most common indication for warfarin therapy is management of patients with VTE.

The NOACs are new alternatives to warfarin (Table 4.5). These medications target thrombin or factor Xa directly and reversibly bind the active site of the coagulation factor. Unlike warfarin, the onset of action is rapid and routine monitoring is not required. These medications should be discontinued >48 hours prior to a procedure.[51] A longer interval of discontinuation should be used in the setting of renal impairment.[50] Routine monitoring of the levels of anticoagulation are not performed, but qualitative assessment of anticoagulation can be performed with prothrombin time for factor Xa inhibitors and activated partial thromboplastin time for direct thrombin inhibitors. Apixaban has a limited effect on PT; anti-factor Xa assays can be used to determine the anticoagulant activity. There are no current antidotes or reversal agents for these medications. A patient who is experiencing severe hemorrhage while taking a NOAC should be managed with fluid resuscitation and repletion of blood products by transfusion as needed. If the last dose of anticoagulant was taken within a 4–6 hour window, then activated charcoal may help reduce absorption. There is no substantial evidence to support the effectiveness of the use of procoagulant factors at this time. Dialysis may be used to remove dabigatran from the circulation but will not remove the highly protein bound rivaroxaban or apixaban.[50]

The management of patients taking warfarin who require an invasive procedure depends on the procedure, the risk of bleeding, and the risk of thromboembolism once the warfarin is stopped. The ACC/AHA perioperative guidelines address management of anticoagulation in patients with atrial fibrillation and prosthetic heart valves.

Patients with atrial fibrillation undergoing a high-risk surgical procedure should stop warfarin 5 days prior to the procedure to allow the INR to normalize. Therapy should be restarted 12 to 24 hours after the procedure if the risk is acceptable.[52]

Patients with prosthetic valves who are at lower risk for thrombosis such as those with bileaflet mechanical aortic valve replacements and no risk factors (atrial fibrillation, previous thromboembolism, left ventricular dysfunction, older generation thrombogenic valve, mechanical tricuspid valves, or multiple mechanical valves) can stop warfarin 48 to 72 hours prior to a procedure to allow the INR to correct,

and restart therapy within 24 hours after the procedure if safe.[51]

Patients with prosthetic valves who are at high risk for a thromboembolic event, including patients with a mechanical mitral valve or an aortic valve replacement with any risk factor (atrial fibrillation, previous thromboembolism, left ventricular dysfunction, hypercoagulable state, older generation thrombogenic valves), should discontinue warfarin 3–5 days before admission and start bridging anticoagulation with unfractionated or low-molecular-weight heparin (LMWH).[51] One consideration is patients with renal failure, in whom LMWH is contraindicated. If emergency surgery is required, then patients receiving warfarin therapy can receive FFP. Vitamin K should be used with caution to reverse the effect of warfarin because it can complicate the re-initiation of warfarin therapy.[54]

Heparin acts by inactivating free thrombin through its interaction with antithrombin III (AT III). The inactivation of thrombin prevents the conversion of fibrinogen to fibrin. Heparin also inactivates factors Xa and IXa of the coagulation cascade. Heparin's anticoagulant effect is monitored by aPTT or anti-factor Xa assay (also called anti-Xa assay), which measures the inhibitory activity of heparin on the activated form of factor Xa. Heparin should be discontinued 3–4 hours before a procedure. If reversal is necessary on an emergency basis, protamine can be given.

Finally, patients with thromboembolic disease that has occurred beyond 3–6 months should be managed by discontinuing anticoagulation 3–5 days preoperatively and resuming it as soon as possible postoperatively. Patients with a history of a more recent thromboembolic event should be managed with concurrent heparin anticoagulation during the discontinuation of warfarin.[53,54] If history of DVT is an issue prior to surgery and bleeding risk and/or pulmonary embolism risk is high, consideration should be given to placement of an IVC filter prior to surgery after consultation with vascular surgery.

Management of Intraoperative Bleeding

On occasion, the urologist is faced with a patient who has extreme intraoperative coagulopathy. This condition has many possible causes, and it is imperative for the surgeon to identify the appropriate factors. When the operative field is infected, such as in abscess drainage or resection of xanthogranulomatous pyelonephritis, coagulopathy should be a clue to progressive intraoperative sepsis. In individuals with excessive surgical bleeding, dilutional coagulopathy is a likely source. Finally, in patients with known abnormalities of hepatic synthetic function, the bleeding may be a function of the underlying disease state. The immediate management of such patients varies according to the cause of bleeding.

In patients with dilutional coagulopathy or transfusion reaction, empirical replacement of clotting factors with administration of FFP, cryoprecipitate, or platelets may be enough to slow bleeding and allow completion of the surgical procedure. The patient's core temperature should be maintained because hypothermia may worsen the bleeding. Devices such as warming blankets, as well as warm irrigation of the surgical field, may allow rapid improvement in core temperature in such a setting. In patients with consumptive coagulopathies, such efforts may be of little help. In these cases, the surgeon's effort should be focused on prompt completion of the procedure with maximal drainage of the infected cavity, to minimize ongoing bacteremia.

In the absence of visible arterial bleeding, exhaustive efforts to control the bleeding with cautery or ligature are often unsuccessful, and liberal use of packing should be implemented. Extensive efforts to achieve hemostasis only delay the completion of the procedure and, indirectly, worsen the coagulopathy through progressive blood loss and hypothermia. On completion of the procedure, widespread coagulation with devices such as the argon beam coagulator can be useful as long as they do not delay completion of the procedure.

On rare occasions if the patient is unstable the procedure must be aborted or packing may be left in place even after completion of the procedure. When this is necessary, packing is generally left in place with the wound closed in a single layer. The patient is then transported to the intensive care unit for resuscitation and correction of coagulopathy before reoperation and removal of packing, usually 24 to 48 hours later. In cases of extirpative surgical procedures, organ resection should be completed if possible to allow more prompt resolution of coagulopathy. Reconstruction can then be carried out at the time of re-exploration. In patients with active infection, drainage or resection of infected tissue is extremely important before the procedure is aborted because ongoing infection may perpetuate the coagulopathy. New infection is a concern in aborted procedures, and the patient should be maintained on broad-spectrum antibiotics while packing materials are in place.

Problems of Increased Coagulation

HYPERCOAGULABLE STATE

Patients with a history of recurrent or spontaneous venous thrombosis may have an underlying *familial or acquired hypercoagulable state* (Table 4.6).[55,56] Historically, it was thought that underlying hereditary defects were the source of <10% of such cases.[56] More recently, it was determined that in fact >50% of such cases have a specific underlying cause. The coagulation cascade is influenced by certain regulatory factors. Abnormalities of these factors may increase the risk of thrombosis and include deficiencies of antithrombin (AT) III, protein C, and protein S. Activated protein C (APC) resistance (factor V Leiden mutation) was discovered to account for the majority of diagnosable coagulation defects (Table 4.7).[57–60] Factor V Leiden occurs with an estimated frequency of 5% in the general population of European ancestry.[61,62]

Physiology

Most coagulation proteins are serine proteases that act sequentially on one another. These proteins are regulated by another series of proteins called *serapins* (serine protease inhibitors). Serapins may be activated under normal

Table 4.6 Familial or Acquired Disorders Leading to Hypercoagulable State

Familial	Acquired
Antithrombin III deficiency	Malignant disease
Protein C deficiency	Regulatory protein deficiency (malnutrition/nephrotic syndrome)
Protein S deficiency	Acute-phase reactants (trauma/surgery)
Activated protein C resistance	Antiphospholipid syndrome
Factor V Leiden	Myeloproliferative disorders
Abnormal factor V cofactor activity	Heparin-associated thrombocytopenia
Hypoplasminogenemia	Disseminated intravascular coagulation
Abnormal plasminogen	Oral contraceptives
Plasminogen activator deficiency	Pregnancy/postpartum state
Dysfibrinogenemia	
Factor XII deficiency	
Abnormal platelet reactivity	

Table 4.7 Prevalence of Hereditary Disorders Leading to Hypercoagulability

Disorder	Prevalence (%)
Elevated Factor VIII:c levels	11
Factor V Leiden	Whites 4–7 Nonwhites 0–1
Prothrombin G20210A	Whites 2–3 Nonwhites 0–1
Antithrombin III, protein C or S deficiency	1

(Adapted from Middeldorp S, Coppens M. Hereditary thrombophilia. In: Kaushansky K, Lichtman MA, Prchal JT, Levi MM, Press OW, Burns LJ, et al., editors. Williams Hematology, 9e [Internet]. New York, NY: McGraw-Hill Education; 2015.)

homeostatic situations, in stress conditions, or as part of administered therapy. Serapin deficiencies may cause the hypercoagulable state. The best-studied serapin is AT III, a heparin cofactor that allows heparin to inactivate factors II, IX, XI, and XII. A decrease in the concentration of AT III predisposes patients to thrombosis by allowing uncontrolled activity of the majority of coagulation factors. AT III deficiency is responsible for hypercoagulability in 2–4% of studied patients, and it is present in 0.2–0.4% of the general population.[53] In addition to regulation by serapins, the clotting cascade is influenced by a complex group of receptors at the endothelial surface termed *thrombomodulins*. These receptors function as anticoagulants because of their ability to neutralize thrombin on the endothelial surface. Once formed, the thrombin-thrombomodulin complex activates a vitamin K–dependent factor called *protein C*, which metabolizes activated factors V and VIII and thus suppresses coagulation. This activation is facilitated by another vitamin K–dependent factor called *protein S*, which also functions to metabolize activated factors V and VIII. Deficiencies in proteins C or S may result in a thrombotic tendency, are observed in 2–5% of hypercoagulable patients, and are present in approximately 0.5% of the general population.[55,56,60]

For APC to exert its control on activated factor V, it must first attach to and then cleave this factor. A mutation in factor V, called *factor V Leiden*, has been identified that results in the inability of APC to cleave factor V, a condition referred to as *APC resistance*. This abnormality accounts for approximately 90% of cases of APC resistance and has a prevalence of approximately 5% in the general population.[57–60,63,64]

Deficiencies of AT III, protein C, and protein S, as well as APC resistance, are all inherited in an autosomal dominant fashion, and deficiencies of these proteins have an incidence of <1% each.[55] APC resistance is present in 3–8% of the population.[55,60] The presence of APC resistance increases the likelihood of a simultaneous additional inherited disorder. In such cases, the risk for thrombosis is dramatically increased compared with the risk in individuals with APC resistance alone.[65–69] Coexisting acquired conditions (see Table 4.6), as well as immobilization, trauma, pregnancy, malignant disease, hormone replacement therapy, and surgery, also significantly add to the risk for thrombosis in individuals with hereditary hypercoagulable states.[55,70]

An acquired condition that has been increasingly recognized as a common cause of thrombosis is the *antiphospholipid syndrome*, which is present in 2–3% of the general population. Antiphospholipids predispose patients to both arterial and venous thrombosis.[71] The diagnosis involves the detection of lupus anticoagulant or anticardiolipin antibodies in conjunction with arterial and venous thromboses or thrombocytopenia.[55,63,64] Individuals with lupus anticoagulant may present with an elevation of serum aPTT. The mechanism of thrombosis in antiphospholipid syndrome, however, has not been well delineated.[64,72,73]

Evaluating the Hypercoagulable Patient

Screening for an underlying coagulation abnormality in cases of venous thrombosis should be performed in the presence of any of the following situations:

1. Family history of thrombosis
2. Thrombosis at an early age (<45 years)
3. Recurrent thrombosis, especially without precipitating factors
4. Recurrent thrombosis despite adequate anticoagulant therapy
5. Thrombosis at an unusual site
6. Elevated aPTT (lupus anticoagulant), hematocrit, white blood cells, and platelets
7. Apparent warfarin-induced skin necrosis.

Several additional indications suggest the need to test for antiphospholipid antibodies. These indications include a history of recurrent fetal loss, venous or arterial thrombosis associated with thrombocytopenia, and thrombosis associated with neurologic abnormalities such as stroke or transient ischemic attacks. A specific cause of spontaneous venous thrombosis is found in ≤50% of outpatients, but all individuals should be evaluated because of the potentially lethal consequences of an untreated underlying abnormality.[63]

Abnormalities of AT III, protein C, or protein S in screened individuals can manifest with either a normal or deficient level. Individuals with normal levels may have dysfunctional or inactive forms of these proteins, thereby resulting in a clinically deficient state. A comprehensive discussion of specific assays is beyond the scope of this chapter, but for the aforementioned reasons, functional assays are initially more informative than antigenic assays that simply measure the presence or absence of the factor. Ideally, the patient should not be in an active thrombotic state or taking anticoagulants at the time of testing.

Whenever possible, anticoagulant therapy should be discontinued several weeks before testing because warfarin and heparin can interact with the various assays. When concern exists that a patient is still at risk for thrombosis if anticoagulation is discontinued, it is possible to continue anticoagulation while testing for certain hypercoagulable states. Deficiencies in AT III, lupus anticoagulant, and anticardiolipin antibodies, as well as APC resistance (in factor V–deficient plasma), can be detected during warfarin administration. Additionally, protein C or S deficiencies or anticardiolipin antibodies can be tested for while patients are receiving heparin (Table 4.8).[63]

A positive test result should be confirmed before the diagnosis of an inherited deficiency is made. To confirm the diagnosis of the antiphospholipid syndrome, antibodies must be shown to be present on two occasions >3 months apart.

Management

Acute thrombosis with an underlying hypercoagulable condition requires treatment as discussed in the next section, but some special considerations should be kept in mind in patients with known hypercoagulable states and an acute thrombotic event. After the initial therapy and the recommended 3–6 months of therapy with anticoagulation, the question remains as to which patients require continued anticoagulation. The number of sites involved, the severity of thrombosis, the presence of recurrent thrombosis, and whether the thrombosis was spontaneous or secondary to a precipitating event should all be taken into consideration. Special attention must be paid to such factors as reproductive status and potential risks for immobilization or trauma.

Table 4.8 Effects of Anticoagulants on Functional Assays for Hypercoagulable States

	Effect of Anticoagulant	
Functional Assay	**Heparin**	**Warfarin**
Antithrombin III	Decrease	No effect
Protein C	No effect	Decrease
Protein S	No effect	Decrease
Activated protein C resistance	False-positive result	Modified assay may avoid interaction
Lupus anticoagulant	Possible false-positive result	Modified assay may avoid interaction
Anticardiolipin antibodies	No effect	No effect

For patients with antiphospholipid syndrome, available studies suggest that lifelong anticoagulant therapy should be considered in the setting of any arterial or venous thrombotic event.[64,72] Conversely, lifetime anticoagulation is recommended only for patients with two or more thromboembolic events following the diagnosis of an inherited deficiency. Finally, in asymptomatic adults with hereditary deficiencies, short-term prophylaxis with heparin (subcutaneous or LMWH) should be considered when the risk of thrombosis is increased, such as during prolonged bed rest, surgery, or trauma.[55,56,63]

DEEP VENOUS THROMBOSIS AND PULMONARY EMBOLISM

Thromboembolic disease, in particular deep venous thrombosis (DVT) and pulmonary embolism (PE), is a significant cause of morbidity and mortality in surgical patients. DVT accounted for nearly 100,000 hospital visits in 2000, according to the Centers for Medicare and Medicaid Services.[54] Approximately 5 million cases of DVT, 500,000 to 630,000 cases of PE, and 200,000 cases of fatal PE occur annually.[51] Patients undergoing abdominal or pelvic surgery for cancer are at a high risk for these complications. In a review of patients who underwent pelvic surgical procedures without prophylaxis, Kibel and associates reported a DVT incidence rate of approximately 30%, a PE incidence rate of 10%, and a fatal PE rate of 5%.[74] Investigators have reported that 1–5% of patients undergoing major urologic surgical procedures have symptomatic VTE.[75]

The risk factors for venous thrombosis can be thought of in the context of Virchow's triad for the pathophysiology of thrombus formation:

1. Stasis
2. Hypercoagulability
3. Intimal injury.

Risk factors include advanced age (>60 years old), obesity, history of previous DVT, prolonged immobility, pregnancy, malignant disease, fracture, estrogen use, major medical conditions leading to venous stasis (congestive heart failure, nephrotic syndrome, sepsis, myocardial infarction, inflammatory bowel disease, erythrocytosis, myeloproliferative disorder), and thrombophilia.[68,76,77] Importantly these risk factors are additive. Wheeler showed that patients with no risk factors had an 11% and 1% rate of DVT and PE, respectively, whereas those patients with one risk factor had a 24% and 4% rate, and finally those with four risk factors had a much higher risk of 100% and 67%.[78]

Thrombus formation is believed to occur during the surgical procedure.[78,79] Investigators have proposed that the likelihood of thrombus formation increases with the duration of anesthesia, especially if it exceeds 1 hour.[80,81] This finding seems to be related to an increase in venous stasis secondary to prolongation of intraoperative muscle relaxation.

Urologic patients, by the nature of the diseases for which they are surgically treated, often have multiple risk factors for thromboembolic disease including advanced age, malignant disease, and prolonged operative time. The incidences of DVT and PE have been examined in various urologic procedures. Historically, Colby in 1948 reported a 6.26%

thromboembolic rate and a 2.64% fatal PE rate in patients undergoing open prostate surgical procedures.[82] Although prophylaxis has reduced the rate of thromboembolic events in urologic surgery, the rates still remain significant. The rate of events has been reported as 0.24–1.5% after nephrectomy,[83,84] 1.3–6.2% after radical prostatectomy,[85,86] and 0.52–5.9% after radical cystectomy.[87,88]

The challenge of diagnosing DVT stems from the nonspecific nature of its clinical presentation. The classic triad of pain, swelling, and erythema can be found in both patients with and without DVT. The classic Homans sign, calf pain on dorsiflexion of the foot, is found in only 10% of patients with DVT.[78] In view of these findings, objective testing is required to confirm the diagnosis before treatment, particularly because the treatment of thromboembolic disease is not without its own additional complications. Once DVT is suspected, compression ultrasonography of the proximal veins or duplex ultrasonography should be performed. Compression ultrasonography has a sensitivity of >90% for detecting proximal vein thrombosis.[89,90] It is less invasive than the gold standard diagnostic test, contrast venography, and is more accurate than impedance plethysmography.[76] If the initial ultrasound finding is abnormal, then a diagnosis of DVT can be comfortably made. Conversely, when the test result is normal, one cannot completely rule out the possibility of a DVT. Ginsberg, in a review of DVT management, recommended a repeat ultrasound study for those patients with clinically suspected DVT who had normal findings on their initial ultrasound examination.[76]

The diagnosis of acute PE is also difficult given the wide range of presentations.[59,79,80] More recent approaches, such as use of the Wells criteria, have suggested using a D-dimer test and categorizing patients as having a low, intermediate, or high probability of PE (Table 4.9).[90,91] When the index of suspicion is high, particularly in patients in the postoperative period, a spiral computed tomography (CT) scan with IV contrast is warranted and is considered by most clinicians to be the standard initial diagnostic test.

At present, we often employ spiral chest CT as a first test for PE. If results are negative, then we proceed with pulmonary angiography only if a strong clinical suspicion still exists for PE. A potential shortcoming of both spiral CT and pulmonary angiography is the need for a large bolus of IV or intraarterial contrast material. In individuals with preexisting renal compromise, a ventilation/perfusion scan is an option to consider.

Table 4.9 Wells Criteria

Criteria	Points
Clinical signs of DVT	+ 3
Alternative diagnosis less likely than PE	+ 3
Previous PE or DVT	+ 1.5
Heart rate >100 beats per min	+ 1.5
Recent surgery or immobilization	+ 1.5
Hemoptysis	+ 1
Malignancy (current or treated in the last 6 months)	+ 1
Score by Model	**PE Rate Overall**
<2 (low)	3.6%
2–6 (moderate)	20.5%
>6 (high)	66.7%

DVT, deep venous thrombosis; PE, pulmonary embolism
(Adapted from Wells PS, Anderson DR, Rodger M, et al. Derivation of a simple clinical model to categorize patient's probability of pulmonary embolism: increasing the model's utility with the SimpliRED D-dimer. Thromb Haemost. 2000 Mar;83(3):416-20.)

Management

The goals of treating thromboembolic disease are to prevent further propagation of the thrombus, to prevent embolization of the thrombus, and in certain situations to promote fibrinolysis. Once the diagnosis is made, then anticoagulation therapy should be instituted unless a contraindication exists. If the patient is hemodynamically unstable or has extensive ileofemoral DVT, cardiac and vascular surgical consultation should be considered for possible intervention.

If the patient is not hemodynamically unstable, then therapeutic anticoagulation usually with heparin should be instituted immediately on confirmation of DVT. Various regimens for the administration of IV unfractionated heparin have been developed and are based on weight or dose titration nomograms.[76] An aPTT of 1.5 to 2.5 times the control is recommended. Furthermore, attempts should be made to achieve therapeutic aPTT values as rapidly as possible because persistent subtherapeutic values likely increase the risk of DVT recurrence.

Warfarin therapy is started 24 hours after heparin therapy and is monitored by INR with a goal of 2.0 to 3.0 time the control. The clinician should confirm that the patient has no evidence of major bleeding with a therapeutic aPTT before warfarin therapy is instituted. Heparin therapy can be discontinued once therapeutic levels of INR have been achieved for 2 days. The duration of treatment is determined by the risk for future thromboembolic disease. Patients with a first episode of thromboembolic disease and a reversible risk factor such as surgery should be treated for 6 weeks to 3 months (depending on the severity of the episode). As described later, patients with idiopathic thromboembolic disease should be treated for 3 to 6 months. Longer and, in certain instances, indefinite treatment is recommended in patients with a predisposition for recurrent venous thrombus.

Complications of heparin therapy include bleeding, thrombocytopenia with and without thrombosis, osteoporosis, skin necrosis, and less common complications including anaphylaxis, hypoaldosteronism, and alopecia.[68,92] Similar complications are associated with warfarin therapy; bleeding is the most common. Particular attention should be paid to concomitant medications that may interact with warfarin and affect INR, the most prevalent of which are fluoroquinolones, macrolides, and sulfonamides in the treatment of urologic patients.[93,94]

Because of potential complications, alternative anticoagulation regimens have been sought. Several studies have been conducted in the past 2 decades to evaluate LMWH.

Table 4.10 American Urological Association Prophylaxis Recommendations

Patient Risk Stratification	
Low risk	Minor* surgery in patients <40 years with no additional risk factors
Moderate risk	Minor* surgery in patients with additional risk factors Surgery in patients aged 40–60 years with no additional risk factors
High risk	Surgery in patients >60 years Surgery in patients aged 40–60 years with additional risk factors (prior venous thromboembolism, cancer, hypercoagulable state)
Highest risk	Surgery in patients with multiple risk factors (age >40 years, cancer, prior venous thromboembolism)
*For the purposes of this table, minor surgery is defined as a procedure with a relatively short operating time in which the patient is rapidly ambulatory.	
Venous Thromboembolism Prophylaxis Recommendations	
Level of risk	Prophylactic treatment
Low risk	No prophylaxis other than early ambulation
Moderate Risk	Heparin 5000 units every 12 hours subcutaneous starting after surgery OR *enoxaparin 40 mg (Cr Cl 30 mL/min =30 mg) subcutaneous daily OR pneumatic compression device if risk of bleeding is high
High risk	Heparin 5000 units every 8 hours subcutaneous starting after surgery OR enoxaparin 40 mg (Cr Cl 30 mL/min 30 mg) subcutaneous daily OR pneumatic compression device if risk of bleeding is high
Very high risk	Enoxaparin 40 mg (Cr Cl 30 mL/min 30 mg) subcutaneous daily and adjuvant pneumatic compression device, OR Heparin 5000 units every 8 hours subcutaneous starting after surgery and adjuvant pneumatic compression device

Enoxaparin dose may vary with patient weight.
(Adapted from Forrest JB, Clemens JQ et al. AUA Best Practice Statement for the prevention of deep vein thrombosis in patients undergoing urologic surgery. J Urol. 2009 Mar;181(3):1170-7.)

LMWHs are synthesized from larger unfractionated heparin molecules by enzymatic or chemical depolymerization.[95–98] The advantages of LMWH include superior bioavailability, lower incidence of bleeding, lower incidence of heparin-induced thrombocytopenia, ease of administration and monitoring (subcutaneous once or twice daily), and the availability of outpatient use.[95,96] Several trials comparing LMWH with unfractionated heparin concluded that LMWH significantly reduced recurrence, had a superior relative risk reduction of thromboembolic complications, and incurred a statistically significant reduction in bleeding.[96,99] Although the actual cost of LMWH is 10 to 20 times that of unfractionated heparin, the potential lower complication rates, the reduced need for laboratory and hospital monitoring, and the availability of outpatient treatment may make LMWH a more cost-effective alternative. For these reasons, LMWH is preferable to unfractionated heparin in most settings.[96] The novel oral anticoagulants can also be used as an alternative to warfarin therapy. For those patients with a contraindication to anticoagulation therapy, an inferior vena cava filter can be considered.

Because of the significant morbidity and mortality associated with thromboembolic disease, prevention is critical, especially in the surgical patient. Radical pelvic surgery is considered to be a serious risk factor for postoperative DVT; it is associated with a DVT rate of approximately 30% and PE rate of 10% in patients without prophylaxis.[74] With prophylaxis, these rates decrease to 10% and 1.5%, respectively.

The American Urological Association in 2009 published best practice statements for the prevention of deep vein thrombosis in patients undergoing urologic surgery, which stratifies patients based on individual risk factors and takes into consideration the risk of the procedure (Table 4.10).

A topic of concern involves late thromboembolic complications. In the past, it was believed that DVT occurred in the first 3 postoperative days and that prophylaxis was indicated during that period. More recent studies, however, suggested that significant numbers of DVT and PE cases occur after hospital discharge. Huber and associates[100] determined that ≤25% of DVT and 16% of PE occurred after hospital discharge. This finding of late DVT has been noted in urologic patients as well. In a series reviewing postoperative complications in patients undergoing radical retropubic prostatectomy, investigators noted that DVT was diagnosed an average of 12 days postoperatively.[101] Late thromboembolism is thought to result from a prolonged hypercoagulable state that extends beyond the period of prophylaxis. Such prolonged states may be of particular concern in patients enduring prolonged bed rest or with concurrent malignant disease. Unfortunately, the trend toward minimally invasive surgical procedures and earlier hospital discharge may make addressing this question more difficult.

Conclusion

A practicing urologist must have a thorough understanding of hematologic complications to ensure safe and efficacious perioperative care. As urologic surgeons work with an increasingly aging population they will encounter more patients on a continually expanding list of anticoagulation medication. The risk of hemorrhage and thrombosis must be carefully weighed and decision making must occur as part of a multidisciplinary team. Patients who undergo urologic surgery are at high risk for complications that can lead to severe morbidity and mortality. The surgeon must focus on risk reduction and proper management of complications to provide excellent care.

Chapter 4 Questions

1. A patient is found to have an isolated elevated bleeding time in preoperative workup. Bleeding time can be used to assess what disorder?
   a. Platelet dysfunction
   b. von Willebrand's disease
   c. Hemophilia
   d. Thrombocytopenic purpura
   e. Christmas disease

2. A male patient is treated with 7 days of ciprofloxacin for a symptomatic urinary tract infection. The patient develops anemia and jaundice with concern for hemolytic anemia. Commonly used antibiotics in urology, such as nitrofurantoin, sulfa compounds, and quinolones, can produce hemolytic anemia in patients with what condition?
   a. Lactate dehydrogenase deficiency
   b. Glucose-6-phosphate dehydrogenase deficiency
   c. Human immunodeficiency virus
   d. Lactose intolerance
   e. Leukemia

3. A 55-year-old man with coronary artery disease underwent percutaneous coronary intervention and placement of a drug eluting stent. What is the minimum time the patient should wait to be scheduled for an elective urologic procedure?
   a. 3 months
   b. 6 months
   c. 12 months
   d. 24 months
   e. 36 months

4. By how much does 1 unit of platelets raise the platelet count?
   a. 5000 to 10,000/mm^3
   b. 10,000 to 20,000/mm^3
   c. 20,000 to 50,000/mm^3
   d. 50,000 to 100,000/mm^3
   e. >100,000/mm^3

5. During preoperative history and physical exam a patient reports a family disorder of bleeding problems. What is the treatment for the most common hereditary coagulopathy?
   a. Factor VIII replacement
   b. Factor frozen plasma
   c. Fresh frozen plasma + DDAVP
   d. Cryoprecipitate + DDAVP
   e. Fresh frozen plasma + cryoprecipitate

6. A 68-year-old male patient is in your office to be scheduled for a transurethral resection of the prostate. This patient has no significant cardiac history and takes 81 mg of aspirin daily for prophylaxis. What is the mechanism of action and duration of action of this medication?
   a. Irreversible inhibition of receptor $P2Y_{12}$ for 7–10 days
   b. Reversible inhibition of receptor $P2Y_{12}$ for 3–5 days
   c. Irreversible inhibition of $P2Y_{12}$ for 3–5 days
   d. Irreversible inhibition of cyclooxygenase 1 for 7–10 days
   e. Reversible inhibition of cyclooxygenase 1 for 3–5 days

7. An 80-year-old male with a history of atrial fibrillation and chronic kidney disease is undergoing a suprapubic prostectomy. During the procedure significant hemorrhage is encountered that is difficult to control. The anesthesiologist reviews the record and confirms that the patient stopped his dabigatran 2 day prior to the surgery as instructed by his cardiologist. What blood products should be ordered in this situation?
   a. Packed red blood cells with fresh frozen plasma and platelets as needed
   b. Fresh frozen plasma
   c. Platelets
   d. Cryoprecipitate
   e. Protamine sulfate

8. A male patient is admitted with acute renal failure and gross hematuria refractory to conservative management. Coagulation labs are sent and the results are reviewed. PT 12 (normal 11–13.5 seconds), PTT 28 (normal 25–35 seconds), Hgb 11 g/dL (normal 13–18 g/dL). What is the defect leading to a coagulopathy in this uremic patient?
   a. Red blood cell problems
   b. Heparin-induced thrombocytopenia
   c. Platelet dysfunction
   d. Dilutional coagulopathy
   e. Disseminated intravascular coagulopathy

9. Virchow's triad for formation of thrombus includes stasis and hypercoagulability. What is the third characteristic?
   a. History of deep venous thrombosis
   b. Smoking history
   c. Malignancy
   d. Obesity
   e. Blood vessel injury

10. A 65-year-old male undergoes radical prostatectomy. On postoperative day 2 the patient is found to have heart rate of 110, oxygen saturation dropped to 90–92%, and right lower extremity swelling. The patient's postoperative creatinine is 2, which is at his preoperative baseline. What is the best initial test for a suspected pulmonary embolus in this patient?
    a. Chest CT scan with IV contrast
    b. Ventilation/perfusion lung scan
    c. Magnetic resonance imaging (MRI) of the chest
    d. Doppler study of the lower extremity
    e. Echocardiogram

Case Studies

CASE 1

A 55-year-old man with rate-controlled atrial fibrillation is anticoagulated with rivaroxaban (Xarelto). The patient is

scheduled to undergo a transurethral resection of a bladder tumor. After consultation with his primary care physician and cardiologist, the decision was made to stop the anticoagulation prior to the procedure due to risk of hemorrhage.

1. How long prior to the procedure should a novel oral anticoagulant be stopped?
   a. >14 days
   b. >7 days
   c. >2 days
   d. 1–2 days
   e. <8 hours

2. What are the available reversal agents for apixiban (Eliquis)?
   a. Vitamin K
   b. Fresh frozen plasma
   c. Protamine
   d. Dialysis
   e. None

3. What laboratory value is used routinely to monitor anticoagulation with the novel oral anticoagulant medications?
   a. INR (international normalized ratio)
   b. None
   c. Bleeding time
   d. aPTT (activated partial thromboplastin time)
   e. Anti-Xa assay

CASE 2

A 36-year-old male was found to have a testicular mass on scrotal ultrasound and is scheduled for a radical inguinal orchiectomy. The patient was found to have von Willebrand's disease after prolonged bleeding during a dental procedure as a child.

1. What is the primary defect in von Willebrand's disease?
   a. Inability to convert prothrombin to thrombin
   b. Lack of functional clotting factor IX
   c. Low plasma fibrinogen
   d. Dysfunction in platelet adhesion
   e. Inhibition of cyclooxygenase

2. After consultation with the patient's hematologist, the patient underwent preoperative transfusion with cryoprecipitate to lower the risk of bleeding. What other intervention could be used to treat this patient's coagulopathy?
   a. Protamine
   b. Aminocaproic acid
   c. Desmopressin (DDAVP)
   d. Dialysis
   e. Red blood cell transfusion

3. The patient is consented for blood transfusion preoperatively. What is the most common viral infection transmitted with contemporary blood transfusion?
   a. Hepatitis C
   b. Hepatitis B
   c. Human immunodeficiency virus
   d. Cytomegalovirus
   e. Human T-lymphotropic virus (HTLV)

Answers

1. **a.** The prothrombin time (PT) measures the activity of the extrinsic clotting system, and the activated partial thromboplastin time (aPTT) measures the intrinsic clotting system. Measurement of the bleeding time is used to identify patients in whom platelet function defects may exist.
2. **b.** Commonly used antibiotics in urology, such as nitrofurantoin, sulfa compounds, and quinolones, can produce hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency. Hemolytic anemia has also been associated with renal cell carcinoma and seminoma.
3. **c.** Elective noncardiac surgery should be delayed 14 days after PCI with balloon angioplasty (no stent placement), 30 days for bare metal stent implantation, and 365 days after placement of a drug eluting stent. Elective noncardiac surgery can be considered after 180 days if the risk of surgical delay is greater than the risk of ischemia or stent thrombosis.
4. **a.** Although a normal platelet count can vary greatly among patients, a count of more than 50,000 platelets/mm^3 is usually adequate for surgical hemostasis. One unit of platelets can be expected to raise the platelet count by 5,000 to 10,000/mm^3.
5. **d.** The most common hereditary disorder is von Willebrand's disease. Symptoms are usually manifested in late childhood and most commonly include easy bruising and bleeding at skin sites or mucus membranes. Treatment is preferably with cryoprecipitate and desmopressin (DDAVP), which induces endothelial release of VWF and coagulation factor VIII.
6. **d.** Acquired intrinsic platelet dysfunction occurs with the use of aspirin, clopidogrel, and nonsteroidal anti-inflammatory drugs (NSAIDs). Aspirin irreversibly inhibits the enzyme cyclooxygenase 1 (COX-1). The platelet life span is approximately 7–10 days, and platelet function typically resumes 7–10 days after the last use of these medications.
7. **a.** Normally the novel oral anticoagulants should be discontinued >48 hours prior to a procedure but a longer interval of discontinuation should be used in the setting of renal impairment. There are no current antidotes or reversal agents for these medications. A patient who is experiencing severe hemorrhage while taking a novel oral anticoagulant should be managed with fluid resuscitation and repletion of blood products by transfusion as needed.
8. **c.** Renal disease can be associated with functional defects in red blood cells, platelets, leukocytes, and coagulation factors. Significant bleeding conditions can occur in the uremic patient, most commonly due to impaired platelet function.
9. **a.** The classic risk factors for venous thrombosis are stasis, hypercoagulability, and intimal injury (i.e., Virchow's triad). Other risk factors include advanced

age (>60 years), obesity, history of deep venous thrombosis, prolonged immobility, pregnancy, malignancy, fracture, estrogen use, and major medical conditions leading to venous stasis.

10. **b.** If the index of suspicion is high and particularly for those in the postoperative period, spiral computed tomography (CT) is warranted and considered by most to be the standard initial diagnostic test. In patients with existing renal dysfunction for whom IV contrast dyes cannot be given, the best initial assessment for pulmonary embolus is a ventilation/perfusion scan.

CASE 1

1. **c.** The novel oral anticoagulants should be stopped at least 48 hours prior to a scheduled procedure. A longer interval of discontinuation should be used in the setting of renal impairment.
2. **e.** There are currently no available reversal agents for the novel oral anticoagulants.
3. **b.** The novel oral anticoagulants are commonly administered without routine monitoring. Qualitative assessment of anticoagulation can be performed with prothrombin time for factor Xa inhibitors (rivaroxaban [Xarelto], apixaban [Eliquis]) and activated partial thromboplastin time for direct thrombin inhibitors (dabigatran etexilate [Pradaxa]). Apixiban has a limited effect on PT, and anti-factor Xa assays can be used to determine the anticoagulant activity.

CASE 2

1. **d.** von Willebrand's factor is a plasma protein that mediates platelet adhesion and binds to and stabilizes coagulation factor VIII in the circulation.
2. **c.** Desmopressin induces endothelial release of VWF and coagulation factor VIII.
3. **b.** The rate of hepatitis transmission is 1 in 220,000. The most common transfusion reactions are febrile nonhemolytic and allergic.

Chapter 5 Questions and Answers

KEY POINTS

1. Unless the patient is severely symptomatic, correction of hyponatremia should proceed slowly so as to avoid the development of central pontine myelinolysis.
2. The mechanism of transurethral resection (TUR) syndrome likely involves a combination of hyponatremia, hyperammonemia, and/or hyperglycinemia. Fluid resuscitation, possibly with hypertonic saline (3% NaCl), is appropriate.
3. Brisk diuresis (>200 mL/hr) following the relief of urinary obstruction constitutes postobstructive diuresis (POD). Patients with POD should be monitored and treated to ensure that volume depletion and electrolyte disturbance do not occur. Most often, however, the diuresis is physiologic and will cease spontaneously without significant sequelae.
4. The frequency and severity of metabolic complications following urinary diversion depend on the segment of bowel used, surface area, contact time, urine composition, renal function, and liver function. Severe metabolic disturbance is most common with the use of jejunum. This segment should only be used if ileum or colon is either unavailable or inadvisable. Complications with continent urinary diversion can be minimized if this form of diversion is limited to patients with a serum creatinine <2.0 mg/dL and a normal urine protein concentration.

Perioperative Management of the Patient With Chronic Kidney Disease

In the United States, the prevalence of chronic kidney disease (CKD) is estimated to be 13% of adults over the age of 20 years and the lifetime risk of developing CKD is >50% for adults living more than 65 years.[1,2] It is associated with numerous complications and comorbid conditions that together pose a definite morbidity and mortality risk. Fortunately, adverse outcomes from renal insufficiency can be delayed or prevented through appropriate monitoring and early treatment. As such, it is essential that urologists maintain a basic understanding of CKD, particularly as it applies to perioperative management.

DEFINITION OF CHRONIC KIDNEY DISEASE

In 2002 the Kidney Disease Outcome Quality Initiative (K/DOQI) defined CKD according to the presence of objective renal damage (e.g., proteinuria >300 mg/day) or a glomerular filtration rate (GFR) below 60 mL/min/1.73 m^2 for >3 months.[2] GFR, the best measure of overall renal function, represents the product of the number of functioning nephrons and single-nephron GFR. GFR can be estimated using the Cockcroft-Gault equation for creatinine clearance. Normal reference levels of GFR vary with age, gender, and body size. A GFR of 60 mL/min/1.73 m^2 represents roughly half the normal adult GFR. The K/DOQI definition allows for the normal age-related decline in GFR (~1 mL/min/1.73 m^2 per year) that occurs after the age of 20 or 30 years.[2]

MANAGEMENT OF COMORBIDITIES AND COMPLICATIONS

The numerous complications and comorbid conditions associated with CKD may negatively impact patient outcomes independent of the renal dysfunction itself. Each deserves individual consideration and management so as to minimize the potential for adverse events in the perioperative period.

Diabetes mellitus and hypertension represent the leading causes of end-stage renal disease (ESRD).[3,4] New-onset or worsening hypertension, secondary to hypervolemia and stimulation of the renin angiotensin system, also represents a common complication of CKD.[5] Strict glycemic control and optimization of blood pressure are obvious goals in the perioperative period. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin-receptor blockers (ARBs) are first-line antihypertensive agents used in this setting; their use is based on studies that demonstrate effective blood pressure control and reduced risk of progression to ESRD in both diabetic and nondiabetic CKD patients.[6,7] Diuretics, followed by calcium channel or beta-blocking agents, may be added if blood pressure remains high despite ACE inhibitors or ARBs.[8] Loop diuretics are preferred over thiazides if the GFR is <30 mL/min/1.73 m^2.[9]

Cardiovascular disease is a common complication of CKD. Relative to the general population, the cardiovascular risk is threefold higher among patients with mild renal insufficiency and 65-fold higher in patients with ESRD.[10,11] Reasons for this include extraskeletal calcification (e.g., valvular, atherosclerosis) secondary to calcium-phosphorous dysregulation, ventricular hypertrophy secondary to chronic anemia, and congestive heart failure (CHF) exacerbated by hypervolemia, as well as hypertension, diabetes, and dyslipidemia.[12] Patients with longstanding CKD or a history of myocardial ischemia warrant preoperative cardiac evaluation, particularly if invasive surgery is planned.

Anemia is common in patients with a GFR <60 mL/min/1.73 m^2.[13] It is typically normochromic normocytic and reflects insufficient production of erythropoietin. Most patients with CKD are symptomatic (e.g., fatigue) at hemoglobin values <11 g/dL. Chronic anemia may promote left ventricular hypertrophy, CHF, and myocardial ischemia if untreated.[12] Supplemental iron and vitamins are usually ineffective, and repeated transfusion risks the development of immune sensitization, which may compromise future transplantation. Recombinant erythropoietin is recommended as primary treatment. Maintaining the serum hematocrit at 33% to 36% or hemoglobin at 11 to 12 g/dL has been shown to reduce cardiovascular mortality by 30%.[14,15]

Patients with renal insufficiency may develop a bleeding diathesis late in the course of disease as demonstrated by a prolongation in bleeding time. The primary defect involves an abnormality in von Willebrand's factor (vWF)-related platelet aggregation and platelet–vessel wall interaction. Measures to correct this include administration of cryoprecipitate, factor III, or DDAVP (1-deamino-8-D-arginine vasopressin), all of which raise circulating levels of vWF. Correction of anemia with either erythropoietin or red blood cell transfusion also may improve the bleeding profile. These strategies are recommended as both prophylaxis and treatment in uremic patients undergoing major surgery.

FLUID AND ELECTROLYTE CONSIDERATIONS

Most patients with CKD are able to maintain fluid and electrolyte homeostasis until the renal function decreases to a GFR of 15 mL/min/1.73 m^2.[16,17] Homeostasis occurs because an adaptive increase in both single nephron GFR and tubular function causes an increase in the fractional excretion of water and electrolytes. Such adaptation can only maintain homeostasis under the conditions of a normal diet, however. Extreme changes in diet, as may occur perioperatively, often lead to fluid and electrolyte imbalance.

Patients with CKD progressively lose the ability to both conserve and excrete sodium. When the GFR falls below 15 mL/min/1.73 m^2, sodium excretion becomes relatively fixed and the kidneys are no longer able to compensate for changes in sodium intake and nonrenal sodium loss.[18] At a GFR of 5 mL/min/1.73 m^2, the excretion of 120 to 140 mEq of sodium per day allows for a daily sodium intake of 5 to 10 g. Dietary intake below 2 g per day risks sodium depletion, whereas intake above 10 g risks total body sodium excess. Sodium depletion secondary to nonrenal loss is not uncommon in the perioperative period. Risk factors for sodium depletion include nasogastric suction, vomiting, diarrhea, and fistula drainage. Perioperative diuretic therapy may worsen the situation by augmenting renal sodium excretion. Patients without risk factors for sodium depletion require 5 to 10 g of sodium per day (diet or

intravenous [IV]) to maintain homeostasis, whereas those with established risk factors require additional supplementation. In the setting of severe peripheral (or pulmonary) edema or hypertension, sodium intake should be limited to 2 g per day in order to avoid further fluid overload.

As renal failure progresses, the kidneys also lose the ability to concentrate and dilute urine. The concentration defect results from an impairment in the medullary solute gradient, which often overshadows the dilution defect until renal failure is quite advanced. Typically, water loads are well tolerated until the GFR approaches 15 mL/min/1.73 m^2.[16,17] In conjunction with the inability to regulate sodium excretion, the concentration defect predisposes patients with CKD to dehydration. The solute load generated by the intake of 5 to 10 g of sodium per day results in an obligate urine volume of 1.5 to 2.0 L.[18] Consideration of perioperative fluid replacement must take into account obligate urine output in addition to the customary loss that occurs through hemorrhage, drainage, or insensible routes. Failure to do so may result in severe dehydration and an acute worsening of renal function through inadequate renal perfusion (pre-renal failure). Fluid intake should be maintained at a minimum of 1.5 L per day unless the patient has ESRD, in which case intake should match urine output plus insensible losses.

Hyponatremia is common in patients with severe CKD due to the impaired excretion of free water (i.e., dilution defect). Fluid restriction to less than 1 L per day is generally sufficient.

Hyperkalemia is uncommon in CKD until the GFR falls below 25% of normal. Patients with severe CKD are unable to fully excrete the daily potassium load; thus they are exquisitely sensitive to changes in intake. Exogenous intake of potassium, be it through diet or medications, is the most common cause of hyperkalemia in CKD. As such, potassium restriction is an important component of therapy.

PREOPERATIVE EVALUATION

Patients with CKD require a careful preoperative determination of overall health. The basic evaluation includes a careful history and physical examination, complete metabolic profile, coagulation times, electrocardiogram, and plain radiograph of the chest. The presence of comorbid or complicating conditions should be determined preoperatively and managed accordingly. A detailed list of prescribed medications should be made because polypharmacy is common. Medications that adversely affect renal function or whose clearance depends on adequate renal function may require substitution or a reduction in dose. Nephrology consultation is advised for both perioperative and long-term care if the GFR is below 30 mL/min/1.73 m^2.

Hyponatermia

Hyponatremia is the most common electrolyte disturbance encountered in clinical practice.[19] Mild hyponatremia defined as a serum sodium of 130–135 mEq/L is seen in nearly 30% of admitted patients while moderate to severe hyponatremia (<125-129 mEq.L) is seen in up to 7% of patients.[20]

ETIOLOGY

Hyponatremia may be due to loss of total body sodium, dilution of sodium in serum, or a false lab test.[19,21] True hyponatremia consists of a dilution of sodium by water leading to a decreased serum concentration of sodium. This results in a hypo-osmolar serum (<280 mOsm/kg water). Sodium may also be diluted due to elevated levels of glucose or mannitol. As glucose levels rise, water is drawn into the extracellular space by osmosis thereby diluting sodium without changing total body water (TBW) or total body sodium. The patient's serum is hyperosmolar (>295 mOsm/kg water). A correction factor of 2.4 mEq/L of sodium per 100 mg/dL of glucose over 100 mg/dL can be used to correct for this dilution.[21,22] Patients with hyponatremia but a normal serum osmolality (280 and 295 mOsm/kg water) have pseudohyponatremia. Normally, water and electrolytes account for 93% of serum volume, while fat and protein account for the other 7%. If a patient develops hyperlipidemia or hyperproteinemia to the point that water accounts for <80% of the serum volume, the concentration of sodium is under estimated. This occurs because standard lab equipment reports a value based on liter of serum not liter of water assuming that the serum is made up of 93% water.[23] The machine samples the same volume of fluid but the increased lipids or protein means that less water and sodium is taken up so the concentration is underestimated.

True hyponatremia is organized into subcategories based on the patient's fluid status: hypovolemic, euvolemic, and hypervolemic states. These can be further delineated based on urine sodium concentration (U_{Na}).[24] See Table 5.1 for common etiologies of hyponatremia based on fluid status and urine sodium concentration.

PRESENTATION

Mild hyponatremia is commonly asymptomatic. Moderate or severe hyponatremia can present with headaches, nausea, vomiting, muscle cramps, lethargy, seizures, and coma secondary to cerebral edema.[21,24,25] To prevent excess swelling, the brain adjusts intracellular solutes to accommodate for serum electrolyte changes.[19] In acute settings, cells do not have time to adapt so the swelling and symptoms are more pronounced. When onset of hyponatremia is slow, the brain is able to adapt to prevent swelling and minimize central nervous system symptoms.[19]

MANAGEMENT

Management of hyponatremia is based on the acuity of onset and severity of symptoms. Rapid correction of hyponatremia can result in osmotic demyelination syndrome (ODS), previously called central pontine myelinolysis.[24] This devastating neurologic complication is usually reported in the context of chronic hyponatremia; however, it also may occur following the overly rapid correction of acute hyponatremia. Unless the patient is severely symptomatic, correction of hyponatremia should proceed slowly to avoid ODS.

For patients with acute onset, severely symptomatic hyponatremia, a 100 mL bolus of 3% NaCl over 10 minutes

Table 5.1 Etiology of True Hyponatremia

Urinary Sodium Concentration	Hypervolemic States	Euvolemic States	Hypovolemic States
Urine sodium >20 mEq/l	Renal failure	Addison's disease (glucocorticoid) SIADH	Jejunal conduit Diuretic overuse Renal salt wasting (RTA) Nephrogenic diabetes insipidus Mineralocorticoid insufficiency
Urine sodium <20 mEq/l	Congestive heart failure Hypoalbuminemia (cirrhosis, nephrotic syndrome)	Psychogenic diabetes insipidus	Excessive fluid losses (GI losses, heat stroke)

GI, gastrointestinal; RTA, renal tubular acidosis; SIADH, syndrome of inappropriate antidiuretic hormone secretion

Table 5.2 Management of Acute (48 Hours) or Symptomatic Hyponatremia

Treatment Level	Indication	Sodium Solution	Dosage	Duration
1	Asymptomatic plus serum Na >120 mEq/L	0.9% NaCl	Based on Na^+ deficit	Until serum Na normal
2	Serum Na <120 mEq/L or symptomatic	3% NaCl	1–2 mL/kg/hr	Until symptoms improve
3	Severe symptoms	3% NaCl	4–5 mL/kg/hr	1–2 hr

Notes
Administer hypertonic saline via central venous catheter is preferred route for continuous replacement
If furosemide is added, it may double the rate of SNa rise
Measure SNa q 1–2 hours in early stages
Regress through levels of treatment as SNa and symptoms improve

Na, sodium; NaCl, sodium chloride; SNa, serum sodium concentration
(Adapted from Decaux G, Soupart A. Treatment of symptomatic hyponatremia. Am J Med Sci. 2003;326(1):25-30.)

may be used up to three times until symptoms subside.[21] The sodium load of 100 mL of 3% Na is equal to 51 mEq Na. For milder acute cases, infusions of 3% NaCl at 0.5–2 mL/kg/hr may be used. Central venous access is recommended for the administration of continuous hypertonic saline; however, in emergency situations 3% NaCl can be given through a large bore peripheral IV without risk of a limb- or life-threatening event.[26]

For patients with chronic hyponatremia, the management is based on a slower controlled rate of correction. In asymptomatic mild hyponatremia, the first line of treatment is fluid restriction.[24] If this is ineffective, salt tabs or loop diuretics may be added. In mildly symptomatic hyponatremia, serum Na should be corrected at a rate of 1 mEq/L/hr.[21,25] The 24 hour goal is to increase serum Na by at least 4–8 mEq/day but to not exceed 10–12 mEq/L in any 24-hour period. Additionally, an increase in Na greater than 18 mEq/L in any 48-hour period should be avoided.[25] In contrast, patients with chronic hyponatremia and severe neurologic symptoms (e.g., seizures, coma) require rapid correction to a serum sodium level of 120 mEq/L over 1 to 2 hours, or until symptoms regress.

Guidelines for hypertonic saline administration are provided in Table 5.2. Calculation of the sodium deficit may serve to guide replacement. Serum electrolytes (sodium) should be monitored frequently to guide treatment every 1 to 2 hours, initially.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

ETIOLOGY

Syndrome of inappropriate antidiuretic hormone secretion (SIADH) is a euvolemic form of hyponatremia due to excess antidiuretic hormone (ADH), also called vasopressin. In normal physiology, endogenous vasopressin is released from the posterior pituitary in response to increasing serum osmolality to increase free water absorption. In pathologic states, abundant release of vasopressin may be the response to CNS disturbances (stroke, trauma, infection), drugs (antiepileptics, chemotherapeutics, antipsychotics, opioids, Ecstasy), pulmonary disease (asthma, pneumonia, atelectasis), and hormone deficiencies (hypothyroidism, hypopituitarism). Extra-pituitary sources of vasopressin that may also cause SIADH include malignancies producing ADH (small cell carcinoma [SCC] of the lung, extrapulmonary SCC, head and neck cancer, olfactory neuroblastoma) or drug administration of vasopressin, desmopressin, or oxytocin.[21,27]

MECHANISM

Vasopressin activates V_2 receptors in the collecting duct of the kidney to increase free water uptake.[21] Activated V_2

Box 5.1 Bartter and Schwartz 1967 Criteria for SIADH

- Hyponatremia (Na <135 mEq/L)
- Clinically euvolemic
- Elevated urinary sodium excretion (U_{Na} >20 mmol/L)
- True plasma hypo-osmolality (P_{osm} <275 mOsm/kg H_2O)
- Inappropriate urinary concentration (U_{osm} >100 mOsm/kg H_2O)
- Normal renal function and absence of diuretic use
- Normal salt and water intake
- Absence of other etiologies of euvolemic hypo-osmolality: hypothyroidism, glucocorticoid deficiency

Na, serum sodium concentration; U_{Na}, urine sodium concentration; P_{osm}, plasma osmolality; U_{osm}, urine osmolality

(Adapted from Verbalis JG, Goldsmith SR, Greenberg A, Korzelius C, Schrier RW, Sterns RH, et al. Diagnosis, evaluation, and treatment of hyponatremia: expert panel recommendations. Am J Med. 2013;126(10 Suppl 1):S1-S42.)

increases cAMP via adenyl cyclase, which causes the transportation of intracellular vesicles containing aquaporin-2 to the apical plasma membrane along with up-regulation of aquaporin-2 synthesis.[28,29] Aquaporins allow water reabsorption through the plasma membrane of the collecting duct. Total body sodium stays the same but TBW is increased, resulting in hyponatremia.[28]

PRESENTATION

SIADH presents similarly to other forms of hyponatremia ranging from asymptomatic to seizure and coma; however, it is important to note that these patients will be clinically euvolemic.

EVALUATION

In 1967 Bartter and Schwartz developed the criteria for diagnosis of SIADH which is still used today.[25] These are listed in Box 5.1.

MANAGEMENT

The management algorithm of SIADH, as with other hyponatremia patients, is based on acuity and severity. For most patients this is a chronic problem requiring slow correction. Asymptomatic patients are initially treated with restriction of fluids, not just free water. Thirsty patients may be offered hard candy or very small volumes of ice chips. Loop diuretics, not thiazides, may be added. Severely symptomatic patients may require hypertonic saline prior to other therapies.

Vasopressin receptor antagonists (vaptans) can be used as adjuvant treatment for SIADH. They prevent excess activation of V_2 receptors by competitively blocking the binding site of vasopressin.[20] This results in diuresis even in the presence of excess vasopressin. Currently in the United States, the only two V_2 antagonists available are conivaptan (IV) and tolvaptan (oral). Both should be started in the inpatient setting, and use is at the discretion of the prescribing physician. These medications are not recommended as a single agent therapy but rather in combination with fluid restriction and sodium replacement.[20]

Transurethral Resection Syndrome

ETIOLOGY

TUR syndrome is a constellation of signs and symptoms caused by the intravascular absorption of hypotonic fluids during endoscopic surgery. It is most commonly reported following transurethral resection of the prostate (TURP), but it may complicate any endoscopic procedure in which hypotonic irrigation is used,[30] including cystoscopy, bladder tumor resection, percutaneous nephrolithotripsy, and transcervical endometrial resection. Intravascular absorption of irrigant occurs primarily through direct infusion into open venous channels; however, reabsorption of extravasated fluid following inadvertent perforation of the prostatic capsule or bladder wall also may occur. This distinction is important because TUR syndrome secondary to direct intravascular absorption presents acutely, whereas TUR syndrome associated with extravasation may be delayed up to 24 hours.[31]

Early reports of TUR syndrome noted reddish discoloration of the serum, progressive oliguria, azotemia, pulmonary edema, and even death following the absorption of large amounts of sterile water during TURP. In initial reports of TUR syndrome, rapid water absorption resulted in severe hemolysis and the resulting sequelae. Nonelectrolyte solutions were subsequently utilized with osmolalities similar to serum (275–290 mOsm/kg H_2O). These solutions included glycine, mannitol, and sorbitol. Although the risk of hemolysis with such solutions is negligible, TUR syndrome remains a concern, albeit less common, because while using monopolar electrocautery, modern irrigants are hypo-osmolar relative to serum (1.5% glycine = 200 mOsm/kg). The incidence of TUR syndrome among patients undergoing TURP with glycine is 1% to 10%.[30] Mortality ranges from 0.2% to 0.8%.[31]

In recent years, alternatives to monopolar TURP have become increasingly popular for the management of benign prostatic hyperplasia (BPH). These include bipolar electrocautery, green light vaporization, and holmium laser enucleation of the prostate. Standard TURP uses monopolar electrocautery, which requires a nonionic fluid to prevent conduction though the irrigant. Alternatively, newer methods utilize normal saline as they do not require electrical conduction through the patient to work. While fluid overload from absorption of fluid is possible, TUR syndrome has not been reported postoperatively in patients undergoing these procedures.[32–34]

MECHANISM

The mechanism of TUR syndrome is not universally agreed upon. Leading theories include the following:[30,35]

1. Intravascular fluid absorption
2. Hyponatremia

3. Hyperammonemia
4. Hyperglycinemia.

Although hyponatremia is the primary cause of TUR syndrome, multiple factors may be responsible resulting in a heterogeneous presentation.

It is estimated that 20 mL of irrigation fluid is absorbed per minute of resection during TURP.[36] Rapid or prolonged intravascular absorption causes a transient hypervolemia as demonstrated by an initial rise in central venous pressure (CVP), which plateaus within 15 minutes.[30,36] Hypertension and reflex bradycardia are common early; however, as the syndrome progresses, a hypokinetic hemodynamic phase characterized by hypotension and bradycardia often develops. This hemodynamic shift reflects a decline in both cardiac output and intravascular volume, which begin once irrigation is discontinued.[30,37,38] Factors responsible include natriuresis, osmotic diuresis, intracellular uptake of water, hyponatremia, hypocalcemia, and hypothermia among others.

Hyponatremia results from (1) expansion of the extracellular compartment by the infusion of hypotonic fluid (i.e., dilutional hyponatremia), and (2) increase in the urinary excretion of sodium (i.e., natriuresis). The relative contribution of dilution and natriuresis toward hyponatremia depends on the amount of irrigation absorbed and the timing of serum sodium analysis.[39] Early in the course of absorption, sodium dilution predominates because the majority of fluid remains extracellular. As the osmotic gradient widens, water is progressively drawn into the intracellular space such that hyponatremia reaches its nadir when hypotonic irrigation is stopped. Less than 50% of the absorbed fluid remains extracellularly 30 minutes after infusion has ended.

Serum sodium is commonly used to quantify extracellular fluid (ECF) volume expansion; however, it is only at the completion of surgery that such an estimate is accurate. The degree of hyponatremia is an inaccurate measure of extracellular hydration at all other points in the postoperative period. Cases of irrigant extravasation represent an exception to this rule because hyponatremia in this setting is most pronounced 2 to 4 hours after surgery due to delayed reabsorption. The systemic absorption of glycine also stimulates renal sodium excretion.[30]

Severe acute hyponatremia secondary to TUR syndrome presents similarly to other forms of acute hyponatremia. Cerebral edema leads to nausea, vomiting, confusion, and even seizures and coma if not treated promptly. Hypertension and bradycardia (i.e., Cushing reflex) also may arise as a consequence of heightened intracranial pressure. Radiologic studies demonstrate that cerebral edema may occur following the absorption of as little as 1 L of hypotonic irrigation.[40] By comparison, irrigation with normal saline causes a greater expansion of the intravascular space, but cerebral edema is uncommon.[30]

The most common irrigant used during TURP today is 1.5% glycine. Independent of volume and electrolyte imbalance, glycine and its metabolites retain properties that directly contribute to TUR syndrome in a dose-dependent manner.[27,28] Glycine is metabolized by the liver into ammonia and glyoxylic acid. A small proportion (10%) is excreted unchanged by the kidneys and promotes an osmotic diuresis and natriuresis.[30] Within the retina and central nervous system, glycine functions as an inhibitory neurotransmitter. Visual disturbance is reported in 10% of patients absorbing more than 500 mL of 1.5% glycine solution.[30,41,42] With continued absorption, this may progress to transient blindness, which generally resolves within 24 hours and requires no specific treatment.[43] Depending on the volume of glycine absorbed, a spectrum of mental status changes may be noted. The spectrum includes confusion, depressed consciousness, and coma. Glycine also impairs cardiac conduction and contractility through the generation of subendocardial hypoxic lesions.[44]

Ammonia represents an intermediate product in the hepatic metabolism of glycine. Normally, ammonia is further metabolized by the liver into urea, which is then excreted by the kidneys. In cases of renal or hepatic insufficiency, however, the metabolism of ammonia is impaired and hyperammonemic encephalopathy may occur. Serum ammonia levels tend to correlate with the incidence and severity of neurologic symptoms.[45] Hyperammonemic encephalopathy secondary to glycine absorption is self-limited and will gradually correct once the infusion is stopped. Only supportive measures need be provided.

RISK FACTORS

Potential risk factors for the development of TUR syndrome are listed in Box 5.2.[30] Although the extent of resection correlates with the volume of irrigation absorbed and the incidence of TUR syndrome, the relationship between TUR syndrome and irrigation pressure is not as precise. Two large studies have failed to demonstrate any correlation between bag height and fluid absorption during TURP.[46,47] Smoking has been shown to be an independent predictor of large-scale fluid absorption (>1 L) in patients undergoing TURP. This is thought to reflect an increase in prostatic micro-vessel density among smokers.[48]

PRESENTATION

The presentation of TUR syndrome is heterogeneous and depends on the volume, rate, route, and type of fluid absorbed. Mild cases usually present 30 to 45 minutes after the completion of surgery and may be overlooked.[30] Symptoms are usually neurologic or cardiovascular in origin

Box 5.2 Risk Factors for Transurethral Resection Syndrome During Transurethral Resection of the Prostate

- Extensive resection
- >45 grams
- >90 minutes
- Open venous sinus
- Capsular perforation
- High pressure irrigation
- >40 cm H_2O
- Intermittent flow resection
- Smoking history

(Data from Hahn RG. Fluid absorption during endoscopic surgery. Br J Anaesth. 2006;96(1):8–20.)

Table 5.3 Symptoms of Transurethral Resection Syndrome

Cardiovascular	Neurologic
Bradycardia	Nausea
Hypertension	Vomiting
Hypotension	Restlessness
Shortness of breath	Confusion
Chest pain	Depressed consciousness Headache Blurred vision Blindness

(Table 5.3). During the intraoperative and early postoperative period, nausea, vomiting, restlessness, confusion, and visual disturbance are common as are the sensations of facial prickling and warmth. Blindness, seizures, and coma may occur in extreme cases. Although transient hypertension and bradycardia can be seen initially, hypotension secondary to gradual ECF volume contraction is more common and problematic. Pulmonary edema may develop in patients with left ventricular dysfunction. In the event of extravasation, abdominal pain radiating to the shoulder is common.

EVALUATION

Suspicion of TUR syndrome intraoperatively warrants prompt termination of the procedure after hemostasis is attained. Serum sodium and osmolality should be measured at the completion of surgery because it is only at this time that they accurately quantify ECF volume expansion. Most patients are not symptomatic until the serum sodium concentration falls to <125 mEq/dL.

Supplementary measures of fluid absorption include volumetric fluid balance (Volume irrigation − Volume recovered = Volume absorbed), patient weight, CVP, and ethanol breath measurement; however, these are not in widespread clinical use. In addition to laboratory evaluation, hemodynamic stability and intravascular volume status should be determined. This may involve central venous or pulmonary capillary wedge pressure monitoring in unstable patients.

MANAGEMENT

The treatment of TUR syndrome must address both volume status and hyponatremia. On one hand, hypertension secondary to volume overload is usually transient and will resolve spontaneously as the osmotic diuresis and intracellular transfer of fluid proceed. Cardiovascular collapse, on the other hand, requires urgent treatment. Unstable patients with profound hypotension and bradycardia are treated with atropine, epinephrine, and IV calcium.[49]

Fluid restriction and loop diuretics can be used to correct volume overload and hyponatremia; however, plasma volume expansion and sodium supplementation should be the goal. This can be achieved using IV normal saline (0.9% NaCl) in patients with mild symptoms and serum sodium >130 mEq/L or, in severe cases, hypertonic saline.[30,37] The primary indication for use of loop diuretics is acute symptomatic pulmonary edema that fails to resolve with spontaneous diuresis. The combination of hypertonic saline and furosemide may be appropriate in severe cases (e.g., seizure, obtundation, or coma) wherein rapid correction of hyponatremia is necessary.[30,50] The addition of furosemide (20–40 mg) in this manner accelerates the rise in serum sodium twofold over hypertonic saline alone.

Postobstructive Diuresis

POD refers to the dramatic urine output that may occur following the relief of bilateral ureteral obstruction (BUO) or obstruction of a solitary kidney. The true incidence of POD is not known; however, it does appear to be an uncommon event. Factors necessary for its development include an accumulation of TBW, sodium, and urea or an impairment of tubular or collecting duct reabsorptive capabilities. Most cases of POD involve chronic urinary obstruction; however, significant changes in glomerular and tubular function are evident within 24 hours of complete ureteral obstruction.[51] Although ipsilateral renal function is compromised in all cases of ureteral obstruction, clinically significant POD is uncommon in patients with a normal contralateral kidney. This reflects the continued maintenance of fluid and electrolyte homeostasis by the contralateral kidney. For the purpose of this review, only the pathophysiology of BUO (or obstruction of a solitary kidney) as it pertains to obstructive uropathy and POD is discussed.

ETIOLOGY

Urinary obstruction may be anatomic or functional (e.g., neurogenic bladder) in etiology and intrinsic or extrinsic in location. A multitude of etiologies exist, the most common of which include BPH or prostate cancer in males and cervical cancer or pregnancy in females. Although nephrolithiasis is a relatively frequent cause of acute obstruction, most cases of POD involve chronic and progressive urinary obstruction as may occur with bladder outlet obstruction (e.g., BPH) or extrinsic bilateral ureteral obstruction (e.g., cervical cancer).

PATHOPHYSIOLOGY OF OBSTRUCTIVE NEPHROPATHY

Obstructive nephropathy refers to the functional and pathologic damage sustained by the renal parenchyma during urinary obstruction. The severity and consequences thereof depend on the degree and duration of obstruction as well as the presence or absence of an unobstructed contralateral kidney. Our present understanding of the involved pathophysiology comes mainly from animal models of complete unilateral or bilateral ureteral obstruction for 24 hours or more.

Upon the initiation of complete obstruction, profound changes in renal hemodynamics and glomerular filtration take place. In the case of BUO, such changes follow a biphasic pattern.[51] Within the first 2 hours of obstruction, GFR begins to fall as a consequence of elevated tubular hydraulic pressure (P_T). Beyond this period, P_T continues to rise and,

more importantly, renal blood flow (RBF) falls dramatically as a result of intense efferent arteriolar vasoconstriction caused by angiotensin II, thromboxane A_2, and neural input.[52] Intrarenal blood flow is also preferentially directed toward the outer cortex in BUO, leaving many glomeruli nonperfused.

The end result is a profound reduction in single nephron and whole kidney GFR by 24 hours. Animal models report ipsilateral GFR at roughly 25% of normal following 1 week of complete unilateral ureteral obstruction.[53] Glomerular filtration appears to be better maintained in BUO, likely on the basis of elevated levels of atrial natriuretic peptide (ANP).[54] Secreted in response to intravascular volume expansion, ANP improves RBF and GFR through the following mechanisms:[55,56]

1. Afferent arteriolar vasodilation
2. Tubulo-glomerular feedback inhibition
3. Renin-angiotensin system (vasoconstrictive) inhibition
4. Glomerular filtration coefficient (Kf) increase.

Along with its direct natriuretic properties, the actions of ANP are thought to contribute to the diuresis, natriuresis, and rapid return to maximal renal function observed following the relief of BUO. Persistent obstruction also exerts deleterious effects on renal tubular function, primarily through the down-regulation of important transporter and co-transporter activity along the entire nephron.[57] This impairs the reabsorption of sodium (Na^+), potassium (K^+), hydrogen (H^+), and water, which, in turn, dissipates the medullary solute gradient and limits the generation of concentrated urine. Together, glomerular and tubular dysfunction manifest as profound natriuresis and diuresis following the relief of BUO.

MECHANISM

POD may involve a water diuresis, a solute diuresis, or a combination thereof. In most cases, POD represents an appropriate and self-limited physiologic response to volume and solute overload. On occasion, however, the diuresis may extend inappropriately beyond the euvolemic state, usually as a result of excessive free-water loss caused by collecting duct insensitivity to antidiuretic hormone (i.e., nephrogenic diabetes insipidus). Similar to physiologic POD, this form of diuresis is often self-limited and easily managed. True pathologic POD usually refers to the inappropriate excretion of both water and solute as reflected by a urine osmolality >250 mOsm/kg water (Table 5.4).[58] The inability to concentrate urine in pathologic POD stems from the defective distal tubular sodium reabsorption and loss of the medullary solute gradient. Reasons for this include the following:[58]

1. Decreased reabsorption of sodium chloride in the loop of Henle and distal tubule
2. Decreased reabsorption of urea in the collecting tubule
3. Medullary solute washout caused by increased medullary blood flow
4. Increased tubular flow rate and solute concentration in the distal tubule.

Table 5.4 Diuresis Subtype Based on Urine and Plasma Osmolalities

Diuresis	Uosm (mOsm/kg Water)	Uosm : Posm
Pure water	<150	<0.9
Solute	≥250	>0.9
Mixed	≥250	<0.9

Posm, plasma osmolality; Uosm, urine osmolality
(Adapted from Gulmi FA, Felsen D, Vaughan ED. Management of post-obstructive diuresis. AUA Update Series. 1998;17(23):177-83.)

PRESENTATION

The manner of presentation of urinary obstruction depends on the etiology, the time over which it develops, whether it is unilateral or bilateral, and whether it is complete or partial. In the context of chronic BUO, the signs and symptoms are often nonspecific. Although most patients with complete obstruction describe anuria or oliguria, some patients with partial obstruction may report polyuria secondary to impaired renal concentrating ability.

Volume expansion is common and may present as weight gain, peripheral edema, or even shortness of breath if CHF is a complicating factor. Patients with long-standing obstruction may present with uremic symptoms including mental status change, tremor, and gastrointestinal (GI) bleeding. Volume expansion or azotemia in the setting of BUO should raise suspicion for possible diuresis following the relief of obstruction. As such, these patients should be monitored and treated accordingly. In clinical practice, a urine output in excess of 200 mL/hr over 12 consecutive hours constitutes POD.[58] It is important to note, however, that significant derangement in fluid and electrolyte status can take place during the initial 12 hours and, as such, appropriate investigation and treatment should not be delayed.

EVALUATION AND MANAGEMENT

Upon presenting with BUO, patients should undergo a thorough baseline evaluation including a complete blood count (CBC) and complete metabolic profile. Elevations in serum blood urea nitrogen (BUN) and creatinine may be identified as well as hyperkalemia and metabolic acidosis, which require correction. The development of a brisk diuresis (>200 mL/hr) following the relief of obstruction constitutes POD and warrants appropriate monitoring, investigation, and, when appropriate, treatment.

Most cases represent physiologic POD and, as such, the diuresis is allowed to proceed until the euvolemic state is reached as determined by clinical parameters such as orthostatic vital signs, breath sounds, jugular venous distention, and peripheral edema. During this time, serum electrolytes should be evaluated every 6 to 12 hours because electrolyte imbalance, particularly hypokalemia and hypomagnesemia, may develop.[59]

If the diuresis persists beyond the euvolemic state, a pathologic concentrating defect or salt wasting nephropathy should be suspected. In this case, urinary diagnostic indices are useful to determine the type of diuresis (water versus solute versus mixed) and to guide fluid replacement (see Table 5.4). With excessive free water loss, plasma osmolality will rise while urine osmolality remains inappropriately low (<150 mOsm/kg water).

Most patients with an intact thirst mechanism and free access to water can compensate for this defect. Patients in whom oral replacement is not an option because of mental status, nil per os (NPO) status, or limited access to water require IV supplementation with hypotonic saline solutions (0.45% NaCl).

Most recommendations call for the replacement of half the urine output at 2 hourly intervals so as to not perpetuate the diuresis. However, animal models suggest that maintenance of a volume-expanded state may improve ultimate renal recovery.[60] This has led some centers to replace the entire urine output until renal function plateaus. Contraindications to excessive hydration include CHF and hypertensive crisis. Fluid replacement may be withheld in these cases until such time that the heart failure or hypertension resolves with diuresis and appropriate medical management.

Pathologic POD secondary to salt-wasting nephropathy is a rare, yet potentially life-threatening, event. Dehydration and electrolyte imbalance (Na^+, K^+, magnesium [Mg^{2+}]) are common as the persistent natriuresis promotes the loss of water, potassium, and magnesium. Urine osmolality (≥250 mOsm/kg water) is often slightly higher than that of plasma. These patients warrant careful hemodynamic monitoring, possibly including CVP, as well as frequent monitoring of both serum and urine electrolytes.

Sodium and volume replacement is accomplished using normal saline (0.9% NaCl) supplemented on occasion with hypertonic saline (3% NaCl) if the sodium deficit is profound. Serum and urine electrolytes serve as a guide in this regard. Volume replacement should match urine output in a 1 : 1 fashion until vital signs and renal function stabilize. Hypokalemia and hypomagnesemia are common and require correction. Hyperkalemia and acidosis also may occur, particularly in the event of profound dehydration and consequent worsening of renal function.

Metabolic Complications of Urinary Diversion

Metabolic complications are common to all forms of bowel urinary diversion as a result of continued solute transport by the interposed segment. These include electrolyte and acid–base abnormalities, altered sensorium, drug toxicity, osteomalacia, urinary calculi, and GI malabsorption syndromes. Factors that influence the type and severity of such complications include the following:[61]

1. Segment of bowel used
2. Surface area (length of bowel)
3. Contact time with urine
4. Urine composition (solutes, pH)
5. Renal function.

These factors are particularly important with regard to the development of electrolyte and acid–base disturbance, the focus of this discussion.

GASTROINTESTINAL TRANSPORT OF WATER AND ELECTROLYTES

A basic understanding of GI transport facilitates the management of potential complications. The primary functions of the GI tract are digestion, absorption of water and nutrients, and excretion of solid waste. Water and electrolyte transport occurs through the paracellular and transcellular pathways.[61]

A Na^+/K^+ ATPase located on the basolateral membrane drives the transport of water and solute across the intestinal mucosa by generating an electrochemical gradient. This gradient favors the absorption of sodium through luminal Na^+/H^+ exchange or noncoupled Na^+ channels. Variable expression of luminal transport proteins helps to explain differences in the type, incidence, and severity of electrolyte abnormalities amongst the different bowel segments used for urinary reconstruction. For example, the jejunum has very loose intracellular junctions, allowing for the rapid movement of fluid and electrolytes through paracellular pathways. It also lacks a Na^+/H^+ antiporter but has a Cl^-/HCO_3^- antiporter, which allows for movement of bicarbonate and chloride.

Sodium rapidly follows the existing concentration gradient such as that between plasma (140 mEq/L) and urine (20–40 mEq/L). The frequent association of hyponatremia and hypovolemia with jejunal conduits reflects this fact. Chloride absorption is linked to bicarbonate secretion throughout the small bowel and colon.[61] Bicarbonate, generated by intracellular carbonic anhydrase, is secreted in a 1 : 1 ratio for chloride. In contrast, gastric parietal cells generate bicarbonate for systemic absorption in the process of acid (H^+) secretion in exchange for potassium. The ileum and colon have less permeable intracellular junctions and can exchange both Na^+/H^+ and Cl^-/HCO_3^-.[62–64] For the most part, the intestinal transport of potassium is passive as dictated by the electrochemical gradient and movement of water. The luminal concentration of potassium is an important determinant of net potassium secretion or absorption.[65]

The majority of water transport and a minority of solute transport occurs paracellularly. GI osmotic permeability, as determined by mucosal tight junctions, decreases caudally such that the permeability of proximal small bowel is four to six times that of the distal ileum and colon.[66] The heightened permeability of jejunum to both solute and water explains the frequent association of electrolyte abnormalities with use of this segment.

STOMACH

The interposition of gastric mucosa in the urinary tract has been performed more commonly in pediatric patients than in adults. Purported advantages to the use of stomach include the prevention of short gut syndrome, less mucus production, a relative reduction in the risk of electrolyte or acid–base disturbance, recurrent infection, and urolithiasis.[67] The most frequent electrolyte abnormality is a hypochloremic, hypokalemic metabolic alkalosis, which occurs as a result of hydrogen, chloride, and potassium secretion (Table 5.5).[68]

Patients are also at risk for dehydration secondary to the loss of water through the gastric mucosa. Rarely does this metabolic abnormality achieve clinical significance except in cases of severe renal dysfunction or acute dehydration. Although patients with normal renal function are able to minimize the development of alkalosis through an increase in renal bicarbonate excretion, those with renal insufficiency cannot.

Table 5.5 Metabolic Abnormalities of Urinary Diversion

Segment	Electrolyte Abnormality	Treatment	Prevention
Stomach	Hyperchloremic, hypokalemic metabolic alkalosis	Rehydration with normal saline KCl replacement H_2 receptor antagonists Proton pump inhibitors	H_2 receptor antagonists Proton pump inhibitors
Jejunum	Hyponatremic, hypochloremic, hyperkalemic metabolic acidosis	Rehydration with normal saline Alkalinization (IV/PO) $NaHCO_3$	PO hydration PO NaCl supplementation PO $NaHCO_3$
Ileum or colon	Hyperchloremic metabolic acidosis ± Hypokalemia	Alkalinization (IV/PO) ± KCl replacement	PO $NaHCO_3$, sodium citrate, potassium citrate Chlorpromazine Nicotinic acid

IV, intravenous; KCl, potassium chloride; PO, oral
(Adapted from Tanrikut C, McDougal WS. Acid-base and electrolyte disorders after urinary diversion. World J Urol. 2004;22(3):168-71.)

Hypergastrinemia also may be important.[68,69] Secreted by gastrin cells in response to distention (among other stimuli), gastrin stimulates proton secretion by parietal cells through activation of the luminal H^+/K^+ ATPase. This mechanism becomes clinically relevant in cases of gastrocystoplasty wherein bladder distention caused by chronic outlet obstruction may stimulate the secretion of gastrin and precipitate this syndrome.

Symptomatic patients may present with lethargy, weakness, altered mental status, seizures, respiratory depression, and cardiac dysrhythmia.[70] Treatment begins with rehydration using IV normal saline (0.9% NaCl) and correction of hypokalemia as outlined in Table 5.5.[68] Long-term supplementation with oral salt or potassium chloride also may be of benefit.[69] Patients with persistent mild metabolic alkalosis warrant treatment with histamine-2 (H_2) receptor antagonists, which competitively inhibit histamine-mediated gastric acid secretion. Proton pump inhibitors, which directly inhibit the gastric H^+/K^+ ATPase, are useful in cases refractory to H_2 blockade.[61,68]

JEJUNUM

Of all bowel segments used for urinary reconstruction, electrolyte abnormalities occur most commonly with the use of jejunum.[68] As a result, this segment is only used when ileum or colon are either unavailable or inadvisable. The typical metabolic changes that occur when jejunum is used include hyponatremia, hypochloremia, hyperkalemia, volume contraction, and metabolic acidosis, all of which reflect the propensity of jejunum for sodium and chloride secretion and potassium and hydrogen ion absorption (see Table 5.5).[71] Significant dehydration is common because the osmotic gradient generated by sodium secretion results in the net loss of water and sodium. Hypovolemia stimulates the secretion of aldosterone, which, in turn, stimulates renal sodium reabsorption and potassium secretion.[72] This produces a urine low in sodium and high in potassium. When exposed to such urine, jejunum loses sodium and absorbs potassium as driven by the electrochemical gradient. This further perpetuates the metabolic disturbance. At least 25% or more of patients may develop metabolic changes, although only 4% are severe if short segments are used.[73–75] The incidence and severity of this syndrome also appears to be less if distal rather than proximal jejunum is used.

In severe cases, patients may present with lethargy, nausea, vomiting, dehydration, and weakness. Treatment involves rehydration with IV normal saline and correction of metabolic acidosis using sodium bicarbonate ($NaHCO_3$). In the acute setting, standard management of hyperkalemia includes the use of insulin or glucose infusion, bicarbonate infusion, and orally or rectally administered potassium-binding resins such as sodium polystyrene sulfonate (Kayexalate). In the normovolemic state, most patients are able to excrete excess potassium if renal function is normal. If this is not the case, thiazide diuretics may be used to augment the renal excretion of potassium in the long term.[76] Likewise, vigilant oral hydration and sodium chloride supplementation are recommended as prophylactic strategies.

ILEUM AND COLON

Ileum and colon, the bowel segments used most commonly in urinary diversion, possess similar transport properties. When exposed to urine in which the concentration of potassium and hydrogen is typically higher and the concentration of sodium is lower than intestinal contents, these segments secrete sodium and bicarbonate and absorb hydrogen, chloride, and ammonium.

Ammonia, generated by the kidneys, buffers free urinary hydrogen ions through the formation of ammonium. Ammonium, in turn, competes with sodium for absorption through the intestinal Na^+/H^+ antiporter, whereas bicarbonate is excreted in exchange for chloride absorption.[68,77] The net result is a hyperchloremic metabolic acidosis.[78] It appears that the absorption of ammonium chloride accounts for the majority of the acid load.[77]

Hypokalemia and total-body potassium depletion also may occur. Most commonly, this reflects intracellular potassium depletion secondary to chronic metabolic acidosis in combination with renal potassium wasting and intestinal potassium secretion.[68,79] Hypokalemia is less common with ileal versus colonic diversions because ileum demonstrates a higher capacity for potassium absorption than does colon.[80]

Hyperchloremic metabolic acidosis is not uncommon following urinary reconstruction with ileum or colon (see

Table 5.5).[78,81] In patients that have diversions with ureterosigmoidostomies, although now uncommon, the severity and frequency of this complication are much higher. In most cases, however, the metabolic disturbance is quite mild because of renal and hepatic compensation. Metabolic acidosis is minimized through an increase in acid excretion by the kidneys, whereas the toxic effects of hyperammonemia are avoided through the hepatic metabolism of ammonium to urea.[61] As discussed, the incidence and severity of metabolic disturbance depend on numerous factors including length of bowel segment (surface area), contact time with urine, and renal function. Commensurate with these risk factors, the incidence of hyperchloremic metabolic acidosis is higher with continent diversions (50%) than with conduit diversions (10–15%) using ileum or colon.[82–84] This highlights the importance of normal renal and hepatic function at baseline in patients considered for continent urinary diversion. Basic requirements for continent diversion include a serum creatinine <2.0 mg/dL and a normal urine protein concentration. Patients with a GFR >35 mL/min and minimal urine protein who are able to generate a urine pH <5.8 following ammonium chloride loading and urine osmolality >600 mOsm/kg following water deprivation also may be suitable candidates.[73] Otherwise, conduit urinary diversion is more appropriate.[85] There are no clinically significant differences in metabolic derangements between continent diversion and orthotopic bladder replacement.[86]

Patients with significant hyperchloremic metabolic acidosis may present with fatigue, weight loss, anorexia, and polydipsia. Laboratory studies reveal a significant nonanion gap metabolic acidosis with hypochloremia and azotemia. It is estimated that up to 10% of patients with conduit diversion and a higher proportion with continent diversion require treatment for chronic acidosis.[73,84] Treatment involves alkalinization and simultaneous potassium replacement. Correction of acidosis without adequate potassium repletion may precipitate or worsen hypokalemia as potassium is driven into the intracellular space. Sodium bicarbonate is used most commonly for alkalinization (1–2 g TID), but patients may suffer from flatulence. Sodium citrate (1–3 g QID) is a suitable alternative, but it has an unpleasant taste.[87] Unless potassium supplementation is contraindicated, potassium citrate may be more appropriate in patients with CHF or renal insufficiency in whom an excessive sodium load may be poorly tolerated. Nicotinic acid (500 mg to 2 g daily) or chlorpromazine (25 to 50 mg QID) has been reported to be useful in animal models, but lacks confirmatory data in humans.[73,87]

Hypocalcemia may also be a problem for patients with urinary diversions. Bone carbonate is used to continuously buffer the chronic metabolic acidosis. Calcium carbonate is mobilized from the bone to supply the buffer. Patients may require calcium supplementation daily (500 mg to 1 g).[87] In addition, patients may experience profound drops in serum phosphorus upon rapid correction of the chronic acidosis as bone stores of calcium phosphate are replenished.

Specific management considerations in patients with a continent urinary diversion are needed due to urine's prolonged contact with the intestinal surface compared to conduit diversions. This includes the establishment of prompt drainage (i.e., indwelling catheter) as well as empiric antibiotic therapy if urinary tract infection (UTI) is suspected. Urinary obstruction perpetuates the transport of water and solute across the bowel segment, whereas systemic infection has been known to precipitate ammoniagenic encephalopathy through bacterial endotoxin-induced hepatic dysfunction.

ALTERED SENSORIUM

Among patients with urinary diversion or reconstruction, an altered sensorium may develop secondary to magnesium deficiency, drug toxicity, or ammoniagenic encephalopathy. Hypomagnesemia, although uncommon, reflects GI malabsorption or renal magnesium wasting caused by chronic acidosis.[88] Drug intoxication may develop whenever a particular medication or its active metabolite is excreted unchanged by the kidneys and then absorbed systemically by interposed bowel. This may occur with such drugs as phenytoin or methotrexate, among others.[89] Although chemotherapy (including methotrexate) has been found to be equally safe among patients with continent and incontinent diversions, it seems prudent to catheterize continent patients during therapy.[90]

Excreted by the kidneys, ammonium is absorbed by the intestinal segment and transported to the liver via the portal circulation. Ammonium (or ammonia) is metabolized by the liver into urea, which is then excreted by the kidneys. Under normal conditions, hepatic metabolism is able to adapt to the increased delivery of portal ammonia such that systemic levels remain unchanged. In the setting of liver dysfunction, however, serum ammonia may accumulate to toxic proportions.

Ammoniagenic encephalopathy is a rare complication of bowel urinary diversion. Although this syndrome develops most commonly in patients with liver dysfunction, case reports also exist among patients with normal hepatic function.[91] Often, such cases involve systemic bacterial infection or UTI with urea-splitting organisms. Systemic infection may induce transient hepatic dysfunction secondary to the proliferation of bacterial endotoxin.[92] Alternately, urea-splitting bacteria may generate ammonia through the enzymatic action of urease on urea.[68,91] In both cases, the absorbed ammonia load may overwhelm hepatic metabolism and precipitate encephalopathy.

Depending upon the degree of hyperammonemia and the time course over which it develops, symptoms of encephalopathy vary from mild changes in mental state to deep coma. Evaluation includes an assessment of liver function as well as a thorough search for possible systemic or UTI. In patients with continent urinary diversion, obstruction should be ruled out because urinary stasis may augment the absorption of urinary ammonium. Acute management includes prompt urinary drainage by way of Foley catheter or rectal tube and empiric systemic antibiotics tailored toward urea-splitting bacteria.[68] Dietary protein restriction, neomycin (oral), and lactulose (oral or rectal), which reduce the production or absorption of ammonia in the GI tract, also are appropriate.[93]

Chapter 5 Questions

1. The leading causes of end-stage renal disease (ESRD) are HTN and:
   a. Myocardial infarction
   b. Drug induced nephropathy
   c. IgA nephropathy
   d. Obesity
   e. Diabetes

2. A patient with ESRD is scheduled to undergo a partial nephrectomy and is found to have a prolonged bleeding time. Which of the following can be given to improve his coagulopathy?
   a. Vitamin K
   b. DDAVP
   c. Protamine sulfate
   d. Platelets
   e. Nothing; the patient needs HD

3. A diabetic male undergoes a TURP. He feels fine the next morning but a basic metabolic panel (BMP) obtained shows the following:

   Sodium: 131 mEq/L
   Potassium: 4.0 mEq/L
   Chloride: 104 mEq/L
   Bicarbonate: 26 mEq/L
   Blood urea nitrogen: 10 mg/dL
   Creatinine: 0.9 mg/dL
   Glucose: 420 mg/dL

   What's your next step in management?
   a. Fluid restriction
   b. Sodium replacement with 0.9% NaCl
   c. Sodium replacement with 3% NaCl
   d. Insulin
   e. IV furosemide

4. A 35-year-old healthy runner comes to the emergency department with a sprained ankle. Besides ankle pain he has no other complaints. A BMP is notable for sodium of 122 mEq/L. He has never had labs checked prior to this incident. At what rate should you increase his Na over a 24-hour period?
   a. 2 mEq
   b. 7 mEq
   c. 12 mEq
   d. 15 mEq
   e. 18 mEq

5. Which of the following is a requirement for SIADH?
   a. Urine sodium >20 mmol/L
   b. Serum osmolality of 280–295 mOsm/kg H_20
   c. GFR <60 mL/min
   d. Pitting edema
   e. Hyponatremia nonresponsive to thiazides

6. What is the most common electrolyte derangement during postobstructive diuresis?
   a. Hyponatremia and hypokalemia
   b. Hyponatremia and hypomagnesemia
   c. Hyponatremia and hypocalcemia
   d. Hypokalemia and hypomagnesemia
   e. Hypokalemia and hypocalcemia

7. An unconscious patient develops postobstructive diuresis after catheter placement. Urine osmolality is <150 mOsm/kg water. The best way to manage the patient's fluids is to:
   a. Restrict free water intake
   b. Provide access to free water
   c. Start maintenance intravenous normal saline (0.9% NaCl)
   d. Replace urine output 1 : 1 with normal saline
   e. Replace half urine output with hypotonic saline (0.45% NaCl)

8. Which of the following is NOT increased due to vasopressin?
   a. Aquaporin along the plasma membrane
   b. Total body water
   c. V_2 receptors on basal membrane
   d. cAMP
   e. Total number of aquaporin

9. A 10-year-old boy with a neurogenic bladder underwent a gastric bladder augmentation 2 years ago. If he is otherwise healthy, which is the most likely lab value to be seen on his BMP?
   a. Sodium = 150 mEq/L
   b. Potassium = 4.7 mEq/L
   c. Chloride = 92 mEq/L
   d. HCO_3 = 20 mEq/L
   e. Creatinine = 2.0 mg/dL

10. The longterm acidosis seen with ileum or colonic urinary diversions is associated with an increased risk of developing:
    a. Osteomalacia
    b. Hyperlipidemia
    c. Hyperkalemia
    d. Diabetes
    e. None of the above

Case Studies

CASE 1

A 65-year-old male complains of significant lower urinary tract symptoms secondary to an enlarged prostate. On transrectal ultrasound he has a 35 gram prostate. After failing medical management, he decides to undergo a transurethral resection of prostate. In the PACU the nurse pages the physicians to inform them the patient is throwing up, confused, and having difficultly seeing. His vital signs are normal. A stat CBC is normal. His BMP is below. The day prior to surgery the patient's labs were normal.

Sodium: 125 mEq/L
Potassium: 4.0 mEq/L
Chloride: 104 mEq/L

Bicarbonate: 26 mEq/L
Blood urea nitrogen: 15 mg/dL
Creatinine: 1.3 mg/dL
Glucose: 120 mg/dL

1. Which of the following is a risk factor for developing TUR syndrome?
   a. Being a nonsmoker
   b. Resection time of 95 min
   c. Incomplete resection of adenoma
   d. Irrigation with 0.9% NaCl
   e. Prostate volume of 35 grams

2. If he weighs 100 kg and an ideal serum sodium is 140 mEq/L, what's his serum sodium deficit?
   a. 300 mEq
   b. 550 mEq
   c. 900 mEq
   d. 1200 mEq
   e. 2100 mEq

3. After placing a central line, you order 3% NaCl to correct the patient's hyponatremia. To increase his serum sodium by 1 mEq/L/hr, what rate would you use?
   a. 66 mL/hr
   b. 84 mL/hr
   c. 120 mL/hr
   d. 157 mL/hr
   e. 310 mL/hr

CASE 2

A 70-year-old man was brought to the emergency department due to acute onset altered mental status. His wife reports that over the past 24 hours he had become more fatigued and less responsive. Urology is consulted because the patient had undergone cystectomy and continent urinary reservoir (CUR) creation 10 years prior for muscle invasive bladder cancer. His wife is concerned because due to his mental state he missed his last scheduled catheterization of his CUR. CT head in the ED was negative for any intracranial processes but his CT abdomen and pelvis showed bilateral grade 2 hydronephrosis and a distended CUR with stones in it. Blood work is pending.

1. Which of the following is least likely to be a cause of his change in mental status?
   a. Drug toxicity
   b. Brain metastasis
   c. Ammoniagenic encephalopathy
   d. Magnesium deficiency
   e. All of the above could cause his mental status change

2. The patient's white blood cell count, serum creatinine, blood urea nitrogen (BUN), and ammonia level are found to be elevated. Which of the following is least likely to improve the patient's condition?
   a. Bilateral nephrostomy tubes
   b. Broad spectrum antibiotics
   c. Placing a catheter into the CUR
   d. Lactulose enemas
   e. Fluid resuscitation

3. The patient makes a speedy recover after initiation of the appropriate treatments. Before they leave the hospital, the patient's wife asks if there was any reason 10 years ago that her husband should not have been allowed to get a CUR. Which of the following would have been a contraindication to this patient getting a continent diversion?
   a. Age >55
   b. Recurrent urinary tract infections
   c. Bilateral hydronephrosis
   d. A history of nephrolithiasis
   e. Serum creatinine of 2.2 mg/dL

Answers

1. **e.** Diabetes and HTN are the two most common causes of ESRD.
2. **b.** Increased bleeding time associated with ESRD is due to an abnormality in von Willebrand's factor (vWF)-related platelet aggregation and platelet–vessel wall interaction. Measures to correct this include administration of cryoprecipitate, factor III, or DDAVP (1-deamino-8-D-arginine vasopressin), all of which raise circulating levels of vWF.
3. **d.** This patient has hyper-osmolar hyponatremia secondary to hyperglycemia. With the correction factor of 2.4 mEq/L per 100 mg/dL glucose greater than 100 mg/dL, this patient's serum sodium is
$$138\ \text{mEq/L} = 131 + 2.4 * \frac{420 - 100}{100}$$
4. **b.** Because duration is unknown and the patient is asymptomatic, aggressive replacement should not be attempted due to concern of osmotic demyelination syndrome. The 24-hour goal is increase serum Na by at least 4–8 mEq/day but do not exceed 10–12 mEq/L in any 24-hour period.
5. **a.** SIADH is a result of increased vasopressin leading to inappropriately concentrated urine with urine sodium >20 mmol/L. See Box 5.1 for the complete list of criteria for SIADH including serum osmolality is <280 mOsm/kg H_20. Kidney disease is not a requirement for SIADH, pitting edema suggests fluid overload not euvolemia, and response to thiazides is not a diagnostic test used for SIADH.
6. **d.** In POD serum electrolytes should be evaluated every 6 to 12 hours because electrolyte imbalance, particularly hypokalemia and hypomagnesemia, may develop.
7. **e.** This patient is losing hypotonic fluid without the ability to self-regulate to thirst. The inappropriately low osmolality of the urine will cause excess free water loss and result in an increased plasma osmolality. To accommodate this a hypotonic solution should be used. To avoid perpetuating diuresis, only half of the patient's urine output is replaced.
8. **c.** Vasopressin activates V_2 to increase cAMP via adenyl cyclase, which causes the transportation of

intracellular vesicles containing aquaporin-2 to the apical plasma membrane along with up-regulation of aquaporin-2 synthesis. Aquaporins allow water reabsorption through the plasma membrane of the collecting duct. The number of V_2 receptors is unchanged.

9. **c.** The most frequent electrolyte abnormality when the stomach is used for augmentation or diversion is a hypochloremic, hypokalemic metabolic alkalosis, which occurs as a result of hydrogen, chloride, and potassium secretion and bicarbonate generation/systemic absorption.
10. **a.** Osteomalacia due to hypocalcemia. Bone carbonate is used to continuously buffer the chronic metabolic acidosis. Calcium carbonate is mobilized from the bone to supply the buffer. Increased serum calcium is renally excreted, where, due to acidosis, reabsorption of calcium is inhibited. Patients may require calcium supplementation daily (500 mg to 1 g).

CASE 1

1. **b.** Resection time >90 min has an increased risk of TUR syndrome, as does being a smoker, irrigation of hypotonic fluids such as water or glycine, and a prostate larger than 45 grams. See Box 5.2 for a list of risk factors for TUR syndrome.
2. **c.** Sodium deficit = Total body water (TBW) × (Desired serum Na − Actual serum Na). The patient's TBW = 60% of total body weight; therefore Sodium deficit = 60L * (140 mEq/L − 125 mEq/L). The patient's sodium deficit is 900 mEq of Na.
3. **d.** Using the Adrogue formula: The increase in the patient's serum sodium if 1000 mL of a fluid was given

$$= \frac{\begin{array}{c}[\text{Sodium in infusion fluid}] \\ +[\text{Potassium in infusion fluid}] \\ -[\text{Patient's serum sodium}]\end{array}}{(\text{TBW}+1)}$$

Therefore per liter of 3% NaCl the equation would be

$$\frac{(513\ \text{mEq/L Na} + 0\ \text{mEq/L K} - 125\ \text{mEq/L Na})}{(60+1)}$$

$$= 6.36\ \text{mEq/L}$$

increase in serum sodium per liter of 3% NaCl administered.

If the goal rate of serum sodium change per hour is 1 mEq/L/hr, the rate of infusion of 3% NaCl is calculated by:

$$\frac{1000\ \text{mL} * \text{Goal rate of serum sodium concentration change (mEq/L/hr)}}{\text{Increase in the patient's serum sodium if 1000 ml of fluid were administered}}$$

$$\text{Infusion rate} = \frac{1000\ \text{mL 3\% NaCl} * 1\ \text{mEq/L/hr}}{6.36\ \text{mEq/L}}$$

$$= 157\ \text{mL/hr}$$

CASE 2

1. **b.** Drug toxicity, ammoniagenic encephalopathy, and magnesium deficiency can all cause altered sensorium. With acute onset and a negative head CT it is unlikely that a brain metastasis caused his mental status changes.
2. **a.** The treatment of ammoniagenic encephalopathy includes prompt urinary drainage by way of Foley catheter and empiric systemic antibiotics tailored toward urea-splitting bacteria. Dietary protein restriction, neomycin (oral), and lactulose (oral or rectal), which reduce the production or absorption of ammonia in the GI tract, also are appropriate. His hydronephrosis is likely due to a distended reservoir, and his elevated BUN and creatinine could be due to dehydration. Bilateral nephrostomy tubes would only be necessary if the patient was found to have an obstruction of his ureters.
3. **e.** Basic requirements for continent diversion include a serum creatinine <2.0 mg/dL and a normal urine protein concentration. Patients with a GFR >35 mL/min and minimal urine protein who are able to generate a urine pH <5.8 following ammonium chloride loading and urine osmolality >600 mOsm/kg following water deprivation also may be suitable candidates. The other options are not contraindications for undergoing creation of a continent urinary diversion.

Chapter 6 Questions and Answers

KEY POINTS

1. Urologic diagnostic and therapeutic procedures can often induce surgical site infections, urinary tract infections, and sepsis; most procedures need to be covered with prophylactic antibiotics. Prophylaxis should be done within 60 minutes of surgical incision. If there is an active infection or any infectious source (e.g., Foley catheter) preoperatively, it should be diagnosed (urinalysis, culture and sensitivity) and specifically treated before surgery. Choice of antibiotics is hospital-specific, and the most active antibiotics are reserved for therapy.
2. The ASA classification system is a useful tool for perioperative risk stratification in conjunction with a specific surgery. Choice of anesthesia must be tailored specifically to the patient (e.g., age, comorbidities), the specific procedure (e.g., potential complications, surgical site, length and difficulty of surgery, patient positioning), and the skills of both the anesthesiologist and the surgeon. Deciding which anesthesia technique to use is a complex by-product of thorough preoperative assessment and good communication between the anesthesiologist and urologist.
3. Adverse pulmonary events are the cause of most anesthetic complications under general anesthesia. Inadequate ventilation, esophageal intubation, and difficult tracheal intubation are responsible for most of these injuries. Less common but equally important mechanisms of adverse respiratory-related events include airway obstruction, bronchospasm, aspiration, airway trauma, and pneumothorax. Proper airway management is essential in order to avoid most of these complications.
4. When there are no contraindications, regional anesthesia (spinal, epidural, CSE) and peripheral nerve blocks are good choices for most urologic surgeries. They ensure good surgical analgesia; fast, alert, comfortable recovery; and excellent postoperative pain relief (8–12 hours) when meperidine spinal anesthesia is used.
5. Complications of regional anesthesia include hypotension, postdural puncture headache, cauda equina syndrome/transient neurologic symptoms, total spinal through inadvertent subarachnoid injection, and systemic local anesthetic toxicity through inadvertent intravascular injection. Although these complications are rare, awareness of them must be maintained and proper patient monitoring and safeguards used.
6. Two of the most common debilitating conditions in the recovery room are pain and postoperative nausea and vomiting (PONV). Both conditions are largely preventable. The use of regional anesthesia, nerve blocks, and meperidine spinal anesthesia can prevent or minimize pain while providing stress-free anesthesia. Most PONV can be prevented by avoiding inhalational anesthetics, N_2O, and unnecessary intraoperative sedatives. Using antiemetics early, along with propofol total intravenous anesthesia (TIVA), further reduces the incidence and severity of PONV, even in high-risk patients.
7. Pudendal and penile nerve blocks are minimally invasive and easy to perform. They are good primary or adjuvant methods for surgical analgesia and postoperative pain relief. These blocks are especially safe and useful in old and sick ASA III/IV patients because they eliminate the risks and complications caused by general anesthesia while providing a stress-free operative and postoperative course (no pain, no PONV, clear postoperative mentation).
8. The prevalence of obesity and frequently associated obstructive sleep apnea (OSA) are increasing. Morbid obesity, when associated with significant comorbidities (coronary artery disease, heart failure, atrial fibrillation, hypertension, kidney disease, metabolic syndrome), poses significant risk and increases poor outcomes. OSA may further aggravate these outcomes. Thorough preoperative evaluation combined with proper patient triage, use of regional anesthesia and perioperative supportive continuous positive airway pressure/bilevel positive airway pressure (CPAP/BiPAP) may improve morbidity and mortality.

9. The best postoperative pain management is based on intravenous or epidural patient-controlled analgesia or a judicious multimodal pain management using narcotics, NSAIDs, acetaminophen, tramadol, etc. Ideally, specific protocol-based management will provide best outcomes.
10. A wide array of urology cases are being performed laparoscopically and robotically. Intimate knowledge of CO_2 insufflation pathophysiology is essential. Intraoperative complications such as shoulder pain, subcutaneous emphysema, pneumopericardium, pneumomediastinum, pneumothorax, tension pneumothorax, and CO_2 gas embolism must be understood, recognized, treated, and prevented. Serious largely preventable positioning complications in laparoscopic/robotic surgery include specific nerve damage, compartment syndrome, and rhabdomyolysis.

Urologists gain significantly from understanding different anesthesia techniques – their risks, their benefits, and their complications. Thorough knowledge of the patient's preexisting medical, surgical, and psychological condition is essential to design a judicious surgical and anesthesia plan. The best and safest results are produced when the urologist and anesthesiologist pursue an integrated strategy together.

This chapter is organized around preoperative, intraoperative, and postoperative management, with a focus on choice of anesthesia technique (general, regional, and peripheral nerve blocks), and the treatment and prevention of complications. Additionally, the chapter includes sections covering the special anesthetic management and complications of urologic laparoscopy/robotic-assisted laparoscopy.

Anesthesia Safety

Safety of anesthesia has been steadily improving for the past several decades. The incidence of anesthetic mortality in which anesthesia was the primary cause of death improved steadily from 1 per 14,075[1] to 1 per 300,000 anesthetics administered.[2] There are multiple reasons for these significant improvements, including more targeted preoperative testing, better intraoperative monitoring, better expert clinical training[3] for anesthesiologists including simulation training,[4] creation of patient-centered clinical pathways and protocols developed from evidence-based medicine, and increased awareness and knowledge of potential surgical and anesthesia complications.

Preoperative Assessment

The best choice of anesthetic technique for any urologic procedure requires a thorough preoperative evaluation of the patient. This minimally includes a detailed assessment of cardiac risks, pulmonary risks and airway, infectious complication risks, and anticoagulation risks. All these data, along with the American Society of Anesthesiologists (ASA) anesthesia risk classification and an understanding of procedure-specific surgical and anesthetic risks, influence the choice of anesthesia technique.

PREANESTHETIC EVALUATION

A preanesthesia evaluation involves assessment of information from multiple sources, including patient's history and physical examination, previous medical records, and findings from preoperative tests. According to the ASA practice advisory for preanesthesia evaluation,[5] the patient's history and physical condition should dictate what kind of preoperative testing is appropriate, and routine preoperative testing should be avoided. A presurgical testing unit (PST) is very useful in determining what selective preoperative tests should be obtained. Each hospital should have its own experience-based decision-making parameters for the timing, quality, and quantity of the specific preoperative tests required for each given procedure. It is beyond the scope of this chapter to greatly detail all required preoperative testing regimens for urologic surgery.

At a minimum, however, complete blood cell count (CBC), basic metabolic panel, blood urea nitrogen (BUN)/creatinine, and urinalysis are obtained. If urinalysis is positive, a culture and sensitivity (C&S) test is obtained and patients are placed preoperatively on a culture-specific antibiotic in order to prevent bacteremia and possibly urosepsis during surgery.

The patient's preexisting cardiac and pulmonary conditions are the two most common risks for anesthetic morbidity and mortality. Additionally, increasingly prevalent significant risks include morbid obesity and obstructive sleep apnea (OSA).

ANESTHESIA RISK: THE AMERICAN SOCIETY OF ANESTHESIOLOGISTS PHYSICAL STATUS CLASSIFICATION SYSTEM

Once all the preoperative information is evaluated, the anesthesiologist assigns an ASA score. The score is intended to create a uniform system of describing the patient's preoperative physical condition. ASA classification is important because studies have demonstrated that with increasing ASA class, there is increased incidence of adverse events and adverse outcomes.[6]

The modern classification system consists of the following six physical status categories:

ASA I: Normal healthy patient
ASA II: Patient with one mild systemic disease

ASA III: Patient with two severe systemic diseases
ASA IV: Patient with several systemic diseases, at least one life threatening
ASA V: Moribund patient who is not expected to survive without the operation
ASA VI: Declared brain-dead patient who will become an organ donor

CHOICE OF ANESTHESIA TECHNIQUE IN UROLOGIC SURGERY

Adult patients requiring anesthesia for renal and genitourinary surgery are often very old, and they may have a host of comorbidities, which pose serious problems before, during, and after surgery and anesthesia. The choice of anesthetic technique depends on a myriad of factors, including the patient's preexisting conditions; type, site, and length of surgery to be performed; skill of the urologist and anesthesiologist and their intimate knowledge of potential surgical and anesthetic complications; and predictability and limitations of the surgical and anesthesia procedures. Based on all of these factors, the ultimate decision of anesthesia method needs to be the product of a well-informed discussion between the surgeon and the anesthesiologist.

Patient-specific Risk Stratification

The modern ASA classification system, in conjunction with the full preoperative workup data of the patient, provides a degree of perioperative risk stratification that is very useful in choosing the optimal anesthetic technique for a given patient undergoing a particular surgery.

ASA I patients who are young, healthy, and with good exercise tolerance and no organic physiologic or psychiatric disturbance may have general anesthesia, regional anesthesia, nerve blocks, or clinical sedation for their procedure. Any obvious difficulty with general anesthesia (e.g., difficult airway, full stomach, allergies to anesthetics, hyperreactive airway) will necessitate modifications in the general anesthesia technique (e.g., fiberoptic intubation, fast sequence induction and endotracheal intubation, avoidance of certain drugs, modification or deepening of induction). General anesthesia will be used in cases in which patient stillness during the procedure is essential, for example, brachytherapy, renal and upper ureteral stone lithotripsy, and most laparoscopic and robotic surgeries.

ASA II patients with mild systemic disease who have no functional limitations and have a well-controlled one body system disease (e.g., diabetes, hypertension [HTN], smoking without chronic obstructive pulmonary disease [COPD]) can tolerate general anesthesia as well as regional anesthesia or nerve blocks. The one system disease must be stabilized. If a patient presents with a full stomach or hyperreactive airway, regional anesthesia or nerve blocks might provide extra safety for the patient and ease postoperative recovery.

ASA III patients have severe systemic disease, involving more than one major body system. They are in no immediate danger of death, but they have some functional limitations (e.g., stable angina, congestive heart failure [CHF], old heart attack, poorly controlled hypertension and diabetes, morbid obesity, OSA, chronic renal failure). With the advent of modern monitoring and mandatory use of pulse oximetry and end-tidal carbon dioxide monitoring ($ETCO_2$), contemporary general anesthesia has greatly improved. Most recent clinical studies comparing general with regional anesthesia show no substantial difference in outcomes. However, when using general anesthesia in this patient population, utmost care must be exercised in maintaining steady normal vital signs throughout the case (e.g., use etomidate for induction, use cardiovascular support, if needed, and maintain normal blood volume). If there are no contraindications, regional anesthesia or nerve blocks with their pulmonary and cardiovascular sparing effect, along with the prolonged postoperative analgesia they provide, are our favorite modalities for predictable, stable, safe, and comfortable outcomes in this patient group.

ASA IV patients have multiple system disease, where one or more diseases may present a constant threat to life. These diseases may be poorly controlled or at their end stage (e.g., unstable angina, symptomatic COPD, symptomatic CHF, hepatorenal failure). Preoperatively, these patients require time and specialist support to maximally control their unstable diseases. Intraoperatively, heavy monitoring (e.g., A-line, central venous pressure [CVP], Swan-Ganz catheter, cardiac output, transesophageal echocardiography [TEE]) and pharmacologic cardiovascular and pulmonary support are needed. In this patient group, general anesthesia poses high risk. For urologic procedures, regional anesthesia in skilled hands, using minidoses of local anesthetic, ensures minimum respiratory and cardiovascular risk, as well as stable, comfortable, and less eventful recovery. Importantly, using only minimum sedation with the regional block, the mental status of these sicker, older patients will remain unimpaired throughout the case and during the recovery period.

Procedure-specific Indications

Because most urologic procedures are performed in an anatomic area primarily innervated by thoracolumbar and sacral nerve supply, these procedures are excellent candidates for regional anesthesia and nerve blocks. The great versatility of regional anesthesia relies on the fact that, if skillfully done, it can greatly preserve pulmonary and cardiovascular functions in all patients. This gives maximum benefit to older patients or those with severe comorbidities. Major contraindications for regional anesthesia are patient refusal, skin infection, sepsis, cardiac outflow tract obstruction (aortic stenosis, idiopathic hypertrophic subaortic stenosis [IHSS]), serious previous neurologic deficiencies, anticoagulation, shock, hypotension, or allergies to local anesthetics.

In some urologic procedures patient awareness is an advantage, as in transurethral resection of the prostate (TURP) using monopolar resectoscope, in which the patient can voice any discomfort and early symptomatology. In other procedures, slight sedation or a total intravenous anesthesia (TIVA) helps the patient tolerate the operative surroundings (operating room noises, uncomfortable positioning) and length of procedure (e.g., long perineal reconstructive procedures done under combined spinal or epidural block, radical prostatectomy under regional block, penile prosthesis insertion, artificial urinary sphincter insertion, complex female incontinence surgery, endourethral procedures, longer procedures done under pudendal or penile block).

TIVA always successfully assures physical and emotional comfort when used before/during pudendal blocks and penile blocks. Patients are unaware of the block, and after the procedure they wake up comfortable and enjoy a prolonged postoperative analgesia. A propofol-based TIVA predictably prevents postoperative nausea and vomiting (PONV) in most patients, including those with a history of PONV. See "Postoperative Nausea and Vomiting," later.

Obesity and Obstructive Sleep Apnea

The prevalence of obesity is rapidly increasing worldwide. Proportionately, the prevalence of OSA is increasing as well. Clinically, these two conditions frequently overlap. Therefore they will be treated together in this chapter.

In adults, the World Health Organization (WHO) and the National Institutes of Health (NIH) define and classify obesity with respect to body mass index (BMI) as:

Overweight: BMI ≥25–29.9 kg/m^2
Obesity: BMI ≥30 kg/m^2
Obesity Class 1: BMI of 30–34.9 kg/m^2
Obesity Class 2: BMI of 35–39.9 kg/m^2
Obesity Class 3: BMI ≥40 kg/m^2 (referred to as extreme, severe, or morbid obesity)

Planning for anesthesia must take account of two aspects of obesity: (1) physiologic changes of obesity, and (2) the presence of specific comorbidities. Other risk factors should be addressed as well.

PHYSIOLOGIC CHANGES OF OBESITY

Obesity produces changes in respiratory, cardiovascular, and airway physiology (difficult ventilation/intubation), which may impact anesthesia delivery to these patients.

Respiratory Physiology

Extra body weight will lead to increased work of breathing and oxygen consumption, as well as a disordered ventilation/perfusion (V/Q) ratio. The lung volumes, functional residual capacity (FRC), and expiratory reserve volume (ERV) are decreased while the respiratory rate (RR) is increased.[7] V/Q mismatch and intrapulmonary shunts increase during general anesthesia (GA) to a greater degree in obese patients. Supine position and OSA will exaggerate these changes.[8,9]

Cardiovascular Physiology

Extra body weight will lead to an increase in blood volume;[10] decrease in systemic vascular resistance;[11] and an increase in cardiac output (CO), which occurs mostly due to an increase in stroke volume,[12] which may lead to heart failure, especially when associated with chronic hypoxia of OSA. Frequently, there is left ventricular hypertrophy (LVH) directly proportionate with the duration of obesity. Hypertension (HTN), which is prevalent in obese patients, may aggravate the entire picture and produces additional physiologic changes.

Dosing of anesthetic drugs is difficult and complex in obese patients. It should be modified because of significant changes in regional blood flow and increases in CO and blood volume. When the recommended dosing scheme is not known, the use of medications should be based on lean body weight (LBW), except with lipophilic drugs, where total body weight (TBW) should be used.

COMORBIDITIES ASSOCIATED WITH OBESITY

Healthy Class 1 obese patients do not seem to be at increased risk of adverse outcomes following noncardiac surgery.[13] However, there is an increase in postoperative morbidity and mortality in morbidly obese patients presenting with comorbidities. A targeted history and physical (H&P) and some additional testing must be obtained and discussed by the medical, surgical, and anesthesia team. It is very important to identify and optimize comorbidities as part of planning for surgery.[14]

Comorbidities prevalent in obese patients may include OSA, obesity hypoventilation syndrome (OHS), heart disease (CAD, heart failure, arrhythmias, HTN), metabolic syndrome, diabetes mellitus (DM), and kidney disease. During preoperative screening, the stage of comorbidities should be evaluated to assess their impact on perioperative management in order to minimize complications from surgery and anesthesia.

Obstructive Sleep Apnea

Obstructive sleep apnea, a prevalent respiratory risk condition in morbidly obese patients, is characterized by repetitive bouts of apnea, hypopnea, and hypoxia during sleep. Obstructive sleep apnea impacts patients' responses to narcotics and sedatives, exaggerating their respiratory depressant effect, and affects the airway (difficult ventilation, intubation). Obstructive sleep apnea is associated with specific cardiovascular effects, which include coronary artery disease (CAD), HTN, pulmonary hypertension, and frequent cardiac arrhythmias. A frequently associated condition is OHS, which is defined as chronic hypoventilation in an awake patient (a CO_2 >45 mm Hg). These patients tend to have pulmonary hypertension, and they are extremely sensitive to the respiratory depressant effects of narcotics and sedatives. Continuous positive airway pressure (CPAP) is frequently needed to support better oxygenation postoperatively. Preoperatively the OHS patient should have an echocardiogram to assess cardiac function and a baseline arterial blood gas (ABG) and chemistries (bicarbonate) to assess the degree of chronic hypercapnia.

Coronary Artery Disease, Heart Failure, and Atrial Fibrillation

CAD, HF, and AF are more common in obese patients and should be recently diagnosed and stabilized preoperatively. Exercise tolerance should be gauged by history and stress test. The American Heart Association (AHA) scientific advisory on obesity recommended in 2009 that obese patients with even one risk factor for CAD (smoking, DM, HTN, or hyperlipidemia) or with poor exercise tolerance should obtain a 12-lead EKG and chest X-ray (BMI >40) in addition to the regular preoperative workup recommended for patients with a normal BMI.[15]

Hypertension

Hypertension is frequently associated with obesity and should be controlled/steadied preoperatively. If BP

>170/110, the case should be postponed and the patient medically stabilized at lower levels of BP. Labile BP during surgery is frequently associated with serious cardiac, renal, and neurologic complications.

Metabolic Syndrome

Metabolic syndrome is associated with greater frequency of complications during surgery. It is characterized by a host of risk factors leading to cardiovascular disease and type 2 DM. Abdominal obesity, dyslipidemia, HTN, and hyperglycemia should be assessed and optimized preoperatively.

Kidney Disease

In morbidly obese patients, it is recommended to obtain a creatinine (Cr) and a GFR prior to major surgeries.

OTHER PREOPERATIVE RISK FACTORS IN OBESITY: DIFFICULT AIRWAY

There are certain predictors of difficult mask ventilation and difficult intubation.

Predictors of difficult mask ventilation are BMI >30 kg/m^2, history of OSA, lack of teeth, presence of beard, age >55, Mallampati III-IV (difficult airway), limited mandibular protrusion test, male gender, and presence of airway masses (tumors, deformities).[16,17]

Predictors of difficult laryngoscopy and intubation are Mallampati III-IV, previous difficult intubation, large circumference of neck, and male gender.[18,19]

PREOPERATIVE CONSIDERATIONS FOR OBESE AND OBSTRUCTIVE SLEEP APNEA PATIENTS

Most general preoperative measures like nil per os (NPO) and medications (doses, timing, etc.) are the same as for nonobese patients. Additionally, BP, blood sugar, and screening for OSA (sleep clinic, home test, STOP-BANG) should be considered. Also, patients should be evaluated for difficult airway, difficult intubation, and chance of rapid hypoxia.

Lap Band

In order to avoid aspiration pneumonitis, patients with previous weight loss surgery (e.g., lap band) will need to have their band released preoperatively by the hospital bariatric team. Even after band release, patients with a history of frequent post–lab band reflux should have their airway protected (endotracheal intubation).

Ambulatory Versus Inpatient

Deciding whether to do surgery in an ambulatory or inpatient setting should be an individualized decision, based on close cooperation between the patient's primary care physician (PCP), surgeon, and anesthesiologist. It is accepted that super-obesity (BMI >50 kg/m^2) might influence outcomes after ambulatory procedures, especially in patients with comorbidities. Several studies report factors influencing morbidity and mortality in ambulatory surgery on the super-obese: BMI >53, inability to walk over 200 feet, history of deep vein thrombosis (DVT), history of OSA, other coexisting medical conditions, and type of surgical procedure.[20] Another study reports higher ASA physical status and longer operations significantly increase mortality for this group.[21]

However, ambulatory surgeries of all kinds are routinely done on morbidly obese patients without undue complications or hospital admissions.[22] To assure safety, proper equipment should be available, e.g., advanced respiratory and intubation tools, proper capacity beds, and appropriate x-ray and lab facilities. For best results, proper clinical protocols and pathways for the care of the morbidly obese should be established.

Obese Patients With Preoperative Diagnosis of Obstructive Sleep Apnea or Obesity Hyperventilation Syndrome

This patient population benefits from daily preoperative use of CPAP or bilevel positive airway pressure (BiPAP), which produces an increase in pharyngeal area, a decrease of tongue volume (which occurs in about 4–6 weeks of therapy),[23] improved ventilatory drive,[24] and improvement of most cardiac parameters.[24–26] Furthermore, recent studies have suggested the utility of CPAP/BiPAP for several days postoperatively when a patient's condition might worsen at home. These patients should be encouraged to use their CPAP or BiPAP both pre- and postoperatively. In some cases of newly diagnosed OHS and/or OSA, surgery might need to be delayed (if it is not an emergency) until the above positive changes can be effected. BiPAP appears to be somewhat superior to CPAP in obtaining these improvements.[27,28]

STRATEGIES FOR ANESTHESIA AND PAIN MANAGEMENT IN OBESE/OBSTRUCTIVE SLEEP APNEA PATIENTS

For obese/OSA patients, regional anesthesia is a safer choice than general anesthesia.[29] Regional anesthesia also may obviate the need for postoperative narcotics and sedatives (thus avoiding their respiratory depressant effect).

If general anesthesia is required, dexmedetomidine is superior to inhalational anesthesia.[30] Ketamine is a useful anesthetic, which also provides prolonged postoperative analgesia.[31–33]

In the context of postoperative multimodal analgesia, acetaminophen IV[34,35] and NSAIDS (e.g., Celebrex, diclofenac, ibuprofen IV, and ketorolac) prove effective (allowing decreased use of opioids). Other opioid-sparing drugs like steroids,[36] pregabalin,[37] tramadol,[38] tapentadol,[39] and dexmedetomidine[40] can be used successfully.

Intraoperative Anesthesia Management

Anesthesia for urologic surgery includes general anesthesia, regional anesthesia, and specific nerve blocks. Each technique has its own specific complications.

COMPLICATIONS DURING GENERAL ANESTHESIA

Adverse pulmonary events are the cause of most anesthetic complications that occur under general anesthesia. In

Caplan's study of the ASA closed claims database, adverse respiratory events accounted for 34% of all adverse events, with death or brain damage occurring in 85% of those patients.[41] Three mechanisms accounted for 75% of these injuries: inadequate ventilation, esophageal intubation, and difficult tracheal intubation.

Less common but equally important mechanisms of adverse respiratory-related events included airway obstruction, bronchospasm, aspiration of gastric contents, airway trauma, and pneumothorax.[42] Proper airway management is essential in avoiding most of these pulmonary event–related anesthetic complications. Other specific complications occurring during general anesthesia administered for urologic procedures also will be mentioned.

Difficult Airway

When the anesthesiologist has difficulty in ventilating or intubating the patient, the airway is defined as difficult. The ASA has devised a complex algorithm to help manage the difficult airway. Preoperatively, the most important question is whether or not oxygenation and ventilation can be provided.[43] Using a laryngeal mask airway (LMA), videoscope or fiberoptic intubation can help solve this problem. Alternatively, using regional anesthesia will circumvent these difficulties. In extreme cases, surgical technique might need to be adapted to the modified anesthesia choice.

Hyperreactive Airway and Bronchospasm

Hyperreactive airway can be anticipated by taking a thorough history and physical. Patients with bronchial asthma (or with a history of it), obesity, or COPD, smokers, patients with atopies (e.g., eczema), or those with recent upper respiratory infections (within 4–6 weeks) frequently present either with a hyperreactive airway or with an overt asthmatic condition. Their usual medications, such as β_2-agonists (e.g., albuterol) and anticholinergics (e.g., ipratropium), should be used preoperatively. Most importantly, an adequate depth of anesthesia should be achieved before manipulating the airway with endotracheal intubation or before patient positioning and any surgical manipulation. The same principle applies when extubating these patients. In this patient population, regional anesthesia techniques are preferable, whenever feasible.

Aspiration Pneumonitis

Aspiration pneumonitis due to aspiration of gastrointestinal contents is associated with a significant degree of morbidity and mortality, especially in patients ASA III and above. Many risk factors exist for aspiration, including full stomach, gastroesophageal reflux disease (GERD), hiatal hernia, ileus or bowel obstruction, pregnancy, obesity, diabetes, emergency cases, trauma, gastric motility disorders, inadequate general anesthesia, difficult intubation, enteral tube feeding, sepsis, and severe renal failure.

Aspiration occurs because the protective airway reflexes (e.g., gag, cough) are missing or blunted by anesthesia. For prevention, patients should be NPO before surgery 6–8 hours for solids and 2 hours for clear liquids. A host of pharmacologic agents may be used preoperatively to diminish gastric acidity and/or volume (e.g., antacids; proton pump inhibitors, such as omeprazole; histamine-2 receptor antagonists, such as cimetidine, famotidine, and ranitidine; or gastrointestinal stimulants, such as metoclopramide). For patients at risk of aspiration pneumonitis, rapid sequence induction and endotracheal intubation should be used in all general anesthesia cases. Alternatively, aspiration of stomach contents can be avoided by using a regional anesthesia technique.

Laryngeal, Pharyngeal, and Esophageal Trauma

In an ASA closed claims analysis, the larynx was the most common site of injury (33%), followed by the pharynx (19%) and the esophagus (18%).[41] Most airway injuries are of minor significance and are temporary, although some can result in severe sequelae (e.g., mediastinitis) or even death. Whenever a difficult intubation is encountered or if the patient complains of specific symptoms postoperatively, the surgeon and the anesthesiologist should keep a high index of suspicion for airway injury. These injuries may require further evaluation by an otolaryngologist and further intervention.

Avoiding intubation altogether (regional anesthesia) or using fiberoptic laryngoscopy, a videoscope, or LMA will prevent most of these complications.

Airway Obstruction

Airway obstruction occurs with some frequency during anesthesia. Most airway obstructions (89%) occur during general anesthesia, and 70% of these involve the upper airway.[42] Causes of upper airway obstruction may include laryngospasm, foreign body, laryngeal polyps, laryngeal edema, pharyngeal hematoma, kinked endotracheal tube (ETT), and kinked breathing circuits. Tracheobronchial obstruction may occur as well, usually secondary to blood or mucus in the lumen or external compression from a mass (e.g., tumor, mediastinal mass, hematoma, thoracoscopy). Airway obstruction also may occur during monitored anesthesia care (MAC). Intense unrelieved airway obstruction in a spontaneously breathing patient may even cause negative pressure pulmonary edema.

Most cases of airway obstruction can be relieved with proper airway management or placement of an LMA or an ETT. Cautious placement of a nasal trumpet can be invaluable in preventing and relieving airway obstruction, especially in MAC cases. Vigilance is the key in preventing airway obstruction – watching the patient's chest and diaphragmatic movement, looking and feeling for exhaled air – along with $ETCO_2$ and airway pressure monitoring.

Pneumothorax

Pneumothorax is a relatively rare complication. Most causes for pneumothorax may be divided into two categories: needle related or airway-management related. Most needle-related pneumothorax cases are due to nerve blocks or central venous catheter placement. Airway management–related pneumothorax cases involve airway instrumentation (e.g., laryngoscopy, ETT placement, bronchoscopy) and barotrauma (e.g., ventilator).[42]

Specific urologic procedures are associated with a higher incidence of pneumothorax. Procedures performed abutting the diaphragm (e.g., nephrectomy, partial nephrectomy, percutaneous nephrolithotomy [PCNL]) and laparoscopic cases run the risk of puncturing the diaphragm and creating a pneumothorax. Pneumothorax should be suspected

when there is an increase in the patient's respiratory rate and peak airway pressure, hypoxemia, hypercarbia, and hemodynamic changes, particularly hypotension and mediastinal shift, as in tension pneumothorax (which is an emergency). Definitive diagnoses can be confirmed with a chest radiograph. Treatment includes needle thoracotomy and chest tube placement along with supportive therapy. Prevention includes avoidance of positive pressure ventilation whenever possible (use manual ventilation instead) and discontinuation of nitrous oxide (N_2O). See also "Pneumothorax" and "Tension Pneumothorax" sections under "Clinical Complications During Pneumoperitoneum," later.

Hypothermia

Perioperative hypothermia and shivering are risks for all patients, especially for older and sicker patients. A 0.5°C drop in body core temperature stimulates the hypothalamus, which initiates shivering. Abnormally large muscle masses are involved in this exothermic reaction to reestablish lost body heat. Shivering increases oxygen consumption by 100% to 400%, with potential deleterious effects; in that respect, shivering mimics a grand mal seizure.[44] The cardiovascular system may be affected with bradycardia, atrial fibrillation, ventricular arrhythmias, and even cardiac arrest.[45,46] It is known that hypothermia prolongs QTC on EKG, which in a familial form of long QT syndrome may cause torsade de pointes. Patients feel extremely cold and uncomfortable and may experience confusion, delayed awakening, brain infarct, and even brain death.[47] The musculoskeletal system will show slowness, rigidity, and cramps, among other effects. Surgical blood loss will be increased.[48,49]

Several pharmacologic treatments for shivering (e.g., meperidine 25–50 mg IV or chlorpromazine 2–5 mg IV) work within a few minutes, and as soon as shivering stops, patients suddenly feel comfortable and warm.[50] Treatment for hypothermia includes body warming and fluid warming. Fast rewarming is dangerous because it rapidly increases oxygen consumption, on a temporary basis (100–200%).

Best prevention for hypothermia includes using a fluid warmer (for all IVs), a body warmer (e.g., Bair Hugger, Bair Paws gown) for all cases, warm irrigation fluids, warm ORs, and shorter surgical procedures. Since most of the heat loss during surgery occurs in the first 10 minutes of the procedure, prewarming patients while waiting for surgery and continuing warming in the OR are important. Tetraplegic and paraplegic patients are at highest risk for prolonged hypothermia. They must be warmed throughout the entire surgery and recovery. They cannot shiver and are vasodilated at all times; therefore, they will take an extremely long time to rewarm postoperatively.

Hyperkalemic Cardiac Arrest

Patients with spinal cord injury (paraplegics and tetraplegics who frequently undergo endourologic procedures) and those who are bedridden long term run the risk of hyperkalemic cardiac arrest secondary to succinylcholine (SCH) administration, which is used to facilitate intubation. This occurs due to massive extrajunctional proliferation of SCH receptors of the neuromuscular junction in this subset of patients and also can be secondary to massive burns, brain and peripheral nerve injury, or muscle atrophies or dystrophies.

In these patients, SCH produces intense muscle fasciculations with massive release of intracellular potassium and cardiac arrest. Avoiding SCH or using regional anesthesia prevents this complication. If muscle relaxants are needed for the procedure, a safer choice is a nondepolarizer (e.g., atracurium, rocuronium, etc.).

Autonomic Hyperreflexia

Autonomic hyperreflexia is characterized by an uncontrolled sympathetic response secondary to a precipitant, due to loss in descending inhibition from higher centers and due to alterations in connections within the distal spinal cord. Autonomic hyperreflexia usually occurs in patients with spinal cord injuries at the T6 level and above; it occurs in 50% to 70% of this patient population. Signs and symptoms of autonomic hyperreflexia are caused by the vasoconstriction and sympathetic response below the level of the spinal cord lesion and by the compensatory parasympathetic response above the level of the lesion.

Major symptoms include hypertension (defined as a minimum increase of 20 mm Hg above baseline), headache, sweating, flushing or pallor above the level of the lesion, and bradycardia. Other less common signs include pupillary changes, Horner syndrome, nausea, and anxiety. The most common precipitants of autonomic hyperreflexia involve the urinary tract. Importantly, bladder distention (mostly urodynamic studies) has been shown to account for up to 85% of cases. Urinary tract infections (UTIs), genital stimulation, urologic procedures, and even catheterization can also elicit a response.[51] When autonomic hyperreflexia is suspected, treatment should begin immediately, before serious complications result, such as intracranial hypertension, seizures, or intracranial hemorrhage. Removal of the stimulus and pharmacologic treatment of the hypertension should be done immediately. A short acting α-blocker (e.g., phentolamine 5–30 mg IV in divided boluses) is generally effective in normalizing BP.

Preventing autonomic hyperreflexia begins by identifying those patients at risk (T6 and above spinal cord lesions) and maintaining a high index of suspicion. For the urologist, measures that reduce the incidence of bladder distention (e.g., anticholinergic, intermittent catheterization) may reduce the incidence of attacks.

For these patients, spinal anesthesia is the anesthesia technique of choice, especially for urologic procedures, because it prevents most cases of autonomic hyperreflexia, avoids the need for general anesthesia, and provides excellent cardiovascular stability.[52] The slight disadvantage of spinal anesthesia is that it may be difficult to reliably determine the level of blockade. General anesthesia also has been used successfully and autonomic hyperreflexia avoided as long as deep anesthesia is maintained. However, these patients have a host of other medical issues associated with their spinal cord injury (e.g., immobility, muscle wasting, respiratory issues, thermoregulation problems), which may increase the risk of general anesthesia. Epidural and MAC (sedation, local anesthetic infiltration) have been reported as less successful in preventing autonomic hyperreflexia when compared with spinal and general anesthesia.

Malignant Hyperthermia

Malignant hyperthermia (MH) is an uncommon pharmacogenetic clinical syndrome of hypermetabolism triggered by specific anesthetic agents. MH is an inherited disorder that occurs in 1 in 10,000 to 1 in 250,000 patients.[53]

MH susceptibility is thought to be due to a defective Ca^{++} channel located on the sarcoplasmic reticulum (SR). This channel is called the ryanodine receptor (RyR1). Various environmental and pharmacogenetic conditions may produce an uncontrolled massive release of Ca^{++} ions from the SR initiating a hypermetabolic state. About 70% of MH susceptible families may carry one of the 34 known mutations for MH.[54] There are about 400 variants connected with the *RyR1* gene.

All inhalational anesthetics, except N_2O, can trigger MH. SCH is a very frequent trigger. Safe anesthetic agents include N_2O, barbiturates/IV anesthetics, all narcotics, and all antianxiety medications. MH can begin during administration of anesthetic agents, or it may occur postoperatively.

Testing for susceptible patients, the so-called *in vitro* caffeine-halothane contracture test (CHCT), is done on freshly collected muscle biopsy specimens. A complete list of testing center locations in North America is available from the Malignant Hyperthermia Association of the United States (MHAUS) at www.mhaus.org.

Predisposing diseases include certain muscle disorders, such as central core disease, Duchenne or Becker muscular dystrophies, specific types of myotonia, and hyper- or hypokalemic paralyses.[53]

Special clinical syndromes have been grouped as masseter muscle rigidity (a sustained contracture of the jaw muscles after SCH administration, which may or may not progress to full MH), sudden unexpected cardiac arrest (especially soon after the use of SCH), and myopathies (muscle rigidity and/or hyperthermia – if hyperkalemia is successfully treated, the outcome may be good). These syndromes may occur alone or in the context of fully developed MH.

To diagnose MH, one should consider both clinical presentation and laboratory data. One of the most consistent clinical indicators is an unanticipated increase (tripling or quadrupling) of $ETCO_2$ when minute ventilation is normal. Sudden unexpected cardiac arrest may occur, especially in boys and young men (aged 5–15 years), and hyperkalemia should be suspected. Unexpected tachycardia is an early symptom, as are tachypnea and masseter spasm. Respiratory and metabolic acidosis usually indicate advanced or fulminant MH (late clinical development). Body rigidity is a specific sign of MH in patients under general anesthesia. Core body temperature elevation is often a late sign of MH. Postoperative rhabdomyolysis and acute myoglobinuric renal failure are usually later events. There is a 25% MH recurrence rate in the postoperative period, thus patients should be watched carefully after any initial MH event.[55]

Differential diagnoses include thyroid storm, sepsis, pheochromocytoma, and intraoperative overheating. Additionally, outside the OR, a similar syndrome may be caused by a cocaine overdose or a subarachnoid injection of ionic contrast materials.

Other conditions may mimic MH, including serotonin syndrome, 3,4-methylenedioxy-methamphetamine (MDMA) hyperthermic syndrome caused by overdose (psychotropes and haloperidol), and sudden hyperkalemic cardiac arrest (HCA). Hyperkalemic cardiac arrest may occur with alarming frequency in Duchenne's muscular dystrophy, a condition found in 1/3500 live births. Since Duchenne's symptomatology frequently occurs for the first time as late as 5–8 years old, use of SCH should be avoided in all young children.[56]

Treatment begins by immediately discontinuing the triggering agent. Hyperventilate with 100% oxygen. Treat with IV 2.5 mg/kg dantrolene sodium (because this solution does not have significant side effects, it should be used for all cases in which MH is suspected) or the newly developed alternative, high-potency dantrolene (Ryanodex 250 mg per ampule). Treat acidosis with bicarbonate; treat hyperkalemia with glucose, insulin, and calcium; and treat hyperthermia with cooling (nasogastric lavage, rectal lavage, intraperitoneal lavage, surface cooling – to end point of 38°C). Avoid calcium channel blockers (use other antiarrhythmics). Carefully monitor serum potassium and measure CPK (a good measure of muscle destruction) every 6 hours until it is decreased (though in severe MH, high CPK might last for 2 weeks). Follow the coagulation profile because disseminated intravascular coagulation may occur. Check serial ABG, electrolytes, blood, and urine myoglobin.

Prevention begins by identifying patients at risk of MH through a positive history or previous testing. Patients with known or suspected MH who need surgery can be safely operated on by using a nontriggering anesthesia technique (total avoidance of triggering agents) and a mandatory fresh oxygen (O^2) flushing of the anesthesia circuit for a minimum 60 minutes preoperatively (in order to eliminate any traces of inhalational agents from the rubber or silicone gaskets found on the newer anesthesia machines). ASA recommends measuring core body temperature in all anesthesia cases lasting >30 minutes. It is recommended that a full complement of fresh dantrolene ampules and chilled IV fluids, along with full resuscitative medications, be readily available at all times in the OR. Patients with a history of exercise and/or emotional stress-induced fevers, and those with severe statin myopathy should be tested for MH preoperatively. The use of isovolumetric contraction time (IVCT) in conjunction with genetic studies improves the chance of diagnosing true MH-positive individuals.

Postoperative Nausea and Vomiting

If untreated, up to 30% of all surgical patients will have PONV after general anesthesia with inhalational anesthetics, whereas high-risk patients will have an incidence up to 80%. Patients with an increased incidence of PONV tend to be young children; women; or patients with preoperative pain and anxiety, delayed gastric emptying, and, most importantly, a positive history of motion sickness and previous PONV. Anesthesia risk factors for PONV include dehydration, general anesthesia with inhalational anesthetics, anesthesia lasting longer than 3 hours, and the use of N_2O, narcotics, sedatives (e.g., ketamine, etomidate), neostigmine, and residual air in the stomach secondary to mask ventilation. Surgical factors that increase the likelihood of PONV include laparoscopic surgery, hernia repair, and orchiopexy. Postoperative risks include sudden motion, pain, and early fluid intake.

Various antiemetic medications are used to treat nausea and vomiting.[57] One group of antiemetics works by antagonizing neurotransmitters at various receptor sites (e.g., dopamine, histamine, serotonin, or cholinergic-muscarinic receptors). These include antihistamines (diphenhydramine and promethazine), butyrophenones (droperidol and haloperidol), phenothiazines (chlorpromazine and prochlorperazine), benzamides (metoclopramide), and anticholinergics (scopolamine). Another group works as specific antiserotonin (5-HT_3) antagonists (ondansetron, granisetron, and dolasetron). Dexamethasone is a corticosteroid that works through antiinflammatory and some unknown properties.

Various side effects occur after using antiemetic medications. Their most significant side effect is sedation.

As prophylaxis for PONV, dexamethasone combined with an antiserotonin antagonist proves to be one of the most efficient regimens, if used at induction of general anesthesia. For treatment of PONV, combinations of antiemetics seem to be more efficient (through their additive effect) than single medications. In our experience, however, when everything else fails, one of the best rescue medications is haloperidol 1.0 mg to 1.5 mg used intramuscularly (an IV dose is too short acting), which provides >15 hours of intense antiemetic effect without excessive sedation or any hallucinations.

The most effective ways to prevent PONV are using a propofol-based TIVA (see next section) and preferentially avoiding inhalational anesthetics, N_2O (which causes a 30% increase in PONV), and unnecessary sedatives. Also, gastric air should be suctioned out. Propofol TIVA proves especially useful in patients at higher risk for PONV (those with a history of motion sickness or previous PONV).

Propofol Total Intravenous Anesthesia (Propofol TIVA). Propofol TIVA is a widely used general anesthetic technique, using a variable mixture of propofol drip and fentanyl. It can be administered with the patient breathing spontaneously or with the patient muscle relaxed and mechanically ventilated. In either TIVA technique, no N_2O, benzodiazepines, or other sedative medications are needed (bispectral index [BIS] monitor tested), and these should be avoided because they tend to produce PONV, delay awakening, and prolong recovery. Propofol TIVA predictably provides a well-anesthetized patient with no operative recall, who is easy to wake up, and who has satisfactory postoperative analgesia, no memory loss, and no PONV.

For patients with a history of hypersensitive (hyperreactive) airway such as asthma (even if childhood asthma), smoking, or obesity or patients with recent upper respiratory infections (within the past 6–8 weeks), chronic bronchitis, or eczema, low concentrations of inhalational agents (e.g., 0.2–0.4% sevoflurane) can be safely added (for deeper anesthesia level and bronchodilation) to the TIVA. The same regimen should be used for any obese patient or intubated patient. Adding low concentration inhalational agents does not diminish the potent antiPONV qualities of the propofol/fentanyl TIVA.

Positioning-related Complications

Urologic surgeries require the patient to be in specific positions (e.g., supine, prone, lithotomy, semilateral or lateral position), which can cause inadvertent nerve injury. Most nerve injuries involve the ulnar nerve (28%), brachial plexus (20%), lumbosacral nerve roots (16%), and the spinal cord (13%).[58] Nerve injuries usually occur as a result of compression or stretching of the nerve.

With patients in the supine position, the most commonly injured nerve is the ulnar nerve, regardless of whether the patient has both arms tucked at his or her side or out on armboards. With patients in the lithotomy position, sciatic, femoral, and peroneal nerves are at increased risk for injury. In the semi-lateral and lateral position, the brachial plexus is at increased risk. Meticulous attention must be paid to the positioning of a patient, ensuring that he or she is not stretched beyond the physiologic range, and padding all the pressure points to reduce the incidence of nerve injury.

According to the ASA practice advisory for prevention of perioperative peripheral neuropathies,[59] arm abduction should be limited to 90 degrees in supine patients. Arms also should be positioned to decrease pressure on the postcondylar groove (ulnar nerve) and the spiral groove of the humerus (radial nerve). A neutral forearm position or supination of the arms with proper padding should meet this recommendation.

For lower extremity positioning, excessive stretching of the hamstring muscle group beyond a comfortable range must be avoided (especially in lithotomy position), as this may cause sciatic neuropathy. Prolonged pressure on the peroneal nerve at the fibular head should be avoided by using proper padding (especially in lithotomy position). Neither flexion nor extension of the hip has been shown to increase the risk of femoral neuropathy, although it is advised that excessive flexion or extension be avoided.

Preventing peripheral neuropathies begins in the preoperative phase. Certain patient characteristics have been shown to be associated with perioperative neuropathies, including smoking, diabetes, vascular disease, arthritis, and extremes of body weight and age. Preoperatively, any preexisting neuropathies should be identified during the initial history and physical examination, and the patient's normal comfortable range of motion should be determined. Intraoperatively, patient positioning and padding should be checked periodically. Postoperatively, patients should be watched for early signs of any nerve injury and appropriate steps taken, including obtaining neurologist consultation if necessary.

For more specific complications of patient positioning in laparoscopic/robotic cases, see "Complications of Patient Positioning in Robotic Surgery," later.

COMPLICATIONS DURING REGIONAL ANESTHESIA

A preponderance of outcome data suggests that regional anesthesia improves patient morbidity and mortality,[60] as compared with general anesthesia. Also, regional anesthesia was found to reduce overall mortality by approximately 30%. Regional anesthesia decreased the odds of deep venous thrombosis by 44%, PE by 55%, transfusion by 50%, pneumonia by 39%, respiratory depression by 59%, MI by 33%, and renal failure by 43%, thus greatly reducing overall morbidity as well. The benefits of regional anesthesia include the following:[60]

- Attenuation of the body's stress response perioperatively (preserves cardiovascular function)
- Preservation of respiratory function and decrease in pulmonary complications
- Faster recovery of postoperative GI function
- Decrease in intraoperative blood loss
- Decrease in postoperative hypercoagulability
- Preservation of perioperative immune function
- Superior postoperative analgesia compared to systemic opiates
- Decreased length of stay in the postanesthesia care unit (PACU) due to adequate pain control
- Increase in patient satisfaction

Contraindications for regional anesthesia include patient refusal, cardiac outflow tract obstruction (as in IHSS and aortic stenosis), the anticoagulated patient (when INR ≥1.4), skin infections, serious previous neurologic deficiencies, hypotension, allergy to local anesthetic, sepsis, and hemorrhagic shock.

Regional anesthesia can be divided into two categories: neuraxial anesthesia (e.g., spinal, epidural, combined spinal/epidural) and peripheral nerve block anesthesia (e.g., pudendal, penile, paravertebral).

Neuraxial anesthesia deposits a local anesthetic within the subarachnoid (spinal) or epidural space. This produces sympathetic block (vasodilation), sensory block (painlessness), and motor block (muscle relaxation), with separate corresponding levels, each producing distinctive physiologic changes.

The sympathetic block results in vasodilation, with an increase in volume of the capacitance vessels, causing a decrease in cardiac preload and secondary hypotension. This undesirable hypotension can be abrupt and severe, directly proportional to the degree of sympathetic denervation, and it must be treated early and aggressively with vasopressors, fluids, and head-down position (thus increasing cardiac preload). The sympathetic denervation may involve the entire lower extremities, the pelvis, or the thoracoabdominal cavity, depending on the height of the sympathetic level achieved. The sympathectomy slowly wears off throughout the surgery and outlasts the sensory block by about 3 hours.

The sensory blockade renders the patient insensitive up to a certain level, which can be manipulated in various ways in order to achieve painlessness for the entire dermatomal distribution of the surgical procedure and for the duration of surgery and recovery.

The motor blockade also can be manipulated at will to produce full muscle relaxation extending from the lower extremities all the way up to the thoracic wall, depending on the type of surgery performed. For surgical anesthesia, solid sensory and motor denervation are needed, whereas for postoperative analgesia only sensory block is required.

Spinal Anesthesia

Spinal anesthesia is achieved by injecting small amounts of various local anesthetics below the L1 spinal level directly into the cerebrospinal fluid (CSF) through a fine needle inserted beyond the arachnoid membrane. A sensory dermatomal level is obtained. The sympathectomy (vasodilation) level will be 3 segments higher than the sensory level. The motor block is about two dermatomal levels lower than the sensory level. Duration of the spinal block depends on the type, dose, and baricity of the local anesthetic used; it also depends on patient positioning. The major side effect of spinal anesthesia is drop in BP, proportionate to the level of sympathectomy (vasodilation). For best treatment of this side effect, see "Further Prevention of Regional Anesthesia Complications," later.

The following important complications may occur with spinal anesthesia.

Postdural Puncture Headache. Postdural puncture headache (PDPH) is a headache that may occur 24 to 48 hours after spinal anesthesia or unintentional dural puncture (UDP) during epidural anesthesia. It is thought to be due to a continuous leak of CSF through the spinal puncture hole, decompressing the subarachnoid space with secondary stretching of the cranial nerves. PDPH has two specific characteristics: It is frontal and positional. It typically appears as a throbbing frontal headache (of variable intensity). Its main positional characteristic is used as a test. When the patient is lying in bed, he or she may have no headache at all. However, when the patient sits up or walks, a throbbing frontal headache will occur, which disappears when the patient lies down again. In severe cases, even a slight lift of the head from the horizontal position elicits the headache. This positional test differentiates PDPH from sagittal sinus thrombosis, which produces a continuous throbbing headache in any position.

Associated symptoms of PDPH include neck ache or stiff neck (57%), upper back ache (35%), nausea (22%), and visual and auditory disturbances. If untreated, PDPH spontaneously resolves within 1 to 6 weeks, but it is very distressing to patients.

Conservative treatment relies on hydration, caffeine (cerebral vasoconstrictor), sumatriptan succinate (serotonin type 1d receptor agonist, a powerful cerebral vasoconstrictor), and adrenocorticotropic hormone (a controversial treatment, which works through increased CSF production and/or β-endorphin release). Some recent work points to more effectiveness when using neuraxial morphine[61] or systemic cosyntropin in cases of UDP.[62,63]

Invasive treatments include epidural blood patch (the gold standard), used only for unrelenting symptomatology.[64] This consists of injecting 10 to 15 mL autologous blood into the patient's epidural space. PDPH disappears immediately in 85% of such cases, and recurrence is rare. There are insufficient data to support the prophylactic use of epidural blood patch after UDP.[65] A recent study suggests that a greater occipital nerve block with added dexamethasone might be effective treatment for PDPH.[66]

Cauda Equina Syndrome/Transient Neurologic Syndrome. Cauda equina syndrome (CES) is a clinical representation of local anesthetic neurotoxicity. It can present as varying degrees of pain or neurologic deficit limited to the lower extremities, and it can create functional deficiencies (e.g., urinary and fecal incontinence). It may present with

transient symptomatology, or it may evolve into permanent neurologic lesions with permanent loss of function. Permanent CES is very rare.

All local anesthetics are potentially neurotoxic in high doses. CES may be caused by maldistribution, high concentration, and/or high and repetitive doses of local anesthetics. See "Local Anesthetic Systemic Toxicity," later.

Transient neurologic syndrome (TNS) is another clinical representation of local anesthetic neurotoxicity. TNS has been described in conjunction with continuous spinal anesthesia, where overly frequent topoff reinjections of the same local anesthetic through an indwelling subarachnoid catheter may cause toxicity. TNS also may appear on rare occasions after spinal administration of single doses of lidocaine, mepivacaine, bupivacaine, or any other spinal anesthetic, if used in excessive doses. However, in our experience, following thousands of subarachnoid meperidine blocks, TNS has not occurred. We strongly recommend using meperidine in regular doses of 40 to 50 mg in all cases. See "Further Prevention of Regional Anesthesia Complications," later.

Epidural Anesthesia

Epidural anesthesia is achieved by injecting local anesthetic into the epidural space, which is located between the dura mater and the yellow ligament (ligamentum flavum). Consequently, a sensory dermatomal block is obtained, associated with a sympathectomy (vasodilation) three to six dermatomal segments higher. A motor block is also obtained. In clinical practice, epidural anesthesia can be obtained with a single injection or through an epidural catheter used for reinjection with local anesthetic in order to prolong surgical anesthesia or to provide postoperative pain relief. The major side effect of epidural anesthesia is hypotension, proportionate to the level of sympathectomy (vasodilation). The onset of this hypotension is slower than the hypotension associated with spinal anesthesia. For best prevention or treatment of this side effect, see the use of combined IV/IM ephedrine in "Further Prevention of Regional Anesthesia Complications," later.

The following complications may occur with epidural anesthesia.

Inadvertent Subarachnoid Injection. Inadvertent subarachnoid injection is an accidental local anesthetic injection into the subarachnoid space (CSF). This occurs when the epidural needle accidentally penetrates the dura mater and arachnoid membranes and ends up in the subarachnoid space. Epidural anesthesia requires much higher local anesthetic volumes than spinal anesthesia (~1.5 mL per dermatomal segment blocked); if some of this high-volume anesthetic ends up in the subarachnoid space, it will create undesirably high levels of subarachnoid block (total spinal). This will cause widespread sympathectomy and vasodilation, with a sudden drop in BP and cardiac output, leading to a clinical picture of shock, often rapidly progressing to respiratory and cardiovascular arrest.

As a first measure, the patient is immediately placed in the Trendelenburg position in order to increase preload to the heart. Treatment then is geared toward cardiovascular and respiratory support.

Prevention includes keeping patients awake and conversant, using a subarachnoid test (injecting small fractionate doses of local anesthetic), and slowly raising the dermatomal sensory level of anesthesia with frequent testing (cold or pinprick test).

Inadvertent Intravascular Injection. Inadvertent intravascular injection is unintended injection of a large dose of local anesthetic into a blood vessel within the epidural space. This may occur during a single injection through the epidural needle or following even small fractionate doses of local anesthetic through an epidural catheter. Local anesthetic intravascular toxicity may occur with the following symptoms, usually appearing in a clinically predictable sequence: tinnitus, perioral numbness, dizziness, fainting, drop in BP, bradycardia, seizures, coma, and death.

Treatment is to immediately stop injecting the local anesthetic and, in cases of seizure or cardiovascular collapse, use sedatives and cardiovascular support measures. In cases of clinical shock with cardiorespiratory arrest, cardiopulmonary resuscitation must be administered. Recent evidence-based practice advocates emergency treatment with lipid emulsion (Intralipid 20%, a 100% long-chain triglyceride emulsion), which is thought to function as a pharmacologic "lipid sink" to eliminate the highly liposoluble local anesthetics.[67–70] See also "Local Anesthetic Systemic Toxicity," later.

Prevention starts with the correct placement of the epidural catheter. Then the epidural catheter is tested with an IV testing dose using small, nonseizure producing, tracer-laced (e.g., epinephrine) local anesthetics while looking for tachycardia on ECG. It is essential to inject slowly, keeping the patient conversant and asking for the presence of early symptoms of local anesthetic intravascular toxicity (i.e., tinnitus, perioral numbness, dizziness). If these symptoms appear, immediately stop the injection and assume toxicity. The use of benzodiazepines at this point will prevent seizures; however, these drugs will not prevent the cardiovascular collapse secondary to a massive intravascular injection. Use basic monitoring (ECG, BP cuff, pulse oximetry, $ETCO_2$) for the entire epidural and surgical procedure in order to observe any other symptoms of inadvertent intravascular injection (e.g., drop in BP, drop in arterial saturation, bradycardia).

Maintain general awareness of this potential complication throughout the case. Even if the local anesthetic is injected properly (negative IV test), if massive toxic doses accumulate over time, a similar delayed clinical picture may occur. The anesthesiologist must not trespass into the generally acknowledged toxic doses of each specific local anesthetic. See also "Local Anesthetic Systemic Toxicity," later.

Combined Spinal/Epidural Anesthesia

Combined spinal/epidural (CSE) anesthesia blends the advantages of both types of anesthesia. Classically, the spinal anesthesia component, with its early onset and dense block, is used for surgical anesthesia; this might be sufficient for the entire surgery. The epidural catheter, however, may be accessed for additional anesthesia during surgery if, at any time, the spinal anesthesia wears off. The same

epidural catheter also can be used for prolonged postoperative analgesia.

Complications can arise from either the spinal or the epidural component of the technique. Prevention of most potential CSE complications is identical to the separate spinal and epidural preventive measures.

Local Anesthetic Systemic Toxicity

Local anesthetic systemic toxicity may occur in two ways: massive reabsorption after tissue injection or secondary to inadvertent intravascular injection. If the quantity (in milligrams) of the local anesthetic injected exceeds certain toxic peak levels, the following symptoms may be produced:

1. *Central nervous system (CNS) excitability/depression:* Tinnitus, perioral numbness, dizziness, confusion, seizures, coma, death
2. *Cardiovascular effect:* Peripheral vasodilation with hypotension, heart block, bradycardia, ventricular tachycardia, asystole, cardiovascular collapse
3. *Respiratory effect:* Respiratory depression due to direct local anesthetic effect and/or secondary to CNS and cardiovascular effects
4. *Methemoglobinemia:* Central cyanosis refractory to supplemental oxygen administration appears at a methemoglobin level >15%. At 50% to 60% methemoglobinemia may produce confusion, arrhythmias, hemodynamic instability, and seizures, leading to death. Chocolate-colored blood that keeps its color despite exposure to air is diagnostic. Methemoglobinemia can occur after large doses of benzocaine topical administration and absorption (usually used for various endoscopic procedures). Also it may occur when large doses of prilocaine (>600 mg) are administered. (Prilocaine is no longer available for use as a local anesthetic.)[71]

There are two general categories of local anesthetics: esters and amides. Esters – tetracaine, procaine, 2-chloroprocaine, and benzocaine – are metabolized in the body by the natural esterases, which limit and terminate their inherent toxicity. The amides – bupivacaine, levobupivacaine, ropivacaine – are metabolized in the liver, a lengthier process, thus making these local anesthetics available free in the blood stream for a longer time, as well as prolonging their potential toxicity.

Treatment. Treatment depends on the severity of the event. CNS excitability can be treated with sedatives such as benzodiazepines. The respiratory and cardiovascular depressant effects should be addressed by supportive measures. Severe methemoglobinemia is treated by using 1 mg/kg IV methylene blue.

IV lipid emulsion (Intralipid 20%, a 100% long-chain triglyceride emulsion) has been used successfully to bind and quickly remove the highly liposoluble local anesthetics from the intravascular system. There are numerous clinical reports of life-saving rapid reversal of major local anesthetic toxic symptomatology.[72–75] However, reversing the toxic effects of less liposoluble local anesthetics (e.g., ropivacaine and others) with lipid emulsion is more controversial.[70] It is recommended that Intralipid 20% should be used as an initial bolus of 1.5 mL/kg followed by an IV infusion of 0.25 mL/kg/minute. If adequate circulation has not been restored, the bolus should be repeated twice at 5 minute intervals with an increased infusion rate of 0.5 mL/kg/minute.[70,76]

Prevention. The overall injected quantity (in milligrams) of local anesthetic always must be kept below the toxic dose. There are various ways to estimate the toxic dose of a given local anesthetic. Clinically useful and generally acknowledged local anesthetic toxic doses (when used with epinephrine) are tetracaine 1.5 mg/kg, bupivacaine 3 mg/kg, ropivacaine 3 mg/kg, lidocaine 7 mg/kg, mepivacaine 7 mg/kg, procaine 20 mg/kg, and 2-chloroprocaine 20 mg/kg. Maintain constant vigilance during and after local anesthetic injection. Resuscitative equipment and medications must be available at all times. Monitor patients fully whenever local anesthetics are injected. When infiltrating tissues, constantly move the needle while injecting, and whenever the needle stops, before injecting, apply 90-degree double aspirations to make sure the needle tip is not inadvertently introduced into a blood vessel. Inject small fractionate doses when performing nerve blocks. Whenever possible, add a tracer substance (e.g., epinephrine) to diminish tissue reabsorption of the local anesthetic and also to provide an early sign (tachycardia) of inadvertent intravascular injection of the local anesthetic. Use of ultrasound guidance aids visualization and increases the accuracy and safety of nerve blocks.

SPINAL HEMATOMA

Bleeding associated with neuraxial blockade is a rare complication, occurring in an estimated 1 in 220,000 for spinal anesthesia and in <1 in 150,000 for epidural anesthesia.[77] Spinal hematoma may occur in patients with known or unknown coagulopathies and in patients who may be anticoagulated for various medical or surgical reasons.

Symptoms include progression of the existing sensory or motor block (68%), bladder or bowel dysfunction (8%), and pain of radicular nature.[78] Whenever spinal hematoma is suspected, a computed tomography (CT) or magnetic resonance imaging (MRI) scan is diagnostic.

If the hematoma is symptomatic, it should be surgically evacuated as soon as possible. If possible, the anticoagulant involved also should be discontinued.

Preventing spinal hematoma requires judicious perioperative planning and good communication among the urologist, anesthesiologist, cardiologist/internist, and pain clinic staff. Nonsteroidal antiinflammatory drugs (NSAIDs) do not seem to pose a serious risk, either on insertion or removal of the neuraxial needle or catheter.[79]

When subcutaneous unfractionated heparin is used, there are no added significant risks on insertion (needling) or epidural catheter removal; however, it is recommended to wait 1 hour post catheter removal before resuming anticoagulation.

When IV unfractionated heparin is used, however, a delay of 2–4 hours is advised before insertion and a delay of 1 hour after insertion before resuming anticoagulation; an additional delay of 2–4 hours is advised before catheter removal and a delay of 1 hour after catheter removal before resuming anticoagulation.

When low-molecular-weight heparin (LMWH) is used, waiting 10–12 hours before catheter insertion is recommended, and >2 hours after insertion before resuming anticoagulation; waiting 10–12 hours before catheter removal is also recommended and >2 hours after catheter removal before resuming anticoagulation. The American Society of Regional Anesthesia recommends the removal of indwelling epidural catheters before starting LMWH.

When warfarin is used for thromboprophylaxis, the INR should be allowed to normalize to ≤1.4 preoperatively.[77] For patients with drug-eluting cardiac stents, there is a specific "bridging" protocol, which recommends that patients continue their antiplatelet medication.[80,81] The American Society of Regional Anesthesia and Pain Medicine publishes highly specific evidence-based guidelines for the management of patients receiving antithrombotic or thrombolytic therapy.[82]

FURTHER PREVENTION OF REGIONAL ANESTHESIA COMPLICATIONS

Meperidine Spinal Anesthesia

In our practice, we use regional anesthesia extensively for a large number of urologic procedures. Judicious use of meperidine spinal anesthesia prevents many major and minor anesthetic complications and provides superior long-lasting postoperative pain relief.

We have perfected a technique over the past several decades in which regular doses or minidoses of meperidine have been used without any respiratory depressant effect or otherwise deleterious side effects in thousands of ASA III–IV patients. We have used this regimen with great success in a wide variety of urologic procedures, ranging from cystoscopy to long TURPs, procedures for female and male incontinence, radical retropubic prostatectomy, and endourology procedures, including transurethral and/or percutaneous lithotripsy.

Meperidine has a fast onset and, when used alone, provides a deep sensory and motor block completely resembling plain lidocaine and/or mepivacaine spinal (50 mg doses yield a similar T6 sensory level, which covers ~1.5 hours of surgical anesthesia). Subarachnoid meperidine is the only short-acting narcotic with local anesthetic properties that provides 8 to 12 hours of postoperative analgesia. In the PACU, patients who received meperidine during surgery are completely awake, have a clear sensorium, are recovered fully from the initial motor block, and do not require pain medications.

As a rare side effect, itchiness occurs in <1% of cases. If itchiness becomes intense, it is treated with naloxone 40 µg IV, followed by naloxone 80 to 100 µg IM for prolonged effect.

Meperidine does not increase the risk of spinal headache (we have observed 0% in our patient population). Meperidine does not produce TNS as do the other local anesthetics.

Meperidine may be used alone or in combinations. We add minidoses of long-acting local anesthetics (bupivacaine, pontocaine) in order to prolong meperidine anesthesia during longer surgeries. This allows great versatility in matching a spinal anesthesia regimen to the length of a particular surgical procedure, so that the motor blockade will wear off very soon after the conclusion of surgery while still providing very long postoperative analgesia.

Meperidine can provide the spinal component of the CSE technique used in extra-long cases where the epidural catheter may be kept in place for several days for prolonged postoperative analgesia.

Combined Intravenous and Intramuscular Ephedrine for Cardiovascular Stability

In order to counteract the potential drop in BP secondary to any spinal anesthesia, we use ephedrine prophylactically immediately following spinal injection, as 5 mg IV bolus, with simultaneous IM injection of 25 mg to 40 mg (depending on patient's size). The IV dose starts working within a minute, without producing undue tachycardia, and lasts up to 10 minutes. The IM dose becomes effective within 10 minutes and works for 2.5 hours (using the muscle as a depot), with only minor increases in BP or heart rate (<10%), thus ensuring a continuum of BP support. This IV/IM regimen may be safely repeated several times, every 2.5 hours in longer procedures.

If given early enough, at the onset of sympathectomy secondary to spinal administration, this ephedrine regimen will always maintain the patient's original heart rate and BP, independent of the actual hydration status. This allows ample time to rehydrate the patient. Thus, a completely stable cardiovascular status is assured for the length of the case and recovery. This ephedrine regimen confers great cardiovascular stability to spinal anesthesia, making it an extremely attractive choice for all patients, and especially older and sicker ASA III–IV patients.

The combined IV/IM ephedrine also is useful to maintain BP in early hemorrhagic shock until the patient is rehydrated to euvolemia (crystalloids, colloids, blood), and to counteract orthostatic hypotension in the PACU (after rehydration fails).

Nerve Blocks in Urology

Nerve blocks offer a safe anesthetic approach to a multitude of urologic procedures and a rapid painless recovery for all patients. These blocks prove to be especially safe and useful in old and sick ASA III–IV patients because these blocks eliminate the risks and complications that general and regional anesthesia cause while providing a stressless operative and postoperative course (pain free, no PONV, clear postoperative mentation).

Contraindications to these nerve blocks include patient refusal, anticoagulation, allergy to the local anesthetic, and local infection.

Pudendal block and penile block are the nerve blocks most frequently used in hospital-based urologic surgery.

PUDENDAL NERVE BLOCK

Pudendal nerve block may be used in all superficial male and female perineal surgeries; male and female lower urinary reconstructive procedures; sling procedures for

incontinence; rectal and urinary sphincter procedures; and procedures on the penis, clitoris, scrotum, and labia majora. The pudendal nerve block can be used in conjunction with a short spinal anesthesia, general anesthesia, or continuous propofol/fentanyl TIVA.

The pudendal nerve innervates the perineum, the anal and urethral sphincters, the penis, and the clitoris. A number of male and female urologic procedures depend on knowledge of pudendal innervation, including anal and stress incontinence surgeries via suprapubic, perineal, or vaginal approaches, and pudendal canal decompression for pudendal canal syndrome and pudendal artery syndrome (with erectile dysfunction).[83]

The sacral plexus gives off the pudendal nerve by using the S_2, S_3, and S_4 anterior rami. The pudendal nerve roots emerge from the anterior sacral foramen. The pudendal nerve contains autonomic and motor nerve fibers together, making it a mixed nerve.

Out of the pudendal canal, the pudendal nerve gives off three terminal branches: the inferior rectal nerve, the perineal nerve, and the dorsal nerve of penis or dorsal nerve of clitoris.[84]

The inferior rectal nerve supplies the external anal sphincter, the mucous membrane, and the lower half of the perianal skin and the inner anal canal. The perineal nerve gives off deep branches to the muscles of the urogenital triangle and superficial branches to the skin of the lower labia majora and lower scrotum. The dorsal nerve of the penis or clitoris supplies sensory nerve endings to the skin surface of the clitoris and penis.

The pudendal nerve runs through three significant anatomic regions: the gluteal region, the pudendal canal, and the perineum. The course of the pudendal nerve in the area of the ischial spine is important because this is where the pudendal nerve block is placed.

There are three approaches to the pudendal nerve block:

1. Transvaginal approach
2. Midperineal approach
3. Direct percutaneous approach (Vaida method).

Transvaginal Approach

This method, often used in obstetrics, provides perineal analgesia during the third stage of delivery, when the presenting part of the newborn is visibly bulging the perineum. It is also useful in female urologic surgery.

The block is done with the patient in the lithotomy position. Palpate with the left hand (5–6 cm intravaginally) the left ischial spine through the left lateral vaginal wall. Affix the tip of an Iowa Trumpet between the palpating fingers and the tip of the ischial spine. Pass a long injecting needle through the trumpet and through the vaginal wall until it punctures the sacrospinous ligament and advances another 1 cm. Perform two 90-degree safety aspirations, and, if there is no blood return, inject 5–8 mL local anesthetic.

Repeat the same exact technique on the patient's right side, using the right hand for vaginal examination and the left hand for the aspiration-injection sequence. The sensory block obtained between the anus and clitoris can be ascertained by pinprick testing the skin of this area. Any local anesthetic may be used, such as 3% 2-chloroprocaine (providing a 1–2 hour block), lidocaine 1.5% or 2% (providing a 2–3 hour block), bupivacaine 0.25% or 0.5% (providing a 6–8 hour block) or ropivacaine 0.5% (providing an 6–8 hour block).

Complications. Potential problems may include accidental rectal puncture, bleeding (rare), pudendal blood vessel puncture (with local anesthetic systemic toxicity), and infection (rare). Avoid injecting large volumes of local anesthetic because toxicity may occur. See "Local Anesthetic Systemic Toxicity," earlier.

Prevention. The 90-degree double safety aspiration before the injection (to ascertain that the needle tip is not in intravascular position) is essential. When the patient is in the lithotomy position, the rectum is located medial and inferior to the ischial spine; therefore the palpating hand entirely protects the rectum. Do not do any puncture until the Iowa Trumpet is firmly affixed between the palpating fingers and the ischial spine.

Midperineal Approach

The midperineal approach can be used in female and male urology cases. With the patient in the lithotomy position, the block is done midway between the rectum and the base of the penis or vagina on the midperineal line. With the area thoroughly prepared, and with the contralateral gloved index finger palpating the ipsilateral ischium, pass the injecting needle posteriorly and laterally from this point, aiming toward the ischial spines, one at a time. When the ischial spine is contacted, walk the needle off the bone, medioinferiorly, about 1 cm past the sacrospinous ligament. After two 90-degree safety aspirations (ensuring no blood return), deposit 5–8 mL local anesthetic. The reverse is applied for the other side.

Complications. Complications include accidental rectal puncture, pudendal vascular puncture (local anesthetic systemic toxicity), and infections (rare). Avoid injecting large volumes of local anesthetic because toxicity may occur. See "Local Anesthetic Systemic Toxicity," earlier.

Prevention. Rectal puncture is prevented by guiding the needle with simultaneous transrectal palpation of the ischial spine. Inadvertent puncture of blood vessels is prevented by the 90-degree double safety aspirations.

Direct Percutaneous Approach (Vaida Method)

This method is an attractive approach for male or female urology, because it is easily performed using the ischial spines as landmarks. It is done with the patient in the lithotomy position, with the entire perineum and gluteal areas thoroughly prepared with antiseptic solution. A syringe containing 10 to 16 mL local anesthetic is outfitted with a 20-gauge spinal needle. In the lithotomy position the ischial spine can be palpated easily directly through the skin about 3–4 cm lateral from the midperineal point. Through a puncture done at this level (over the ischial spine), insert the needle in a 10-degree posterolateral direction. When the needle tip contacts the ischial spine, walk it off medially, through the sacrospinous ligament, for an extra 1 cm. After two 90-degrees aspirations, deposit 5–8 mL local anesthetic. Repeat again over the other ischial spine.

Complications. The direct percutaneous approach avoids rectal injury, which is more likely in the midperineal approach, and inadvertent intravascular injection (the slight angulation keeps the injecting needle in a more medial position away from the pudendal vessels). However, infection is a potential (although rare) complication.

Prevention. Double 90-degree safety aspirations are used in order to prevent local anesthetic systemic toxicity. Thorough skin preparation is essential to prevent infections.

PENILE BLOCK

Thorough understanding of pudendal nerve anatomy is necessary to administer the penile block. Terminal branches of the pudendal nerve innervate the rectum, the perineum, the scrotum, and the penis.

Perineal Nerve

After emerging from the pudendal canal, the perineal nerve courses downward for 2–3 cm and gives rise to two terminal divisions: a lateral scrotal branch and the medial striated urethral branch.[85,86] The scrotal branch unites with the inferior rectal nerve to form the common scrotal branch, which innervates the posterior aspect of the scrotum.

Deep Dorsal Nerve of Penis

This is one of the two branches of pudendal nerve leaving the pudendal canal. It courses forward along the inferior pubic ramus, along the end of the ischiorectal fossa, into the deep perineal pouch. The nerve courses forward into the suspensory ligament of the dorsum of penis, sending terminal branches to the entire dorsum.[87] It is noteworthy that very often a well done dorsal penile block spares the anterior lower part of the penis, which is innervated by rami of the perineal branch of the pudendal nerve as well.[88] By contrast, the circumferential block done at the base of the penile shaft is a complete block of the dorsal nerve of penis and the perineal branches of the pudendal nerve, which provide sensory innervation to the mid-anterior aspect of the penis all the way up to the frenulum.[89]

Indications of Penile Block (Adults Only)

Although circumcision is performed on an estimated one in six newborn males worldwide and about 60% of newborn males in the United States,[90] adult circumcision is much less frequently performed. The usual indications for adult circumcision are social, personal, or medical, including the following: phimosis, paraphimosis, acute paraphimosis (emergency), recurrent infections such as balanitis and posthitis, or preputial neoplasms. General anesthesia, penile block, or a combination of both is used in the majority of these cases.

The penile block is always done before the surgery begins, preferably using long-acting local anesthetics (e.g., 30 mL bupivacaine 0.375% or 0.5% provides 8–15 hours analgesia). Because the penis is an organ with terminal circulation, the local anesthetic used for penile block must never contain epinephrine. See "Penile Ischemia and Necrosis," later. The block is intensely painful; therefore, it should be done under a TIVA using continuous propofol/fentanyl technique, with the patient spontaneously breathing oxygen by mask. This technique may be continued throughout the entire surgical procedure, as a light or medium sedation. See "Propofol Total Intravenous Anesthesia (Propofol TIVA)," earlier.

Penile Nerve Block Techniques

There are two accepted penile nerve block techniques that may be used separately or together. Keep in mind that a bilateral pudendal nerve block will effectively provide full sensory block of the penis.

Dorsal Penile Nerve Block. Dorsal penile nerve block[91] is done by injecting 5–8 mL local anesthetic through a 27-gauge needle, deep to Buck's fascia, where the two (left and right) dorsal nerves of the penis emerge from under the pubic bone. Inject at the 10-o'clock and 2-o'clock positions at the base of the penis, walking the needle off caudad the pubic bone and popping through Buck's fascia.

A 4–6.7% failure rate has been reported using the dorsal block alone.[89] See "Deep Dorsal Nerve of Penis," earlier. To complete the block on the upper ventral side of the penis, a subcutaneous ring block must be done at the base of the frenulum.

Circumferential Block. This is our preferred technique because it provides 100% sensory block of the penis.[91] With the penis pulled up vertically and thoroughly prepped, 15–30 mL of local anesthetic is injected subcutaneously at the very base of the penile shaft, circumferentially. The injection is done with a 25-gauge needle, continuously moving the needle forward then backward while injecting, raising a contiguous ring around the base of the penis. When close to the dorsal vein of the penis, lift the needle over the vein subcutaneously while constantly advancing and injecting, making sure that no local anesthetic is deposited intravenously. The needle must be kept subcutaneous at all times.

Complications and Prevention

Bleeding and Hematomas. Bleeding and hematomas can be prevented by using a continuous mode of injection with small 25- or 27-gauge needles. When approaching the large dorsal vein of the penis, it is possible to skillfully lift the needle and course it subcutaneously above the vein while still injecting. This will avoid inadvertent IV injection of local anesthetic and bleeding or hematoma.

Local Anesthetic Toxicity. Even small amounts of local anesthetic, if directly injected intravenously, may cause toxicity. Additionally, if overly large volumes of local anesthetics are used for the block, they may get absorbed and cause delayed systemic toxicity. It is important to calculate and stay below the tissue toxic dose of the local anesthetic used. See "Local Anesthetic Systemic Toxicity," earlier.

Penile Ischemia and Necrosis. The arterial supply of the penis is through terminal branches of the pudendal artery, which gives rise to the bulbourethral arterial branches. The glans is supplied by the dorsal arteries, which give off circumflex branches perforating the tunica albuginea and supplying the distal end of corpora penis.

Penile ischemia/necrosis is a grave complication, usually caused by accidental use of vasoconstrictors (e.g.,

epinephrine).[92] All end organs with terminal vasculature are at risk of prolonged ischemia and necrosis (nose, fingers, toes, penis). Many cases of penile necrosis have been described in the pediatric literature; never use epinephrine in a penile block.

A possible temporary ischemia (presenting as pallor, pain, swelling, necrosis) has been successfully treated with vasodilation provided either by a regional block (caudal, spinal, epidural) or use of prostacyclin (PGI_2), the major prostanoid produced by the blood vessels. PGI_2 relaxes smooth vasculature, inhibits platelet aggregation, and can be administered intravenously or intraarterially.

Infection. Both methods of penile block must be done respecting full sterility precautions. In case of any infection, suspect skin flora.

Intraoperative Penile Erection

Intraoperative penile erection is a serious problem that may preclude Foley catheterization or cystoscope insertion and may increase bleeding and injuries to the corpora cavernosa and urethra during penile surgery. The mechanism for intraoperative penile erection is complex and poorly understood. It can be traced to a combination of neuroendocrine, vascular, and psychological factors acting upon the penile erectile organs.

Parasympathetic fibers (nervi erigentes) originating from S_2–S_4 sacral spinal segments innervate the penis. If parasympathetic tone predominates, the arteriolar dilation with subsequent erection of the corpora cavernosa causes erection. High sympathetic nervous tone causes arteriolar vasoconstriction with a subsequent reduction of the blood flow to the corpora cavernosa, causing penile detumescence. Vasoactive mediators also can affect the tumescence of the penis through a host of mediators like nitric oxide, bradykinin, or vasopressin.

The overall incidence of intraoperative penile erection is 2.5% for all male patients undergoing surgery, affecting those under general and epidural anesthesia evenly. The lowest incidence of 0.3% is encountered in spinal anesthesia.[93]

Clinically, intraoperative penile erection may occur from a multitude of factors. The most frequent are Foley catheterization (in 1% of general anesthesia cases) and penile manipulation (most frequently in patients <50 years of age).

A prolonged intraoperative erection is a urologic emergency.[94,95]

TREATMENT

Cooling the penis with ethyl chloride spray or anesthetizing with a penile block or pudendal block are frequently effective. Additionally, numerous pharmacologic methods have been used to obtain detumescence. Phenylephrine, a pure α-blocker, injected as 50–150 μg intracavernosally, provides detumescence within a few minutes. Vasodilators such as IV nitroprusside and inhaled amyl nitrate act through their relaxing effect upon the corpora cavernosa to produce detumescence. These might be contraindicated in hypotension, during regional blocks (sympathectomy), and in cases of increased intracranial or intraocular pressure. IV ketamine in doses of 0.5–1 mg/kg may be used. Ketamine's dissociative affect upon the limbic nervous system, coupled with its penile relaxing effect (decrease in central parasympathetic outflow), produces detumescence.[93]

Terbutaline 0.2–0.5 mg IV, a β_2-adrenergic agonist, has been used successfully to terminate erections. It causes a direct relaxing effect over the corpora cavernosa smooth muscles. Care must be taken in cardiac patients due to the tachycardia it may cause. Inhaled salbutamol, another β_2-adrenergic agonist, will work without cardiovascular symptoms. It will need a higher dose of 8–16 puffs (1600 μg).[96] Glycopyrrolate 0.2–0.3 mg IV, an anticholinergic with reduced chronotropic and CNS effects (better than scopolamine or atropine), works through its acetylcholine blocking effect in the nitric oxide penile erection mechanism.

Most sympathomimetics mentioned as useful penile detumescents in the urologic literature need to be evaluated seriously against their major cardiovascular complications. Epinephrine, norepinephrine, and metaraminol, to name a few, should be avoided if possible due to their intense β_1 activity.[93]

PREVENTION

Initial deepening of general anesthesia and avoiding early penile stimulation are important in preventing intraoperative penile erection. Pudendal block, penile block, or spinal anesthesia (instead of general) need to be considered more frequently for urologic procedures. In some elective cases, if prevention or milder treatment methods do not work, cancelling the case might be a better choice than causing inadvertent cardiovascular complications in a very sick ASA III–IV patient.[97]

Obturator Reflex

Obturator reflex is a problem potentially encountered during transurethral bladder tumor resections (TURBTs). Whenever the tumor resection gets close to the lateral wall of the bladder, the energy of the resectoscope can directly stimulate the obturator nerve through the bladder wall, which initiates a sudden violent pelvic thrust secondary to powerful contraction of the thigh adductor muscles. This may cause the resectoscope to inadvertently perforate the bladder. Obturator nerve block,[98,99] however risky[100] and difficult to perform, seems to be useful in preventing obturator reflex in conjunction with general or regional anesthesia. It was hoped that the use of the newest technologies, such as the new bipolar thermocoagulation devices,[101,102] would diminish the incidence of obturator reflex.

However, the obturator reflex can be totally prevented only if the patient is under general anesthesia and fully muscle relaxed. General anesthesia can be selected at the beginning of the case or initiated at any point later during the case if the tumors to be resected seem to be positioned on the unfavorable lateral wall of the bladder. Awareness of the problem and good communication between the urologist and anesthesiologist are essential to prevent the occurrence of obturator reflex.

Postoperative Pain Management

Most urologic procedures produce significant postoperative pain. Postoperative pain management should be discussed and planned jointly by the urologist and anesthesiologist before the surgery. The choice of anesthesia is crucial in partially or totally preventing postoperative pain. Patients waking up after general anesthesia have full pain, whereas patients after regional anesthesia have somewhat less pain.

The use of heavy pain medication postoperatively may produce its own undesirable symptomatology, such as PONV, unpleasant sedation, confusion (prolonged in the very old), residual pain, and longer recovery times. Ideally, the best anesthesia technique will simultaneously provide adequate stress-free anesthesia for the urologic procedure and prolonged postoperative pain relief in the PACU. This is best accomplished through the judicious use of nerve blocks and meperidine spinal anesthesia in association with propofol TIVA. See "Further Prevention of Regional Anesthesia Complications," earlier.

Various pain management techniques can be employed postoperatively.

NARCOTICS

Major narcotics still are relied upon heavily for immediate postoperative pain management. Morphine has been successfully used in single injectable doses on demand. It produces only moderate pain relief, with deep sedation, confusion, PONV, and histamine release. Morphine is very useful in narcotic sensitized patients, alone or in association with other methods of analgesia. See "Intravenous Patient-controlled Analgesia" later.

We find that fentanyl 100–150 μg (depending on patient's weight), used IM rather than IV (using the patient's large quadriceps muscle as a drug depot) along with 10 mg lidocaine added to alleviate injection discomfort, is a more potent analgesic than morphine and causes less deleterious side effects: Fentanyl used in this fashion causes no significant immediate respiratory depression, less PONV, and no histamine release (tachycardia, hypotension, itchiness) and provides very good pain relief for several hours. Fentanyl proves even more useful in patients with relative or absolute contraindications to other pain medications such as morphine, meperidine, hydromorphone (Dilaudid), or NSAIDs.

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

NSAIDs are very useful after shorter, less painful procedures, alone or in conjunction with minor narcotics, or in the context of multimodal analgesia. Most patients tolerate NSAIDs well for short treatment courses. Patients with known asthma history, allergy to NSAIDs, renal failure, GI problems (e.g., gastritis, ulcer), or coagulopathies should not be given NSAIDs. Acetaminophen (Tylenol) is a viable substitute, alone or in conjunction with narcotics.

Ketorolac tromethamine (Toradol) is safe in a single IM dose of 60 mg and provides excellent 6- to 8-hour analgesia without any sedation. IV Toradol has a short effect, and thus is never useful for significant postoperative pain relief (as per label warning). Toradol also may be used in combination with other medications. We prefer a novel combination injection of Toradol 60 mg IM, combined with a separate dose of 75–100 μg fentanyl IM, for a long-acting postoperative analgesia without significant respiratory depressant effect.

TRAMADOL

Tramadol (Ultram), a centrally acting moderate analgesic, is used in doses of 50 mg or 100 mg PO every 4–8 hours, and is safe for patients <75 years old. Tramadol decreases the seizing threshold of patients with seizure disorder and interacts negatively with a host of psychotomimetic drugs (serotoninergic syndrome).[103]

MULTIMODAL ANALGESIA

Different regimens mixing NSAIDs with minor or major narcotics and local anesthetics/nerve blocks prove to be very efficient, facilitating a rapid recovery.[104,105] Multimodal analgesia is heavily relied upon in ambulatory surgery.

INTRAVENOUS PATIENT-CONTROLLED ANALGESIA

The decision of what intravenous patient-controlled analgesia (IV-PCA) to use should be based on the type of procedure, expected intensity of postoperative pain, and type of patient (narcotic-naïve versus narcotic-sensitized).

We have found that patients frequently become narcotic-sensitized after only a few days of receiving μ-receptor stimulators (e.g., Percocet, Vicodin, morphine, hydromorphone) at any time during the past 6–12 months. Those patients will require a μ-receptor stimulator IV-PCA (morphine or hydromorphone) and will not respond well to fentanyl IV-PCA (which is mainly a κ-receptor stimulator).

Morphine IV-PCA is frequently used for in-patients. Many physicians tend to underdose morphine IV-PCA. We prefer fentanyl IV-PCA in all cases, except for the narcotic-sensitized (μ-receptor) patient.

Fentanyl IV-PCA provides superior analgesia, with less respiratory depressant effect (shallow breathing, respiratory rate <6/min, CO_2 retention), less CNS depressant effect (somnolence, disorientation), less histamine release (tachycardia, hypotension, itchiness), and less PONV than morphine. PCA doses should be down-adjusted for smaller patients and less painful surgeries (e.g., laparoscopies, robotics).

IV-PCAs are mainly maintenance regimens. For them to be successful, the patient must already be comfortable (painless) before leaving the OR and arriving in the PACU. Sometimes several narcotic boluses have to be administered to render the patient comfortable before starting the IV-PCA in the PACU.

EPIDURAL PATIENT-CONTROLLED ANALGESIA

Compared to any IV-PCA, epidural PCA has the advantage of better analgesia achieved with diminished sedative effect and even less frequent PONV. Epidural PCA uses various combinations of low concentration local anesthetic mixed with a potent narcotic (fentanyl, sufentanil).

THE OBSTRUCTIVE SLEEP APNEA PATIENT

For safe treatment of the clinically documented obstructive sleep apnea patient, use a nonnarcotic-based epidural PCA (e.g., bupivacaine 0.1% or 0.125%).

Laparoscopy and Robotic-assisted Laparoscopy

Robotic surgery in urology is a natural evolution of laparoscopic GU surgery. A large number of urologic procedures were developed robotically, along with continually evolving robotic platforms and methods. Various new intraoperative imaging techniques have been integrated into the robotic platform, including ultrasound (US) and near infrared fluorescence imaging (NIRF).

Anesthesia knowledge, experience, and versatility have directly paralleled this surgical evolution not only in achieving great patient outcomes but also in diagnosing, treating, and preventing the anesthesia-related complications associated with robotic urologic surgery.

The physiology and pathophysiology of laparoscopic and robotic surgery in urology are virtually identical. Therefore, we treat them together in this section.

Pathophysiology of pneumoperitoneum is different in patients under general anesthesia versus patients who are awake or sedated under regional anesthesia.

PATHOPHYSIOLOGY OF PNEUMOPERITONEUM (CO_2 INSUFFLATION)

Pneumoperitoneum Under General Anesthesia

Several processes constantly interplay during CO_2 insufflation: mechanical effects, neurohormonal effects, cardiovascular effects, temperature effects, respiratory effects (mechanical and CO_2 absorption), and circulatory effects.

Mechanical Effects of CO_2 Insufflation. Normal supine intraabdominal pressure (IAP) is 5–7 mm Hg, with a higher baseline level for morbidly obese patients (9–14 mm Hg). Increasing IAP with CO_2 insufflation significantly reduces the functional residual capacity of the lungs. Also, it causes a transient increase in venous return followed by a drop in cardiac preload ultimately resulting in a drop in cardiac output (CO) of up to 48%.[106] These effects may diminish at lower insufflation pressures. Remarkably, in an animal model, insufflation at a pressure of 12 mm Hg exerted a minimal effect on hemodynamic function.[107] This has useful potential implications for the laparoscopic/robotic surgeon.

Neurohormonal Effects. Increase in IAP and subsequent hypercapnia cause a release of catecholamines and vasopressin. The renin-angiotensin-aldosterone axis becomes activated. A parallel time course profile between these changes and changes in BP, systemic vascular resistance (SVR), and cardiac index (CI) suggests a cause–effect relationship.[108]

Cardiovascular Effects. Cardiovascular performance during pneumoperitoneum is affected by the interaction of several factors including neurohormonal release,[108] intravascular volume,[109] cardiorespiratory status,[110] and positioning.[111]

In patients with mild heart disease or in ASA III and ASA IV patients with severe systemic disease, the direction of changes in CI, SVR, and mean arterial BP is the same as in healthy patients, except that the initial decrease in CI and increase in SVR are more pronounced. Also, there is a significant increase in oxygen demand as expressed by great increases in left ventricular stroke work index.[111–114] CO_2 insufflation done in the supine position (versus Trendelenburg) produces a lesser initial decline in CI (of significant clinical implication). All these changes revert to normal upon release of the CO_2 (deflation).

Temperature Effects. Body core temperature drops significantly during surgery with continuous CO_2 insufflation.[110] This change is more pronounced in older patients and tends to continue despite warming throughout the procedure.

Respiratory Effects: Mechanical. Changes in pulmonary function during CO_2 insufflation include reduction in lung volumes, decrease in pulmonary compliance, increase in peak airway pressures, and reduction in FRC.[115–117] Insufflation of CO_2 at 15 mm Hg lowers an already decreased FRC (due to induction of general anesthesia and positioning), exacerbating the ventilation/perfusion (V/Q) mismatch.[118] Positive pressure ventilation will recover some of the FRC, reducing the potential for hypoxia.[119,178] The greatest reduction in FRC is seen in obese patients, thus creating a significant V/Q mismatch during pneumoperitoneum.[120] The existence of intrapulmonary shunting in COPD patients places them at extra risk of hypoxia during laparoscopic surgery.

Respiratory Effects: Carbon Dioxide Absorption. Interestingly, CO_2 absorption is greater during extraperitoneal procedures than during intraperitoneal procedures.[121,122] Elimination of CO_2 is biphasic. Early rapid elimination occurs at the beginning of insufflation and is followed by a slower elimination later on. This biphasic mode is maintained at lower as well as at higher inflating pressures.[121] Intentional hypercarbia increases plasma catecholamines and cardiac output and it decreases SVR directly through the vasodilating effect of CO_2 and indirectly by stimulating the sympathetic nervous system. Nitrous oxide (N_2O) administered during CO_2 insufflation tends to exaggerate the cardiovascular depressive effects of CO_2. Elimination of CO_2 is not problematic in healthy patients. For sicker ASA III or ASA IV patients, minute ventilation requirements and peak airway pressures are higher in order to assure normocarbia during laparoscopy.[123] Furthermore, in some sicker patients, end tidal CO_2 may not be a true reflection of their arterial partial pressure ($PaCO_2$). In these patients, refractory hypercapnia might occur during laparoscopy. Preoperatively, a pulmonary function test (PFT) showing diffusion defects <80% of predicted and FEV1 <70% of predicted identifies patients at risk.[124]

Specific Circulatory Changes. Regional blood flow changes during laparoscopy have been carefully studied. These circulatory effects alter organ perfusion in specific

ways and pose problems when operating on ASA III and ASA IV patients.

CEREBRAL BLOOD FLOW. Cerebral blood flow and intracranial pressure (ICP) increase significantly during CO_2 insufflation regardless of the level of $PaCO_2$.[125] There is a linear increase in ICP with increasing IAP. Trendelenburg position further increases ICP to 150% of initial.[126]

SPLANCHNIC BLOOD FLOW. Changes in splanchnic blood flow are mediated through a direct increase in IAP and through mesenteric vasculature compression.[127] Normal IAP is 4–5 mm Hg. The effect of low IAP (7 mm Hg) on splanchnic perfusion is negligible. Higher IAP (14 mm Hg) decreases portal and hepatic blood flow and decreases intestinal mucosal pH.[128] Increased IAP through CO_2 insufflation stimulates the release of antidiuretic hormone (ADH) with subsequent vasoconstriction of the splanchnic bed. Splanchnic ischemia is a serious risk factor for sepsis and multi-organ system failure, which can outlast CO_2 deflation by as much as 18 hours.[129]

HEPATIC BLOOD FLOW. Hepatoportal blood flow varies in direct proportion to changes in IAP. At low IAP (7 mm Hg) the portal blood flow is reduced 37%. At higher IAP (14 mm Hg) portal blood flow is reduced 53%.[130] The reverse Trendelenburg position significantly reduces the hepatoportal flow.[131]

RENAL BLOOD FLOW. CO_2 insufflation reduces flow in the renal cortex and medulla. There is a transient reduction in GFR, creatinine clearance, and urinary output.[132,133] Urine output and creatinine clearance tend to decrease at higher IAP (14–15 mm Hg). Any method that diminishes IAP such as low inflating pressures, retraction,[134] or abdominal wall lifting[135] promotes stable renal dynamics during laparoscopy. Humoral factors such as renin[136] and ADH are released by increased IAP and cause vasoconstriction with decreased urine output and urea excretion (GFR unchanged).[137]

Pneumoperitoneum Under Regional Anesthesia

Respiratory Changes. The previously described respiratory changes in patients under general anesthesia are less evident in patients under regional anesthesia. On insufflation, expired volume per unit time increases significantly, with respiratory rate increasing about 50% from baseline. During pneumoperitoneum under regional anesthesia, venous CO_2 remains unchanged along with $PaCO_2$.[138] Under epidural anesthesia, respiratory mechanisms remain intact, so patients can adjust their minute ventilation during CO_2 insufflation in order to normalize their $ETCO_2$. These results suggest that epidural anesthesia may be a safer alternative to general anesthesia because it is not associated with significant ventilatory depression.

Cardiovascular Changes. Hemodynamic changes during regional anesthesia are different from general anesthesia. The Trendelenburg position and CO_2 insufflation have little effect on heart rate and mean arterial pressure.[138] However, they affect the sensory level of the hyperbaric spinal anesthesia, which ends up significantly higher than expected thus magnifying the normal cardiovascular impact of the spinal block. To counteract this, smaller doses (minidoses) of local anesthetic in combination with potentiating narcotic minidoses are recommended.[139] Additionally, simultaneous use of the IV/IM ephedrine regimen will provide stable cardiovascular parameters throughout the case. See "Combined Intravenous and Intramuscular Ephedrine for Cardiovascular Stability," earlier.

OPERATIVE MANAGEMENT

Patient Monitoring

During laparoscopy/robotics, general monitoring (e.g., electrocardiogram, SaO_2, $ETCO_2$, BP, and temperature) is appropriate for healthy and slightly obese patients.[140] There might be larger fluctuations in $ETCO_2$ and $PaCO_2$ in patients with serious pulmonary disease or the morbidly obese; therefore, an arterial line is advisable for serial blood sampling, SaO_2 determinations, and tighter BP monitoring. Unchecked increases in CO_2 might cause arousal in patients under general anesthesia because of the intense catecholamine release secondary to hypercarbia. Using a BIS monitor helps with anesthesia depth assessment.[141]

General Anesthesia

The great majority of laparoscopies and robotically assisted laparoscopies in urology, both diagnostic and therapeutic, are done under general anesthesia in the United States. Propofol TIVA is also a good choice, with specific benefits for patients with a past history of PONV. See "Propofol Total Intravenous Anesthesia (Propofol TIVA)," earlier.

Choice of Airway. Endotracheal intubation is used for most patients. This ensures an airway protected against gastroesophageal reflux and enables the anesthesiologist to effectively control $ETCO_2$. During pneumoperitoneum, satisfactory $ETCO_2$ (34–35 mm Hg) is obtained by only a 15–25% increase in minute ventilation. In patients with COPD, it is safer to increase the respiratory rate rather than the tidal volume because of the risk of tension pneumothorax caused by potential rupture of alveolar bullae.[142,143]

LMA also has been used extensively in laparoscopic surgeries.[144] The fear of inadvertent gastroesophageal reflux has not been substantiated in studies done with clinical monitoring[144] and continuous esophageal pH monitoring.[145] General anesthesia can be safely performed using a correctly placed LMA.

When the patient is breathing spontaneously through an LMA or a mask, if inappropriately high levels of $ETCO_2$ are reached or are difficult to prevent (as in patients who are morbidly obese or who have severe pulmonary disease), the surgery should be stopped, the abdomen deflated, and the patient intubated for the conclusion of the surgery. High ASA status (III or IV) coupled with preoperative low vital capacity volumes and low forced expiratory volumes are good predictors of intraoperative hypercapnia and acidosis in laparoscopic procedures.[124]

Nitrous Oxide. N_2O is the second most diffusible gas in the body after CO_2. In conjunction with insufflated CO_2, N_2O readily overdistends most closed cavities such as the bowel, colon, inner ear, and bladder and increases the resident gas volumes by 100–200%. N_2O exaggerates the

deleterious cardiovascular effects of CO_2. It also is associated with increased rates (30%) of PONV. Because of these negative characteristics, N_2O should never be used during laparoscopic/robotic surgery.

Regional Anesthesia

Regional anesthesia (spinal, epidural, or combined spinal/epidural) can be used in laparoscopic/robotic surgery as an alternative anesthesia choice in patients with severe cardiopulmonary disorders that contraindicate general anesthesia. Other advantages of regional anesthesia include decreased or lack of postoperative pain, decreased PONV, more rapid recovery with shorter PACU stay, fewer hemodynamic changes,[143] fewer respiratory changes,[146] and the availability of an epidural catheter for extended postoperative analgesia.[147] A disadvantage of regional anesthesia for laparoscopy is that it often requires the surgeon to work with a lower insufflation pressure (9–12 mm Hg). Additional disadvantages include the requirement of a cooperative patient and gentler surgical technique. Oversedation can cause hypoxia.[148]

Epidural Anesthesia. Epidural anesthesia is considered safe and practical in short procedures and in outpatient laparoscopic surgery. It does not significantly inhibit respiratory function, thus patients can increase their minute ventilation easily to compensate for the increase in $PaCO_2$, assuring that $ETCO_2$ remains unchanged.[138] The epidural technique has been used successfully for patients with advanced COPD.[138,146,147] Epidural anesthesia also has been used successfully in gasless laparoscopic procedures, providing cardiovascular and respiratory safety similar to general anesthesia.[149]

Spinal Anesthesia. In this age of short outpatient laparoscopic surgery, spinal anesthesia may be used to provide fast onset, deep, reliable blocks with easily controllable length of action. The classic hyperbaric spinal technique should be replaced by minidose spinals because of the propensity for cephalad spread of the sensory level during increased IAP and in the Trendelenburg position.[139,150] Ideally, minidoses of local anesthetic, potentiated by the addition of minidoses of narcotics, are used.[151] Even more effectively, minidoses of meperidine (30–40 mg) also provide long-lasting postoperative pain relief. See "Meperidine Spinal Anesthesia," earlier.

Local Anesthesia. However controversial, local anesthesia is used for ultra-short diagnostic laparoscopies and is adequate for special microlaparoscopic procedures done in nonobese patients.[143,152–157] In all these cases, preemptive port site local anesthetic infiltration greatly diminishes postoperative pain.

Peripheral Nerve Blocks. Several nerve block techniques have been described in conjunction with laparoscopic surgery, including rectus sheath block,[158] inguinal block,[158] and paravertebral block.[159] These blocks prove to be useful adjuncts to general anesthesia or TIVA, and they provide effective postoperative pain relief in various types of laparoscopic surgery. They result in reduced PONV and increased patient satisfaction.

COMPLICATIONS OF PATIENT POSITIONING IN ROBOTIC SURGERY

Positioning the patient for various robotic urologic procedures is very specific. See also "Positioning-related Complications," earlier. Some cases require a supine position (radical prostatectomy, sacrocolpopexy); others require a semi-lateral position (radical nephrectomy, partial nephrectomy, adrenalectomy, nephroureterectomy) or flank position (partial and/or radical nephrectomy-posterior retroperitoneal approach).

In most cases the legs are symmetrically placed in stirrups. In some cases, they are purposely placed asymmetrically. Most cases will be positioned in a steep (30–45 degrees) Trendelenburg position, though a moderate 20–30 degrees is sufficient to maintain the advantages of the position (e.g., moving bowels away from pelvis) while minimizing the negative effects of steep Trendelenburg.

Various complications have been described as a result of positioning, including nerve injuries, compartment syndrome, rhabdomyolysis, dermal injuries, and eye injuries. Understanding the mechanism and etiology of these complications is vital for effective prevention and treatment.

Two general pathophysiologic mechanisms are responsible for position-related complications in robotic urology: neural mechanisms and vascular mechanisms.

Neural Mechanisms

Neural mechanisms clinically present as peripheral neuropathies and intraocular neuropathy (ION). These neuropathies can be mild or severe. Nerves can be stretched or compressed or can get ischemic. Depending on the degree of insult, the result is a neuropathy that can have a short (neuropraxis = weeks) or long (months) duration, or sometimes may become permanent. Once degenerated, a damaged nerve's regrowth rate is about 1 mm/day.[160]

Peripheral Neuropathy of Lower Extremity. Superficial peroneal nerve injury is frequently encountered, occurring mostly in the high lithotomy position, especially in surgeries lasting over 6 hours. This type of neural complication is nearly eliminated by repositioning to the supine position.[161]

Peripheral Neuropathy of Upper Extremity. Nerve trauma can occur secondary to sliding in steep Trendelenburg position, during the use of shoulder braces, or due to compression from low-positioned robotic arms. Ulnar nerve lesions can occur frequently in these cases. Awareness, correct positioning, additional padding, and the use of lateral bed extenders (as padded arm rests) nearly eliminates ulnar nerve injuries and other upper extremity injuries. In the lateral or semi-lateral position, careful padding and positioning of the upper arm minimizes the risk of upper arm neural damage. Brachial plexus injury occurs when arms are hyperextended with or without contralateral tilt of the head. "Axillary" roll (high thoracic roll) should be used to elevate the upper thorax from the OR table and thus prevent brachial plexopathy.

Aggravating factors for these neuropathies include increased BMI, a high lithotomy position, shoulder braces, inadequate padding, and lack of axillary roll.

Intraocular Neuropathy. Etiology of intraocular neuropathy (ION) may be multifactorial: local edema due to the Trendelenburg position, orbital stretching, direct compression of the eye in the prone position, the increase in end expiratory CO_2 that may increase intraocular pressure (IOP) directly and/or through choroidal vasodilation, and increased secretion of aqueous humor.[162] To prevent ION, minimize the degree of Trendelenburg position, avoid direct compression of the eye, and maintain normocarbia.

Vascular Mechanisms

Ischemic compression of any extremity may cause compartment syndrome and/or rhabdomyolysis. The Trendelenburg position causes a significant decrease in deep calf muscle mixed tissue oxygen saturation (hypoxia) during urogenital robotic surgery.[163] Additionally, a steep (30–45 degrees) Trendelenburg position while in the lithotomy position may cause patient slide cephalad with resulting pressure on the calves and legs (ischemia). Prevention involves the use of special nonslip pads. A lesser Trendelenburg (16 degrees) position will preserve the surgical advantages while minimizing the risks associated with Trendelenburg position (increased intra-abdominal, intrathoracic, intracranial, and intraocular pressure).

Compartment Syndrome. Compartment syndrome (CS) is a condition that results from prolonged impairment of limb perfusion secondary to compression, edema, and ischemia of a body compartment. CS may lead to internal cellular swelling and to further self-sustaining ischemia, followed by potential vascular and nerve damage, along with massive muscle destruction leading to rhabdomyolysis. A wide range of complications can arise from CS, including temporary to permanent nerve damage, muscle necrosis, sepsis, rhabdomyolysis, amputation, and death.

Risk factors for CS are patient related (morbid obesity, peripheral vascular disease [PVD], hypovolemia/dehydration, hypotension, hypothermia, drug-induced prolonged peripheral vasoconstriction) and/or procedure related (high lithotomy position, Trendelenburg position, compression of extremity circulation, dependent limb).[164] CS can be diagnosed using the six "P"s: progressive pain, paresthesia over peripheral nerve distribution, pain upon passive stretch of the involved muscle, pink skin, pulse, and compartment pressure (CP) over 30 mm Hg in any compartment.[165]

The presence of pedal pulse or pulse oximetry is not adequate for excluding the CS diagnosis, though in advanced CS cases pulse would be absent. Myoglobin in the urine heralds impending CS; however, the amount of myoglobin does not directly correlate with the degree of tissue destruction. The best method to ascertain the gravity of the CS syndrome is to directly measure CP, which can be done invasively or noninvasively, using a more modern fiberoptic device employing near infrared spectroscopy (NIRS) for continuous display of CP.

PREVENTION OF COMPARTMENT SYNDROME. Preoperatively, advise patients to lose weight and prehydrate to euvolemia.

Intraoperatively use the correct positioning (lower the lithotomy position, use 16 degrees Trendelenburg, no pressures, no constrictions). Avoid prolonged surgery over 5 hours, and in longer surgeries (over 6–7 hours) try to reposition the patient midway during the procedure. Use transparent drapes to observe limbs for changes in color and size. Maintain adequate blood pressure and adequate perfusion pressure, and avoid vasoconstrictor drugs; use mannitol if necessary as a free radical scavenger. In very high–risk patients (ASA IV, heavy smokers, super-obese, PVD, etc.) use prophylactic intraoperative CP monitoring. If regional anesthesia is being used, be sure to maintain normal mean arterial pressure (MAP).

Postoperatively, it is important to keep a high awareness, since CS may appear some time after the injury as a result of tissue reperfusion. Use close monitoring.

TREATMENT OF COMPARTMENT SYNDROME. Treatment should start early. Pressures of 50 mm Hg or over for 4–8 hours will likely produce irreversible muscle changes. Fasciotomy is generally recommended somewhere around pressures of 30–45 mm Hg and it is recommended not to wait too long. Current belief is that a CP within 20 mm Hg below the diastolic BP of the patient will likely prevent unnecessary fasciotomies and irreversible neuromuscular damage.[166]

Identify and discontinue ischemia (e.g., transparent drapes, repositioning), decompress all compartments involved (fasciotomy), and properly rehydrate the patient (he or she may lose significant plasma volume by oozing post-fasciotomy). When intense CS leads to rhabdomyolysis, medical treatment must begin early in order to be successful. Diuresis must be forced with mannitol and is considered important in treating renal failure secondary to rhabdomyolysis. In very advanced cases of CS, a delay of 8–10 hours should trigger a reassessment of the need for fasciotomy.

Rhabdomyolysis. Rhabdomyolysis is a complication of muscle trauma–related crush injuries. It also may occur secondary to muscle ischemia due to prolonged muscle compression.[167] Rhabdomyolysis is frequently associated with CS.[168,169] In advanced CS, increased tissue pressures (due to edema and secondary regional ischemia) lead to muscle necrosis and release of toxic catabolytes and large quantities of acidic myoglobin. High levels of CPK (a marker) are released as well in the general circulation, which somewhat parallels the clinical course of the rhabdomyolysis. Acute renal failure (ARF) is a common complication. There are numerous case reports of rhabdomyolysis after laparoscopic/robotic cases of donor nephrectomy, partial nephrectomy, radical nephrectomy,[170–172] and long bariatric surgeries in morbidly obese patients.[173,174]

PATHOPHYSIOLOGY OF RHABDOMYOLYSIS. The pathophysiology is multifactorial. Rhabdomyolysis is the result of an ischemic injury to the nephrons secondary to intravascular volume depletion, coupled with renal vasoconstriction and intraluminal cast formation. Ischemic muscle edema reduces intravascular blood volume, creating pre-renal conditions for acute renal failure as well. Furthermore, heme proteins will reduce the nitric acid reserves of the kidney with a secondary vasoconstrictive effect, which further reduces the glomerular filtration rate (GFR).

Complications of rhabdomyolysis include metabolic acidosis, disseminated intravascular coagulation (DIC), respiratory failure, and shock. Electrolyte abnormalities include

hypocalcemia, hyperkalemia, and hyperphosphotemia. These electrolyte changes may occasionally cause severe cardiac arrhythmias.

TREATMENT OF RHABDOMYOLYSIS. Most treatment guidelines are based on the animal model of ARF secondary to rhabdomyolysis.[175,176] They recommend vigorous hydration, alkalinization with sodium bicarbonate, and diuresis (mannitol, loop diuretics, and "renal" dopamine). Alkalinization greatly increases the solubility (and elimination) of myoglobin (2% solubility at pH 5 increases to 80% at pH of 8).[175] In advanced cases (shock), invasive monitoring, dialysis, and other supportive therapies are needed.

Patients may present to the PACU with bruising, excessive muscle (compartment) pain, local swelling, dark brown urine, and oliguria. Serum levels of creatinine, CPK, and myoglobin should be measured. If there is compartment swelling, an immediate vascular consult with tissue pressure monitoring should be obtained. A more precise noninvasive technology using near infrared technology to quantify tissue ischemia by measuring dioxyhemoglobin levels has been developed.[177]

PREVENTION OF RHABDOMYOLYSIS. Very muscular and/or high BMI patients are at highest risk for rhabdomyolysis. Use proper heavy cushioning of the OR table, shorten procedures, and in long cases call for time out and reposition the patient. Do not use kidney rest.

CLINICAL COMPLICATIONS DURING PNEUMOPERITONEUM

Normal intraabdominal pressure (IAP) is 5–7 mm Hg. During pneumoperitoneum, the inflating pressures get transmitted from the abdomen to the chest, head, neck, and eyes. These pressures tend to be exaggerated by the steep Trendelenburg position.

Pneumopericardium, Pneumomediastinum

Complex cases of pneumothorax associated with pneumopericardium, pneumomediastinum, and periocular emphysema have been described. High inflating pressures probably contribute to the occurrence of these complications.[178–180] Signs of cardiac tamponade may occur, including arrhythmias, muffled heart sounds, jugular vein distention (JVD), drop in BP and cardiac output, and superior vena cava syndrome. Superior vena cava syndrome manifests as a "blue cape" cyanosis and swelling of the head and neck (due to the impingement upon the venous return to the right heart). Decreasing the inflating pressures to <15 mm Hg or completely releasing the CO_2 from the abdominal cavity is sufficient to halt and reverse these complications.[181]

Pneumothorax

Pneumothorax may occur upon insufflation in congenital defect of the diaphragm. Iatrogenic pneumothorax may occur during inadvertent percutaneous or transdiaphragmatic puncture of the lung (e.g., during posterior retroperitoneal approach in nephrectomy and partial nephrectomy). Existing pulmonary blebs (or bullae) may rupture during mechanical ventilation. A bleb is a small (less than 1 cm) air collection located within the visceral pleura. It can rupture spontaneously or through mechanical ventilation. Sometimes patients present with multiple blebs. Bulla is a larger (greater than 1 cm) air space formed in the lung parenchyma. A giant bulla (larger than 30% of the hemithorax) is at great risk of rupturing. A Sudden hypoxia (drop in SaO_2), increase in airway pressure, and/or cardiac arrhythmias should alert to the possibility of pneumothorax. Prevention, once blebs or bullae are noticed, involves the use of small tidal volumes coupled with higher respiratory frequency on mechanical ventilation. Treatment comprises correct side diagnosis and chest tube placement, which assures lung re-expansion.

Tension Pneumothorax

Pneumothorax leading to tension pneumothorax, a rare but potentially life-threatening complication, has been described in both intraperitoneal[182] and extraperitoneal[183] laparoscopy. CO_2 can enter the thoracic cavity through the natural esophageal or aortic hiatus, or it might dissect through a congenitally open pleuroperitoneal hiatus.[184,185] A sudden large accumulation of CO_2 in the pleural cavity or an accidental rupture of lung bullae may cause tension pneumothorax.

The ipsilateral lung gets collapsed, and there is a contralateral mediastinal shift. The lung's respiratory surface is quickly diminished leading to hypoxia. This is a life-threatening emergency. There is a gradual compression of the vena cava with a diminishing of venous return to the heart and a sudden decrease of cardiac output (CO). There is a noticeable contralateral shift of the trachea as well as cyanosis, increased engorgement of the neck veins (JVD), sudden increase in ventilatory airway pressure, and hypoxia. The patient's condition deteriorates quickly. An emergency chest x-ray is diagnostic.

Treatment should be immediate. In emergencies, when cardiovascular collapse is imminent, the best method is to stop surgery and immediately deflate the abdomen. Careful manual ventilation soon promotes CO_2 reabsorption, re-expands the affected lung, and restores normal cardiovascular function. In extreme cases, an emergency thoracocentesis (most frequently done over the second intercostal space at the mid-clavicular level using a 3.5-inch 14-gauge – or larger – needle) releases the CO_2, allowing manual re-expansion of the lung. Maintaining inflating pressures at <15 mm Hg might prevent such occurrences.

Subcutaneous Emphysema

Following CO_2 insufflation, an inadvertent subcutaneous emphysema might occur, with a reported incidence of 0.4–2%.[186,187] It may be limited to the abdominal wall, or it may dissect all the way around the chest wall, neck, head, and thighs, creating a lot of easily palpable subcutaneous crepitus. On some extreme occasions, increased $ETCO_2$ and respiratory acidosis have been described.[188] Careful deep insertion of the Veress needle, maintaining the inflating pressures at <15 mm Hg, and visualization of the intraperitoneal position prevent this complication.[189]

Subcutaneous emphysema is usually benign and resolves spontaneously. CO_2 with its known high diffusability is not dangerous subcutaneously and will be spontaneously eliminated through reabsorption (and lungs) within a few hours. In advanced cases, $ETCO_2$ should be monitored in the PACU and patients placed on O_2 by mask to avoid hypoxia through rebreathing.

Cardiac Arrhythmia

Bradycardia sometimes occurs during the intraperitoneal CO_2 insufflation. It is thought to be due to a vagally mediated action due to peritoneal distention. Prevention involves being mindful and attentive. Treatment comprises an anticholinergic administered simultaneously with abdominal deflation. When normal heart rate reappears, re-insufflation and the procedure may continue.

Carbon Dioxide Gas Embolism

CO_2 embolism (CO_2 entry into the vascular bed) can occur following accidental puncture of veins or a very vascular organ (e.g., liver). CO_2 gas embolism during laparoscopic surgery can be nonfatal[190] or fatal.[191] Hypoxia, arrhythmias, cyanosis, precordial "mill wheel" murmur, and sudden drop in $ETCO_2$ and $PaCO_2$ (due to the reduction in pulmonary venous return) may be followed by cardiovascular collapse. Gas embolism may occur at any time during CO_2 insufflation. In the presence of a patent right to left communication (e.g., patent atrial septal defect, patent foramen ovale), coronary and cerebral CO_2 embolism may result.[192]

Subclinical forms of CO_2 embolism occur somewhat frequently and may be detected using transesophageal echocardiography (TEE).[193]

Careful surgery done by an experienced surgeon, a high suspicion index by the anesthesiologist, the use of a precordial stethoscope, a large bore central line, and TEE used in high-risk patients with advanced multisystem disease help in early detection and treatment of gas embolism. Insufflation should be done in supine position since Trendelenburg position is known to decrease venous pressures. Air entry and air embolism are considered much more serious than CO_2 embolism, because CO_2 has a much higher diffusing capacity and can be eliminated faster. Thus, the air from the insufflating tube should be replaced with CO_2.

Once CO_2 embolism is diagnosed, immediately stop insufflation, deflate the abdomen, and flood the operative area with fluid (NS, Ringers lactate). The patient should be rolled onto his or her left side to facilitate CO_2 elimination from the heart. A CVP line may be inserted, and/or in desperate cases direct cardiac puncture may be needed to aspirate the CO_2.[194]

Shoulder Pain

Although the mechanism of postoperative shoulder pain is unclear, it is theorized that CO_2 entrapment under the diaphragm produces phrenic nerve irritation and referred pain to C4 (shoulder). Many surgical maneuvers have been described as potential treatment, including low pressure pneumoperitoneum.[195] The use of an abdominal wall lifter (AWL) is no longer recommended.[195] Various postoperative medications (e.g., NSAIDS, narcotics, pregabalin) were found to have limited usefulness.[196]

The most successful methods involve eliminating intra-abdominal CO_2 either by filling the abdomen with saline solution at the end of surgery[197] or using the Valsalva maneuver in Trendelenburg position at the the end of surgery.[198,199] At our institution, we routinely use the Valsalva maneuver at the end of all laparoscopic/robotic surgeries with excellent results.

Chapter 6 Questions

1. What are the most common risks for anesthetic morbidity and mortality?
   a. Age >50
   b. Chronic renal failure, multiple genitourinary (GU) surgeries
   c. Preexisting cardiac and pulmonary conditions
   d. Smoking, chronic obstructive pulmonary disease (COPD)
   e. Previously encountered difficult airway

2. Which of the following statements is true for morbid obesity and obstructive sleep apnea?
   a. Morbid obesity is defined as BMI of 35–39.9 kg/m^2
   b. A morbidly obese patient with multiple comorbidities presents a reasonable risk for ambulatory surgery
   c. Obstructive sleep apnea is rarely associated with morbid obesity
   d. Continuous positive airway pressure (CPAP) and/or bilevel positive airway pressure (BiPAP) should be discontinued 2 days before surgery
   e. Ambulatory surgery is safely done on morbidly obese patients without comorbidities

3. When doing preoperative anesthesia risk stratification, an ASA III patient is:
   a. A patient with one well-controlled systemic disease
   b. A patient with childhood history of asthma, gastroesophageal reflux disease (GERD), and history of smoking
   c. A patient with obstructive sleep apnea and mitral valve prolapse
   d. A patient with ejection fraction = 30%, poorly controlled diabetes mellitus, and coronary artery disease with two drug-eluting stents (12 months ago)
   e. A patient with systemic lupus erythematosus (SLE), 3 months postradical cystectomy

4. Which of the following statements are true about patients with hyperreactive airway?
   a. Preoperative history taking is very important in identifying patients with a hyperreactive airway
   b. Adequate depth of anesthesia should be achieved before operating or manipulating the airway of these patients
   c. Patients with bronchial asthma (or with a history of it), obesity, or COPD, smokers, patients with eczema, or those with recent upper respiratory infections (within 4–6 weeks) frequently present with a hyperreactive airway
   d. All of the above
   e. b and c

5. Which of the following statements are true about patients with malignant hyperthermia (MH)?
   a. All inhalational anesthetics and succinylcholine can trigger MH
   b. There is a nontriggering general anesthesia technique that may safely be used in a well-documented MH patient
   c. Quadrupling of end tidal CO_2 ($ETCO_2$), deep metabolic acidosis, and hyperkalemic cardiac arrest indicate fulminant MH
   d. Discontinuing triggering agent, cooling, hyperventilating, treating high potassium and arrhythmias, and the use of dantrolene sodium are part of the treatment for MH
   e. All of the above

6. Which of the following statements is true about postoperative nausea and vomiting (PONV)?
   a. The most effective way to prevent PONV is to use a light, short, general anesthesia
   b. NSAIDs, narcotics, and epidural PCA are the best way to treat PONV
   c. Patients with a positive history of PONV and/or motion sickness, general anesthesia with inhalational agents lasting longer than 3 hours, orchiopexy, hernia repair, and laparoscopic surgery are most likely to develop PONV
   d. In most studies, a combination of dexamethasone and antiserotonin antagonist prove to be the least effective in treating PONV
   e. Propofol total intravenous anesthesia (TIVA) does not have any preventative effect on PONV

7. The advantages of regional anesthesia for GU surgery, as compared to general anesthesia, are as follows:
   a. Regional anesthesia decreases the odds of blood transfusion by 50%, pneumonia by 39%, respiratory depression by 59%, MI by 33%, DVT by 44%, PE by 55%, and renal failure by 43%
   b. Regional anesthesia attenuates the body's stress response, decreases hypercoagulability, and preserves perioperative immune function
   c. Regional anesthesia decreases length of stay in the PACU, provides superior postoperative pain control, and increases patient satisfaction
   d. Contraindications for regional anesthesia are cardiac outflow tract obstruction (IHSS and aortic stenosis), the anticoagulated patient (when INR ≥1.4), skin infection, sepsis, allergy to local anesthetic, and shock
   e. All of the above

8. Which of the following statements are true about the pathophysiology of pneumoperitoneum (CO_2 insufflation) under general anesthesia?
   a. It increases intraabdominal pressure (IAP) and decreases cardiac output and functional residual capacity (FRC) of the lungs. It produces drops in body temperature (more pronounced in elderly patients)
   b. The increased IAP and hypercapnia activates the renin-angiotensin-aldosterone axis through a release of catecholamines and vasopressin
   c. Insufflation of CO_2 at 15 mm Hg lowers the FRC, exacerbates the ventilation/perfusion (V/Q) mismatch, and increases intrapulmonary shunting with hypoxia in COPD patients
   d. Cerebral blood flow and intracranial pressure (ICP) increase significantly while the splanchnic, hepatic, and renal blood flows are reduced. All these effects

are prevented by using CO_2 inflating pressures of 9–12 mm Hg
e. All of the above

9. Which one of the following statements is false regarding the Trendelenburg position?
   a. The steep Trendelenburg position (30–45 degrees) exaggerates complications during laparoscopic/robotic surgery, including nerve injuries, compartment syndrome, rhabdomyolysis, dermal injuries, and eye injuries
   b. Intraocular neuropathy (ION) due to choroidal vasodilation and increased secretion of aqueous humor can be prevented by minimizing the degree of Trendelenburg position (to 20–30 degrees)
   c. A lesser (16 degrees) Trendelenburg position is insufficient to provide surgical advantage (e.g., moving bowels away from the pelvis, etc.)
   d. Nonslip pads are effective in preventing patient sliding in Trendelenburg position
   e. A steep Trendelenburg position combined with lithotomy may put undue pressure on the patient's calves and legs

10. Which of the following is a true statement regarding shoulder pain as a postoperative complication of pneumoperitoneum (CO_2 insufflation)?
    a. The most successful ways to treat post-CO_2 insufflation shoulder pain are filling the abdomen with saline solution at the end of surgery or using the Valsalva maneuver at the end of the procedure
    b. It is theorized that shoulder pain is secondary to CO_2 entrapment under the diaphragm, with cervical nerve stimulation and referred pain to C4
    c. Abdominal wall lifters (AWL) are recommended as the most useful method to prevent postoperative shoulder pain
    d. b and c
    e. All of the above

Answers

1. **c.** The patient's preexisting cardiac and pulmonary conditions are the two most common risks for anesthetic morbidity and mortality. Additionally, increasingly prevalent significant risks include morbid obesity and obstructive sleep apnea.
2. **e.** Deciding whether to do surgery in an ambulatory or an inpatient setting should be an individualized decision, based on close cooperation between the patient's primary care physician (PCP), surgeon, and anesthesiologist. Several studies report factors influencing morbidity and mortality in ambulatory surgery on the super-obese: BMI >53, inability to walk over 200 feet, history of deep vein thrombosis (DVT), history of OSA, coexisting medical conditions, and type of surgical procedure. However, ambulatory surgeries of all kinds are routinely done on morbidly obese patients without undue complications or hospital admissions.

   Morbid obesity is defined as BMI ≥40 kg/m^2. Obstructive sleep apnea is often associated with morbid obesity. Since the numbers of morbidly obese patients are continually increasing, obstructive sleep apnea cases are similarly increasing. Patients should be encouraged to use CPAP and/or BiPAP continuously preoperatively and postoperatively. There are certain benefits in the preoperative period to the use of CPAP or BiPAP, specifically an increase in the pharyngeal area, decrease of tongue volume (which occurs in about 4–6 weeks of therapy), improved ventilatory drive, and improvement of most cardiac parameters. Furthermore, recent studies have suggested the utility of CPAP/BiPAP for several days postoperatively when the patient's condition might worsen at home.
3. **d.** ASA III patients have severe systemic disease, involving more than one major body system. They are in no immediate danger of death, but they have some functional limitations (e.g., stable angina, coronary heart failure [CHF], old heart attack, poorly controlled hypertension and diabetes, morbid obesity, chronic renal failure).
4. **d.** A hyperreactive airway can be anticipated by taking a thorough history and physical. Patients with bronchial asthma (or with a history of it), obesity, or COPD, smokers, patients with atopies (e.g., eczema), or those with recent upper respiratory infections (within 4–6 weeks) frequently present either with a hyperreactive airway or with an overt asthmatic condition. Their usual medications, such as β_2-agonists (e.g., albuterol) and anticholinergics (e.g., ipratropium), should be used preoperatively. Most importantly, an adequate depth of anesthesia should be achieved before manipulating the airway with endotracheal intubation or before patient positioning and any surgical manipulation. The same principle applies when extubating these patients. In this patient population, regional anesthesia techniques are preferable, whenever feasible.
5. **e.** All inhalational anesthetics, except N_2O, can trigger MH. Succinylcholine (SCH) is a very frequent trigger. Safe anesthetic agents include N_2O, barbiturates/IV anesthetics, all narcotics, and all antianxiety medications. MH can begin during administration of anesthetic agents, or it may occur postoperatively. To diagnose MH, one should consider both clinical presentation and laboratory data. One of the most consistent clinical indicators is an unanticipated increase (tripling or quadrupling) of $ETCO_2$ when minute ventilation is normal.

   Treatment for MH begins by immediately discontinuing the triggering agent. Hyperventilate with 100% oxygen. Treat with IV 2.5 mg/kg dantrolene sodium (because this solution does not have significant side effects, it should be used for all cases in which MH is suspected). Treat acidosis with bicarbonate; treat hyperkalemia with glucose, insulin, and calcium; and treat hyperthermia with cooling (nasogastric lavage, rectal lavage, intraperitoneal lavage, surface cooling – to an end point of 38°C). Avoid calcium channel blockers (use other antiarrhythmics). Carefully monitor serum potassium; measure creatine phosphokinase (a good measure of muscle destruction) every 6 hours until decreased (though in severe MH, high creatine phosphokinase might last for 2 weeks). Follow coagulation

profile because disseminated intravascular coagulation may occur. Check serial ABG, electrolytes, blood, and urine myoglobin.

6. **c.** The most effective way to prevent PONV is to use a propofol-based TIVA and to preferentially avoid inhalational anesthetics, N_2O (which causes a 30% increase in PONV), and unnecessary sedatives. Propofol TIVA proves especially useful in patients at higher risk for PONV (those with a history of motion sickness or previous PONV).

   Various antiemetic medications are used to treat PONV. One group of antiemetics works by antagonizing neurotransmitters at various receptor sites (e.g., dopamine, histamine, serotonin, or cholinergic-muscarinic receptors). These include antihistamines (diphenhydramine and promethazine), butyrophenones (droperidol and haloperidol), phenothiazines (chlorpromazine and prochlorperazine), benzamides (metoclopramide), and anticholinergics (scopolamine). Another group works as specific antiserotonin ($5\text{-}HT_3$) antagonists (ondansetron, granisetron, and dolasetron). Dexamethasone is a corticosteroid that works through antiinflammatory and some unknown properties.

   As prophylaxis for PONV, dexamethasone combined with an antiserotonin antagonist proves to be one of the most efficient regimens, if used at induction of general anesthesia. For treatment of PONV, combinations of antiemetics seem to be more efficient (through their additive effect) than single medications. In our experience, however, when everything else fails, one of the best rescue medications is haloperidol 1.0 mg to 1.5 mg used intramuscularly (an IV dose is too short acting), which provides >15 hours of intense antiemetic effect without excessive sedation or any hallucinations.

7. **e.** All of the statements are true. A preponderance of outcome data suggest that regional anesthesia improves patient morbidity and mortality, as compared with general anesthesia. Regional anesthesia can be divided into two categories: neuraxial anesthesia (e.g., spinal, epidural, combined spinal/epidural) and peripheral nerve block anesthesia (e.g., pudendal, penile, paravertebral). See text section on "Regional Anesthesia."
8. **e.** All of the statements are true.
9. **c.** A lesser Trendelenburg (16 degrees) position will preserve the surgical advantages while minimizing the risks of the Trendelenburg position (increased intra-abdominal, intrathoracic, intracranial, and intraocular pressure). The rest of the statements are true.
10. **a.** Although the mechanism of post-CO_2 insufflation shoulder pain is unclear, it is theorized that it occurs due to CO_2 entrapment under the diaphragm, which produces phrenic nerve irritation and referred pain to C4. Many surgical maneuvers have been described as potential treatment, including low pressure pneumoperitoneum and the use of AWL, which is no longer recommended. Various postoperative medications (e.g., NSAIDS, narcotics, pregabalin) were found to have limited usefulness.

    The most successful methods were abdominal filling with saline solution at the end of surgery or the use of the Valsalva maneuver in Trendelenburg position at the end of surgery (eliminates intraabdominal CO_2), which yields very good results. At our institution, we routinely use the Valsalva maneuver at the end of all laparoscopic/robotic surgeries with excellent results.

7 Infectious Complications of Urologic Surgery

MARC A. BJURLIN

CHAPTER OUTLINE

Antimicrobial Prophylaxis in Urologic Surgery
Endourologic Procedures
Open, Laparoscopic, and Robotic Urologic Surgery
Special Consideration: Heart Valves, Prostheses
Management of Surgical Infections
Surgical Site Infections
Intraabdominal Infections
Postoperative Urinary Tract Infections
Sepsis: Early Recognition and Treatment
Antibiotic Resistance
***Clostridium difficile* Colitis**
Special Considerations
Prostate Biopsy
Inflatable Penile Prostheses
Conclusion
Chapter 7 Questions and Answers

KEY POINTS

1. The duration of antimicrobial prophylaxis should extend throughout the period when bacterial invasion is facilitated and/or likely to establish an infection.
2. Prophylaxis should begin within 60 minutes of the surgical incision (120 minutes for intravenous fluoroquinolines and vancomycin) and generally should be discontinued within 24 hours.
3. American Heart Association no longer recommends antimicrobial prophylaxis for genitourinary surgery solely to prevent infectious endocarditis.
4. Surgical site infections can be reduced by appropriate antibiotics prophylaxis, surgeon hand antiseptic, patient skin preparation, and hair removal.
5. The mainstay management of intraabdominal infections remains initial fluid resuscitation, antibiotic therapy, and drainage of infectious fluid collections .
6. UTIs are the most common type of nosocomial infection, and are frequently postoperative in nature, most commonly the result of manipulating the urinary tract or having an indwelling catheter.
7. Increasing antibiotic resistance and a lack of new antibiotics in the near future call for a variety of coordinated strategies in an effort of antibiotic stewardship.
8. Early recognition and management of sepsis optimizes outcome.
9. Aims to reduce the overuse of antimicrobial agents in conjunction with urologic surgery may reduce antibiotic resistance and limit C. difficile colitis.
10. The appropriate use of antimicrobial prophylaxis in an individual patient requires not only consideration of guidelines but also a comprehensive evaluation of the patient's specific circumstances.

Infectious complications in urologic surgery range from asymptomatic urinary tract infection (UTI) to sepsis and comprise some of the most feared and life-threatening situations in current urologic practice. In this chapter we focus on appropriate antibiotics for surgical and procedural prophylaxis and supporting guidelines, surgical site infections and postoperative UTIs, early recognition and treatment of sepsis, and management of intraabdominal infections. Special consideration is also given to the emerging role of antibiotic resistance, *Clostridium difficile* colitis, and antibiotic stewardship. Emphasis is placed on identification of early postoperative events that could lead to infectious complications in order to achieve a prompt diagnosis and reduce morbidity and mortality.

Antimicrobial Prophylaxis in Urologic Surgery

Infectious complications, including surgical site infections and UTIs, are major sources of postoperative morbidity. Surgical site infections complicate up to 5% of

clean extra-abdominal operations and up to 20% of intraabdominal procedures. UTIs are the most common type of nosocomial infection and are frequently postoperative in nature. Surgical site infections almost double the direct costs of hospitalization, and patients with surgical site infections are more likely to be readmitted, require a stay in the intensive care unit, and suffer mortality. Antimicrobial prophylaxis is an important preventative measure and is a modifiable component of a program to reduce postoperative infections. The American Urologic Association (AUA) published a best practice policy statement on urologic surgery antimicrobial prophylaxis in 2008, which has been updated as recently as 2014.[1] The AUA highlights five principles of surgical antimicrobial prophylaxis:

1. Surgical antimicrobial prophylaxis is the periprocedural systemic administration of an antimicrobial agent intended to reduce the risk of postprocedural local and systemic infections.
2. The potential benefit of surgical antimicrobial prophylaxis is determined by three considerations: patient-related factors (ability of the host to respond to bacterial invasion), procedural factors (likelihood of bacterial invasion at the operative site), and the potential morbidity of infection.
3. Surgical antimicrobial prophylaxis is recommended only when the potential benefit exceeds the risks and anticipated costs.
4. The antimicrobial agent used for prophylaxis should be effective against the disease-relevant bacterial flora characteristic of the operative site. Cost, convenience, and safety of the agent also should be considered.
5. The duration of surgical antimicrobial prophylaxis should extend throughout the period in which bacterial invasion is facilitated and/or is likely to establish an infection.

A surgical wound classification has been developed to help clinicians identify and describe the degree of bacterial contamination of surgical wounds at the time of surgery (Table 7.1). Because of its predictive value, wound classification plays a valuable role in driving quality-improvement initiatives that incorporate risk-adjusted outcomes. All procedures entering the urinary tract are considered "clean contaminated." The likelihood of bacterial invasion is increased if bacteriuria is present or wound preparation and sterile surgical technique are not applied.

ENDOUROLOGIC PROCEDURES

Antimicrobial prophylaxis for urologic surgery is stratified by lower tract and upper tract instrumentation, along with patient risk factors (Table 7.2). Simple cystoscopy has traditionally been a procedure that does not warrant routine antimicrobial prophylactics. Although the literature is not conclusive, it appears there is limited evidence for the use of antibiotics for ambulatory patients who undergo cystoscopy without risk factors such as advanced age, smoking, anatomic anomalies, steroid use, decreased immune function, and urethral catheters.[2–5] In a study of 3108 patient cystoscopies without antibiotic prophylaxis, 673 (22%) had asymptomatic bacteriuria and 2435 (78%) had sterile urine. A febrile UTI developed within 30 days of cystoscopy in 59 patients (1.9%). Therapy before outpatient flexible cystoscopy does not appear necessary in patients who have no clinical signs or symptoms of acute UTI, including bacteriuria.[6] Guideline recommendations for cystoscopy with manipulation including transurethral resection of bladder tumor and prostate, include antimicrobial prophylaxis. Although prophylactic antibiotics have been shown to decrease the incidence of post-TURP bacteriuria, high fever, bacteremia, and additional antibiotic treatment,[7] the prescribing patterns of urologists vary significantly prior to TURP with low compliance to guidelines.[8] Berry and Barratt conducted a meta-analysis of 32 randomized controlled trials evaluating antimicrobial prophylaxis in TURP patients, including 4260 patients.[9] The authors found antibiotic prophylaxis significantly decreases the incidence of bacteriuria and clinical septicemia in men with preoperative sterile urine undergoing TURP. Taken together, these studies highlight (1) the need for preoperative urine culture when feasible, (2) that a single dose of perioperative antibiotics appears sufficient to decrease infectious risk, and (3) that maintaining closed urinary drainage and minimizing drainage may reduce postoperative infection rates. Even

Table 7.1 Surgical Wound Classification

Surgical Wound Classification	
Clean	■ Uninfected operative wound where no inflammation is encountered and respiratory, GI, genital, and urinary tracts are not entered ■ Wounds are primarily closed, and a drain (if needed) is connected to a closed system. ■ Risk of infection: 2% or lower
Clean contaminated	■ Operative wound that enters the respiratory, GI, genital, or urinary tract under controlled conditions without unusual contamination when no infection or major break in technique has occurred ■ Risk of infection: 2–8%
Contaminated	■ Open, fresh, accidental wound from surgery with a major break in sterile technique or gross spillage from GI tract; incision in which acute, nonpurulent inflammation is encountered (including necrotic tissue without evidence of purulent drainage, such as dry gangrene) ■ Risk of infection: 5–15%
Dirty-infected	■ Old traumatic wounds with retained devitalized tissue; procedures with existing clinical infection (purulence already present in wound) or perforated viscera ■ Risk of infection: greater than 30%

Table 7.2 Recommended Antimicrobial Prophylaxis for Urologic Procedures

Procedure	Organisms	Prophylaxis Indicated	Antimicrobial(s) of Choice	Alternative Antimicrobial(s)	Duration of Therapy*
Lower Tract Instrumentation					
Removal of external urinary catheter	GU tract†	If risk factors‡,§	■ Fluoroquinolone¶ ■ TMP-SMX¶	■ Aminoglycoside (aztreonam¥) ± ampicillin¶ ■ 1st-/2nd-gen. cephalosporin¶ ■ Amoxicillin/clavulanate¶	=24 hours¶
Cystography, urodynamic study, or simple cystourethroscopy	GU tract	If risk factors§	■ Fluoroquinolone ■ TMP-SMX	■ Aminoglycoside (aztreonam¥) ± ampicillin ■ 1st-/2nd-gen. cephalosporin ■ Amoxicillin/clavulanate	=24 hours
Cystourethroscopy with manipulation|	GU tract	All	■ Fluoroquinolone ■ TMP-SMX	■ Aminoglycoside (aztreonam¥) ± ampicillin ■ 1st-/2nd-gen. cephalosporin ■ Amoxicillin/clavulanate	=24 hours
Prostate brachytherapy or cryotherapy	Skin	Uncertain	■ 1st-gen. cephalosporin	■ Clindamycin**	=24 hours
Transrectal prostate biopsy	Intestine††	All	■ Fluoroquinolone ■ 1st-/2nd-/3rd-gen. cephalosporin	■ TMP-SMX ■ Aminoglycoside (aztreonam¥)	=24 hours
Upper Tract Instrumentation					
Shock-wave lithotripsy	GU tract	If risk factors	■ Fluoroquinolone ■ TMP-SMX	■ Aminoglycoside (aztreonam¥) ± ampicillin ■ 1st-/2nd-gen. cephalosporin ■ Amoxicillin/clavulanate	=24 hours
Percutaneous renal surgery	GU tract and skin‡‡	All	■ 1st-/2nd-gen. cephalosporin ■ Aminoglycoside (aztreonam¥) + metronidazole or clindamycin	■ Ampicillin/sulbactam ■ Fluoroquinolone	=24 hours
Ureteroscopy	GU tract	All	■ Fluoroquinolone ■ TMP-SMX	■ Aminoglycoside (aztreonam¥) ± ampicillin ■ 1st-/2nd-gen. cephalosporin ■ Amoxicillin/clavulanate	=24 hours
Open or Laparoscopic Surgery					
Vaginal surgery (includes urethral sling procedures)	GU tract, skin and Grp B *Strep.*	All	■ 1st-/2nd-gen. cephalosporin ■ Aminoglycoside (aztreonam¥) + metronidazole or clindamycin	■ Ampicillin/sulbactam ■ Fluoroquinolone	=24 hours
Without entering urinary tract	Skin	If risk factors	■ 1st-gen. cephalosporin	■ Clindamycin	Single dose
Involving entry into urinary tract	GU tract and skin	All	■ 1st-/2nd-gen. cephalosporin ■ Aminoglycoside (aztreonam¥) + metronidazole or clindamycin	■ Ampicillin/sulbactam ■ Fluoroquinolone	=24 hours
Involving intestine§§	GU tract, skin and intestine	All	■ 2nd/3rd gen. cephalosporin ■ Aminoglycoside (aztreonam¥) + metronidazole or clindamycin	■ Ampicillin/sulbactam ■ Ticarcillin/clavulanate ■ Piperacillin/tazobactam ■ Fluoroquinolone	=24 hours
Involving implanted prosthesis	GU tract and skin	All	■ Aminoglycoside (aztreonam¥) + 1st/2nd gen. cephalosporin or vancomycin	■ Ampicillin/sulbactam ■ Ticarcillin/clavulanate ■ Piperacillin/tazobactam	=24 hours

*Additional antimicrobial therapy may be recommended at the time of removal of an externalized urinary catheter.
†GU tract: Common urinary tract organisms are *E. coli, Proteus sp., Klebsiella sp., Enterococcus.*
‡See Table 1 "Patient-related factors affecting host response to surgical infections."
§If urine culture shows no growth prior to the procedure, antimicrobial prophylaxis is not necessary.
¶Or full course of culture-directed antimicrobials for documented infection (which is treatment, not prophylaxis).
¥Aztreonam can be substituted for aminoglycosides in patients with renal insufficiency.
|Includes transurethral resection of bladder tumor and prostate, and any biopsy, resection, fulguration, foreign body removal, urethral dilation or urethrotomy, or ureteral instrumentation including catheterization or stent placement/removal.
**Clindamycin, or aminoglycoside + metronidazole or clindamycin, are general alternatives to penicillins and cephalosporins in patients with penicillin allergy, even when not specifically listed.
††Intestine: Common intestinal organisms are *E. coli, Klebsiella sp., Enterobacter, Serratia sp, Proteus sp., Enterococcus*, and anaerobes.
‡‡Skin: Common skin organisms are *S. aureus*, coagulase negative *Staph. sp.*, Group A *Strep. sp.*
§§For surgery involving the colon, bowel preparation with oral neomycin plus either erythromycin base or metronidazole can be added to or substituted for systemic agents.
Key: gen, generation; GU, genitourinary; TMP-SMX, trimethoprim-sulfamethoxazole.

though guidelines recommend antimicrobial prophylaxis for TURBT, data remain controversial. Studies have shown antibiotics for TURBT in patients with no risk factors for infectious complications may not be necessary where use of antibiotics might be deferred until postoperative infections develop.[10]

Fluoroquinolone and TMP-SMX remain the mainstay prophylactic antibiotic of choice for the majority of endourologic procedures. Ureteroscopy, which is the mainstay for ureteral and renal calculi and a diagnostic procedure for upper tract urothelial tumors, merits antibiotic prophylaxis. For ureteroscopic stone treatment, the postoperative UTI rate is low (<2.5%).[9] Antibiotic prophylaxis significantly reduces the incidence of pyuria and tends to diminish the risk of bacteriuria and UTI.[11] However, recent studies have demonstrated that in patients with a negative baseline urine culture undergoing ureteroscopy for ureteral or renal stones, rates of postoperative UTI and fever were not reduced by preoperative antibiotic prophylaxis, highlighting the need for antibiotic stewardship.[9] A continuous antibiotic low-dose treatment during the entire JJ stent indwelling time does not reduce the quantity or severity of UTIs compared with a peri-interventional antibiotic prophylaxis only.[12] The use of oral peri-stent removal antibiotic prophylaxis is sufficient to prevent symptomatic UTIs in patients who have undergone uncomplicated ureteroscopy for urolithiasis.[13] The judicious use of antibiotics in uncomplicated cases may help lower the incidence of resistant organisms and other complications related to the widespread use of antibiotics. In patients with pyelonephritis secondary to obstructive stones, antimicrobial resistance makes the selection of empiric antibiotic treatment challenging because of discordance between voided urine cultures and those captured at the time of decompression.[14] It is imperative to obtain both voided urine and urine from the kidney to ensure adequate antibiotic coverage. After uncomplicated ureteroscopy for urolithaisis, the use of oral peri-stent removal antibiotic prophylaxis has been found to be sufficient to prevent symptomatic UTIs.[13]

Percutaneous access to the renal collecting system may put the patient at increased risk for bacteremia and sepsis due to traversing the renal parenchyma and merit antimicrobial prophylaxis with a first- or second-generation cephalosporin, or aminoglycoside with metronidazole or clindamycin. Reports have demonstrated a significant risk of postoperative infectious complications including sepsis despite prophylactic antibiotics during PCNL; however, the optimal duration of perioperative antibiotic administration in stone patients remains an area of debate. Antibiotic prophylaxis of patients undergoing percutaneous nephrolithotomy with a negative baseline urine culture is associated with a significant reduction in the rate of postoperative fever (2.5% vs 7.4%, p = 0.040) and other complications.[15] Deshmukh et al. observed comparable rates of immediate fevers after PCNL with no difference in postoperative infections between patients undergoing 24 hours of perioperative antibiotics (consistent with AUA guidelines) versus −7 days of antibiotics after surgery.[16] However, other studies have shown the benefits of prolonged antibiotic prophylaxis. Mariappan et al. prospectively evaluated patients with a stone burden of at least 2 cm or pelvicaliceal dilation and a negative preoperative urine culture who received a 7-day course of ciprofloxacin or standard antibiotics before PCNL.[17] They noted a threefold lower rate of systemic inflammatory response syndrome in patients in the extended antibiotic arm. Multidrug resistant preoperative urine culture has been shown to be significantly predictive of an infectious complication in patients undergoing PCNL compared to the presence of a positive urine culture alone.[18] As such, efforts have focused on curtailing the indiscriminant use of antibiotics and promoting use only when indications for administration are clear. A common finding of these studies remains that no antibiotic prophylaxis regimen will completely eliminate the risk of infection after endoscopic stone surgery.

The incidence of infectious complications after extracorporeal shock wave lithotripsy (ESWL) in patients without risk factors is low.[19] A recent meta-analysis of nine randomized controlled trials assessing the efficiency of antimicrobial prophylaxis for shock wave lithotripsy demonstrated no statistically significant benefit of therapy in terms of reducing postoperative bacteriuria, clinical UTIs, or fever.[20] In a prospective study evaluating the use of targeted antibiotic prophylaxis in preventing UTIs in patients undergoing shock wave lithotripsy, Honey et al. found of the 389 patients included in the determination of the primary outcome, UTI developed in only one (0.3%), urosepsis did not develop in any patients, and asymptomatic bacteriuria developed in 11 (2.8%), suggesting universal use of antibiotic in ESWL may not be needed.[21]

AUA guidelines do not recommend routine use of antimicrobial prophylaxis during ESWL; however, it may be justified for those with increased risk for infection.[19]

OPEN, LAPAROSCOPIC, AND ROBOTIC UROLOGIC SURGERY

Studies indicate that antimicrobial prophylaxis is most effective when provided prior to the initial surgical incision, which is supported by the Surgical Care Improvement Project (SCIP) sponsored by The Joint Commission. The SCIP measure dictates that prophylactic antibiotic must be received within 1 hour prior to incision (or within 2 hours before incision if vancomycin is required for prophylaxis). This allows the establishment of bactericidal tissue and serum levels at the time of skin incision to reduce the risk of infection. A landmark study in 1992 consisting of 2847 surgery patients found that the lowest incidence of postoperative infection was associated with antibiotic administration during the 1 hour prior to surgery.[22] The risk of infection increased progressively with greater time intervals between administration and surgical incision. Results of this study showed lowest infection rates (less than 1%) for patients undergoing surgery when an antimicrobial dose was administered within 1 hour before the incision. Patients who received the antibiotics too soon (more than 2 hours prior to incision) had an infection rate of 3.8%. Likewise, patients who received the antibiotics 3 hours after incision had an infection rate of 3.3%.

Antimicrobial prophylaxis can be stratified based on entry into the urinary tract or intestine. Surgery without entry into the urinary tract includes a variety of invasive and superficial urologic procedures. Results in a cohort of 83 patients undergoing transabdominal radical

nephrectomy randomized to a single dose of intravenous cephalosporin versus no perioperative prophylaxis revealed a significantly lower overall infection rate in the treatment group (8% vs 27%).[23] In a prospective but nonrandomized comparison of 424 hand-assisted laparoscopic nephrectomies with and without antimicrobial prophylaxis (cephalosporin), wound infections occurred significantly more often in patients without prophylaxis (13% vs 5.4%).[24]

In a comprehensive review of the literature regarding surgery with entry into the urinary tract, the authors concluded that the expected rate of febrile UTI is 5–10% without prophylaxis and that antimicrobial prophylaxis would significantly reduce the rate of febrile UTI, to 2–3%.[25] In a randomized controlled trial of 91 men undergoing open prostatectomy, intravenous cefotaxime (compared to no prophylaxis) significantly reduced the incidence of postoperative infection from 46% to 5%.[26]

Although randomized controlled trials (RCTs) involving urologic surgery involving bowel (primarily urinary diversion, with or without cystectomy) have not been reported, supportive literature from neighboring surgical specialties confirm the benefit of antimicrobial prophylaxis in the setting of surgery involving intestinal components. Tailoring preoperative antimicrobial prophylaxis during radical cystectomy to broader, culture-directed antimicrobial prophylaxis, based on institutional data to include antifungal coverage, has been shown to decrease postoperative infections.[27] Additionally, longer durations of antibiotic coverage beyond 24 hours appear not to improve rates of septic complications during cystectomy.[28]

SPECIAL CONSIDERATION: HEART VALVES, PROSTHESES

Patients with preexisting implanted surgical hardware, such as artificial joints and prosthetic heart valves, are of particular interest because this foreign material may become hematogenously seeded from bacteremia induced during surgical manipulation. These infections are frequently difficult to treat and often require surgical removal of the infected material. Antibiotic prophylaxis for the prevention of infective endocarditis is not recommended in patients undergoing urologic procedures, even in patients with the highest risk of heart conditions (see Chapter 3).

Antimicrobial prophylaxis is not indicated for urologic patients on the basis of orthopedic pins, plates, and screws, nor is it routinely indicated for most urologic patients with total joint replacements on that basis alone.[1] However, antimicrobial prophylaxis intended to reduce the risk of hematogenous total joint infection is recommended in patients who meet both sets of criteria shown in Table 7.3. The recommended antimicrobial regimen in these patients include a single systemic level dose of a quinolone (e.g., ciprofloxacin, 500 mg; levofloxacin, 500 mg; ofloxacin, 400 mg) orally 1–2 hours preoperatively or ampicillin 2 g IV (or vancomycin 1 g IV over 1–2 hours in patients allergic to ampicillin) plus gentamicin 1.5 mg/kg IV 30–60 minutes preoperatively. Alternative culture-specific antibiotics may also be considered in some cases.

Management of Surgical Infections

SURGICAL SITE INFECTIONS

Surgical site infections (SSIs) are associated with substantial morbidity and mortality, prolonged hospital stay, and increased cost. The US Centers for Disease Control and Prevention (CDC) has developed criteria that define an SSI as an infection related to an operative procedure that occurs at or near the surgical incision within 30 days of the procedure or 90 days if prosthetic material is implanted at surgery. SSIs are the most common nosocomial infection, accounting for 38% of nosocomial infections. However, the overall risk of SSI is low; it is estimated that SSIs develop in 2–5% of the more than 30 million patients undergoing surgical procedures each year (i.e., 1 in 24 patients who undergo inpatient surgery in the United States has a postoperative SSI).[29] SSIs complicate up to 5% of clean extraabdominal operations and up to 20% of intraabdominal procedures.[30] SSIs almost double the direct costs of hospitalization, and patients with SSIs are more likely to be readmitted, require

Table 7.3 Criteria for Antibiotic Prophylaxis in Total Joint Replacements

Increased Risk of Hematogenous Total Joint Infection	Increased Risk of Bacteremia Associated With Urologic Procedures
Patients during the first 2 years after prosthetic joint replacement Immunocompromised patients with prosthetic joint replacements ■ Inflammatory arthropathies (e.g., rheumatoid arthritis, systemic lupus erythematosus) ■ Drug-induced immunosuppression ■ Radiation-induced immunosuppression Patients with prosthetic joint replacements and comorbidities ■ Previous prosthetic joint infections ■ Malnourishment ■ Hemophilia ■ HIV infection ■ Diabetes ■ Malignancy	Any stone manipulation (includes shock-wave lithotripsy) Any procedure with transmural incision into urinary tract (does not include simple ligation with excision or percutaneous drainage procedure) Any endoscopic procedures of upper tract (ureter and kidney) Any procedure that includes bowel segments Transrectal prostate biopsy Any procedure with entry into the urinary tract (except for urethral catheterization) in individuals with higher risk of bacterial colonization: ■ Indwelling catheter or intermittent catheterization ■ Indwelling ureteral stent ■ Urinary retention ■ History of recent/recurrent urinary tract infection or prostatitis ■ Urinary diversion

(Reproduced with permission from Best Practice Policy Statement on Urologic Surgery Antimicrobial Prophylaxis. https://www.auanet.org/education/guidelines/antimicrobial-prophylaxis.cfm#3)

stay in the intensive care unit, and suffer mortality.[31] Using the Healthcare Cost and Utilization Project National Inpatient Sample, de Lissovoy et al. evaluted 723,490 surgical hospitalizations, of which 6891 cases of SSI were identified (1%). On average, SSI extended length of stay by 9.7 days while increasing cost by $20,842 per admission. From the national perspective, these cases of SSI were associated with an additional 406,730 hospital-days and hospital costs exceeding $900 million. An additional 91,613 readmissions for treatment of SSI accounted for a further 521,933 days of care at a cost of nearly $700 million.[32]

Clinical criteria for defining SSI include one or more of the following:[33] (1) a purulent exudate draining from a surgical site, (2) a positive fluid culture obtained from a surgical site that was closed primarily, (3) a surgical site that is reopened in the setting of at least one clinical sign of infection (pain, swelling, erythema, warmth) and is culture positive or not cultured, and (4) the surgeon's diagnosis of infection. SSIs are classified as incisional or organ/space. Incisional SSIs are further divided into superficial, those involving only the skin or subcutaneous tissue, or deep, those involving deep soft tissues of an incision. Organ/space SSIs account for one-third of all SSIs, but are associated with more than 90% of deaths related to SSIs.

In addition to antibiotic prophylaxis, several other measures may decrease rates of SSIs including surgeon hand antiseptic, patient skin preparation, and hair removal. In a Cochrane database review of preoperative skin antiseptics for preventing surgical wound infections after clean surgery, the authors found evidence that preoperative skin preparation with 0.5% chlorhexidine in methylated spirits was associated with lower rates of SSIs following clean surgery than alcohol-based povidone iodine paint.[34] In a cohort of patients submitted to open prostatectomy, the type of antiseptic did not affect SSI risk (0.5% povidone-iodine or chlorhexidine in an alcohol base).[35]

The alcohol-based hand rub has been shown to be more efficacious for surgical antisepsis when compared to conventional surgical scrub.[36] Whether this translates into a decrease in SSI is not clear. In a literature review of surgical hand antisepsis to reduce surgical site infection, alcohol rubs used in preparation for surgery by the scrub team are as effective as aqueous scrubbing in preventing SSIs, but the analysis data were limited by study methods and quality.[37] Avagard Hand Antiseptic (3M, St. Paul, MN) has been shown to provide comparable hand antisepsis to the traditional surgical scrub in a variety of pediatric urologic procedures. Avagard Hand Antiseptic was noted to be superior to the surgical hand scrub in cost-effectiveness and time efficiency.[38]

Preoperative hair removal has been used to prevent surgical site infections; however, a meta-analysis of 19 randomized controlled trials confirmed the absence of any benefit of depilation to prevent surgical site infection, as well as the higher risk of surgical site infection when shaving is used for depilation.[39]

The proportion of patients developing SSIs depends on the type of surgery. Although SSI rates are low in urologic surgery, minimally invasive surgery compared to open surgery is significantly associated with reduced rates of SSIs, including prostatectomy (1.0% vs 2.4%)[40,41] and partial nephrectomy (0.54% vs 1.3%).[42] The SSI rate in minimally invasive adrenal and renal surgery is low (1.6%), and reports have suggested that antimicrobial prophylaxis may be avoided in this clean category minimally invasive surgery. On-demand use of antibiotics in the renal and adrenal surgery seem to be sufficient for perioperative infectious management.[43] In 556 patients undergoing urologic laparoscopic procedures, 14 surgical site infections (2.5%) were identified at mean postoperative day 21.5.[44] Of the 14 surgical site infections, 10 (71.4%) were located at a specimen extraction site. Infection is associated with prolonged operative time and increasing body mass index.

In a study of 200 patients who underwent either inguinal or scrotal surgery, both of which are classified as clean surgery, the overall SSI infection rate was 3.5%. However, the frequencies of SSI were 6.5% in the patients with urologic inguinal surgery and 1.6% in those with scrotal surgery even though all patients received a first- or second-generation cephalosporin as antimicrobial prophylaxis. The frequency of SSI in the patients with urologic inguinal surgery was not negligible even though it is considered a clean operation, and this highlights the need for SSI prevention.[45]

Implanted urologic devices are at increased risk for infection. Haraway et al. evaluated 136 patients who underwent sacral neuromodulation implantation and found 5.9% experienced infections that required device explantation. Preoperative antibiotic selection was a significant factor in preventing subsequent infection and explantation where cefazolin was less effective in preventing infection compared with the other antibiotic regimens.[46] Implanted seeds do not appear to have the same risk of infection. In 826 patients with localized prostate cancer who underwent a transperineal (125)I brachytherapy, all of who received antimicrobial prophylaxis, 0.73% of patients had a perioperative infection.[47] Bacteriuria and preoperative hair removal were risk factors of perioperative infection with statistical significance ($p = 0.007$ and $p = 0.004$, respectively), highlighting additional measures to prevent perioperative infectious complications.

Historically, preoperative mechanical bowel preparation has been considered the standard of care for patients undergoing radical cystectomy with urinary diversion. Recent data have shown the use of mechanical bowel preparation for patients undergoing radical cystectomy with an ileal conduit or orthotopic neobladder does not seem to impact the rates of perioperative infections or wound and bowel complications.[48,49]

INTRAABDOMINAL INFECTIONS

Intraabdominal infections are the second most common cause of infectious mortality in intensive care units. Complicated intraabdominal infection, which extends into the peritoneal space, is associated with abscess formation and peritonitis. Uncomplicated infection, which involves intramural inflammation of the gastrointestinal tract, may progress to complicated infection if left untreated. Treatment of intraabdominal infections has evolved in recent years because of advances in supportive care, diagnostic imaging, minimally invasive intervention, and antimicrobial therapy. Based on these new advances, evidence-based guidelines for managing patients with intraabdominal infection were prepared by an Expert Panel of the Surgical

Infection Society and the Infectious Diseases Society of America.[50]

Fluid resuscitation is a key initial step in managing intraabdominal postoperative infections. Volume depletion is common in febrile patients and is worsened by poor fluid intake because of nausea and/or vomiting and in the presence of ileus induced by intraabdominal inflammation. Patients should undergo rapid restoration of intravascular volume and additional measures as needed to promote physiologic stability. For patients with septic shock, such resuscitation should begin immediately when hypotension is identified. For patients without evidence of volume depletion, intravenous fluid therapy should begin when the diagnosis of intraabdominal infection is first suspected. Antibiotic therapy involves the administration of parenteral empirical antibiotics and should be initiated once a patient receives a diagnosis of an intraabdominal infection or once such an infection is considered likely. For patients with septic shock, antibiotics should be administered as soon as possible. They should be initiated before abscess drainage and concluded when all systemic signs of sepsis have resolved. Because abscess fluid usually contains a mixture of aerobic and anaerobic organisms, initial empiric therapy must be directed against both types of microbes. This may be accomplished with antibiotic combination therapy or with broad-spectrum, single-agent therapy. Specific therapy is then guided by the results of cultures retrieved from the abscess. In patients who are immunosuppressed, candidal species may play an important pathogenic role, and treatment with antifungals may be indicated. Fluconazole is an appropriate choice for treatment if *Candida albicans* is isolated. For fluconazole-resistant *Candida* species, therapy with an echinocandin is appropriate. Because of toxicity, amphotericin B is not recommended as initial therapy.

Drainage of infectious fluid collections is mandatory and is the first line of defense against progressive sepsis. Percutaneous computed tomography (CT)-guided catheter drainage has become the standard treatment of most intraabdominal abscesses and is preferable to surgical drainage. Patients with diffuse peritonitis should undergo an emergency surgical procedure as soon as is possible, even if ongoing measures to restore physiologic stability need to be continued during the procedure. Percutaneous drainage avoids anesthesia and possibly difficult laparotomy, prevents the possibility of wound complications from open surgery, and may reduce the length of hospitalization. It also obviates the possibility of contaminating other areas within the peritoneal cavity.

Cultures should be performed from one specimen, provided it is of sufficient volume (at least 1 mL of fluid or tissue, preferably more) and is transported to the laboratory in an appropriate transport system. For optimal recovery of aerobic bacteria, 1–10 mL of fluid should be inoculated directly into an aerobic blood culture bottle. In addition, 0.5 mL of fluid should be sent to the laboratory for Gram stain and, if indicated, fungal cultures. If anaerobic cultures are requested, at least 0.5 mL of fluid or 0.5 g of tissue should be transported in an anaerobic transport tube. Alternatively, for recovery of anaerobic bacteria, 1–10 mL of fluid can be inoculated directly into an anaerobic blood culture bottle. Susceptibility testing for *Pseudomonas, Proteus, Acinetobacter, Staphylococcus aureus*, and predominant *Enterobacteriaceae*, as determined by moderate-to-heavy growth, should be performed, because these species are more likely than others to yield resistant organisms.

After drainage, clinical improvement should occur within 48–72 hours. Lack of improvement within this time frame mandates repeat CT scanning to check for additional abscesses. Surgical drainage becomes mandatory if residual fluid cannot be evacuated with catheter irrigation, manipulation, or additional drain placement. Contraindications to surgical correction of abdominal abscesses are based on the patient's comorbidities and on the individual's ability to tolerate surgery. The surgical approach may be either laparoscopic or open. Transperitoneal exploration is indicated for multiple abscesses not amenable to CT-guided drainage, such as interloop collections or an enteric fistula feeding the abscess. In the latter situation, draining the abscesses with an enteric communication may be possible for several days before a laparotomy is performed to control the fistula.

Criteria for removal of percutaneous catheters include resolution of sepsis signs, minimal drainage from the catheter, and resolution of the abscess cavity as demonstrated by ultrasonography or CT. Antimicrobial therapy of established infection should be limited to 4–7 days, unless it is difficult to achieve adequate source control. Longer durations of therapy have not been associated with improved outcome. In patients who have persistent or recurrent clinical evidence of intraabdominal infection after 4–7 days of therapy, appropriate diagnostic investigation should be undertaken. This should include CT or ultrasound imaging. Antimicrobial therapy effective against the organisms initially identified should be continued. Persistent drainage usually reflects the presence of an enteric fistula, and a CT scan with contrast should be performed. Frequently, this fistula can be documented by sinography.

Complications of percutaneous drainage include bleeding or inadvertent puncture of the gastrointestinal tract.

POSTOPERATIVE URINARY TRACT INFECTIONS

UTIs are the most common type of nosocomial infection and are frequently postoperative in nature, most commonly the result of manipulating the urinary tract or having an indwelling catheter.[51]

Postoperative UTIs are observed more commonly after major urologic surgery compared with endoscopic procedures, especially after prostate surgery. There are two critical times for the development of infectious complications following prostatic surgery: the perioperative period and the time of catheter removal where 25% of men will have a positive urine culture.[52] In a study of 729 consecutive radical prostatectomies, UTI was observed less frequently among patients receiving short-term antibiotic therapy (3.1% vs. 7.3%) after catheter removal compared with those not receiving antibiotics ($p = 0.019$).[53] One would need to prescribe antibiotic therapy to 24 patients to prevent one case of UTI.[53]

A positive urine culture is a very common finding in patients with an orthotopic bladder, occurring in >50% of patients.[54] Symptomatic UTI, however, occurs at lower rates but remains a common complication after neobladder

reconstruction, usually occurring within the first 3 months of surgery.[55]

SEPSIS: EARLY RECOGNITION AND TREATMENT

Development of sepsis after surgery imposes a significant clinical resource and health-care burden. Factors associated with the development of postoperative sepsis are frequently procedure dependent and are more common with bacteriuria, but also patient comorbidities such as diabetes and hypertension, as well as smoking history along with race, age, hospital size, and hospital location, impact sepsis rates. The American College of Chest Physicians and Society of Critical Care Medicine originally classified the continuum of an inflammatory response to microorganisms as systemic inflammatory response syndrome, sepsis, severe sepsis, and septic shock. These definitions have recently been modified in a consensus by the European Society of Intensive Care Medicine and the Society of Critical Care Medicine and no longer employ the term *systemic inflammatory response syndrome*.[56] The change in definitions was prompted by the increased recognition of the pathobiology and need to clinically define sepsis and septic shock. In addition, a new score called quickSOFA (Sequential Organ Failure Assessment score: qSOFA) was devised and validated for the clinical criteria of sepsis.[57] Early recognition and management of sepsis optimizes outcome. Therefore patients in whom this problem is suspected after genitourinary surgery should be prioritized and receive timely care. To diagnose sepsis and septic shock as early as possible, it is necessary to have clear definitions of infection, organ dysfunction, and global tissue hypoxia and to recognize the clinical and laboratory findings that are indicative of these conditions (Table 7.4).

Fever is the most common manifestation of sepsis. The absence of fever and sepsis-induced hypothermia is more likely in patients at the extremes of age, debilitated patients, patients with chronic alcohol abuse, and patients with uremia.[58] Hypotension is the presenting abnormality in approximately 40% of patients with sepsis. Withdrawal and agitation can be subtle and may be the sole presentations of sepsis in older persons. Immunocompromised patients and those with neutropenia often lack an obvious source of infection.

Appropriate therapy is a continuum of infection management ranging from drainage, such as maintaining an indwelling catheter or opening the nephrostomy tube in cases of percutaneous renal surgery and broad-spectrum antibiotics, to aggressive fluid resuscitation and invasive monitoring with medical management in the intensive care setting until the causative agent is found and eradicated. Published consensus guidelines have been in place to direct the management of septic patients.[59] The guidelines highlight the need for continuous monitoring of vital signs, pulse oximetry, urine output, and initial laboratory testing to assess the severity of global tissue hypoxia and organ dysfunction and should be instituted as soon as possible in patients in whom severe sepsis/septic shock is suspected to facilitate the earliest recognition of this condition.

Early management of sepsis requires respiratory stabilization. Supplemental oxygen should be given to all patients. Mechanical ventilation is recommended when supplemental oxygen fails to improve oxygenation, when respiratory failure is imminent, or when the airway cannot be protected. Perfusion is assessed after respiratory stabilization. Hypotension signifies inadequate tissue perfusion. Clinical signs of hypoperfusion include cold or clammy skin, altered mental status, oliguria or anuria, and lactic acidosis.

After initial respiratory stabilization, treatment consists of fluid resuscitation, vasopressor therapy, infection identification and control, prompt antibiotic administration, and the removal or drainage of the infection source. Early goal-directed therapy is a strategy implemented within 6 hours of suspected sepsis or septic shock. Goals during the first 6 hours of resuscitation are (a) central venous pressure (CVP) 8–12 mm Hg, (b) mean arterial pressure (MAP) ≥65 mm Hg, (c) urine output ≥0.5 mL/kg/hr, and (d) central venous (superior vena cava) or mixed venous oxygen saturation 70% or 65%, respectively. In patients with elevated lactate levels, resuscitation should be targeted to normalize lactate. Crystalloids are the initial fluid of choice in the resuscitation of severe sepsis and septic shock.

Early appropriate antibiotic therapy is associated with improved clinical outcomes. Consensus guidelines recommend antibiotic therapy within 1 hour of suspected sepsis.[59] Initial empiric anti-infective therapy of one or more drugs that have activity against all likely pathogens (bacterial and/or fungal or viral) and that penetrate in adequate concentrations into tissues presumed to be the source of sepsis should be initiated. In septic shock, the initiation of antibiotic therapy within 1 hour increases survival; with each hour antibiotic therapy is delayed, survival decreases by about 8%.[60] The usual bacteria cultured from urinary sources are aerobic gram-negative bacilli and enterococci. Cultures should be drawn as clinically appropriate before antimicrobial therapy if it does not result in significant delay (>45 mins) in the start of antimicrobial(s), including blood, urine, stool (for diarrhea or recent antibiotic use), sputum, and skin and soft tissue culture. At least two sets of blood cultures (both aerobic and anaerobic bottles) should be obtained before antimicrobial therapy with at least one drawn percutaneously and one drawn through each vascular access device, unless the device was recently (<48 hours) inserted. However, blood culture results are negative in 50–65% of patients with sepsis.[18]

Recommended tests include a complete blood count with differential, basic metabolic panel, measurement of lactate and liver enzyme levels, coagulation studies, and urinalysis.

Table 7.4 Terms and Definitions of Sepsis and Septic Shock

Sepsis	Suspected or documented infection and an acute increase of ≥2 SOFA points (a proxy for organ dysfunction)
Septic shock	Sepsis and vasopressor therapy needed to elevate MAP (mean arterial pressure) ≥65 mm Hg and lactate >2 mmol/L (18 mg/dL) despite adequate fluid resuscitation

SOFA; Sequential [Sepsis-related] Organ Failure Assessment
(Reproduced from Singer M, Deutschman CS, Seymour CW, et al. The Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3). JAMA. 2016;315(8):801-10.)

Suspected respiratory infections should be evaluated using chest radiography and arterial blood gas testing to assess hypoxemia and acid–base abnormalities. If disseminated intravascular coagulation is suspected, fibrin degradation products, D-dimer levels, and fibrinogen levels should be measured. Several biologic markers of sepsis such as C-reactive protein, procalcitonin, activated partial thromboplastin time, and interleukin-6 may have diagnostic and prognostic implications, although lack of standardized assays limits their practical use.

Empiric antimicrobial combination therapy should not be administered for more than 3–5 days. De-escalation to the most appropriate single therapy should be performed as soon as the susceptibility profile is known. Duration of antimicrobial therapy is typically 7–10 days; longer courses may be appropriate in patients who have a slow clinical response, undrainable foci of infection, bacteremia with *S. aureus*; some fungal and viral infections, or immunologic deficiencies including neutropenia.

Antibiotic Resistance

Increasing antibiotic resistance and a lack of new antibiotics in the near future call for a variety of coordinated strategies, called "antibiotic stewardship," to improve antibiotic use with the goal of enhancing patient health outcomes and reducing the emergence of resistance to antibiotics.[61] Multidrug-resistant (MDR) uropathogens are increasing in prevalence and may contribute to significant morbidity. Specifically, antibiotic resistance in gram-negative uropathogens is a major global concern. Worldwide, the prevalence of Enterobacteriaceae that produce extended-spectrum β-lactamase or carbapenemase enzymes continues to increase at alarming rates. Likewise, resistance to other antimicrobial agents including aminoglycosides, sulfonamides, and fluoroquinolones is also escalating rapidly. Trimethoprim-sulfamethoxazole (TMP-SMX) resistance rates for *E. coli* UTIs have increased substantially over the last decade to where TMP-SMX is no longer a suitable empirical antimicrobial for UTI in some studies.[62] Similarly, there has been a 10-fold increase in *E. coli* resistance to ciprofloxacin for UTIs and therefore may be an unsuitable empirical therapy for nosocomial UTIs and UTIs in the urology population.[62–64] Recently Teillant et al. studied the ability of antibiotic prophylaxis to prevent infections and deaths from infections for the 10 most common surgeries and blood cancer chemotherapy regimens in the United States, including transrectal prostate biopsy.[65] They calculated the additional number of infections and deaths related to infections that would occur under different scenarios of reduced efficacy of antibiotic prophylaxis and found that in the United States, 38.7% to 50.9% of pathogens causing surgical site infections are resistant to standard prophylactic antibiotics.[65]

Bacterial resistance has major implications for urologic practice, particularly in relation to catheter-associated UTIs and infectious complications following transrectal ultrasonography-guided biopsy of the prostate or urologic surgery. Uropathogenic *E. coli* attach to and invade uroepithelial cells and form intracellular bacterial communities. These aid evasion of the host's immune system and provide some protection against antibiotic exposure. The formation of a quiescent reservoir within the transitional cell layer might contribute to relapsing or persistent infection. Biofilm formation enables the organism to avoid host defenses and resist antibiotic therapy and provides a reservoir for ongoing infection if the catheter is not removed. Transrectal biopsy allows direct transfer of bacteria from the rectum to the prostate, including a potential reservoir of resistance that can be enhanced by prior antibiotic exposure.

Studies evaluating the adherence to society guidelines have shown a reduction in the rate of bacterial resistance and reduced costs without increasing the risk of postoperative infection after urologic procedures.[66] Responding to the challenges of antibiotic resistance will require a multifaceted approach including considered use of current antimicrobial agents, improved diagnostics (including the rapid detection of resistance) and surveillance, better adherence to basic measures of infection prevention, development of new antibiotics, and research into nonantibiotic treatment and preventive strategies.[67] Use of appropriate urine testing in order to only treat when indicated and tailor broad-spectrum therapy, use of selective antibiotics per guidelines, and use of local antibiograms with inpatient versus outpatient data may be a starting point to reducing antibiotic resistance.

Clostridium difficile Colitis

Hospital-acquired infections such as *C. difficile* colitis contribute nearly $10 billion in excessive expenditures to the US health-care system.[68] Each episode of *C. difficile* colitis confers an increased cost of $11,285 to the hospital admission.[68] Misuse of antibiotics has been associated with bacterial resistance, greater patient morbidity, increased health-care costs, and suppression of normal bacterial flora, leading to *C. difficile* colitis. Antibiotics may be overused after genitourinary surgery, and this overuse is associated with hospital-acquired *C. difficile* infections. The AUA guidelines emphasize that the duration of surgical antimicrobial prophylaxis should only extend throughout the period in which bacterial invasion is likely to establish an infection and that antimicrobial prophylaxis is unnecessary after surgical wound closure. With few exceptions, antimicrobial prophylaxis should not extend beyond 24 hours after the procedure. The specific classes of antibiotics that have been most strongly associated with *C. difficile* colitis include clindamycin, fluoroquinolones, and cephalosporins.[69] Importantly, these are also the classes of antibiotics recommended by the AUA as first- and second-line antibiotic prophylaxis for radical prostatectomy, nephrectomy, and radical cystectomy. Calvert et al. evaluated the incidence of *C. difficile* colitis in genitourinary cancer surgery and found extended antibiotic prophylaxis was associated with higher odds of *C. difficile* infection.[70] C. *difficile* colitis rates have been reported to be as high as 8.8% after radical cystectomy.[71] On multivariate analysis, antibiotic exposure greater than 7 days (odds ratio = 2.2, 95% CI: 1.11–4.44, $p = 0.02$) was independently associated with developing this infection. Efforts are needed to minimize antibiotic exposure and encourage greater compliance with perioperative antimicrobial prophylaxis guidelines.

Special Considerations

PROSTATE BIOPSY

According to the AUA Best Practice Statement, TRUS-guided prostate biopsy (see Chapter 20), performed through a grossly contaminated field, requires important preventative considerations. There is wide variation in the approach to the preparation of the rectum. Some studies found no benefit to either preprocedural povidine-iodine[72] or sodium biphosphate enemas.[73] However, another study found that a bisacodyl suppository rectal preparation the night before or morning of the procedure decreased infectious complications.[74]

The AUA Best Practice Policy Statement on Urologic Surgery Antimicrobial Prophylaxis recommends a fluoroquinolone or first-/second-/third-generation cephalosporin prior to biopsy.[75] Currently, no conclusive data have been found to support either the use of long-course (3 days) over short (1 day) fluoroquinolone regimens, or multiple- versus single-dose schedules.[76] Although antibiotic prophylaxis is effective in preventing infection, leading to a low incidence of sepsis, recently there have been increasing incidences of quinolone-resistant infection resulting from more frequent use of quinolones in the population overall, including at the time of transrectal prostate biopsy.[77] Prebiopsy screening with rectal swabs may allow identification of those men harboring antibiotic-resistant organisms in their endogenous gastrointestinal flora prebiopsy, and for whom fluoroquinolone prophylaxis may not be appropriate.[78] This strategy has revealed a prevalence of about 22% of men harboring fluoroquinolone-resistant bacteria.[78,79] Taylor and colleagues targeted specific antimicrobial prophylaxis based on rectal swab results.[80] These authors were able to show a reduction in post-prostate biopsy infections from 2.6% to 0% ($p = 0.12$) and a cost saving per infectious complication, although this was not statistically significant. However, these methods have not been broadly used and require further prospective investigation.

The need for routine urine culture prior to prostate biopsy is unclear; urine culture appears only to be useful in the decision to refrain from prostate biopsy when bacterial growth is evident.[81] The use of urinalysis or urine dipstick prior to prostate biopsy is widespread; however, there are no published studies to document its benefit.

Most infectious complications after prostate biopsy are limited to symptomatic UTIs and low-grade febrile illness, which can be readily treated with oral or intravenous antibiotics; however, post-biopsy sepsis has emerged as a risk of this procedure. The incidence of infectious complications following prostate biopsy in large multi-institutional studies ranges from 0.1% to 7%, depending upon the antimicrobial prophylactic regimen used,[78,82,83] with approximately 30–50% of these patients having accompanying bacteremia.[72,84] The risk of hospitalization for infectious complications in contemporary studies ranges from 0.6% to 4.1%.[82] The reported incidence of UTI after prostate biopsy typically ranges between 2% and 6%.[85] Bacteremia is frequently accompanied by severe sepsis, which has an overall incidence of 0.1–2.2% following prostate biopsy.[72] One recent study reported that among post–TRUS biopsy patients hospitalized with *E. coli* bacteremia, 25% had severe sepsis requiring intensive care unit admission.[86] In terms of repeat prostate biopsy, Loeb et al. demonstrated a repeat biopsy session was not associated with a greater risk of infectious (OR 0.81, $p = 0.39$) or serious noninfectious urologic complications (OR 0.94, $p = 0.82$) compared to the initial biopsy.[87]

INFLATABLE PENILE PROSTHESES

There are no RCTs regarding the antimicrobial prophylaxis for the insertion of penile prostheses. Data extrapolated from the insertion of mesh during hernia repair and orthopedic implants confirm the benefits of antimicrobial prophylaxis. A significant difference between practice patterns of Sexual Medicine Society of North America member urologists and nonmember urologists in terms of antibiotic irrigation usage, modifications for high-risk patients, and consensus about the importance of antibiotic use with IPP has been observed,[88] even though the AUA guidelines recommend aminoglycoside (or aztreonam*) + first-/second-generation cephalosporin or vancomycin (*aztreonam can be substituted for aminoglycosides in patients with renal insufficiency). Evidence from orthopedic literature suggests that prophylaxis for 24 hours or less is adequate during insertion of penile prosthesis.

Conclusion

Infectious complications from urologic surgery are major sources of postoperative morbidity. Antimicrobial prophylaxis is the periprocedural systemic administration of an antimicrobial agent intended to reduce the risk of post-procedural local and systemic infections. Management of periprocedural infectious complications requires prompt recognition and appropriate intervention. Increasing antibiotic resistance and a lack of new antibiotics in the near future call for a variety of coordinated strategies in an effort of antibiotic stewardship. The appropriate use of antimicrobial prophylaxis in an individual patient requires consideration of not only guidelines but also a comprehensive evaluation of the patient's specific circumstances.

Chapter 7 Questions

1. AUA guidelines for antibiotic prophylaxis for infective endocarditis during percutaneous nephrolithotomy recommend:
   a. Aminoglycoside
   b. First- or second-generation cephalosporin
   c. Fluoroquinolone
   d. Antibiotic prophylaxis for the prevention of infective endocarditis is not recommended
   e. Clindamycin

2. A 64-year-old female with a history of diabetes mellitus and a hip replacement 1.5 years prior is planned for a right ureteroscopy for a 1-cm mild pole renal calculus. Preoperatively she should receive:
   a. A single dose of quinolone
   b. First- or second-generation cephalosporin
   c. Metronidazole
   d. Clindamycin
   e. TMP-SMX

3. Antibiotic(s) that is/are most commonly associated with *C. difficile* colitis include:
   a. Flagyl and gentamicin
   b. Clindamycin, fluoroquinolones and cephalosporins
   c. Metronidazole and ampicillin/sulbactam
   d. TMP-SMX
   e. Piperacillin/tazobactam

4. A 53-year-old female with quinolone allergy and a history of a prosthetic heart value undergoes left ureteroscopy for a 6-mm midureteral calculus. Preoperatively she should receive:
   a. Aminoglycoside and ampicilin
   b. Clindamycin
   c. Aminoglycoside and first- or second-generation cephalosporin
   d. Flagyl and gentamicin
   e. TMP-SMX

5. A 68-year-old male with a penicillin allergy along with a history of diabetes mellitus and coronary artery disease undergoes placement of an inflatable penile prosthesis. AUA-recommended antimicrobial prophylaxis includes:
   a. Ciprofloxacin and flagyl
   b. Vancomycin
   c. Ampicillin/sulbactam
   d. TMP-SMX
   e. Clindamycin

6. A 62-year-old man presents to the emergency department after outpatient ureteroscopy with a 2-day history of fever, chills, cough, and right-sided pleuritic chest pain. The patient's vital signs are temperature, 101.5°F; heart rate, 120 bpm; respiratory rate, 30 breaths/min; blood pressure, 70/35 mm Hg; and oxygen saturation as measured by pulse oximetry, 80% without oxygen supplementation. A chest radiograph shows a right lower lobe infiltrate. His lactate is 4 mm/L and he requires vasopressin to maintain a MAP ≥65 after appropriate resuscitation. This patient's condition can best be defined as which of the following?
   a. Multi-organ dysfunction syndrome
   b. Sepsis
   c. Septic shock
   d. Severe sepsis
   e. Systemic inflammatory response syndrome

7. What is the first step in the initial management of this patient?
   a. Antibiotic therapy
   b. β-Blocker therapy to control heart rate
   c. Intravenous (IV) fluid resuscitation
   d. Supplemental oxygen and airway management
   e. Vasopressor therapy with dopamine

8. The factor that is independently associated with *C. difficile* colitis after urologic surgery is:
   a. Uncontrolled diabetes mellitus
   b. Immunosuppression
   c. Malignancy
   d. Positive preoperative urine culture
   e. Antibiotic exposure greater than 7 days

9. A 52-year-old female with no growth on a preoperative urine culture undergoes a transvaginal placement of a midurethral sling with inadvertent perforation of the bladder. The surgical wound classification of this procedure is:
   a. Sterile
   b. Clean
   c. Clean contaminated
   d. Contaminated
   e. Dirty-infected

10. A 59-year-old male with cT1c prostate cancer and a penicillin allergy undergoes transperineal prostate focal cryotherapy. Preoperatively, he should receive:
    a. A single dose of quinolone
    b. First- or second-generation cephalosporin
    c. Metronidazole
    d. Clindamycin
    e. TMP-SMX

Answers

1. **d.** AUA guidelines do not recommend antibiotics for prevention of infective endocarditis.
2. **a.** A hip replacement within 2 years and diabetes places the patient at risk for hematogenous spread of infection; AUA guidelines recommend a single dose of quinolone.
3. **b.** Clindamycin, fluoroquinlones, and cephalosporins place the urologic patient at greatest risk for *C. difficile* colitis.
4. **c.** AUA guidelines recommend aminoglycoside and first- or second-generation cephalosporin for antibiotic prophylaxis involving an implanted prosthesis.
5. **b.** AUA guidelines recommend vancomycin in penicillin -allergic patients for antibiotic prophylaxis involving an implanted prosthesis.

6. **c.** The definition of septic shock is sepsis and vasopressor therapy needed to elevate MAP (mean arterial pressure) ≥65 mm Hg and lactate >2 mmol/L (18 mg/dL) despite adequate fluid resuscitation.
7. **d.** Respiratory stabilization is the first step in management.
8. **e.** Prolonged antibiotic use >7 days have been associated with C. *difficile* colitis (odds ratio 2.2).
9. **c.** The definition of a clean contained procedure is an operative wound that enters the respiratory, GI, genital, or urinary tract under controlled conditions without unusual contamination when no infection or major break in technique has occurred.
10. **d.** AUA guidelines recommend clindamycin in those with a penicillin allergy undergoing surgery not involving the urinary tract or bowel (Case Table 7.1).

Case Table 7.1 Recommended Antimicrobial Prophylaxis for Urologic Procedures

Procedure	Organisms	Prophylaxis Indicated	Antimicrobial(s) of Choice	Alternative Antimicrobial(s)	Duration of Therapy*
Lower Tract Instrumentation					
Removal of external urinary catheter	GU tract†	If risk factors‡,§	■ Fluoroquinolone¶ ■ TMP-SMX¶	■ Aminoglycoside (aztreonam¥) ± ampicillin¶ ■ 1st-/2nd-gen. cephalosporin¶ ■ Amoxicillin/clavulanate¶	=24 hours¶
Cystography, urodynamic study, or simple cystourethroscopy	GU tract	If risk factors§	■ Fluoroquinolone ■ TMP-SMX	■ Aminoglycoside (aztreonam¥) ± ampicillin ■ 1st-/2nd-gen. cephalosporin ■ Amoxicillin/clavulanate	=24 hours
Cystourethroscopy with manipulation|	GU tract	All	■ Fluoroquinolone ■ TMP-SMX	■ Aminoglycoside (aztreonam¥) ± ampicillin ■ 1st-/2nd-gen. cephalosporin ■ Amoxicillin/clavulanate	=24 hours
Prostate brachytherapy or cryotherapy	Skin	Uncertain	■ 1st-gen. cephalosporin	■ Clindamycin**	=24 hours
Transrectal prostate biopsy	Intestine††	All	■ Fluoroquinolone ■ 1st-/2nd-/3rd-gen. cephalosporin	■ TMP-SMX ■ Aminoglycoside (aztreonam¥)	=24 hours
Upper Tract Instrumentation					
Shock-wave lithotripsy	GU tract	If risk factors	■ Fluoroquinolone ■ TMP-SMX	■ Aminoglycoside (aztreonam¥) ± ampicillin ■ 1st-/2nd-gen. cephalosporin ■ Amoxicillin/clavulanate	=24 hours
Percutaneous renal surgery	GU tract and skin‡‡	All	■ 1st-/2nd-gen. cephalosporin ■ Aminoglycoside (aztreonam¥) + metronidazole or clindamycin	■ Ampicillin/sulbactam ■ Fluoroquinolone	=24 hours
Ureteroscopy	GU tract	All	■ Fluoroquinolone ■ TMP-SMX	■ Aminoglycoside (aztreonam¥) ± ampicillin ■ 1st-/2nd-gen. cephalosporin ■ Amoxicillin/clavulanate	=24 hours
Open or Laparoscopic Surgery					
Vaginal surgery (includes urethral sling procedures)	GU tract, skin and Grp B *Strep.*	All	■ 1st-/2nd-gen. cephalosporin ■ Aminoglycoside (aztreonam¥) + metronidazole or clindamycin	■ Ampicillin/sulbactam ■ Fluoroquinolone	=24 hours
Without entering urinary tract	Skin	If risk factors	■ 1st-gen. cephalosporin	■ Clindamycin	Single dose
Involving entry into urinary tract	GU tract and skin	All	■ 1st-/2nd-gen. cephalosporin ■ Aminoglycoside (aztreonam¥) + metronidazole or clindamycin	■ Ampicillin/sulbactam ■ Fluoroquinolone	=24 hours
Involving intestine§§	GU tract, skin and intestine	All	■ 2nd/3rd gen. cephalosporin ■ Aminoglycoside (aztreonam¥) + metronidazole or clindamycin	■ Ampicillin/sulbactam ■ Ticarcillin/clavulanate ■ Piperacillin/tazobactam ■ Fluoroquinolone	=24 hours
Involving implanted prosthesis	GU tract and skin	All	■ Aminoglycoside (aztreonam¥) + 1st/2nd gen. cephalosporin or vancomycin	■ Ampicillin/sulbactam ■ Ticarcillin/clavulanate ■ Piperacillin/tazobactam	=24 hours

*Additional antimicrobial therapy may be recommended at the time of removal of an externalized urinary catheter.
†GU tract: Common urinary tract organisms are *E. coli, Proteus sp., Klebsiella sp., Enterococcus.*
‡See Table 1 "Patient-related factors affecting host response to surgical infections."
§If urine culture shows no growth prior to the procedure, antimicrobial prophylaxis is not necessary.
¶Or full course of culture-directed antimicrobials for documented infection (which is treatment, not prophylaxis).
¥Aztreonam can be substituted for aminoglycosides in patients with renal insufficiency.
|Includes transurethral resection of bladder tumor and prostate, and any biopsy, resection, fulguration, foreign body removal, urethral dilation or urethrotomy, or ureteral instrumentation including catheterization or stent placement/removal.
**Clindamycin, or aminoglycoside + metronidazole or clindamycin, are general alternatives to penicillins and cephalosporins in patients with penicillin allergy, even when not specifically listed.
††Intestine: Common intestinal organisms are *E. coli, Klebsiella sp., Enterobacter, Serratia sp, Proteus sp., Enterococcus*, and anaerobes.
‡‡Skin: Common skin organisms are *S. aureus*, coagulase negative *Staph. sp.*, Group A *Strep. sp.*
§§For surgery involving the colon, bowel preparation with oral neomycin plus either erythromycin base or metronidazole can be added to or substituted for systemic agents.
Key: gen, generation; GU, genitourinary; TMP-SMX, trimethoprim-sulfamethoxazole.

8 Classification of Complications and Assessment of Quality of Care

MARK D. TYSON and DAVID F. PENSON

CHAPTER OUTLINE

Introduction
Definition of Complications
Common Terminology Criteria for Adverse Events
Clavien-Dindo System
The International Continence Society and the International Urogynecological Association Classification of Complications Related Directly to the Insertion of Grafts and Prosthetics
National Quality Registries
Quality Improvement Strategies
Plan-Do-Study-Act Cycle
Statistical Process Control
Root Cause Analysis
Lean Production System
Failure Mode and Effects Analysis
Summary
Chapter 8 Questions and Answers

KEY POINTS

1. A surgical complication is any event that deviates from the normal or expected course of action either during or after surgery.
2. The Common Terminology Criteria for Adverse Events system is a comprehensive set of criteria for the standardized classification of complications after cancer therapy and has been broadly accepted and extensively used by cooperative research and industry groups.
3. The Clavien-Dindo classification system is centered around the risk and invasiveness of the therapy required to resolve the complication.
4. The International Continence Society and the International Urogynecological Association classification system is extraordinarily complex and incorporates site, timing, and category of complications into six- or seven-digit code (with three numbers and three to four letters) to cover any conceivable complication after graft or prosthetic placement.
5. Despite the lack of unanimity in how surgical complications should be classified, significant strides have been made in national outcome registries such as the National Surgical Quality Improvement Program and the American Urological Association Quality registry.
6. Plan-Do-Study-Act, also known as rapid cycle improvement, is an iterative, four-stage, problem-solving model aimed at making positive changes in health-care processes.
7. Statistical process control is a set of methods for assessing ongoing quality improvement measures in real time and relies on the early identification of special cause variation. Alternatively, a process that displays only common cause variation may be stable and predictable and yet still unacceptable.
8. Root cause analysis is a formalized investigation and problem-solving method focused on identifying and understanding the underlying cause of an untoward event.
9. Lean methodologies – used in the manufacturing of Toyota cars – aims to improve processes by removing activities that are nonvalue-added through retrospective investigations of errors that interrupt the sequence of efficient operations.
10. Failure mode effects analysis aims to prevent errors through proactive risk assessment – that is, to prevent errors by identifying all the ways a process could fail, estimating the predicted probabilities and consequence of failures, and then taking action to prevent the potential failures from occurring.
11. The key factors necessary for success in quality improvement are strong and committed senior leadership, buy-in from rank-and-file members of the organization, and open lines of communication between leadership and involved stakeholders.

Introduction

Since the publication of *Crossing the Quality Chasm*,[1] there has been a renewed interest in improving outcomes after surgery in the United States. However, it remains unclear what constitutes a "bad" outcome after surgery as some complications are inherent to the procedure and expected to occur. Despite this uncertainty, the rate of surgical complications remains one of the most commonly used surrogate measures of surgical quality. In an effort to guide the systematic measurement and reporting of surgical complications for quality improvement purposes, several different classification systems for surgical complications have been developed despite none having emerged with universal acceptance. In this chapter, we provide a contextual framework for understanding how surgical complications are classified and how these reporting systems can be leveraged for quality improvement. Specifically, our objective is to review the available reporting systems used for complications after urologic surgery, to highlight deficiencies in these reporting systems, and to review how these classifications systems can be conceptualized within the framework of one or more prevailing quality improvement paradigms.

Definition of Complications

Before a classification system for surgical complications can be adopted, a standardized definition of what exactly constitutes a surgical complication is needed. In broad terms, a surgical complication is any event that deviates from the normal or expected course of action either during or after surgery. While many patient-, provider-, and system-level factors contribute to variations in surgical complications, a standardized reporting system is the sine qua non of effective surgical quality–improvement initiatives. There are several different proposed classification systems for reporting and classifying surgical complications, and these are summarized below.

COMMON TERMINOLOGY CRITERIA FOR ADVERSE EVENTS

The Common Terminology Criteria for Adverse Events (CTCAE) system is a comprehensive set of criteria for the standardized classification of complications after cancer therapy and has been broadly accepted and extensively used by cooperative research and industry groups since its introduction in the early 1980s.[2,3] Now in its fourth version, the CTCAE system uses a range of grades from 1 to 5 to classify surgical complications, ranging from mild complications to death (Table 8.1). In general, one advantage to the CTCAE system is that it is a relatively simple classification system, at least with respect to surgical complications. While this makes it ideally suited for NCI-sponsored trials where the focus is on unexpectedly serious and/or life-threatening surgical complications, it does not have the granularity needed to be used for comparative effectiveness research or quality improvement.

Table 8.1 CTCAE System for the Classification of Surgical and Medical Procedures

1	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not required
2	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental activities of daily living (ADL)
3	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADL
4	Life-threatening consequences; urgent intervention indicated
5	Death

Table 8.2 Clavien-Dindo Classification of Complications

Grade	Definition
Grade I	Any deviation from the normal course without the need for pharmacological treatment or surgical, endoscopic and radiologic interventions. Allowed therapeutic regimens are: drugs as antiemetics, antipyretics, analgesics, diuretics and electrolytes, and physiotherapy. This grade also includes wound infections opened at the bedside. Example: wound infection, postoperative ileus not requiring total parenteral nutrition (TPN)
Grade II	Requiring pharmacological treatment with drugs other than such allowed for grade I complications. Example: blood transfusion, urinary tract infection, ileus requiring TPN
Grade III	Requiring surgical, endoscopic or radiological intervention. Grade IIIa complications do not require anesthesia. Grade IIIb complications require anesthesia Example: take back to the OR for any reason, stent placement for ureteral injury
Grade IV	Life-threatening complication (including CNS complications)* requiring IC/ICU management. Grade IVa is single organ dysfunction. Grade IVb is multi-organ dysfunction. Example: sepsis, stroke, cardiopulmonary event
Grade V	Death of a patient. If the patient suffers from a complication at the time of discharge, the suffix "d" (for "disability") is added to the respective grade of complication. This label indicates the need for a follow-up to fully evaluate the complication

*brain hemorrhage, ischemic stroke, subarachnoidal bleeding, but excluding transient ischemic attacks (TIA)

IC: intermediate care; ICU: intensive care unit

(With permission from Dindo D, Demartines N, Clavien PA. The Clavien-Dindo Classification of Surgical Complications. Ann Surg. 2004; 244: 931–937.)

CLAVIEN-DINDO SYSTEM

In an attempt to standardize surgical outcome reporting with increased precision, Clavien et al. published a grading system for the severity of surgical complications. This new system, published in 1992, was centered on the risk and invasiveness of the therapy required to resolve the complication (Table 8.2).[4] In theory, this minimizes the influence of subjective interpretation on complication scoring because it is rooted in objective outcomes. Initially, four grades of complications were described; however, in 2004,

Dindo et al. introduced a modification to the Clavien classification system using five grades contained within seven levels.[5] This revision added further precision by characterizing whether an intervention required general anesthesia or whether a complication led to organ failure and/or admission to an intensive care unit. This reporting system, known as the Clavien-Dindo classification system, has been extensively validated and evaluated for interobserver variability.[6]

While this classification method has increased in popularity in recent years, it is not without its limitations. First, many of these complications remain susceptible to subjective interpretation, which may create variability within the grading assignments. For example, urologists may grade a recognized rectal injury during a radical prostatectomy differently: grade I for prolonged hospital stay versus grade III for intraoperative repair under general anesthesia.[7] Second, some interventions may be performed under local anesthesia at one institution but general anesthesia at another, which introduces inter-rater variability within grades III and IV.[8] Third, this system may not capture patients who have multiple complications within the same grade. Last two patients with the same complication may be managed differently at two separate institutions (e.g., IVC filter versus heparinization alone for DVT). Because of these challenges, the utility of the Clavien-Dindo classification system for national quality-improvement initiatives has been limited.

THE INTERNATIONAL CONTINENCE SOCIETY AND THE INTERNATIONAL UROGYNECOLOGICAL ASSOCIATION CLASSIFICATION OF COMPLICATIONS RELATED DIRECTLY TO THE INSERTION OF GRAFTS AND PROSTHETICS

In an effort to clarify terminology and to promote a registry for the improvement of pelvic-floor surgical procedures, the International Continence Society (ICS) and International Urogynecological Association (IUGA) have established a joint working group for classifying complications related to the insertion of prosthetics and grafts for female pelvic floor surgery.[9] The article recommends precise definitions for specific complications by distinguishing among local systemic complications. Novel terms such as *exposure, compromise, perforation, extrusion, separation, contraction,* and *prominence* are described in this report. The classification system itself is extraordinarily complex and incorporates anatomic site, timing, and category of complication into a six- or seven-digit code (with three numbers and three to four letters) to cover any conceivable complication after graft or prosthetic placement. By way of example, the code 1AaT1S1 would indicate asymptomatic vaginal prominence with no epithelial separation in the area of the suture line within 48 hours of surgery. While the complexity of this system may limit its use in daily practice, this system may be useful for comparative effectiveness research or surgical registries. A user-friendly calculator can be found online at the ICS website.[10]

NATIONAL QUALITY REGISTRIES

Despite the lack of unanimity in how surgical complications should be classified, significant strides have been made in national outcome–based surgical-quality assessment. The National Surgical Quality Improvement Program (NSQIP), for example, has been measuring outcomes for many types of surgeries and, for a small subset of institutions, publically reporting them.[11] Originally established in 1994, the goal of NSQIP was to prospectively collect surgical outcome data at Veterans Affairs (VA) hospitals and compare observed outcomes to risk-adjusted, model-based predictions. In 1999, it began expanding to include private hospitals to test the feasibility of implementing the system outside the VA. However, participation in NSQIP has not necessarily resulted in improved outcomes compared with nonparticipating hospitals. While initially showing promise for the VA system, recent data have challenged the association between hospital participation in NSQIP and improvement in outcome measures over time.[12] Furthermore, many important patient-centered outcomes are not captured by NSQIP such as margin status, return to work, and survival beyond 90 days.

With the aim of improving quality of care for urologic patients, the American Urological Association (AUA) established the AUA Quality registry (AQUA) in the summer of 2014. The AQUA registry is a national urologic disease registry designed to measure and report quality and patient-centered outcomes after urologic surgery. Using data directly extracted from commercially available electronic medical records, AQUA aggregates and organizes clinical and patient-reported data on diagnostic and therapeutic interventions, outcomes, and resource utilization.[13] While still in its infancy, data generated from AQUA will be used to support evidence-based decision support mechanisms and will provide feedback to urologists regarding their individual and/or practice-level performance on a range of quality measures benchmarked against their peers at the national and regional levels.

Quality Improvement Strategies

With an understanding of the basic principles of performance measurement and quality improvement, the next question is how to actually improve the quality of care. Unfortunately, the answer is often not simple. The overall goals of measuring health care are to ascertain whether the delivery of health care results in desired outcomes and to determine the degree to which health care adheres to processes that are rooted in scientific evidence, professional consensus, and patient preference. The theoretical framework that underlies successful quality-improvement programs emphasizes strategic vision, an understanding of organizational culture, streamlined data management, and infrastructure for efficient dissemination of results.[14] As such, it is important to understand many different process-improvement techniques that can identify inefficiencies, ineffective care, and preventable errors that arise from system or process failures.[15] The remaining portion of this chapter will focus on strategies and tools for quality improvement, including failure modes and effects analysis, plan-do-study-act (PDSA), statistical process control, Lean methodologies, and root cause analysis.

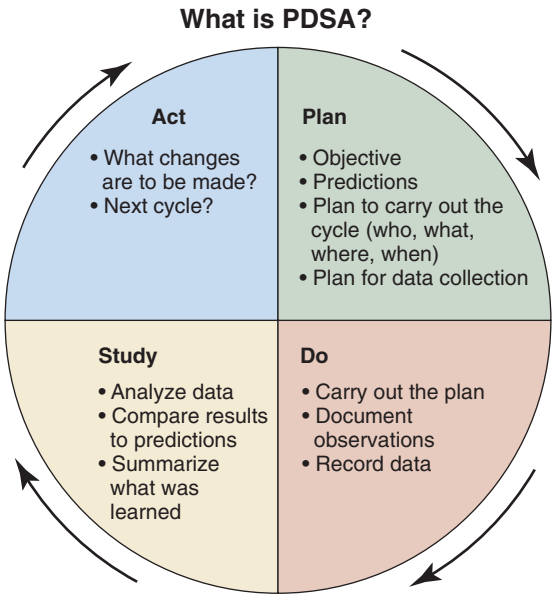

Figure 8.1 What is PDSA?

PLAN-DO-STUDY-ACT CYCLE

PDSA, also known as rapid cycle improvement, is an iterative, four-stage problem-solving model aimed at making positive changes in health-care processes (Fig. 8.1). This approach has been widely used by the Institute for Healthcare Improvement.[16,17] This strategy invokes a cyclic approach to assessing the impact of successive changes in the process.[18,19] The basic structure of PDSA is:

1. Plan. Assemble a team that has knowledge of the problem, describe the problem, and identify and analyze causes.
2. Do. Implement the action plan in a trial or small test group, collecting data prospectively.
3. Study. Analyze the data collected, and assess whether the new process has a level of performance and/or random variation that is superior to that displayed by the old process.
4. Act. If deemed successful, standardize the improvement and begin to use it regularly. If not successful, either modify it and test it again or discard it.

There are good examples of large-scale quality–improvement efforts using the PDSA approach in urology. The Michigan Urological Surgery Improvement Collaborative (MUSIC) is a physician-led group collaboration that aims to improve quality related to prostate cancer care in Michigan through consortium-wide provider and practice feedback on performance.[20] While this physician-led innovative regional collaborative has demonstrated promising results,[21–23] its reproducibility in markets without the financial support of the dominant insurer, the collegial interplay between community and academic urologists, and the committed time and support of clinical thought leaders is yet to be determined.

STATISTICAL PROCESS CONTROL

Statistical process control (SPC) is a set of methods used in the assessment of ongoing quality-improvement measures in real time. Originally developed by Walter A. Shewart in the early 20th century to help AT&T make better telephones, SPC methods have also been used in a wide variety of quality-improvement efforts including munitions manufacturing in World War II, software engineering, and health care.[24–26] Shewart hypothesized that the best way to improve a process was to identify and reduce variation and, when possible, to move the entire process in the preferred direction. In so doing, he distinguished between two general types of variations: special cause variation and common cause variation.

Common cause variation is variation that is inherent to the process itself (i.e., noise *within* the system) and is predictable and stable. Special cause variation arises from data that vary in an unpredictable way and signal a change in the process. Neither type of variation is desirable or undesirable in and of itself. When a process incurs an unanticipated special cause, it's usually undesirable (e.g., higher rate of retained sponges in the current year compared to previous years). However, a special cause may be desirable if improvements are made to the process and the special cause signals a change in the desired direction (e.g., lower rate of retained sponges after implementation of policy that mandates correct instrument counts prior to fascial closure). Alternatively, a process that displays only common cause variation may be stable and predictable and yet still altogether unacceptable. Turnover time between surgical cases, for example, may be stable and predictable at 2 hours plus or minus 5 minutes, but most hospitals (and surgeons!) would consider this amount of time unacceptable.

Because quality-improvement strategies rely on understanding the type of variation exhibited by a process, methods to correctly identify types of variations are imperative. To assist researchers in differentiating common cause from special cause variation, Shewart developed a tool called the *control* chart. The basic elements of a control chart are exhibited in Fig. 8.2. The sample data describe the number of surgical readmissions a large busy hospital experienced on a monthly basis over the past 2 years. Several features of this chart are important to recognize. First, the control chart is a real-time, ongoing record of an event over time (X-axis). Second, the performance characteristic being measured is plotted on the Y-axis. Third, control charts have a measure of central tendency called the centerline (usually the mean). Fourth, upper and lower control limits allow interested parties to quantitatively identify special causes that reveal instability in the process. Last green observations represent common cause variation while red observations indicate special cause variation. While it is beyond the scope of this chapter to go into great detail regarding chart types, an excellent source of additional information in this regard is *Improving Healthcare with Control Charts*.[26]

Several limitations of SPC methods should be acknowledged. First, control charts assume that each event under consideration is separate and independent of the preceding and succeeding events and also that each event has a constant or equal probability of occurring.[27] Because one is rarely able to prove or disprove this assumption, most tend to ignore it.[27] Second, control charts also have a potential issue with skewness. If the subgroup size for the event under examination is too small, then it will be difficult to discern special causes accurately. Stated differently, the

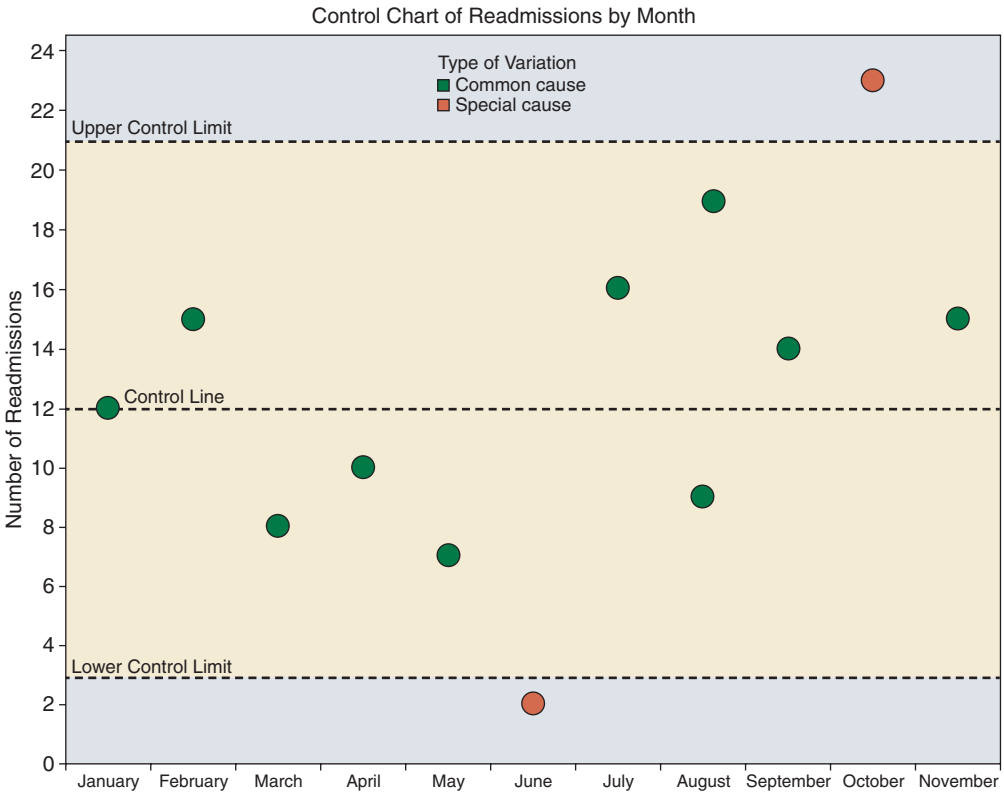

Figure 8.2 Control chart of readmissions by month.

smaller the subgroup size, the less sensitive the control chart. As a result, most SPC experts recommend at least 20–25 observations before control limits are calculated.[26]

ROOT CAUSE ANALYSIS

Root cause analysis (RCA) is a formalized investigation and problem-solving method focused on identifying and understanding the underlying cause of an untoward event. Used extensively in engineering,[28] RCA is now a requirement by The Joint Commission for all sentinel events.[29] Operating on the assumption that the system, rather than the individual, is the most likely root cause of most problems, RCA is a technique used to identify trends and assess risk whenever an error is suspected.[30] Because the analysis begins after an event, RCA procedures are reactive in nature, retrospectively outlining the sequence of events leading to that event, charting possible causative factors, and identifying root causes to completely vet the origins of the event in question.[31] Given that the process is labor-intensive, typically a multidisciplinary quality team will corroborate the principal findings of the RCA to increase the validity of the findings (Fig. 8.3).[32]

The last phase of the RCA analysis is developing recommendations for system-wide process improvement, based on the pertinent findings from the investigation. The significance of this final stage is underscored by a review of the literature on RCA, where the authors conclude that there is little evidence to substantiate the claim that RCA can improve patient safety by itself.[33] To improve the generalizability of the findings from the RCA, some groups have moved to performing several RCA processes simultaneously

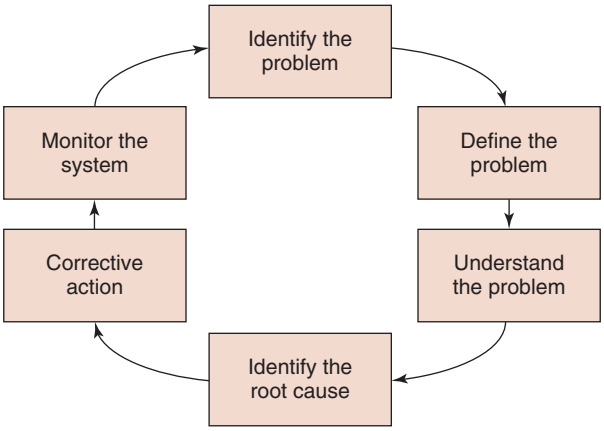

Figure 8.3 Root cause analysis flowchart.

to examine multiple cases within a single review for certain categories of events.[34–36] Due to the myriad types of adverse events, special consideration is required to differentiate system from process factors. Furthermore, most experts in RCA will reiterate that it is imperative to avoid assigning individual blame. A commonly held notion is that it is truly rare for errors to be associated with provider neglect or malfeasance.[37] The majority of individual factors can been addressed through system-wide education, training, and installing fail-safes that make errors difficult to commit.

LEAN PRODUCTION SYSTEM

Lean methodologies – used in the manufacturing of Toyota cars – overlaps with SPC and RCA methods in that this

approach aims to improve processes by removing activities that are nonvalue-added (also known as waste) through retrospective investigations of errors that interrupt the sequence of efficient operations.[38–41] In this way, quality improvement efforts not only look at effectiveness but also costs and in essence determine the value of each step in the process. Using these principles, health-care stakeholders have evaluated nonvalue-added processes in the operations of pathology labs,[42–45] pharmacies,[46–49] and blood banks[50,51] – similar to the Toyota Production System. These methods rely on accurately defining the problem, using RCA analysis to investigate the problem, setting goals to address the problem, and clarifying who is responsible for removing ambiguity and implementing workarounds. In health care, analogous measures are taken to ensure the right patient gets the right service (output), who delivers the service (responsibility), when the service is delivered (connection), and precisely how the service is delivered.[52]

FAILURE MODE AND EFFECTS ANALYSIS

All the previous quality-improvement measures up to this point have focused on reactionary planning to events that have already occurred, even if the techniques employ prospective analysis of changes to the system. In 2001, however, The Joint Commission began requiring proactive risk management activities in an effort identify and predict system weaknesses so that patient harm could be prevented as opposed to being studied in retrospect.[53] While failure mode and effects analysis (FMEA) techniques had been used in health care for decades, this mandate generated renewed interest in the field of proactive risk assessment using FMEA. FMEA techniques were initially used by engineers in the mid-20th century to evaluate failures in military, automotive, and aeronautic and space industries.[54,55] FMEA is an inductive reasoning (forward logic) single point of failure analysis that identifies potential problems based on experience with similar products and processes.[56,57] Failure indicates a loss of function whereas failure mode indicates the specific manner in which the function was lost. Effects analysis refers to downstream consequences of failure on different levels within the system. The goal of FMEA is to prevent errors through proactive risk assessment – that is, to prevent errors by identifying all the ways a process could fail, estimating the predicted probabilities and consequences of failures, and then taking action to prevent the potential failures from occurring.[58,59] In health care, this method focuses on the system of care and uses multidisciplinary teams to assess processes from quality-improvement perspectives.[60] FMEA methods have been used to prevent chemotherapy errors,[61] PCA oversedation,[62] misadministration of IV contrast in outpatients,[63] and blood transfusion errors in pediatric emergencies.[64]

Summary

In this chapter, we have reviewed the dominant methods for classifying complications, which should equip the urologic surgeon not only to be able to effectively recognize areas that need improvement but also to begin to formulate strategies that promote effective disease management throughout all levels of the health-care organization. We have also provided the reader with a comprehensive review of how quality improvement is approached from a practical standpoint. This understanding will undoubtedly assist the next generation of urologic surgeons in navigating the emerging quality and value-based health-care environment.

Chapter 8 Questions

1. A patient undergoes a holmium laser enucleation of the prostate for a 250-g prostate. His intraoperative course was notable for prolonged and difficult tissue morcellation. Postoperatively, he was noted to have massive abdominal distention, pain, and minimal urine output. A cystogram reveals an intraperitoneal bladder perforation. He undergoes emergent repair of the bladder perforation. He does not require ICU care and he remained hemodynamically stable throughout. According to the Clavien-Dindo classification system, what grade of complication does this constitute?
   a. Grade I
   b. Grade II
   c. Grade III
   d. Grade IV
   e. Grade V

2. A patient develops nausea after a cystectomy necessitating the administration of Zofran for relief. According the Clavien-Dindo classification system, what grade of complication is this?
   a. Not a complication
   b. Grade I
   c. Grade IIa
   d. Grade IIb
   e. Grade III

3. A patient requires a blood transfusion after a cystectomy. According to the Clavien-Dindo classification system, what grade complication is this?
   a. Grade I
   b. Grade II
   c. Grade IIIa
   d. Grade IIIb
   e. Grade IV

4. A patient requires total parenteral nutrition for a prolonged ileus after a cystectomy. According to the Clavien-Dindo classification system, what grade complication is this?
   a. Grade I
   b. Grade II
   c. Grade IIIa
   d. Grade IIIb
   e. This is not a complication according to the Clavien-Dindo classification system

5. What are the types of variations in statistical process control?
   a. Common cause variation
   b. Special cause variation
   c. Both A and B
   d. Neither A or B
   e. Stochastic variation

6. In the context of statistical process control, special cause variation:
   a. Is always undesirable
   b. May be desirable if improvements are made to the process and the special cause signals a change in the desired direction
   c. Arises from data that signal a change in the process
   d. Both b and c
   e. None of the above

7. Which of the following are limitations to the statistical process control methods?
   a. Control charts assume that each event under consideration is separate and independent of the preceding and succeeding events
   b. Each event on the control chart has a constant or equal probability of occurring
   c. If the subgroup size for the event under examination is too small, then it will be difficult to discern special causes accurately
   d. All of the above
   e. None of the above

8. Limitations of the Clavien-Dindo classification include:
   a. Complications may be susceptible to subjective interpretation
   b. Some interventions may be performed under local anesthesia at one institution but general anesthesia at another
   c. May not capture patients who have multiple complications within the same grade
   d. All of the above
   e. None of the above

9. Which of these quality improvement measures uses proactive risk assessment?
   a. Plan-Do-Study-Act
   b. Statistical process control
   c. Failure mode and effects analysis
   d. Root cause analysis
   e. None of the above

10. Which is true regarding root cause analysis?
    a. It operates on the assumption that an individual, not the system, is the most likely root cause
    b. The analysis begins after the event
    c. The majority of individual factors cannot be addressed through system-wide education, training, and installing fail-safes that make errors difficult to commit
    d. All of the above
    e. None of the above

Answers

1. **c.** Because the patient required a surgical intervention under anesthesia, this is a grade IIIb complication.
2. **b.** This is a grade I complication because the patient required an antiemetic.
3. **a.** Because the patient received a pharmacologic intervention other than what was allowed for a grade I complication, this constitutes a grade II complication.
4. **b.** Total parenteral nutrition is a pharmacologic intervention that falls under the grade II designation.
5. **c.** Both common cause and special cause variation are types of variations within the statistical process control framework.
6. **d.** Special cause variation in and of itself is neither undesirable nor desirable. If the special cause variation

signals a change in the desired direction after an intervention, then this is clearly special cause variation that is desirable. An example of this would be a lower retained sponge rate after implementing a policy that states every patient must have a correct instrument count before fascial closure.

7. **d.** First, control charts assume that each event under consideration is separate and independent of the preceding and succeeding events and also that each event has a constant or equal probability of occurring. Because one is rarely able to prove or disprove this assumption, most tend to ignore it. Second, control charts also have a potential issue with skewness. If the subgroup size for the event under examination is too small, then it will be difficult to discern special causes accurately. Stated differently, the smaller the subgroup size, the less sensitive the control chart. As a result, most SPC experts recommend at least 20–25 observations before control limits are calculated.
8. **d.** Despite improvements to the classification system meant to reduce subjectivity within grade designations, some complications may be susceptible to variation in interpretation. Furthermore, some interventions may be performed under anesthesia at one institution but not under anesthesia at another.
9. **c.** Failure mode and effects analysis is an inductive reasoning (forward logic) single point of failure analysis that identifies potential problems based on experience with similar products and processes. The other quality improvement paradigms focus on reactionary planning to events that have already occurred, even if the techniques employ prospective analysis of changes to the system.
10. **b.** Operating on the assumption that the system, rather than the individual, is the most likely root cause of most problems, RCA is a technique used to identify trends and assess risk whenever an error is suspected. Because the analysis begins after an event, RCA procedures are reactive in nature, retrospectively outlining the sequence of events leading to that event, charting possible causative factors, and identifying root causes to completely vet the origins of the event in question.

Injuries Related to Positioning for Robotic Surgery
Chapter 9 Questions and Answers

KEY POINTS

1. Large hematomas that collect in the retroperitoneum or rectus sheath may cause paralytic ileus, anemia, and ongoing bleeding resulting from the consumption of coagulation factors.
2. Wounds that involve large skin flaps or those with large potential spaces in which blood could collect should be drained with a closed-suction surgical drain until the output of these drains decreases.
3. Intraoperative strategies to prevent wound infection include aseptic technique to reduce the microbial inoculum as well as good surgical practice to minimize dead space and devitalized tissue.
4. Antibiotic prophylaxis is recommended for all class II (clean-contaminated) wounds and for class I_D (clean) wounds in which prosthetic material or a vascular graft is implanted because the consequences of infection are serious in these instances.
5. Severe infections, such as necrotizing fasciitis, represent surgical emergencies, and patients should be taken immediately back to the operating room for wide debridement.
6. The use of vacuum-assisted closure should be limited when wounds are near conduits, anastomoses, and neobladders because this technique may be associated with an increased rate of cutaneous fistula formation.
7. If clinical suspicion of dehiscence remains despite equivocal physical examination findings, imaging studies such as ultrasound or computed tomography can be used.
8. Investigators have demonstrated that wounds that have been closed with a suture length that is twice as long as the wound have a higher rate of wound dehiscence than do wounds closed with suture that is four times the length of the wound.
9. Although brachial plexus injuries have been reported to result from excessive extension and external rotation during surgical procedures in the supine position, including radical prostatectomy, most brachial plexus injuries occur during procedures in the flank position, which is commonly used for procedures involving the kidney and retroperitoneum.
10. Retractor injuries to the femoral nerve occur when the blades of the retractor are placed directly on the psoas muscle, where they may compress the nerve directly or indirectly by trapping the nerve against the lateral pelvic wall.
11. Robotic-assisted surgery may be associated with increased risk of positioning injuries, including both traditional neuromuscular injuries to the upper and lower extremities as well as less common injuries such as vision loss, rhabdomyolysis, and compartment syndrome.

Successful surgical therapy depends on proper healing of the surgical wound. Problems with wound healing can lead to seromas, hematomas, surgical site infections (SSIs), dehiscence, and incisional hernias. In addition, nerve injuries related to patient positioning or retractor placement may affect postoperative mobility. All these complications increase morbidity and can contribute to mortality in surgical patients.

Complications related to the incision and patient positioning are important for all surgeons to be aware of because they are among the most common complications following operative procedures. Often, these complications are relatively minor and may resolve with conservative management (e.g., simple wound seromas or hematomas). However, at times their resolution may be expensive and time-consuming (e.g., complicated wound infection), may require additional surgical procedures (e.g., incisional hernia), or may cause permanent disability (e.g., postoperative neurapraxia). Therefore management of these complications is focused on prevention, as well as prompt recognition and appropriate treatment. The objective of this chapter is to review common complications of the incision and patient positioning with respect to their pathogenesis, clinical features, prevention, and management.

Seroma

PATHOGENESIS AND CLINICAL FEATURES

One of the most common and likely underreported complications following operative procedures is the development of a wound seroma (Fig. 9.1A). Although typically a benign finding, when not treated, seromas may lead to more serious wound infections, wound breakdown, or potentially skin necrosis. A *seroma* is a collection of sterile, clear, ultrafiltrated serum, lymphatic fluid, or liquified fat.[1] The fluid is usually clear, amber, and slightly viscous.

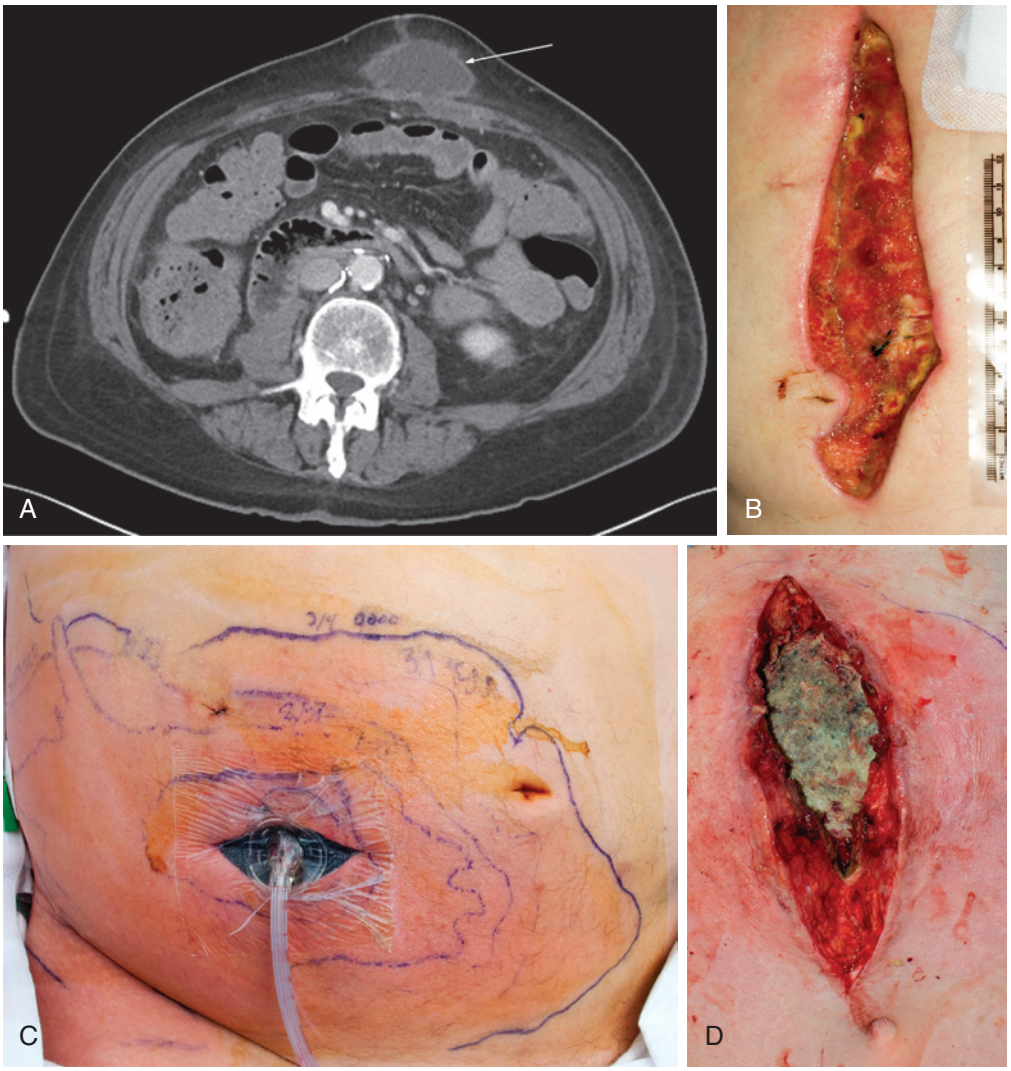

Figure 9.1 Selected wound complications. A, Seroma (arrow) as seen on postoperative cross-sectional imaging. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.) B, Superficial surgical site infection (SSI) healing by secondary intention. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.) C, Superficial SSI managed with vacuum-assisted closure with surrounding cellulitis. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.) D, Fascial wound dehiscence. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

Seromas are located under the incision, above the fascial layer, and directly beneath the dermis of the skin. They are more likely to occur when large tissue flaps are mobilized or when extensive lymphadenectomy is performed, such as during axillary[2] or inguinal lymph node dissection.[3] Thus, efforts to limit the extent of dissection where feasible without compromising cancer control such as sentinel lymph node procedures[4] or preservation of the saphenous vein during inguinal lymphadenectomy[5,6] may reduce the risk of seroma formation.

PREVENTION AND MANAGEMENT

Most postoperative seromas are discovered incidentally and require no active intervention. However, when large or symptomatic, seromas can be evacuated by opening the overlying skin edges, packing the wound with sterile saline-soaked gauze, and allowing the wound to heal by secondary intention. Seromas that develop under flaps (i.e., after inguinal lymph node dissection), however, may be more difficult to manage because these have the potential to damage the delicate vascular supply to the flap. Therefore, in incisions that involve extensive skin flaps, placement of closed-suction drains is typically performed and recommended. These drains are left in place until their output decreases to a minimal amount (typically <30 mL in a 24-hour period). Pressure dressings may be useful postoperatively when seroma formation is of concern. Occasionally, premature removal of the drains may allow a seroma to develop, and percutaneous aspiration or drain placement may be required.

Hematomoa

PATHOGENESIS AND CLINICAL FEATURES

A *hematoma* is a collection of blood in or near a recent surgical incision. Hematomas typically occur in the subcutaneous space, but they may also occur deeper in the incision, such as in the rectus sheath. Wound hematomas are most often caused by inadequate hemostasis after the skin has been closed. Many factors contribute to the formation of hematomas. First, hemostasis at the time of wound closure may be inadequate. Extra care should be taken in patients who are hypotensive or in shock at the time of wound closure. Additionally, the use of epinephrine may mask small bleeding vessels during closure. Postoperatively, anticoagulants such as aspirin, nonsteroidal antiinflammatory drugs, heparin, and warfarin also increase the likelihood of postoperative bleeding and therefore should be used with care in the perioperative period. Finally, a host of disease processes may be present that may predispose patients to the development of hematomas, including myeloproliferative disorders, renal or hepatic insufficiency, deficiency of clotting factors, and platelet dysfunction.

Hematomas usually manifest by ecchymosis of the overlying skin, localized wound swelling, pain or pressure, and drainage of blood from the surgical site. The diagnosis can be confirmed by inspection, palpation, and gentle probing of the wound. If these measures prove insufficient, ultrasound evaluation can be useful to delineate the hematoma.[7]

In addition, large rectus sheath hematomas may manifest with signs of significant hemorrhage, including hemodynamic shock. Often these hematomas result in large ecchymoses that track subcutaneously a long distance from the patient's surgical site. Large hematomas that collect in the retroperitoneum or rectus sheath may cause paralytic ileus, anemia, and ongoing bleeding resulting from the consumption of coagulation factors. One of the most common problems associated with the development of a surgical hematoma is the risk of secondary infection. Blood is a good medium for growth of bacteria that may infiltrate the hematoma and result in a substantial surgical site infection (SSI).

PREVENTION AND MANAGEMENT

The most important factor in the prevention of wound hematoma is meticulous hemostasis at the time of closure of the subcutaneous tissue. Prevention is also facilitated by correction of all clotting abnormalities preoperatively and by discontinuing all medications that can prolong the bleeding time. In addition, wounds that involve large skin flaps or those with large potential spaces in which blood could collect should be drained with a closed-suction surgical drain until the output of these drains decreases. Management of wound hematomas is similar to management of wound seromas, discussed earlier.

Surgical Site Infection

Since the development of modern surgical technique and the innovations of Joseph Lister, surgeons have battled microbial infection. However, despite advances in antimicrobial therapy, aseptic technique, and perioperative patient management, SSIs continue to be the most common infectious complications suffered by surgical patients. Monitoring for these complications is even more complex because shorter hospital stays, outpatient surgery, and the mobility of patients who often see several physicians during the recovery period may affect the rates of complication reporting.[8] In healthy, nonobese patients, the overall SSI rate is estimated at 2.5% of all open surgical procedures, whereas this rate can be many-fold higher in patients with additional risk factors.

The impact of these infections is not insignificant. From an economic standpoint, patients with SSI often require extended hospital stays, additional nursing care, wound supplies, and possibly additional surgical procedures.[9] The estimated cost of this additional care can exceed $30,000 in patients with complicated infections.[10] Moreover, SSIs have significant quality of life implications for patients who may require weeks to months of additional treatment following a surgical procedure. Finally, some series have linked SSIs to an overall increase in postoperative mortality.[11,12]

DEFINITION

The term *surgical site infection* distinguishes a postoperative infection from a traumatic wound infection. The Centers for Disease Control and Prevention (CDC) developed a universal nomenclature for SSIs that involves categorization

according to the depth of infection (Fig. 9.2).[13] Infections that are confined to the skin and subcutaneous tissue (above the fascia) are considered *superficial incisional SSIs*. These infections account for the majority of all SSIs. Infections that involve the deep soft tissue (below the fascia) are termed *deep incisional SSIs*. Deep incisional SSIs include postoperative necrotizing fasciitis and osteomyelitis. Finally, an infection that involves an organ space that was manipulated during a procedure is termed an *organ space SSI*. Organ space SSIs may include peritonitis or other infections that involve the cavitary space entered during the procedure. Usually these infections are diagnosed within 30 days of the procedure. An exception to this rule is the case of implanted material, when SSIs are recorded up to 1 year from the surgical procedure and appear to be related to the operation.[13]

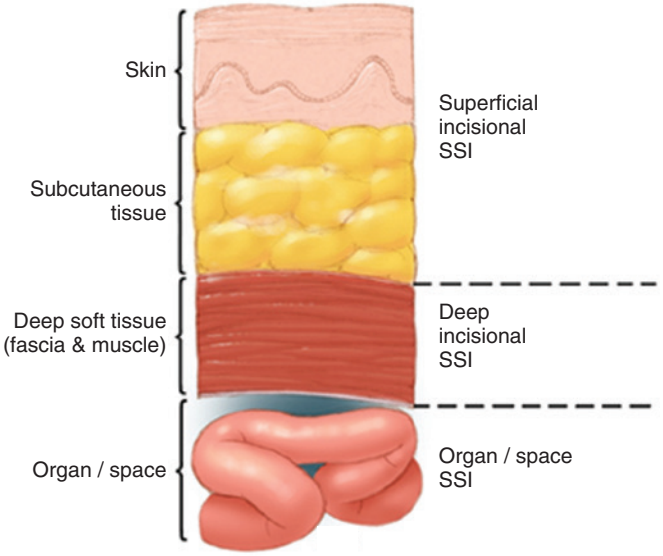

Figure 9.2 Centers for Disease Control and Prevention classification of surgical site infection (SSI). Superficial incisional SSIs are limited to skin and subcutaneous tissues and deep incisional SSIs involve muscle and fascia, whereas organ space SSIs include infections within the cavitary space of the procedure. (Copyright © 2007, Mayo.)

RISK STRATIFICATION

The development of an SSI depends on complex interactions between the pathogenic organism and the host's local and systemic defense mechanisms. Factors influencing the pathogenic organism include the virulence of the contaminating organism itself and the number of organisms inoculated into the wound. In 1964, the National Research Council (NRC) of the National Academy of Sciences reported on a study designed to evaluate the effect of ultraviolet irradiation on postoperative infections.[14] Although this study did not reach its desired end point, it was the first effort to categorize incisions based on the estimated degree of bacterial contamination. The four categories of incision described by the NRC (Table 9.1) remain the most widely accepted classification of surgical wounds to date, and the system remains useful to estimate the risk of SSI, predict pathogens, and determine the need for antimicrobial prophylaxis. This effort represented the first connection between the contaminating flora at various surgical sites and the subsequent infecting pathogens:

Class I, or clean, wounds: Those wounds in which only skin flora are likely to contaminate the operative field because no hollow viscus has been entered. The risk of infection in these cases is low (0.5–2%). A subset of class I wounds, class I_D, consists of wounds in which prosthetic material is implanted. These wounds are classified differently because, although the incidence of infection is also low, the consequences of the infection can be dire and may obviate the entire purpose of the procedure.

Class II, or clean-contaminated, wounds: Those wounds in which a hollow viscus likely to harbor bacteria is entered under controlled circumstances. In these cases, both skin flora and microbes within the viscus may contribute to the SSI and thus the incidence of infection is higher (2–5%).

Class III, or contaminated, wounds: Those wounds in which substantial microbial contamination exists and the risk of infection is even greater (5–15%), particularly if the skin is closed.

Class IV, or dirty-infected, wounds: Those wounds in which the wound is infected preoperatively and the organisms

Table 9.1 Surgical Wound Classification

Classification	Wound Description	Example	Definition
Class I	Clean	Varicocele ligation; herniorrhaphy	An uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, or uninfected genitourinary tract is not entered; in addition, clean wounds are primarily closed and, if necessary, drained with closed drainage
Class I_D	Clean; prosthetic material implanted	Penile prosthesis implantation	Same as class I (clean), with the exception of placement of prosthetic material
Class II	Clean-contaminated	Radical prostatectomy	Operative wounds in which the respiratory, alimentary, or genitourinary tract is entered under controlled circumstances and with minimal contamination
Class III	Contaminated	Radical cystectomy with stool spillage	Open, fresh, accidental wounds; in addition, wounds with a major break in sterile technique or gross spillage from the gastrointestinal tract and incisions in which acute nonpurulent inflammation is encountered
Class IV	Dirty-infected	Perineal debridement for Fournier's gangrene	Old, traumatic wounds with devitalized tissue and those in which purulent infection is encountered

causing the postoperative infection are presumed to be present before the surgical procedure.

In an effort to improve this risk stratification for SSIs the CDC introduced the National Nosocomial Infection Surveillance (NNIS) risk index.[15] The NNIS risk index incorporates additional patient- and procedure-related factors into the previously described wound classification. It is operation specific and assigns points based on patient-related risk factors (as defined by the American Society of Anesthesiologists preoperative assessment score), the duration of the operation, and the degree of microbial contamination of the incision. The duration of the operation is important because lengthy procedures may result in increased exposure to microbial contamination as well as compromised local defenses resulting from desiccation, hypothermia, and lower concentrations of prophylactic antibiotics.

Since the NNIS risk index was produced, additional risk factors for SSIs have been identified. For example, hypothermia has been identified as an independent risk factor for infection, and therefore maintenance of normothermia is an important aspect of intraoperative and postoperative care.[16] Strict glucose control has been independently associated with decreased wound infection rates as well as with decreased mortality in an intensive care setting.[17] Serum albumin level has long been identified as an important risk factor because it reflects a wide range of comorbid conditions that contribute to wound healing.[18] Other important risk factors are age, vascular insufficiency, diabetes, radiation, preoperative smoking, and obesity.

MICROBIOLOGY

Endogenous pathogenic organisms implicated in SSI most commonly come from the patient's skin, alimentary tract, or genitourinary tract. The patient's microflora may be altered by preoperative admission to the hospital. In fact, a demonstrable shift in the microbial environment toward more resistant bacterial species occurs within 48 to 72 hours of hospital admission.[9,19] Exogenous contamination can be minimized by strictly following aseptic technique and maintaining a sterile operating room environment.

The most common organisms isolated from surgical sites remain gram-positive cocci, specifically *Staphylococcus aureus* (Table 9.2). However, gram-negative infections are common in class II wounds. It is important to recognize the type of infection associated with various operative sites to select appropriate antimicrobial prophylaxis.

Table 9.2 Prevalence of Organisms Isolated From Surgical Sites

Organism	Percentage (%)
Staphylococcus aureus	26.9
Escherichia coli	18.8
Streptococcus epidermidis	10.1
Pseudomonas aeruginosa	9.6
Enterococcus faecalis	3.8
Enterococcus faecium	3.8
Proteus mirabilis	3.4
Candida albicans	3.0
Klebsiella pneumoniae	1.5

PREVENTION

Preoperative and Intraoperative Techniques

Prevention of infection in the surgical wound begins by reducing the potential number of microbial contaminants that have access to the wound. Therefore whenever possible, one should identify and treat all infections before surgical intervention. As discussed earlier, lengthy preoperative hospitalizations can increase bacterial antimicrobial resistance and can make any future SSIs more difficult to manage.[19] Patients should be encouraged to stop use of tobacco products for ≥30 days before the operation.[20]

The value of preoperative bowel preparation for reducing SSIs has been debated because several randomized trials[21–24] and meta-analyses[25] demonstrated an increased rate of anastomotic leakage and wound complications when mechanical bowel preparations were used. Indeed, evidence indicates that preoperative bowel preparation is associated with increased stool spillage intraoperatively.[26] Therefore we no longer routinely utilize mechanical bowel preparation for patients undergoing procedures involving bowel interposition.

When the patient reaches the operating room, surgical preparation should consist of an appropriate antiseptic agent for skin preparation. Removal of hair at the surgical site can create nicks and cuts in the skin that may become colonized and increase postoperative infection rates.[27] The CDC recommends that hair not be removed unless excess hair at the operative site would interfere with the operation.[13] When necessary, hair removal should be performed with clippers, rather than razors, because razors are associated with more frequent epithelial damage. Some evidence indicates that the hair should be removed as close to the surgical time as possible.

Intraoperative strategies to prevent wound infection include aseptic technique to reduce the microbial inoculum as well as good surgical practice to minimize dead space and devitalized tissue. An adequate preoperative surgical scrub of at least 2 to 5 minutes should be performed for surgical procedures. Instruments should be adequately sterilized, and efforts should be made to avoid breaks in aseptic technique. During the procedure, gentle handling of the tissue minimizes desiccation and necrosis that may serve as a nidus of infection. Electrocautery was thought to increase the incidence of wound complications because of devitalized tissue. However, more recent studies[28,29] did not show a relationship, and electrocautery may be used according to the surgeon's preference. Foreign bodies such as staples and sutures may provide a nidus of infection, and their use must be weighed against the risks of poor hemostasis and hematoma formation.

Antimicrobial Prophylaxis

The purpose of antimicrobial prophylaxis is to reduce microbial contamination of the incision and to decrease the

incidence of SSI. Surgeons have recognized the importance of antimicrobial prophylaxis in the prevention of SSI for many years.[30–32] For optimal prophylaxis, an antibiotic with a targeted spectrum should be administered at sufficiently high concentrations in serum, tissue, and the surgical wound during the entire time that the incision is open and at risk for bacterial contamination.[33]

To optimize the effectiveness of antibiotic prophylaxis, the antibiotic should be given approximately 60 minutes before surgical incision and dosed according to body mass. In lengthy cases, the antibiotic will need to be readministered approximately every two half-lives of the drug, at which point only 25% of the drug remains in active circulation. In cases with excessive blood loss, an additional dose should be given for every 4 U of estimated blood loss.

Antibiotics, when given in a prophylactic setting, should be discontinued within 24 hours of the procedure.[34] Antibiotics given too late (<30 minutes before surgical incision) do not reach effective tissue concentrations and are less effective in the prevention of SSI,[35] whereas antibiotics given too long afterward (>24 hours after the procedure) increase the incidence of bacterial resistance[36] and raise the economic cost of therapy[37] without decreasing the rate of SSI.

Prophylaxis is recommended for all class II (clean contaminated) wounds and for class I_D (clean) wounds in which prosthetic material or a vascular graft is implanted because the consequences of infection are serious in these instances. The routine use of prophylactic antibiotics is less clear in elective class I cases with no prosthetic material. In addition, patients with class III or IV wounds are considered to have an infected wound, and most of these patients are treated with antibiotics empirically.

DIAGNOSIS AND MANAGEMENT

Most SSIs manifest within 4 to 8 days of the surgical procedure. However, they may manifest within 30 days of the operation or up to 1 year in cases with implanted prosthetic material. This finding implies that, in the current medical environment of outpatient surgery or early discharge, most of these infections occur in the outpatient setting.[8] This implication emphasizes the importance of patient education in the postoperative period. Patients should be aware of the signs and symptoms of SSI and should know when to seek additional care.

The diagnosis of SSI is clinical and has been described for as long as surgical procedures have been performed. Classically, the most common symptoms have been described (in Latin) as *rubor* ("erythema"), *dolor* ("pain"), *tumor* ("induration"), and *calor* ("warmth"). Some patients may also note drainage from the wound or separation of the skin closure. If the SSI is not treated, systemic symptoms may develop, including fever (38–39°C), fatigue, leukocytosis, and increased heart rate.

The management of SSI depends on the extent and type of infection. Drainage and debridement have been and remain the cornerstones of management. Superficial SSIs are treated by opening the incision to provide adequate drainage. A small piece of saline-soaked gauze may be placed in the wound to serve as a wick and to prevent closure of the skin while allowing deeper aspects of the wound to heal by secondary intention. Wet-to-dry dressing changes have been a staple of wound care after SSI, although it may take several weeks to months for the wound to heal by secondary intention (see Fig. 9.1B). A culture and Gram stain may identify the offending organism, although these methods are not always necessary. In the setting of superficial SSI, antibiotics need be given only when patients are at risk for systemic dissemination of the infection. Severe infections, such as necrotizing fasciitis, represent surgical emergencies, and patients should be taken immediately back to the operating room for wide debridement. The identification of only "dishwater" pus, subcutaneous crepitus, or sepsis should alert the clinician to the possibility of necrotizing fasciitis. These infections progress rapidly and are caused by either *Clostridium perfringens* or group A β-hemolytic streptococci.

The development of vacuum-assisted closure has eased the process of multiple daily dressing changes (see Fig. 9.1C). Vacuum-assisted closure was designed to promote healing of large wounds by constant or oscillating application of negative pressure. This negative pressure promises to increase local blood flow, control exudates, and reduce edema of the surrounding tissue.[38–40] In our experience, these negative pressure techniques have proved useful in treating large, chronic wounds. However, their use should be limited when wounds are near conduits, anastomoses, and neobladders because in our experience, they may be associated with an increased rate of cutaneous fistula formation.

Wound Dehiscence

PATHOGENESIS AND CLINICAL FEATURES

Surgical wound dehiscence (see Fig. 9.1D) is one of the most alarming complications faced by abdominal surgeons. Put simply, a *dehiscence* represents the mechanical failure of wound healing and is defined as a separation of the facial layers early in the postoperative period. *Evisceration,* in turn, is a related term referring to the extrusion of peritoneal contents through the dehisced wound. Dehiscence is of great concern because it may rapidly lead to evisceration. Abdominal dehiscence with evisceration has been associated with a mortality rate nearing 50%.[41] When diagnosed early in the postoperative period, complete wound dehiscence almost always requires a return to the operating room for fascial closure or repair. However, small partial wound dehiscences that are diagnosed >2 weeks postoperatively may often be watched with delayed repair of the resultant incisional hernia, because the risk of evisceration is very low in such patients.

Unfortunately, wound dehiscence frequently occurs without warning. Up to 80% of the time, it manifests as sudden, dramatic drainage of a large volume of clear, serous fluid from the incision. Patients may also note a pulling or ripping sensation. This often occurs when the patient is standing or changing positions, because the pressure on the incision is greatest at these times. The diagnosis is then confirmed by gently probing the incision with a sterile, cotton-tipped applicator to determine the integrity of the fascia. If clinical suspicion remains despite equivocal physical examination findings, imaging studies such as

Table 9.3 Risk Factors Associated With Wound Dehiscence

Preoperative Risk Factors	Intraoperative and Postoperative Risk Factors
Malnutrition	Technical error with fascial closure
Anemia	Emergency procedures
Hypoproteinemia	Wound complications (infection, seroma, hematoma)
Obesity	
Comorbid disease (e.g., diabetes, renal failure, chemotherapy, irradiation)	
Increased intraabdominal pressure (e.g., coughing, straining, ascites)	
Advanced age	
Long-term corticosteroid use	

ultrasound or computed tomography can be used. When a large segment of the incision is open, immediate plans for closure in the operating room should be made. In the event of evisceration, the eviscerated intraperitoneal contents should be covered with a sterile saline moistened towel until an emergency operation can be performed.

Numerous factors can contribute to wound dehiscence (Table 9.3). However, despite advances in suture material and perioperative care, the incidence of abdominal fascial dehiscence has remained steady at nearly 1% of abdominal wounds.[42,43] Other factors that contribute to wound dehiscence remain. Obesity, for example, is associated with increased difficulty in identifying the fascia and in closing the incision. Corticosteroids, over long periods, can decrease the tensile strength of healing wounds.[44] Patients with cancer are more likely to have problems with wound healing, because these patients are more likely to have a contaminated wound and have undergone previous irradiation or chemotherapy.[45] Radiation causes obliterative sclerosing endarteritis that can decrease the microvascular arterial supply to the wound.[46] Malnourished patients nearly uniformly have decreased protein synthesis and turnover, which lead to poorer fascial integrity. Finally, diabetic patients encounter more healing problems than do patients without diabetes and have a greater risk of wound dehiscence.[41] The likely reason is that diabetic patients have less collagen synthesis and deposition, decreased wound breaking strength, and impaired leukocyte function.

SUTURE SELECTION AND TECHNIQUE

Wounds have <5% of normal tissue strength during the first postoperative week and may not ever develop normal tensile strength. In fact, studies have demonstrated that abdominal fascia regains 50% to 59% of this original tensile strength at 7 weeks and 70% to 90% at 20 weeks but may never exceed 93% of uninterrupted fascia.[47,48] Therefore initial postoperative wound security depends solely on suture strength and technique of closure.[49] As such, the choice of suture material is of critical importance in closing abdominal surgical wounds. The suture material should be strong enough to reapproximate the tissue and keep the wound intact during normal postoperative activity.

Numerous suture materials are available for wound closure. These sutures can be classified as natural or synthetic as well as rapidly absorbable, slowly absorbable, and nonabsorbable. Synthetic material has the advantages of being more uniform, inducing less tissue reaction, having greater tensile strength for a given diameter, and eliminating the risk of disease transmission. In 2001 the United Kingdom eliminated the use of catgut suture because of the risk of transmission of bovine spongiform encephalopathy (BSE, or mad cow disease).

Nonabsorbable sutures have been widely used to close abdominal incisions for many years. However, stainless steel wire and braided silk, once commonplace, have been replaced by more modern suture materials. Nonabsorbable monofilament sutures are associated with less tissue reaction[50] and more resistance to infection[51] than are absorbable sutures. However, they are associated with a higher incidence of sinus formation and long-term wound pain.[52–55] The primary benefit of nonabsorbable sutures is that they maintain tensile strength throughout the process of wound healing.

Absorbable sutures are designed to reapproximate the fascia through the initial phases of wound healing until the fascia itself has regained enough tensile strength. Rapidly absorbable sutures are not recommended for closure of abdominal incisions because this suture type has been demonstrated to have a higher incidence of wound dehiscence[56] and postoperative hernia formation[55,57] when compared with nonabsorbable sutures. However, slowly absorbable sutures, such as polydioxanone (PDS) and polyglyconate (Maxon), have been shown to cause less incisional pain and suture sinuses, with no effect on the long-term hernia rate. Additionally, these newer-generation monofilament sutures are more resistant to infection than are multifilament sutures.[58,59] They are degraded by hydrolysis and are not as subject to enhanced absorption resulting from bacterial enzymatic activity.[60]

When a suture is placed through the fascia in the operating room, wound dehiscence has three potential causes:

1. The suture may break
2. The knot may slip
3. The suture may cut through the tissue.

Several studies have demonstrated that suture breakage and knot failure are rarely the source of wound dehiscences, and in the majority of wounds that have dehisced, the suture and knots are intact but the suture has torn through the fascia.[49,61] This finding brings to light the importance of suture diameter because smaller-diameter sutures are associated with a greater likelihood of tearing through tissue.[43,62,63] Therefore most sutures used for abdominal wound closure are number 0 or larger. Additionally, the use of continuous running looped sutures has gained popularity as a method to increase the speed and tensile strength of wound closure. A double-looped closure has been demonstrated to be the strongest method of wound closure, but it has been associated with increased pulmonary complications, potentially because of decreased abdominal compliance.[43]

Surgical dictum states that sutures should be placed ≥1 cm from the fascial edge while advancing ≤1 cm with each throw. This recommendation results from concern for thermal injury related to the use of electrocautery on the fascial edge. Jenkins[64] demonstrated that the length of a midline laparotomy can increase up to 30% in the postoperative period as a result of elasticity and increased intra-abdominal pressure. Therefore it is important when closing using a running suture that the suture is of adequate length. Investigators have demonstrated that wounds that have been closed with a suture length that is twice as long as the wound have a higher rate of wound dehiscence[64] than do wounds closed with suture that is four times the length of the wound. This concept is referred to as the *suture-to-wound length ratio,* and a ratio of at least 4 : 1 provides good wound security.[65–68] Theoretically, this approach affords adequate approximation of the fascial tissues while minimizing the ischemic effects of increased tension along the suture line.

LAYERED VERSUS MASS CLOSURE

Layered closure of the abdominal wound involves separate closure of each of the distinct fascial layers with or without closure of the peritoneum. *Mass closure,* or Smead-Jones closure, is the closure of all layers of the abdominal wall, except the skin, as a single structure. Classically, this approach involved interrupted sutures. However, no benefit has been demonstrated over a continuous suture technique. Layered closure was believed to decrease intraperitoneal adhesions, increase wound strength, and promote hemostasis. These effects were especially noted with paramedian incisions,[69–71] which currently are used less frequently than are muscle-splitting midline incisions. However, several prospective, randomized studies[54,72] and large meta-analyses[57,73,74] demonstrated that layered closure is associated with higher rates of dehiscence and prolonged operative times as compared with mass closure. Separate peritoneal closure, in particular, has been associated with more intraperitoneal adhesions, increased operative times, and obscured fascial closure.[75–77] Furthermore, evidence indicates that the peritoneum re-epithelializes within 48 to 72 hours without closure,[78] and separate closure of this layer is unnecessary.

Retention sutures are sutures that are placed through all layers of the abdomen, including skin. They are often secured around a piece of rubber tubing and tied down (Fig. 9.3). Although historically they were used to decrease the incidence of abdominal dehiscence in patients at high risk, more recent studies did not demonstrate a beneficial effect on the rate of dehiscence. These sutures have also been associated with increased pain and inconvenience.[79]

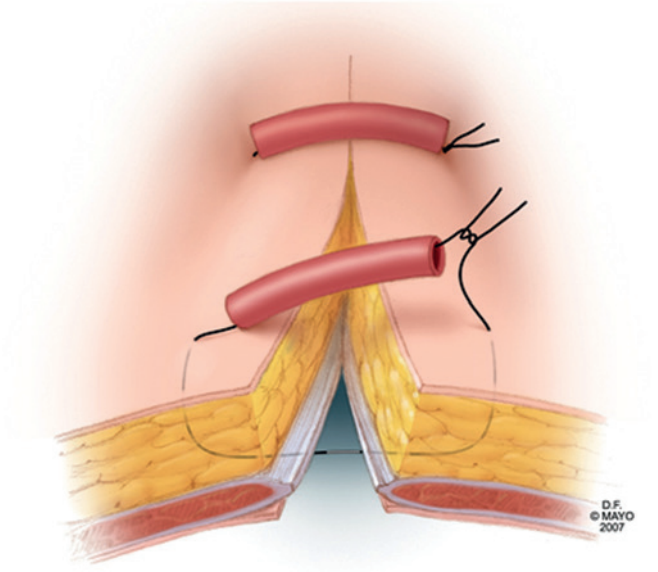

Figure 9.3 Retention sutures are placed through all layers of the abdominal wall and are secured around rubber tubing. (Copyright © 2007, Mayo.)

Nerve/Plexus Injuries

Nerve injury during urologic surgery may be caused by direct surgical trauma (i.e., nerve transection) or by stretch and compression of nerves from improper patient positioning or retractor placement. With regard to injuries caused by surgical trauma, all surgical incisions risk division of cutaneous sensory nerves and thereby may result in abdominal wall neuralgias or sensory deficits.[80] These complications are likely underreported by physicians, and therefore the incidence of such events is difficult to quantitate. The following discussion is a review of nerve injuries resulting from stretch and compression.

Improper patient positioning or retractor placement may cause stretch and compression of nerves that manifest as a deficit in postoperative neurologic function. In addition, ischemic injury compromising the blood supply of a nerve (i.e., ischemia of the intraneural vasa nervorum) may result in nerve injury as well.[81] Anesthetized patients have reduced muscle tone and are unable to report the discomfort of improper positioning, factors that place these patients at particular risk of injury. Although such nerve injuries are usually temporary, they significantly affect patients' quality of life and may result in permanently debilitating complications. For example, nerve injuries may limit postoperative ambulation and thereby increase the risk for thromboembolic events. Therefore a thorough understanding of the risk factors, presentation, and management of nerve injuries associated with common urologic procedures is essential for the urologic surgeon.

Although nerve injuries may occur during any of a variety of urologic procedures, the most common circumstances in which we have encountered these events involve brachial plexus injuries after surgery in the flank position, femoral nerve injuries from radical pelvic surgery, and lower extremity nerve injury from procedures in the lithotomy position. Therefore, these injuries are the focus of this section.

UPPER EXTREMITY NERVE INJURIES

Upper extremity nerve injuries during urologic surgery most often are the result of injuries to the brachial plexus, which contains the C5–T1 nerve roots and runs between the prevertebral fascia and the axillary fascia of the arm.

This plexus supplies multiple nerve branches including the musculocutaneous, axillary, radial, median, and ulnar nerves. The brachial plexus is particularly vulnerable to injury because of its lack of mobility, being fixed to the vertebrae, prevertebral fascia, and axillary fascia, as well as its proximity to bony structures, including the first rib, clavicle, coracoid process, and the head of the humerus.[82] Injuries to the brachial plexus may be the result of direct trauma, excessive stretching, external pressure, or a combination of these factors. In our experience, although brachial plexus injuries have been reported to result from excessive extension and external rotation during surgical procedures in the supine position (Fig. 9.4), including radical prostatectomy,[83] most brachial plexus injuries occur during procedures in the flank position, which is commonly used for procedures involving the kidney and retroperitoneum.

Given that the flank position is one of the most common positions for urologic surgery, we describe here our technique of flank positioning, which aims to achieve optimum operative exposure while avoiding neurologic injury (Fig. 9.5). After general anesthesia is established, patients should be placed in the lateral decubitus position with the nonoperative side against the operating table. The lower leg is then flexed at the knee and hip, the upper leg is kept straight, and pillows are placed between the knees to prevent contact of potential pressure points. Heels and knees are padded, and the patient is secured to the operating table using either cloth tape or Velcro straps. The head is padded as well to prevent angulation of the neck. Indeed, excessive dorsal extension or lateral flexion of the neck risks stretching of the brachial plexus to the opposite side of the patient between the fixed points at the transverse processes of the cervical vertebrae and the axillary fascia of the upper arm.[81]

The downside arm is then placed at an approximately 90-degree angle to the table and is secured to the armboard. Suspension of the upside arm (i.e., from an anesthesia screen, from a bar anchored to the operating table, or on blankets placed over the downside arm) must be done with care because excessive tension or abduction may stretch the brachial plexus around the clavicle and compress the nerves against the tendon of the pectoralis minor muscle.[81] A somewhat misnamed "axillary roll," which should more correctly be considered a chest roll, is then placed just beneath the true axilla. In fact, placement of this roll (we use a blanket) within the true axilla may result in compressive injury to the brachial plexus or vascular obstruction of the upper extremity.

After securing the patient to the bed, we then flex the operating table and raise the kidney rest, which should lie just above the iliac crest, until the muscles of the flank become tight.[81] This maneuver maximizes separation of the costal margin and iliac crest for surgery while minimizing the risk of vena caval compression.

Despite vigilant attention to patient positioning, injuries to the brachial plexus may occur during procedures in the

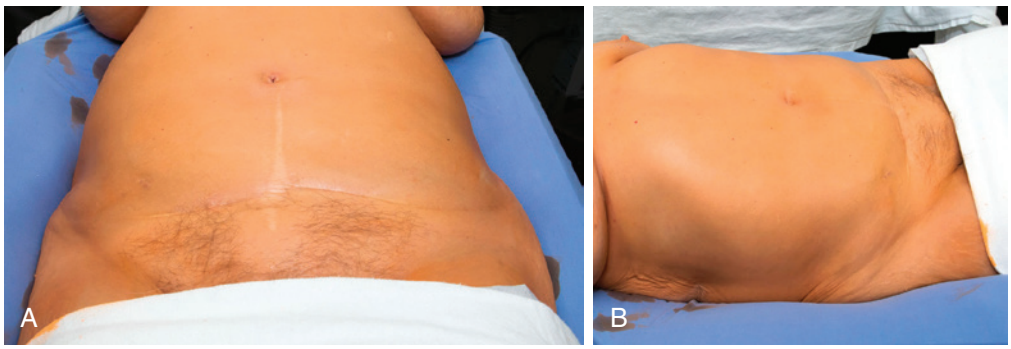

Figure 9.4 Supine position for midline approach. A, Anterior view. The arms are tucked at the sides and supported by toboggans. Figure 9.5 Flank position. A, Posterior view of flank position. The patient is placed in the lateral decubitus position with the head padded to prevent excessive neck flexion or extension. The lower leg is flexed at the knee and hip, with the heel and knee padded for protection. The upper leg is straight, and a pillow is placed between the upper and lower legs at the knees. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.) B, The lower arm is supported on a gel-padded armboard at an approximately 90-degree angle and secured. The upper arm is supported in a padded armrest. The torso is positioned so that the upper arm rests in a neutral position. An axillary roll is placed underneath the chest just below the axilla, and the table is flexed and the kidney rest raised to expand the flank. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

flank position. Injuries to the brachial plexus of the downside arm during flank positioning, for example, are most often compressive, although stretch injuries may occur if the dependent arm shifts position during the surgical procedure.[81] Brachial plexus injuries of the upside arm in the flank position, meanwhile, are most often the result of abduction, extension, and external rotation of the humerus that stretch the plexus around the clavicle, the tendon of the pectoralis minor, and the head of the humerus.[84]

The presentation of brachial plexus injuries varies somewhat with the level of injury but most often involves some degree of weakness of the affected upper extremity, including the deltoid, supraspinatus, biceps, brachioradialis, and triceps muscles, as well as the wrist and finger flexors and extensors.[82] Patients may also report decreased pinprick sensation along a dermatomal (i.e., C7–T1) distribution. Deep tendon reflexes of the biceps and brachioradialis muscles are characteristically absent on physical examination. Peripheral branches of the brachial plexus may be injured after their exit from the axilla, and these injuries may manifest as isolated nerve deficits; for example, the median and ulnar nerves can be damaged if the arm is allowed to hang unsupported over the edge of the operating table, whereas the radial nerve of the downside arm may be injured if the arm is pushed cephalad against the vertical bar of the anesthesia screen, thus compressing the nerve between the humerus and the bar.[81] The role of electromyography in the evaluation of patients with a suspected nerve injury is discussed further later in the section on femoral nerve injuries.

Management of a suspected brachial plexus injury includes careful neurologic examination, protection of potentially hypesthetic skin from injury, and physical therapy consultation to prevent muscle wasting.[82] Other treatments including intermittent galvanic stimulation to the affected muscle and surgical repair have been described.[82,85] We have seen considerable variability in the course of recovery of function after brachial plexus injury, from hours to months. Nevertheless, we, as others,[82,86] have noted that sensation consistently returns before motor function, and that the lower nerve roots recover function before the upper nerve roots.

LOWER EXTREMITY NERVE INJURIES

Various injuries to the nerves that innervate the lower extremities have been described during urologic procedures. These injuries include direct trauma to the nerves, such as intraoperative transection, injuries that relate to patient positioning, and injuries that result from retractor compression. Here, we separate the discussion into injuries of the femoral nerve, which may occur by any of these mechanisms but are most commonly the result of compression from retractor placement, and nerve injuries related to the lithotomy position that may involve the femoral nerve but often affect other nerves of the lower extremity.

INJURIES TO THE FEMORAL NERVE

The femoral nerve, which arises from the second through the fourth lumbar nerve roots, represents the largest branch of the lumbar nerve plexus. The femoral nerve is formed within the body of the psoas major muscle and then passes inferolaterally within the psoas before emerging just superior to the inguinal ligament, in a groove between the psoas and iliacus muscles.[87] The blood supply to the extrapelvic portion of the femoral nerve is the lateral femoral circumflex artery, whereas the intrapelvic component of the femoral nerve is supplied by the iliolumbar and deep circumflex iliac arteries.[88] A more extensive collateral blood supply to the right femoral nerve has been demonstrated,[89] a finding suggesting that the left femoral nerve may be more susceptible to ischemic injury than is the right.[88]

The femoral nerve contains both sensory and motor components, including the sensory branches of the anterior and medial femoral cutaneous nerve, as well as the long saphenous nerve. Motor innervation from the femoral nerve is provided to the psoas, iliacus, quadriceps femoris, pectineus, and sartorius muscles. Therefore injury to the femoral nerve may result in weakness of hip flexion, knee extension, adduction, and external rotation.[88,90,91] Clinically, femoral nerve injuries usually manifest as difficulty with ambulation in the early postoperative period. Patients whose injuries are not recognized before discharge commonly report difficulty in climbing stairs at home.[91] In addition, patients may report numbness and paresthesias of the anteromedial thigh.[92] On physical examination, weakness of the quadriceps muscles and diminished or absent deep tendon reflexes at the knee (patellar reflex) are consistent findings.

Femoral nerve injuries may result from patient positioning, retractor-related compression, or direct operative trauma. Direct injury is usually suspected intraoperatively, and careful inspection along the course of the nerve is recommended in such cases. Positioning-related femoral nerve injuries in urology have most consistently been reported from procedures in the lithotomy position,[93,94] and they are discussed in the next section.

The most common mechanism for femoral nerve injury during urologic procedures, however, is compression of the nerve by self-retaining retractors. This situation typically occurs during prolonged abdominal cases such as radical cystectomy, although injuries have been reported after radical prostatectomy and even perineal prostatectomy.[95] Retractor injuries occur when the blades of the retractor are placed directly on the psoas muscle, where they may compress the nerve directly or indirectly by trapping the nerve against the lateral pelvic wall (Fig. 9.6).[88] In addition, retractor blades may compromise the blood supply to the femoral nerve by compressing the iliolumbar artery.[92] Thin patients, in whom the retractor blades are more likely to compress the psoas muscle, are at particular risk for femoral nerve injury from retractor compression.[96] Moreover, the length of time of retraction has been correlated with the severity of nerve injury.[97] Therefore care should be taken to ensure that retractor blades retract only the rectus muscle and do not sit directly on the psoas muscle. Periodic inspection of retractor placement during the surgical procedure by placing the surgeon's fingers beneath the blades to ensure clearance off the psoas muscle is mandatory to avoid inadvertent compression injury.

The initial evaluation of a suspected femoral nerve injury includes careful documentation of the neurologic findings, along with physical therapy consultation. Immediate

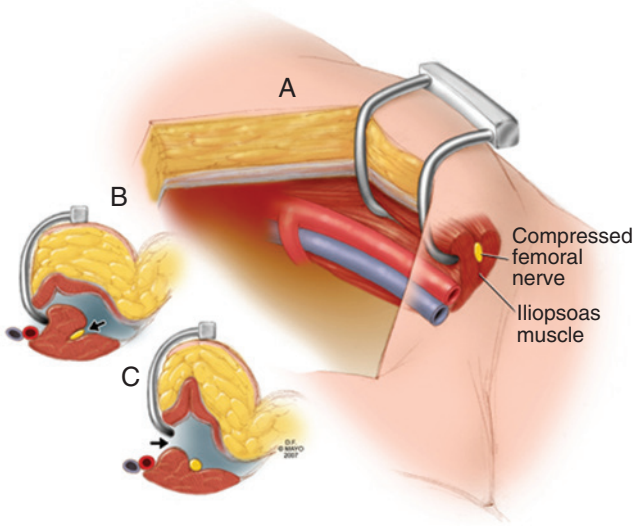

Figure 9.6 Common mechanism of femoral nerve injury by retractor placement. A and B, Compression of the femoral nerve by placement of the retractor along the iliopsoas muscle. C, Correct position of the retractor to retract the rectus muscle only. (Copyright © 2007, Mayo.)

physical therapy helps to prevent muscle atrophy and may decrease the risk of thromboembolic complications associated with prolonged bed rest.[96] Ambulation may be facilitated in the case of femoral nerve injury by locking the ipsilateral knee to compensate for the associated thigh muscle weakness.[88] Although most femoral nerve injuries in our experience are caused by retractor-related compression, nerve compression from pelvic or retroperitoneal hematomas has been described.[88,98] Therefore, if one clinically suspects bleeding, three-dimensional imaging should be obtained as well.

In the setting of a persistent postoperative nerve deficit clinically consistent with a femoral nerve injury, neurologic consultation and an electromyogram to evaluate for anatomic denervation are warranted. Electromyography should be performed ≥3 weeks from the time of injury to maximize its prognostic value.[99] Although the recovery process may be prolonged, compression-related nerve injuries usually resolve over time, and patients regain nerve function. Early return of function has been thought to correlate with full recovery,[91] and sensory lesions are more frequently transient than are motor lesions.

Prevention of femoral nerve injury is paramount because the consequences may significantly affect patients' quality of life. Vigilant attention to patient positioning, limiting surgical time, and periodically inspecting retractor placement are key to avoiding these injuries.

INJURIES RESULTING FROM LITHOTOMY POSITION

Standard lithotomy position requires the patients' legs to be separated from the midline into 30 to 45 degrees of abduction, with the hips flexed until the thighs are angled between 80 and 100 degrees. The patient's legs are placed into stirrups, with the knees bent such that the lower legs are parallel to the plane of the torso.[100] An understanding of potential postoperative complications related to this position is essential to the care of urologic patients. In addition to neurologic complications, which are discussed here, other complications that have been reported after procedures in the lithotomy position include lower extremity compartment syndrome, venous thrombosis, and rhabdomyolysis.[101,102] The frequency of perioperative complications may increase with an exaggerated or "high" lithotomy position because the angle of the hips and lower extremities in this position is even more pronounced.[103]

Neurologic injuries related to the lithotomy position may affect the femoral, sciatic, and common peroneal nerves. One series found that the most common lower extremity neuropathies associated with procedures in the lithotomy position were common peroneal (81%), sciatic (15%), and femoral (4%).[104] Other, less commonly injured nerves include the obturator and femoral cutaneous nerves. A study of 1170 patients operated on in the lithotomy position found postoperative neurapraxic complications in 1% of patients.[103] Age >70 years, operative time >180 minutes, and improper positioning were cited as risk factors for neurologic injury.[103] These findings were supported by a separate investigation, which noted lower extremity neuropathies in 1.5% of 991 patients undergoing procedures in the lithotomy position and found that prolonged (>2 hours) positioning in the lithotomy position was a risk factor for injury.[105] A previous study reported postoperative neurapraxia in 21% of patients undergoing perineal prostatectomy using the exaggerated lithotomy position.[106]

Positioning-related nerve injuries in the lithotomy position have been attributed to overflexion of the hips and knees, which causes stretching and compression of the nerves. For example, hyperabduction of the thighs with external rotation of the hips may lead to injury of the femoral nerve secondary to ischemia from compression of the nerve beneath the inguinal ligament.

The sciatic nerve, meanwhile, is the largest nerve in the body. It arises from the fourth lumbar through the third sacral nerve roots of the lumbosacral plexus and exits the pelvis through the sciatic foramen, traveling through the thigh before dividing in the popliteal fossa into the common peroneal and tibial nerves. The sciatic nerve functions to provide cutaneous innervation to the foot and leg, as well as motor innervation of the biceps femoris (hamstring muscle), leg, and foot.[107]

Excessive stretching of the sciatic nerve by overflexion of the hip and extension of the knee during establishment of the lithotomy position or by shifting of the patient during the procedure may result in injury. In particular, investigators have suggested that excessive hip flexion in the lithotomy position may compress the nerve as it passes through the sciatic notch, thus potentially resulting in ischemic neuropathy.[108,109] The potential sequelae of sciatic injury depend on the location of the insult along the course of the nerve. Injury to the thigh portion of the sciatic nerve, for example, results in difficulties with flexion of the leg, whereas disruption of the tibial nerve abolishes the ankle jerk reflex.

The common peroneal nerve arises from the sciatic nerve behind the knee and then wraps around the head of the fibula before separating into the superficial peroneal, which provides sensory innervation to the lateral leg, and the deep peroneal, which provides motor innervation to the tibialis

anterior that allows dorsiflexion of the foot. Because this nerve is very superficial when it crosses the head of the fibula, it may easily be compressed and injured at this point (i.e., by direct contact of the leg against an immobile, hard support). Therefore padding the lateral leg supports during positioning for lithotomy procedures is recommended. Injury to the peroneal nerve most commonly manifests as foot drop, resulting from an inability to dorsiflex the foot. In addition, patients may experience numbness of the lateral aspect of the lower leg and dorsum of the foot.[109]

Overall, nerve injuries during procedures in the lithotomy position may be minimized by careful attention to proper patient positioning, including padding of exposed peripheral nerves, avoiding unnecessary tension on the hips and knees by checking to see that the muscles of the lower extremity are not taut after the lithotomy position is established, and minimizing operative times. Modifications in stirrup design have also been proposed to help minimize the complications of lithotomy positioning.[110]

INJURIES RELATED TO POSITIONING FOR ROBOTIC SURGERY

Robotic-assisted surgery has undergone rapid dissemination in the last decade and is now the most frequently employed surgical approach for radical prostatectomy,[111] with increasing utilization for renal and bladder surgery as well. While robotic renal surgery may be performed in a modified flank position, robotic-assisted pelvic surgery poses unique considerations for patient positioning (Fig. 9.7) and presents new risks for positioning injuries.[112,113] Notably, the incidence of positioning injuries associated with robotic surgery may be greater than that in conventional laparoscopic or open surgery. For instance, a recent single-institutional study reported a 6.6% incidence of upper or lower extremity injury with robotic urologic surgery,[114] compared with 2.7% for conventional laparoscopic urologic surgery,[80] and 0.3% in open radical prostatectomy.[115] Interestingly, the rate of positioning injury may be greater with upper abdominal or retroperitoneal procedures.[80,114]

Robotic-assisted pelvic surgery is most frequently performed in a modified lithotomy position in conjunction with steep Trendelenberg.[112,113] The arms may be either tucked or abducted on armboards. Accordingly, robotic pelvic surgery carries risks of upper extremity nerve injuries analogous to those discussed above for the supine position, which include injuries to the brachial plexus, as well as median, ulnar, and radial nerves.[116] Careful attention must be paid to arm positioning, as one study noted that 84% of upper extremity injuries were associated with an extremity that was tucked or at the patient's side.[114] Lower extremity nerve injuries may occur from the lithotomy position as discussed above and may include injuries to the common peroneal, sciatic, and femoral nerves.[112,117] Increased operative time has been associated with an increased risk of such injuries.[80,104,118]

The use of steep Trendelenburg presents special considerations to attempts to prevent positioning injuries. For instance, the risk of cephalad patient movement requires careful attention to patient fixation on the operating table. The use of shoulder braces has been discouraged as they may increase the risk of brachial plexus injuries when used improperly.[112,117,119] Alternatively, some surgeons utilize a bean bag[114] or anti-skid material[119] to prevent cephalad migration. Our practice has been to use a gel pad, which when placed directly underneath the patient's back, provides resistance to cephalad migration on the operating table. In addition, the patient is secured using a padded chest strap and further stabilized by the feet anchored in stirrups (Fig. 9.7A).

Robotic surgery in the steep Trendelenburg position also poses unique considerations for the anesthesia team,

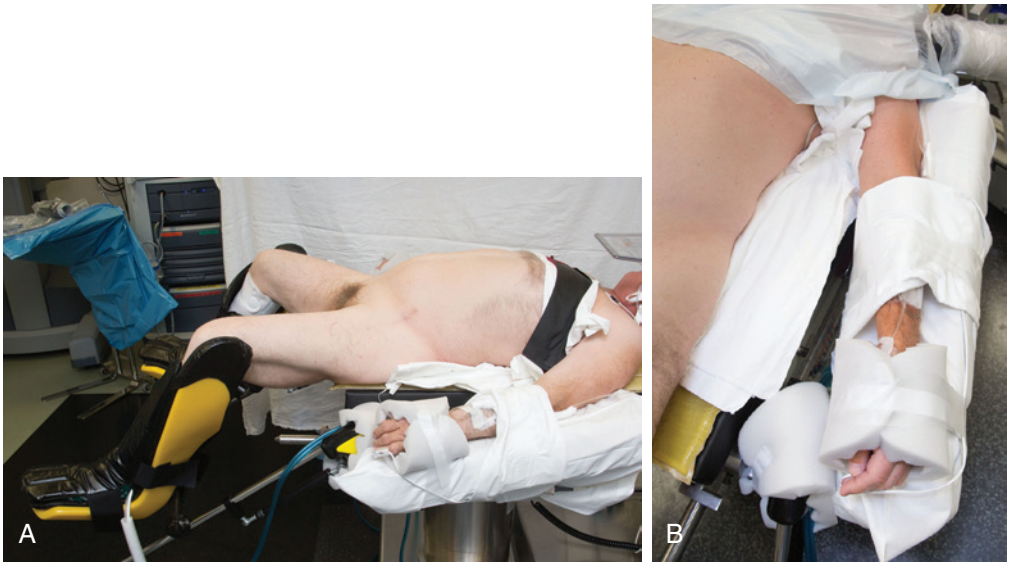

Figure 9.7 Modified lithotomy position for robotic-assisted radical prostatectomy. A, Overview of modified lithotomy position used for robotic-assisted radical prostatectomy. The patient is placed on a nonskid gel pad to prevent cephalad migration during Trendelenburg position and secured using a padded chest strap and stirrups. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.) B, The arms are positioned on padded armboards with minimal abduction, with Gelfoam used to protect the wrists. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

including increased difficulty with respiratory gas exchange and ventilation, cardiopulmonary changes related to pneumoperitoneum, and restricted access to the patient.[120–122] Communication between the surgeon and anesthesiologist is essential to ensure patient safety. Robotic surgery in the steep Trendelenburg position has been associated with vision loss from ischemic optic neuropathy.[117,123,124] The mechanism is hypothesized to be related to increased intraocular pressure (IOP) stemming from increased intracranial pressure and disturbed cerebrovascular and ophthalmic circulatory autoregulation.[120,125,126] Duration of surgery in steep Trendelenburg has been identified as a risk factor for increased IOP.

Compartment syndrome and rhabdomyolysis have also been reported related to positioning for robotic surgery.[113,125,127–130] The use of lithotomy position combined with steep Trendelenburg increases risk for both injuries due to direct pressure on muscles in conjunction with reduced perfusion from elevation of lower extremities above the level of the heart. Prolonged hypoxia from compartment syndrome may lead to rhabdomyolysis. Gluteal compartment syndrome has been reported from direct muscle pressure.[128] A recent population-based study of renal surgery reported an increased incidence of rhabdomyolysis with the robotic compared to laparoscopic approach.[131] Several studies have identified obesity and prolonged operative time as risk factors for compartment syndrome and rhabdomyolysis in robotic surgery.[127,130–132]

Prevention of robotic positioning injuries begins with careful attention to positioning of upper and lower extremities as discussed above and coordination with the entire operating room team.[133] Interestingly, a volume–outcome relationship has been described for positioning injuries, including positioning for robotic surgery,[80,118,134] highlighting that experience is an essential component to preventing such injuries. It is also important to recognize that some risk factors for positioning injuries, such as obesity, are not modifiable, whereas others, such as operative time and degree of Trendelenburg, may be modifiable. Specific suggestions for prevention of perioperative peripheral neuropathies have been outlined by the American Society of Anesthesiology.[135] In addition, side docking of the robot has recently been described as a novel approach to reduce risk of positioning injuries associated with either lithotomy position or steep Trendelenberg.[136]

Chapter 9 Questions

1. When closing fascial wounds using a running suture, the suture length should be at least ____ times the length of the wound:
   a. 1.5
   b. 2
   c. 3
   d. 4
   e. 6

2. Which of the following is not an important factor in reducing the incidence of surgical site infections (SSIs) after radical cystectomy?
   a. Antimicrobial prophylaxis given 60 minutes before incision
   b. Adequate mechanical bowel preparation
   c. Maintenance of normothermia during and after the procedure
   d. Length of preoperative hospitalization
   e. Redosing of the antimicrobial prophylaxis every two half-lives

3. What is the most common nerve injured by self-retaining retractors during open urologic procedures in the supine position?
   a. Common peroneal nerve
   b. Iliolumbar nerve
   c. Obturator nerve
   d. Sciatic nerve
   e. Femoral nerve

4. What is the most likely clinical manifestation of injury to the common peroneal nerve?
   a. Foot drop
   b. Weakness of flexion of the leg
   c. Weakness of hip extension
   d. Numbness of the posterior lower leg and ankle
   e. Weakness of hip adduction

5. Which of the following has been reported as a risk factor for positioning injuries related to robotic surgery?
   a. Steep Trendelenburg position
   b. Increased operative time
   c. Obesity
   d. Abduction of the arms
   e. All of the above

6. A 55-year-old obese male is planned to undergo robotic-assisted laparoscopic prostatectomy. He has a history of previous colon resection with postoperative bowel leak and abscess drainage, and thus prolonged lysis of adhesions is anticipated. The best technique to reduce the likelihood of calf compartment syndrome is:
   a. To carry out staged lysis of adhesions, with return to OR for prostatectomy
   b. To perform procedure in flat supine position, without Trendeleburg
   c. To use compression stockings
   d. To use side docking of the robot
   e. To administer subcutaneous heparin

7. In preventing dehiscence of fascial closure, which of the following techniques should be avoided:
   a. Mass closure
   b. Retention sutures
   c. Peritoneal closure
   d. Use of nonabsorbable suture
   e. Passage of suture 5 mm from cut fascial edge

8. The most common organism found in wound infection cultures is:
   a. *Escherichia coli*
   b. *Candida albicans*
   c. *Staphylococcus aureus*
   d. *Streptococcus epidermidis*
   e. *Klebsiella pneumoniae*

9. The procedure presenting the greatest risk for wound infection is:
   a. Radical prostatectomy
   b. Hydrocelectomy
   c. Penile prosthesis
   d. Cystectomy/ileal conduit
   e. Inguinal lymph node dissection

10. Potential consequences of steep Trendelenburg position utilized for robotic-assisted radical prostatectomy include all of the following except:
    a. Increased intraocular pressure
    b. Increased peak airway pressure
    c. Brachial plexus injury
    d. Hearing loss
    e. Vision loss

Answers

1. **d.** Fascial sutures should be placed at least 1 cm from the fascial edge while advancing no more than 1 cm with each throw. The length of a midline laparotomy may increase up to 30% in the postoperative period due to elasticity of the fascia and increased intraabdominal pressure. Several studies have demonstrated a higher rate of dehiscence and hernia formation when the length of suture used to close the wound is less than four times the length of the wound itself.
2. **b.** Several randomized trials have failed to demonstrate an improved rate of SSI with the use of mechanical bowel preparation. Instead, it may be associated with a higher rate of stool spillage during the procedure. All of the other factors listed have been associated with decreased rates of SSIs.
3. **e.** The femoral nerve arises from the second through fourth lumbar nerve roots. It is then formed within the psoas major muscle and emerges superior to the inguinal ligament. It is most commonly injured by retractors during prolonged abdominal cases when the nerve is compressed against the lateral pelvic wall. The common peroneal nerve is located in the lower extremity. The sciatic nerve arises from the fourth lumbar to third sacral nerve roots and exits the pelvis through the sciatic foramen. It may be injured during the

dorsolithotomy position. The obturator nerve is not commonly injured because of retractor positioning.

4. **a.** The common peroneal nerve is the most common nerve injured in the lithotomy position. It provides motor innervation to the tibialis anterior, which allows dorsiflexion of the foot, and sensory innervation to the lateral leg. Injury to the sciatic nerve results in difficulties with flexion of the leg, whereas weakness of hip extension may be caused by injury to the femoral nerve.
5. **e.** Robotic-assisted surgery has been associated with increased risk of positioning injuries. The use of steep Trendelenburg position may result in patient movement on the operating table, increased pressure on nerves and muscles, and elevated intraocular pressure. Prolonged operative time, obesity, and abduction of the arms have also been associated with increased risk of positioning injuries.
6. **d.** By side docking the robot, the legs can be placed supine rather than in stirrups, thus reducing the risk of calf compartment syndrome due to compression. While avoidance of Trendelenburg position would reduce the risk of positioning injury to the upper extremities, the procedure would not be feasible. Compression stockings and subcutaneous heparin reduce the risk of venous thromboembolic complications, but not compartment syndrome.
7. **e.** Of the listed factors, peritoneal closure and retention suture utilization have been theorized to reduce fascial dehiscence though the benefit of peritoneal closure is unclear. Mass closure has been demonstrated in multiple studies to have lower dehiscence rates than does layered closure. Use of nonabsorbable suture has not been associated with fascial dehiscence and is thought to be preferable to the use of rapidly absorbing sutures. Placement of sutures too close to the fascial edge risks tearing of the fascia, either upon tying the stitch or upon strain in the postoperative setting. This is the most common cause of dehiscence.
8. **c.** The organism most commonly found in wound infections is *Staphylococcus aureus*. Gram-negative organisms are less commonly found, but are frequently encountered in bowel and bladder surgery.
9. **d.** Hydrocelectomy, penile prosthesis, and inguinal lymph node dissection would all be considered "clean" procedures with low risk of infection upon proper observance of aseptic techniques. Both prostatectomy and cystectomy are considered "clean-contaminated" since a hollow viscus potentially harboring bacteria is opened during the case. Cystectomy with ileal conduit diversion carries the highest risk of infection given the exposure of the field to both urinary tract and bowel contents. Infectious risk would be greatest in the setting of excessive or gross fecal spillage.
10. **d.** Steep Trendelenburg position, commonly utilized in pelvic robotic-assisted laparoscopic procedures, is associated with increased peak airway pressure due to elevation of the diaphragm, increased intraocular pressure, and brachial plexus injury if shoulders and upper extremities are not supported. Vision loss has been reported as a result of ischemic optic neuropathy as a result of increased intraocular pressure, but hearing loss has not been directly linked.

10 Management of Vascular Complications in Urology

SCOTT LUNDY and VENKATESH KRISHNAMURTHI

CHAPTER OUTLINE

Introduction
Overview
Instruments and Supplies
Instruments for Dissection
Instruments for Vascular Control and Repair
Endovascular Instruments
Hemostatic Agents
Causes and Prevention of Vascular Injuries
Causes of Vascular Complications
Types of Vascular Injuries
Identification of Vascular Injuries
Initial Management of Bleeding
Definitive Operative Management of Vascular Injuries
Anticoagulation
Embolectomy
General Principles of Vascular Repair
Approaches to Definitive Repair
Complications of Vascular Injuries
Pelvic/Retroperitoneal Hematoma
Thrombosis and Embolization
Arteriovenous Fistula
Stenosis
Specific Cases of Vascular Injury
Laparoscopic Access Injuries
Arterial Injuries
Aortic Injuries
Visceral Artery Injuries
Thoracic and Lumbar Segmental Artery Injuries
Iliac Artery Injuries
Venous Injuries
Inferior Vena Cava Injuries
Renal Vein Injuries
Hypogastric (Internal Iliac) Vein Injuries
Lumbar Vein Injuries
Inferior Vena Cava Tumor Thrombus
Chapter 10 Questions and Answers

KEY POINTS

1. Vascular injuries are a common type of major intraoperative complication in urology and occur in open, minimally invasive, and even endourologic procedures.
2. A thorough understanding of vascular anatomy and rigorous preoperative planning can minimize, though not entirely exclude, the possibility of an intraoperative vascular injury.
3. Even experienced surgeons encounter vascular complications, and, if unidentified or inadequately repaired, these injuries can have catastrophic consequences.
4. Following control of brisk bleeding, surgeons should pause to reorient themselves and reestablish situational awareness in order to prevent further complications.
5. Well-executed digital pressure can temporarily control nearly all sources of abdominal bleeding.
6. Vascular complications should be identified quickly and managed decisively, and surgeons should not hesitate to convert laparoscopic or robotic cases to open surgery upon injury to major vascular structures.
7. Repair should focus on ensuring tension-free repair and adequate luminal diameter and prevention of embolic and thrombotic complications.
8. Occlusion of the left renal vein does not cause venous hypertension due to collateral drainage, whereas occlusion of the right renal vein may result in venous hypertension, acute tubular necrosis, and renal insufficiency.
9. If not experienced in vascular surgical techniques, surgeons should consider intraoperative consult to vascular surgery or transfer to a tertiary care center if indicated.

Introduction

OVERVIEW

From open surgery to minimally invasive procedures and even endourology, vascular complications truly span the spectrum of urologic interventions and can result in significant short- and long-term morbidity and mortality. This chapter will discuss techniques and approaches to preventing, identifying, and managing intraoperative and postoperative vascular complications in urology and is intended to be a broad overview of the topic. While the chapter will reference laparoscopic, robotic, and endourologic concepts and injuries, the majority of this discussion will focus on traditional open surgical techniques, and the reader is directed to the respective chapters focusing on these other modalities for further information.

Representing 40% of all major intraoperative and postoperative laparoscopic urologic complications,[1] hemorrhage from vascular injury is the most common cause of morbidity and mortality in the perioperative period. While the exact nature of these injuries varies with the specific case and surgical approach, the incidence of hemorrhage requiring transfusion reported in the literature varies from 0.3%[2] for percutaneous nephrolithomy to 52% in one cohort undergoing radical retropubic prostatectomy.[3] As with any surgical procedure, complication rates vary with the nature of the procedure, patient comorbidities and anatomy, and surgeon experience. Interestingly, while intraoperative blood loss was strongly inversely correlated with surgeon experience, major vascular injuries appeared to occur with equal frequency in both novice and experienced surgeons.[4] This finding underscores the need for all surgeons, even those with significant experience, to follow key surgical principles such as careful tissue handling and meticulous dissection.

If a catastrophic vascular injury does indeed occur, surgeons must be willing to act decisively and take appropriate steps to control the bleeding and prevent exsanguination. Often, this includes rapid conversion of minimally invasive procedures to open surgery for direct control and subsequent repair of bleeding. Furthermore, these situations require clear and constant communication with the anesthesia team should it be necessary to implement aggressive resuscitation measures with intravenous fluids, blood products, and vasoactive medications. Even if the senior urologic surgeon is experienced in vascular repair, emergent intraoperative consultation to vascular surgery is often prudent and warranted. Finally, if the surgeon is practicing in a clinical setting where extensive resources including ICU critical care medicine are unavailable, damage control surgery (e.g., rapid identification and temporization of bleeding, abdominal packing, and temporary abdominal closure) and emergent transfer to a tertiary care referral center may be warranted.

Instruments and Supplies

Vascular surgery is a technically demanding surgical discipline requiring numerous surgical supplies in order to be performed correctly. While the entire gamut of instruments and supplies may not be available in an emergent setting, the surgeon should at a minimum have at his or her disposal a series of vascular instruments necessary for dissection, vascular control, and anastomotic repair.

INSTRUMENTS FOR DISSECTION

Dissection, particularly when conducted in close proximity to major vessels, is conducted bluntly using right angle clamps and/or sharply using vascular forceps with Metzenbaum or Church scissors. Vascular forceps are critical for active manipulation of vessels and surrounding tissue. These typically have small rows of interlocking serrations capable of atraumatically grasping even thin-walled veins if used appropriately. Right angle forceps provide a useful tool to encircle vessels and dissect a window for vessel loop or vascular clamp placement. Initial superficial dissection and/or rapid dissection away from critical structures can often be conducted using electrosurgical instruments. While traditional hemostatic surgical instruments such as electrocautery are still indispensable, newer devices that apply bipolar current (Ligasure, Covidien, Dublin, Ireland) or ultrasonic energy (Harmonic scalpel, Ethicon, Somerville, NJ) can also be used to rapidly dissect with good hemostasis. Caution must be used, however, as these devices are capable of significant vascular injury if used carelessly or inappropriately.[5,6] Finally, next-generation devices that use radiofrequency (Aquamantys, Medtronic, Dublin, Ireland) or argon gas (ABC system, Conmed, Utica, NY) show promise in providing superficial hemostasis. It must be noted, however, that none of these devices are capable of controlling hemorrhage from a major blood vessel, and use of these devices in the setting of uncontrolled hemorrhage, while tempting, will likely worsen the injury and exacerbate the problem.

INSTRUMENTS FOR VASCULAR CONTROL AND REPAIR

Vessel loops are brightly colored Silastic loops that can be placed proximally and distally and assist in rapid identification and, if necessary, atraumatic temporary occlusion of the vascular structure of interest until an appropriate vascular clamp can be applied. Vascular clamps are available in a wide variety of shapes and sizes for various applications and are designed to occlude vessel flow without traumatizing the vessel walls. These clamps can be categorized by their intended functionality; fully occlusive transverse clamps (Fogarty, Debakey, Wylie, Henly, etc.) are intended to occlude the entire vessel lumen, whereas partially occlusive side-biting clamps (Satinsky, Cooley, Lemole-Strong, etc.) are used to preserve partial flow while excluding a region of damage for repair. Bulldog clamps can also be useful in some settings, particularly where small vessels are involved and must be temporarily occluded. Potts scissors and aortic punches can then be used to create, modify, and/or prepare an arteriotomy or venotomy for subsequent repair. Needle holders are then used to grasp the appropriate suture/needle and conduct the repair. While the specific needle drivers used (Castroviejo, Jacobson, Cohan, etc.) vary widely according to surgeon preference, at a minimum they must be able to accurately control small-caliber

sutures and place the needle accurately in the intended tissue.

The suture used for vascular repairs is typically nonresorbable to provide adequate tensile strength until the vessel heals. One exception to this rule is in pediatric applications, where a slowly absorbable suture such as PDS (polydioxanone) can be used to facilitate future growth at the anastomotic site. Most commonly, these sutures are monofilament and composed of polypropylene (Prolene, Ethicon Inc, Somerville, NJ; Surgipro, Covidien Inc, Dublin, Ireland) or polytetrafluoroethylene (GORE-TEX, Newark, DE). Suture size varies with the specific application, but typically 2-0 to 3-0 suture is chosen for aortic reconstructions, 5-0 is used for renal and iliac repair, and 7-0 is appropriate for small vessel work. Sutures are usually double-armed with a tapered needle swaged at both ends of a continuous suture to allow for continuous suturing bidirectionally from the apex of the defect toward the opposite apex, where they can be tied to each other.

ENDOVASCULAR INSTRUMENTS

The Fogarty thromboembolectomy catheter is a key device with several useful features and applications in vascular surgery. Briefly, these catheters consist of a long catheter with a distal balloon that can be inflated and deflated manually to the proper diameter corresponding to the vessel of interest. In the setting of uncontrolled bleeding, these catheters can be placed directly into a bleeding vessel and inflated to the proper size to occlude the vessel until a more permanent solution can be employed. Standard Fogarty catheters range in size from 2F to 10F; for example, a 5F balloon is appropriate for iliac vessels. Following anastomosis, these catheters can also be used to remove any distal thrombus or emboli that may be present. To accomplish this, the catheter is inserted to a point far proximal or distal to possible thrombus, inflated with saline (or air for 2F balloons), and slowly withdrawn to expel the vessel contents into the operative field. Care must be taken to avoid overpressurizing the balloon, however, and causing endothelial damage and further thrombosis.

It is also worth mentioning that Fogarty occlusion catheters are also available for situations where endovascular occlusion is necessary. These catheters are available in balloon diameters ranging from 5 mm to 45 mm. If used properly, these catheters are capable of temporarily occluding nearly any vessel (including the abdominal aorta) to facilitate diminished blood loss and subsequent vascular repair in a bloodless field.

HEMOSTATIC AGENTS

A number of hemostatic agents are now available for rapid hemostasis in the setting of diffuse and/or uncontrolled bleeding (Table 10.1). Gelatin-based (Gelfoam, Pfizer, New York, NY), oxidized cellulose-based products (Surgicel, Ethicon, Somerville, NJ), and polysaccharide spheres (Arista, Bard Davol, Warwick, RI) all provide a physical matrix for clot formation to occur, but each has potential drawbacks (e.g. gelatin can swell and cause tissue compression, polysaccharide spheres also swell and are relatively contraindicated in diabetics, and cellulose can cause localized tissue acidosis). Other agents such as thrombin (Evithrom, Ethicon) and fibrin (Tisseel, Baxter, Deerfield, IL; Evicel, Ethicon) achieve hemostasis via active participation in coagulation and may be useful in controlling venous or even small arterial bleeding vessels or in damage control settings. Newer products derived from chitin and chitosan (HemCon Patch, HemCon, Portland, OR) have now recently become available, though data on effectiveness remain limited. Unfortunately, none of these products are able to stem blood loss from a significant defect in a major artery. If more extensive bleeding is present, surgical clips, including titanium clips and/or Weck polymer clips (Teleflex, Limerick, PA), are often used to control small- to medium-sized vessels rapidly if the vessel can be visualized and accessed. These clips can subsequently be removed if necessary to allow for a more definitive repair. Studies have shown that both of these solutions offer satisfactory hemostasis, even on larger vessels such as the renal artery.[7] It should be noted, however, that the use of Weck or Hem-o-lok clips is contraindicated in living donor nephrectomy because three deaths occurred from clip displacement and hemorrhage.[8]

Causes and Prevention of Vascular Injuries

CAUSES OF VASCULAR COMPLICATIONS

Surgical errors can occur preoperatively, intraoperatively, and postoperatively and can have devastating consequences on patient morbidity and/or mortality. While previous studies have invoked numerous specific causes for surgical errors including excessive workload,[9] sleep deprivation,[10] and poor communication,[11] most intraoperative vascular complications can be fundamentally categorized within three domains (Fig. 10.1): (1) technical errors, (2) cognitive factors, and (3) biologic characteristics. Within this framework, technical errors are most common[12] and encompass incidents such as inadequate tissue dissection and exposure leading to inadvertent vessel damage,

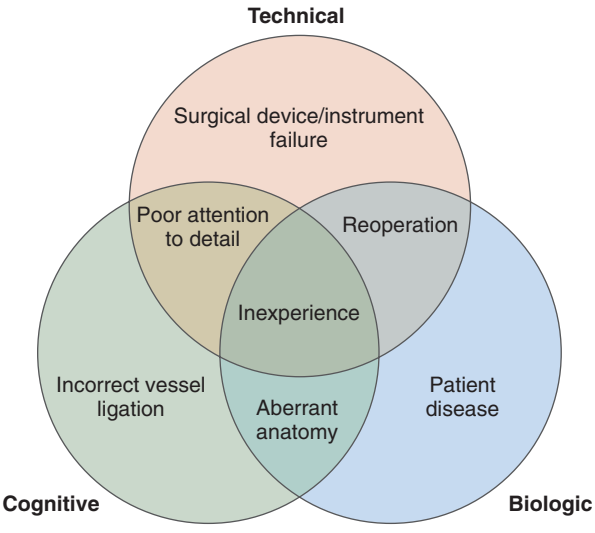

Figure 10.1 Domains of surgical error causes with examples listed within each category.

Table 10.1 Comparison of Commercially Available Hemostatic Agents Grouped by Category, With Advantages and Disadvantages Listed for Each

Category	Name	Description	Examples	Advantages	Disadvantages
Passive Mechanical Agents	Gelatin	Highly absorbent purified porcine hydrocolloid	Gelfoam Surgifoam	Low cost, off-the-shelf, room temperature storage Easy to work with and pliable	Can swell extensively and cause neighboring tissue damage, cannot be used for skin closure
	Oxidized regenerated cellulose	Dry absorbable alpha-cellulose mesh causing platelet adhesion and intrinsic pathway activation, low pH causing vasoconstrction	Surgicel	Can be rolled, cut, and manipulated Can be applied to anastamoses or organ surfaces Bactericidal (low pH)	Can swell extensively and cause neighboring tissue damage, can impair bone healing
	Collagen	Scaffold for clot formation and platelet activator	Ativene	Numerous formulations (sheets, powder, sponge, etc.) Rapid, easy to use Stored at room temperature	Cannot be used in blood scavenging systems (risk for DIC), cannot be used for skin closure
	Microporous polysaccharide spheres	Potato starch-derived, acts to remove water and concentrate platelets/proteins	Arista	Low cost, no preparation needed No increased risk for infection or foreign body reaction Rapid absorption (48 hr)	High sugar content; use with caution in diabetic patients
Active Biologic Agents	Thrombin	Converts fibrinogen to fibrin, directly catalyzing coagulation	FloSeal	Liquid application No inhibition by urine Can be used on arterial bleeding	Expensive, requires mixing
	Fibrin	Fibrinogen/factor XII and thrombin/calcium solutions that, when mixed, form fibrin clot	Tisseel, Evicel	Can be used on arterial bleeding No mixing required Rapid hemostasis	Must be thawed and mixed prior to use, risk of immune reactions
Other Agents	Chitosan-based	Natural polymer causes erythrocyte aggregation and platelet activation	HemCon	Rapid deployment, room temperature storage	Contraindicated in patients with shellfish allergies
	Cyanoacrylate-based	Free radical polymerization	Dermabond	Rapid exterior hemostasis (e.g. skin closure)	Cannot be used on mucosal surfaces
	Glutaraldehyde-based	Glutaraldehyde cross links albumin to wound	BioGlue	Can be used on moderate arterial bleeding	Expensive, possibly mutagenic, hypersensitivity reactions
	PEG-based	Polyethylene glycol polymerization	Coseal	Fast-acting	Can swell extensively and cause neighboring tissue damage
	Tranexamic acid	Synthatic lysine analog that blocks plasminogen and fibrinolysis	Cyklokapron (TXA)	IV administration (can be used postoperatively)	Ocular side effects, rare cases of anaphylaxis

instrument failure causing hemorrhage (e.g., endovascular stapler malfunction[13]), or careless/aggressive dissection causing traumatic injuries to fragile structures. Isolated biologic factors including aberrant anatomy and/or advanced disease processes can also deceive even the most cautious and experienced surgeons. For example, a recent case report described the development of significant scrotal edema following left living donor nephrectomy and large gonadal vein ligation in a patient with a known duplicated infrarenal inferior vena cava.[14] Bridging the domains of biologic and technical causes, patient characteristics such as morbid obesity or prior abdominal surgeries can make an otherwise straightforward case far more complicated. Gabr et al. showed that morbid obesity was associated with a 21-fold greater likelihood of conversion from laparoscopic to open radical nephrectomy,[15] and a recent study by Seifman and colleagues demonstrated that abdominal operations in patients with a prior abdominal surgical history were associated with longer mean hospital stay and higher rate of complications but surprisingly no difference in mean operative time.[16]

Perhaps the most insidious of these potential sources of complications is the cognitive domain and what can be best described as lapses in clinical judgment. These are likely the most difficult to accurately identify and minimize because of human nature and the difficulty in introspectively identifying and acknowledging these as a surgeon. Data from malpractice claims for surgical errors in Belgium showed that 57% of lawsuits with medical mistakes were directly attributable to errors in judgment.[12] These errors can be clustered as oversights in situational awareness and/or poor decision making.[17]

Central to all three of these domains, however, is surgeon experience. A recent case series of robotic-assisted radical cystectomies with intracorporeal neobladder highlighted the importance of experience in minimizing operative time and complication rate. The study showed that as the surgeons became more familiar with the operation over their

first 67 cases, operative time dropped by nearly 40%, conversion to open surgery dropped by 30%, and complications fell by 40%.[18] These data underscore the ability of experience to potentially mitigate some of the risk associated with aberrant biology and/or difficult judgment calls based upon limited information.

Types of Vascular Injuries

From minor puncture wounds to complete transection of the aorta,[19] iatrogenic vascular injuries in urologic surgery occur in both arteries and veins and truly span the gamut of morbidity. Injuries can occur from a variety of traditional open surgical instruments (scalpels, dissecting scissors, forceps, electrocautery, staplers[13,20]), minimally invasive surgical instruments (Veress needles,[21–23] trochars,[24] needle carriers[25]), and even endoscopic instruments (ureteroscopes[26,27] and JJ ureteral stents[28]). These instruments can be responsible for injuries of various types, including punctures, lacerations, transections, and avulsions. Punctures occur particularly frequently during laparoscopic or robotic port placement (e.g., Veress needle puncture of the iliac artery[21]) and vary in severity from small-caliber needle puncture wounds to the epigastric vessels to trochar injuries to the aorta[25,29–31] and/or IVC[32] that require immediate conversion via laparotomy. Lacerations[33] represent perhaps the most common form of vessel injury during the dissection phase of the operation and typically occur from sharp dissection with dissecting scissors or more commonly with electrocautery. These injuries can commonly be repaired primarily. Transection injuries,[34] on the other hand, are typically more severe and require more extensive repair. Avulsion injuries[35] can represent possibly the most complex injuries to repair, as they most commonly involve a major venous structure (e.g., lumbar vein to IVC) and require extensive mobilization of poorly visualized structures and considerable skill to repair.

Identification of Vascular Injuries

The rapid identification of iatrogenic vascular complications is critical to minimize blood loss and ensure the best possible outcomes for patients who suffer an arterial or venous insult. In many cases the presence of a vascular injury is self-evident. The acute loss of surgical field visualization due to the rapid accumulation of blood and/or the visual identification of blood spraying from a vessel wall defect are obvious signs of the presence of a problem. In other cases, however, the findings can be subtle and include the presence of a pulsatile hematoma (particularly in the retroperitoneal space) or the gradual distention of the abdomen in the postoperative period. While these findings may appear to be less pronounced or dramatic, the consequences of missing such a sign are every bit as severe. Nausea and vomiting may also be present. Finally, intraoperative or postoperative bleeding can often also be identified via changes in vital signs and hemodynamic instability. Classically, the first signs of hypovolemic shock are isolated tachycardia, anxiety, and low urine output,[36] but caution must be taken when interpreting data based solely upon the presence or absence of these findings, as a significant proportion of surgical patients will be on pharmacologica agents such as beta-blockers and may not have the capability to mount an appropriate physiologic response to biologic stress. If left unchecked, ongoing volume losses will eventually lead to hypotension, signs of end-organ dysfunction, and circulatory collapse.

If the rate of bleeding is less catastrophic, then the only evidence for ongoing losses may be a gentle drift in the hemoglobin and hematocrit on daily labs. This can often be difficult to interpret in the setting of significant postoperative fluid shifts and crystalloid resuscitation, and a high index of suspicion is often necessary. Imaging studies may also play a role if ordered in a timely fashion. Plain film examination of the abdomen has little role in the diagnosis of acute bleeding, but cross-sectional imaging can sometimes aid in the identification and location of bleeding.

Initial Management of Bleeding

Upon identification of rapid intraoperative bleeding, the surgeon should attempt to rapidly identify the source of bleeding while simultaneously minimizing blood loss and achieving relative hemostasis (Fig. 10.2). If the damaged vessel is small and clearly visualized, then electrocautery may be a viable first choice. If the bleeding is more substantial and visualization becomes impaired, the surgeon should consider adding a second suction device for visualization purposes while simultaneously continuing to work to control the bleeding. In some situations the source of bleeding is not easily appreciated and the rate of blood loss is not immediately life threatening; these circumstances may favor aggressive wound packing with sponges to allow for the coagulation process to stem the bleeding in time. When successful, the removal of these sponges will demonstrate a dramatic improvement (or even cessation) of bleeding, and the damage can then be definitively repaired if necessary.

If the vessel is large, however, and the source of bleeding has not been well dissected, then the use of the Bovie is likely to obfuscate the tissue planes/structures, cause further vessel damage, and ultimately make subsequent repairs far more difficult. A better option in these circumstances is to apply direct pressure to slow the bleeding. In open surgery, this is best accomplished using digital pressure for a variety of reasons. First, the use of a finger or hand to stem the bleeding is rapid and does not require any specialized equipment to be passed into the operating field. Second, the technique is easy and intuitive to all surgeons, and it is unlikely that further damage will occur even with vigorous pressure. This approach also provides instantaneous tactile feedback, which may assist in identifying a pulsating vessel in tissue that is not yet clearly visualized. If an attentive assistant surgeon performs this maneuver, then the primary surgeon can also continue to dissect and expose the surrounding tissue in a relatively bloodless field. It is important to note, however, that while this technique can often slow the bleeding dramatically, rarely will it result in perfect hemostasis; often secondary maneuvers are needed to more definitively control the bleeding.

If the vessel has been previously identified and a vessel loop has been applied, then hemostasis is rapidly achieved

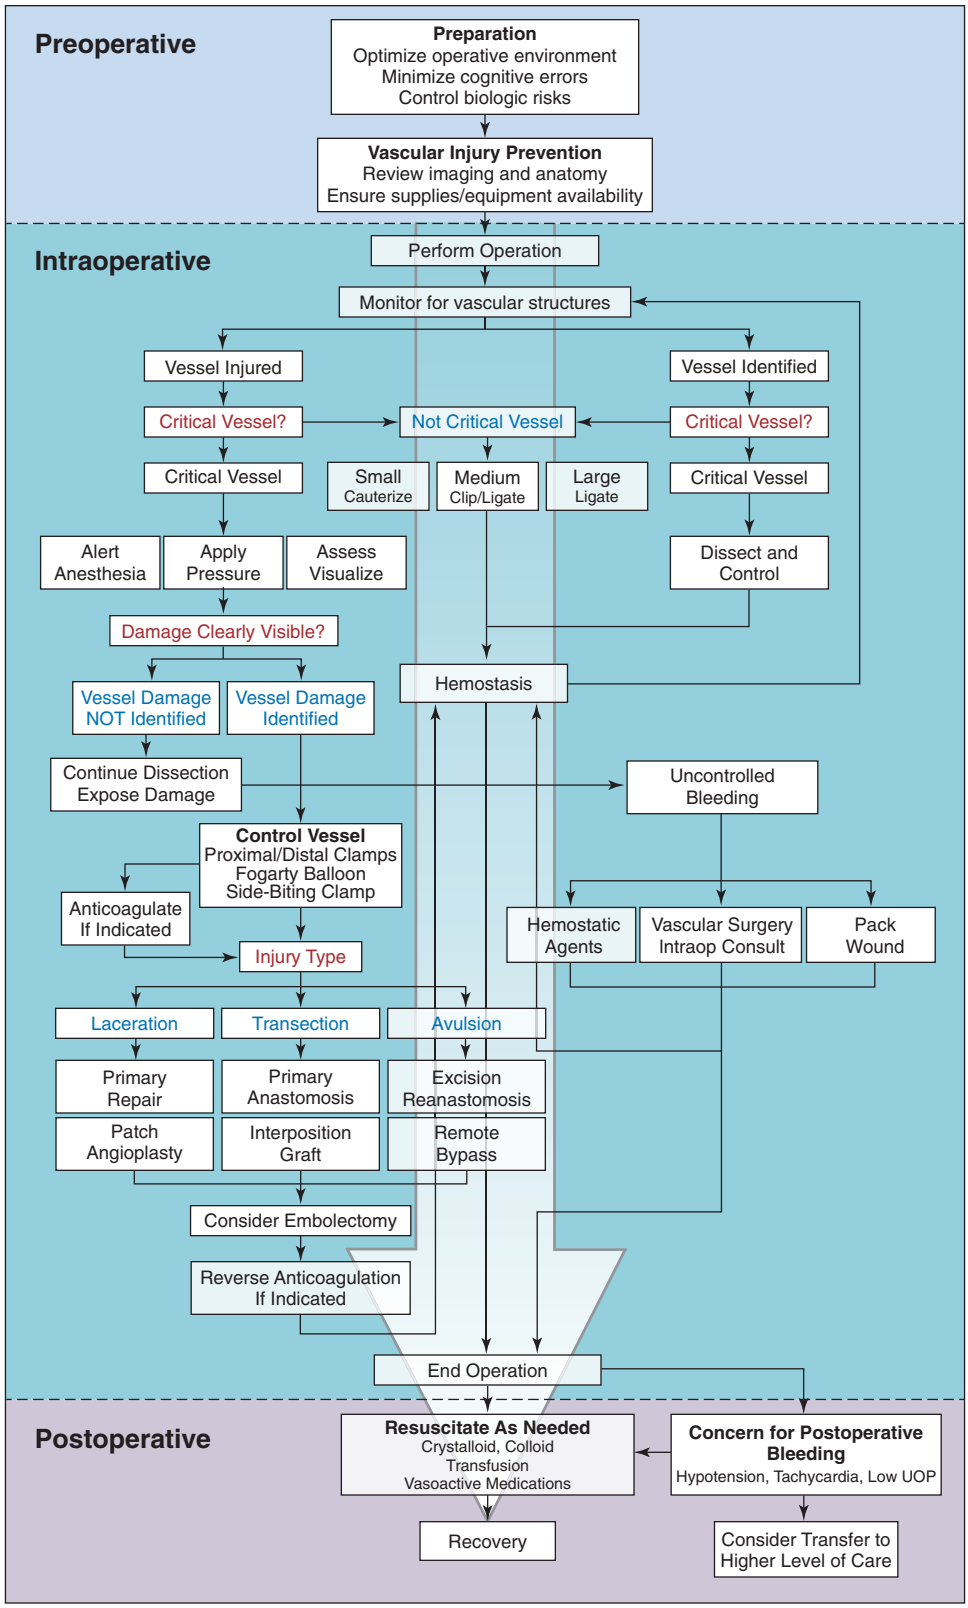

Figure 10.2 Flow chart demonstrating representative management approach to intraoperative hemorrhage. Note decision points highlighted in red.

by cinching the loop. If the vessel has been fully transected, however, this technique runs the risk of allowing the vessel loop to slip off (sometimes unexpectedly). On the other hand, if the vessel is clearly identifiable and the surrounding anatomy is well defined, then a vascular clamp can often be applied to the proximal aspect of the vessel. It is tempting to attempt to clamp in suboptimal conditions; however, the blind application of these instruments can often result in additional damage and worsening hemorrhage. An alternative approach that may be useful includes the placement of an occlusive Fogarty catheter proximal to the defect; this technique can be used as a temporizing measure while further dissection is completed in anticipation of clamp placement. In the hands of an experienced surgeon, this approach may also be used while the repair is completed, with removal of the catheter just prior to final closure and suture tying.

If bleeding is encountered in laparoscopic or robotic surgeries, similar fundamental principles still apply but key differences also exist. The primary difference is that poor visualization can rapidly compound the problem if action is not immediately taken. The first step is to apply direct pressure to the damage with an appropriate laparoscopic instrument (a sponge stick or blunt tip suction works well) to slow the bleeding. Simultaneously the pneumoperitoneum should be increased to help tamponade the bleeding, particularly if venous in nature. Additional access ports can then be rapidly placed to assist in suctioning, retraction, or suture passing. It must be noted, however, that controlling and subsequently fixing the bleeding vessel laparoscopically is often very difficult, and the prudent surgeon must quickly give serious consideration to decisive conversion to traditional open surgery. While laparoscopic management may be feasible for injuries to smaller vessels, any injury to the major vessels (aorta, IVC, iliac vessels, renal vessels, etc.) warrants immediate conversion, and even smaller injuries that are unable to be controlled quickly should be addressed via laparotomy. If the decision is made to open, then the presence of a midline port can be useful. By angling the port upward and placing it against the abdominal wall, the abdomen can be sharply entered over the port without concern for bowel injury.

Postoperatively, bleeding patients should be given aggressive fluid resuscitation and blood products as needed (Fig. 10.2). Numerous studies have now demonstrated noninferiority in restrictive blood product transfusion strategies in patients undergoing abdominal surgery.[37,38] Emerging data from the trauma literature also support transfusion with a 1:1:1 ratio (plasma: platelets: red blood cells),[39] though this finding has not yet been replicated in the perioperative hemorrhage setting. Transfer to the ICU may be warranted if the bleeding is brisk and there is concern for shock. If the patient becomes unstable or persistently bleeds, then operative exploration is indicated.

Definitive Operative Management of Vascular Injuries

ANTICOAGULATION

Following initial control of bleeding, definitive management of the injured vessel is critical to ensure re-bleeding does not occur. Prior to performing the vascular repair, the surgeon should confirm that adequate tissue dissection and mobilization has been completed. The surgeon should then determine the need for systemic anticoagulation and/or proximal and distal embolectomy. If efforts to restore flow will require greater than ~30 minutes, then the risk of thrombus formation increases and further efforts must be undertaken to prevent thrombosis and/or embolization. Unless contraindicated (e.g., prior episode of heparin-induced thrombocytopenia), heparin is the agent of choice for systemic anticoagulation. Heparin is a naturally occurring glycosaminoglycan that binds to and activates antithrombin III, which subsequently inactivates thrombin and factor Xa and prevents clot propagation. Heparin activity onset occurs within 1 minute of administration,[40] and heparin clearance occurs through both rapid saturatable mechanisms (e.g., depolymerization) and slower first-order mechanisms (e.g., renal clearance);[41] practically, this means that the half-life varies from 30 minutes for small IV boluses (25 U/kg) to 150 minutes for larger doses (400 U/kg).[42] Heparin dosing can be titrated intraoperatively by frequent measurements of the activated clotting time (ACT) via point-of-care testing. Once the repair is completed, heparin can be rapidly reversed by administration of protamine sulfate, a cation that directly binds to and inactivates the anion heparin. Protamine should be administered at 1 milligram protamine to 100 IU heparin and should be given first as a test dose to assess for anaphylactoid reactions. Of note is that giving excessive protamine has been shown to paradoxically cause a hypocoagulable state.[43]

EMBOLECTOMY

In addition to systemic anticoagulation, serious consideration should be given to arterial or venous embolectomy in situations where the definitive repair takes a significant amount of time (more than 30 minutes) and there is concern for thrombus formation. Failure to do so can result in flow impairment, clot propagation, and distal embolization causing ischemia. In order to perform proximal and distal embolectomy, a Fogarty catheter is inserted and advanced with the balloon deflated. The balloon is then inflated and the catheter withdrawn while using tactile feedback to maintain proper balloon tension on the vessel wall. The maneuver should be repeated until no further clot is obtained. Care must be taken not to denude the endothelium, which can exacerbate the situation and worsen the thrombosis.

GENERAL PRINCIPLES OF VASCULAR REPAIR

In general, vascular repair is considered one of the most technically challenging aspects of any surgery. The construction of a watertight tension-free anastomosis without luminal narrowing requires both knowledge and proper technique to perform correctly. When suturing vessels, the needle should be placed directly perpendicular to the vessel wall and across all layers of the vessel to minimize risk of pseudoaneurysm formation. This is particularly important in the setting of a possible intimal flap, which if left uncontrolled can result in occlusion and thrombosis of the vessel. Sutures should typically be placed at 1-mm intervals and with 1 mm of tissue purchase. If the vessel

is atherosclerotic, the placement of these sutures can be challenging and will ultimately be dictated by the location that most easily allows the needle to pass. If the vessel is small in diameter (<4 mm), then the vessel ends should be spatulated on opposite sides and anastomosed to prevent anastomotic narrowing.

APPROACHES TO DEFINITIVE REPAIR

Numerous repair or ligation techniques are available to surgeons depending on the nature and location of the injury. In most cases of venous injury, the vessel can simply be ligated and the venous drainage allowed to collateralize as needed. If, however, the injury is arterial in nature, then the surgeon must assess whether permanent ligation will result in ischemia of any critical tissues being perfused by the artery. If adequate collateral flow is present (e.g., in the pelvis) or the artery is small (<2 mm), then vessel ligation is the quickest and simplest approach. This can be accomplished using surgical clips, Hem-o-lok clips, a vascular stapler, or silk ligatures (2-0 or 3-0). The area can then be inspected for hemostasis and the operation continued. If the vessel is critical to end-tissue perfusion and the vessel is larger (>2 mm), then the defect should be repaired and blood flow restored.

Primary repair is often the most straightforward approach if the defect is small and the surrounding vessel wall tissue remains uncompromised. These repairs can be performed using running or interrupted suture of the appropriate size, and care must be taken not to narrow the lumen, which predisposes the vessel to further stenosis and thrombosis.

If primary repair is not feasible due to the size or complexity of the lesion, then onlay patch repair (patch angioplasty) is warranted. This technique is also indicated if primary closure of the defect would result in significant stenosis to the vessel. While data from iatrogenic injuries remain limited, a Cochrane review meta-analysis of data from the carotid endarterectomy literature suggests that, at least in the isolated setting of controlled arteriotomy, patch closure is far superior to primary closure with regard to stenosis rate, thrombosis, and stroke.[44] The choice of patch material seems to be less critical than the decision itself to patch, and several options are routinely used.

Broadly speaking, these patch material choices can be categorized as biologic or synthetic. Biologic options include autologous vein, bovine pericardium,[45] or parietal peritoneum,[46] while synthetic alternatives include Dacron and Teflon grafts. Dacron is a polyester-based graft composed of polyethylene terephthalate. Modern grafts are either woven or knitted; woven grafts are stronger but less compliant, while knitted grafts are also widely used and often treated with collagen, gelatin, or albumin. Teflon or PTFE (polytetrafluoroethylene) grafts are also commonly used. There appears to be no strong data to support the use of autologous tissue (saphenous vein), synthetic (Dacron), cadaveric (bovine pericardium), or peritoneal peritoneum for vessel patches, and the decision seems entirely dependent on surgeon preference and access to these various options.

In some cases, the damage to the vessel is too severe or geometrically unsuitable for primary repair or patch repair; in these circumstances an excision and reanastomosis is often indicated. This approach, however, often requires further dissection either proximally or distally (or both) in order to mobilize adequate vessel length to ensure a tension-free anastomosis. If this approach appears to impart significant tension on the repair, then an interposition graft should be used. The material selection of this graft follows similar principles to patch repair as described above.

If open repair is not feasible or fails, then alternative approaches, including endovascular repair, should be considered. Two case reports from the literature describe patients with prior ureteroileal diversion complicated by strictures and treated with cutting balloon endoureterotomy complicated by common iliac artery damage and massive hemorrhage.[26,47] Both cases were successfully treated with endovascular stent repair of the damage. Aortoureteric fistulas also appear to be amenable to endovascular management in select circumstances. A recent case series identified 20 ureteroarterial fistulas, 74% of which were associated with pelvic radiation and 84% of which occurred in the setting of chronic indwelling ureteral stents. While endovascular repair appeared to confer similar morbidity when compared to open surgical repair, the overall mortality still approached 50%.[48] Further tempering enthusiasm for this approach is the concern for placement of a foreign body (e.g., covered stent) in a contaminated space in direct contact with urine. While the initial intervention may stem blood loss and temporarily alleviate concerns over exsanguination, there exists a long-term risk for graft infection and recurrent bacteremia/sepsis. In this setting, it may be prudent to consider acute endovascular stent placement followed by definitive open surgical management including stent graft removal at a later date when the patient is more stable.

Complications of Vascular Injuries

PELVIC/RETROPERITONEAL HEMATOMA

Hematomas represent either a prior hemorrhage that is now hemostatic via physiologic hemostatic mechanisms, or – in the case of a rapidly expanding hematoma – uncontrolled ongoing bleeding. If the hematoma occurs in a hemodynamically stable patient, then observation is possible. If, however, the hematoma is large, rapidly expanding and pulsatile, associated with hemodynamic instability, and/or located in an anatomic location capable of containing enough bleeding to cause exsanguination, then further intervention is usually warranted. In the setting of urology, the most common location for this life-threatening bleeding is in the pelvis (particularly in trauma) or in the retroperitoneum (e.g., with renal surgery). In both of these spaces, extrinsic compression (traditionally the first maneuver with a hematoma) is not possible. In these cases, endovascular management via interventional radiology and embolization is commonly performed. If this fails or the patient is extremely unstable, then surgical exploration is indicated.

THROMBOSIS AND EMBOLIZATION

Given adequate disturbance to Virchow's triad of hypercoagulability, endothelial damage, and stasis, any vessel in the

body can and will thrombose. This is most clinically relevant within urology in procedures requiring significant involvement or manipulation of major vascular structures (e.g., renal arteries, vena cava, aorta, iliac arteries, etc.). Thrombosis can occur due to excessive vessel manipulation causing endothelial denudation, stasis from decreased or absent flow while a repair is being completed, and/or hypercoagulability from lack of adequate anticoagulation.

As with all intravascular thrombosis, the acute consequences of arterial or venous compromise depend both upon the degree to which flow is impaired and upon the tissue that is both upstream and downstream of the lesion. Of the two, arterial thrombosis is the more acutely concerning entity and can rapidly cause downstream ischemia and necrosis if inadequate collateral flow is present. Venous thrombosis, on the other hand, is usually less immediately concerning because of the distributed nature of venous drainage and the presence of collaterals, which can dilate to accommodate increased flow. The converse is true for subacute or chronic thrombosis. If the downstream tissue survives the initial insult, arterial thrombosis will often resolve spontaneously with adequate collateralization and without long-term sequelae. If, however, a venous thrombosis is allowed to propagate, then the risk for distant embolic events (e.g., pulmonary embolus) increases. Most of these complications (both acute and chronic) can be prevented with intraoperative attention to detail and appropriate interventions such as Fogarty embolectomy and/or heparinization. Furthermore, fastidious postoperative care, including prevention of deep venous thrombosis, is critical to ensuring optimal outcomes and minimizing rates of pulmonary emboli.

Arteriovenous Fistula

Iatrogenic arteriovenous fistula (AVF) formation represents an unexpected but potentially devastating complication from several routine urologic interventions, particularly with renal surgery. The literature describes several cohorts of patients undergoing partial or radical nephrectomy and the subsequent development of pseudoaneurysm with or without AVF.[49–51] The incidence of this complication has been reported to be as high as 2.7%.[52] It appears that en bloc stapling of the renal hilum may represent a risk factor for the development of a renal hilar AVF.[53] Less commonly, these have also been reported for endourologic procedures such as laser lithotripsy.[54] Finally, spontaneous fistulas can occur rarely and present in bizarre and unexpected ways, with case reports describing the development of a large varicocele from abdominal aortic aneurysm causing aorto-renal vein fistula[55,56] or pudendal artery-pampiniform plexus AVF.[57] Regardless of the etiology, the majority of AVFs are treated using endovascular selective embolization.

Stenosis

Vascular stenosis can occur following intraoperative vascular repair and subsequent anastomotic narrowing, fibrosis, and intimal hyperplasia. The functional consequences of the stenosis can be understood using the Law of Pouiselle, which relates pressure across a vessel to length, flow, viscosity, and radius. Simplified, the law states that a flow across a stenosis is linearly inversely proportional to its length and directly proportional to the fourth power of the radius. In other words, a narrowing of 50% will result in a 16-fold reduction in flow. This relationship underscores the necessity to avoid luminal narrowing and employ patch angioplasty if there is any concern for significant luminal narrowing. Stenoses can be managed using endovascular approaches (balloon angioplasty, stenting),[58] or they can be operatively repaired at a later date.

Specific Cases of Vascular Injury

LAPAROSCOPIC ACCESS INJURIES

While both Veress and trocar injuries[22,24,30,32] (including during Hasson access[29,59]) have been reported during laparoscopic entry, it is now clear that Veress needle access carries a significantly higher rate of vascular injury[60] and must be undertaken with caution. A recent review article identified a 0–0.03% risk of vascular injury during open Hasson access and up to a 1.33% risk for the closed Veress approach,[60] but due to systematic bias associated with underreporting, it is likely that the true incidence is even higher. While there have been case reports describing laparoscopic and robotic repair of iliac[34,61,62] and aortic[63] injuries, we believe that these injuries warrant emergent open conversion and repair by all but the most experienced of minimally invasive surgeons.

ARTERIAL INJURIES

Aortic Injuries

Injuries to the aorta represent perhaps the most catastrophic of all iatrogenic vascular injuries. Aortic trauma most commonly occurs during initial access for laparoscopic cases,[22,24,29] during dissection for open surgical cases,[64] and as a result of less common urologic situations. The aorta is particularly vulnerable during retroperitoneal dissections such as nephrectomy or partial nephrectomy[65] or retroperitoneal lymph node dissection.[66] In many cases the injury occurs because of disease adherence to the aortic adventitia, and preoperative imaging can guide intraoperative management. Care must be taken to develop the proper peri-aortic plane during dissection, as patients who have previously received chemotherapy or other neoadjuvant therapy are prone to weakened tissue layers and the subadventitial plane can inadvertently be dissected, resulting in a weakened aortic wall and increased risk for future hemorrhage. In some cases management may even require vascular surgery coordination and aortic replacement.

In the majority of cases these injuries can be identified and repaired intraoperatively, though exsanguination remains a serious risk. Once encountered and identified, it may be tempting to explore and cross-clamp the suprarenal aorta as a first-line maneuver. This approach, however, carries the risk of further damage to the diaphragmatic crura and the neural and lymphatic network overlying the aorta at this location. Instead, the surgeon should attempt to access the supraceliac or distal thoracic aorta by retracting the stomach caudally and the left lateral segment of the liver to the right, exposing the lesser omentum and allowing digital compression of the aorta

until the bleeding can be controlled elsewhere. In addition to those injuries identified and repaired immediately, there are at least two case reports of intraoperative aortic insult that was not identified immediately and required reoperation.[19,30] In both cases the patient underwent nephrectomy (one for nephrolithiasis and the other for Wilms' tumor) complicated by immediate postoperative lower limb numbness and pulselessness. In both cases the patient was explored and found to have a ligated infrarenal aorta, which was repaired with a synthetic interposition graft. Both patients experienced partial recovery of sensory and motor function, and neither required amputation. While operative details for these cases are scant, it appears that brisk bleeding impairing surgeon situational awareness and inducing panic and/or desperation to control bleeding caused the injuries. It is paramount in these stressful situations to control the bleeding, stop, and reorient with regard to anatomy and patient status before completing the operation and leaving the operating room.

In addition to traditional intraoperative complications, the urology literature contains several other references to unusual cases involving the aorta and the upper tract. Vagnoni and colleagues described the case of a patient who underwent pelvic surgery complicated by ureteral injury and subsequent reanastomosis who presented with massive hematuria later found to be secondary to ruptured aortic pseudoaneurysm requiring operative repair.[67] Other reports describe the formation of aorto-ureteric fistula causing massive hematuria.[68] Finally, another report describes the development of an abdominal aortic aneurysm after BCG treatment for bladder cancer; further workup revealed the presence of *Mycobacterium bovis* within the excised tissue.[69] Taken together, these case reports suggest that urologists should have a high index of suspicion for a variety of vascular complications, both common and uncommon, when patients present with significant hematuria and/or abdominal pain in the absence of obvious explanation.

Visceral Artery Injuries

Numerous case reports now exist describing injury to the visceral arteries during urologic surgery. Injury to the superior mesenteric artery (SMA) during renal or adrenal surgery is the most common scenario,[70–73] but case reports have also identified celiac compromise.[72,73] Most reports identify distorted anatomic relationships due to heavy tumor burden as the primary causative factor. This disease burden can often malrotate or translate the renal hilum in unexpected ways. Extreme care must be taken when evaluating the preoperative imaging studies to help identify cases at risk for these complications, and intraoperatively the surgeon must have a high index of suspicion for aberrant anatomy. In our practice, we employ a threefold strategy to ensure that the SMA is not inadvertently ligated. We first critically assess whether the vessel in question is located laterally on the aorta and behind the renal vein (except in the case of a retroaortic vein), and we dissect the vessel out more clearly if there is any doubt. This is particularly difficult, however, if the patient is in the right lateral decubitus position and/or when there is a large left-sided mass being resected. Due to this, we then proceed to atraumatically occlude the artery of interest via vessel loop and assess for changes in the turgor and appearance of the kidney that may suggest blanching. Finally (and most importantly) we palpate the mesenteric arcade to confirm adequate pulsations remain. Following vessel transection, upon completion of the case we always run the bowel and assess for any signs of ischemia. If these maneuvers fail to elucidate the nature of the vessel in question, then it is also possible to approach the hilum from the posterior aspect of the kidney and to palpate the vessels individually prior to ligation. Once identified, repair of the visceral vessels should be undertaken without delay to avoid prolonged ischemia. Vascular repair can be conducted via direct reanastomosis, placement of an interposition graft, aortic reimplantation, bypass via the splenic artery, or construction of a patch angioplasty. If these injuries are identified intraoperatively and promptly fixed, outcomes remain good. If the injury is missed, however, then extensive bowel and/or foregut ischemia and ultimately death will occur.

Thoracic and Lumbar Segmental Artery Injuries

Thoracic and lumbar arteries are paired posterior arteries associated with the thoracic and upper lumbar bodies. These arteries can be encountered during posterior dissections for lymph node dissection. It is important to keep the dissection far enough from the aorta that if transection does indeed occur, the artery stump can directly be controlled and ligated. If the dissection is carried directly adjacent to the aorta and there is no proximal stump available, then primary closure of the aorta is indicated. The critical maneuver in doing so is to mobilize the aorta adequately to permit satisfactory visualization when oversewing the defect.

Iliac Artery Injuries

Numerous case reports exist describing iatrogenic injury to the common or external iliac artery during urologic procedures. These can occur during minimally invasive pelvic procedures,[5,26,34] during renal transplantation,[58,74,75] or during other less common urologic situations (e.g., via needle carrier during vaginal sling placement[25]). It is important to note that the external iliac is the sole provider of blood flow to a significant region of the lower limb, and prompt repair of this vessel is critical to maintain perfusion and prevent ischemia and limb amputation. Repair can be conducted as previously described here (e.g., primary repair for small defects or reanastomosis for uncomplicated transections), but in this setting three other options are also available. First, if an interposition graft is deemed necessary, then the native hypogastric artery can be transected, the distal portion ligated, and the proximal component reanastomosed to the distal external iliac artery as an in situ interposition graft. Alternatively, the external iliac vein can also be harvested and placed in a reversed fashion as an interposition graft. Finally, if these options are deemed unsuitable or the defect is significant, then vascular surgery should be consulted intraoperatively to assess the suitability bypass using prosthetic conduits or extra-anatomic approaches (axillofemoral or femoral-femoral bypass).[76]

VENOUS INJURIES

Inferior Vena Cava Injuries

Brisk bleeding from the vena cava can be a truly frightening experience associated with rapid development of

hemodynamic instability and exsanguination if not quickly addressed. We employ a stepwise fashion to interventions to control vena caval bleeding. If the defect is small (e.g., avulsed lumbar vein), then digital pressure is satisfactory to minimize bleeding while arrangements are made for primary repair. An exclusion clamp (e.g., Satinsky) can then be placed to allow for venous return to recommence. Defects of this nature can usually be closed primarily with running nondegradable suture. If the defect is larger and digital pressure is insufficient, then the IVC can be controlled proximally and distally and further mobilized for more extensive repair. If the defect is large enough that primary closure would lead to significant luminal narrowing, then patch venoplasty should be undertaken with one of the patch types previously discussed in this chapter.

If the above maneuvers are unable to provide relative hemostasis, then more aggressive measures should be employed. Sequential Allis clamps can be cautiously placed to oppose the IVC walls across the defect and slow bleeding. Extreme care must be taken, however, when performing this maneuver, as the venous walls are fragile and can easily tear further and exacerbate the problem. If the above measures continue to fail and the defect is infrarenal, then IVC ligation has been described by several groups.[77,78] This maneuver is best tolerated in situations where gradual IVC occlusion has occurred prior to the operation (e.g., renal cell carcinoma with progressive tumor thrombus) and adequate collateralization has previously taken place. If a previously patent IVC must be ligated intraoperatively for massive hemorrhage, the incidence of deep venous thrombosis and distal venous congestion is extremely high, and preservation of the remaining venous collaterals should be prioritized. Suprarenal IVC ligation may also be considered in some cases where death would otherwise be imminent, but the surgeon must understand that kidneys without satisfactory venous outflow will likely be lost and hemodialysis may be necessary.

Renal Vein Injuries

Hemorrhage from the renal vein can result in rapid exsanguinating blood loss. Damage to the left renal vein is more forgiving because of the presence of venous collaterals (gonadal, adrenal, lumbar branches). In this setting, the left renal vein can be ligated with minimal concern for venous hypertension or nephron compromise. The right renal vein is particularly thin-walled and fragile and lacks this network of collateral drainage, and occasionally a posterior branch can be injured during circumferential dissection. If such an injury occurs, immediate digital pressure should be applied. If the injury occurs in the context of performing a radical nephrectomy, then the surgeon should attempt to control the renal artery first and then address the vein afterward. If this proves to be difficult, then a large vascular clamp can be placed across the entire hilum and the kidney removed. The edges of the artery and vein can then be identified and carefully oversewn. If the intended operation is renal-sparing in nature (e.g., partial nephrectomy), then the surgeon must work quickly to find an alternative solution. One option is to rapidly mobilize the entire kidney to facilitate posterolateral exposure of the vein for subsequent repair. Alternatively, in rare situations with appropriate expertise and resources, a renal autotransplant may be performed. It should be noted, however, that right renal vein transection – except in very rare circumstances – will result in excessive bleeding and will necessitate nephrectomy.

Hypogastric (Internal Iliac) Vein Injuries

Bleeding from injuries to the hypogastric veins can occur during renal transplantation or pelvic lymph node dissection. The number and location of these can vary slightly, and dissecting these branches can be challenging. We typically mobilize the common, external, and proximal internal iliac arteries and retract these medially. We then obtain circumferential control of the external and common iliac veins and encircle them with umbilical tape, which aids in upward traction and further dissection of the hypogastric branches. Alternatively, these branches can be approached and controlled from the lateral approach by retracting the psoas muscle laterally. Once identified, if necessary the hypogastric veins can be clipped or ligated and divided to allow full mobilization of the external iliac vein. If these branches are damaged and vascular control is lost and the vein retracts, then digital pressure can be applied and a slender clamp inserted and the vein wall grasped. The vessel can then be delivered into the operative field, twisted to stem the bleeding, and suture ligated.

Lumbar Vein Injuries

Lumbar veins can be particularly troublesome if damaged during IVC or retroperitoneal operations. In order to avoid damaging – or if necessary repair – these vessels, the IVC is gently lifted anteriorly via umbilical tape and any veins encountered are ligated and/or clipped. If the vessel is entirely transected and the posterior stump retracts into the surrounding tissue, then a similar technique as described for hypogastric control can be employed (e.g., grasp the vein well, gently retract, twist, and suture ligate). If this proves to be unsuccessful, then a hemostatic stitch can be applied directly to the posterior body wall musculature to control the bleeding.

INFERIOR VENA CAVA TUMOR THROMBUS

While not an iatrogenic vascular complication per se, renal cell carcinoma (RCC) with venous extension represents a unique biologic situation that may be initially encountered, though not necessarily treated, by many practicing urologists. Surgical management of this condition represents one of the most challenging conditions that urologists face, and a comprehensive team-oriented approach is necessary to achieve the best outcomes. Here we discuss the general principles surrounding diagnosis, prognosis, and management of IVC thrombus.

With an incidence of over 60,000 new cases annually, RCC is the third most common genitourinary malignancy in the United States and represents 3.7% of all new cancer diagnoses each year.[79] It is also the most lethal form of genitourinary cancer, with an estimated 14,000 deaths annually. RCC is unique in its affinity for intravascular extension via the renal veins and inferior vena cava. This intravascular tumor growth is referred to as tumor thrombus or IVC thrombus, and this complication can be identified in 4–36%[80] of patients carrying a diagnosis of RCC. The disease most commonly presents with microscopic or gross

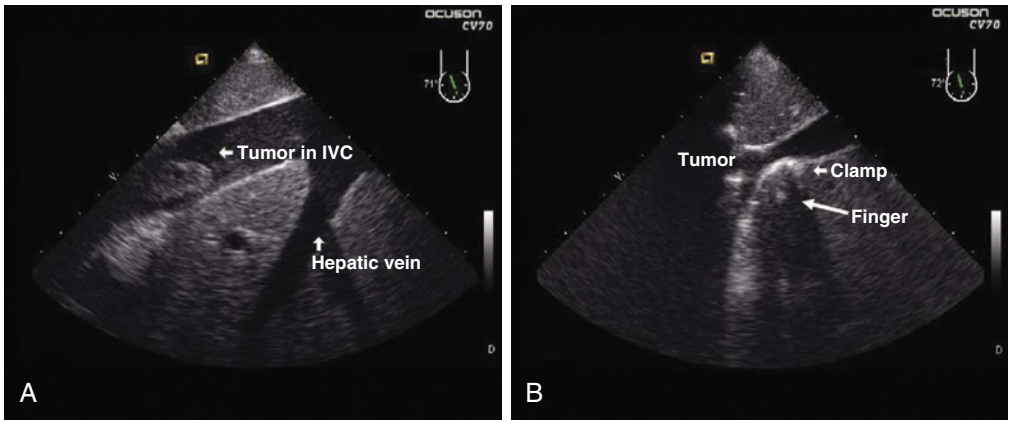

Figure 10.3 Intraoperative transesophageal echo demonstrating intrahepatic renal cell carcinoma tumor thrombus without hepatic vein compromise. The inferior vena cava can be digitally compressed and the thrombus visualized in real-time to monitor for embolic events.

hematuria (70% and 42% of cases respectively), flank pain (46%), fever (45%), anemia (23%), or incidentally (19%).[81] The imaging study of choice for diagnosis and staging remains the contrast-enhanced MRI, which offers 100% sensitivity[82] and can aid in delineating between tumor thrombus and associated bland thrombus. CT with contrast is also frequently used and offers a less expensive and time-consuming option at the expense of sensitivity (84%).[83]

Left untreated, the natural history of this disease is sobering; median disease-specific duration of survival is a mere 5 months, and only 29% of patients survive greater than 1 year. Surgical resection offers a tremendous benefit with regard to life expectancy, and patients without metastatic disease who underwent radical nephrectomy with IVC thrombectomy can expect a 5-year disease-free survival rate approaching 60%.[84] Even patients with metastatic RCC in the absence of IVC thrombus benefit greatly from surgical intervention; this was conclusively demonstrated by two pivotal randomized controlled trials, the Southwest oncology (SWOG) 8949 trial by Flanigan et al.[85] and the European Organization for Research and Treatment of Cancer (EORTC) 30947 trial by Mickisch et al.[86] Both trials compared interferon treatment to radical nephrectomy plus interferon, and both trials conclusively demonstrated survival benefit to the surgical arm. This finding appears to apply to those patients with IVC thrombus as well. Our group has recently published a case series of 76 patients with metastatic RCC with level II–IV IVC thrombus who underwent cytoreductive nephrectomy with IVC thrombectomy and demonstrated increased life expectancy to a median of 14 months.[87] Despite these promising results, it must be acknowledged that an operation of this magnitude is associated with an elevated rate of morbidity and mortality. A study by Abel et al. showed a 10% perioperative mortality rate and 34% major complication rate for advanced stage (level III–IV) IVC thrombus. Multivariate analysis highlighted poor performance status and low serum albumin as two independent risk factors associated with poor outcomes.[88] Taken together, these data suggest that surgical management of RCC with IVC thrombus remains a primary therapeutic option for both localized and metastatic renal cell carcinoma in patients with good performance and nutrition status and minimal comorbidities.

Surgical planning for radical nephrectomy and IVC thrombectomy is critically important to achieving the best outcomes, and the surgical approach and intraoperative management is predominately influenced by the level of IVC extension. The extent of IVC thrombus can be described using a number of classification schemes, but the majority of providers now use the Mayo classification scheme first described by Neves and Zincke.[89] Briefly, this scheme describes the severity of the thrombus by the extent of migration from the kidney; this ranges from level I thrombus (confined to or within 2 cm from the renal vein confluence) to level IV thrombus (above the diaphragm or into the atrium). Interestingly, recent data from our group and others suggest that the level of thrombus appears to have minimal bearing on outcomes.[87,90] Regardless of stage, in our practice the abdominal incision is almost exclusively a transverse or chevron incision. We almost always employ intraoperative transesophageal echo (TEE) to visually identify the extent of the IVC thrombus in real time for clamp placement and to monitor for embolic events (Fig. 10.3). Beyond this, however, the surgical approach varies widely depending on the stage of thrombus being excised.

Tumors with level I thrombus can be approached in a manner similar to a standard open radical nephrectomy. We typically focus on early arterial ligation to minimize renal inflow and subsequent blood loss. Depending on the specific subtype of disease, significant venous collateralization can be present, and these small thin-walled vessels bleed profusely if the artery is left intact. Once the artery has been ligated, we mobilize the entire kidney and then carefully obtain circumferential control of the renal vein. If the tumor thrombus is isolated to the renal vein and the IVC confluence, then it is possible to simultaneously gently palpate and retract the thrombus toward the kidney while applying a partially occlusive caval clamp to preserve the majority of venous return. We then resect the renal vein and a cuff of vena cava and then perform our cavorrhaphy with 4-0 sutures placed in the apex and run continuously to the center of the defect and tied together. If following this maneuver it becomes clear that the thrombus excision remains incomplete and the thrombus remains, then the clamp is left in place and circumferential control of the IVC and left renal vein is obtained.

Tumors with level II thrombus require more extensive IVC dissection and mobilization. It is critical in these lesions to identify and secure the contralateral renal vein, lumbar veins, adrenal veins, and any other small tributaries that may be present. In our experience, it is rare to identify suprarenal IVC lumbar veins, and the only posterior branch that is reliably encountered is the right adrenal vein. The caudate lobe of the liver can then be gently retracted as needed for clamp placement. If short hepatic veins are encountered while performing this maneuver, they can be ligated and divided. Once these have been identified and controlled, the IVC is controlled by first occluding the contralateral renal vein with a bulldog clamp, followed by the infrarenal IVC, and finally the suprarenal IVC. At this point the IVC is carefully palpated for the extent of thrombus. If the IVC remains distended, the surgeon should consider the possibility of inflow from an uncontrolled source. Once the IVC is decompressed, the cavotomy can be performed on the anterolateral aspect of the cava and extended as needed to facilitate thrombus extraction. Following this, the lumen should be carefully inspected, and any portions of the wall with adherent disease should be fully excised and reconstructed using primary closure or patch repair as previously described (Fig. 10.4). Once the repair is complete, we leave the final suture untied and flash the suprarenal clamps to fill the cava and vent any remaining air. We then remove clamps in the following sequence: suprarenal IVC, contralateral vein, and infrarenal IVC.

Level III lesions require extensive liver mobilization and further vascular control. This involves first dividing the falciform ligament and left triangular ligament to expose the suprahepatic IVC. The right lobe is then mobilized from the kidney in a very gentle fashion, as excessive traction can cause liver laceration and bleeding. Next, the right triangular ligament is divided using traction applied from the left side of the patient. Care must be taken to isolate and control the short hepatic veins that directly drain from the liver into the IVC. These vessels are often short and fragile, and doubly ligating them can occasionally prove to be challenging. Alternatively, the veins may be doubly clamped, divided first, and then oversewn with permanent suture. Control of these veins can be difficult and is occasionally complicated by the fact that failure to control the hepatic side can result in vein retraction into the parenchyma. If this occurs, hemostasis can be obtained by suture ligature with incorporation of the surrounding hepatic parenchyma. Once the liver is sufficiently mobilized, the surgeon should assess via both palpation and intraoperative TEE the extent of the IVC thrombus just inferior to the hepatic veins. If the thrombus can be retracted sufficiently to allow for clamp placement just below the hepatic veins, then control of hepatic outflow (and thus inflow) does not need to be compromised and IVC control proceeds in a similar fashion to level II thrombi. If, however, the thrombus remains at or above the hepatic veins, then the porta hepatis (portal vein and hepatic artery) must be controlled. This can be accomplished via the Pringle maneuver, which involves placement of an atraumatic vascular clamp to the porta hepatis. First, however, the contralateral renal vein is excluded, followed by the proximal IVC (including the second lumbar vein). At this stage the Pringle maneuver is performed, and finally the suprahepatic IVC is clamped. If the tumor originates from the left kidney and extends through the left renal vein, we almost always occlude the right renal artery and vein so that the right kidney does not become distended due to only venous outflow obstruction. Working quickly to minimize liver ischemia, an anterolateral cavotomy, which includes the affected renal vein, is then performed and the thrombus removed. Once complete, the IVC is controlled below the hepatic venous outflow and the suprahepatic and Pringle clamps removed. The repair then proceeds as before and the nephrectomy is completed.

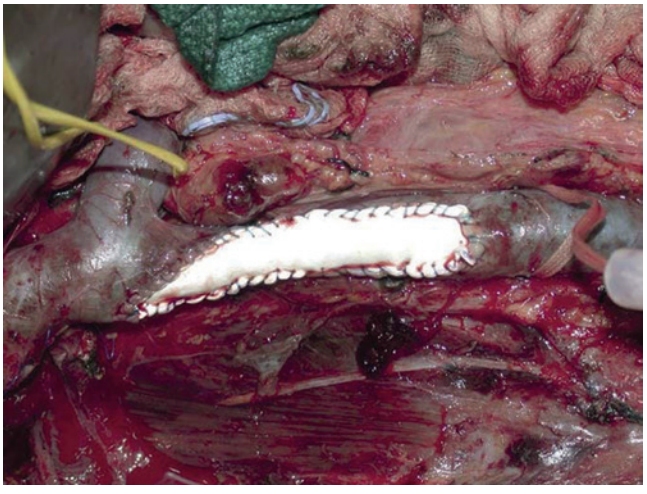

Figure 10.4 Inferior vena cava (IVC) reconstruction using bovine pericardial patch following right-sided radical nephrectomy and IVC thrombectomy with partial IVC resection.

In contrast to the lesions described above, level IV (supradiaphragmatic) lesions require collaboration with cardiac surgery and intrapericardial control via median sternotomy. This can be accomplished using deep hypothermic circulatory arrest (DHCA), veno–veno bypass, or, more commonly, cardiopulmonary bypass (CPB), with or without concomitant DHCA. Historically we used DHCA alone but found the complication rate to be unacceptably high. More recently we now favor the use of CPB. Interestingly the use of DHCA in conjunction with CPB has been shown in a relatively small series to be associated with significantly decreased perioperative mortality.[91] While promising, these results warrant further investigation and validation. Of note, the use of bypass also necessitates maximal anticoagulation, and meticulous hemostasis in the abdomen is critical to prevent excessive blood loss.

Historically many centers have combined the above surgical techniques with preoperative renal artery embolization, under the hypothesis that decreased or absent arterial inflow may confer diminished blood loss, increased edema and clearer resection planes, and/or early ligation of the renal vein. Data from our institution, however, does not support these hypotheses and instead surprisingly suggested that preoperative embolization conferred a fivefold higher risk of perioperative death and increased transfusion and intensive care requirements when compared to surgery alone.[92] We now no longer embolize these masses prior to surgery except in extenuating circumstances, such as Budd–Chiari syndrome from IVC thrombus obstructing hepatic outflow. These patients are extremely poor operative

candidates and have a significantly elevated rate of perioperative mortality and likely benefit from renal artery embolization and subsequent surgery if hepatic outflow can be restored and the sequelae from it reversed.

Finally, recent reports from several groups have described the application of robotic techniques to IVC thrombus.[93–98] These reports describe successful robotic radical nephrectomy and IVC thrombectomy for level I–III disease. The theoretical benefits of such a procedure include decreased morbidity and postoperative pain. From a practical standpoint, much of the operation is conducted in a similar stepwise fashion as described for open procedures. After initial exposure and dissection, the renal artery is controlled using Hem-o-lok clips. Minimally invasive control of the vessels is accomplished using Rummel tourniquets, and the renal vein is transected using an Endo GIA stapler (or alternatively the tumor and IVC thrombus can be removed en bloc).[98] Outcomes to date using this approach appear promising, with a short length of stay (3–5 days) and minimal blood loss (150–375 mL), but further work is necessary to refine these techniques before this approach can be widely adopted.

Chapter 10 Questions

1. Which of the following renal artery control strategies is contraindicated?
   a. Endo GIA stapler with vascular load in a living donor nephrectomy
   b. Endo TA stapler in in radical nephrectomy
   c. Placement of two Hem-o-lock clips in laparoscopic living donor nephrectomy
   d. Suture ligation in a radical nephrectomy
   e. Statinsky clamp across hilum during profuse bleeding

2. Which of the following hemostatic agents must be used with caution in diabetic patients?
   a. Gelfoam
   b. Tisseel
   c. HemCon
   d. Arista
   e. Extrinsic pressure

3. Why should protamine be given as a test dose prior to full heparin reversal?
   a. Paradoxical reaction causing hemorrhage
   b. Hypotension
   c. Hypertension
   d. Arrhythmias
   e. Hypoxia

4. Which of the following is the most devastating consequence that can occur during left radical nephrectomy?
   a. Lumbar artery injury
   b. Ligation of the superior mesenteric artery
   c. Splenic artery laceration
   d. Pseudoaneurysm formation
   e. Acute kidney injury

5. What is the median disease-specific survival for untreated renal cell carcinoma with inferior vena cava thrombus?
   a. 3 months
   b. 5 months
   c. 10 months
   d. 3 years
   e. 6 years

6. According to the Neves classification, a patient with renal cell carcinoma with tumor thrombus extending into the infrahepatic inferior vena cava (IVC) is classified as level:
   a. I
   b. II
   c. III
   d. IV
   e. Depends on the laterality of the primary lesion

7. A patient undergoes vascular repair following iliac artery injury, and the repair subsequently becomes stenotic to 50% of its initial diameter. According to the law of Pouiselle, the flow through this stenotic vessel is changed to:
   a. $\frac{1}{2}$ of initial flow rate
   b. $\frac{1}{4}$ of initial flow rate
   c. $\frac{1}{8}$ of initial flow rate
   d. $\frac{1}{16}$ of initial flow rate
   e. Twice the initial flow rate

8. Upon injury to a major vascular structure, which of the following initial maneuvers can minimize blood loss prior to undergoing definitive repair?
   a. Massive transfusion
   b. Digital pressure
   c. Bovie electrocautery
   d. Intraoperative vascular surgery consult
   e. Application of Gelfoam

9. A 23-month-old male is diagnosed with Wilms' tumor and undergoes surgical resection. Intraoperatively the superior mesenteric artery is transected. Which of the following suture materials is most appropriate for repair?
   a. Polypropylene
   b. Polydioxanone
   c. Polyglactin
   d. Polytetrafluoroethylene
   e. Silk

10. What are the three components of Virchow's Triad?
    a. Hemostasis, thrombolysis, coagulation
    b. Hypocoagulability, thrombocytopenia, anemia
    c. Hypercoagulability, endothelial damage, stasis
    d. Hemorrhage, hypotension, tachycardia
    e. Hypercoagulability, hypocoagulability, shock

Answers

1. **c.** Hem-o-lock clips are contraindicated in living donor nephrectomy per FDA regulations.
2. **d.** Arista is a polysaccharide that can increase blood glucose levels. Caution is recommended when using >50 g in diabetic patients.
3. **b.** Protamine can cause anaphylactoid reaction, particularly in diabetic patients on neutral protamine Hagedorn (NPH) insulin.
4. **b.** Superior mesenteric artery ligation, while rare, will – if unidentified – rapidly cause bowel ischemia, clinical deterioration, and death.
5. **b.** Without surgical intervention, the median life expectancy is a mere 5 months.
6. **b.** A level II thrombus extends into the IVC but remains infrahepatic in location.
7. **d.** Pouiselle flow dictates that flow is inversely proportional to the fourth power of the radius.
8. **b.** While the other interventions may be indicated in some cases, digital pressure is the only intervention listed that will minimize intraoperative blood loss.
9. **b.** Typically vascular anastomoses are performed with permanent suture, but in this pediatric setting, repair using a slowly resorbing suture material such as polydioxanone (PDS) is indicated.
10. **c.** Virchow's triad (hypercoagulability, endothelial damage, and stasis) describes the three fundamental principles that contribute to thrombosis.

11 Management of Bowel Complications

BROCK O'NEIL and SAM S. CHANG

CHAPTER OUTLINE

Ileus
Bowel Preparation
Bowel Injury
Bowel Leak, Abscess, and Fistula
Bowel Obstruction
Ogilvie's Syndrome
Chapter 11 Questions and Answers

KEY POINTS

1. Prolonged ileus lengthens the patient's discomfort, increases the need for parenteral nutritional support, and constitutes the most common reason for delayed discharge after abdominal surgery.
2. Following surgical procedures, the small intestine first regains function within 24 hours, the stomach in 24 to 48 hours, and the colon in 3 to 5 days.
3. Enhanced recovery after surgery protocols (standardized care pathways) that comprehensively incorporate strategies to prevent ileus, including elimination of routine use of perioperative bowel preparation and nasogastric decompression, minimization of narcotic pain medication, and utilization of μ-receptor antagonists improve time to return of bowel function.
4. Once an intraabdominal abscess has been identified, antibiotic treatment is not adequate; the abscess must be drained.
5. The most important initial step in treating a patient with bowel obstruction is to replace intravascular volume. Surgical intervention should occur early in patients with complete bowel obstruction. In approximately 80% of patients, a partial bowel obstruction will resolve on its own.
6. Bowel injury, including rectal injury, recognized intraoperatively can usually be primarily repaired with consideration for proximal bowel diversion in certain circumstances. Delayed recognition of bowel injury can lead to profound illness and requires reoperation.
7. Fistula after urinary diversion is uncommon, and initial management focuses on diversion of urine away from the fistula and delayed repair when these measures do not result in resolution.
8. When conservative and pharmacologic management of Ogilvie's syndrome has failed, colonic diameter measures >12 cm, colon size is increasing rapidly, or the duration is >3 days, the colon should be decompressed.

Urologists are often faced with clinical and operative decisions that involve the bowel. The bowel can be invaded by urologic tumors, may be used as a urinary conduit, and simply may be in the way of complex urologic procedures. The approach to some common problems associated with operating in the abdominal cavity and the management of potential complications associated with the gastrointestinal tract (GI) are outlined in this chapter (Table 11.1).

Ileus

Ileus, or intestinal paralysis, represents delay in coordinated bowel activity and is experienced by most patients following an intraperitoneal procedure but can also be exhibited following extraperitoneal procedures. This condition falls on a continuum from a normal physiologic process of recovery to a prolonged delay in bowel motility and function and is characterized by abdominal distention, decrease in bowel sounds, delayed passage of flatus and defecation, and accumulation of gas and fluids in the bowel that may result in nausea and vomiting. Prolonged ileus lengthens the patient's discomfort, increases the need for parenteral nutritional support, and constitutes the most common reason for the delayed discharge after abdominal surgery occurring in 10–22% of patients undergoing major abdominal surgery.[1–3] The economic impact of ileus in the United States is estimated to be $750 million to $1 billion annually.

Following abdominal surgical procedures, each section of the GI tract recovers at a different rate. The small

Table 11.1 Summary of Bowel Complications and Management Principles

Complication	Incidence	Management Principles
Abscess	1.1–3.6%	Percutaneous drainage, washout in specific cases
Bowel leak	<1%	Early: reoperation and repair; late: control leak, delayed repair with possible bowel diversion
Bowel obstruction	1.6–16%	Fluid resuscitation, reoperation
Ileus	10–22%	Nasogastric decompression, nonoperative support (e.g., enteral nutrition)
Rectal injury	<1%	Intraoperative recognition: primary repair with consideration for proximal bowel diversion in certain cases Delayed recognition: washout and proximal bowel diversion
Urinary fistula	3–4%	Diversion of urine, delayed surgical repair if doesn't resolve

intestine first regains function within 24 hours, the stomach in 24 to 48 hours, and the colon in 3 to 5 days. Therefore once the patient has experienced flatus following an operation, it is likely that the colon and the remaining GI tract have recovered.

The pathophysiologic mechanism of ileus is incompletely understood but appears multifactorial, involving neurogenic, inflammatory, and pharmacologic mechanisms.[4] Neurogenic hypotheses suggest ileus may be a result of activation of a spinal reflex that inhibits GI motility, which is further reinforced through sympathetic hyperactivity induced by the stress of surgical trauma.[5,6] For this reason, epidural/spinal anesthesia has been suggested to prevent prolonged ileus but must be adequately proximal to block the sympathetic chain and should utilize local anesthetics rather than narcotic agents to maximize effectiveness.[7,8] Narcotic medication, frequently used in the perioperative setting, contributes to prolonged ileus through activation of μ-opioid receptors in the GI tract.[9]

Electrolyte disturbances including hypomagnesemia, hyponatremia, and hypokalemia have all been cited as contributing to prolonged ileus.[4] Additional contributors include prolonged operative time, significant manipulation of the bowel, increased blood loss, and body mass index.[2,10] Inflammation is thought to contribute to postoperative ileus as a systemic response to surgery as well as due to direct manipulation of the bowel through both the innate and adaptive immune system and is the subject of research to identify pharmacologic interventions that may reduce its duration.[11] It may be that the benefit in terms of shorter duration of ileus with laparoscopy compared to open surgery despite average longer operating times is due to the induction of less inflammation through a smaller degree of manipulation and/or improved temperature and humidity control of the bowel.[12]

Several abnormalities common in urologic procedures can initiate and propagate ileus. Ileus can also be a sign of a more severe condition, and urologic patients experiencing a prolonged return of bowel function should be assessed for sources of electrolyte abnormalities and infection including intraabdominal abscess, bowel leak, urinary tract infection or leak, and urinoma. If any of these conditions are identified, correction is necessary to aid in the resolution of ileus and to prevent further development of complications. Finally, the acute withdrawal or accelerated taper of steroids in the postoperative period has been shown to prolong or even precipitate ileus and is corrected with bolus steroid administration.[13]

In some patients, ileus may continue despite best efforts at prevention and treatment, and the mainstay of treatment remains nasogastric decompression. It is not our routine practice to surgically intervene in the setting of prolonged ileus when bowel obstruction and other inciting conditions have been ruled out or otherwise addressed. While the use of routine nasogastric decompression for abdominal procedures has fallen out of favor due to increased rates of pulmonary complications such as fever, atelectasis, and pneumonia as well as higher rates of wound complications and prolonged hospital length of stay,[14] if the patient does become distended or experiences severe nausea or vomiting, a nasogastric tube should be placed.

Parenteral nutrition should be started if it is anticipated that prolonged ileus will continue (>7–10 days). Once bowel obstruction has been ruled out and the correctable abnormalities have been addressed, a trial of prokinetic agents may be considered; although, while this route may be potentially helpful for symptomatic relief of nausea, their use has not been consistently shown to reduce time of ileus.[15]

Prevention of prolonged postoperative ileus remains a critical component of the management of the urologic patient. Minimization of narcotics with substitution/addition of nonsteroidal antiinflammatory medications (NSAIDs) or epidural, spinal, or regional (e.g., On-Q) local anesthetics has been shown to have beneficial impact on ileus.[7,8,16] Perioperative use of peripheral μ-receptor antagonists (e.g., alvimopan) also reduces the time of postoperative ileus and may represent a cost-effective strategy.[17,18] Other proven strategies include early enteral feeding,[19] chewing sugar-free gum,[20] early administration of coffee,[21] electroacupuncture,[22] and readaptation of the peritoneum after cystectomy and pelvic lymphadenectomy.[23] Early postoperative ambulation may not expedite GI tract function recovery but is encouraged for benefits in reducing thromboembolism and pulmonary complications.[24] Enhanced recovery protocols (standardized clinical pathways) that incorporate some or all of these strategies have shown significant reductions in hospital stays without increasing perioperative complications or readmissions.[25,26]

Bowel Preparation

Considerable debate continues on the value of preoperative mechanical and/or antibiotic bowel preparation for the prevention of bowel-related complications. Dogma in favor of bowel preparation has been around for over 50 years and was challenged more recently with several trials and a Cochrane review suggesting no advantage for colectomy in terms of bowel anastomosis leaks, deep abscess, or

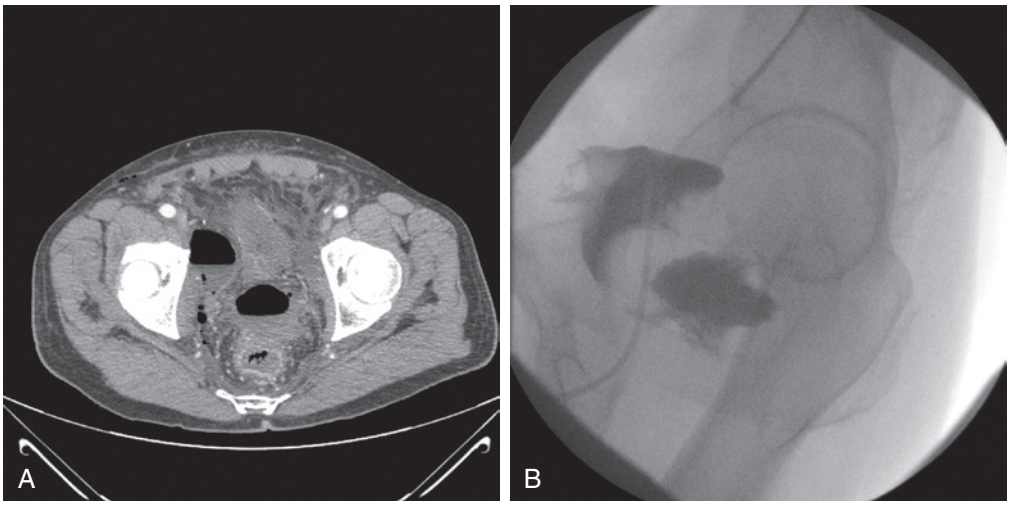

Figure 11.1 A, CT after radical prostatectomy showing large free air between bladder and rectum and lateral to the bladder in a patient with a rectal injury not recognized at the time of surgery requiring proximal diversion of bowel. B, Subsequent cystogram showing development of fistula between urethra and rectum.

superficial surgical-site infection and with possible worsening with prolonged ileus.[27,28] Largely based on these data, several enhanced recovery protocols have eliminated routine use of bowel preparation for radical cystectomy patients.[25,26,29,30] Additional data suggest it can be safely eliminated with radical prostatectomy.[31] However, recent retrospective studies now suggest mechanical preparation along with enteral antibiotic preparation reduces infectious complications, anastomotic leak, and ileus in patients undergoing colectomy.[32,33] It is unknown whether these data translate to urologic patients undergoing surgical manipulation of small bowel rather than colon.

Bowel Injury

Any procedure in or near the abdomen risks inadvertent bowel injury with reports after cystectomy,[34] laparoscopy,[35] percutaneous nephrolithotomy,[36] suprapubic tube placement,[37] and even transvaginal surgery.[38] A simple serosal injury should be oversewn with Lembert-type suture, usually 3-0 silk. If the bowel is perforated, the approach varies depending on the size and location of the injury as well as whether the injury involved electrocautery. When the majority of the circumference of the bowel is violated the segment does not appear viable, or if the injury was caused by electrocautery, segmental resection should be performed. The small bowel can usually be reconnected safely. The large bowel can also often be reconnected, as long as fecal impaction or spillage is minimal.

If the bowel is perforated but the perforation does not appear to involve a large segment or circumference, primary repair in two layers with an inner layer of 3-0 polydioxanone (PDS) and an outer layer of interrupted 3-0 silk suture can be used. Closing the injury transverse to the longitudinal axis of the bowel should be considered so that the luminal diameter is not compromised. One may consider proximal bowel diversion if the patient is immunocompromised, has poor nutritional status, has had prior radiation of the involved segment, or there is gross contamination by colonic contents.

Delayed recognition of bowel injury typically presents with prolonged ileus, abscess (contained leak), or intraperitoneal sepsis (uncontrolled leak), and these patients can be profoundly ill. Initial presentation after laparoscopy is often more subtle, and patients may simply demonstrate pain at a single trocar, abdominal distention, diarrhea, and leukopenia.[35] Surgical exploration and washout are indicated in patients with uncontrolled leak to gain source control and generally requires proximal diversion of the bowel. Consultation with general or colorectal surgery is often recommended in this setting to assist with bowel repair and diversion. Controlled leak (abscess) or retroperitoneal bowel injury in a patient who is otherwise stable may be successfully managed with percutaneous drainage.

Rectal injury represents a special case of bowel injury of specific interest to urologists. It has been reported in less than 1% of cases in modern prostatectomy series[39,40] (Fig. 11.1). Recognition of the injury is generally intraoperative with minimal spillage of rectal contents. In this case, primary closure in two or three layers with absorbable suture has been described without diverting colostomy in both open and laparoscopic/robotic series. A peritoneal or omental flap may be used to interpose between the repair and the urethra-bladder anastomosis. Fecal diversion should be more strongly considered in the setting of an immunocompromised patient or prior pelvic radiation. Recto-urethral fistula uncommonly develops after primary repair (2/16 in one series),[40] management of which is discussed elsewhere in this text. Rectal injury during cystectomy can be managed similarly. However, avoidance of urinary diversion that will place suture lines directly over rectal repair should be considered. Delayed presentation of rectal injury, thought to be caused by thermal injury, typically presents with bloody stool or pneumaturia and is initially managed by washout and fecal diversion.

Bowel Leak, Abscess, and Fistula

Procedures that require anastomosis of bowel segments, as are commonly performed in urology, risk development of bowel leakage. This can present in a variety of manners including enteric contents captured in drains, intrabdominal or pelvic abscess, or development of a fistula.

Leakage from bowel anastomosis after urologic surgery is rare.[3,41] Patients may present with eneteric contents from a surgical drain, persistent ileus, leukocytosis, or fevers. Reoperation and repair may be considered in the early postoperative period. However, presentation of anastomotic leak has been reported over 30 days postoperatively, and reoperation after 7–10 days after the initial surgery is often very difficult due to edema and adhesions and is likely to result in additional harm.[42] In this case, management focuses on control of the enteric contents through drainage and delayed surgical repair.

An intraabdominal abscess represents a walled-off infection and collection of bacteria, purulence, blood, and possibly enteric contents, urine, or foreign material. Most intraabdominal abscesses develop in the postoperative period and have been reported in 1.1% to 3.6% of patients after cystectomy with urinary diversion.[3,43] The diagnosis should be suspected in a patient who is not progressing adequately following an operation. Ileus, abdominal distention, and anorexia are common symptoms. Spiking fevers are common but may be masked in immunosuppressed patients, in elderly patients, and in patients receiving antibiotics.

Diagnosis is made by ultrasound or CT scan (Fig. 11.2). Treatment of the abscess requires drainage as antibiotics alone will not provide adequate resolution. For most intraabdominal, pelvic, and retroperitoneal abscesses, a percutaneous approach should be attempted before operative intervention.[44] In general, a pigtail catheter should be left in the abscess cavity and removed when drainage has subsided. Catheter drainage also allows for additional management decisions including assessment for ongoing urine or bowel leakage as contributing factors. The indications for open surgical drainage include inability to safely drain due to location, failure of percutaneous drainage, or presence of interloop abscesses.

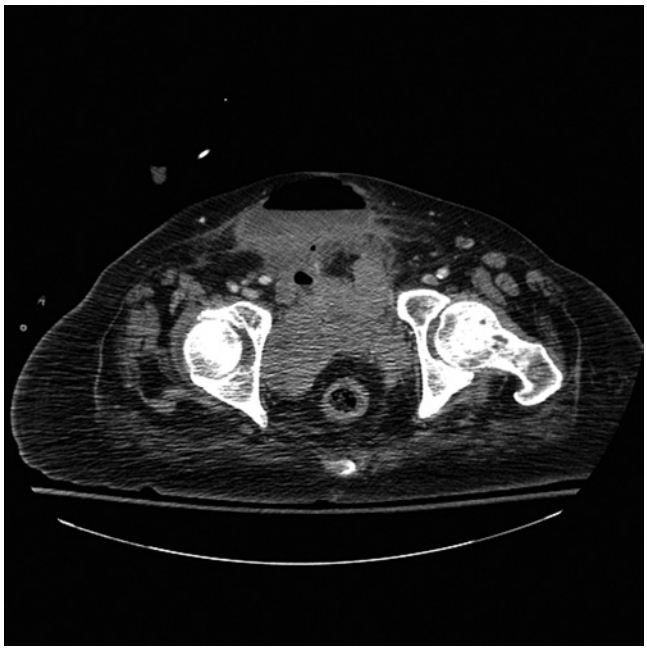

Figure 11.2 CT with IV contrast showing a subcutaneous abscess tracking from an intraabdominal location after radical cystectomy.

Antibiotic use should be directed by culture information until signs of infection have resolved. It is not necessary to continue antibiotics for long periods after adequate drainage. If the patient does not improve within 24 to 48 hours, additional imaging should be performed to ensure adequate drainage.

Fistula is defined as the abnormal communication between two structures and occurs not uncommonly in urologic surgery. Fistula to bowel used for urinary diversion occurs in up to 4% after radical cystectomy[45,46] and between neobladder and vagina in up to 3.1%.[47] Initial conservative management with maximal urinary drainage with an indwelling catheter and low residual diet may be undertaken.[48] Surgical repair should not be undertaken in the acute setting due to the high risk for failure and potential to cause further injury. Surgical management principles when conservative management is not successful include (1) locating and excising the fistula tract, (2) closure of neobladder defect in two layers, and (3) interposition of healthy tissue with an omental flap. Temporary proximal diversion of bowel can also be utilized to maximize successful repair.[45]

Vesicoenteric fistula, or the abnormal communication between bladder and bowel, is rare and most commonly occurs as a result of inflammatory and neoplastic processes of the bowel rather than as a result of urologic intervention. Management principles are similar to enterocutaneous fistula and include diversion of fluid crossing the fistula such as urine in a fistula to an ileal conduit. Patients often present with infection and may have undrained fluid collections leading to intraabdominal abscess that both require treatment.

Bowel Obstruction

Intraabdominal adhesions are the most common cause of bowel obstruction in the United States. The incidence of postoperative obstruction varies with the approach and procedure performed but is much less common. The short- and long-term risk of obstruction ranges from 1.6% to 16.0% after cystectomy[41,43,49,50] and 5% for retroperitoneal lymph node dissection.[51] Cases have been reported involving less invasive procedures including laparoscopy[50,52] and even penile prosthesis placement.[53]

Intestinal obstruction in the early postoperative period must be distinguished from ileus. Ileus is associated with many intraabdominal and extraabdominal processes that interfere with normal bowel motility and resolves spontaneously once the provoking source has been addressed.

Most patients with bowel obstruction exhibit abdominal pain, nausea, vomiting, obstipation, and abdominal distention. Delayed return of bowel function may also represent

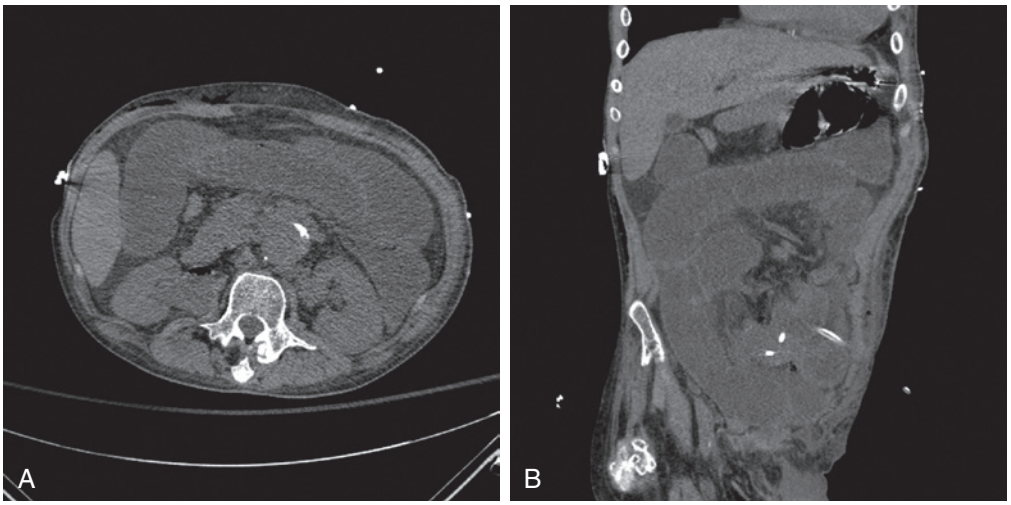

Figure 11.3 CT showing bowel obstruction after radical cystectomy with ileal conduit and bilateral ureteral stent placement. A, Axial. B, Coronal.

bowel obstruction. Pain is usually intermittent and may become constant if the bowel becomes compromised. However, pain severity may decrease over time as a result of bowel fatigue and atony. Patients usually become profoundly intravascularly depleted, manifested by orthostatic hypotension, tachycardia, and low urinary output. Eventually, patients manifest hypokalemic, hypochloremic metabolic alkalosis secondary to gastric loss of hydrogen and chloride and renal compensation of potassium wasting.

In patients with suspected bowel obstruction radiologic studies are indicated. Computed tomography (CT) scanning has sensitivity and specificity of >90% for small bowel obstruction (Fig. 11.3).[54] In addition, it is capable of detecting the cause as well as the presence of closed-loop obstruction and strangulation and therefore is usually the first radiologic examination performed. In contrast to ileus, which may also produce air–fluid levels, gas is not seen through the entire GI tract, especially distal to the point of obstruction.

The most important initial step in treating a patient with bowel obstruction is to replace intravascular volume. The patient may require several liters of fluid before rehydration is complete. Serum electrolytes should be monitored and adjusted as indicated. Antibiotics should not be used unless the patient is to go to the operating room or ischemic bowel is considered. Finally, a nasogastric tube should be placed to decompress the GI tract proximal to the obstruction, and oral intake should be strictly limited.

Strangulation of the bowel is a potential complication of obstruction and must be quickly corrected to avoid a poor outcome as it carries a much higher mortality rate than simple obstruction. The diagnosis of bowel strangulation is made by a combination of signs and laboratory findings including fever, tachycardia, nausea, and vomiting. Physical examination reveals localized tenderness. Laboratory findings include leukocytosis and elevated serum lactic acid or amylase levels.[55] When a strangulated bowel is suspected, operative exploration is mandatory following adequate resuscitation.

Internal hernia through the bowel mesentery is a special type of bowel strangulation that can occur after urologic surgery and often results in catastrophic outcomes.[56] Closure of any mesenteric defect during the procedure, especially with diversion of bowel as with urinary diversion, is commonly done to reduce this risk, and evidence from bariatric surgery supports this practice.[57]

Partial bowel obstruction in the immediate postoperative period almost always resolves with conservative treatment. The initially aggressive nature of adhesions usually improves and leads to resolution of symptoms. In nearly 90% of these patients, the condition resolves with nasogastric decompression. Two-thirds of these bowel obstructions resolve within 7 days and the remainder resolve within 14 days.[58] During this period, parenteral nutrition should be considered. If the condition has not resolved after 2 weeks of conservative measures, reoperation may be considered.

Once a determination has been made that reoperation is necessary to relieve obstruction, the patient should be prepared with perioperative antibiotics and careful induction of general anesthesia to avoid aspiration. Special care should be taken while entering the abdomen to avoid injury to the intestine.

On entering the abdomen, the surgeon should note the character of the peritoneal fluid. Turbid or dark fluid is an indication of ischemic bowel. The entire intestine should be freed of adhesions using sharp dissection from the ligament of Treitz to the sigmoid colon. Blunt dissection tends to injure the bowel serosa. The bowel should be repaired if the mucosa is visible. A point of transition between proximal dilated and distal decompressed bowel should be identified and the inciting cause corrected. If one determines that completely dissecting the bowel free of adhesions is dangerous, a bypass of the segment should be considered. The intestine should be examined for coloration, presence of motility, and arterial pulsations or Doppler signals. If dead bowel is identified, a segmental resection with primary anastomosis should be performed.

Laparoscopy offers the potential for a minimally invasive approach for diagnostic as well as therapeutic intervention. Several clinical studies have demonstrated that patients with bowel obstruction who underwent laparoscopic management of bowel obstruction had fewer postoperative

complications, quicker recovery of bowel movements, and a shorter hospital stay than those who underwent conventional laparotomy.[59,60] However, complications such as perforations may be more common overall in the laparoscopic group, and patients with two or more previous laparotomies have demonstrated higher rates of these complications. Therefore proper patient selection is critical to maximizing outcomes.[61]

Ogilvie's Syndrome

Ogilvie's syndrome, or colonic pseudo-obstruction, was first described by Sir William Ogilvie in the *British Medical Journal* in 1948. This condition manifests by colonic distention that appears mechanical but is actually functional. It is thought that this condition results from an autonomic imbalance leading to increased sympathetic tone or excessive parasympathetic suppression. The precise physiologic mechanism, however, is still poorly understood.

Ogilvie's syndrome occurs most commonly in patients who are long-term residents of a nursing home or psychiatric ward with conditions such as stroke, dementia, orthopedic procedures, sepsis, neuroleptic use, narcotic use, or electrolyte abnormalities but can also present after gynecologic and urologic surgeries. Most patients present with massive abdominal distention and few other complaints. Patients rarely complain of much pain. Physical examination reveals a distended and tympanic abdomen with diminished bowel sounds. Fever and leukocytosis are rare. The presence of marked abdominal pain, fever, and leukocytosis should alert the physician to ischemia or perforation. When ischemia or perforation is present, the mortality rate is ≤40% compared with 15% in patients with viable bowel.[62]

The diagnostic process begins with flat and upright abdominal radiographs, which demonstrate a massively dilated colon beginning in the cecum and extending no farther than the splenic flexure. One must be sure that volvulus or bowel obstruction is not the cause of the colonic distention. A gentle enema contrast study can be ordered to rule out these causes and confirm the diagnosis.

For most patients, treatment is conservative. Electrolyte abnormalities should be corrected and the medication list reviewed. Patients with a cecum measuring <12 cm should receive nothing by mouth, and a nasogastric tube should be placed. These patients should be monitored with serial examinations and abdominal films.

Patients who do not show improvement with conservative management may respond to neostigmine, a reversible acetylcholinesterase inhibitor. Neostigmine, administered intravenously, results in stimulation of muscarinic parasympathetic receptors and contraction of the affected colon. A randomized, double-blind, placebo-controlled trial found that 10 of 11 patients who received neostigmine had colonic decompression but none in the placebo group did.[63] Because neostigmine can cause bradycardia, bronchoconstriction, and tremors, close monitoring of cardiorespiratory status is required, and any toxicity should be treated with atropine.

When conservative and pharmacologic management fails, colonic diameter measures >12 cm, colon size is increasing rapidly, or the duration is >3 days, the colon should be decompressed colonoscopically with placement of a long rectal compression tube.[64,65] Surgical management is indicated in patients with ischemia or perforation or when pharmacologic methods and decompression have failed.

Chapter 11 Questions

1. Postoperative day 4 after radical cystectomy with neobladder, a 72-year-old male develops severe nausea and emesis. He is otherwise stable without fever or leukocytosis but does have a distended abdomen. A nasogastric tube is placed with return 750 mL of bilious material. Which of the following has been implicated in the development of the most likely cause of his condition?
   a. Decreased sympathetic outflow
   b. Use of NSAIDs
   c. μ-receptor activation
   d. All of the above
   e. None of the above

2. A patient who underwent a radical cystectomy with ileal conduit was discharged on postoperative day 5. Fourteen days later he presents to the emergency room with fever, distended abdomen, and leukocytosis. A CT scan is performed that shows a rim-enhancing fluid collection in the pelvis. What is the appropriate management?
   a. Percutaneous drainage
   b. Observation only
   c. Prescribe an antibiotic and observation
   d. Take the patient to the operating room for open surgical drainage
   e. Take the patient to the operating room for repair of ureteral anastomosis

3. After dividing the bowel to obtain a segment and reanastomosing the divided bowel for urinary diversion during radical cystectomy, what can be done to reduce the occurrence of an internal hernia?
   a. Close the fascia with nonabsorbable suture
   b. Close the peritoneum with mesh
   c. Avoid use of an omental flap
   d. Close the mesenteric defect
   e. Keep the patient on bowel rest for 48 hours after surgery

4. An afebrile 68-year-old female underwent cystectomy with neobladder 14 months ago. She presents to the emergency room with abdominal pain, emesis, and obstipation. A CT scan is performed. Which of the following is the most likely cause of her condition?
   a. Gastric inflammation
   b. Increased sympathetic outflow
   c. μ-receptor activation
   d. Intraabdominal abscess
   e. Intraabdominal adhesions

5. A 64-year-old male undergoes a robotic-assisted laparoscopic prostatectomy and presents to your office on postoperative day 3 with diarrhea, abdominal distention, and focal but severe pain at the right most lateral trocar site. Which of the following is the most likely diagnosis?
   a. Urine leak
   b. Ileus
   c. Appendicitis
   d. Injury of ascending colon
   e. Urinary tract infection

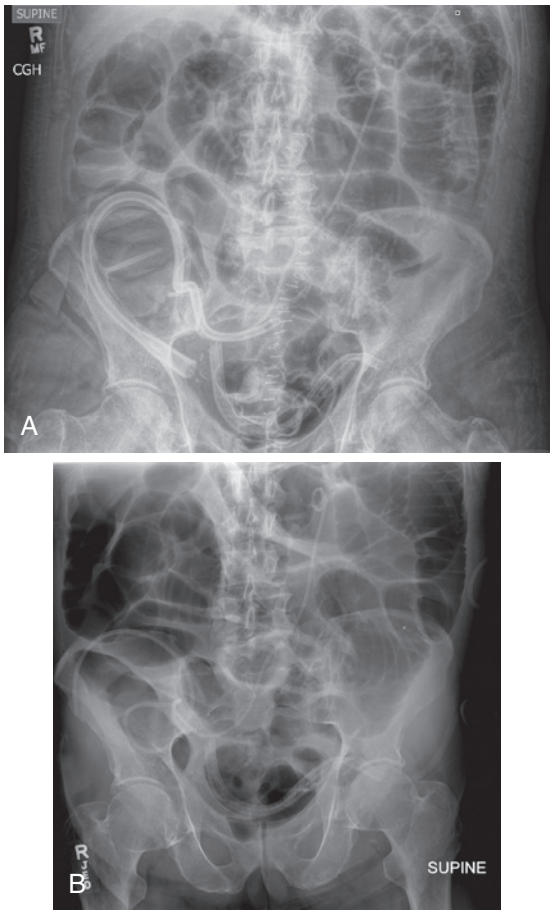
6. A 53-year-old female who previously underwent pelvic surgery and radiation for cervical cancer undergoes pelvic exenteration with ileal conduit urinary diversion for a local cancer recurrence. Her postoperative course is complicated by prolonged ileus requiring total parenteral nutrition. On postoperative day 12, she begins draining enteric contents from the upper portion of her incision. After ensuring she does not have an undrained fluid collection within the abdomen or pelvis, which of the following is the best course of action?
   a. Continue total parenteral nutrition and strict nil per os (NPO) status
   b. Emergently explore her abdomen and repair the bowel injury
   c. Begin enteral feeding
   d. Initiate broad spectrum antibiotics
   e. Cauterize the site of the draining fluid

7. An 80-year-old male undergoes a radical nephrectomy for a 13-cm renal mass. He develops postoperative nausea and ileus, and a nasogastric tube is placed. Abdominal x-rays reveal no free air but do show air throughout the small and large bowel. His large bowel is distended to greater than 12 cm. Which of the following is an appropriate next step?
   a. Discontinue the nasogastric tube (NGT) and place a gastric tube
   b. Administer neostigmine
   c. Administer alvimopan
   d. Perform esophagogastroduodenoscopy
   e. Administer atropine

8. A 46-year-old female develops a postoperative ileus after undergoing a radical nephrectomy. Impaired motility of which of the following is most likely responsible for this process?
   a. Stomach
   b. Duodenum
   c. Small bowel
   d. Large bowel
   e. Rectum

9. All of the following strategies are helpful for preventing or reducing the duration of postoperative ileus except:
   a. Nasogastric tube drainage
   b. Alvimopan
   c. Minimization of narcotic pain medication
   d. Use of epidural anesthesia
   e. Chewing sugar-free gum

10. A 62-year-old male undergoes a radical cystectomy and ileal conduit for urothelial cell carcinoma. Prior to incision, he received a dose of an IV second-generation cephalosporin. He did not undergo a preoperative mechanical or antibiotic bowel preparation, which places him at an increased risk for which of the following?
    a. Pelvic abscess
    b. Entero-enteric anastomosis leak
    c. Entero-ureteral anastomosis leak
    d. Superficial surgical site infection
    e. None of the above



Case Studies

CASE 1

A 62-year-old male undergoes revision of a left ureteroenteric stricture due to a stricture that developed after radical cystectomy with ileal conduit urinary diversion. His postoperative course is uneventful until day 4 when he develops large volume emesis. He is afebrile, without leukocytosis, and his exam reveals a minimally tender abdomen that is distended and tympanitic. An abdominal series is obtained, and representative images (Case Fig. 11.1) are shown.

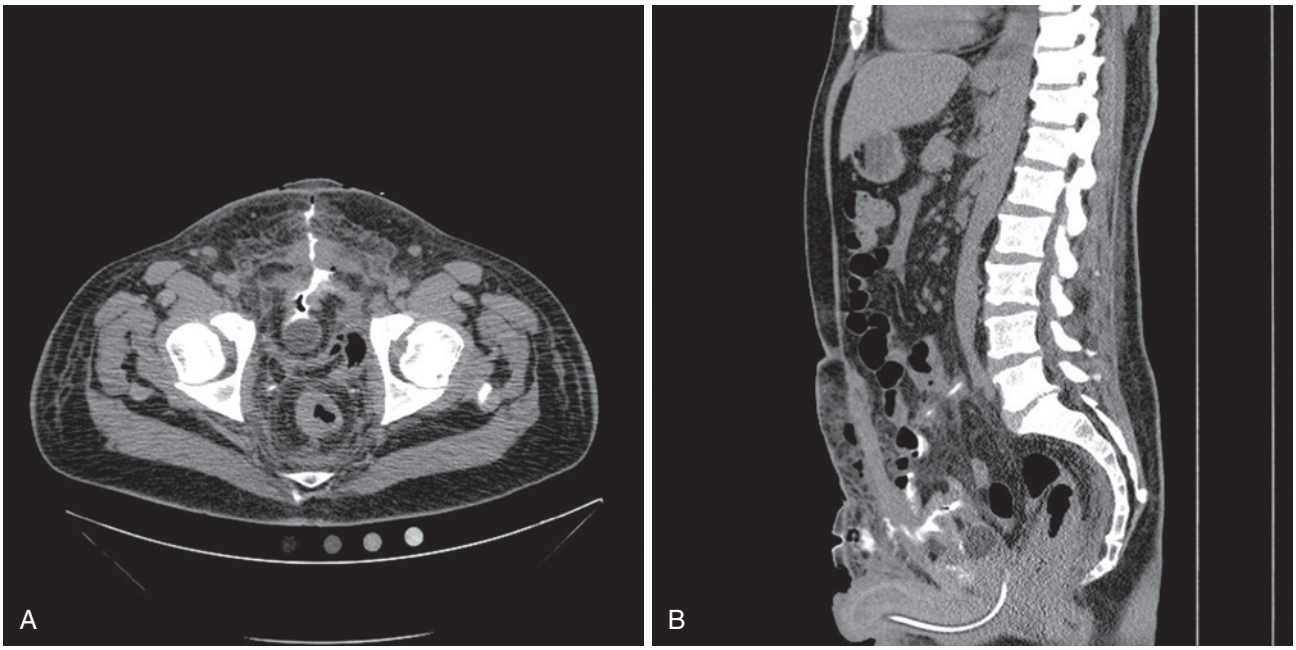
1. Which of the following is the most likely diagnosis?
   a. Bowel injury
   b. Bowel obstruction
   c. Retained foreign body
   d. Ureteroenteric leak
   e. Ileus

2. The patient continues with moderate nasogastric tube output despite occasionally passing flatus and stool. He is unable to tolerate clamping of the nasogastric tube. On postoperative day 8, which of the following is an important step in his management?
   a. Initiate total parenteral nutrition
   b. Explore abdomen to lyse adhesions

Case Figure 11.1

   c. Begin broad spectrum antibiotics
   d. Begin enteral feeding
   e. Continue current care without changes

3. He remains hospitalized for 2 weeks with persistent nausea. He is able to have the nasogastric tube removed but is unable to take any solid food and can only tolerate a few hundred milliliters of fluid per day. He remains without concerning vital signs or laboratory or imaging studies. His abdominal exam remains moderately distended and tympanitic, and a CT scan confirms no evidence of bowel obstruction. Which of the following is the next step in management?
   a. Place a gastric tube for enteral feeding directly into the stomach
   b. Make arrangements for outpatient total parenteral nutrition
   c. Place a pelvic drain
   d. Initiate alvimopan therapy
   e. Make arrangements for outpatient fluids together with oral nutrition supplements



CASE 2

A 59-year-old male undergoes a radical cystoprostatectomy with ileal neobladder urinary diversion for muscle invasive bladder cancer. His initial postoperative course is uneventful, but he then presents to clinic postoperative day 12 hemodynamically stable but with fluid draining from the midline abdominal incision. A CT scan is obtained, and representative images (Case Fig. 11.2) are shown. Fluid is collected from the midline incision and found to have an elevated creatinine level.

1. What is the most likely cause for the fluid draining from the patient's incision?
   a. Bowel injury
   b. Superficial surgical site infection
   c. Urine leak from neobladder
   d. Chylous ascites
   e. Seroma

2. What is the initial management for this patient?
   a. Cauterize the fistula tract
   b. Abdominal exploration and closure
   c. Bowel rest with total parenteral nutrition
   d. Treatment of urinary tract infection
   e. Place bilateral percutaneous nephrostomy tubes

3. Despite maximal drainage of the neobladder, the drainage from the midline does not stop. After 4 months, he presents for definitive repair. Which of the following is an important principle to maximize the success of the procedure?
   a. Administration of antibiotics for 48 hours after surgery
   b. Mechanical bowel preparation
   c. Placement of ureteral stents
   d. Coverage of the repair with a tissue flap
   e. Use of mesh for closure

Case Figure 11.2

Answers

1. **c.** This patient has likely developed postoperative ileus. Increased sympathetic outflow and opioid use leading to activation of μ-receptors contribute to this process. NSAIDs may be helpful in reducing postoperative ileus by minimizing need for narcotics and reducing inflammation.
2. **a.** Intraabdominal abscesses can be identified by ultrasound or CT. Percutaneous drainage is necessary after an intraabdominal abscess has been identified. In 80–90% of cases, the abscess can be successfully drained using this approach. An antibiotic alone is not adequate. The patient should be started on an antibiotic based on the culture information. Indications for open surgical drainage include failure of percutaneous drainage, inability to percutaneously drain, or interloop abscesses. While a urine leak may be the underlying cause of an abscess, percutaneous drainage is the first step in management.
3. **d.** Internal hernias occur as a result of the protrusion of bowel through peritoneal or mesenteric defects. Closure of these defects during an operation eliminates potential defects. Fascial closure method, use of mesh, omental flap, and bowel rest do not prevent internal hernias.
4. **e.** The patient most likely has a bowel obstruction, which can be caused by adhesions after intraabdominal procedures. a–c are causes of ileus and an intraabdominal abscess is a less likely diagnosis.
5. **d.** Severe trocar site pain, diarrhea, abdominal distention, and leukopenia are consistent with an unrecognized bowel injury.
6. **a.** This patient has developed an entero-cutaneous fistula. Reoperation at this point after surgery is likely to result in more harm than benefit. Many well-drained fistulas will spontaneously close with bowel rest and total parenteral nutrition without need for surgical intervention or antibiotics.
7. **b.** This patient has developed Ogilvie's syndrome, or colonic pseudo-obstruction. When the diameter measures greater than 12 cm, the risk of perforation is substantial and warrants urgent intervention. Neostigmine, colonoscopic decompression, or placement of a cecostomy tube are all appropriate options.
8. **c.** Normal return of bowel function follows a predictable pattern of small intestine, stomach, and colon. However, impaired small bowel motility is the most likely cause of postoperative ileus.
9. **a.** While important for intraoperative management, routine use of nasogastric drainage in the postoperative period does not reduce prolonged ileus and may lead to other complications while all of the other strategies have some level of evidence to suggest benefit in reducing or preventing ileus.
10. **e.** While the quality of the evidence is not very high for urologic surgery, data from the colorectal literature suggest no increased risk for developing any of the listed complications in the setting of forgoing mechanical or antibiotic bowel preparation. In the setting of colon or rectal surgery, there does appear to be a benefit for bowel preparation. Early recovery protocols in urologic surgery that do not routinely use bowel preparation have also not demonstrated an increased risk for perioperative complications.

CASE 1

1. **e.** The abdominal x-ray shows distended loops of both large and small bowel with air in the rectum consistent with ileus. His laboratory and exam findings are also consistent with ileus.

2. **a.** The patient continues with postoperative ileus and is not able to tolerate enteral nutrition. To minimize risk from malnutrition, total parenteral nutrition should be instituted. There is no indication that he has now developed a bowel obstruction and antibiotics are not indicated.
3. **b.** Occasionally, postoperative ileus will persist for weeks after abdominal surgery and continued parenteral nutrition is needed to minimize the risk of malnutrition. Eventually the ileus will resolve, but recovery of normal gastrointestinal motility can be slow. While infection can contribute to the development of ileus, no evidence suggests he has a pelvic abscess. Enteral feeding, even if bypassing the oral route, will not be successful as the problem remains distal to the stomach. While alvimopan has been shown to decrease the time to return of bowel function, it is properly administered prior to and continued after surgery. There is no evidence that initiating therapy after 2 weeks would provide benefit. In addition, it is contraindicated in patients taking narcotics prior to initiation of therapy, which this patient was certainly taking. Finally, while it would be preferable to have the patient obtain nutrition through an oral route, he cannot take in adequate volume to obviate the need for total parenteral nutrition.

CASE 2

1. **c.** The CT scan shows inflammation and air tracking from the neobladder to the anterior wall and the elevated creatinine level on the collected fluid as consistent with a cutaneous-neobladder fistula.
2. **d.** A cutaneous fistula after urinary drainage uncommonly occurs in the postoperative setting. Treatment of infection of the urinary tract and maximizing drainage of the urine is important. Foley catheter drainage will likely be adequate, and the fistula tract may close without further intervention. Urgent treatment of the fistula is likely to cause greater harm than benefit and should not be attempted in the early postoperative period. Bowel rest with total parenteral nutrition is indicated for enterocutaneous fistula, but as the segment of bowel used for the neobladder is no longer in continuity with the GI tract, this is not necessary.
3. **d.** Repair of a fistula tract that does not heal with maximization of drainage should be undertaken in a delayed fashion. Interposition of healthy tissue between the repaired neobladder and the fascia will help to ensure a recurrent fistula does not recur.

Chapter 12 Questions and Answers

KEY POINTS:

1. Vesicovaginal fistulas (VVF) occur when there is an injury to the bladder creating a communicating tract with the vagina eventually leading to seepage of urine.
2. The occurrence of trauma to the lower urinary tract during surgery for benign gynecological conditions has been classically reported as high as 76% in some series; however, more recent studies have suggested this number is much lower and <1%.
3. The clinical manifestation of urogenital fistula are dependent on the size, location (i.e. proximal or distal to the continence mechanism), and structures with which the fistula connects.
4. A targeted history and physical examination including a thorough pelvic examination are in order when evaluating for a VVF.
5. Imaging of the upper tract is important as 10% of VVF may have concomitant injury to the ureters.
6. Complex fistulas include radiation-induced fistula, previously failed fistula repairs, multiple fistulas, or those measuring greater than 2.5 cm.
7. Surgical repair is the mainstay of therapy for urinary tract fistulas.
8. Radiation induced or recurrent fistulas should be biopsied to exclude malignancy.
9. A transvaginal approach should be considered when attempting to repair the uncomplicated, or simple, VVF.
10. The general goal of fistula repair is to provide a tension free, water tight closure allowing for non-overlapping suture lines with multiple layers.
11. Tissue interposition grafts should be considered for complex fistula.

Introduction

The word "fistula" finds its roots in Latin, meaning pipe or tube, and as such is used to describe any abnormal communication in the body that allows for the aberrant passage of bodily fluids or feces. The incidence and etiology of fistula formation follows a geographic variance. In regions with ample access to health care, iatrogenic injury of the urothelium is the most common cause of urinary tract fisutlae. In countries where access to health care is a challenge, prolonged labor during the birthing process is often considered to be the leading culprit behind fistula formation (Fig. 12.1). Some studies suggest that in countries with limited access to health care, physicians not aptly trained in performing emergent cesarean section are often unable to execute these procedures, leading to prolonged labor and the complications associated with the prolonged labor complex, including subsequent fistula formation. In these countries death

is often associated with obstetric complications.[1] Improvement in obstetric care has seen a decrease in the incidence of fistulas, which can occur in up to 2% of obstetric cases.[2] Alternately fistulas may be congenital or arise in the setting of urinary obstruction, chronic inflammation, or malignancy. In rare cases, fistulas may even arise after traumatic intercourse and have been seen to manifest in victims of sexual assault earlier in the paragraph as noted.[3,4]

Regardless of the etiology, fistulas are often bothersome to the patient and may have a significant negative impact on his or her quality of life. This is particularly true if the patient suffers from continuous and uncontrolled leakage of urine. This also adds morbidity in terms of infections and degradation of the skin. Control and correction of urinary leakage helps minimize patient distress, and therefore prompt surgical intervention to repair the primary deficit is of paramount importance. Continence management devices such as pads, diapers, catheters, collection bags, or closed suction systems can be cumbersome and costly to the affected. Constant and compassionate reassurance and communication with the patient and a concerted effort to bring a timely resolution to the issue will assure the best possible outcome.

Vesicovaginal Fistula

ETIOLOGY

Vesicovaginal fistulas (VVFs) occur when there is an injury to the bladder, creating a communicating tract with the vagina eventually leading to seepage of urine. There are several implicating factors including infection, inflammation, and radiation as well as malignancies of the pelvic organs including colon, uterus, ovaries, and cervix. Surgical misadventure during routine operative interventions remains the most prominent perpetrator of urinary tract fistula. In the United States 90% of VVFs ensue after surgery.[1] The occurrence of trauma to the lower urinary tract during surgery for benign gynecologic conditions has been classically reported as high as 76% in some series; however, more recent studies have suggested this number is much lower and <1%.[5,6] There are approximately 240,000 hysterectomies performed in the United States on a yearly basis, although this trend is decreasing.[7] Systematic reviews on laparoscopic hysterectomies have shown the rate of injury to the genitourinary system to be 0.73%.[8] Untoward harm to the genitourinary tract may also occur during colorectal surgeries. The rate of injury to the genitourinary tract during colorectal surgeries is 0.18%.[9] Patients with preoperative exposure to radiation have been shown to have a higher incidence of surgical complications and worse prognoses.[9] In a study by Fujikawa et al. following 271 females receiving radiotherapy for cervical cancer, the authors noted that 8% of patients receiving pelvic radiation had a genitourinary complication arising from the treatment, and an additional 13.7% suffered complications associated with the rectum including fistula and bleeding.[10] The reported rate of iatrogenic injury to the urinary tract is likely under-reported, particularly in cases where routine intraoperative cystoscopy is not employed.[11]

There are over 300,000 procedures for pelvic organ prolapse (POP) and over 100,000 procedures for stress urinary incontinence (SUI) performed across the world every year.[12,13] A third of those patients with POP will require reintervention for recurrence of the prolapse.[12] Cases where the surgeon elects to use synthetic mesh material can present a risk for fistula formation and have been reported with both midurethral slings for SUI and slings used during sacrocolpopexy to correct POP.[14,15] The incidence of fistula formation from synthetic sling material used to correct SUI is low and reported across the medical literature as occurring in 0.1% of cases.[16] Erosion of foreign bodies into the vagina can occur after placement of synthetic mesh for POP or SUI as well as from retained objects introduced into the vagina such as pessaries or tampons that may find their way into the bladder over time (Fig. 12.2).

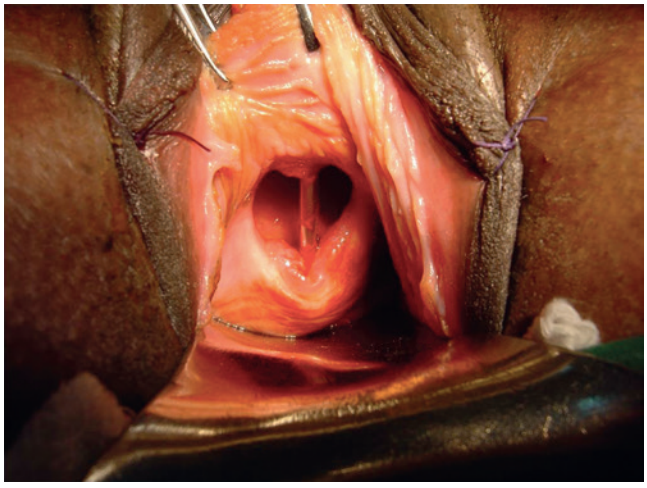

Figure 12.1 Vesicovaginal fistulas secondary to prolonged labor complex. (Photograph courtesy Dr. Andrew Browning.)

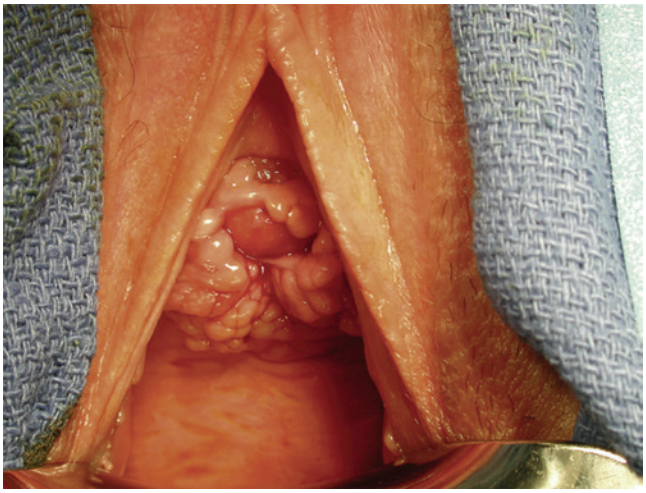

Figure 12.2 Urethrovaginal fistula associated with a midurethral synthetic sling. The urethra is exposed directly underneath the vaginal epithelium with no obvious periurethral fascia. The actual fistula (not seen) is located at the proximal border of the area where the vaginal epithelium meets the urethra. (From Nitti VW, Rosenblum N, Brucker BM. Vaginal Surgery for the Urologist. 1st ed. Philadelphia: Elsevier/Saunders; 2012:xvi.)

Meta-analysis of the global medical literature has suggested that the worldwide prevalence of urinary tract fistula is lower than suspected and reported to truly occur in 0.3% of all women. This value rises in women of reproductive age. There are regions of the world where the incidence is distinctly higher, including sub-Saharan Africa and South Asia where the prevalence is 1.5% and 1.6% respectively. The pooled incidence of vesicovaginal fistula in these countries in women that had recently given birth was 0.09%.[17]

PATHOPHYSIOLOGY

Iatrogenic fistula formation is thought to arise secondary to traumatic instrumentation or radiation along the genitourinary tract. The initial injury causes tissue ischemia. Eventually the affected area will undergo necrosis, and a fistulous communication will be formed with the genitourinary tract allowing for the aberrant passage of urine. The temporal relationship between the inciting event and actual leakage of urine is variable and can range from days, weeks, to even years after the traumatic incident. Delayed presentation of genitourinary manifestations is particularly notorious in patients undergoing pelvic radiation.[10] Ischemic microvascular damage arising secondary to obliterative endarteritis may take years to become apparent. A fistula that arises in the setting of prior radiation must raise suspicion for a possible malignancy and should be biopsied prior to surgical repair. The ischemic changes that caused the fistula may also compromise the surrounding tissue available for reconstruction. These repairs are challenging and are often with inferior outcomes.[18] In a fistula arising after surgery for malignancy, one must also exclude the possibility of a recurrence within the fistulous tract with a biopsy prior to surgery.

Any surgery in the vicinity of the genitourinary organs can lead to the formation of a fistula. Lacerations to the bladder if unrepaired will cause leakage of urine. A concomitant injury or opening in another pelvic structure raises the possibility of establishing a fistulous tract. The persistent output of urine production allows for the tract to persist by not allowing the injured tissue to heal. Once the fistulous tract is epithelialized it truly declares itself. Hysterectomy is a notorious culprit behind fistula formation particularly at the site of the vaginal cuff and along the anterior wall of the vagina. Fistulas can also form after retroperitoneal lymph node dissections, low anterior or abdominoperineal resections, or surgery to the uterus or cervix.

PRESENTATION

The clinical presentation of VVF is variable and highly dependent on the mechanism of injury to the bladder and vagina. Leakage of urine usually occurs within 1 week of catheter removal, although the presentation may be delayed. Patients that incur surgical injuries may develop signs and symptoms of peritonitis including fever, chills, vomiting, rebound, and guarding in the postoperative period suggesting the presence of a urinoma or possibly urinary ascites. A study in the prevention of fistula formation in women undergoing hysterectomies concludes that patients with abdominal pain and distention or paralytic ileus in the postoperative period should be assessed for trauma to the lower urinary tract. Hematuria or voiding symptoms such as frequency and urgency are also highly suggestive of injury to the bladder.[19] Often it is difficult to distinguish discharge after vaginal surgery from urinary leakage, and one must maintain a high index of suspicion for a fistula. The majority of patients with a VVF will declare themselves within a month of catheter removal with complaints of continuous leakage of urine per the vagina; however, the presentation may also be delayed. Very large fistulas may cause continuous or gravitational incontinence.

DIAGNOSIS

A targeted history and physical examination including a thorough pelvic examination are in order when evaluating for a VVF. A half speculum should be employed to assess all three vaginal compartments. In the acute setting there can be severe erythema and inflammation concealing the opening of the tract. Intraabdominal and vaginal collections of fluid may be sent for creatinine and urea measurements. A rectal examination should be considered to assess the posterior vaginal wall and rule out rectal involvement.[20] If digital rectal examination is suggestive of rectal involvement, proctoscopy should be performed.

Once a fistula is suspected, attention must be turned to promptly identifying the size and location, as this will dictate management. Imaging of the upper tract is mandated as 10% of VVFs may have concomitant injury to the ureters.[21] Historically this had been achieved with intravenous pyelograms. This has in great part been replaced by retrograde pyelograms and contrast-enhanced, cross-sectional imaging with a urographic phase, given its superior anatomic detail. Direct inspection of the fistulous tract with cystoscopy is important in its characterization. One can identify necrotic tissue of possible recurrence of malignancy that may alter management. Cystograms can also aid in visualization of the tract. Some fistulas are clearly evident and may be stented with a ureteral catheter or feeding tube for ease of resection. If the fistula is not clearly evident, any patch of erythema or bullous edema must raise suspicion as the offending site. A vaginoscopy may also be performed at the time of cystoscopy, adding minimal time to the procedure and enhancing diagnostic value.[22] If the upper tract has not been assessed or if the patient has a contraindication to intravenous contrast or cross-sectional imaging, retrograde pyelograms should be employed at the time of intraoperative cystoscopy (Figs. 12.3, 12.4).[23,24]

When there is doubt as to whether the discharge is urine or vaginal secretions, a "dye test" may be performed. A simple way to diagnose lower tract fistula is to fill the bladder with methylene blue and observe for leakage across the vaginal epithelium. If not clearly evident, the patient can insert a tampon and walk around the clinic to elicit leakage in the way it occurs naturally. If there is suspicion of an injury to the upper tract, phenazopyridine may be administered orally and a "double dye test" employed. The presence of the orange dye in the proximal tampon suggests a ureterovaginal fistula versus blue dye, a VVF. The presence of dye on the distal tampon may be indicative of leakage from the urethra, perhaps secondary to SUI. Urodynamic studies

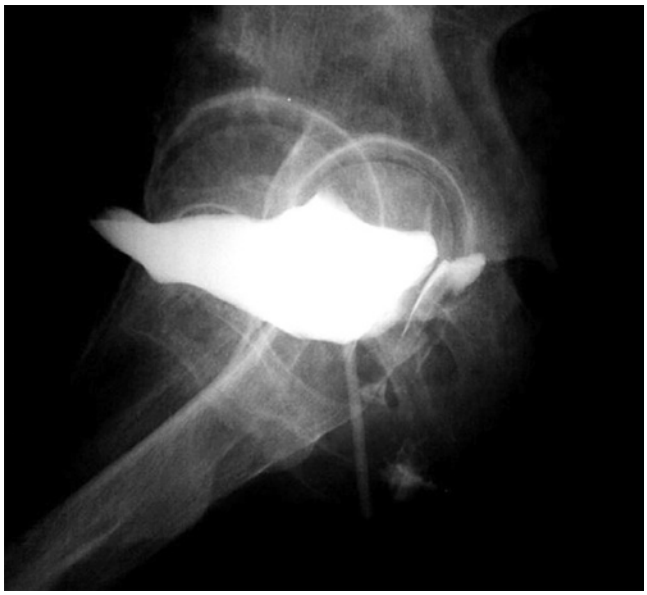

Figure 12.3 Cystogram demonstrating contrast in the vagina. (From Roslan M, et al. Suprapubic transvesical laparoendoscopic single-site surgery for vesicovaginal fistula repair: a case report. Wideochir Inne Tech Maloinwazyjne. 2012;7(4):307-10.)

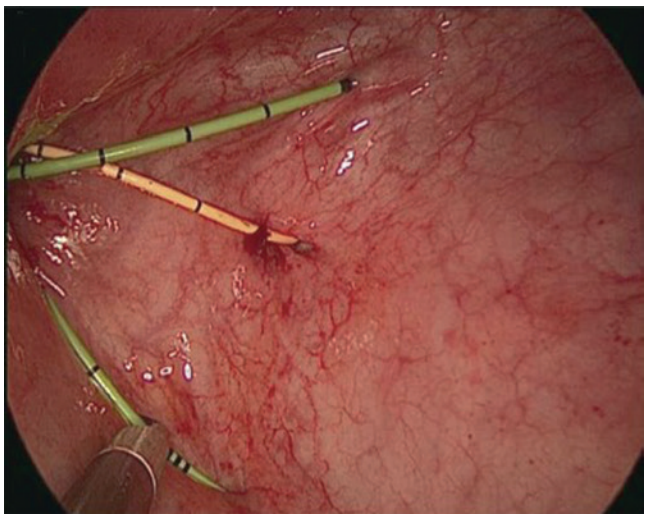

Figure 12.4 Catheterized ureters (green) and fistulous tract (yellow). (From Roslan M, et al. Suprapubic transvesical laparoendoscopic single-site surgery for vesicovaginal fistula repair: a case report. Wideochir Inne Tech Maloinwazyjne. 2012;7(4):307-10.)

may be of diagnostic value in the evaluation of a fistula, particularly if there is suspected concomitant storage or voiding dysfunction. Urodynamics allow for determination of capacity and compliance, which may be useful for patients that have been radiated. Videourodynamic testing has the added benefit of providing anatomic as well and functional information. Patients with injuries in the trigone or bladder neck are at risk for developing detrusor overactivity and SUI.[25] Patients that have received radiation may have decreased compliance and capacity as a consequence. Urodynamic studies may help plan for concomitant augmentation cystoplasty at the time of fistula repair or consideration of urinary diversion in severe cases (Box 12.1; Fig. 12.5).

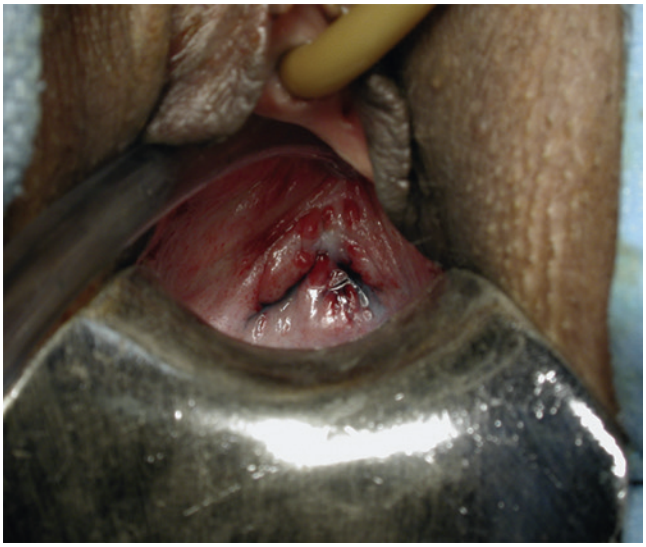

Figure 12.5 Instillation of indigo carmine in the bladder can help to locate the fistula. (From Nitti VW, Rosenblum N, Brucker BM. Vaginal Surgery for the Urologist. 1st ed. Female pelvic surgery video atlas series. Philadelphia: Elsevier/Saunders; 2012:xvi.)

PREVENTION

Vesicovaginal fistulas are largely a consequence of synchronous injury to the bladder and injury or incision of the vagina. This usually occurs after hysterectomy. The rate is highest after radical hysterectomy for malignancy and lowest following hysterectomy for pelvic organ prolapse.[6] Tissue is more prone to damage in patients with active malignancy or prior radiation. Injury to the bladder occurs during dissection from the cervix, especially when the procedure is complicated by prior radiation therapy, obesity, or prior surgery. Excessive fulguration and/or suture placement through the vaginal epithelium and into the bladder are notorious offenders. Prevention of VVF formation is contingent on proper surgical technique and postoperative urinary drainage. Using a Foley catheter during pelvic or vaginal surgery can help in identifying the bladder and maintains the bladder decompressed by allowing for adequate bladder drainage. The surgeon must maintain a high index of suspicion for injury, and in cases of suspected bladder or ureteral injury the urologist should be consulted at once.

Intraoperative use of cystoscopy should be employed whenever there is suspicion of bladder injury that is not readily identified. Studies suggest the combined used of cystoscopy and vaginoscopy can be of added benefit to identify

bladder injury.[22] The use of dyes and retrograde filling of the bladder, such as with dilute methylene blue, can also reveal an injury. The intravenous injection of indigo carmine can assist in the diagnosis of a ureteral injury. In the absence of indigo carmine, sodium fluorescein may be used to visualize the ureteral jets.[26] In some cases an intentional cystotomy is needed to ensure that the bladder is fully inspected and the ureteral orifices are identified. Whether from an endoscopic or open approach, ureteral support stents (i.e., open ended catheters, feeding tubes) can also be used to ensure patency of the distal ureter and serve as a referent point during bladder closure. Technical points in closing a bladder injury include watertight bladder anastomosis, tension-free repair, and in many cases, if possible, interposition of healthy tissue between the bladder repair and vaginal cuff closure.

Postoperatively, adequate urinary drainage should be accompanied by maximal detrusor relaxation induced by anticholinergic/antimuscarinic medication. In many cases a cystogram can be utilized prior to catheter removal to confirm integrity of the bladder. Any complaint of vaginal discharge before or after catheter removal should prompt evaluation. This would involve a complete history, and, if suspicious for recurrence or persistence of a VVF, a full vaginal examination (i.e., with a half speculum) is warranted. If the exam in the immediate postoperative period confirms persistence of a fistula, a longer period of bladder drainage is needed. Hypothetically, if a foreign body was identified (i.e., suture) one could consider removal in the early recovery period.

MANAGEMENT

Vesicovaginal fistulas can be categorized with a basic system of "simple," "intermediate," or "complex." Angioli et al. consider a singular fistula measuring less than 0.5 cm as "simple."[27] "Complex" fistulas include radiation-induced fistula, previously failed fistula repairs, multiple fistulas, or those measuring greater than 2.5 cm. These are often the result of chronic disease or radiation. Fistulas falling in the range of 0.5 to 2.5 cm in size are termed intermediate. For management purposes, intermediate fistulas are treated as complex fistulas (Table 12.1).

Simple fistulas may be amenable to conservative management, which includes bladder drainage, fulguration of the fistulous tract, and plugs with surgical glue.[28] Conservative treatment has been attempted in simple fistula 2 weeks to 2 months after injury, with success rates ranging from 0% to 100%. Retrospective studies have shown the best rate for spontaneous closure occurs with bladder drainage.[29] No prospective study has correlated the duration of drainage with the chance for spontaneous healing, and often this is based on personal experience. At best, one-fourth of small fistulas will close with prolonged catheter drainage.[27] Other conservative options for closure of VVFs include electrofulguration with or without injection of bovine collagen, fibrin glue, and/or autologous platelet rich plasma injection and platelet rich fibrin glue interposition.[30] The bladder is subsequently drained for 4 weeks. We find that these approaches have limited utility, are seldom effective, and are rarely employed. They are best reserved for nonsurgical candidates. Surgical repair remains the mainstay of therapy.

There are several caveats to ensure successful surgical correction of any fistula. One must confirm removal of any foreign bodies or necrotic tissue in the offending site. The surgeon must consider the need to extract the fistulous tract or whether to include it in the surgical reconstruction. In cases of fistula from a recent surgery, with low suspicion of malignancy a well-healed fistula track may provide strong tissue to anchor sutures. Meticulous dissection and visualization are important for the reconstruction of the genitourinary tract. Lesions near the ureteral orifice merit stenting of the ureter. The closure of the bladder and fistula site must aim to be watertight and tension free in multiple nonoverlapping layers. Interposition grafts are useful in complex, radiated, or recurrent cases.[31] The patient must be optimized for surgery. Infections must be cleared using targeted antimicrobial therapy. Atrophic vaginal epithelium in the postmenopausal woman should be fortified with topical estrogen replacement therapy preoperatively (Box 12.2).

Correct timing of the repair is imperative. Surgical repair should not be performed in the presence of active infection or significant inflammation. Conventional wisdom dictated a delayed repair with a 3- to 6-month "cooling-off" period to allow the fistula tract to mature and inflammatory process to subside. However, studies have shown that if a fistula is identified in the acute setting it may be treated successfully.[32] Zimmern et al. observed that surgical repair performed within 2 to 3 weeks of the injury had no increased morbidity or failure rates when compared with delayed repair. Contraindications to early closure include multiple unsuccessful closures, associated enteric fistula with pelvic phlegmon, and previous radiation. These types of fistulas are usually repaired after a 4- to 8-month waiting period.[20] Ultimately, the timing of surgery should be based on the

Table 12.1 Classification of Vesicovaginal Fistulas

Simple	Intermediate	Complex
Singular fistula	0.5 to 2.5 cm in diameter	Greater than 2.5 cm in diameter
Less than 0.5 cm in diameter		Radiation-induced fistula Multiple fistulas Previously failed fistula repairs

Box 12.2 Important Steps to Ensure Successful Vesicovaginal Fistulas Repair

Critical Steps for Successful Surgical Repair of Vesicovaginal Fistulas

- Removal of any foreign bodies or necrotic tissue
- Meticulous dissection and visualization of tissue planes
- Stent the ureter(s) if near the lesion
- Closure of the bladder and fistula site must be watertight and tension free
- Multiple nonoverlapping layers
- Interposition grafts in complex, radiated, or recurrent cases[31]
- Resolution of infectious/inflammatory process prior to surgical repair
- Atrophic vaginal epithelium should be fortified with topical estrogen replacement therapy preoperatively
- Patient must be optimized for surgery

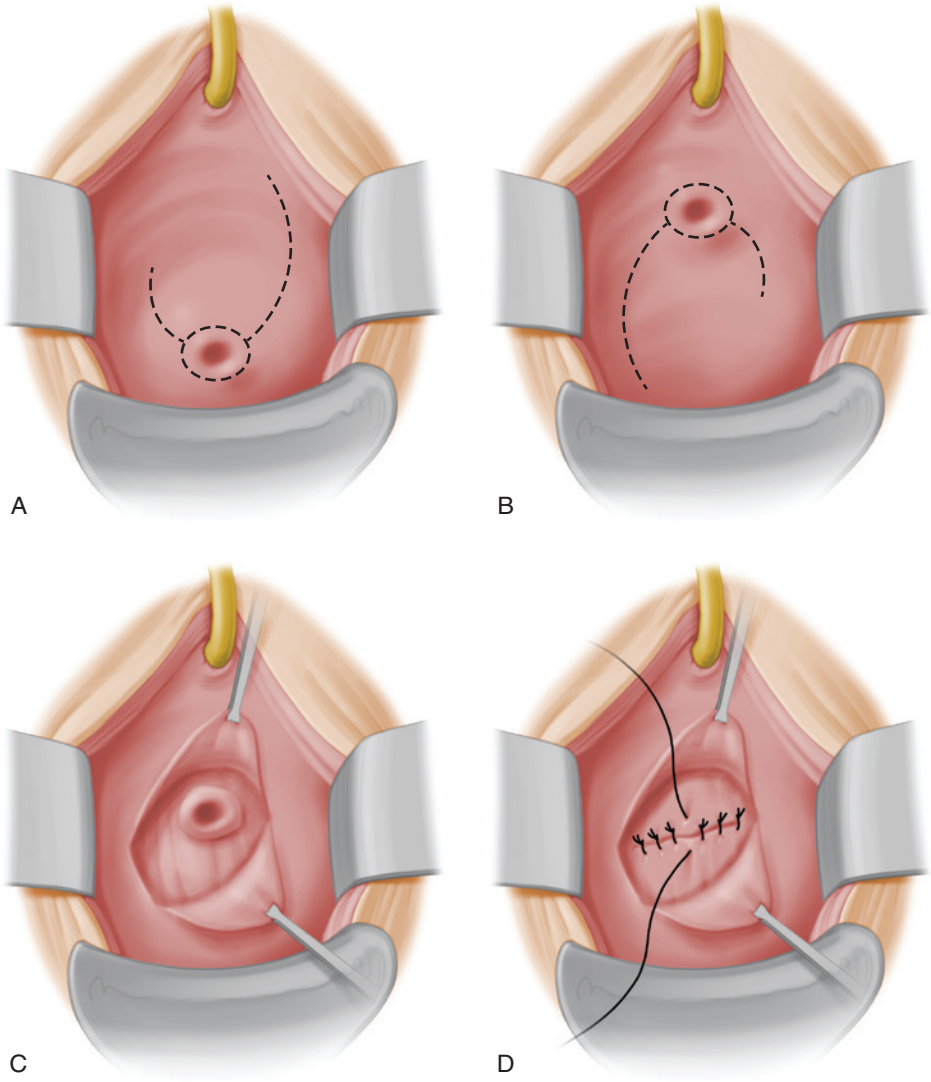

Figure 12.6 Incisions for vaginal flap repair of a vesicovaginal fistula. The configuration of the J incision will depend on the location of the fistula. A, For a more proximally located fistula, an anterior J is made. This allows for an anteriorly based flap. B, For a more distally located fistula, a posterior J is made to allow a posteriorly based flap to be mobilized. C, After mobilization of the vaginal wall, the fistula is fully exposed and ready for a two-layer closure. Ideally, there should be a distance of at least 1.0 to 1.5 cm from the fistula to the vaginal wall in all directions. D, Two-layer closure of the fistula. The deep layer is full thickness, including the bladder mucosa. The more superficial layer is an imbrication of the seromuscular wall of the bladder. (From Nitti VW, Rosenblum N, Brucker BM. Vaginal Surgery for the Urologist. 1st ed. Female pelvic surgery video atlas series. Philadelphia: Elsevier/Saunders; 2012:xvi.)

preference of the surgeon and the patient, and other factors involving the specific clinical scenario.

Convention had dictated an abdominal approach for supratrigonal fistulas, whereas a vaginal approach was used for infratrigonal, bladder neck, and proximal urethral fistulas. Current practice among experienced transvaginal surgeons is a vaginal approach in cases of VVF with a few exceptions. The advantages of a vaginal approach include patient comfort and recovery time.[20] It provides excellent exposure, access to multiple types of tissue interpositions, and the ability to perform multilayered closures without the morbidity associated with procedures that enter the abdominal cavity. Contraindications to a vaginal approach include severely indurated vaginal epithelium around the fistula, small capacity or poorly compliant bladder requiring augmentation, repair requiring ureteral reimplantation, involvement of other pelvic structures, vaginal stenosis, or the inability to obtain proper exposure[32].

An attempt should be made to repair the uncomplicated, or simple, fistula through the transvaginal approach (Fig. 12.6). This technique was refined by Dr. Raz.[33] The patient should be placed in dorsal lithotomy with care being taken to ensure protection of pressure points and adequate positioning. A cystoscopy is performed along with bilateral retrograde pyelograms if the upper tracts have not yet been assessed. An attempt should be made to catheterize the tract with a wire or conversely with a small Foley catheter or Fogarty catheter allowing for ease of dissection. A Foley catheter is inserted at the beginning of the case, the bladder is drained, and the catheter is clamped. Allis clamps and a ring retractor with sharp hooks are useful in retracting the vaginal epithelium ensuring adequate visualization for the

dissection. A vaginal flap is raised using the inverted "J" or "U" configuration to include the fistulous tract. It is useful to mobilize the vaginal epithelium away from the fistula. The margins of the fistula are trimmed and closed using absorbable sutures. The fistulous tract may be left or excised. Excision provides the advantage of eliminating the fibrous tract and closure of mucosa-to-mucosa. The disadvantage is increasing the size of the repair. If the bladder is friable it may not hold stitches well. The fistulous tract provides tensile strength to the closure. The perivesical fascia is then closed with absorbable sutures in a perpendicular fashion (over the fistula tract), with the edges inverted. The bladder is filled with fluid or diluted methylene blue dye at this point to check for a watertight closure. At this point if a flap is needed it would be used to cover the repair. Finally, the vaginal wall is closed in a third layer, in a nonoverlapping absorbable suture line. A suprapubic tube and/or a Foley catheter are left for straight drainage, and anticholinergic/antimuscarinic medications are given liberally.[34] Not all surgeons elect to leave two catheters in place postoperatively. A cystogram is performed 10–14 days postoperatively; if no extravasation is evident, the Foley and suprapubic catheters are sequentially removed. Refractory cases or those with fistulas near or at the vaginal cuff in patients that do not wish to preserve sexual function may be treated with obliterative procedures (Fig. 12.7). In cases where the uterus is present a partial colpocleisis, such as the Latzko repair, will achieve closure of the fistula and vaginal canal while preserving the uterus. A 3- to 4-cm elliptical segment of the vaginal epithelium is excised on the anterior and posterior portion of the prolapsed vaginal wall. Linear sutures are then placed to invert the bladder wall while avoiding the bladder lumen. Further layers continue to invert the bladder wall. The vaginal wall is then closed with a running suture. A benefit of this procedure is that it requires minimal resection, as the vaginal space is obliterated.

Fistulas associated with mesh complications or radiation, or complex fistulas will require the use of tissue interposition grafts. Nonoverlapping suture lines in the vaginal and vesical repair ensure a successful reconstruction. The well-vascularized adipose tissue in the labia majora provides a supple graft for distal fistulas. A peritoneal flap may be harvested for a fistula high in the vaginal vault, particularly if there is a fresh closure of the vaginal cuff. The selection of autologous tissue depends on the size of the fistula, its location, the quality of patient tissues, and the surgeon's preference. The bulbocavernosal fat, or Martius flap, is reliable, but it requires a separate incision. The pedicle originates from the posterior labial artery, a branch of the internal pudendal artery. The Martius flap may not reach fistulas high in the vaginal vault. The vagina may be shortened during attempts to extend the flap from the labia to the vagina. Peritoneum is an excellent substitute in these high fistulas; however, it can be challenging to mobilize to the lower vagina. The peritoneal flap is well vascularized and readily available, can be done with an open or closed peritoneum, and can be harvested with no additional incision.[34] Patients that have devastating fistulas that require complex vaginal repairs can be treated with a Singapore flap. This is a fasciocutnaeous flap with a pedicle that is supplied by the pudendal artery. One can rotate the graft superior and medially to reconstruct the vaginal canal (Fig. 12.8).

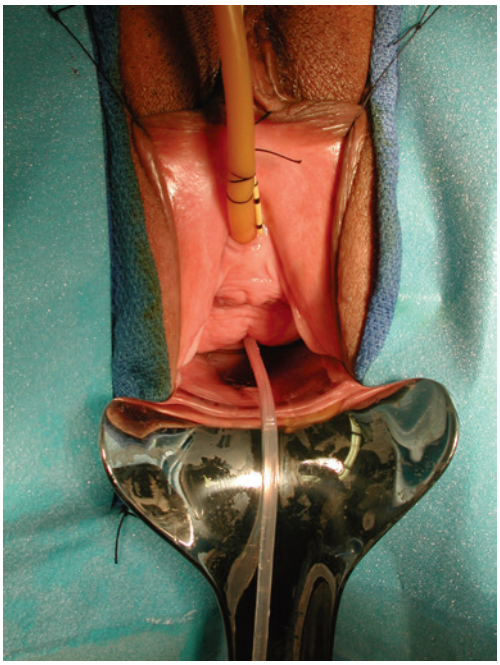

Figure 12.7 A vesicovaginal fistula located near the vaginal cuff has been catheterized with a small Foley catheter. Traction on the Foley catheter allows easy exposure and dissection. (From Nitti, V.W., N. Rosenblum, and B.M. Brucker, *Vaginal surgery for the urologist*. 1st ed. Female pelvic surgery video atlas series. 2012, Philadelphia: Elsevier/Saunders. xvi, 200 p.)

When the Martius flap fails or in the case of a larger fistula as associated with obstructive labor, there are adjuvant flaps and techniques in the armamentarium of the reconstructive urologist. Techniques include the use of vaginal wall flaps, omental flaps, biologic patches, and muscle flaps. In a series of patients with complex urethrovaginal fistulas (UVFs) that were refractory to anatomic repair with Martius interposition flap, Bruce and colleagues used rectus abdominus flaps based on the inferior epigastric artery to successfully treat 83% of their patients. These flaps are not only useful as interposition flaps but also have been proposed to fortify the bladder neck in cases of intrinsic sphincter deficiency.[35] The rectus flap has the advantage of being the least deforming to the exterior appearance of the patient. Similar techniques have been described using the gracilis muscle.[36] In cases where the urethra is completely obliterated, tubularized bladder wall flaps and/or vaginal wall flaps are used to create a neourethra. An autologous fascial sling is then placed to reestablish the continence mechanism.[37]

An open abdominal approach may be considered for complicated fistulas, previous failed repairs, a narrowed or stenotic vagina, those in close proximity to the ureters, or when concomitant procedures are being considered, such as ureteral reimplant or bladder augmentation.[38] Further, if the surgeon is not well versed in vaginal surgery or is more comfortable with the abdominal approach, it is reasonable to perform the surgery with the probability of the best outcome. Abdominal surgery allows for harvesting of omentum, which serves as a supple interposition graft

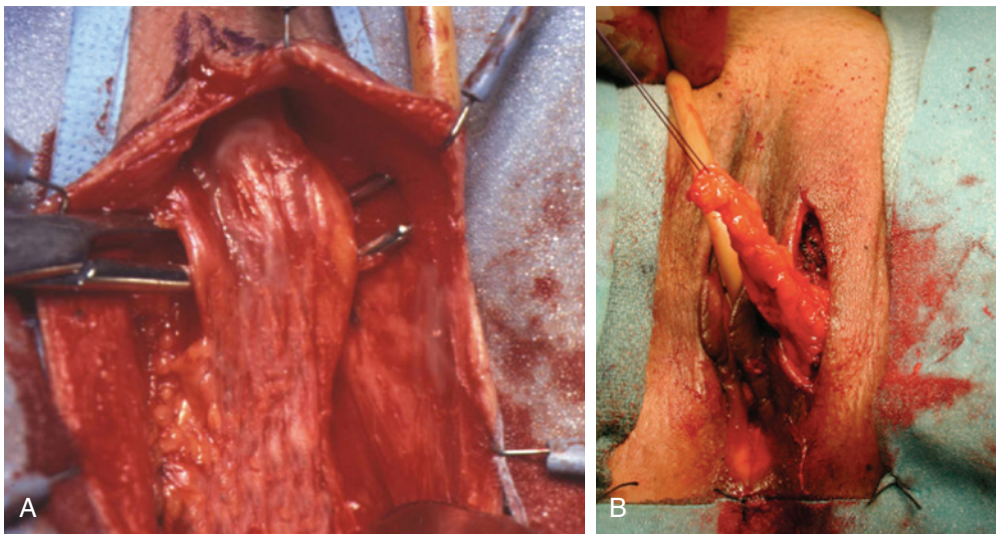

Figure 12.8 A, A Martius flap can be mobilized by making a longitudinal incision over the labia majora or in the crease between the labia minora and majora. Just underneath the skin is an avascular plane that sits between the skin and the underlying fat pad. B, In this case the flap is based on the blood supply from the inferior pudendal artery. The flap has been mobilized off the pubic bone and can now be tunneled under the labia minora and vaginal epithelium. (From Nitti, V.W., N. Rosenblum, and B.M. Brucker, *Vaginal surgery for the urologist*. 1st ed. Female pelvic surgery video atlas series. 2012, Philadelphia: Elsevier/Saunders. xvi, 200p.)

for the repair. A laparotomy does have the advantage of excellent exposure and visualization of the fistulous tract; however, it is at the expense of higher complications and the prolonged convalescence associated with abdominal surgery. Patients with abdominal repair also require longer hospitalizations when compared to transvaginal repairs.[39] An abdominal surgery approach may be extraperitoneal or transperitoneal, as well as extravesical or transvesical. The classic approach as described by O'Connor and Sokol entails a transabdominal transvescial repair where the bladder is bivalved to the fistulous tract. The vaginal wall is dissected off the bladder, and the fistulous tract is closed on both ends. An omental or peritoneal flap is placed in between the bladder and vaginal wall to prevent recurrence.[40] The incidence of bladder spasms is usually more pronounced following abdominal repairs and the standard use of a suprapubic tube. Urethral catheters and anticholinergics/antimuscarinics are maintained until a voiding cystourethrogram is performed 2–3 weeks postoperatively.[34] In severely refractory cases one may consider the use of urinary diversion. This has been found useful in patients with multiple failed attempts, patients with extensive radiation, or very large soft tissue defects. One may consider a continent pouch (i.e., Indiana pouch) versus an incontinent diversion (i.e., ileal conduit); however, orthotopic neobladders (i.e., Studer) are usually not employed.

Advances in minimally invasive techniques have seen a rise in the surgical repairs approached via pure laparoscopy or with robotic assistance. While this technology is still being developed and refined, successful outcomes have been reported. There were some initial difficulties maintaining pneumoperitoneum, but this has been overcome with the use of a vaginal packing and placing the Foley to mild traction.[38] In a comparative analysis of outcome between open and robotic surgical repair of recurrent supratrigonal VVF, Gupta et al. noted similar outcomes in terms of fistula resolution, exceeding 90% in both groups. Surgical complications such as blood loss and hospital stay were less in the robotic versus open group. They concluded that due to the decreased morbidity of the robotic over open approach, a transabdominal robotic repair should be considered in refractory cases.[41] The vaginal approach, however, may still remain the truly most minimally invasive approach, but does require a unique skill set.

The success rate of VVF repairs appears to be independent of the surgical approach, as long as the surgeon ensures a watertight repair with nonoverlapping suture lines and the use of interposition flaps as needed. In the absence of infection, inflammation, or previous radiation there is no additional benefit to delay of the surgical repair if the injury is recognized early in the postoperative period. This also minimizes the patient's distress and discomfort. The ideal timing of repair is at the time of injury.[42] The success rates of repairs are equivalent for the abdominal and vaginal approach and in most series exceed 80–90%.[32] Fistulas in radiated patients and those with prior failed repairs have inferior results; patients must therefore be counseled adequately. These patients can be treated temporarily with urinary diversion. This allows for tissue healing and resolution of inflammatory processes. Healing can occur and large defects may decrease in size and granulate. Primary closure at times can be achieved using interposition grafts or muscle flaps. Some patients that persist with urinary leakage, even after successful fistula repair, may call for a permanent urinary diversion.[43]

Urethrovaginal Fistula

ETIOLOGY

Cephalopelvic disproportion during prolonged vaginal delivery can lead to a prolonged and obstructive labor. Ischemia secondary to compression of the vaginal epithelium,

urethra, detrusor, and bladder mucosa can create such an injury. The principal causes of dystocia are problems with the birth canal, a large baby, or a small pelvis. Some studies have supported this claim by noting that fistula formation as well as obstructed labor is more common in primiparous mothers of male offspring due males' larger circumference.[44] Pressure on the symphysis pubis with forceps may also cause these injuries.

When there are injuries secondary to dystocia, one must address more than just the area of the fistula itself, as the affected field usually extends beyond the hiatus. Patients may suffer from urethral loss, stress incontinence, rectovaginal fistula formation, anal sphincter incompetence, and foot drop. In addition to their physical injuries, women who have experienced prolonged obstructed labor often develop serious social problems, including divorce, exclusion from religious activities, separation from their families, worsening poverty, malnutrition, and unendurable suffering.[45]

As with VVF, in the industrialized world, the most common cause of urethrovaginal fistula (UVF) formation is iatrogenic injury. Surgical procedures in the vicinity of the urethra pose the highest risk. Surgical repair of urethral diverticulum and anterior colporrhaphy constitute 15% and 45% of these injuries, respectively.[34] While uncommon, cases have been reported of urethrovaginal fistula from traumatic catheterization. Other causes include bladder neck suspensions and anti-incontinence surgeries as well as malignancy and radiotherapy (Table 12.2).

Midurethral sling procedures pose a particular risk due to the sheer volume of these procedures performed on a yearly basis.[46] Reports have estimated the prevalence of urinary incontinence in women between 30 and 60 years old to be 30%.[47] Any laceration or thermal injury during dissection increases the possibility of subsequently developing a fistula. The risk of developing a fistula during a sling procedure for SUI is cited at 1%.[48] This risk may increase in patients with preexisting microvascular damage such as diabetes or radiation therapy. When there is concomitant injury to the urethra during placement of a synthetic midurethral sling, one should repair the urethra primarily and abort placement of the mesh. In cases where there is concomitant SUI at the time of fistula repair, one can always consider an autologous fascial pubovaginal sling as the use of synthetic mesh is contraindicated.

PRESENTATION

The clinical presentation of urethrovaginal fistulas is dependent on their size, location, and relation to the urethral sphincter. Fistulas proximal to the urinary sphincter may be associated with complaints of SUI or, if close to the bladder neck, could cause continuous leakage of urine. Patients may present with vaginal pain or recurrent urinary tract infections.[49] Vaginal pooling of urine can also be a complaint and lead to skin irritation and breakdown. This may lead to recurrent yeast infections or candidiasis. Patients with distal fistulas may be completely asymptomatic or present with split urinary stream and/or dribbling. Very large fistulas can also cause continuous or gravitational incontinence.

As with VVF the timing of presentation can be varied and depends greatly on the mechanism of action behind the inciting injury. Obstetric trauma usually manifests within a few days of the injury or removal of the Foley catheter. The majority of iatrogenic fistulas will declare themselves within a month of surgery or catheter removal. Urethrovaginal fistulas secondary to radiotherapy for malignancy may have a delayed presentation from months to years and include symptoms such as hematuria and recurrent infections.[50]

DIAGNOSIS

When there is a suspicion of a fistula the standard evaluation should begin with a thorough history and physical examination. Direct visual interrogation of the urethra with the cystoscope allows for a comprehensive assessment of its luminal aspect. Visual inspection of the vagina should note areas of erythema or inflammation. Validated lower urinary tract questionnaires allow for standardized follow-up of bothersome symptoms.[51] It is important to exclude coexisting injuries such as vesicovaginal and ureterovaginal fistula. An in-office "double dye" test and/or retrograde pyelogram at the time of repair can aid in dismissing these pathologies. Voiding cystourethrograms may be helpful in establishing the diagnosis and excluding others. Fistulas in the setting of previous pelvic malignancy or radiation should be biopsied prior to repair to exclude tumor growth. Urodynamic testing can be used to assess the capacity of the bladder and ensure adequate compliance. It can also assess for the presence of other causes of incontinence when trying to diagnose a fistula. Findings such as detrusor overactivity incontinence or stress incontinence can mimic symptoms of a fistula or can be concomitant diagnoses that need to be managed. If the mechanism of injury (e.g., pelvic fracture, recent radical pelvic surgery) suggests more global lower urinary tract dysfunction associated with a urethral injury, the ability of urodynamics to assess detrusor function can be useful. However, starting with a noninvasive test such as uroflow and postvoid residual may be sufficient to rule out significant dysfunction. Particularly important in the diagnosis, and ultimate management, of urethral vaginal fistula is the presence or absence of incontinence and the presence or absence or obstruction (i.e., UVF from midurethral sling). In cases of incontinence the clinician may be much more likely to suggests a concomitant autologous sling (i.e., fascia lata or rectus fascia). If obstruction is seen, more aggressive sling take down or urethrolysis may be advisable. The fluoroscopic image from video urodynamics can confirm the level of continence at the bladder neck, explain the variability of symptoms, and influence the postoperative catheter management.

MANAGEMENT

The correction of urethrovaginal fistulas is a challenge and poses a particular set of problems for the surgeon in order

to achieve a watertight, tension-free, multilayer closure. Their distal location makes harvesting local tissue for interposition flaps difficult. The inciting factors usually lead to extensive defects with significant periurethral scarring and fibrosis leading to difficult resections. This can lead to fascial defects that may compromise creating a repair with multiple layers.[52] The patient must be optimized for surgery, clearing infections with appropriate antibiotic therapy, and the atrophic vaginal epithelium in the postmenopausal woman should be fortified with topical estrogen replacement therapy to ensure optimal tissue quality at the time of repair.

Several factors must be considered at the time of the surgical intervention. All inflamed and erythematous tissue should be debrided and sent to pathology for microscopic examination, especially in the setting of recurrent fistulas, malignancy, or previous radiation. Foreign bodies present such as a synthetic mesh must be removed in their entirety as these may predispose to fistula recurrence.[49] Devitalized tissue must be excised to ensure margins with viable tissue that is adequate for the final closure. Distal fistulas in asymptomatic patients that do not have voiding complaints may be safely observed. Alternatively, these lesions may be eliminated by spatulating the meatus down to the fistulous tract.[53] Proximal and large lesions may require extensive dissection, and often the urinary sphincter mechanism is compromised. Patients must be adequately counseled preoperatively of the possibility that SUI may develop after their repair. Successful anatomic repair may lead to the development of SUI or obstructed voiding in up to 50% of patients. Conversely all synthetic mesh should be removed during fistula repair, which may result in the propagation of SUI.[50] One study following 71 women after urethrovaginal fistula repair reported 52% of the patients developed postoperative SUI.[54] These patients were treated with autologous pubovaginal slings or synthetic slings. Patients at risk for developing SUI and patients with existing SUI may be offered concomitant treatment with autologous sling (i.e., pubovaginal slings using rectus fascia or fascia lata). The use of synthetic mesh is contraindicated at the time of fistula repair.

The positioning of the patient and instruments used to achieve adequate exposure for repairs of a urethrovaginal fistula are the same as for a VVF with the exception of including a urethroplasty set with fine, sharp dissecting instruments. The timing of the repair follows the same line of reasoning as with VVF. Fistulas that are not infected or present in the setting of radiation may be repaired in the acute setting successfully. The procedure should commence with a cystoscopy and an attempt to catheterize the fistulous tract with a wire of feeding tube. The Foley catheter is inserted and the bladder is drained. An inverted J or U incision is made and a vaginal flap is raised to include the fistula tract. Dissection is carried out to the periurethral fascia surrounding the fistula, and it is carefully incised. The edges of the tract are refreshed, and the fistula is closed with absorbable sutures. The periurethral fascia is closed in a perpendicular fashion to avoid suture overlap. The ureteral caliber needs to be considered for large defects. Other reconstructive techniques may be needed if the repair would result in a significant narrowing. Vaginal flaps and anatomic repairs have a higher failure rate when compared to using pedicle-based interposition flaps.[55] The bulbocavernosal fat from the labia may be harvested and interposed over the repair at this time. The vaginal epithelium is approximated to include the previous site of the fistula.

Once the reconstruction is complete the surgeon may consider placement of a suprapubic tube (SPT) in complex or difficult repairs. This allows for quicker removal of the urethral catheter and does not keep the bladder neck open allowing for the repair to heal free of urine finding its way around the catheter. If an SPT is to be placed, the decision should be made prior to reconstruction of the urethra, as one should avoid passing the cystoscope over a fresh repair. Patients with SUI, or when a fascial sling is used to reinforce a repair, also benefit from SPT placement as this would also avoid the need to catheterize over a fresh repair if the patient experiences urinary retention.

The cystotomy should be made under direct visualization with the cystoscope and a Foley catheter left to drain the bladder. The length of catheter use depends on the complexity and location of the repair. Anticholinergic/antimuscarinic medication should be used liberally, and the surgeon may choose to discontinue prior to performing voiding cystourethrogram (VCUG). If no extravasation is noted the urethral catheter is removed and the suprapubic tube is clamped and sequentially removed. If there is evidence of extravasation, the surgeon has the option of replacing the uretheral catheter with care not to injure the repair. The suprapubic tube would be left for drainage. The VCUG is then repeated in 1–2 weeks. When autologous pubovaginal slings are used, the harvesting of the sling and passing of needles into the retropubic space are performed at the beginning of the case. This avoids passing the cystoscope over the newly reconstructed urethra. Occasionally, a urethral catheter is avoided to prevent ischemia or pressure on the repair, especially in the case of middle or distal urethrovaginal fistulas.[34]

Ureteral Fistula

Ureteral fistula comprised 10% of genitourinary fistulas treated in a recent 8-year case series from a tertiary referral center.[56] They have been reported in 2–3% of laparoscopic hysterectomies[8,57] and in 4.5% of 6000 obstetric or gynecologic surgeries in a multinational study conducted in the developing world.[58] Ureteral fistula can involve any neighboring organ, most commonly the vagina, but fistulous connections with abdominal or pelvic vasculature, bowel, skin, and cervix have been described.[59] An understanding of ureteral fistula is important given their significant propensity for upper tract injury and the possibility of morbidity due to a missed diagnosis.

ETIOLOGY

As described in our discussion of VVFs, ureteral fistulas generally arise from ischemic necrosis, leading to urinary extravasation creating an inflammatory condition that induces the fistulous connection to form. Fistulas may also form after unrecognized injury of the ureter. Sequentially, ascending and descending branches from the renal and gonadal arteries and the aorta supply the ureter with

overlapping segments that protect the ureter from ischemia. However, the delicate terminal branches run along the adventitia of the ureter and are vulnerable to intraoperative avulsion, injury, and occlusion. Consequently, when possible surgical practice should involve minimizing the use of a clamp on the ureter and traumatic grasping of the ureter. Manipulation needs to be done carefully and with understanding of the delicate vasculature.

Iatrogenic injury is by far the most common cause of ureteral devascularization and ischemia; by comparison, patient series from the busiest trauma centers only report 10 ureteral injuries per year, a fraction of which result in fistulas.[60] From 52% to 82% of iatrogenic ureteral injuries are estimated to occur during gynecologic surgery[61] with the remainder occurring during abdominal pelvic surgeries – specifically obstetric, urologic, colorectal, or vascular surgery – or following radiation therapy. Complications, such as ureteral transection, ligation, puncture, or crushing, occur in 0.05% to 30% of such cases, depending on surgeon expertise, patient factors, and the technical difficulty of the procedure.[60] A recent systematic review of urinary tract injury in benign gynecologic surgeries found a ureteral injury rate of 0.3%, compared to a 0.8% bladder injury rate.[62] Ureteral injuries are missed at the time of the initial surgery in 33% to nearly 90% of cases in reported series.[61]

Early management of the injury may decrease the likelihood of fistula formation.[8,61] Patients with early postoperative findings, such as anuria, urinary ascites, or hydronephrosis, will require workup and subsequent diagnosis of the cause and should be evaluated for ureteral injury; this early recognition and subsequent management may decrease their risk of ureteral fistula formation. However, many ureteral injuries are difficult or impossible to diagnose intraoperatively, such as thermal injury or devascularization. These types of insults may present later than things like cut injuries, avulsions, etc. Ureteral fistulas due to intrinsic patient risk factors alone are rare, but have been reported in trauma and oncology literature.[61,63] More commonly, risk factors predispose patients to have a ureteral injury go unrecognized by increasing the difficulty of the surgical intervention or by contributing to poor wound healing; such factors include obesity, diabetes, chronic inflammation, endometriosis, prior surgeries, and radiation (Box 12.3).

Ureterovaginal fistulas are the most common ureteral fistulas. They typically form following an undiagnosed ureteral injury during hysterectomy if the ureter is inadvertently clamped or ligated in an attempt to control bleeding from the uterine artery. More broadly, the complex pelvic anatomy surrounding the distal third of the ureter and its proximity to the vagina and uterus pose a notable risk in any female pelvic surgery, such as hysterectomy, cesarean section, low anterior resection, and abdominal perineal resection of the colon. The incidence of ureteral injuries during hysterectomy initially increased with the introduction of laparoscopic techniques; however, this rate appears to be decreasing with the increased adoption of robotic surgery.[34] This has been attributed to the improved visualization afforded by robotic assistance and to surgeons' increased familiarity with the minimally invasive approach to this surgery.[64]

Ureteroarterial fistulas (UAFs) are rare, with 118 reported cases identified in a recent review.[65] Women are 50% more likely to be affected. Overall, they are associated with 10–38% mortality. Fistulas involve the aorta in 1.6% of cases; however, these fistulas are universally fatal if not diagnosed and treated. The common iliac (60%) and external iliac (20%) arteries were most likely involved in patients with no history of urinary diversion. Chronic ureteral stents are a significant risk factor for UAFs, with 74% of patients known to have a history of stenting. Radiation, pelvic cancers (bladder, cervical, and colorectal), and vascular disease are also risk factors for UAFs.[65,66]

Ureteroenteric fistulas (UEFs) comprise about 1% of urinary tract fistulas[67] and usually involve the duodenum. Penetrating trauma and iatrogenic injury are the most common etiologies of UEF, but very often they result from chronic inflammation of the ureter or intestines by medical disease or foreign bodies (ureteral calculi or ingested objects).[68,69] Radiation therapy and malignancy have also been reported as causes of UEFs.[67]

Box 12.3 Factors That Affect Wound Healing

Obesity
Diabetes
Chronic inflammation
History of radiation
Prior surgeries

PRESENTATION

Ureterovaginal fistulas typically present as persistent urinary incontinence. This can often be difficult to differentiate from VVFs at initial presentation, as both entities present approximately 1–4 weeks after surgery with continuous leakage.[56,70] Ureteral violation, such as ureterotomy or avulsion, leads to more immediate fistula formation than do ischemic insults from crush injury or radiation. This is related to the pathologic process of necrosis and the initial absence of an inflammatory reaction to extravasated urine. Some UVFs occur secondary to ureteral stricture, which also results in a prolonged interval to presentation. A careful history can distinguish between the unchanged voiding patterns in UVF from the decreased voiding per urethra in significant VVF.[71] The description of flank pain should increase suspicion of ureteral involvement. Associated pathology contributes additional symptoms, such as abdominal pain and ileus with urinoma formation, lower urinary tract symptoms with cystitis, or systemic illness and flank pain with pyelonephritis.

Ureteroarterial fistulas universally present with painless hematuria, ranging from microhematuria to hemorrhage, with hemodynamic instability seen in 17.8% of patients, due to the size of the fistulas and the involved vessels. Hematuria may be intermittent. In 13.5% of cases, this is precipitated by stent change; in most cases, some precipitating event is found.[65] Patients with ureteroenteric fistulas clinically present with recurrent UTIs and pneumaturia. Cultures typically demonstrate enteric flora. Patients may be systemically ill, but not necessarily.

DIAGNOSIS

Evaluation for UVF should include evaluation for concomitant VVF, as discussed earlier in this chapter. Physical examination can be useful in ruling out alternative etiologies. Some clinicians find the double dye test useful to distinguish between vaginal and ureteral fistulas.[70] The presence of the orange dye in the proximal tampon suggests a ureterovaginal fistula; blue dye suggests a VVF. Laboratory analyses should include serum creatinine and blood urea nitrogen (BUN), which may be elevated due to absorption if there is urine leaking into the peritoneal cavity, in addition to urine studies. A complete blood count and inflammatory markers may also be useful in the patient with symptoms concerning for infection. In order to ensure adequate evaluation of the ureters, we favor computed tomography (CT) of the abdomen and pelvic with and without contrast, including delayed excretory phase for ureteral opacification as well as a full assessment of the peritoneum and both kidneys.[61,72] The clinical history should be provided to the radiologist so that the study can be tailored to the clinical question. In some cases with concomitant ureteral obstruction additional delayed imaging may be needed. Magnetic resonance imaging (MRI) can also provide a cross-sectional representation of a UVF and superior soft tissue contrast, which is especially useful in patients with pelvic malignancy.[73] Intravenous pyelograms and retrograde ureterograms can be used to identify urinary extravasation; however, positive findings may still require further investigation with CT or MRI studies for more complete delineation of the ureter and adjacent structures.[60] Ultrasound can identify hydronephrosis and large fluid collections, which will lead the clinician to obtain other diagnostic tests but may fall short of identifying small urinomas or any specific ureteral pathology. Doppler also can be used to look for ureteral jets to suggest patency of the ureter. Ultrasound alone is limited in its utility and it is not recommended for the definitive diagnosis of ureteral injuries.[72]

The most critical tool in diagnosis of ureteroarterial fistulas is a high degree of clinical suspicion.[74] Patients with gross hematuria with risk factors for UAF, such as chronic ureteral stents or advanced abdominopelvic malignancy, may benefit from emergent workup of hematuria, rather than the standard elective outpatient workup. Cystoscopy can localize hematuria to a specific ureter with visualization of bloody efflux.[75] Extravasation from a UAF is not typically seen on standard upper tract imaging, as the ureter is often occluded by blood products, but remains useful in ruling out renal or other ureteral pathology.[65,74,76] Ureteroscopy is not recommended given the potential for instigating a large-volume bleed.[75] Angiography is the present standard of care for diagnosis of ureteral fistulas.[65] It is also a potentially therapeutic test; if the ureter is opacified, the fistulous connection can be embolized, as we will discuss later in this chapter. The sensitivity of angiography has been estimated to be between 50% and 69%.[77,78] This can be increased with provocative maneuvers to dislodge clots; however, this has inherent risks of brisk blood loss and should only be attempted in a controlled setting with the ability to rapidly occlude the fistula or to proceed to operative exploration.[75]

Ureteroenteric fistulas are diagnosed with CT with late excretory phase contrast in most of the cases in the literature. This is more reliable than opacifying the intestinal tract given the high transit time and low-pressure system as compared to the urinary system.[79]

PREVENTION

The mainstays of prevention of ureterovaginal fistulas remain a thorough knowledge of anatomy, avoidance of ureteral vascular supply, and caution during hemostatic control.[80] Should ureteral injury occur, intraoperative recognition allows for prompt evaluation, possibly repair with stenting, and may decrease the likelihood of fistula formation.[60] This is not always feasible in surgeries complicated by significant blood loss, or aberrant anatomy from malignancy, radiation, or prior surgeries. Ureteral stent placement has been suggested to aid in preventing ureteral injury, but there does not appear to be a decrease in the incidence of ureteral injury with this technique.[70] The added operative time, risk, and morbidity must then be weighed against the chance of recognizing an intraoperative injury.[60]

The risk of UVF can be minimized by limiting long-term use of ureteral stents, especially in patients with other risk factors for fistula formation.[65] Avoiding ureteroenteric fistula is best accomplished by addressing the underlying disease processes.[68]

MANAGEMENT

After diagnosis of a ureterovaginal fistula, the priority is achieving adequate drainage of the urinary system.[60,81] While there have been reports of spontaneous closing of UVF with urinary diversion,[82] it requires a narrow set of circumstances and is not an option in many cases. If the ureter appears to remain in continuity on imaging, a retrograde ureteral stent can be placed. Ureteral patency and anatomy should be confirmed intraoperatively with a retrograde pyelogram prior to stent placement.[60] If this is not possible, anterograde drainage with a nephrostomy tube can be attempted. This may also allow for attempted anterograde ureteral stent placement if the clinical scenario warrants. Ureteral stent placement in patients with favorable anatomy and a small fistula has been reported to successfully treat the fistula, with the largest series reporting 71% success at 1 year[56,83,84] after stent placement for 6 weeks.[85]

In many cases, operative repair may ultimately be needed. Repair would be indicated, for example, if stenting was not possible, there was persistence of the fistula after stenting, other concomitant fistulas needed surgical repair, or there was an associated finding like a large structure that was going to require intervention. Care must be taken to eradicate infection, nutritionally optimize the patient, and, in some cases, rule out an occult malignancy. Historically, repair was delayed for 3–6 months, but recent studies have shown no difference in outcomes for earlier repair in uncomplicated patients.[86] Repair is often delayed for at least 6 weeks to allow full delineation of the diseased ureter.[71] In a radiated patient, additional time to repair is prudent given the slow appearance of injury, which is usually about 6 months. An indwelling nephroureteral stent or an internal ureteral stent can result in periureteral inflammation, and some would advocate removal for several weeks prior to repair.

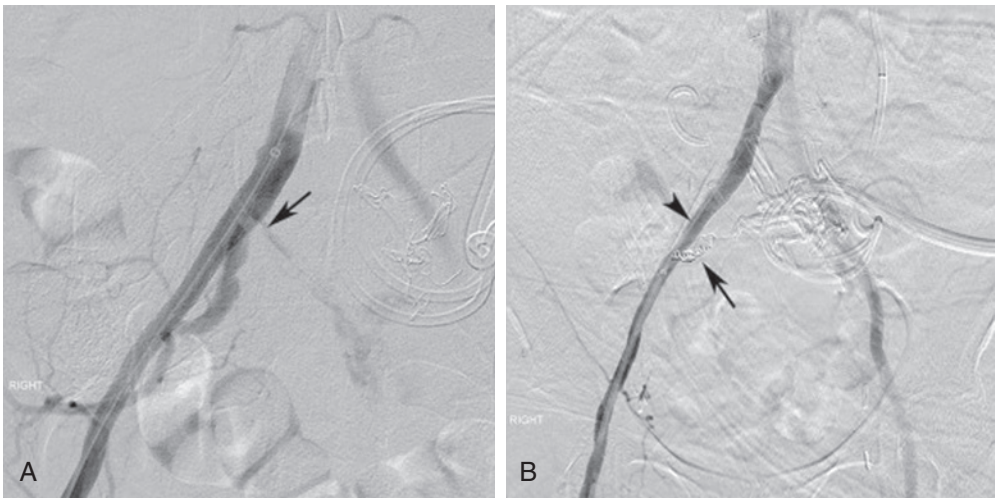

Figure 12.9 A, Right common iliac artery digital subtraction angiography demonstrating fistulous communication at the level of the bifurcation with the passing right ureter (arrow). B, Successful exclusion of the ureteroarterial fistula on post contrast angiography by right common iliac artery covered stent placement (arrowhead) and coil embolization of the internal iliac artery (arrow). (From Siorek M, et al. Ureteroarterial fistula following retrograde ureteral stenting in a patient with a double-barreled wet colostomy for cervical cancer. Gynecol Oncol Rep, 2015;13:44-6.)

As we have discussed, most ureteral fistulas, including all ureterovaginal fistulas, involve the distal third of the ureter. Given this, the standard practice is to excise the damaged ureter and perform a ureteral reimplant, with or without intramural tunneling. Relaxing maneuvers such as a psoas hitch or Boari flap can prove useful to ensure a tension-free anastomosis.[70,87,88] Several series have demonstrated equivalent outcomes with robotic-assisted UVF repair, with the additional benefit of improved intraoperative visualization.[42,64] Middle and upper ureteral fistulas, not involving the vasculature, can often be managed with a ureteroureterostomy given the short length of defect.[80] Whenever possible, tissue interposition is recommended to provide additional blood supply to the healing ureter, as well as isolate the repair from intraperitoneal structures or additional suture lines created as part of concomitant bowel or vaginal repairs.[61] An omental wrap is best suited for this purpose; however, care must be taken to form a broad pedicle to allow the wrap to maintain viability after mobilization. Urinary diversion can be considered when a patient presents with a recalcitrant or devastating injury.

Management of ureteroarterial fistulas is an active area of inquiry. Historically, open intervention was necessary,[66] but with advances in interventional radiology and endovascular stents, minimally invasive management is now preferred in the hemodynamically stable patient,[65,75,78] with success rates of 76% in a contemporary series (Fig. 12.9).[89]

Intestinal Fistula

ETIOLOGY

Abnormal communications from bowel to bladder may occur in many settings including intestinal disease and surgical misadventure. Inflammation secondary to diverticulosis is a common cause of intestinal fistulas, as are Crohn's disease, colorectal malignancy, pelvic trauma, and radiotherapy. Diverticular disease usually occurs in the sigmoid colon in about 90% of cases and, when complicated, accounts for about 60% of all colovesical fistulas.[90] Colon and bladder malignancies may also account for up to 20% of all cases. Crohn's disease is the third most common cause of intestinal fistulas and is the most common cause of ileovesical fistulas in younger patients. Crohn's disease should be considered in all patients with bowel stenosis and an associated intraabdominal abscess.[91] A ruptured diverticulum or pelvic phlegmon are risk factors for development of a fistula.

Radiation to the pelvis and prostate may be delivered via an external beam or by brachytherapy. The mechanism of injury is secondary to obliterative endarteritis eventually leading to ischemia of the mucosa and subsequent fistulization. The more common techniques for external beam therapy are three-dimensional conformal therapy and intensity modulated radiation therapy. Alternatively, one may elect to have proton beam therapy. Genitourinary complications seem to be similar with external beam or proton beam therapy so there may be no benefit to one over the other. Permanent interstitial brachytherapy is a definitive treatment for localized prostate cancer.

Radiation for prostate cancer brings unique complications including rectourethral fistulas (RUFs). There has been a shift in the cause of RUFs from iatrogenic injury to approximately 50% resulting from some derivative of radiotherapy for malignancy.[92] There has been a demonstrated correlation between radiation dose to the prostate and subsequent urethral stricture formation; it is believed RUF follows this correlation. Urethral stricture and bladder neck contracture leading to high-pressure voiding may also have a positive correlation. RUF has been associated with post-radiation transurethral resection of the prostate, post-radiation rectal biopsy, and post-radiation pelvic surgery. Salvage procedures for prostate cancer such as salvage

prostatectomy and cryotherapy also carry high rates of RUF. Salvage high-intensity focused ultrasound (HIFU) and brachytherapy have a 16% and 12% rate of developing RFU, respectively.[93]

PRESENTATION

The presenting symptoms associated with fistulas involving the intestines and bladder are those common to the lower urinary tract. Often patients will report frequency urgency and recurrent urinary tract infections. Intestinal fistula should be considered in the differential diagnosis of patients with urinary tract infections refractory to antibiotics. Fifty per cent of patients with a vesicoenteric fistula will present with pneumaturia and fecaluria. Patients with colovesical fistulas may complain of tenesmus. The symptom complex of tenesmus, suprapubic pain, frequency, and dysuria is known as Gouverneur's syndrome.[94] The presentation of radiation-induced intestinal fistula is similar as described previously in this chapter. They are associated with a delayed presentation and may declare themselves months to years after the initial therapy. While rare, patients may develop signs and symptoms of sepsis. Abdominal pain associated with abdominal abscess is common in fistulizing Crohn's disease. RUFs are usually small and located in the bladder neck or trigone. RUF secondary to radiation may be large and involve the posterior urethra. Fecaluria may be a presenting symptom.[92]

DIAGNOSIS

Cross-sectional imaging is the modality of choice for the diagnosis of intestinal fistulas. This may be enhanced with oral and intravenous contrast. Triphasic CT offers excellent anatomic detail of the genitourinary system. MRI is useful to delineate complex fistulas involving multiple bowel segments as well as the viability of the surrounding tissue. Ultrasound has a limited role in the diagnosis of enterovesical fistulas (Fig. 12.10).[94]

Patients with enterovesical fistulas should undergo a careful preoperative evaluation. Cystoscopy is a useful diagnostic tool; however, it may be nondiagnostic 60% of the time.[94] Patients with a RUF should undergo examination under anesthesia, retrograde urethrogram, voiding cystogram, biopsy of the fistula if indicated, and proctoscopy. This allows for evaluation of the fistula's size and location, but also determine if a concurrent bladder neck contracture or urethral stricture is present. Colonoscopy is not of high yield in patients with an intestinal fistula; however, it should be an integral part of the patient evaluation, particularly in patients with history of radiation or malignancy or if malignancy needs to be ruled out. Physical examination should assess for patency of the urethra and ensure there is no evidence of urinary obstruction present as high-pressure voiding may be an inciting factor. An RUF may be palpated and characterized on digital rectal examination.[93]

MANAGEMENT

The surgical management of intestinal fistula includes resection of the fistulizing segment of bowel with primary anastomosis of healthy tissue. Fecal diversion should be considered in cases of frank contamination of the abdomen and/or sepsis. One of the larger series on the treatment of RUF boasted robust results, which they feel in part is secondary to performing fecal diversion on all their patients prior to fistula repair. They reported 100% success repairing RUF in nonradiated patients and 84% in radiated patients with a single procedure (buccal onlay and gracilis muscle interposition flap) and 20 months of follow-up.[95] Resection of the fistulous tract from the bladder is at the discretion of the surgeon; however, closure of the cystotomy in a primary fashion is always recommended.

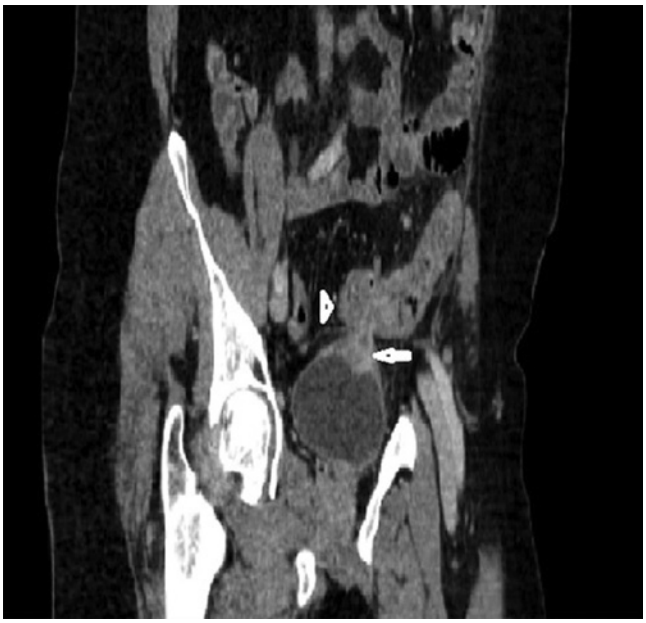

Figure 12.10 Sagittal image shows bladder wall thickening (arrow) adjacent to a loop of thickened sigmoid colon (arrow head). (From Golabek T, et al. Enterovesical fistulas: aetiology, imaging, and management. Gastroenterol Res Pract. 2013;2013:617967.)

RUF often requires a combination of onlay grafting and interposition muscle flap for closure. The anterior, perineal sphincter-sparing approach is the optimal approach for closure of all RUFs (simple or complex). RUF in the bladder neck/trigone region can be closed in a primary fashion.[95] Minimally invasive approaches have been described but are best reserved for experienced surgeons as the inflammatory reaction and subsequent adhesions often lead to a loss of surgical planes and difficult dissections.[90] Attempted repairs in patients with history of radiation are at a higher risk for failure, and some patients will require urinary diversion.[93] A transanosphincteric (York-Mason) approach allows for better exposure of the RUF with limited permanent damage to the anal sphincter. This approach also provides adequate space for the use of tissue interposition with gracilis muscle flaps, rectal advancement flaps, and multilayered closure.[93] These approaches are best left for referral centers that offer the services of experienced reconstructive genitourinary surgeons.

Colovaginal fistulas may be encountered particularly in the setting of diverticular disease. These patients have poor outcomes with primary repair and may require ileostomies in cases of primary anastomosis of the colon in order to prevent the high morbidity rates associated with

anastomotic leak. There are other rarer fistulas that are infrequently encountered in clinical practice, but which should be mentioned for the sake of completion, such as communications between the bladder and uterus as well as fistulas to the fallopian tubes.

Conclusions

The key to the successful management of any fistula is adherence to a few basic principles. Early intervention decreases patient discomfort and is as successful as delayed repairs in the nonradiated patient. A high index of suspicion must always be maintained to diagnose fistulas, as the presenting symptoms can be variable. The first repair is the best chance at a successful repair. Surgical principles include maintaining separate, nonoverlapping suture lines, a multilayered closure, a water-tight repair, and adequate postoperative urinary drainage. It is always important to maintain meticulous medical documentation as these cases may often have legal implications.

Chapter 12 Questions

1. What is the most common cause of urethrovaginal fistula in the developing world?
   a. Obstructed labor
   b. Chronic catheterization
   c. Pelvic prolapse repair
   d. Malnutrition
   e. Urethral diverticulectomy

2. What is the risk of developing a urethrovaginal fistula following synthetic midurethral sling placement?
   a. 1 in 10,000
   b. 1 in 1000
   c. 1 in 500
   d. 1 in 100
   e. 1 in 50

3. What percentage of vesicovaginal fistulas (VVC) involves the ureter?
   a. 0.1%
   b. 1%
   c. 5%
   d. 10%
   e. 25%

4. Ureteral fistulas are most commonly the sequelae of:
   a. Urologic surgery
   b. Colorectal surgery
   c. Gynecologic surgery
   d. Vascular surgery
   e. Obstetric surgery

5. Undiagnosed ureteral injury during hysterectomy is most common during vascular control of the:
   a. Uterine artery
   b. Vaginal artery
   c. Internal iliac artery
   d. Ovarian artery
   e. Superior vesical artery

6. What is the optimal diagnostic approach when ureteroarterial fistula is suspected?
   a. CT of the abdomen and pelvic with delayed contrast images
   b. Ureteroscopy
   c. Intravenous pyelogram (IVP)
   d. Angiography
   e. Laparoscopic evaluation

7. Ureteral fistula repair is performed in a delayed fashion in order to:
   a. Allow the serum creatinine to plateau
   b. Ensure the full extent of the injury will be apparent
   c. Provide the patient with adequate recovery from initial surgery
   d. Minimize further trauma to GU tract
   e. Ensure adequate workup can be completed

8. A 54-year-old female with history of uterine malignancy complains of frequency and leakage of urine 6 months after completion of radiation therapy. CT urogram demonstrates no hydronephrosis and a vesicovaginal fistula. What is the best next step in management?
   a. Cystoscopy with biopsy
   b. Urodynamic testing
   c. Retrograde pyelogram
   d. Vaginoscopy
   e. VCUG

9. What is the incidence of vesicovaginal fistula formation with the placement of midurethral sling?
   a. 1/10
   b. 1/100
   c. 1/1000
   d. 1/5000
   e. 0

10. What is the main irrigation of a Martius flap?
    a. Anterior labial artery
    b. Obturator artery
    c. Internal pudendal artery
    d. Uterine artery
    e. Gluteal artery

Case Studies

CASE 1

A 72-year-old female patient is diagnosed with locally advanced cervical cancer status post radiation, complicated by right ureteral obstruction. The patient is managed with periodic right ureteral stent exchanges. One week after an uncomplicated stent exchange, the patient presents to the emergency department after her aide witnessed gross hematuria. In the ER, her vital signs are stable. Her abdominal and gynecologic exam show no blood in the vaginal vault. She is found to have an unchanged hematocrit and creatinine. Her urinalysis reveals yellow urine with 30–50 RBC and 30–50 WBC with few bacteria.

1. What is a risk factor for ureteroarterial fistula (UAF) formation in this patient?
   a. Age
   b. Indwelling ureteral stent
   c. Hematuria
   d. Pyuria
   e. Obesity

2. What is the best option for management of this patient?
   a. Antibiotics
   b. Angiography
   c. Open repair
   d. Ureteral stent exchange
   e. Watchful waiting

3. What is the optimal timing for surgical repair?
   a. Immediate surgical repair
   b. Surgical repair in 6 weeks
   c. Remove the stents now and repair in 3–6 weeks
   d. Repair in 6 months
   e. Do not repair

CASE 2

A 36-year-old G3P2 female patient presents for evaluation of frequency, urgency, nocturia, and leakage of urine onset 2 days after cesarean section. She reports leakage with activity as well as with urgency. She feels she is always leaking urine. She denies nausea, vomiting, fever, chill, or flank pain. Cystoscopy is normal.

1. What is the best test to exclude damage to the upper tracts?
   a. CT urogram
   b Double dye test
   c. Renal ultrasound
   d. Urodynamic testing
   e. VCUG

2. What is the best test to diagnose concomitant voiding dysfunction?
   a. CT urogram
   b. Double dye test
   c. Cystoscopy
   d. Urodynamic testing
   e. Renal sonogram

3. When should this be surgically corrected?
   a. Immediate repair
   b. 2 weeks
   c. 3 months
   d. 6 months
   e. 3 years

Answers

1. **c.** Studies suggest that in countries with limited access to health care, physicians not aptly trained in performing emergent cesarean section are often unable to execute these procedures leading to prolonged labor and the complications associated with the prolonged labor complex including subsequent fistula formation. In these countries death is often associated with obstetric complications.[1]
2. **d.** The risk of developing a fistula during a sling procedure for stress urinary incontinence is cited at 1%.[48]
3. **d.** Once a fistula is suspected, attention must be turned to promptly identifying its size and location, as this will dictate management. Imaging of the upper tract is mandated as 10% of VVFs may have concomitant injury to the ureters.[21]
4. **c.** They have been reported in 2–3% of laparoscopic hysterectomies[8,57] and in 4.5% of 6000 obstetric or gynecologic surgeries in a multinational study conducted in the developing world.[58]
5. **a.** Ureterovaginal fistulas are the most common ureteral fistulas. They typically form following an undiagnosed ureteral injury during hysterectomy if the ureter is inadvertently clamped or ligated in an attempt to control bleeding from the uterine artery.
6. **d.** Angiography is the present standard of care for diagnosis of ureteral fistula.[66]
7. **b.** Repair is often delayed for at least 6 weeks to allow full delineation of the diseased ureter.[72]
8. **a.** In fistula arising after surgery for malignancy or radiation, one must also exclude the possibility of a recurrence within the fistulous tract with a biopsy, prior to surgery.
9. **c.** The incidence of vesicovaginal fistula formation from synthetic sling material used to correct stress urinary incontinence is low and reported across the medical literature as occurring in 0.1% of cases.[16]
10. **c.** The pedicle originates from the posterior labial artery, a branch of the internal pudendal artery.

CASE 1

1. **b.** Chronic ureteral stents are a significant risk factor for UAF with 74% of patients known to have a history of stenting. Gender, radiation, pelvic cancers (bladder, cervical, and colorectal), and vascular disease are also risk factors for UAF.[66,67]
2. **b.** Angiography is the present standard of care for diagnosis of ureteral fistula.[66] It is also a potentially therapeutic test; if the ureter is opacified, the fistulous connection can be embolized. The sensitivity of angiography has been estimated to be between 50% and 69%.[78,79]
3. **c.** Repair is often delayed for at least 6 weeks to allow full delineation of the diseased ureter.[72] In a radiated patient, additional time to repair is prudent given the slow appearance of injury, usually about 6 months. Indwelling nephroureteral stent or an internal ureteral stent can result in periureteral inflammation, and some would advocate removal for several weeks prior to repair.

CASE 2

1. **a.** Imaging of the upper tract is mandated as 10% of VVF may have concomitant injury to the ureters.[21] Historically this had been achieved with intravenous pyelograms. This has in great part been replaced by retrograde pyelograms and contrast-enhanced cross-sectional imaging with a urographic phase, given its superior anatomic detail.
2. **d.** Urodynamic studies may be of diagnostic value in the evaluation of a fistula, particularly if there is suspected concomitant storage or voiding dysfunction. Videourodynamic testing has the added benefit of providing anatomic as well and functional information. Patients with injuries in the trigone or bladder neck are at risk for developing detrusor overactivity and stress urinary incontinence.[25]
3. **a.** Studies have shown that if a fistula is identified in the acute setting it may be treated successfully.[32] Zimmern et al. observed that surgical repair performed within 2 to 3 weeks of the injury had no increased morbidity or failure rates when compared with delayed repair.

KEY POINTS

1. Many cases of post operative urinary leak are asymptomatic and seen on imaging only. When symptoms of Urinary Leakage occur – they are extremely variable and can include ascites, electrolyte abnormalities, ileus, or sepsis. A high index of suspicion by the surgeon is always required even in the absence of elevated drain outputs.
2. Risk factors for urinary leak after partial nephrectomy include intra-renal pelvis, complex nephrometry score, prolonged ischemic times and complex collecting system entries and repairs.
3. Risk factors for urinary leak after radical prostatectomy include prior TURP, anatomic considerations leading to difficult intraoperative anastomosis (obesity, narrow pelvis, pelvic lipomatosis, short urethral length etc), increased EBL, pelvic hematoma, postoperative UTI, early learning curve, and salvage prostatectomy after radiation therapy.
4. Risk factors for urinary leak after cystectomy include palliative exenteration, obesity, prior pelvic radiation, extensive mobilization of the ureters (particularly left) and short enteroureteric anastomoses under tension.
5. Management strategies involve maximal drainage of the leak (via a stents and/or drains) which is often followed by delayed but spontaneous closure. Occasionally close observation under select circumstances may be acceptable.
6. Patience is essential and individuals should be counseled that their stent and drain may occasionally need to stay in place for weeks or rarely months. Operative intervention should be infrequent and only if infection or other systemic manifestations mandate.
7. Surgical intervention, other then endoscopic, is rarely necessary. Reoperations should be avoided in most stable patients until all endoscopic options are exhausted and a prolonged period of maximal drainage is attempted.

Introduction

Urinary leak is one of the more common complications that urologists encounter. Urinary leak occurs with both major and minor urologic interventions including radical cystectomy with urinary diversion, radical prostatectomy, partial nephrectomy, ureteral reimplant, transurethral resection of the bladder as well as urologic trauma and stone disease. The incidence of urinary leak associated with these events is unknown and likely underreported.

Two broad categories of urinary leak exist: intraperitoneal and extraperitoneal. Presenting symptoms may be different

depending on the location. Extraperitoneal leaks may present earlier with pelvic pain or a pelvic pressure-like sensation as the urine becomes contained in a fixed space (retroperitoneal) and compresses adjacent organs. Additionally, leakage from the surgical incision site (usually lower midline or port site) can occur as fluid flows down the path of least resistance. The urine may become infected secondary to recent surgical interventions, thereby promoting wound infection or abscess formation. It can incite an ascending urinary tract infection involving the entire retro peritoneum and investing fascial layers. The management of extraperitoneal urine leaks is generally more conservative and consists primarily of supportive care and tube drainage.[1]

Intraperitoneal urine leaks are usually not contained. If there is no associated urinary tract infection, the presence of sterile urine in the peritoneal space can be tolerated for several days and can present in a delayed fashion with increasing abdominal distention, ascites, or progressive azotemia.[2,3] Patients often develop electrolyte imbalances including hyponatremia, hyperkalemia, and metabolic acidosis whereas the peritoneum functions as a dialysis membrane.[4–6] Spontaneous or traumatic intraperitoneal urinary leaks can represent a diagnostic dilemma. Indeed, some patients have been placed on hemodialysis by unsuspecting clinicians to reverse azotemia only to realize later the presence of urine in the paracentesis fluid.[6,7] Uroperitoneum can also result in a paralytic ileus,[3] fascial dehiscence as a result of increased abdominal pressure,[8,9] and a predisposition to intraabdominal and wound infections. In the setting of urinary tract infection, immediate peritonitis can ensue, leading to sepsis, which may require pressors and ICU support and potentially can lead to death.

This chapter will focus on the incidence, management, and prevention of urinary leak specifically as it relates to individual urologic procedures including partial nephrectomy, radical prostatectomy, and urinary diversions.

Urinary Leak Associated With Partial Nephrectomy

DEFINITION AND DIAGNOSIS OF URINARY LEAK

The definition of what constitutes a urinary leak following partial nephrectomy varies in published literature. Two main definitions exist. The first is clinical and requires a persistent drain output varying from 2 to 7 days whose chemical analysis is consistent with urine, defined as an elevated drainage creatinine level greater than that of the simultaneous serum level.[10,11] While there is no specific cutoff for how much higher the drainage creatinine must be when compared to serum, any elevation should arouse suspicion in postoperative patients; however, a level of twofold or more is most suggestive.[11] Care must be taken when interpreting these results in patients with severe impairment of GFR and CKD 4 and 5. The second definition of a urine leak following a partial nephrectomy is radiographic and based on the appearance of perioperative fluid collection on postoperative imaging.[12,13] In this case, the differential diagnosis includes a serous, lymph, or urine collection, and the diagnosis must be confirmed by aspiration and creatinine analysis.

In cases of elevated or persistent drain output, a drain fluid creatinine level can be checked based on clinical suspicion (complex partial nephrectomy, prolonged ischemic time, etc.) or radiographic findings of contrast extravasation on CT, MR, or retrograde pyelogram. The timing of a urinary leak is typically within the first 14 days post partial nephrectomy. Care should be taken to avoid a false sense of security with low drain outputs after resection of complex tumors with prolonged ischemia whereas acute tubular necrosis may prevent the kidney from making urine within the first several days. Therefore as the kidney recovers and urine production increases, the drainage may pick up as the leak evolves. If a serum creatinine enables the use of iodinated contrast, a CT urogram is the single best test to perform with particular attention to the excretory phase to evaluate the renorraphy, collecting system, and the entire ureter for sites of urinary leak.

SYMPTOMS OF URINARY LEAK

In the majority of series in the published literature, most patients with a urinary leak are asymptomatic and present with increased drain output that is then confirmed to be consistent with urine.[11,14–19] In a study by Potretzke et al. evaluating urinary leak following robotic partial nephrectomy, the authors only tabulated symptomatic undrained urinary leaks, whereas all drains were removed prior to discharge. Patients presented at a median postoperative day (POD) 13 with symptomatic urinary leak with fever (14%), gastrointestinal complaints including ileus (29%), and pain (36%).[12]

INCIDENCE AND DIFFERENTIAL OF URINARY LEAK

The incidence of urine leak from renorraphy sites ranges from 1.5% to 18.5% after open partial nephrectomy (OPN),[10,11,14,18,20–28] 1.5–16.5% after laparoscopic partial nephrectomy (LPN),[14–17,19,25–27,29] and 0.78–3.7% after robotic partial nephrectomy (RAPN).[12,13,18,19,27,28,30] The incidences vary with respect to the definition of urinary leak used (clinical, biochemical, and/or radiographic). Additionally, the literature is replete with inaccurate information regarding the timing of postoperative urinary leaks vis-à-vis drain removal. In one RAPN series (n = 1791) where all patients' Jackson-Pratt (JP) drains were removed prior to hospital discharge, the authors report an absolute-symptomatic leak rate of 0.78%.[12] In a combined OPN/LPN series consisting of 1118 cases, an overall leak rate of 4.4% was noted with delayed leak after drains were removed occurring in 0.4%.[16] It is certainly likely that not all urine leaks following partial nephrectomy are clinically symptomatic, and the true incidence is therefore unquantifiable. According to the American Urological Association (AUA) guidelines on the management of the stage 1 renal masses, the incidence of a urinary leak following partial nephrectomy is 4.1–4.4%[31] while that of symptomatic leaks requiring drainage is closer to 0.78%.

When a urinary leak is diagnosed following partial nephrectomy, a clinical incidence of suspicion must remain for the possibility of a ureteral injury or necrosis as its cause. Ureteral injuries are reported to occur in 0.3% after LPN and

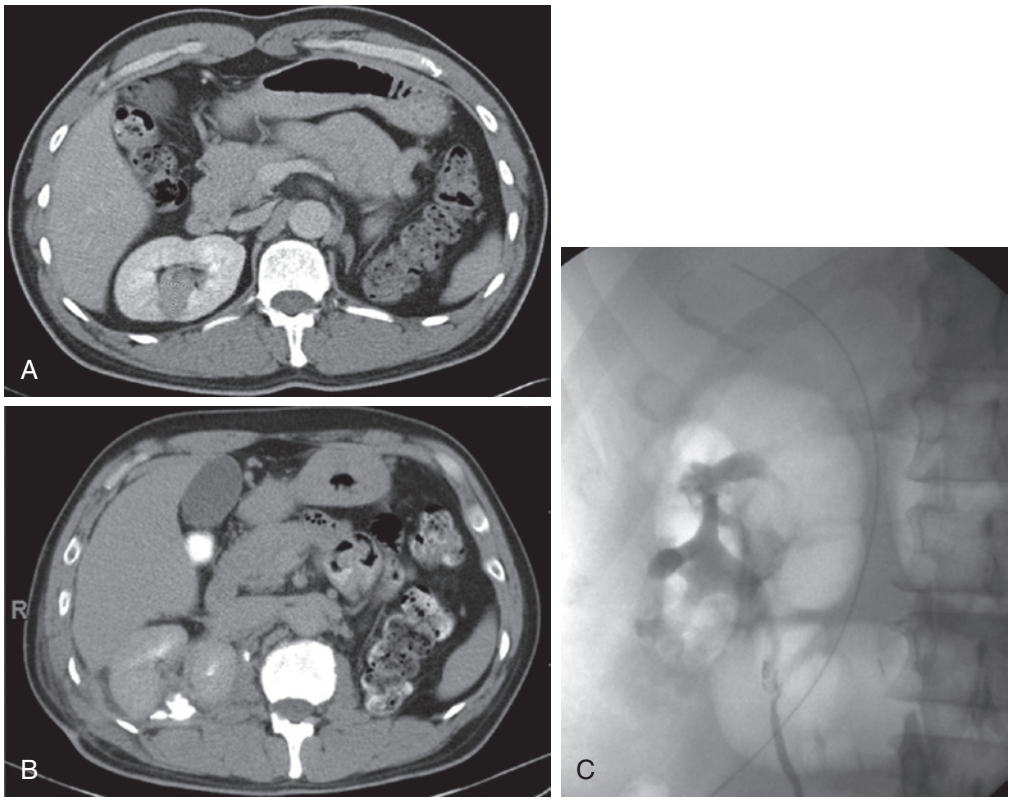

Figure 13.1 Urinary leak after partial nephrectomy in a solitary kidney of a patient with a highly complex tumor (nephrometry score 2+3+3+P+3 = 11P) with proximal ureteral stricture. Ureteral stent was placed on postoperative day 4, leading to resolution of urinary leak in 35 days.

0.6% after RAPN.[25] Idiopathic ureteral injuries are usually identified intraoperatively and do not result in a urinary leak if repaired and properly drained. However, unidentified ureteral injuries can occur and need to be considered if a persistent urinary leak is encountered. Additionally, ureteral obstruction must always be considered and excluded, particularly for high-output urinary leaks following PN. While new-onset ureteropelvic junction obstruction (UPJO) is described in 1% of patients following PN,[26,29] most cases of ureteral injury or obstruction occur as a result of iatrogenic crush, thermal or transection injury, and/or ischemia due to over-dissection. Downstream obstruction from the site of leakage can increase the persistence and amount of a urinary leak from the renorrhaphy site (Fig. 13.1).[14]

RISK FACTORS OF URINARY LEAK

Most studies evaluating risk factors of urinary leak compare those with and without a leak without adjusting for other clinicopathologic characteristics of a patient. These studies indicate that central/endophytic tumor location,[11,12,14] large tumor size,[11,12,14,16] collecting system entry,[11,12,14,15,18,19,22] RENAL nephrometry complexity,[22,27] downstream obstruction (UPJO, ureteral stricture, infundibular stricture, BPH with high-pressure voiding),[14] intrarenal pelvis >50%,[18,22] increased estimated blood loss,[16–19] preoperative CKD stage ≥III status,[19] increased warm ischemia time,[12,16,18] increased operative time,[12] surgeon's learning curve,[19] and surgical approach (increased with OPN vs RPN)[18] are all risks and more highly associated with urinary leak. Other studies indicate that surgical approach,[16,28] tumor multifocality,[11,16] operative time,[22] or EBL[22] are not predictive of urinary leaks.

Two studies evaluated the risk factors for urinary leak following PN using multivariable models. One study suggested that a surgeon's early operative experience (odds ratio [OR] 7.8), tumor proximity to collecting system (OR 9.2), and preoperative CKD stage ≥ III (OR 3.1) are indicative of urinary leak after adjusting for other factors including surgical technique, operative time, warm ischemia time, race, BMI, individual RENAL score attributes, and use of intraoperative ureteral catheterization.[19] Tomaszewski and Uzzo et al. demonstrated that an intrarenal pelvis (OR 24.8), endophytic tumor (OR 4.5), and collecting system entry (6.1) are most predictive after adjusting for age, gender, race, BMI, Charlson comorbidity index, surgical approach, ECOG score, individual RENAL attributes, ischemia time, and operative time.[18] To measure intrarenal pelvis anatomy these authors developed the renal pelvic score (RPS) as measured on CT or MRI by drawing a line connecting the two polar lines (upper and lower) and quantifying the proportion of renal pelvis volume within the kidney parenchyma. An RPS >50% is considered intrarenal and at a higher risk of urinary leak with prolonged time to closure in cases of complex PN.

PREVENTION OF URINARY LEAK

The knowledge of risk factors for urinary leak is paramount in efforts to avoid this complication. Techniques

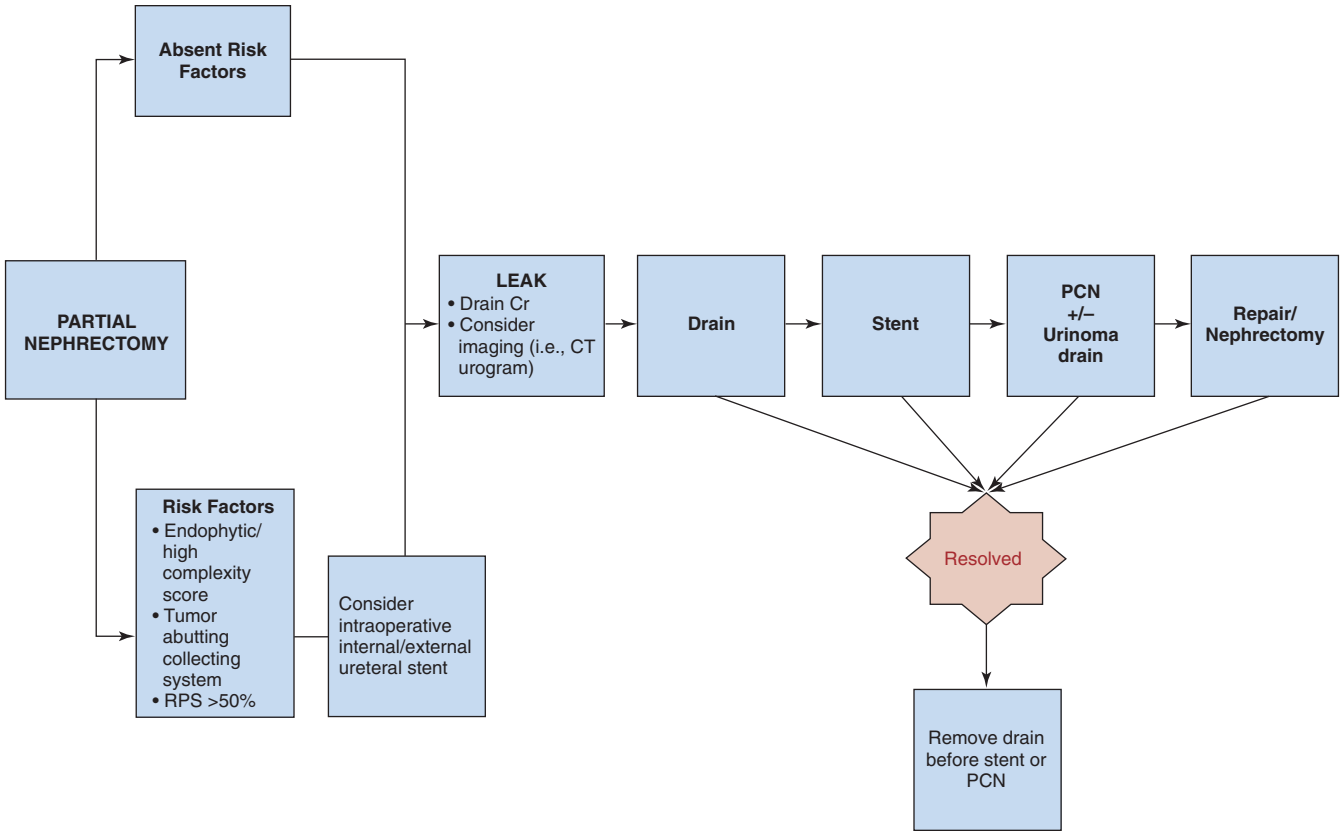

Figure 13.2 Treatment algorithm of urinary leak after partial nephrectomy.

used include the placement of a preoperative ureteral catheter for localization, injection of methylene blue to identify collecting system entries, and "priming" with intravenous indigo carmine prior to arterial clamping. Early series of partial nephrectomy routinely place ureteral catheters and inject saline or methylene blue to help identify intraoperative urinary leakage during excision and reconstruction.[11,14,15,25] However, recent studies question the utility of this since no difference in postoperative urinary leak was seen in those with and without the ureteral stent despite a higher incidence of collecting system entry detection intraoperatively.[10,19,32]

In our practice, we are highly selective regarding in whom we place preoperative ureteral stents based primarily on complex nephrometry score, prior surgery, and intra-abdominal or retroperitoneal anatomy. In these cases we place a 5Fr ureteral stent using a flexible cystoscopy prior to patient positioning and leave it for 24–48 hours as a preventive measure to decrease renal pelvis pressure in select patients with intrarenal pelvis, endophytic tumors, or tumors abutting the collecting system. Occasionally we will use it to instill retrograde saline with 1 mL of methylene blue to identify the collecting system entry. As these are the patients with highest odds of developing a urinary leak, we feel that this may contribute to identifying and preventing a urinary leak. This is, however, difficult to test in a prospective study. Additionally robotic or loupe magnification during excision and renorrhaphy is considered very helpful. The complexity of a collecting system entry should be assessed prior to and during excision, with care taken to avoid complete infundibular transection or extensive unroofing, which would make reconstruction complicated. Moreover, suture occlusion during fastidious repair should be carefully avoided.[33]

TREATMENT OF URINARY LEAK (SEE FIG. 13.2)

More than 80% of urinary leaks following PN are diagnosed in otherwise asymptomatic patients with prolonged output per JP drain, while the remainder is diagnosed after drains have been removed.[14,16] Given that the majority of patients presents asymptomatically, we routinely place JP drains in those who have significant risk factors for urinary leak (large endophytic lesion, collecting system entry, or intrarenal pelvis). Avoidance of JP drains in many of these patients without risk factors has been shown to be safe without an increase in operative interventions for urinary leak drainage.[20,30]

Fortunately, the majority of patients who develop a urinary leak can be managed with a combination of prolonged JP drain and selective use of Foley catheterization without any other operative intervention.[10,11,13,14,16,18,19,22–24] If, however, prolonged JP drain does not decrease the outputs, a ureteral stent should be considered. Ureteral stents have been employed in 20–60% of cases[10–12,14–16,18,19,22,23] of prolonged urinary leak with successful resolution of the leak in the vast majority of cases.[14] The stents are usually placed at a median time of 2–3 weeks[12,14] after partial nephrectomy but could be placed sooner in the case of excessively high drain outputs. A gentle retrograde pyelogram should be

done at the time of stent placement to assess patency of the ureter and good positioning of the stent. A leak does not need to be demonstrated on retrograde if there is clinical evidence of a leak. The JP drains are kept until output significantly declines. The stents may be kept in place for 6–12 weeks,[14,15] and a retrograde pyelogram may be done to evaluate for leak before they are removed; however, our practice is to omit retrograde unless clinically indicated. The combination of a ureteral stent with intraabdominal JP drain may result in over 90% resolution of urinary leak.[14,16,18] The median duration of a urinary leak is between 20 and 64 days.[14,16,22,24] It is expected that unobstructed patients will heal within a reasonable time period of 1 to 4 weeks.[14] Some experts advocate that the drain be placed to straight drainage as opposed to bulb suction as this may prolong urinary leakage.[34]

The use of Foley catheters has been advocated in cases of prolonged or high-output drainage, but we reserve this primarily for men with high-pressure voiding. Alpha-blockers are often used to minimize bladder pressures, which may induce reflux up the stent. Care should be taken to maintain good hygiene of the drain site. Drainage may reduce gradually or occasionally quite precipitously. If this occurs, an ultrasound is often helpful to assess for retroperitoneal fluid reaccumulation or hydronephrosis. Drains are usually removed before the stent, which should be maintained for several additional weeks after the leak has clinically resolved. In cases of persistent high-output leakage despite maximal drainage, ureteral or stent obstruction, unrecognized additional injuries, or necrosis should be considered. Although not scientifically evaluated, desmopressin administration has been suggested to reduce the duration of urinary leak.[35,36]

Whereas the majority of urinary leaks resolve on their own following PN, patience is essential, and individuals should be counseled that their stent and drain may occasionally need to stay in place for weeks or, rarely, months. In these cases some have successfully accelerated resolution with dual ureteral stents or a fashioned 14Fr to 16Fr ureteral catheter.[37,38] An additional urinoma drain or a nephrostomy tube may rarely be necessary and has been utilized along with stents on occasion.[12,16,18,19,22–24]

The astute clinician should be very hesitant to ever reoperate on a urinary leak following PN as long as obstruction is ruled out and drainage is maximized. Very rare instances of persistent leakage may require attempted renal or ureteral reconstructive or completion nephrectomy.[11,22,23,25] However, prior to undergoing nephrectomy, a careful pyelogram is needed to assess and to rule out ureteral strictures, infundibular stenosis, or ureteropelvic junction obstruction, all of which may prolong the urinary leak.[14] If infundibular stenosis or strictures are identified, endoscopic dilations may be attempted and have been shown to be successful in case reports.[39,40] Additionally, there have been case reports of fibrin sealants that can be successfully injected in the offending calyx either percutaneously or by retrograde ureteroscopy to resolve any further urinary leakage.[41–43] However, any salvage endoscopic measures may require multiple operative procedures, and patients need to be counseled appropriately. Reconstruction may be preferable to nephrectomy depending on clinical circumstances.

Urinary Leak Associated With Radical Prostatectomy

DEFINITION AND DIAGNOSIS OF URINARY LEAK

There is no consensus on a definition regarding urinary leak following radical prostatectomy.[44] Similar to urinary leak after partial nephrectomy, two main definitions exist, one based on the persistence of prolonged drain output[45–48] with chemical analysis consistent with urine and the second based on radiographic findings on cystogram.[49–53]

In the majority of historical prostatectomy series, cystogram was routinely performed before catheter removal. It is diagnostic for a urinary leak with the identification of contrast extravasation. Several groups have attempted to classify and quantify cystogram findings. Fenig et al. classified these into no extravasation, mild leak (wisp of extravasation), moderate leak (extravasation 25% or less of instilled contrast medium), and major leak (>25% extravasation).[54] The purpose of the classification was to determine the need for a repeat cystogram. Patients with mild leak were recommended to undergo removal of Foley catheter without a repeat study. Patil et al. classified these into grade I (extraperitoneal within 6 cm of the urethrovesical anastomosis), grade II (extraperitoneal extending to the sidewall) >6 cm, and grade III (intraperitoneal).[49] Here, the purpose was to report on clinically significant versus nonsignificant leakage where patients with higher grades tended to require intervention. Both of these classification schemes illustrate the importance of a uniform definition of a urinary leakage.

Several other modalities including CT cystogram have been described to evaluate the urethrovesical anastomosis following radical prostatectomy. Although TRUS has been described, we do not recommend its use in the perioperative setting due to patient discomfort and less precise image resolution compared to CT.[55,56] CT cystogram has been shown to be more sensitive and accurate than cystogram.[57] Indications for CT cystogram as opposed to standard cystogram remain unclear. We recommend consideration of CT cystogram if the patient has suffered a prolonged or complicated course of urinary leakage with secondary complications such as bleeding, uroperitoneum, sepsis, or abscess. More extensive imaging may identify drainable collections or additional concurrent pathology. In these cases it is more critical that a leak is not present when catheter is removed.

Recently, many have questioned the overutilization of cystogram and attempted to stratify patients in whom it may be omitted. A study on open prostatectomy suggested that cystogram could be omitted in the absence of red or pink urine on POD 8 with a negative predictive value of 98.6%.[58] Another study suggested that an intraoperative test for a watertight anastomosis is predictive of no leakage. Ischia et al. recommended that over 97% of patients might avoid cystogram on POD 7 if a negative intraoperative leak test was confirmed.[59] With the advent of robotics and improved visualization and degrees of freedom during suturing, many have questioned the need in robotic procedures and perform a cystogram only in patients with a high clinical suspicion or risk of a leak such as in salvage prostatectomies following radiotherapy.[45,60] Guru et al. prospectively analyzed the

use of cystogram after robotic prostatectomy and illustrated that it can be safely avoided.[61]

SYMPTOMS OF URINARY LEAK

In the majority of published series, patients with urine leaks following prostatectomies are asymptomatic and present with increased drain output that is then confirmed to be consistent with urine or on a routine postoperative cystography. In Guillonneau et al.'s study, while 8.1% were diagnosed as having immediate postoperative urinary leak (persistent drain output for more than 6 days), 1.9% presented with secondary anastomotic leakage days after catheter removal.[48] These patients were diagnosed with acute pain, acute urinary retention, and peritoneal irritation symptoms. The study also illustrated that acute retention develops as a function of duration of catheterization where the incidence may be 5–25% at POD 2–3 and around 1% by POD 6. This may be due to resolution of anastomotic swelling. Removal of the catheter earlier in the postoperative course is, indeed, a risk factor for urinary retention.[54] While not all patients with retention develop a secondary urinary leak, retention appears to be a risk factor for anastomotic breakdown and leakage, particularly if the catheter is replaced traumatically.

An important subacute manifestation of urinary leak from the urethrovesical anastomosis includes osteomyelitis of pubic bone in the setting of a urinary tract infection. These patients can present with recurrent urinary tract infections, significant pubic and pelvic pain, and disturbance in gait.[62,63] Often these patients are not diagnosed in time and treated with repeat courses of antibiotics, which fails to improve their symptoms. These can present as early as 1 month postoperatively or can present over the next several months to several years.[62] Pelvic MRI remains the most sensitive and specific test to diagnose osteomyelitis of the pelvis.[64] When osteomyelitis has progressed, pelvic CT may reveal extravasation of intravesicle contrast from the fistulous tract into the bone causing fractures of pubic rami.[63]

While urinary leak may delay the return of continence following prostatectomy, it does not seem to worsen long-term continence rates at 1 year.[49,54] Several studies have suggested that urinary leak may predispose to the development of bladder-neck contractures (BNC),[45,49,60,65] while other studies indicate no significant relationship.[46,52,54] Postoperative urinary leakage when the anastomotic apposition is good seems unlikely to lead to BNC. However, prolonged and more extensive urinary leakage, resulting from an anastomotic gap, may cause scarring due to healing by secondary intention.[49,66]

INCIDENCE AND DIFFERENTIAL OF URINARY LEAK

The incidence of urine leak from urethrovesical anastomoses ranges from 0.5% to 29% after open radical prostatectomy (ORP),[51–54,60,67] 0.9%–22.3% after laparoscopic radical prostatectomy (LRP),[47,48,67–70] and 1.1%–12.7% after robotic-assisted laparoscopic prostatectomy (RALP).[46,49,50] The incidence varies with respect to the definition used with the radiographic definition, yielding higher incidences with a diagnosis of subclinical leak.[47,49,60] The incidence of leak is also time-dependent. In one ORP series, the leak rate at POD 8 was as high as 78% and decreased to 38% and 20% on POD number 11 and 14, respectively.[71] Similar data are available for LRP and RALP. However, due to improved continuous suturing with RALP, it is thought that RALP yields lower leak rates overall given improved tissue coaptation.

While there are several series with a high incidence of urinary leak overall, clinically significant anastomotic leaks are infrequent. Clinically significant anastomotic leaks can be defined as those that extended intraperitoneally, those that necessitated additional drainage, those that necessitated readmission due to ileus or dehydration, and those associated with fever and sepsis.[72] The incidence of clinically significant anastomotic leaks ranges from 0.36% to 2.3% in multiple series.[49,60,72]

Other sources of urinary leak following prostatectomy include bladder or ureteral injury not identified intraoperatively. The incidence of ureteral injury has been described to be 0.1% to 1.4%[68,70,73] and that of bladder injury 0.2% to 1.6%.[48,69,70] If bladder or ureteral injuries are suspected, a CT urogram or a cystogram is recommended.

RISK FACTORS OF URINARY LEAK

Risk factors for urethrovesical anastomotic leakage include previous TURP,[52,74] difficult intraoperative anastomosis,[51] increased EBL,[52,54,68] pelvic hematoma,[52,54,68] positive intraoperative flush test,[51] postoperative UTI,[51] ischemic heart disease,[52] obesity (due to difficulty accessing the urethra during anastomosis),[75] early learning curve,[47,67,68] and salvage prostatectomy after radiation therapy.[76] Additionally bladder neck reconstruction during RALP has also been shown to increase urinary leakage rates.[46] Neither suture type, number of sutures, nor interrupted versus running anastomotic sutures has been shown to be associated with leakage.[68,77,78] Barbed V-lock suture, rather than monofilament, has been shown to reduce the incidence of positive intraoperative leakage test, and the need for additional tightening of sutures.[79] However, it has not been directly related to postoperative urinary leakage. There has been no difference in leakage rate with open versus minimally invasive approach[60] or by extraperitoneal versus intraperitoneal surgical approach.[68]

PREVENTION OF URINARY LEAK

Several preventative measures to minimize urinary leak during prostatectomy have been described in the literature. The use of a side-fenestrated catheter over a conventional Foley catheter has been advocated in one study. In side-fenestrated catheters, the fenestration is located in the catheter below the balloon at the site of the anastomosis. The aim is to improve drainage emanating from the healing anastomosis. In a prospective randomized study of 250 patients undergoing RALP, patients randomized to a fenestrated catheter had a significantly decreased incidence of urinary leak (4.6% vs 12.3%).[80] Another preventive measure described is using fibrin sealant over the anastomosis to prevent leakage across the anastomosis. The maneuver may decrease overall intraabdominal drain output; however, the evidence is not strong for reducing the incidence of urinary leak.[81]

Another technical modality to prevent a leak is to relieve tension exerted on the urethrovesical anastomosis. Patel

et al. investigated the use of the posterior reconstruction of rhabdosphincter with the secondary outcome being leak rate.[50] The free edge of the Denonvillier's fascia is sutured to the posterior rhabdosphincter underneath the urethral plate. The intent is to minimize the downward mobilization of the urethra and reduce tension across the anastomosis. With this approach, the incidence of urinary leak was shown to reduce significantly (0.4% vs 2.1% in those without). Tewari et al. evaluated three different techniques of anastomosis – conventional anastomosis, anterior reconstruction, total anatomic restoration (anterior plus posterior reconstruction).[72] The aim of the latter two techniques was to relieve the tension on the anastomosis. Clinically significant urinary leak rates were lowest with total anatomic restoration (0.3%) followed by anterior reconstruction (1%) and highest with conventional anastomosis (2.3%). Ultimately, the best prevention of urinary leak following radical prostatectomy is the achievement of a tension-free, watertight urethral anastomosis.

TREATMENT OF URINARY LEAK (SEE FIG. 13.3)

Depending on the risk factors for urinary leak, an intraabdominal drain is considered at the time of prostatectomy. There are two divergent maxims associated with the pelvic drain: "when in doubt, drain" and "drains have only one role, they suck." In between these two extremes exists the informed approach. The goal of the drain is to avoid the sequela of uroperitoneum with its associated risks of ileus and electrolyte abnormalities and to minimize the need for an interventional procedure in the postoperative period.

Many utilize the intraoperative leak test as the main indicator as to whether or not to place a drain. Other factors taken under consideration include the technical difficulty with anastomosis (such as suture breakage, increased robotic arm collisions due to suture angles, tearing of urethra), prior TURP, or radiotherapy. In a prospective study on 846 patients undergoing prostatectomy, patients did not undergo drain placement if they had a negative leak test, adequate hemostasis, and no surrounding organ injury. This study illustrated no differences between those with and without drain placement with respect to leak rates.[82]

When leakage is confirmed in the postoperative period either by drain output or on radiographic imaging, the Foley catheter should be examined to ensure that it is draining and that it is not kinked or clogged. A gentle flush may be needed to clear away the debris. If high-output leakage is seen, the drain can be taken off suction and allowed to drain passively. The drain may be withdrawn a few centimeters as well to avoid suctioning against the anastomosis.

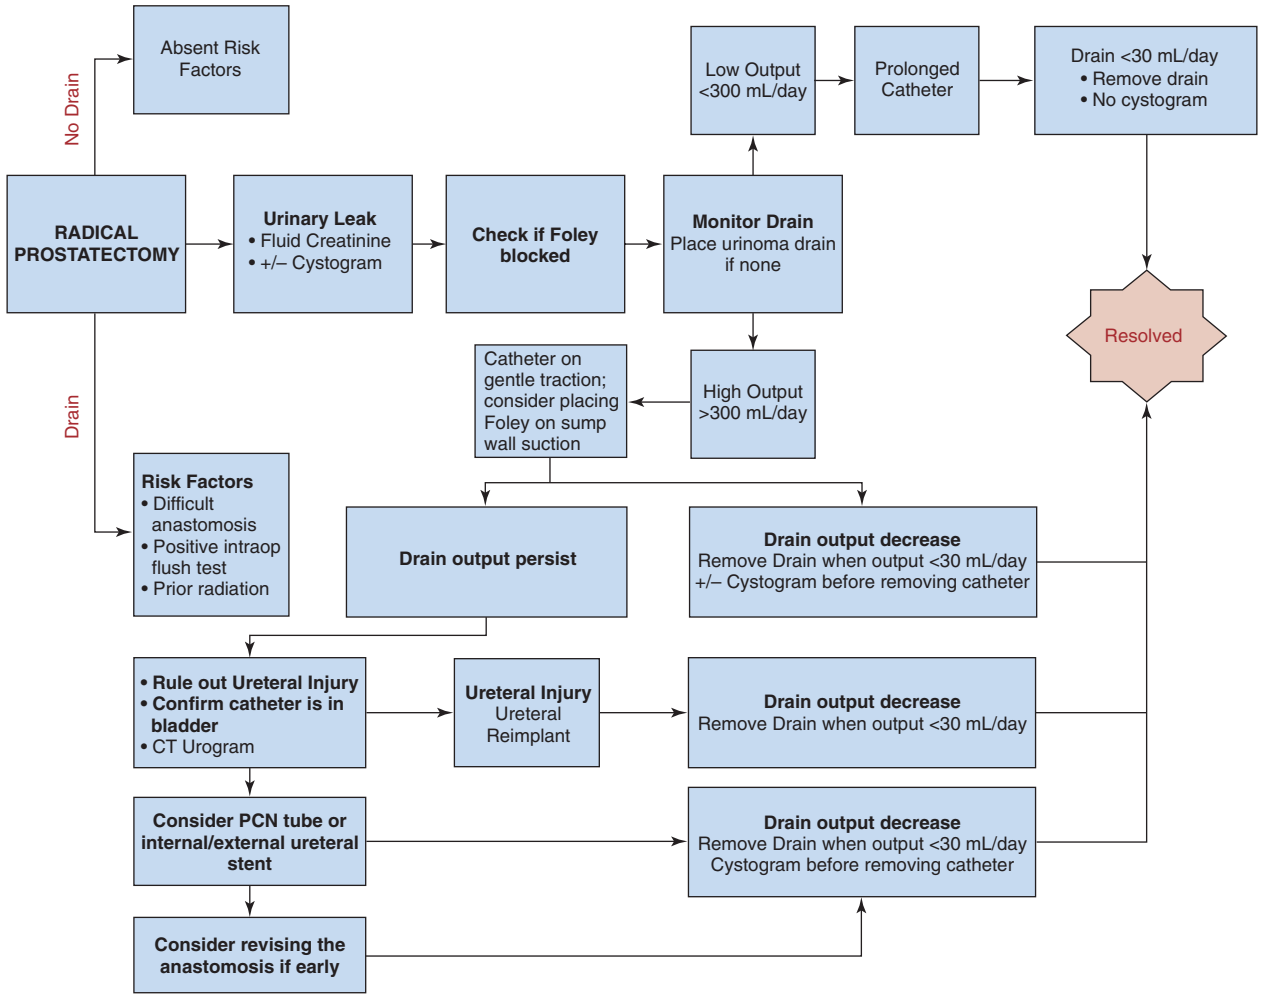

Figure 13.3 Treatment algorithm of urinary leak after radical prostatectomy.

Fortunately, the majority of urinary leak can be managed with prolonged Foley and pelvic drain without the requirement for additional maneuvers.[48,49] Less than 5% of patients may require additional percutaneous drainage of the uroperitoneum.[48]

If the leakage remains high despite the above maneuvers, the Foley catheter can be placed on gentle traction against the anastomosis. The drain output subsequently may be dependent on the closeness between the ureteral orifices and urethrovesical anastomosis.[68] If the ureteral orifices are situated far away from the urethrovesical line and there is profuse leakage, gentle traction or apposition of the catheter against the bladder neck can reduce leakage and external fixation may help.[68] If the ureteral orifices are close to the anastomosis, the Foley balloon can oppose the ureteral orifices or lie above the ureteral orifices and impair urinary drainage, thereby worsening leakage. Traction against this will only increase the urinary leak. As such, in this case, gentle radiologic guided mobilization of the catheter with deflation of the balloon and proper external fixation of the catheter can be done to avoid dislocation and allow improved drainage via the indwelling catheter.[44,68] Alternatively, 14-16Fr Cope loop nephrostomy tube can be placed as a urethral catheter to allow improved urinary drainage through several drainage holes.

In the presence of high-output leakage where the majority of urine is coming from the perianastomosis drain rather than per the catheter, CT urogram should be performed to rule out an iatrogenic ureteral injury and to ensure that the catheter balloon remains in the bladder. In cases of ureteral injury, a decision to do ureteral reimplantation or nephrostomy with delayed ureteral reimplantation is left up to the discretion of the surgeon, and no complication differences are seen with early versus delayed reimplantation,[83] although it is our practice to repair early. If no ureteral injury is thus identified and urinary leakage exceeds >1.5 L, revision of the anastomosis can be performed even up to POD 6–12.[47,48,69] This option should be reserved for rare circumstances.

Rather than a repeat revision of the anastomosis, several other options have been described as potentially effective. One option is to continue to observe the patient ensuring that all leaked urine is diverted effectively. This may be accomplished by leaving the JP drain or placing an additional drain under radiographic guidance.[49] Another approach described is a needle-vented suction of the Foley catheter.[84] The Foley catheter is connected to low wall suction at 15 to 20 mm Hg. To avoid continuous suction against the bladder mucosa, a sump is created by placing an 18-gauge angiocatheter needle in the tubing connecting the Foley to the wall suction. This technique allows a gentle vacuum to allow urine to preferentially drain through the catheter rather than leaking through the anastomosis. Another approach described is to divert all of the urine away by placing single J internal–external ureteral stents bilaterally. This allows all urine to become diverted and will minimize all urinary leakage.[69] A final approach described is to place either bilateral nephrostomy tubes to divert all urine or a unilateral nephroureteral stent, which can be placed on intermittent wall suction.[85]

Ultimately, the drain output is monitored daily. When the output decreases significantly, another fluid creatinine can be done to rule out any residual leak. The drain is subsequently removed and after a repeat cystogram has ensured healing, the Foley catheter can safely be removed.

Urinary Leak Following Urinary Diversions and Bladder Reconstruction

DEFINITION AND DIAGNOSIS OF URINARY LEAK

Compared to leakage after radical prostatectomy or partial nephrectomy, urine leak after urinary diversions has not been studied as extensively in the literature as a primary end point. Richard et al. defines a urine leak as elevated drain fluid creatinine level beyond POD 7,[86] while other studies define it as early as POD 1.[87–89] A small amount of urinary extravasation in the early postoperative period seems to be acceptable[90] and may resolve by POD 7 with adequate drainage.[87,91]

The study of choice to confirm laterality or location of leakage is a combination of CT urogram and loopogram/pouchogram.[88–90] However, while radiographic studies are more sensitive for a identifying a leak, they are generally done to localize the presence of a clinical leak. In a study by Ankem et al. on patients with continent urinary diversion, five of six leaks diagnosed with a pouchogram were clinically detectable.[92] In a study by Brown et al., of 15 urinary leaks, three were localized by CT urogram, 10 by CT conduitogram, and the remaining two on nephrostogram done at the time of percutaneous nephrostomy tube insertion.[88] Many patients with urine leak can also have an infected urinoma, and it is imperative to identify this early on CT imaging.[90,93]

SYMPTOMS OF URINARY LEAK

Two studies evaluated urinary leak as a primary end point and tabulated presenting symptoms.[88,89] In 21 patients, Hensle et al. showed ileus to be a presenting symptom of a leak in four (19%), urinary drainage from wounds in seven (33.3%), elevated BUN without increased creatinine in 20 (95.2%), and sepsis in 10 (47.6%).[89] In a study of 15 patients, Brown et al. indicated sepsis as a presenting symptom in eight (53.3%), increased drain output in six (40%), leakage from wound in five (33.3%), and decreased urine output in four (26.6%), with one asymptomatic patient diagnosed on a routine "stentogram" prior to removal of stent.[88] In other series, urinary leak is also associated with prolonged ileus and prolonged length of hospitalization.[93,94]

There appears to be a bimodal temporal presentation of urinary leak. In Hensle et al.'s study, 8 of 21 (38%) presented within the first 24 hours and 13 of 21 (62%) presented after POD 6.[89] Additionally, those who presented after POD 6 had worse outcomes. Brown et al. noted a median time to leak of 12 days, with 2 of 15 (13%) presenting within the first 6 days and 13 of 15 (87%) presenting after POD 6.[88] Patients who presented within the first few days postoperatively may represent technical errors. In the Brown et al.'s study, for the two patients who presented with early leak the sources were "technical construction of ureteroenteric anastomosis" in one and a stoma catheter perforating

staple line at the blind end of the conduit in another. On the other hand, those who presented after POD 6 may represent a manifestation of ischemic necrosis of the anastomosis.[91] As such urinary leak is also thought to be a risk factor for development of ischemic ureteroenteric stricture.[86]

Urinary leak has an adverse effect on mortality,[89,93] which may be due to multiorgan failure from concomitant sepsis[89,93,95] or may also be due to rapid cancer progression theorized to be a result of proinflammatory cytokines and suppressed antitumor inflammation response.[88] Sepsis is one of the more common causes of mortality following radical cystectomy and urine leak has been diagnosed up to 40% of septic patients who died within 30 days.[95] In the Hensle et al.'s study, alarmingly, 48% of patients with a urinary leak died perioperatively.[89] Additionally, mortality risks are also associated with elevated serum BUN, an indirect marker of urinary leak, where rates are 5.8% if BUN <30 and increase to 33.3% with BUN >100.[96]

INCIDENCE AND DIFFERENTIAL OF URINARY LEAK

The incidence of urine leak after ileal conduit ranges from 1.87% to 16%.[88,89,93,96,97] If limited to series with >500 patients, the incidence ranges from 1.87% to 2.57%.[89,96] In more than 60% of cases, leakage occurred from the ureteroenteric anastomosis, but it can also occur anywhere along the loop including the butt-end of the conduit.[89]

The incidence of urine leak after continent reservoir ranges from 2% to 12.8%.[90,98–101] Leakage can occur from the ureteroenteric anastomosis or from the extensive suture lines.

The incidence of urine leak after neobladder ranges from 2.1% to 11.6%.[102–105] If limited to series with >300 patients, the incidence ranges from 2.1% to 7.7%.[103,104] Leakage can occur from either the ureteroenteric anastomosis, the neovesico-urethral anastomosis, or anywhere along the extensive suture lines of the neobladder. In a series by Hautmann et al., the incidence of leakage per ileourethral anastomosis was 6.6% and from the ileoureteral anastomosis was 1.1%.[103]

RISK FACTORS OF URINARY LEAK

Evidence on the risk factors of urinary leak after urinary diversion is limited compared to the evidence of risk factors predisposing leakage after radical prostatectomy or partial nephrectomy. Studies describing risk factors are descriptive or achieve marginal statistical significance. No current multivariate model for urinary leakage exists following urinary diversion. Perhaps this is because urinary leak represents only a fraction of postoperative complications after cystectomy while it represents major complications after radical prostatectomy or partial nephrectomy. However, urinary leak after a diversion represents a greater concern as most are symptomatic and leakage can be a poor predictor of outcomes.

Risk factors for urinary leak after urinary diversion include palliative exenteration,[88,93] BMI >30,[99] prior pelvic radiation,[89,93,106] and cardiovascular medical history.[93] These factors may influence the vascular supply to the ureter or the ability to perform a high-quality diversion. Increasing medical comorbidities may also be associated with postoperative genitourinary complications, although no specific effect of comorbidities on urinary leakage is described.[107]

Urinary leakage is more common on the left ureter than on the right,[89] perhaps due to devascularization of left ureter with extensive mobilization or because the left anastomosis is more predisposed to be under tension. There do not appear to be any differences in urinary leak with interrupted or running suture anastomosis of the ureter.[108] Stomal edema/obstruction may increase the intraconduit pressure and increase the risk of ureteroileal anastomosis disruption.[91] Additionally, placement of a catheter postoperatively is the most common cause of iatrogenic injury to the stump of the conduit.[88] Extraluminal hematoma/seroma may also increase the risk of urinary leak by disrupting the blood supply.[91] Poor surgical technique (case reports of spermatic vein anastomosis to conduit)[109] and early learning curve can also predispose to a urinary leak. Recurrence of malignancy can be a risk factor for late presentation of urinary leaks.[110]

Prevention of Urinary Leak

Mattei et al. performed a prospective randomized trial on 54 patients with ileoureteral anastomosis to study the impact of perioperative ureteral stent on urinary leaks. The study revealed a significantly increased urinary leakage on POD 1 in the absence of stents, which becomes comparable by POD 3–7.[87] Additionally, stenting improved recovery of bowel function and reduced metabolic acidosis, perhaps by reducing the leakage in the early postoperative period. Another study confirmed an association of ileus in those with nonstented anastomosis.[94] A retrospective study by Beddoe et al. on patients with transverse colon conduits after pelvic radiation also demonstrated a significant decrease in urinary leakage after stented anastomosis (3% stented vs 18% nonstented).[111] On the other hand, Regan et al. illustrated a nonstatistically significant decrease in urinary leak rate in patients with stented anastomosis (0% stented vs 2.5%, $p = 0.09$).[112]

Management of Urinary Leak (see Fig. 13.4)

Management of urinary leak differs with respect to the etiology and timing. Patients who present with urinary leak within POD 1–6 are more likely to have an iatrogenic leak while those who present after POD 7 are due to poor healing and poor vascularization. As such, management differs in those who present early versus those whose presentation is delayed.

Open operative intervention may be favored in the very early postoperative period in patients with high-output urinary leakage, particularly when an iatrogenic injury is suspected. Endoscopic maneuvers including catheters per stoma, pelvic drains, and/or nephrostomy tubes may not lead to complete resolution of urinary leakage.

Of those who present in a more delayed fashion, early operative intervention <72 hours after diagnosis is

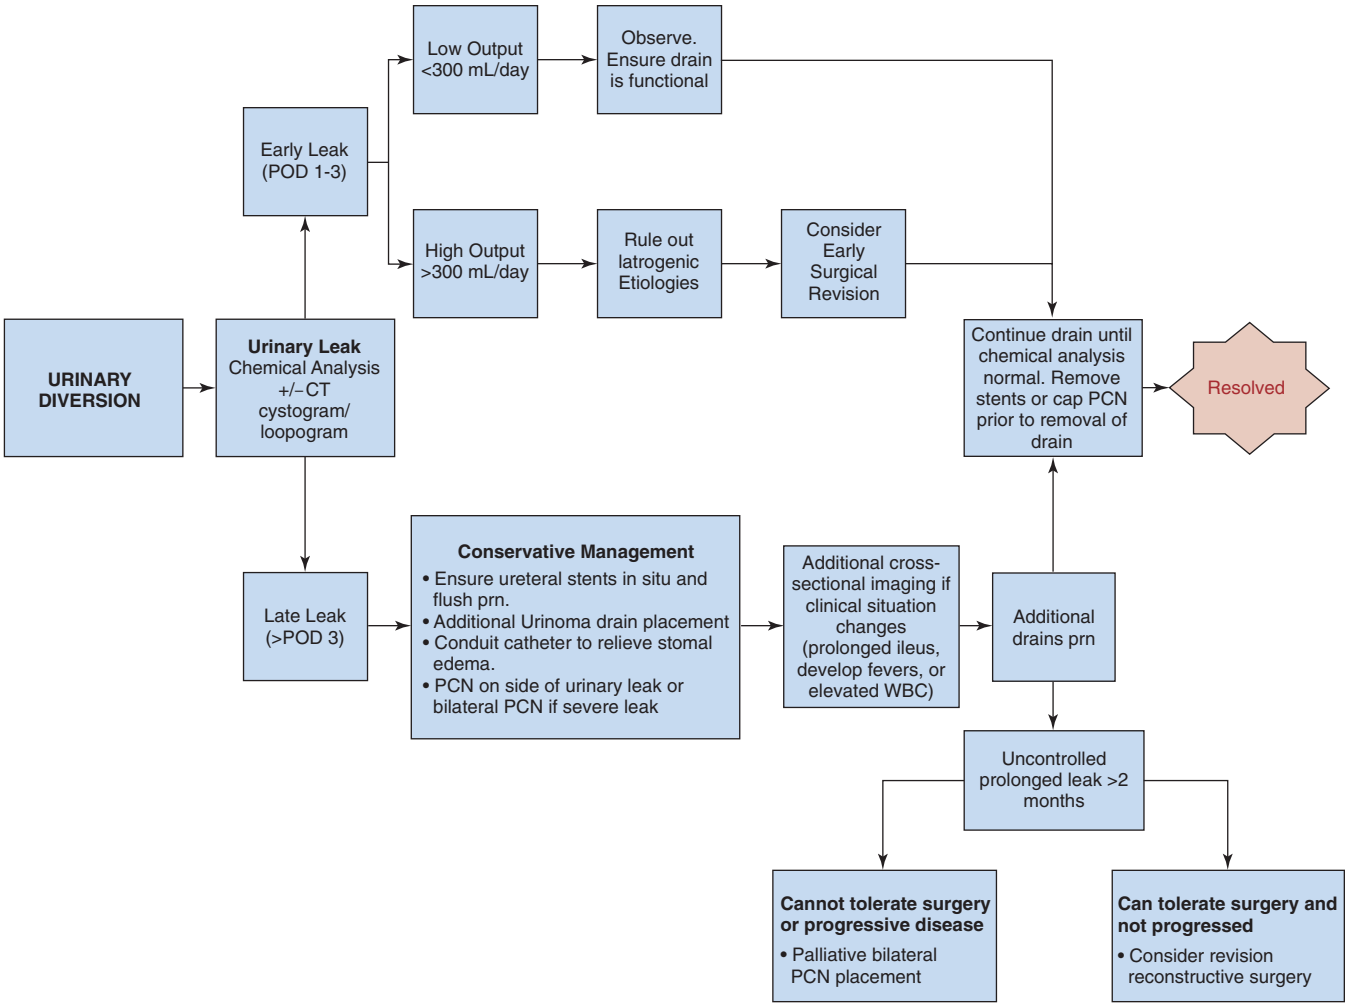

Figure 13.4 Treatment algorithm of urinary leak after urinary diversion.

indicated if conservative maneuvers fail. In a study by Hensle et al., of 12 patients managed with operative intervention, no patients died when explored within 72 hours, while 5 of 6 died when exploration was delayed until after 72 hours. Although provocative, case selection may have been an issue.[89] Additionally, 4 of 9 patients survived when managed nonoperatively (intraabdominal drain and drain per stoma). Fortunately, since the Hensle et al. study, endoscopic procedures (nephrostomy tubes and percutaneous urinoma drain) in addition to the antibiotics have augmented the armamentarium of conservative management.

Initial conservative maneuvers include placing a catheter in the stoma (with precaution due to the possibility of iatrogenic stomal injury) and ensuring that the intraabdominal drain is taken off suction and placed on gravity. If a urinoma collection is seen on cross-sectional imaging, we also recommend placing a CT-guided percutaneous drain within it and treating the patients with antibiotics if infection is suspected. However, if, despite these maneuvers, a clinically symptomatic urine leak persists, we recommend placing a nephrostomy tube on the side of the ureteroenteric leak. A "stentogram" or nephrostogram may also be performed at the time of placing a nephrostomy tube to confirm laterality. If no stent is present at this time, an attempt to stent across the ureteroenteric anastomosis in an antegrade fashion can be made.

In the Brown study, of 15 patients with a urinary leak, 2 patients with early presentation of urinary leak underwent early revision of the diversion, 3 patients were managed with a catheter in the stoma or JP drain, 11 with radiological diversion including nephrostomy tubes, and 1 with late open revision.[88] Of 11 patients managed with radiological diversion, 7 patients healed with a nephrostomy tube in place for a median duration of 40 days (range 21–57), 3 failed to heal after prolonged duration and developed progressive disease, and 1 underwent late revision.

Despite having a leak, many patients may not be in optimal condition to undergo an open revision. In these patients, bilateral nephrostomy tubes may be considered to divert all urine as a palliative measure. In one case report, a VAC therapy was also employed to close the leakage in addition to bilateral nephrostomy tubes.[113] The VAC tube was inserted through the abdominal wound and positioned at the leakage site. The suction was adjusted to 125 mm Hg, and after 32 days of VAC therapy, the urinary leakage resolved. In another study, angioplasty balloon catheters were deployed in the distal ureters to divert all urine per nephrostomy tubes.[114]

Once the urinary leak is effectively controlled, repeat fluid creatinine of the urinoma drain or intraabdominal drain should be done. If a nephrostomy tube is placed, a nephrostogram can be done periodically as clinically indicated to ensure resolution of the urinary leak. If no leakage is documented, nephrostomy tubes are capped and drain outputs are monitored to ensure that the leakage has not resumed. The nephrostomy tubes are then removed followed by the drain removal.

Urinary Leak Following Miscellaneous Procedures

URETERAL RECONSTRUCTION

Outcomes after ureteral reconstruction (uretero-ureterostomy or ureteral reimplant) come primarily from the transplant literature. Urine leak after a renal transplant can occur from multiple sites, including the upper tract, or ureteroneocystotomy site. Upper tract leakage may be due to segmental infarction in patients with injured accessory renal artery or due to ligation of a polar artery.[115] Urinary leakage is diagnosed clinically initially and confirmed on CT urogram or renal ultrasound. Renal ultrasound is generally preferred after transplant rather than a contrast-based study.

The incidence of a urinary leak can range from 0% to 9.3% of cases.[116] In a meta-analysis of 1154 renal-transplant patients from seven studies, the overall incidence of urinary leak was 3.1%.[117] In a study of 677 patients undergoing ureteroneocystotomy and 14 undergoing uretero-ureterostomy, the incidence of anastomotic urinary leakage, as opposed to upper tract leakage, after ureteroneocystotomy was 1.47% and after uretero-ureteral anastomosis was 7.1%.[118] Another study of 166 patients undergoing uretero-ureteral anastomosis after transplant suggested an anastomotic leak rate of 4.2%.[119]

Two prospective randomized trials between transvesical (Politano-Leadbetter) or extravesical (Lich-Gregoire) ureteroneocystotomy techniques indicate no difference in urinary leak rate,[120,121] while retrospective studies suggest an increased rate with transvesical approach due to leakage from cystotomy site.[118,122] Among the extravesical approaches, the Lich-Gregoire technique demonstrated a lower rate of urinary leakage compared to U-stitch techniques due to lack of mucosal-mucosal anastomosis in U-stitch technique.[123,124] Retrospective studies suggest no differences between refluxing and antirefluxing techniques.[125–127] Male gender has a higher incidence of urinary leakage, perhaps due to high-pressure voiding.[128]

Ureteral stents have not been consistently used at the time of ureteral reimplant in the transplant literature. In a large Cochrane collaboration meta-analysis, only 50.8% were stented at the time of transplant, and stenting reduced the rates of urinary leakage with a hazard ratio 0.29 (0.12–0.74).[117] Omental wrap has also been suggested to reduce the rates of urinary leakage, although the evidence for this is not strong.[129–131]

Conservative management of a urinary leak following any ureteral reimplant or primary repair includes placement of an indwelling Foley catheter to reduce urine refluxing up the ureter and ensuring that the stent is across the anastomosis. If an intraabdominal drain is in place, suction can be removed from the drain. The drain is maintained until low urine output is seen. If, despite the stent and Foley catheter, significant and prolonged drainage is seen, then a nephrostomy tube may be placed. For upper tract leak from ischemic calyceal necrosis after a transplant, a nephrostomy tube may be needed to ensure adequate drainage.[115] Before removal of any drains either an antegrade or retrograde pyelography can be done to illustrate the resolution of any urinary leaks.

If despite all endoscopic measures, urine leak continues, operative interventions include reconstruction, re-do ureterovesical reimplantation (may need psoas hitch or broari flap), pyelovesicostomy if bladder is adjacent to transplanted kidney, ileal interposition or nephrectomy. Between 40% and >75% of patients are managed with operative intervention.[119,132] in the transplant literature, although it is not known what proportion would have been salvaged with the further use of a nephrostomy tube or perioperative ureteral stents.

PYELOPLASTY

Urinary leak after pyeloplasty typically occurs at the site of the ureteropelvic anastomosis. Urinary leak is generally diagnosed clinically due to an increased drainage with chemical confirmation of leak. In a meta-analysis of 12 studies, the incidence of urinary leak following robotic, laparoscopic and open pyeloplasty was 2.92%, 2.75%, and 1.92%, respectively.[133] Han et al. performed a multivariate analysis to identify factors associated with the need for additional ureteral stenting in pediatric patients undergoing unstented pyeloplasty.[134] Of 285 pyeloplasties performed, 28 needed ureteral stent at a median of 0.8 months (range 0.3–1.6) and in 26 cases, urinoma formation was an indication for a stent. Preoperative differential renal function >60% in the obstructed kidney was an independent factor associated with a need for postoperative stent. Gender, laterality, age, and preoperative hydronephrosis were not associated with a need for stent.

In multiple studies, pyeloplasties performed with either intraoperative PCN or a stent decreased the risk of postoperative urinary leak.[135–137] In a population-based study consisting of 2435 pyeloplasty patients, which compared patients with and without intraoperative stent/PCN placement, those with intraoperative stent/PCN use had clinically significant urinary leak requiring the need of postoperative stent/PCN placement.[137]

When urinary leak is diagnosed after pyeloplasty, management options include prolonged surgical drainage with or without urethral catheter, stent replacement/repositioning, or an immediate nephrostomy tube placement. Conservative management with reinsertion of a urethral catheter, drainage, and time is often successful in the absence of obstruction. The drain is removed when output ceases.[138] Several other studies on stented pyeloplasty support resolution of leak with prolonged duration of drain.[139,140]

Conversely, Cadeddu et al. favors immediate placement of a nephrostomy tube to stop leakage across the anastomosis.[141] In their opinion, persistent exposure of perianastomotic tissue to urine may induce fibrosis and can compromise

the success of a pyeloplasty. In their series of 125 patients, 6 patients developed a urinary leak and were managed with placement of a PCN tube at a median of 4.5 days (range 2–7). In each case, drainage stopped upon PCN placement, allowing the surgical drain to be removed within the next 48 hours. The PCN was removed after an antegrade nephrostogram showed resolution of the leak. The PCN was placed for median 9.5 (range 5–42) days.[141]

Conclusions

Urinary leak is one of the common complications of urological surgeries. Patients may present with a spectrum of signs and symptoms or may be completely asymptomatic depending on the size, extent, anatomy, and timing of the leak. In clinically significant cases, urinary leak may lead to ascites, electrolyte abnormalities, ileus, or sepsis. Sepsis is among the most concerning sequelae of a urinary leak and is associated with poor survival. Prevention strategies include intraoperative technical fastidiousness, placement of a stent across any urinary anastomosis including a catheter in the case of urethrovesical anastomosis, or a stent in the case of pyeloplasty or ureteral reimplant. All management strategies involve maximal drainage of the leak, which is often followed by delayed but spontaneous closure. Often a prolonged surgical drain with the tincture of time is sufficient to bring about such closure. At other times a drain may be placed within the urinary tract at an upstream location to a urinary leak (PCN for ureteral anastomotic leakage, bilateral PCN for urethra-vesical leakage, and ureteral stent for leakage from partial nephrectomy defect). Downstream obstruction must always be clinically assessed and eliminated. If endoscopic measures fail, operative intervention may become necessary but in stable patients should be delayed in an attempt to achieve spontaneous closure. Management of urinary leakage can be frustrating both for the physician and for the patient, leading to a prolonged course of hospitalization and recovery, and adequate communication and expectations are essential.

Chapter 13 Questions

1. Which of the following signs/symptoms are consistent with intraperitoneal urinary leak?
   a. Hyponatremia
   b. Hyperkalemia
   c. Rising creatinine with elevated BUN levels
   d. Progressive abdominal distention followed by peritonitis
   e. All of the above

Case Study 1: Urinary Leak After Partial Nephrectomy

A 50-year-old female presented with gross painless hematuria in the absence of prior history of genitourinary malignancy or stones. Her prior medical history was unremarkable. She denied smoking. Her exam was unremarkable. Her glomerular filtration rate was normal.

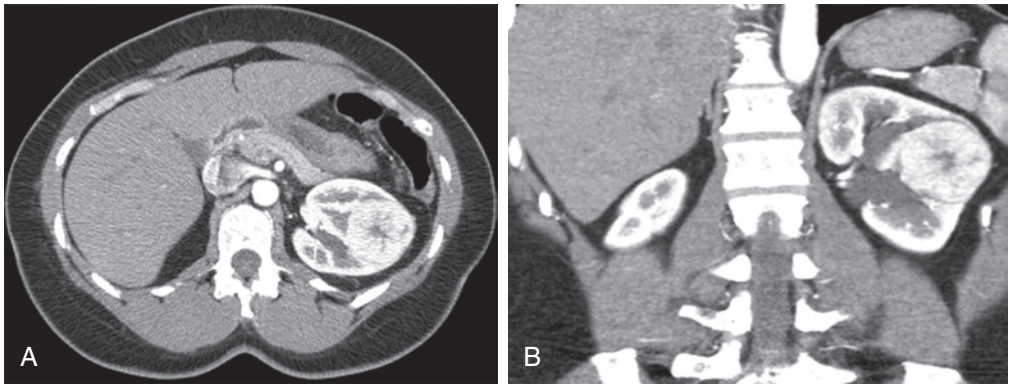
She underwent CT abdomen/pelvis with and without contrast as part of the workup with the imaging as follows (Case Fig. 13.1).

1. Which of the following is a risk factor for urinary leak in this patient?
   a. Endophytic tumor
   b. Nearness to collecting system
   c. Renal pelvic score >50%
   d. All of the above
   e. Option b and c

CT scan demonstrated a nephrometry score 11 tumor, clinical T1b. Options were discussed and the patient opted for an open left partial nephrectomy.

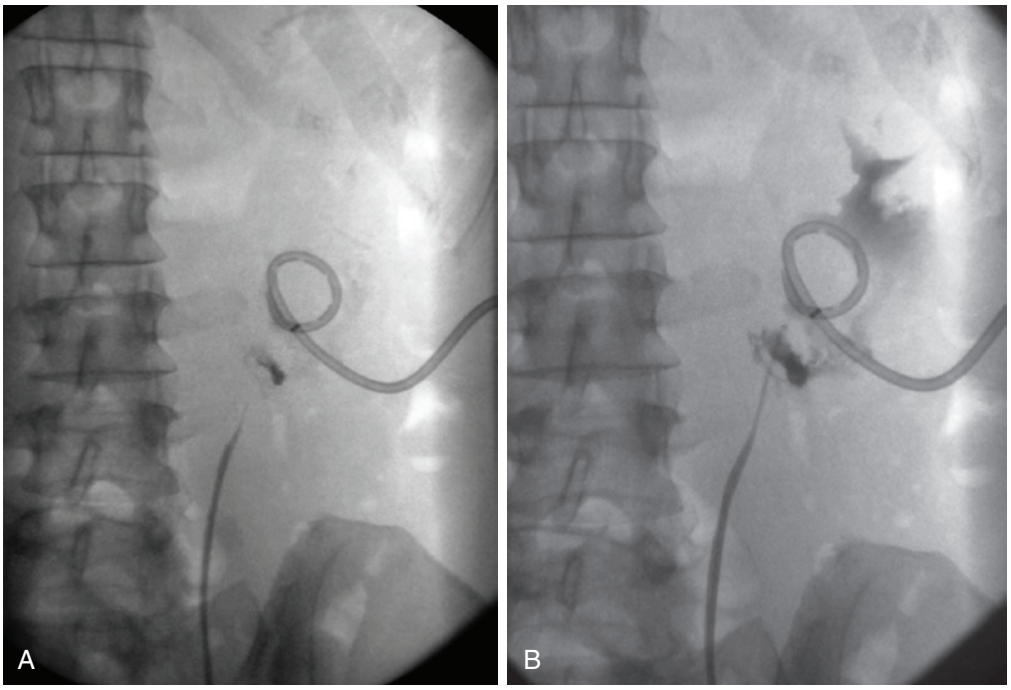
A flexible cystoscopy was performed while the patient was positioned supine after induction of anesthesia. A left open-ended ureteral access catheter was placed. The patient was then positioned into a lateral decubitus position and underwent an uncomplicated partial nephrectomy. A complex renal hilum was encountered with multiple renal vessels including an accessory upper pole artery. A bulldog clamp was placed across the isolated accessory renal artery and a Satinsky clamp was used for hilar control.

The renal mass was then resected. Collecting system entries were identified and over-sewn under loop magnification. Methylene blue was injected per ureteral stent to identify any other entries. The repair appeared watertight. The renorrhaphy was performed in a standard fashion. Total warm ischemia time was 47 minutes and 37 seconds. A JP drain was placed in the retroperitoneum.



The patient's postoperative course was uneventful. She was discharged home on POD 4 with modest JP outputs of approximately 100 mL/day. She was seen in clinic on POD 7. Her JP drain was producing <30 mL/day. A CT urogram with excretory phases indicated no urinary leakage, and her drain was removed.

Over the next 24 hours, the patient developed increasing abdominal pain, fevers, and malaise. She was admitted for further evaluation. Her WBC at admission was 33. Cultures were sent. A CT scan was performed that revealed an ipsilateral pleural effusion, a perinephric collection with air–fluid levels, and a urine leak. She subsequently underwent a left pleural drain as well as placement of left perinephric drain collection. Fluid chemical analysis revealed elevated creatinine to 65.5 mg/dL. Fluid culture grew *Serratia* sensitive to fluoroquinolone. Her fevers and WBC improved on antibiotics. Her drain output continued to be steady at approximately 150 mL/day over the next 2 weeks.



2. Which of the following is the next step in a patient with persistent urinary drainage after partial nephrectomy?
   a. Radical nephrectomy
   b. Nephrostomy tube
   c. Retrograde pyelogram/stent placement
   d. Continue to observe
   e. Open exploration with re-do renorrhaphy

Given her persistent JP output, the patient underwent left retrograde pyelogram (Case Fig. 13.2) noting leakage of contrast from the proximal ureter. Attempts at retrograde stenting were unsuccessful and resulted in increased JP output to approximately 400–600 mL/day. Given distal obstruction a nephrostomy tube was placed (Case Fig. 13.3). At least two failed antegrade and retrograde attempts were made endoscopically to place a stent across the leakage.

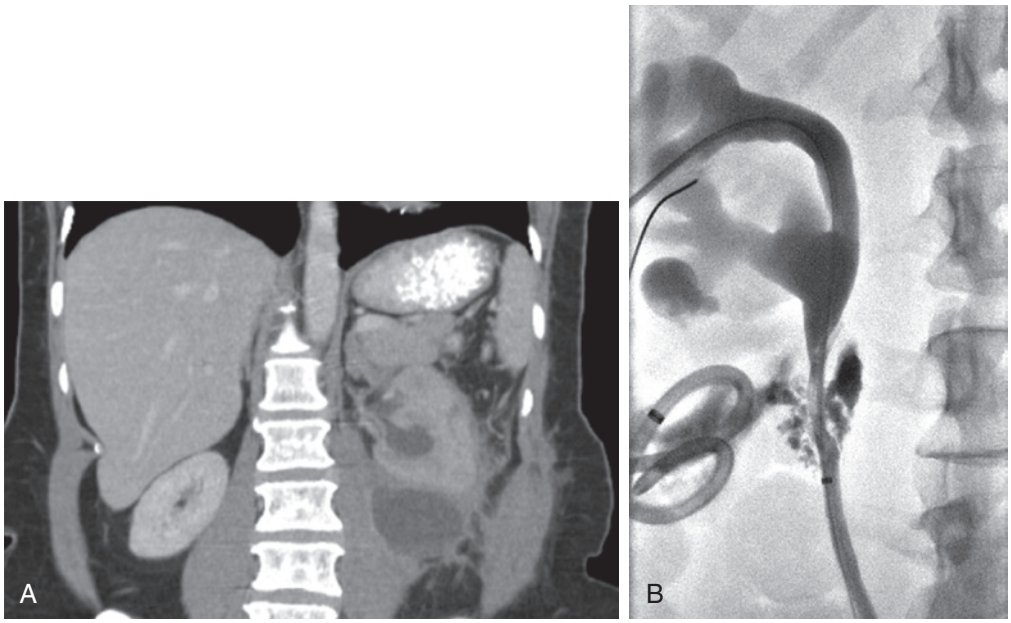
The patient was hospitalized twice in the interim with pyelonephritis and urinary sepsis.

Case Figure 13.1

Case Figure 13.2

Case Figure 13.3

3. In this patient who failed endoscopic attempts following partial nephrectomy, what options remain for management of a urinary leakage?
   a. Ureteroureterostomy (open reconstruction)
   b. Ileal interposition
   c. Completion nephrectomy
   d. Autotransplant
   e. All of the above



All of the above options were discussed with the patient. She elected to proceed with attempted reconstruction. Six months following her initial surgery, she was taken to the operating room for attempted robotic ureterolysis, ureteroureterostomy and omental flap. Despite a difficult dissection, uretero-ureterostomy was performed, leaving both a nephrostomy tube and ureteral stent in place in addition to a JP drain. She was discharged home on POD 4 with a JP drain, PCN tube to gravity, indwelling ureteral stent, and a Foley catheter to maximize drainage. Her drain output was minimal at about 10–30 mL/day. Her Foley catheter was removed POD 9 from reconstruction. On POD 16, her JP drain was removed, and PCN was left on gravity. On POD 23, antegrade nephrostogram was performed, which revealed no urinary leakage. Subsequently, PCN was capped for another week and was then removed on POD 30. The stent was left in place for complete healing.

One month later she presented with fevers, chills, and leukocytosis. Imaging noted a perinephric abscess. Percutaneous drainage revealed a fluid creatinine of 10.8. Cultures grew candida. Antegrade nephrostogram demonstrated a recurrent urinary leak at the site of anastomosis despite a well-positioned ureteral stent (Case Fig. 13.4). Delayed CT imaging showed delayed nephrostogram in the left kidney, suggesting reduced function.

Given her prolonged course, she elected radical nephrectomy rather than open repeat reconstruction and had an uneventful postoperative course.

Case Study 2: Urinary Leak After Radical Prostatectomy

A 66-year-old male presented with a PSA of 8.3. Biopsy noted Gleason 6 prostate cancer. His AUA symptom score was 14 with a QOL score of 2–3 despite alpha blockade. He

Case Figure 13.4

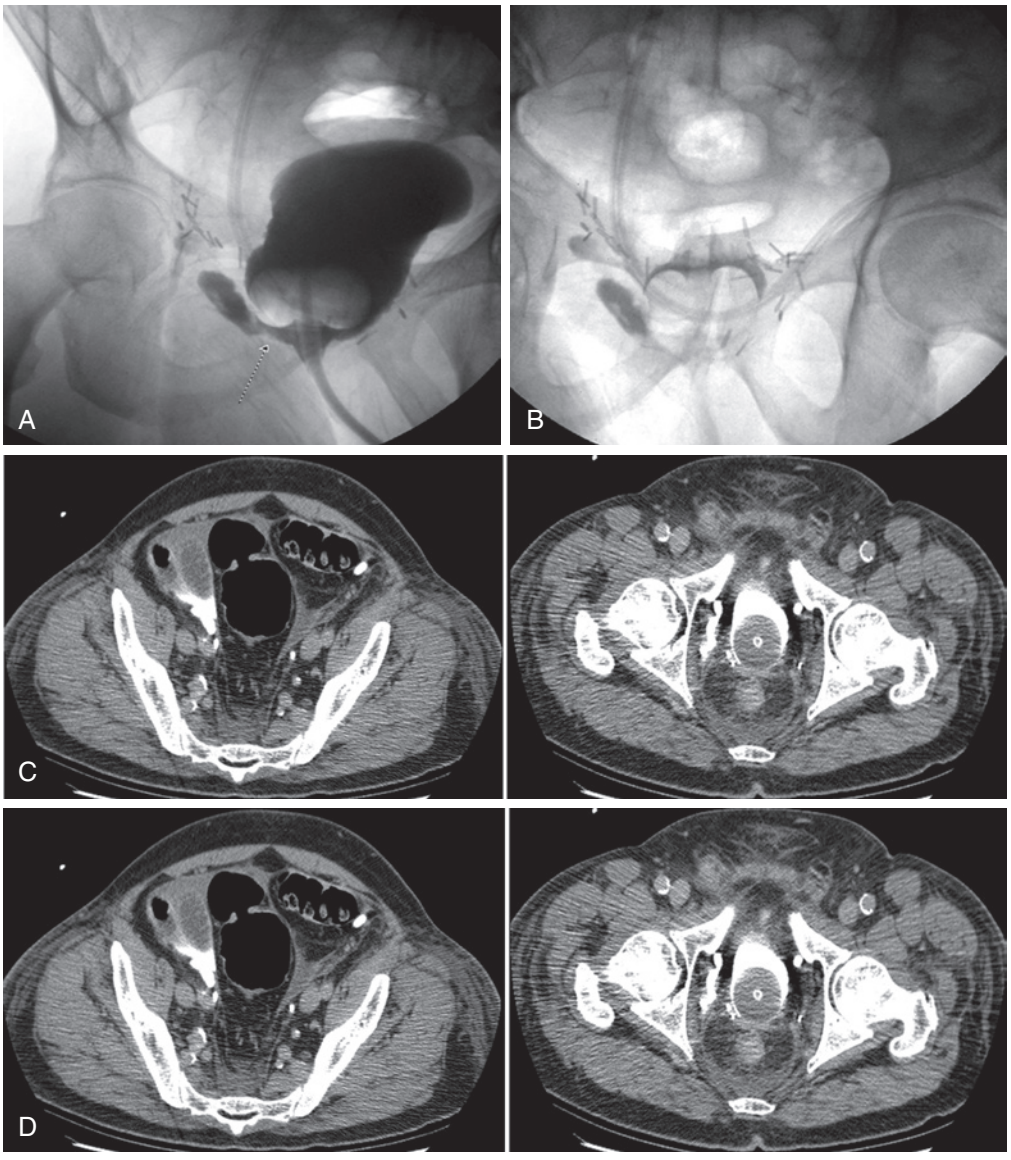
had baseline urinary dribbling, frequency, and occasional urge incontinence. His SHIM score was 17. On exam, he had an enlarged prostate measuring approximately 80 g.

He elected to undergo robotic radical prostatectomy. The procedure was the tenth procedure done independently by the surgeon. Intraoperatively, an enlarged trilobar prostate was encountered, which resulted in an abnormally large bladder neck complicating the urethrovesical anastomosis. The reconstruction was time consuming and technically difficult. However, an intraoperative flush test was deemed acceptably watertight. A Blake drain was left to suction at the end of the procedure.

1. Which of the following is not a risk factor for urinary leak after radical prostatectomy?
   a. Early learning curve
   b. Technically complicated anastomosis
   c. Imperfect intraoperative flush test
   d. Surgical approach (open vs robotic)
   e. Increased blood loss

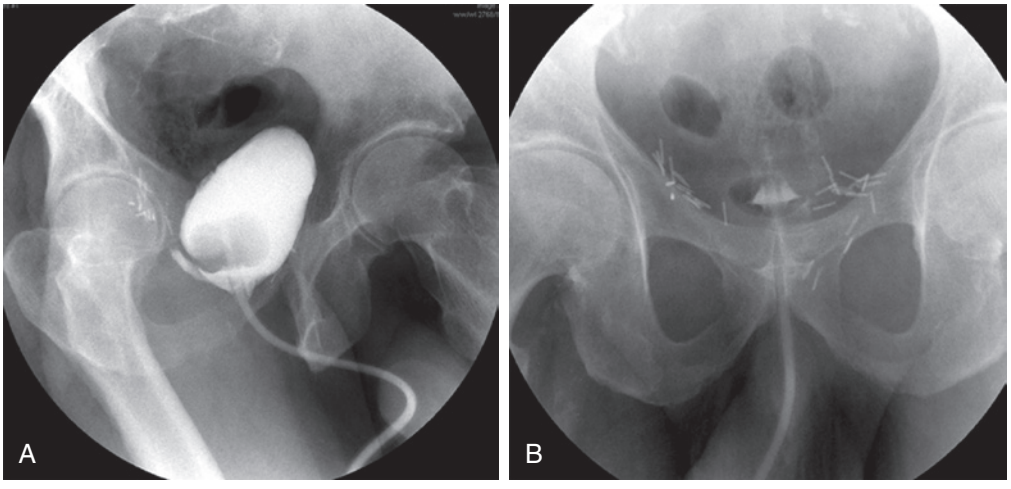
Postoperatively, drain output was approximately 200 mL/day. Additionally, he developed progressive abdominal distention and ileus and was started on total parenteral nutrition (TPN). By POD 7 he developed signs and symptoms of peritonitis with high fevers. Blood, urine and fluid cultures were all negative. His serum creatinine was noted to be elevated to 1.6 from a baseline of 0.8. He became hyponatremic with elevated BUN levels.

A drain creatinine was consistent with urine at 75.9 mg/dL. Cystogram indicated a urinary leak lateral to the right posterior bladder neck. A CT urogram done to rule out ureteral injury indicated intact drainage from the ureters to the bladder but a leak again posterior to the right bladder neck. Additionally, the urinary leak extended into the intraperitoneal cavity (Case Fig. 13.5).



2. Which of the following is not a characteristic of clinically significant anastomotic leak?
   a. Those that extend into intraperitoneal cavity
   b. Prolonged ileus
   c. Urinary sepsis
   d. Leakage that is drained completely by the pelvic drain
   e. Significant electrolyte abnormalities

As the leak was close to the right posterior bladder neck, the decision was made to place a right nephrostomy tube. His peritonitis improved. His ileus progressively resolved. The Blake drain output slowed, and he was discharged home on POD 17 without a drain but with right PCN and Foley catheter.



He was seen in clinic on POD 25 with a cystogram. Cystogram showed resolution of urinary leak, and the Foley catheter was removed (Case Fig. 13.6). His PCN was capped. On POD 33 he underwent a nephrostogram prior to removal of the PCN tube.

By his 6-month follow-up, he was not using any pads and denied any incontinence. He did not gain spontaneous recovery of sexual function.

3. Which of the following is true about urinary continence and risk of bladder neck contracture (BNC) after prostatectomy complicated by a urinary leak?
   a. Long-term urinary continence is compromised, but risk of BNC is unchanged
   b. Return to continence is delayed but usually complete, and risk of BNC may be elevated
   c. Long-term urinary continence is compromised, and risk of BNC is elevated
   d. Return to continence is delayed, and risk of BNC is elevated
   e. Return to continence is same and risk of BNC is minimal

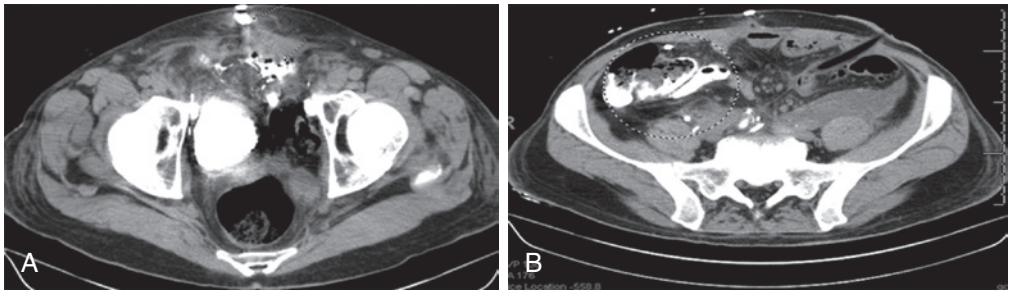
Case Figure 13.6

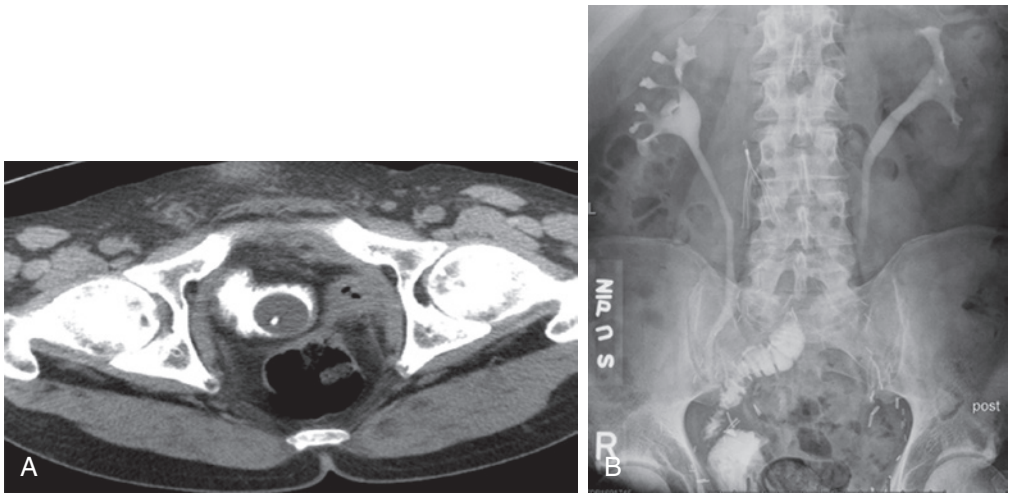
Case Study 3: Urinary Leak After Urinary Diversion

A 56-year-old male former smoker was diagnosed with muscle-invasive bladder cancer and underwent neoadjuvant chemotherapy. He was hoping to avoid subsequent cystectomy and despite several opinions elected to delay pelvic exenteration. He recurred locally in the bladder within the next 6 months and subsequently agreed to undergo cystectomy with creation of ileal neobladder. CT scan noted interval development of hydronephrosis on the right from tumor obstruction with a creatinine of 1.67. Preoperative serum albumin was 2.1 g/dL, suggesting preexisting malnutrition from disease.



He underwent radical cystoprostatectomy, bilateral pelvic lymphadenectomy, and creation of Studer neobladder with an EBL of 1800 mL requiring 2 units pRBC intraoperatively. A large omental flap was interposed between the neobladder and the small bowel anastomosis. An SPT and Foley catheter were left to drain the neobladder. He also had internal–external ureteral stents for full urinary diversion and a pelvic drain.

His postoperative course was complicated by prolonged ileus requiring TPN and subsequent deep vein thrombosis (DVT) and clinically symptomatic pulmonary embolism (PE) requiring anticoagulation and IVC filter placement on POD 15. His albumin levels declined to 1.2, suggesting worsening nutrition. He was maintained on TPN until he was tolerating regular diet by POD 20. He was ready to be discharged on POD 21, but on the day of discharge he had significant diarrhea and appeared to have profuse clear drainage from the wound. Irrigation of the Foley catheter would increase drainage per wound.



CT cystogram was done at this point, which indicated a neovesico-cutaneous fistula as well as a fistula between the small bowel anastomosis and neobladder (Case Fig. 13.7). General surgery consult was obtained for assistance in management of the entero-neovesical fistula. The overall impression was to conservatively manage him at this point until his nutrition status improved to the point where he could tolerate entero-neovesical fistula takedown and possible conversion of the neobladder to an ileal conduit.

He was restarted on TPN. Bilateral nephrostomy tubes were placed to completely divert the urine from the pouch. He became uroseptic twice and was treated on IV antibiotics for *Escherichia coli* and *Enterobacter* bacteremia. His leakage from the wound resolved, and the wound appeared to heal well. He became stable by POD 35 and was then advanced to a clear liquid diet with TPN, which he continued to tolerate. The majority of his urine output was from PCN and ureteral stents with small volumes from the Foley catheter. He was discharged home on POD 42 on TPN/clear liquids with Foley catheter, pelvic drain, bilateral PCN, ureteral stents, and aggressive wound care.

On POD 71 his pelvic drain was removed. Ureteral stentograms were done that showed no leakage, and the stents were removed. On POD 87 CT cystogram was repeated, which illustrated resolution of both neovesico-cutaneous and neovesico-enteral fistula (Case Fig. 13.8A). He was

Case Figure 13.7

Case Figure 13.8

then advanced to a full liquid diet. His TPN was weaned and he was advanced to regular diet. His nephrostomy tubes were capped for a week and were removed after nephrostogram illustrated urine draining into the bladder with no urinary leakage. A repeat cystogram was done on at 3 months postoperatively (Case Fig. 13.8B), which illustrated no urinary leakage or fistula and urine refluxing up both ureters. His Foley catheter was then removed and he began voiding spontaneously.

At 1-year follow-up, he has no spontaneous sexual recovery and remains with significant stress incontinence and is contemplating correction.

1. Which of the following is a risk factor for delayed urinary leak in this patient?
   a. Poor nutrition
   b. Omental flap
   c. Anticoagulation
   d. All of the above
   e. Option a and c

2. Urinary leakage is associated with all of the following except?
   a. Elevated BUN without necessarily an increase in creatinine
   b. Urinary drainage from wounds
   c. Prolonged length of hospitalization
   d. No effect on mortality
   e. Urinary Sepsis

3. Management of urinary leakage can:
   a. Be frustrating for the physician and the patient
   b. Require adequate communication of expectations
   c. Involve maximal drainage of the leak, which is often followed by delayed but spontaneous closure without requiring surgical re-exploration in the majority of patients
   d. All of the above
   e. Option a and b

Answers

1. **e.** Intraperitoneal urinary leak is often not contained and can present in delayed fashion with increasing abdominal distension, ascites, or progressive azotemia. Electrolyte abnormalities such as hyponatremia, hyperkalemia, elevated serum creatinine, increasing blood urea nitrogen, and metabolic acidosis are present. Urinary leak can be a nidus for infection and can lead to peritonitis.

CASE STUDY 1: URINARY LEAK AFTER PARTIAL NEPHRECTOMY

1. **d.** Risk factors for urinary leak after partial nephrectomy include endophytic tumor, intrarenal pelvis (Renal pelvic score > 50%), and nearness to the collecting system.
2. **c.** When a patient with partial nephrectomy presents with symptomatic urinary leak (increased JP drain output, UTI, pleural effusion, infected fluid collection), it is most appropriate to ensure a perinephric drain is patent and place a ureteral stent. The combination of ureteral stent with intraabdominal JP drain may result in resolution of the leak in the vast majority of patients.
3. **e.** In this patient where the leakage is from the ureteropelvic junction (likely from the Satinsky clamp placement across the entire hilum including proximal ureter) with failed endoscopic management, reconstructive procedures such as pyeloplasty, ureteroureterostomy, ileal interposition, completion nephrectomy or autotransplant should be considered.

CASE STUDY 2: URINARY LEAK AFTER RADICAL PROSTATECTOMY

1. **d.** Early learning curve, technically complicated anastomosis, imperfect intraoperative flush test and increased blood loss/hematoma are all risk factors for urinary leakage after radical prostatectomy. There has been no difference in leakage rate with open versus minimally invasive approach or by extraperitoneal versus intraperitoneal surgical approach.
2. **d.** Clinically significant anastomotic leaks after radical prostatectomy are those that extend into intraperitoneal cavity and show signs and symptoms of urinary leakage which may include ileus, electrolyte abnormalities, or urinary sepsis if they get infected. Leakage that is drained completely by the pelvic drain generally does not present with any clinical symptoms and may resolve with observation.
3. **b.** Prolonged and extensive urinary leakage, resulting from an anastomotic gap, may cause scarring leading to healing by secondary intention. Thus, risk of bladder neck contracture is elevated. Return to continence is usually delayed but overall continence rates are similar.

CASE STUDY 3: URINARY LEAK AFTER URINARY DIVERSION

1. **a.** Poor nutrition and vascular compromise/ischemia are risk factors for delayed urinary leakage. Omental flap or need for anticoagulation should not effect the urinary leakage.
2. **d.** Studies have shown that urinary leakage can have adverse effect on mortality. This may be due to multiorgan failure from concomitant sepsis or may also be due to rapid cancer progression theorized to be a result of pro-inflammatory cytokines and suppressed antitumor inflammatory response.
3. **d.** Management of a urinary leak can be anxiety provoking and frustrating for both the physician and the patient. It requires adequate communication of expectations. Further urinary diversion with additional drains or nephrostomy tubes may be needed. However, maximal drainage of the leak generally is followed by delayed, but spontaneous, closure without requiring surgical re-exploration.

Other Considerations
Summary
Chapter 14 Questions and Answers

KEY POINTS

1. An understanding of the anatomy of the ureter, including its course and blood supply, is necessary for successful management of ureteral injury.
2. Timely and accurate diagnosis of the ureteral injury, including the etiology and extent of injury, is critical for minimizing sequelae and facilitating repair.
3. The key principles of ureteral reconstruction include isolation of viable tissue, tension-free anastomosis, and intraluminal stent drainage in the short-term postoperatively.

Introduction

When injury to the ureter occurs, the passage of urine from the kidney to the bladder is disrupted. Timely recognition is important to avoid renal deterioration and morbidity. Management of ureteral injury is often elective, but may require emergent intervention. Therefore it is important that the urologic surgeon is prepared to manage injuries that may occur along the entire length of the ureter. The primary aims of management include restoring quality of life, preserving renal function, and minimizing complications including urinoma, fistula, infection, and stricture.

Anatomy

Between the renal pelvis and the bladder, the course of the ureter travels through the retroperitoneum posterior to the colonic mesentery. The ureter can be divided into the upper, middle, and lower segments. From proximally to distally, the 22- to 30-cm ureter travels anterior to the psoas muscle, under the gonadal vessels as they cross from medial to lateral about 2–3 cm below the inferior margin of the kidney, over the iliac vessels at the bifurcation of the common iliac artery, and into the pelvis, where it enters the bladder trigone. Two good locations to identify the ureter are over the iliac bifurcation and lateral to the gonadal vessels at the level of the lower pole of the kidney. The blood supply of the ureter is segmental and enters the proximal ureter medially and pelvic ureter laterally (Fig. 14.1). The vascular plexus of the ureter is located in the adventitia. Branches that supply the ureter are difficult to visualize and arise from the renal, gonadal, lumbar, aorta, and iliac arteries. The layers of the ureter include the urothelium, lamina propria, smooth muscle (longitudinal and circular), and surrounding adventitia.

Etiologies of Ureteral Injury

Ureteral injuries can be classified by their etiologies, which most commonly include iatrogenic causes[1] or blunt or penetrating trauma.[2]

Iatrogenic causes often include endoscopic trauma during the management of stone disease.[1] Urinary stone impaction may predispose to additional injury to the ureter,[3] leading to submucosal, extraluminal, or a Steinstrasse pattern that may eventually lead to the development of a ureteral stricture. Ureteroscopic misadventure may lead to perforation, avulsion, or mucosal tears. Forgotten or neglected encrusted ureteral stents may also lead to ureter stricture. A history of retroperitoneal or pelvic radiation for malignancy may predispose to ureteral stricture. Complications related to gynecologic surgery including hysterectomy may lead to ureteral ligation or injury that may be initially recognized or at a delayed presentation (Fig. 14.2).[4] Abdominoperineal resection, hemicolectomy, and other colorectal procedures may predispose to distal ureteral injuries. Neurosurgical and orthopedic procedures of the spine may also

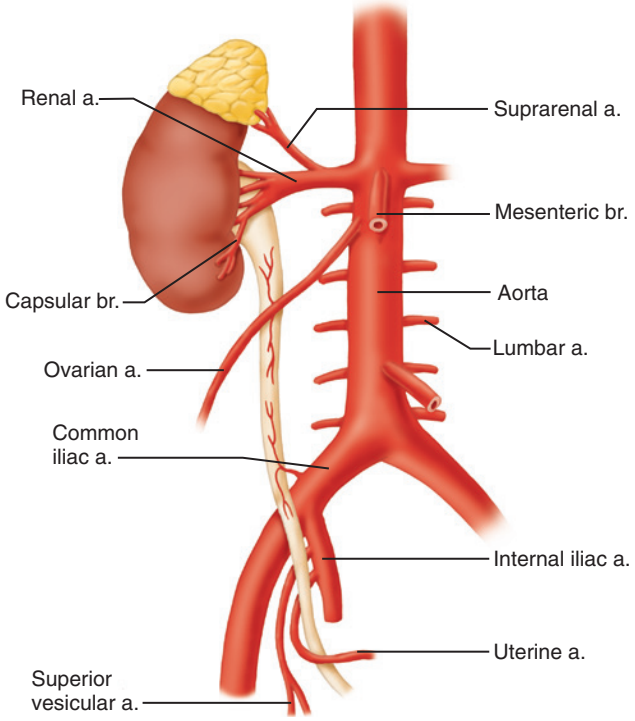

Figure 14.1 Blood supply to the ureter. Segmental blood supply to the ureter enters the proximal ureter medially and the pelvic ureter laterally. (With permission from Smith RB, Skinner DG (eds.). Complications of Urologic Disorders. Philadelphia: WB Saunders; 1976:131.)

In: McAninch JW, ed. Traumatic and Reconstructive Urology. Philadelphia: WB Saunders; 1996:213.)

injure the ureter. Vascular grafts and repairs may injure the mid-ureter (Fig. 14.3).

Furthermore, several systemic illnesses may necessitate ureteral reconstruction. These include infection (tuberculosis, schistosomiasis), primary ureteral malignancy, ureteral fibroepithelial polyps (Fig. 14.4), and retroperitoneal or pelvic cancer with extrinsic invasion. Other benign diseases that affect the ureter include retroperitoneal fibrosis, inflammatory bowel disease, aortic and iliac aneurysms, ovarian vein entrapment, and pelvic lipomatosis.

External trauma to the ureter can be divided into blunt and penetrating trauma.[5] It is critical to note that ureteral injuries in these settings are frequently associated with concomitant injuries in other organ systems, so these also need to be explored.[6] For penetrating trauma (gunshot wounds), it is important to know the caliber of the weapon, as higher penetrating velocities have greater collateral damage. During emergent exploration, the ureter can appear normal, but over time tissue necrosis can result. Penetrating non-gunshot wounds such as knife wounds rarely have delayed tissue necrosis. It is important to visualize all sides of the potentially injured ureter. Blunt injuries may involve rapid deceleration, and the ureteropelvic junction is at risk for avulsion most commonly seen in children. Ureteral injuries associated with blunt and penetrating trauma are further reviewed in Chapter 15.

Diagnosis

The diagnosis of ureteral injury includes not only identifying the nature and extent of injury, but also assessment of the kidneys and bladder as a priority. It is important to know the overall renal function and account for the presence and condition of the contralateral kidney. The presence of bladder outlet obstruction, a small capacity bladder, and/or dysfunctional voiding may affect the outcome of the repair.

Intraoperative identification and direct inspection of the ureter allow for the characterization of the ureteral injury. Indigo carmine or methylene blue can be directly injected into the ureter or through a nephrostomy tube to determine if a leak is present. Retrograde pyelography can be performed to determine the area of extravasation, obstruction, or narrowing that would suggest a stricture. Intravenous pyelography can be performed in a trauma setting to evaluate the contralateral kidney. Tricks to identify the ureter intraoperatively include identification of the rhythmic peristalsis of the ureter with or without squeezing the ureter with forceps, movement of a previously placed yellow angiographic exchange catheter, or lighted ureteral catheters. The best method for identifying the ureter is to rely on anatomic knowledge. Two reliable areas are located anterior to the iliac bifurcation and lateral to the gonadal vessels at the level of the lower pole of the kidney.

Figure 14.3 Bilateral midureteral obstruction from vascular grafts. Intravenous pyelogram 90 minutes after contrast injection shows severe hydronureternephrosis to the level of the midureter.

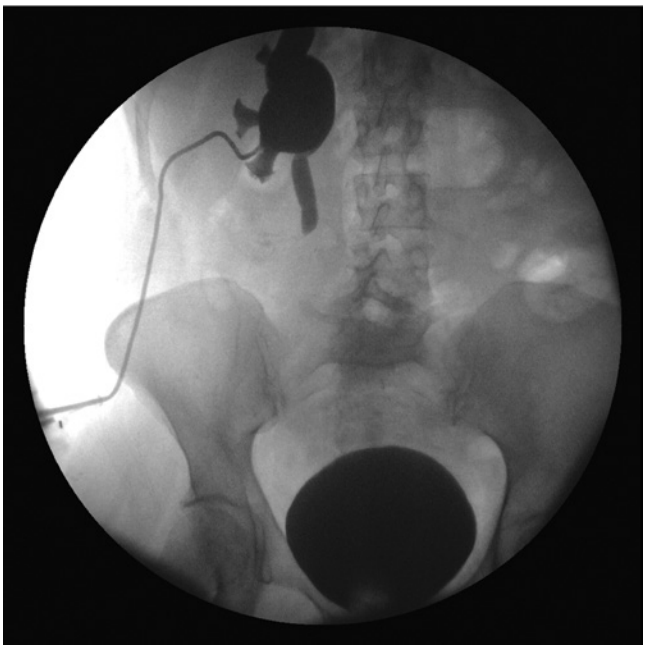

Figure 14.5 Antegrade nephroureterogram of a proximal ureteral injury. The flow of contrast abruptly stops at the level of the proximal ureter. A cystogram was also performed to determine bladder capacity.

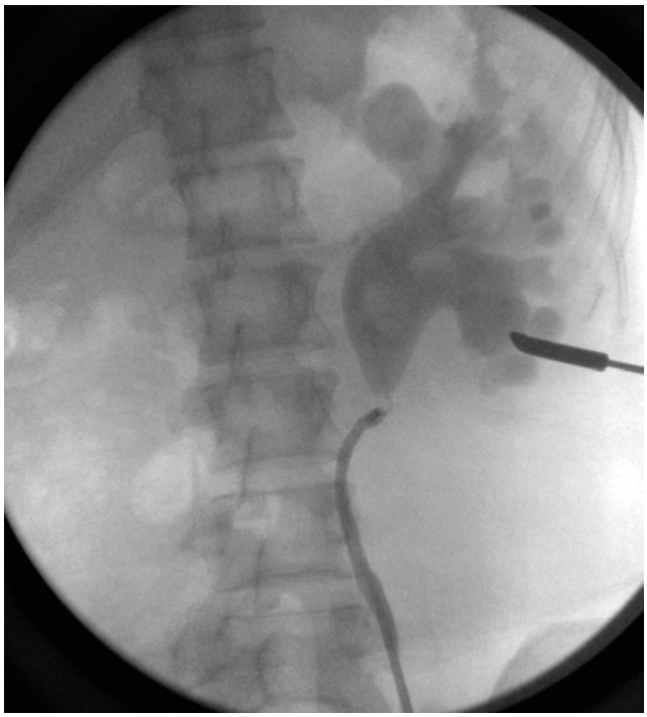

Figure 14.4 Fibroepithelial polyps causing obstruction at the ureteropelvic junction. Retrograde pyelography was performed showing the filling defect at the ureteropelvic junction. Visual confirmation of a fibroepithelial polyp was obtained with flexible ureteroscopy.

Most often, urologic imaging is best performed by the treating urologist, which allows for the assessment of the location and length of the injury. Retrograde imaging can delineate the status of distal ureteral pathology and evaluate the contralateral ureter. If a nephrostomy tube is present to protect renal function, antegrade imaging can be performed to delineate the extent of the proximal disease (Fig. 14.5). During cystoscopy, one can quantify capacity and compliance of the bladder and infer evidence of bladder outlet obstruction.

Anatomic imaging with computer tomography (CT) with delayed contrast imaging can be used to evaluate penetrating trauma with hematuria or any suspicion of genitourinary injury.[7] If nonenhanced contrast CT is performed, data are limited to the renal parenchymal thickness, status of the retroperitoneum and pelvis, and adjacent structures. MRI has the benefit of no ionizing radiation delivered and detection of hydronephrosis; however, it is a poor modality for stone detection and is limited in cases of low GFR (<40 mL/min) to administer gadolinium due to the risk of nephrogenic systemic fibrosis.[8] Delayed contrast imaging can provide information regarding the level of ureteral injury.

The length and location of the stricture is an initial marker for the type of repair feasible. Strictures >2 cm in length are unlikely to be resolved with endoscopic techniques. For segments ~2 cm, a ureteroureterostomy can be considered, with a centimeter on either side of the lesion needed to provide healthy tissue. For distal strictures or strictures of 4–5 cm, a ureteroneocystotomy can be performed. For 6- to 10-cm defects in the mid- to distal ureter, a psoas hitch can be considered. For 12- to 15-cm mid- to distal ureteral defects, a Boari bladder tube flap +/- combination with a psoas hitch can be considered. For repairs >15 cm or proximal defects, bowel interposition or autotransplant can be performed. Renal mobilization has been described to gain additional ureteral length; however, in our experience, mobilization of the kidney does not gain much length at the level of the proximal ureter.

Additional factors to consider for the affected kidney are the parenchymal thickness and the presence of incidental, asymptomatic hydronephrosis or symptomatic

hydronephrosis. It is important to have an understanding of the function of the contralateral kidney, presence of systemic diseases, and related infection or pyelonephritis if present, and to be able to rule out malignancy as a source of the obstruction.

Timing of Repair

A critical decision for surgeons is determining the optimal timing of repair relative to the timing of the injury. This decision is heavily influenced by how quickly the ureteral injury is recognized. In cases of delayed recognition, often local inflammation, urinary extravasation, intraabdominal adhesion of bowel distention, and/or the presence of infection may serve as obstacles to successful immediate repair. These factors contribute to failed repair owing to the condition and mobility of the tissues, and often delayed repair is warranted.

In the setting of an intraoperatively recognized ureteral injury, immediate repair is generally warranted in the absence of hemodynamic instability of medical compromise of the patient. In cases of ureteral laceration, debridement of devitalized tissue, followed by primary repair or selection of an appropriate reconstructive procedure is usually carried out. In cases of ureteral ligation, primary reimplantation, with or without ureteral interposition, is indicated. If the patient is unstable, then a temporizing maneuver to achieve proximal urinary drainage, with a plan to return at a delayed interval for definitive repair, is appropriate. In such cases, proximal drainage can be achieved by stent placement, or nephrostomy, depending upon the severity of the injury, and the patency of the distal ureter. In cases of ureteral transection, surgeons have often considered ureteral ligation with proximal nephrostomy drainage as a temporizing maneuver. It should be noted that devitalized ureters often break down leading to ureteral leakage or fistula, despite intraoperative ligation. Drainage of the ureteral injury site to ensure control of any delayed extravasation is wise.

When ureteral injury is not identified intraoperatively, but becomes evident 48–72 hours postoperatively, immediate repair can be considered, depending upon the mechanism of injury, severity of extravasation, and the medical condition and emotional state of the patient. Many patients are not mentally prepared for immediate return to the operating room or may be having difficulty with recovery. In these cases, temporizing maneuvers to relieve obstruction, drain extravasated urine, and achieve proximal diversion are very reasonable. In the case of a patient who is motivated for rapid resolution of the problem, has minimal to no urinoma collection, and is medically fit, early repair is an appropriate consideration. Beyond 72 hours, edema and local inflammatory reaction leading to friability of the tissue may lead to a lower likelihood of successful repair. In these cases, or in cases of more delayed recognition of the injury, immediate repair is not wise. Proximal drainage and control of any urinary fistula are warranted. Surgical repair may be delayed for 6–12 weeks to allow the injured region to scar in place and local inflammation to resolve completely. At the time of delayed repair, placement of an antegrade catheter to the point of the injury may aid in intraoperative identification of the injury.

Preoperative Management

Before repair is attempted, it is important to carefully document the location, length, and nature of the injury. It is important to define expectations and anticipate potential complications, and ask the questions, is the ureteral reconstruction likely to succeed or should a nephrectomy be performed? Can the reconstruction be performed in situ or does a backtable repair with autotransplant need to be considered to optimize success?

A ureteral injury worth repairing is dependent on the function of the ipsilateral and contralateral kidney and the age and overall health of the patient. The patient's cardiovascular status, anesthetic risk, and life expectancy should be considered. As a general rule, if the kidney can provide ~20% of the overall renal function, then it is worth saving. In other words, would the contralateral kidney support life if the kidney in question were removed? Relieving ureteral obstruction will rarely increase ipsilateral renal function; however, it will prevent further deterioration. Isotopic nuclear renography can provide information on renal split function if the kidney parenchyma appears marginal, and also the isotopic retention and excretory slope may indicate a patulous collecting system or presence of obstruction.

In the trauma setting, the primary goal is first achieving hemodynamic stability followed by identification of injuries.[7] There may be situations where a ureteral injury cannot be initially repaired due to hemodynamic instability or the poor or uncertain condition of the ureteral tissue. It may be necessary to ligate the ureter immediately proximal to the site of injury, place a nephrostomy tube, and return in a delayed setting for repair.

The timing of the repair should allow for optimization of nutrition and other systemic diseases, including diabetes mellitus, hypertension, and anticoagulation status. Drainage of the kidney can be temporized with a nephrostomy tube or a ureteral stent if continuity can be established. If definitive ureteral repair is planned but a ureteral stent is indwelling, the ease of the repair will be dramatically improved if the stent is removed at a minimum of 3–4 days prior to the procedure to allow for resolution of tissue edema. A sterile urine culture should be documented prior to reconstruction.

If the morbidity of reconstruction or nephrectomy outweighs the chance of success, permanent nephrostomy tube drainage or a chronic double J stent can be considered.[9] A downside of this approach is the discomfort related to these tubes and the need for frequent ureteral stent or nephrostomy tube changes to avoid encrustation. A metal Resonance stent[10] or tandem ureteral stents[11] can be considered as alternative options.

Strategies for the Management of Ureteral Injuries

Beyond an understanding of the anatomy, location, length, and type of ureteral injury, what is most important to approaching the management of ureteral injuries is an understanding of the nuances and limitations of each technique (Fig. 14.6). Here, we present technique-related tips

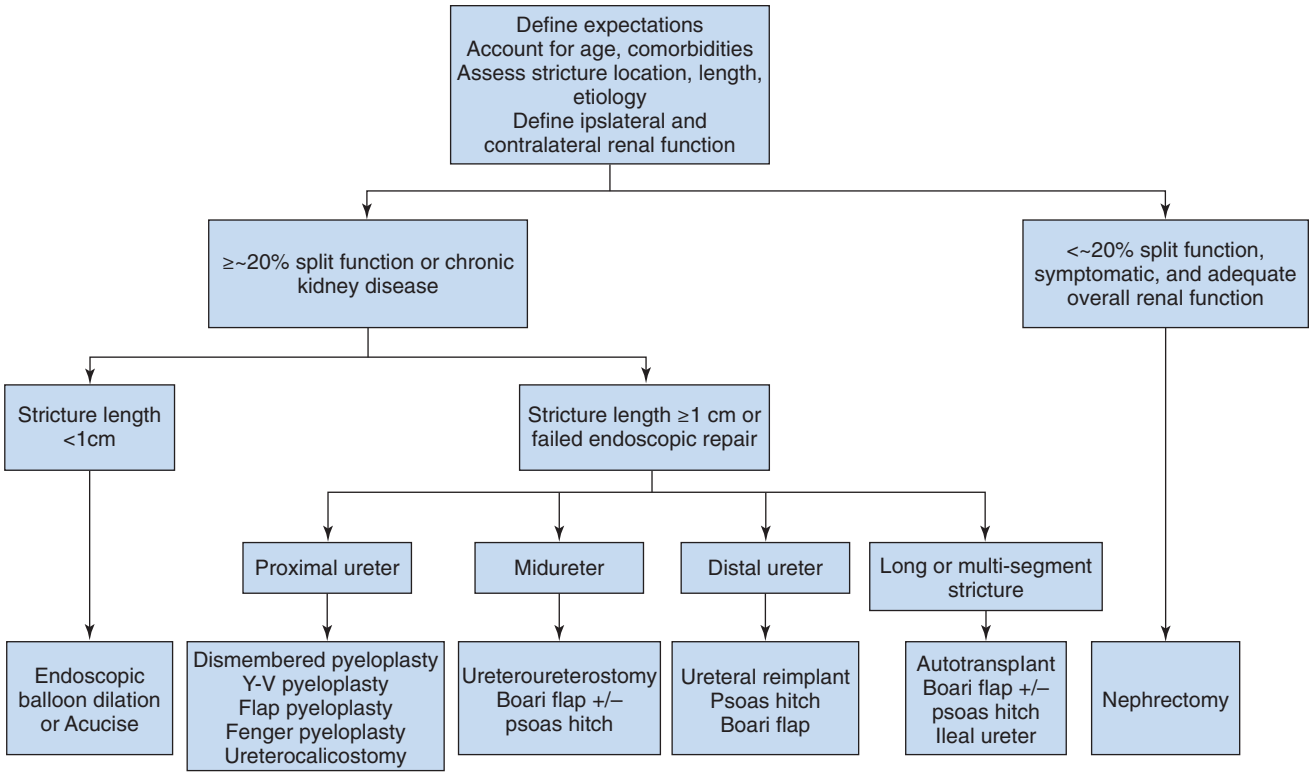

Figure 14.6 Workflow of ureteral injury management. The management strategy should incorporate the patient's expectations; age and comorbidities; stricture location and length and etiology; and overall and split renal function.

and tricks in the management of ureteral injury based on our experience. We separate the endoscopic approaches from the reconstructive techniques based on ureteral location. A complete guide to how to perform specific techniques or procedures can be found in several excellent atlases and references (*Hinman's Atlas of Urologic Surgery,*[12] *Glenn's Urologic Surgery,*[13] *Campbell's Urology*[14])[15] and will not be repeated here. Furthermore, whether the repair is performed using open, laparoscopic, or robotic-assisted approaches is less important than the approach with which the surgeon is most facile.[16]

The key principles of ureteral reconstruction include isolation of viable and healthy ureteral tissue, tension-free anastomosis, and intraluminal ureteral drainage with a ureteral stent for approximately 6 weeks. We generally perform refluxing repairs on all reconstructive cases because the goal is to minimize the risk of a future stricture, and usually there is a paucity of tissue to mobilize. We typically place a drain near the ureteral repair in the short term and a Foley catheter to prevent reflux and an overdistended bladder to facilitate drainage of the upper tracts.

ENDOSCOPIC REPAIR

The primary indication for endoscopic repair is for a short segment ureteral stricture. Endoscopic approaches can be divided into stricture incision or dilation.[17] The major advantage of these techniques over other reconstructive techniques is their minimal morbidity. Classically the ideal patient has a short, focal stricture ≤1 cm in length. For dense, longer strictures >1 cm in length, the rate of failure is high.

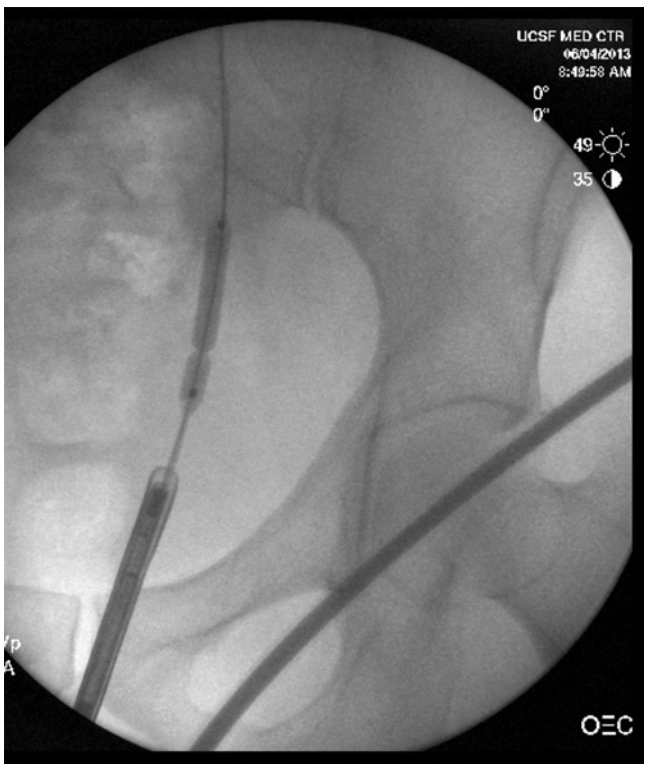

Figure 14.7 Balloon dilation of distal ureteral stricture. Note that the "waist" of the balloon indicates the location and caliber of the stricture. The goal of this technique is to have the "waist" disappear with sufficient pressure.

Balloon dilation of the stricture is relatively straightforward,[18] but several key points should be emphasized (Fig. 14.7). Retrograde pyelography should be obtained to fully identify the stricture, and the C-arm fluoroscopy unit should not be moved to ensure one can identify the stricture in relation to fixed boney landmarks. It is essential to pass the guidewire beyond the stricture. Initially a hydrophilic guidewire (straight or coude tipped – with or without a locking torque device) can help successfully pass the guidewire. It should be exchanged over an angiographic exchange catheter to place a nonhydrophilic guidewire to limit unintended dislodgement. In addition, ensure that that balloon profile is as tight as possible prior to back-loading it onto the wire so that it will most easily traverse the stricture. Inflate the balloon with contrast under fluoroscopy to ensure the balloon straddles the stricture.

Endoscopic stricture incision can be performed with a holmium laser[19,20] or the Acucise device[21,22] for endopyelotomy or endoureterotomy. The direction of the cut is critical to avoid injury to surrounding structures. If the stricture is proximal near the ureteropelvic junction, aim lateral. If the stricture is located near the iliac vessels, aim anterior. The holmium laser allows for more precision, as this is performed under direct vision. The laser should be passed beyond the stricture and cut as it is withdrawn. Laser settings should use a high frequency with low-power energy settings. The goal is to visualize the stricture "pop" open to allow visualization of fat, representing a transmural cut. The Acucise device can be deployed similarly, and, again, it is important to ensure that the balloon straddles the stricture. We typically initially fill the balloon with 1.0 mL and visualize the stricture under fluoroscopy and then cut for 5 seconds as one fills the balloon to a total of 2.2 mL. We recommend a 75-watt pure cut setting. If there is a concern whether the cut has occurred, after device removal there should be a characteristic cautery smell along the cutting wire. If the device needs to be reused, be aware that the profile of the balloon may be too large to successfully pass through the strictured segment. A nice trick is to use the writing on the Acucise port to guide the direction of the cut – if a lateral cut is desired, the writing should also be lateral. Finally, in our experience, we find that the cut is less effective if there is a high contrast concentration present. We therefore use dilute contrast during the initial retrograde pyelography. Finally, the 7/10Fr Acucise endopyelotomy stent can be placed for 4–6 weeks. It has no sideholes to prevent tissue ingrowth and narrowing of the lumen. Alternatively one can use a traditional 8–8.5Fr double J stent or a Schueller ureterotomy stent set manufactured by Bard (Covington, GA). This ureteral stent has an adjustable sleeve with a wider caliber that can be placed at the location of the stricture. It is widely used in Europe and is used less frequently in the United States.

As an aside, ureteral avulsion has been reported during ureteroscopy,[23,24] especially early in the adoption of the technique. In these cases, when this injury has been identified, it is best to stop the case, place a nephrostomy tube, and decide to come back at a later time to address the ureter. This is the time to regroup, talk to the patient and his or her family, and avoid a rash procedure (usually late at night). After the patient has been temporized with a nephrostomy tube, it is important to inform the patient what to expect from the different reconstruction options, and after a decision has been made on which repair to perform, it is important to assemble the right team to perform a definitive repair.

PROXIMAL URETERAL REPAIR

Ureteral reconstruction in the proximal ureter or ureteropelvic junction can often be challenging. The key to a successful outcome is achieving a tension-free anastomosis.[15] It has been described that renal mobilization can provide additional mobility of the proximal ureteral segment; however, in our experience, mobilization of the kidney does not gain much length. Additional factors that may complicate repair include surrounding hilar vessels, severe scarring, and a small intrarenal pelvis. Endoscopic endopyelotomy has been previously discussed, and it is best performed for short segment focal stricture ≤0.5 cm in length. Longer strictures can be treated; however, increasing stricture lengths have a higher failure rate in our experience.

A number of reconstructive techniques have been described for the ureteropelvic junction and proximal ureter, but one needs to be selective about which approach is best warranted dependent upon anatomy. These include the Foley Y-V pyeloplasty,[25] Anderson-Hynes dismembered pyeloplasty (Fig. 14.8),[26,27] Fenger pyeloplasty employing the Heineke–Mikulicz technique,[28] and use of different flaps created from a dilated, redundant renal pelvis. If a crossing vessel is present, a Hellstrom procedure can be considered, where the vessel is mobilized and displaced away (typically cephalad) from the area of obstruction using a hammock of surrounding fascia or fat.[29] For the dismembered techniques, it is critical that a wide spatulation is performed on both ends of the anastomosis to avoid stricture recurrence. We place interrupted, absorbable sutures to allow coaptation of tissue. In general, it is easiest to close the back wall of the anastomosis first, followed by ureteral stent placement, and then completion of the anterior wall.

Alternatively, if the renal pelvis is insufficient to perform a repair, one can perform a ureterocalicostomy.[30–32] Such decisions are typically anticipated with preoperative imaging. The prerequisite for this procedure is minimal parenchyma overlying the lower pole. The key to this procedure is to make a wide anastamosis to avoid stricture recurrence. Over the long term, however, a fundamental problem with these repairs is that they often do not drain well, as there is the propensity of urine from the lower pole to propel toward the renal pelvis due to physiologic peristalsis, rather than through a wide-open anastomosis. This may result in subsequent stones, infections, and pain. These are often very complicated cases with the repairs being the option of last resort.

Ureteral stent placement during these cases can sometimes be tricky, especially during laparoscopic or robotic-assisted cases. We recommend having a 3-way Foley catheter in place at the start of the case. The bladder can be filled to ~200 mL (with or without methylene blue), so that when a wire is placed antegrade, it will easily coil in the bladder. This will ensure a reliable distal stent curl. The methylene blue may be seen refluxing after appropriate placement into the bladder. A pre-soaked wire in mineral oil will facilitate the passage of the stent. One can use ultrasound or a flexible cystoscope to ensure accurate placement.

Frequently these cases have concomitant stone disease. It is better to address these at the time of reconstruction

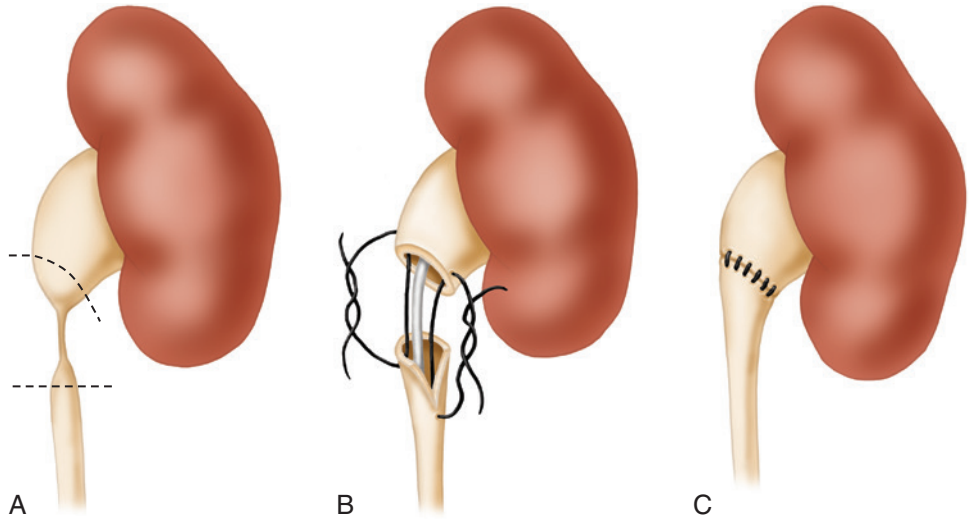

Figure 14.8 Dismembered pyeloplasty. A, Dotted lines denote area of diseased ureter and planned incision. B, After excision of the diseased segment, the proximal ureter is spatulated. We find it easiest to place full-thickness, interrupted absorbable sutures along the back wall first, followed by antegrade ureteral stent placement, then completion of the anastomosis of the anterior wall. C, After completion of the anastomosis, we prefer to leave the stent in place for 6 weeks and the Foley catheter for 1 week. (With permission from Wein AJ, Kavoussi LR, Campbell MF. Campbell-Walsh Urology, 10th ed. Philadelphia, PA: Elsevier Saunders, 2012: Figure 41.16.)

rather than later. The extraction of stones can be performed using a flexible cystoscope or ureteroscope through a laparoscopic port.[33,34] Often these cases can be frustrating due to the additional equipment required and the irrigation fluid flowing into the operative field.

MIDURETERAL REPAIR

Midureteral repairs are challenging because they are located near the iliac vessels and it is difficult to gain mobility of the ureter proximally or distally. These are often the most difficult reconstructive cases to perform. For short segment strictures of 2 cm or less a ureteroureterostomy can be performed (Fig. 14.9).[35–37] After transection of the ureter is performed at the level of the stricture, we perform a wide spatulation and place interrupted, absorbable sutures to allow tissue coaptation. It is easiest to close the back wall of the anastomosis first, followed by ureteral stent placement, and then completion of the anterior wall. If omentum is available, this can add additional backing to the repair.

Additionally, other approaches can be considered, but caution should be exercised as to the limitations of each technique. For right-sided repairs, it is tempting to use the appendix or the fallopian tube because of a good native blood supply. However, in our experience these all uniformly fail in the long term. On the left side the ureter can be anastomosed directly into the sigmoid or descending colon. There is a known neoplastic potential in these cases;[38] however, these are typically desperate situations when they are performed. In addition, buccal graft ureteroplasty recently has been described, although with limited follow-up.[39–42] Different approaches have been described, including using the ureteral adventitia as a backing or using perirenal or omental fat behind an augmented graft. Additional follow-up is needed to determine the durability of such repairs.

Often creativity can provide a successful outcome for these especially difficult repairs. If there is a nonfunctioning kidney on the contralateral side, a nephrectomy can be performed on that kidney, and end-to-end ureteroureterostomy can be performed.[43,44] The contralateral ureter can be mobilized and anastamosed to the proximal ureter on the ipsilateral side. The kidney would then drain to the contralateral trigone. In these rare cases, it is critical to know the overall renal function and relative function of each kidney. If there are bilateral strictures, we have performed a "reverse 7" procedure using a segment of small bowel. Maintaining an isoperistalic orientation, the proximal end of the bowel is delivered through a window in the mesentery. The proximal end is anastamosed to the ureter or renal pelvis on each side (typically required through a mesenteric window), and then the distal end is connected to the dome of the bladder. As in other cases where bowel segments are placed in the urinary tract, there should be adequate renal function (serum creatinine >2 mg/dL) and absence of inflammatory bowel disease or radiation enteritis. Postoperative issues include the risk of urinary tract stones, infection, and electrolyte imbalance.

Finally, a psoas hitch (Fig. 14.10) combined with a Boari flap pyelovesicostomy is an option for high midureteral strictures or longer segment strictures.[45,46] In these cases both separate or combined, it is critical to ensure an adequate starting bladder capacity of at least 300 mL, as these procedures will invariably diminish the size of the bladder. If there is a small capacity bladder, then another reconstructive approach should be considered. For both procedures, a key step is mobilization of the contralateral bladder from the peritoneal attachments. We typically do not divide the contralateral pedicle, as this is often unnecessary.

With the psoas hitch procedure alone, it is usually possible to elevate the bladder to a level above the iliac vessels (Fig. 14.10).[47,48] Prior to creating the oblique anterior cystotomy, we distend the bladder with irrigant to get a sense of how much length the psoas hitch alone will provide. When placing the nonabsorbable sutures into the psoas muscle, it is important that the direction of the sutures is longitudinal, not transverse, to avoid entrapment of the genitofemoral or femoral nerves.

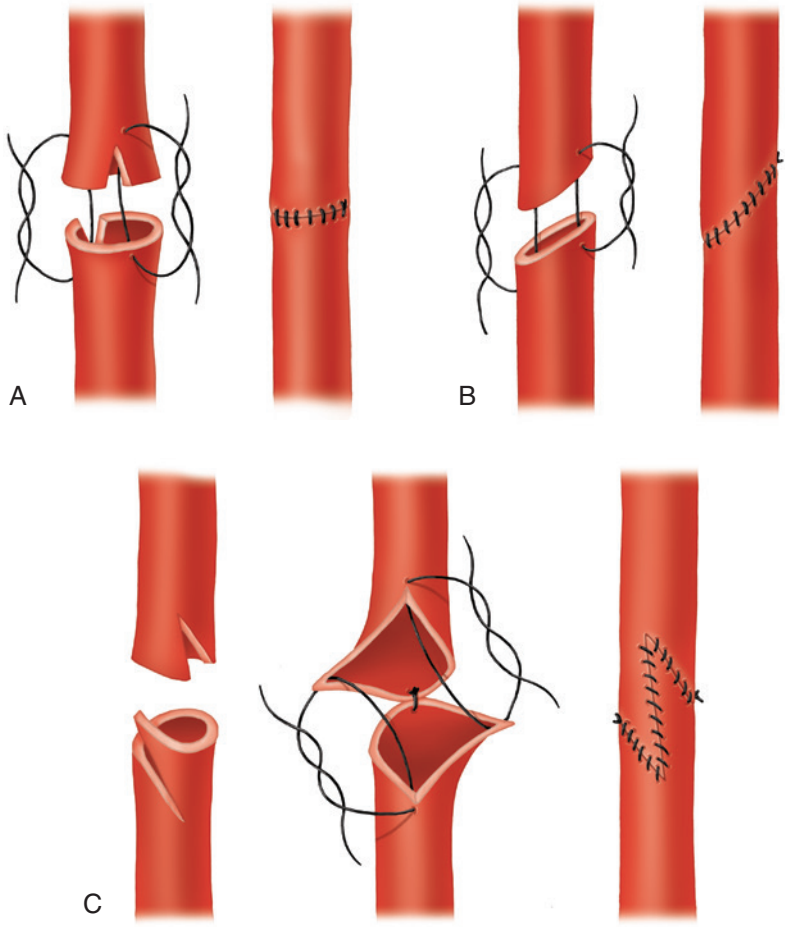

Figure 14.9 Ureteroureterostomy techniques to maximize luminal diameter. A, Spatulation of ureteral margins. B, Oblique anastomosis. C, Z-plasty technique. (With permission from Smith RB, Skinner DG (eds.). Complications of Urologic Disorders. Philadelphia: WB Saunders; 1976:137.)

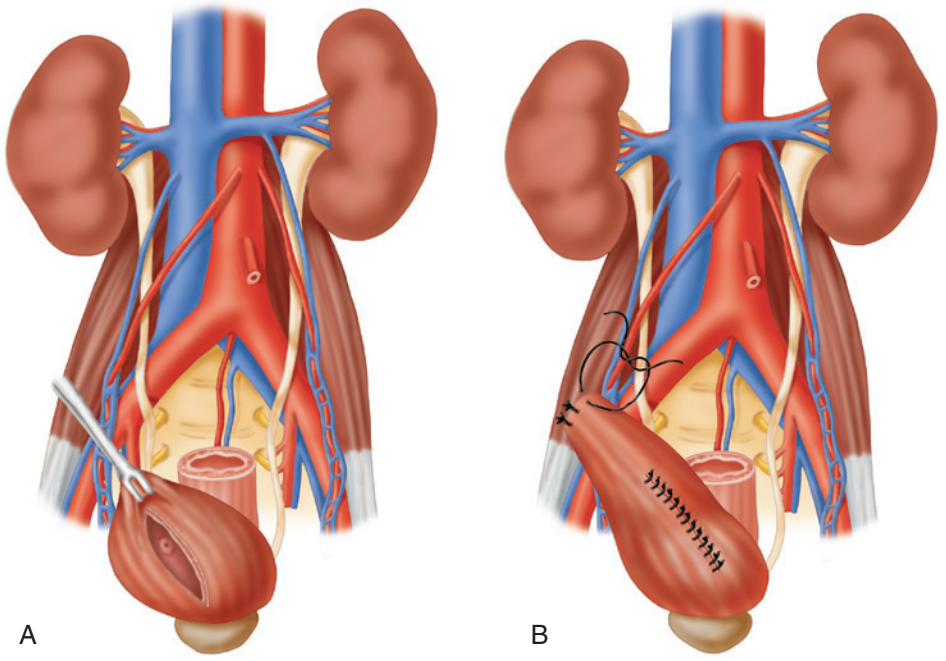

Figure 14.10 Psoas hitch. A, An anterior cystotomy is performed following bladder mobilization. We typically do not divide the contralateral bladder pedicle. B, The bladder dome is fixed to the ipsilateral psoas tendon, and the ureteral reimplantation is completed. (With permission from Wein AJ, Kavoussi LR, Campbell MF. Campbell-Walsh Urology. 10th ed. Philadelphia, PA: Elsevier Saunders, 2012: Figure 41.31.)

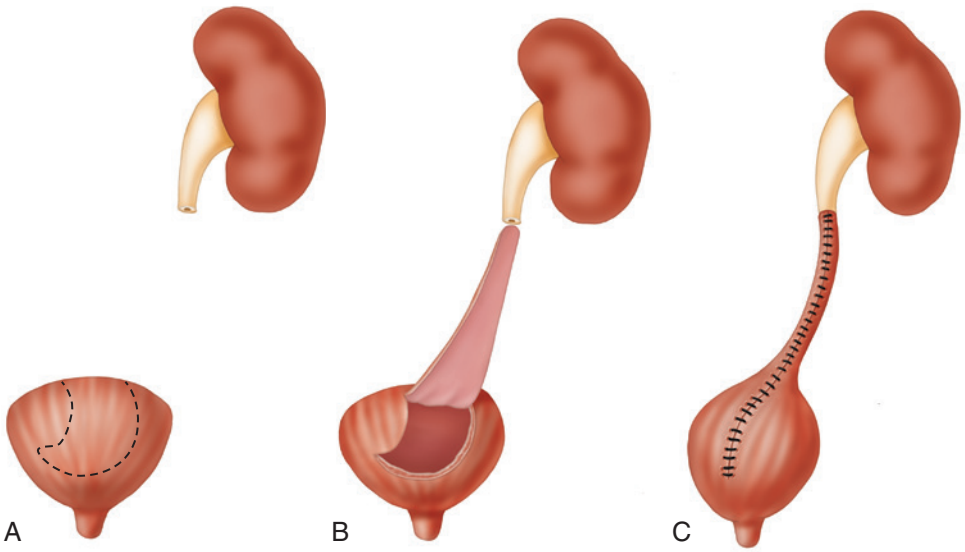

Figure 14.11 Boari flap. A, The intended flap is marked on the mobilized bladder. B, The flap is created with the base ~4 cm in width, and the flap length not exceeding three times the width of the flap. C, Completion of the flap. (With permission from Wein AJ, Kavoussi LR, Campbell MF. Campbell-Walsh Urology. 10th ed. Philadelphia, PA: Elsevier Saunders, 2012: Figure 41.33.)

The key to a successful Boari flap is being aware of the vascular supply in relation to the flap length (Fig. 14.11).[49–51] Typically, the base of the flap should be ~4 cm in width, and the flap length should not be more than three times the width of the flap. It is important to avoid an hourglass deformity by creating a wider base with a slow taper toward the tip of the flap.

DISTAL URETERAL REPAIR

Distal ureteral repairs can be deceptively challenging because after crossing the iliac vessels, the course of the ureter dives into the deep pelvis, and it is often difficult to identify the ureter and surrounding structures. In our experience, we feel it is important to inform male patients that there is risk of injury to the vas deferens during these repairs. Often there is significant scarring in these cases, and ligation of the vas is needed to expose and mobilize the distal ureter.

The main options for distal ureteral repair include direct reimplant into the dome of the bladder[37,52,53] or a psoas hitch.[47,48] The selection of which procedure to perform depends on the location and length of the stricture and the bladder capacity of the patient. Distally located and short-segment strictures are best addressed with a reimplantation. More proximally located and longer strictures may require a psoas hitch or a combined psoas hitch with a Boari flap.

LONG-LENGTH URETERAL REPAIR

There are few options for treating long-length or multisegment ureteral strictures. The main options include a psoas hitch combined with a Boari flap, ileal ureter, and autotransplant. As mentioned before, a contralateral nephrectomy with a transureteroureterostomy can be performed if the contralateral kidney has minimal function. While others have reported good outcomes,[45,54–57] it is our preference that we avoid performing ileal ureters, primarily because we have now added a second organ system to the picture.[58] Furthermore, there are metabolic consequences of interposed bowel segments,[59] in addition to the risk of stone formation, mucus production, and urinary tract infection. These cases should be restricted to patients with adequate bladder capacity and renal function (GFR >30 mL/min) who have no inflammatory bowel disease or radiation enteritis.

More recently, we have been doing more laparoscopic nephrectomy followed by autotransplant procedures for the most difficult strictures.[60] This is a last-ditch effort where there is a tremendous amount of scar tissue. The advantage of this procedure is that it allows for reconstruction of the ureter and renal pelvis under cold ischemia on the back table, which is much easier than with an open or minimally invasive approach. The key is to identify the proximal point at which there is no scarring. Depending on the degree of scarring of the ipsilateral iliac fossa, sometimes we need to place the kidney on the contralateral side. If the extent of the stricture is very proximal, a pyelovesicostomy can be performed on the transplanted kidney.[61] It is important to develop a good relationship with the transplant team and perform these procedures as a team effort to optimize success.

OTHER CONSIDERATIONS

Often anatomic kidney variants can add further complexity to ureteral reconstruction. For pelvic kidneys, we often perform a pyelovesicostomy due to the proximity of the kidney to the bladder.[62] For horseshoe kidneys it is important to be aware of the location of the multiple hilar vessels that are often present. The ureters travel anterior to the isthmus of the kidney, which is located below the inferior mesenteric artery. It has been reported that transecting the

isthmus along an avascular plane can facilitate reconstruction. However, each of these unique cases requires specific attention to each situation.[63]

Summary

Ureteral injuries are frequently multifactorial in etiology, and successful management requires an intimate knowledge of the anatomy and the available tools for repair. The goal of repair is to restore quality of life and preserve renal function, while minimizing morbidity. Often this requires more than one procedure over the course of weeks to months. The best-equipped surgeon is not only a creative surgeon who understands the advantages and limitations of each technique, but also one who can communicate and connect with the patient and his or her family to determine the optimal repair.

Chapter 14 Questions

1. Two good areas to identify the ureter include:
   a. At the crossing of the gonadal vessels and insertion into the bladder
   b. At the hilum and lateral to the gonadal vessels at the level of the lower pole of the kidney
   c. At the iliac bifurcation and crossing of the vas deferens
   d. At the iliac bifurcation and lateral to the gonadal vessels at the level of the lower pole of the kidney
   e. At the level of the lower pole of the kidney lateral to the gonadal vessels and crossing of the vas deferens

2. The length and location of a ureteral injury can be determined by:
   a. Retrograde ureterography
   b. CT scan
   c. MRI
   d. MAG3 renogram
   e. Ultrasound

3. A 73-year-old male presents with a symptomatic 3-cm distal ureteral stricture secondary to multiple stone procedures. Serum creatinine is 1.2 mg/dL. CT imaging shows left-sided hydronephrosis and thinned parenchyma. Renogram shows 18% split function on the left and 82% on the right. What is the next step?
   a. Endoscopic balloon dilation
   b. Nephrectomy
   c. Ureteral reimplant
   d. Ureteral stent
   e. Observation

4. During exploratory laparotomy for penetrating gunshot wounds, it is noted that there is a right midureteral injury. While the ureter is being inspected for repair, the patient becomes unstable. What is the next step?
   a. Ligate the ureter proximal to the site of injury and plan a postoperative nephrostomy tube
   b. Complete the ureteroureterostomy
   c. Place a ureteral stent
   d. Perform an intraoperative intravenous pyelogram
   e. Nephrectomy

5. A 46-year-old female presents with a failed ureteropelvic junction (UPJ) repair with a 1-cm stricture 1 year postoperatively. An endopyelotomy is planned. The thickness and direction of the cut should be:
   a. Intraluminal and lateral
   b. Transmural and lateral
   c. Intraluminal and medial
   d. Transmural and medial
   e. Transmural and superior

6. For a Boari flap repair of a midureteral stricture, the ratio of the length of the flap to the base should be not more than:
   a. 1:1
   b. 2:1
   c. 3:1
   d. 4:1
   e. 5:1

7. A 64-year-old female with Crohn's disease and a long history of stone disease presents with a symptomatic left 1-cm proximal ureteral stricture and a 3-cm distal ureteral stricture. Serum creatinine is 1.5. Split function of the left kidney is 41%. What is the next step?
   a. Autotransplantation
   b. Ileal ureter
   c. Combined UPJ repair and ureteral reimplant
   d. Boari flap with renal mobilization
   e. Nephrectomy

8. In a horseshoe kidney where is the the UPJ located?
   a. Medial to the inferior calyx
   b. Lateral to the inferior calyx
   c. Over the isthmus
   d. Posterior to the renal parenchyma
   e. Lateral to the superior calyx

9. The blood supply of the ureter arises from:
   a. Segmental sources medially, proximally, and laterally in the pelvic ureter
   b. Segmental sources laterally, proximally, and medially in the pelvic ureter
   c. Segmental sources laterally
   d. Segmental sources medially
   e. Segmental sources anteriorly and medially

10. The smooth muscle of the ureter is thinnest at:
    a. UPJ
    b. Proximal ureter
    c. Midureter
    d. Over the iliac vessels
    e. Ureterovesical junction

Case Study

You are managing a 68-year-old male has a history of Crohn's disease, long history of urinary stone disease and multiple stone surgeries. He is referred to your office after a recent surveillance ultrasound showed a large left renal stone and sided moderate hydroureteronephrosis. He has a history of brachytherapy for prostate cancer and PSA has remained stable. He has left sided flank pain. He has moderate urinary symptoms and denies any gross hematuria. He is otherwise healthy. Serum creatinine is 1.9 mg/dL.

1. What diagnostic imaging workup would you recommend as the next step?
   a. Noncontrast CT abdomen and pelvis
   b. Repeat renal ultrasound
   c. Lasix renogram
   d. Retrograde pyelogram
   e. CT abdomen and pelvis with and without contrast (urogram)

The CT shows no ureteral stones, but there is a 2cm nonobstructing renal stone. The moderate hydroureteronephrosis extends down to the left distal ureter, where the caliber abruptly narrows near the ureterovesical junction. The parenchyma of the right kidney appears thicker than the kidney on the left.

2. What is the next course of action for your patient?
   a. Lasix renogram
   b. Cystsocopy and retrograde pyelogram and possible ureteral stent placement
   c. Percutaneous nephrolithotomy
   d. Bone scan
   e. Antegrade ureteroscopy

Retrograde pyeloureterogram shows a left sided distal ureteral stricture. His risk factors for stricture development include brachytherapy and multiple stones surgeries. A wire is unable to access beyond the stricture. Retrograde ureteroscopy shows a blind-ending lumen. No bladder lesions or tumors are seen. The patient undergoes a nephrostomy tube placement. His flank pain resolves but he has pain from the nephrostomy tube.

3. What is the next best step to determine the length of the stricture?
   a. Lasix renogram
   b. CT pelvis with and without contrast
   c. MRI pelvis with and without contrast
   d. Antegrade nephrostogram
   e. Cystogram

The stricture length is 3 cm and the cephalad border is at the position of the iliac vessels.

4. To help determine his options for reconstruction, what diagnostic study is indicated next?
   a. MAG3 lasix renogram
   b. PET CT
   c. DMSA renogram
   d. CT abdomen and pelvis with and without contrast (urogram)
   e. Cystogram

5. If his split renal function on the left is 8%, what is the next best step?
   a. Ureteral reimplant and possible psoas hitch
   b. Ureteral reimplant and possible Boari flap
   c. Ileal ureter
   d. Renal autotransplantation
   e. Nephrectomy

6. If his split renal function on the left is 40%, and he strongly wishes to maintain renal function (keep his left kidney). What is the next best step?
   a. Evaluate bladder capacity
   b. Ureteral reimplant and possible psoas hitch
   c. Ureteral reimplant and possible Boari flap
   d. Ileal ureter
   e. Renal autotransplantation

A cystogram is performed and his bladder capacity is 250mL.

7. What is the best reconstruction option for the patient?
   a. Ureteral reimplant and possible psoas hitch
   b. Ureteral reimplant and possible Boari flap
   c. Ileal ureter
   d. Renal autotransplantation
   e. Transuretero-ureterostomy

Answers

1. **d.** The iliac bifurcation and lateral to the gonadal vessels at the level of the lower pole of the kidney are two areas that are most easily identified intraoperatively.
2. **a.** In contrast to the other diagnostic studies listed, retrograde ureterography allows for the identification of the length and location of a ureteral injury.
3. **b.** Nephrectomy is the best choice due to the presence of a minimally functioning left kidney and symptoms.
4. **a.** Because the patient is hemodynamically unstable, it is best to temporize the injury. After the patient is stabilized, a repair can be planned in the elective setting.
5. **b.** The depth of the cut should be transmural, and the direction of cut should be away from hilar/vascular structures.
6. **c.** The Boari flap length should not be more than 3 times the width of the flap to avoid ischemia of the anastomosis.
7. **a.** Autotransplantation is the best answer because of the need to preserve renal function (presence of renal sufficiency), presence of bowel disease (avoid ileal ureter), and having a multifocal and long-length stricture.
8. **a.** In a horseshoe kidney, the inferior calyx is located inferior and medial to the UPJ. The proximal ureter travels anterior to the isthmus of the kidney.
9. **a.** The blood supply of the ureter is segmental and arises from medially proximally and laterally in the pelvic ureter.
10. **b.** The smooth muscle of the ureter is thinnest at the UPJ, which makes this area particularly susceptible to injury.

CASE STUDY

1. **a.** A noncontrast CT abdomen and pelvis is indicated to determine if an obstructing ureteral stone is present, given his history, and the extent of the hydroureteronephrosis. It is also helpful to elucidate the parenchymal thickness of his kidneys as a surrogate for split renal function.
2. **b.** The next step needed is to determine the etiology of the hydroureteronephrosis, including the location and length of a potential stricture. This is likely the cause of his symptoms. The stone is non-obstructing and does not need to be addressed immediately.
3. **d.** Antegrade nephrostogram will delineate the cephalad extent of the stricture, and combined with the retrograde ureterogram, a length can be determined.
4. **c.** It is important to evaluate the split function of his left kidney compared to the right kidney to determine if nephrectomy versus reconstruction is indicated. A Lasix washout study is not needed because it is already known he is obstructed.
5. **e.** Given his kidney is minimally functional on the left, his best option is nephrectomy.
6. **a.** He has moderate urinary symptoms and history of brachytherapy. Because the stricture is located in the distal ureter, it would be indicated to determine his bladder capacity prior to reconstruction. If his bladder

capacity were very limited, performing a psoas hitch or Boari flap would be difficult and may worsen his urinary symptoms.

7. **d.** He would likely require a Boari flap to reach the anastomosis, however patient has a limited bladder capacity. Mobilization of the bladder will be also difficult given his history of brachytherapy. His history of Crohn's disease and borderline renal insufficiency makes him not a good candidate for an ileal ureter. Autotransplantation is the best option given the lack of remaining options and would allow for pyelolithotomy to address his renal stone during cold ischemia.

Chapter 15 Questions and Answers

KEY POINTS

1. With enhanced diagnostic accuracy in modern imaging techniques, hemodynamically stable renal trauma patients should be managed with non-invasive treatment, reserving either endovascular or surgical intervention only if unstable.
2. Intraperitoneal and complicated extraperitoneal bladder ruptures should be managed operatively, and uncomplicated extraperitoneal injuries with urethral drainage.
3. In pelvic trauma patients, indicative symptoms (blood at the meatus, inability to urinate, palpable bladder), or the inability to pass a urethral catheter, should prompt evaluation for a urethral injury with a retrograde urethrogram.
4. Management of posterior urethral disruption injuries due to pelvic trauma includes immediate bladder decompression with a suprapubic catheter, followed by either primary endoscopic realignment or a delayed elective urethroplasty.
5. Patients with a classic history suggestive of penile fracture should undergo immediate surgical repair, while imaging (ultrasound or magnetic resonance imaging) may aid in diagnosis in unclear cases.

Renal Trauma

Management of renal injuries has evolved significantly over the preceding decades, concomitant with advances in validated organ injury scaling systems and minimally invasive angiographic interventions. Whereas nephrectomy was common and the traditional standard of care, the vast majority of both blunt and penetrating injuries can now be managed nonoperatively.

Etiology and Management

Injury to the kidneys is the most common genitourinary trauma encountered, accounting for 24% of traumatic abdominal solid organ injuries.[1] Due to their retroperitoneal location, the kidneys are fixed only by the renal pelvis and vasculature, rendering them susceptible to deceleration injuries. Contrast-enhanced computed tomography (CT) scanning, with delayed images, remains the most common method for evaluating both vascular and collecting system trauma.

Although operative exploration was the traditional method of treatment, the paradigm has shifted to nonoperative management. Emergent surgery often results in nephrectomy,[2] and with advances in imaging, monitoring, and endovascular techniques, most injured kidneys can now be effectively preserved.[3] The current American Urological Association guidelines on urotrauma now advocate

for noninvasive management of any patient with a renal injury who is hemodynamically stable, and compulsory intervention (either endovascular or surgical) in unstable patients with poor response to resuscitation.[4]

Complications

A common problem following renal trauma is persistent urinary extravasation, which can result in urinoma, perinephric infection, or even renal loss. Systemic antibiotics and close observation result in resolution in many patients.[5] In patients with a persistent urine leak on repeat imaging (48 hours later), or with complications such as enlarging urinoma, fever, pain, ileus, fistula, or infection, urinary drainage with an internalized ureteral stent should be performed.[4] Drainage helps to avoid further complications, such as perinephric abscess.

Occasionally, patients may present with a delayed hemorrhage several weeks following the initial trauma, and the immediate treatment is bed rest and hydration. If the bleeding persists, then endovascular arteriography can usually localize the vessel, which can then be controlled with embolization. Rarely hypertension can be encountered, resulting from stimulation of the renin-angiotensin axis from renal ischemia due to renal artery stenosis (Goldblatt kidney), compression of the parenchyma by hematoma or urinoma (Page kidney), or arteriovenous fistula.[6,7]

Ureteral Trauma

Traumatic injuries to the ureter are rare, comprising only 1% of urologic trauma. Although external and endoscopic trauma can injure the ureter, a common cause is iatrogenic injury, occurring in gynecologic, urologic, or colorectal surgical cases.[8] The management of iatrogenic ureteral injury is discussed in detail in Chapter 14, and reconstructive procedures are discussed in Chapter 43. As injuries of the ureter associated with trauma are typically penetrating in nature, treatment with either placement of a ureteral stent or surgical repair depends on the location and severity of the injury.

Etiology and Management

Because of its anatomic location in the retroperitoneum protected by the vertebrae and musculature, the ureter is less susceptible to traumatic forces. For this reason, ureteral injury is present in less than 4% of all penetrating and less than 1% of all blunt trauma cases.[9]

In cases where ureteral injury is suspected, intravenous contrast-enhanced axial imaging with delayed films is recommended, or direct visualization during laparotomy if no preoperative imaging is available. In stable patients, lacerations can be primarily repaired, and contusions can be stented or resected and repaired, depending on the nature and severity of the injury. Either a stent or percutaneous nephrostomy (if a stent cannot be placed) can divert the urine from a partial or delayed presentation of a ureteral injury, with a definitive repair at a later date when the patient has recovered from the acute trauma.[4]

Complications

If unrecognized, significant complications can arise, making a prompt, accurate diagnosis imperative in managing these patients. A missed and persistent ureteral urine leak can lead to urinoma formation (Fig. 15.1), abscess, ureteral stricture, fistula, and potentially the loss of an entire ipsilateral kidney. Patients with missed ureteral injuries can suffer increased nephrectomy rates and prolonged hospital stays.[10]

Bladder Trauma

Etiology and Management

As the bladder is anatomically located deep in the bony pelvis, it is relatively protected from external traumatic forces. Significant blunt forces, such as rapid decelerations, falls, or crushes, can rupture the bladder, as well as penetrating injuries such as bone shards, projectiles, or surgical iatrogeny. Because of the forces necessary to compromise the bladder inside of the bony pelvis, concomitant injuries are common (80–94%), and mortality rates can be high, usually from nonurologic causes.[11–13]

Diagnosis can be made when clinically suspected, such as when conscious patients have suprapubic or abdominal pain and inability to void following the inciting event. Associated injuries or altered mental status can mask the symptoms; therefore when the mechanism suggests a potential bladder injury, evaluation should be undertaken. Gross hematuria upon catheter placement is typically the first indication and is nearly universally present.[14,15] Difficult catheter placement or blood at the meatus can indicate a concomitant urethral injury, and a retrograde urethrogram should be performed in these cases.

Bladder ruptures are best evaluated with a cystogram with drainage films. Alternatively, axial imaging with contrast instilled in the bladder can be utilized in stable patients. In uncomplicated patients, extraperitoneal bladder ruptures should be managed conservatively with urethral drainage alone, typically for 14 days following injury, which can be removed when a cystogram confirms no leak of contrast. If a patient is complex, with other injuries that necessitate laparotomy or orthopedic intervention, once stable the patient should undergo immediate repair of extraperitoneal injuries, as complications rates are lower.[16,17]

Intraperitoneal ruptures should be managed by immediate operative repair, as these injuries are unlikely to heal with conservative management and are often more severe than suggested in imaging studies. Careful inspection of the ureters and evaluation for clear efflux can evaluate for ureteral injury, with repair or stenting as indicated. A urethral catheter is again left and bladder integrity confirmed via cystogram prior to removal to ensure proper healing.

Complications

When promptly diagnosed and appropriately managed, complications following bladder injuries are minimized. Delayed or missed diagnoses can result in significant morbidity, as in patients with devastating complex pelvic trauma. If missed, patients can develop acidosis, azotemia, infection with fever and sepsis, acute renal failure, peritoneal signs, ileus, urine ascites, and even respiratory compromise from abdominal compartment syndrome. In complex genitourinary or concomitant colorectal injuries,

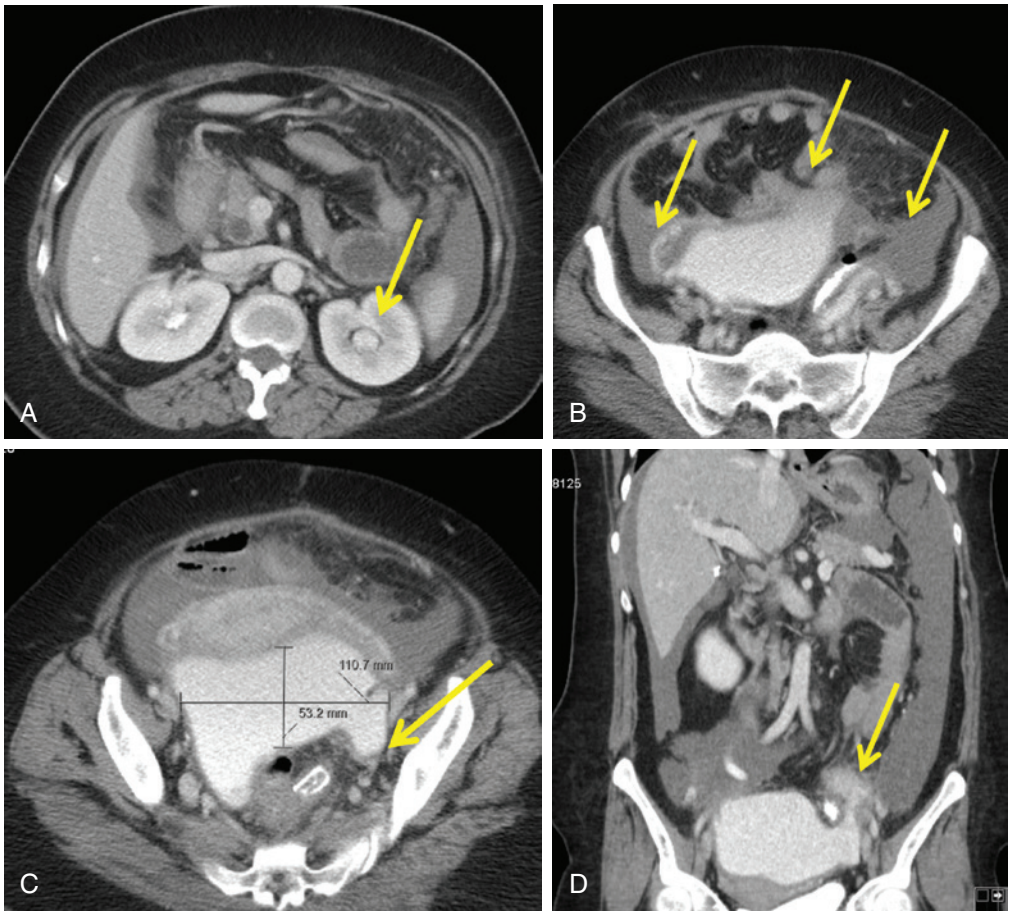

Figure 15.1 Delayed recognition of a ureteral injury following colon surgery. The patient presented with fevers and concern of pelvic abcess. A CT urogram demonstrates (A) proximal left hydronephrosis (arrow), (B) urinary ascites with layering contrast within ascites fluid (arrows), (C) extravasation into the urinoma from the site of ureteral injury (arrow), and (D) a phlegmon surrounding the uteral extravasation (arrow). (Figure provided by Samir Taneja.)

incontinence, fistulas, or strictures can develop, necessitating difficult and complex reconstructive surgery.

Urethral Trauma

Prompt recognition and diagnosis of urethral injuries are critical to successful management to optimize outcomes and prevent delayed complications. The location of the stenosis guides management, with specific mechanisms of injury to either the anterior (pendulous and bulbar) or posterior (membranous and prostatic) urethra influencing therapies. Acute management of any urethral trauma typically involves diverting urine away from the injury, and while many anterior urethral defects are amenable to immediate surgical management, many patients with posterior injuries ultimately require formal surgical repair several months later.

POSTERIOR URETHRAL INJURIES

Injuries of the posterior urethra are typically "disruption" type injuries, usually occurring in conjunction with multisystem trauma such as motor vehicle accidents, falls, or industrial accidents. These injuries are almost always encountered in conjunction with fracture of the anterior pelvic ring or pubic diastasis, with the degree of displacement correlated to a higher risk of urethral injury.[18] Conversely, only 10–15% of pelvic fractures are associated with urethral injury. Bladder injury has also been diagnosed in 10–20% of patients with pelvic fracture and urethral injury.[19]

The clinical and surgical appearance of each form of posterior urethral injury may differ. Endoscopic or open prostate surgery is associated with continuity strictures and preservation of the distal external urinary sphincter. In contrast, pelvic fractures are associated with urethral disruptions of the membranous urethra. These injuries have been termed "pelvic fracture urethral injuries" (PFUIs). Interestingly, a report has found that 7 of 10 patients examined at autopsy had urethral disruption after pelvic fracture *distal* to the external urinary sphincter, disputing the historical view that these injuries occur at the interface of the fixed prostatic apex and the less supported membranous urethra.[20] Additionally, urodynamic studies have demonstrated a functional rhabdosphincter at the prostatomembranous region in many patients after anastomotic posterior urethroplasty for PFUI.[21]

Diagnosis

Because of the typical association of PFUI with more serious concomitant injuries, above all else resuscitation and stabilization of the patient is paramount. When the mechanism of injury portends a possible PFUI, the triad of blood at the

meatus, inability to urinate, and a palpably full bladder may indicate a urethral disruption. Because these classic signs or others (a "high-riding" prostate or perineal hematoma) may be clinically absent, a PFUI is often first suspected when a urethral catheter cannot be placed into the bladder.[22] When a PFUI is suspected, an immediate retrograde urethrogram can aid in the diagnosis.

Management

Debate continues regarding whether primary endoscopic realignment (PER) or suprapubic tube (SPT) diversion (with delayed posterior urethroplasty) is better for acute management of PFUI. There is no consensus among experts, with varying literature regarding the impact of each on eventual incontinence, impotence, and urethral stricture rates.[23–37] The obvious benefit of primary alignment is the potentially lower stricture rate of 56% versus the 97% seen with suprapubic catheter placement alone;[37] however, a more recent series reported that PER is only successful in 21% (4/19) of patients.[34] Additionally, a recent report of a large series showed that strictures that form after realignment can be shorter and therefore potentially easier to treat when undergoing urethroplasty, though this too remains controversial.[32]

While PER and SPT placement are currently both acceptable for the acute management of PFUI, placement of an SPT, with definitive and durable treatment via posterior urethroplasty 2 months postinjury, can avoid a prolonged and complicated clinical course to establishing urethral patency.[38] Additionally, in the setting of a severely injured or unstable patient, one should perform percutaneous SPT placement as the more expeditious procedure. This allows for stabilization and treatment of concomitant injuries, and the posterior urethroplasty can be performed electively in a controlled setting.

Complications

At the time of repair, complete excision of the fibrotic scar tissue is absolutely imperative, with outcomes directly related to complete scar removal (Fig. 15.2).[39] After a posterior urethroplasty, 5–15% of patients can experience recurrent stenosis at the anastomosis.[40–43] However, as the majority of the fibrotic scar tissue has been excised, endoscopic treatment (with a direct vision internal urethrotomy) has proven successful in managing these patients.

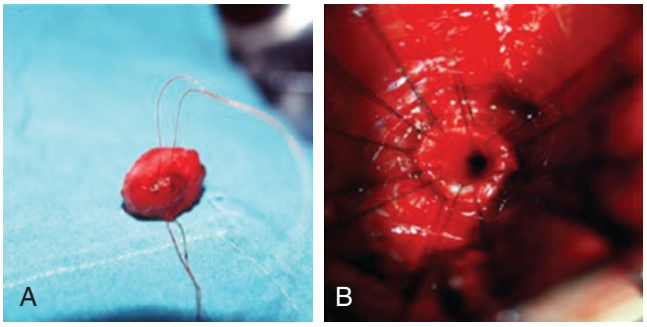

Figure 15.2 During the posterior urethroplasty for a PFUI, complete excision of the fibrous scar (A) that results from hematoma resorption is imperative to a successful outcome, allowing for precise mucosal apposition of healthy urothelium (B).

Erectile dysfunction (ED) commonly results following pelvic fractures, with an average rate of about 50%,[41,44–46] and reported as high as 82%.[43] Similar to PFUI itself, the incidence of ED is related to the nature of the pelvic ring disruption itself.[47] The precise etiology of post-PFUI ED is unclear, but theoretically could include cavernosal nerve injury, arterial insufficiency, venous leak, and direct corporal injury, although in most cases the cause of ED is likely multifactorial.[48–50] The varying rates and causative mechanisms have relied mainly on individual study methods, rendering a meaningful conclusion impossible. Anatomically, the proximity of the erectile nerves and vessels to the mechanism of injury leads one to conclude that damage to either or both may be responsible. Additionally, neurogenic ED has been reported to improve with time, suggesting that neuropraxia rather than complete disruption may be a cause.[50]

Urinary incontinence is surprisingly rare following PFUI (<4%),[41] with redundancy of continence mechanisms helping to preserve continence in the vast majority of patients following PFUI. Both the bladder neck and urethral sphincter help to prevent involuntary urine leakage; following PFUI the urethral sphincter may be damaged, but only when the bladder neck is also injured will the patient be incontinent.[51] More recently, urodynamic data have shown that a significant proportion of patients will also have identifiable rhabdosphincter function following repair.[21] In patients with persistent incontinence, placement of an artificial urinary sphincter is recommended.

ANTERIOR URETHRAL INJURIES

The anterior urethra extends distally from the membranous urethra to the urethral meatus, with the penoscrotal junction dividing the shorter, proximal bulbar urethra from the longer, distal pendulous urethra. Given the external anatomic location, the anterior urethra is more susceptible to penetrating trauma (e.g., stab or gunshot wounds), but the majority of injuries involve blunt compression ("straddle") injuries, penile fractures with urethal disruption, or iatrogenic trauma (e.g., after Foley catheterization or endoscopic urethral surgery) (Fig. 15.3).

Compression of the bulbar urethra against the pubic bone, or a "straddle injury," is the most commonly encountered

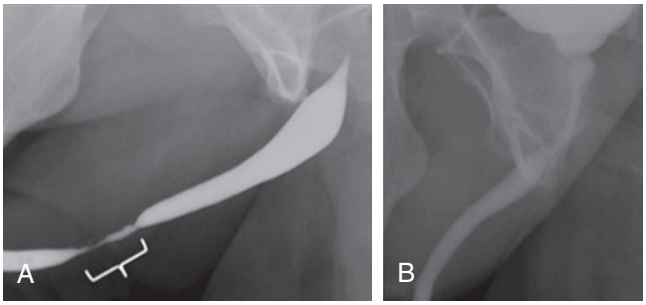

Figure 15.3 A retrograde urethrogram (A) of a patient who underwent endoscopic treatment of prostatic hyperplasia with laser vaporization. He presented 2 months later with obstructive voiding, and a pendulous stricture was found (bracket). This failed one dilation and given its location and 2.5-cm length, an overlapping buccal mucosa dorsal inlay and ventral onlay with pseudospongioplasty was performed, with excellent postoperative result on voiding cystourethrogram (B).

anterior urethral injury and occurs after a direct force to the perineum compresses the bulbar urethra against the pubic bone. Alternatively, penile constriction rings can damage the anterior urethra secondary to tissue ischemia while Foley catheterization or endoscopic urethral surgery can damage the bulbar urethra, resulting in contusion or partial urethral disruption. The true extent of iatrogenic injuries, along with trauma from constriction rings, may not become evident until many years after the original event.[52] Although rarely associated with pelvic fractures, anterior urethral injuries may be encountered in approximately 15% of penile fractures.[53]

Diagnosis

A careful history and physical examination should raise suspicion for anterior urethral injury, as these insults may arise immediately or after a substantial period of time. Straddle injuries often present in a delayed fashion with obstructive voiding symptoms and an idiopathic etiology. In a large series of 78 patients with straddle injuries, Park and McAninch reported great variability in the time to presentation with 40% of patients presenting to the emergency department in an acute setting and 60% of patients presenting 6 months to 10 years after the original injury.[54] Hematuria, penile sleeve hematoma (injury confined to Buck's fascia), difficulty voiding, and perineal "butterfly" hematoma (injury penetration of Buck's fascia) are common presenting symptoms in the acute setting. In addition to a perineal "butterfly" hematoma, penetration of Buck's fascia can allow the spread of urine and/or blood to the scrotum (dartos fascia), anterior abdominal wall (Colles fascia), and/or thighs (fascia lata). In patients with a suspected anterior urethral injury, a retrograde urethrogram should be performed. Flexible cystoscopy may also be utilized to aid with the diagnosis of urethral trauma, although radiographic imaging is usually sufficient for a diagnosis of urethral trauma.

Management

Anterior urethral injuries are classified into three groups based upon radiographic, clinical, or endoscopic findings. Though *contusions* may appear normal on retrograde urethrogram, these injuries are best determined with clinical suspicion through cystoscopy in the setting of a "normal" retrograde urethrogram. Alternatively, *partial disruptions* appear as extravasated urine on retrograde urethrogram with visualization of contrast in the urethra or bladder proximal to the injury. *Complete disruptions* appear as total extravasation without visualization of contrast in the more proximal urethra or bladder.

Contusions to the anterior urethra should be managed with a urethral catheter for approximately 2 weeks followed by a voiding cystourethrogram (VCUG) to confirm urethral patency. The patient should be counseled on the possibility of delayed development of a urethral stricture at the site of contusion.

Partial urethral disruptions diagnosed by retrograde urethrogram may be managed via various algorithms. Urinary diversion (via SPT) with formal repair after a minimum of 2 months allows resolution of inflammation and maturation of scar tissue. Although some experts support one attempt at Foley catheter placement, the possibility of causing a complete urethral disruption during this attempt should be considered. If urethral catheter placement is unsuccessful, percutaneous suprapubic tube placement should be performed. The preservation of urethral mucosa with partial disruptions may be adequate for re-epithelialization and eventual luminal recanalization; however, this requires periodic evaluation with uroflow studies and counseling regarding the possibility of future stricture development.

In patients with a complete disruption, either immediate or delayed repair can be considered, depending on any concomitant injuries or surgeon experience. In straddle injuries of a lesser degree, primary anterior urethral alignment alone has shown promising results with respect to stricture rate and ED.[55,56] In patients with low-velocity gunshot wounds, primary repair is recommended, as catheter placement alone results in far worse stricture rate.[57] Limited debridement of the corpus spongiosum should be performed in these cases, as the robust corporal blood supply allows for spontaneous healing of most contused areas.[58,59] In high-velocity gunshot wounds, SPT diversion and delayed repair should be undertaken, as the degree of tissue damage is greater in these patients.

Complications

As the risk of ED and incontinence are much lower in anterior compared to posterior urethral injuries, the major complications relating to anterior urethral trauma include urethral stricture formation and infection. If untreated, persistent extravasation of infected urine or blood may lead to urethrocutaneous fistula, urethral abscess, or urethral diverticula. Prolonged urine extravasation into the corpus spongiosum may also lead to added spongiofibrosis, resulting in a longer urethral stricture. Consequently, a longer anterior urethral stricture necessitates more complex management with a buccal mucosa graft (BMG) or fasciocutaneous flap.

Patients with resultant urethral strictures are often subjected to endoscopic procedures such as dilations or urethrotomies that frequently need to be repeated. Such interventions can subject patients to pain and complications negatively impacting quality of life.[60] The success rate of dilations is also low, with most patients eventually requiring definitive urethral repair.

In patients with recurrent strictures following urethroplasty, direct visualization and incision of the urethra (DVIU) may be considered for singular bulbar stenoses that are < 1 cm and recur > 6 months following the initial procedure. In this setting, success rates of 9–52% can be achieved; however, longer, multiple, penile, or distal strictures do not respond to repeat dilation/incision.[61–66] In patients with long (>3 cm), complex, or multifocal recurrent strictures, substitution urethroplasty with either buccal mucosa grafting or penile skin flaps is necessary (Fig. 15.4). However, typically, patients who fail urethroplasty suffer from a focal, short-segment stricture, which can be effectively treated with anastomotic techniques, with excellent success rates of up to 93%.[67]

In order to optimize success of urethroplasty, several aspects need to be considered. Above all, complete excision of all scar tissue must be assured. In the reoperative setting, it is common to find that the stenosis extends proximally to virgin tissue planes, indicating inadequate

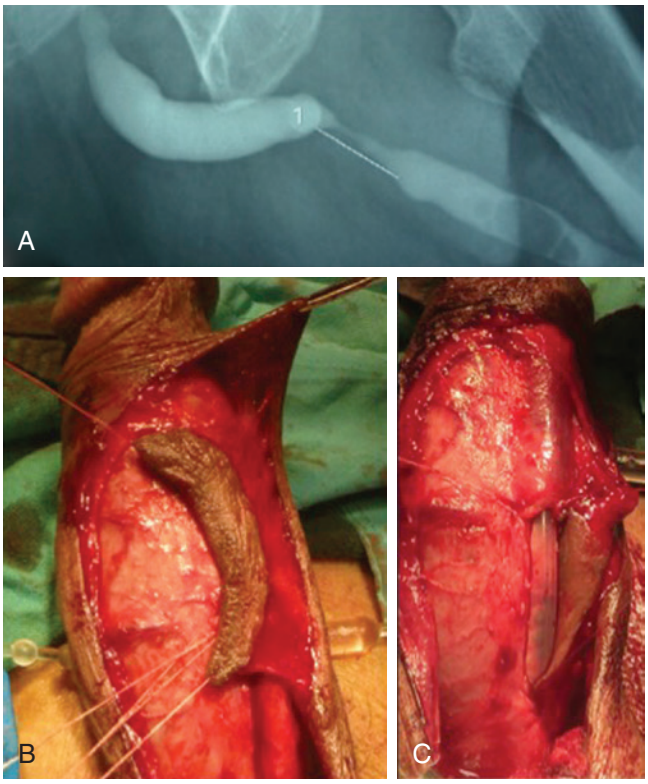

Figure 15.4 Retrograde urethrogram (A) of a patient with a pendulous stricture following a transurethral procedure. After failing previous attempts at dilation, an Orandi penile skin flap was mobilized (B) and used as a substitution for the scarred segment (C).

proximal dissection during the initial procedure. In order to best achieve complete scar excision, precise control of the proximal urethral lumen can be facilitated by preoperative guidewire placement or antegrade instrumentation via a SPT tract (when available).[67] The distal-most extent of the scar is easily identified with urethroscopy and visualization or palpation of the scope at the site of the stricture.[68]

After the urothelial scar is excised, the surrounding fibrotic tissue must also be removed. Often, scalpel dissection is required as scissors may not be effective in cutting the dense fibrosis encasing the urethra. For these reasons, excisional techniques may be superior to nontransecting methods, as scar tissue is more developed in the reoperative setting.

External Genitalia

PENILE FRACTURES

Etiology and Management

Due to its external location and relative mobility, penile injuries are uncommon. Blunt injury typically occurs only with an erect phallus, when the resilient tissues of the tunica albuginea can be compromised, as in a penile fracture. Generally, penile fractures occur from vigorous sexual or masturbatory techniques, such as when the rigid phallus slips out of the vagina and strikes the perineum or pubic bone. Intracavernosal pressures must exceed 1500 mm Hg in order for fracture to occur, such as when the erect penis bends abnormally and the intracavernosal pressure exceeds the tensile strength of the tunical tissue.[69]

The injury is usually a transverse tear in the tunica albuginea, typically 1–2 cm in length, and generally located ventrolaterally (where the tunica is the thinnest) distal to the suspensory ligament.[53,70] Diagnosis is often straightforward and can be made reliably with history and physical examination. A popping sound is often heard, followed by pain, immediate detumescence, and penile ecchymosis ("eggplant deformity"). Because of the psychosocial implications of the injury, patients are often embarrassed and can delay their presentation to the emergency room or clinic.

Urethral injuries can occur with penile fractures, reportedly as often as 24%.[71] A high index of suspicion should be given to patients with blood at the meatus, microscopic or gross hematuria, or difficulty voiding. Retrograde urethrography can be inaccurate and time-consuming, thereby delaying operative repair.[72] As the patient is likely undergoing operative repair of the tunical defect, direct visualization with flexible urethoscopy should be performed to evaluate the urethra. If a urethral defect is found, open repair should be undertaken with care to excise injured tissue and precise urothelial reapproximation.

In cases that are clinically unclear, such as when the history and physical exam are incongruent, imaging may be considered to evaluate the tunical integrity. Magnetic resonance imaging has been proven as a noninvasive and accurate method of demonstrating tunical defects,[73] but the test is expensive and time-consuming. Ultrasound is a more widely available modality that can be readily performed and can assist surgeons in preoperative evaluation and planning[74] (Fig. 15.5).

Complications

Prompt diagnosis and treatment optimizes outcomes and reduces complication rates. If treated within 8 hours of injury, patients have significantly better results than with delayed (>36 hours) repairs.[70] Penile curvature occurs in less than 5% of patients if treated surgically, while conservative management yields curvature rates in excess of 10%, abscess or plaques in 25–30%, and prolonged hospital stays.[75–78] A feared complication is prolonged erectile dysfunction, as the integrity of the corpus cavernosum is compromised. However, this too can be minimized, with erectile function rates similar to those of controls when fractures are promptly treated surgically.[79]

PENILE AMPUTATION

Etiology and Management

Penile amputation is quite rare and is usually the result of genital self-mutilation. The vast majority (65–87%) of these patients suffer from pyschosis, and psychiatric consultation should be obtained in all cases.[80,81] The best results are achieved with reanastomosis of the corporal bodies and the urethra, along with microsurgical repair of the dorsal penile vessels and nerves (Fig. 15.6). If microsurgical support is not available, reapproximating the corpora cavernosa and the urethra can suffice, with the potential for loss of penile skin and sensation.

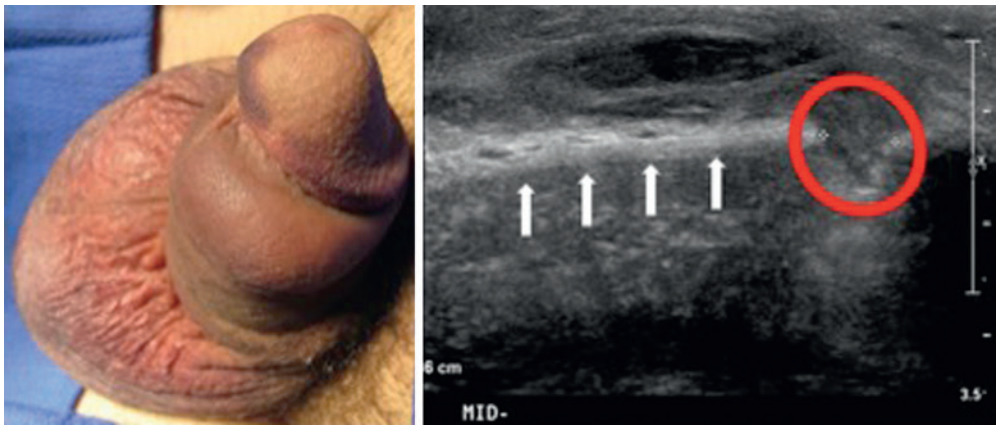

Figure 15.5 A case of a patient who presented 1 week following a penile injury sustained during intercourse. He did not lose his erection and had been able to engage in intercourse since the injury. His exam showed mild ecchymosis and swelling, but given his history, an ultrasound was performed. It clearly showed the tunica albuginea (arrows) and a defect (circle) consistent with penile fracture. Operative exploration confirmed the injury and the defect was repaired.

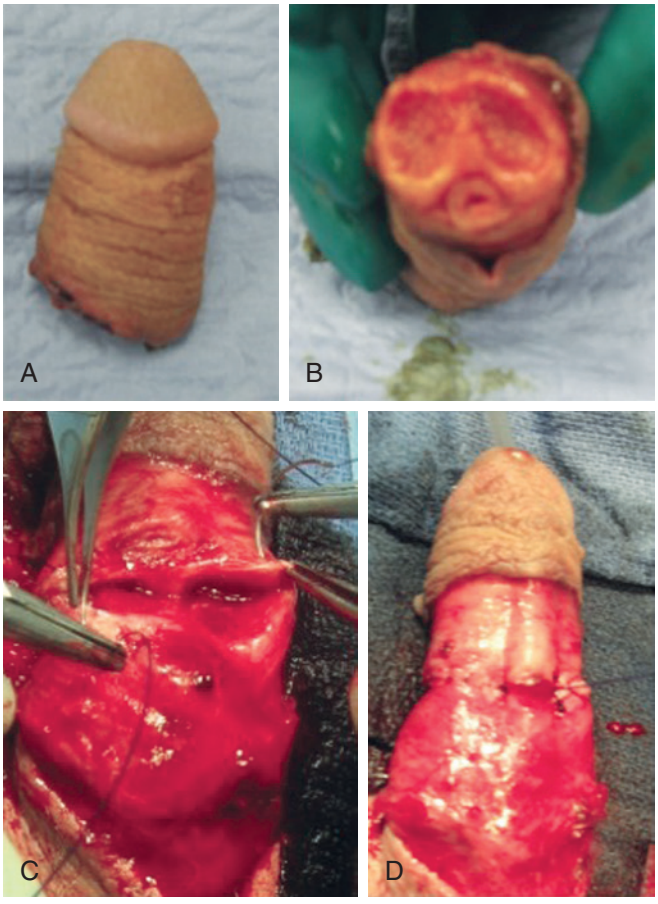

Figure 15.6 Self-amputation of a penis in a psychotic patient. The distal end (A) was found and preserved in a "double-bag" technique and transported with the patient. The proximal stump was cleaned and all devitalized tissue was debrided. The corpora cavernosa were then reapproximated (C) and the urethra was closed over a Foley catheter (D). Microsurgical techniques were used to reconnect the dorsal neurovascular structures.

The severed end of the penis should be preserved by rinsing with saline, wrapping in saline-soaked gauze, and placement in a sterile plastic bag. This bag is then placed in an outer bag filled with ice and transferred along with the patient.[82] Direct contact with ice for a prolonged period can result in hypothermic injury, and if care is taken to transport the severed end carefully, replantation can be successful after 16 hours of cold or 6 hours of warm ischemia time.[83]

Complications

The most common potential complications of penile reattachment surgery are loss of the distal segment (either from vascular compromise or repeated self-mutilation), penile numbness, and erectile dysfunction. Careful attention to the neurovascular anastomoses with microsurgical techniques helps establish blood flow and enables nerve regeneration. Return of erectile function is possible in about 50% of patients with either a macroscopic or microscopic repair; however, complications of urethral strictures and skin or sensation loss are decreased with microvascular repair.[82]

TESTICULAR TRAUMA

Diagnosis and Management

Scrotal ecchymosis and swelling, along with difficulty palpating the testicular contour on exam, can suggest a testicular rupture following blunt or penetrating scrotal trauma. Immediate exploration may be considered, if the mechanism and clinical exam are consistent with rupture. In delayed or unclear cases, ultrasound may aid in diagnosis (Fig. 15.7).

Ultrasound is the modality of choice in evaluating for testicular injury. The most common specific finding is loss of testicular contour with heterogeneous parenchymal echotexture.[84] Early exploration and repair should be undertaken to prevent complications arising from rupture of the tunica albuginea.

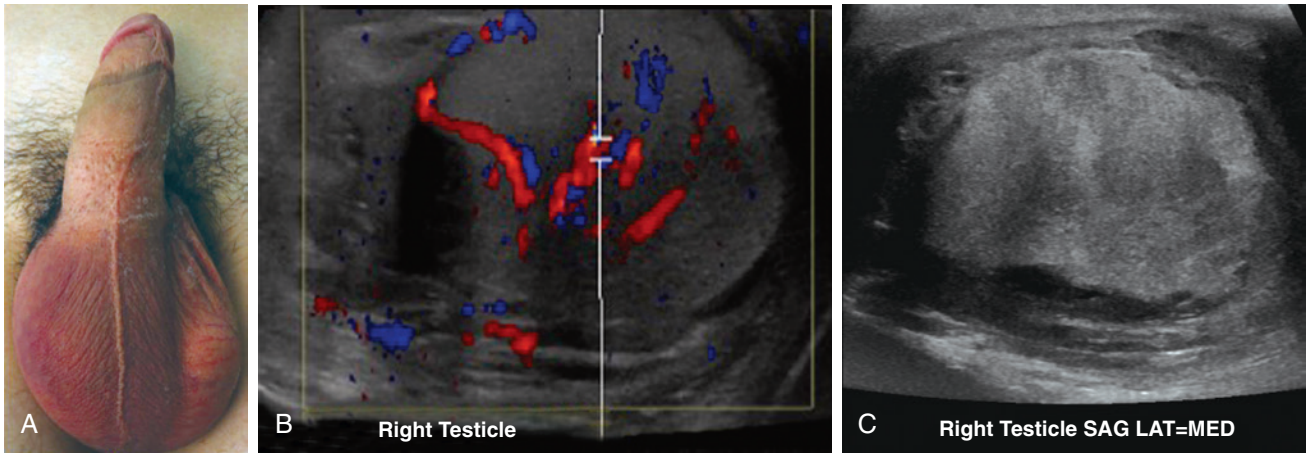

Figure 15.7 A 15-year-old patient sustained a scrotal injury with a lacrosse ball (not wearing genital protection). His exam (A) showed a tender, ecchymotic hemiscrotum, and sonogram (B) confirmed presence of arterial flow to the right testicle. Note the loss of contour and parenchymal heterogeneity that are signs indicating testicular rupture (C).

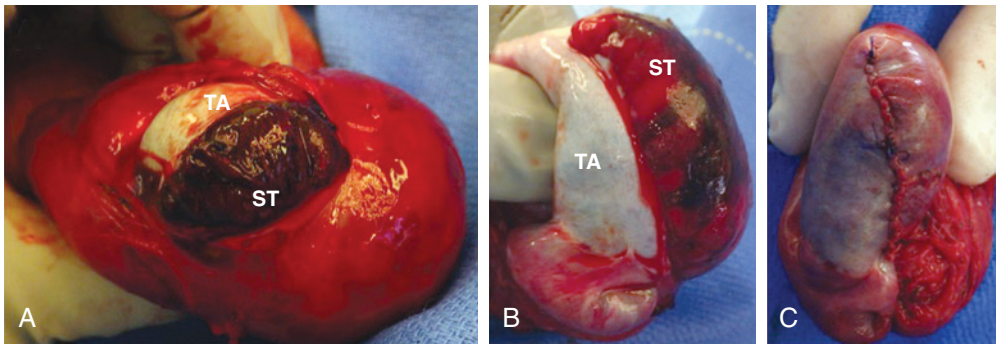

Figure 15.8 Scrotal exploration (A) revealed a defect in the tunica albuginea (TA) with extrusion of seminiferous tubules (ST). The linear tear extended along the entire longitudinal axis of his right testis (B). After debridement of any nonviable tissue, the tunica albuginea was closed with 5-0 PDS suture (C), preserving approximately 75% of his testicular volume, with arterial flow confirmed by Doppler signals.

Complications

Prevention of complications is best achieved by prompt recognition and repair of any tunical defects, with debridement of devitalized parenchyma (Fig. 15.8). This minimizes the chance for testicular atrophy from ischemia and infection.[85] If the injury is not diagnosed and treated promptly, the chance for testicular loss increases significantly, as well as potential infertility issues due to the development of antisperm antibodies resulting from the exposure of seminiferous tubules to systemic blood.

Repair should consist of debriding all nonviable tissue and closure of the tunica albuginea whenever possible. In cases where the tunica albuginea is not viable or too damaged to close primarily, a tunica vaginalis graft can be considered to cover the defect.[4] In cases where the initial trauma is penetrating in nature, immediate exploration is recommended to reduce complications.

Chapter 15 Questions

1. The most common genitourinary organ injured is the:
   a. Ureter
   b. Bladder
   c. Kidney
   d. Testicles
   e. Prostate

2. 48 hours after a patient sustained a blunt abdominal injury that initially showed a renal laceration, she develops fever and flank pain. She is hemodynamically stable. The next step is:
   a. Observation
   b. Axial imaging
   c. Angiography
   d. Operative exploration
   e. Immediate nephrectomy

3. Axial imaging 48 hours after a blunt renal imaging in the patient above shows an enlarging urinoma. The next step in management is:
   a. Observation
   b. Repeat imaging
   c. Internalized ureteral stent placement
   d. Operative exploration and repair
   e. Nephrectomy

4. A patient sustains a gunshot wound to the left flank. He is stable, and imaging shows a through and through trajectory, with no intraabdominal injury. He is admitted for observation and, on the following day, develops left flank pain and hematuria. Serum creatinine is normal, but you suspect a missed ureteral injury. What is the best imaging study to evaluate initially?
   a. Plain film KUB
   b. Magnetic resonance imaging
   c. Ultrasound
   d. CT scan with IV contrast and delayed images
   e. Lasix renogram

5. In a stable patient with a penetrating ureteral injury diagnosed 24 hours after the initial trauma, options for management include:
   a. Observation
   b. Ureteral stent placement
   c. Percutaneous nephrostomy with delayed repair
   d. b and d
   e. All of the above

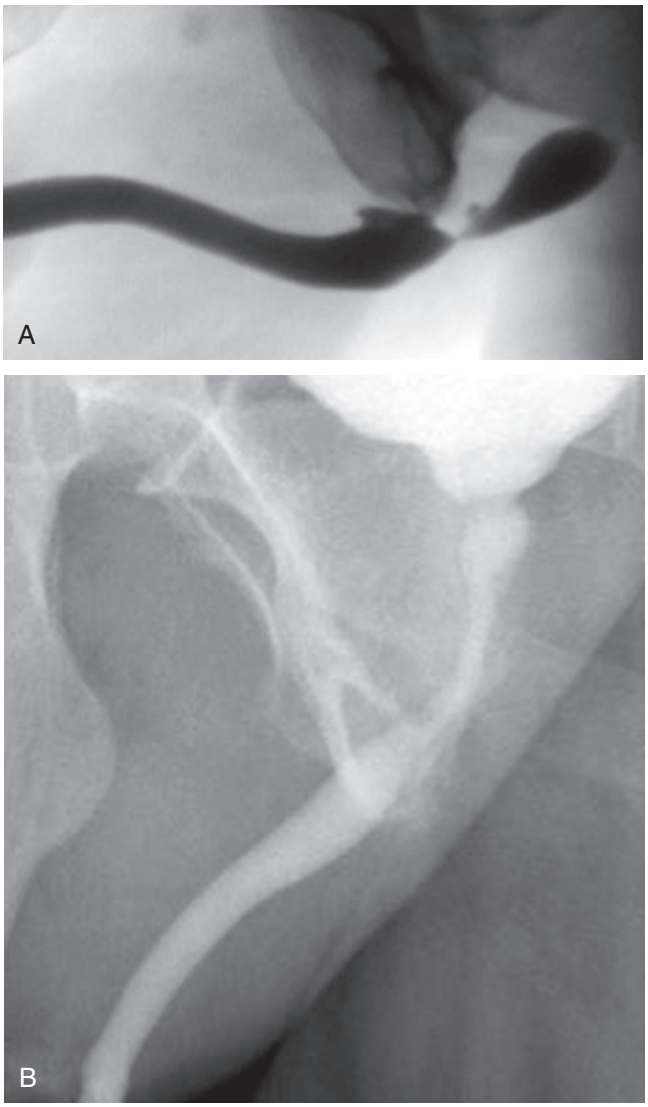
6. Which of the following statements is true regarding bladder trauma?
   a. Intraperitoneal bladder ruptures can be observed, provided the patient is stable
   b. All extraperitoneal bladder injuries should be managed conservatively with a catheter for 2 weeks
   c. Bladder ruptures are best diagnosed with ultrasound, as it does not expose the patient to radiation
   d. If a patient is undergoing exploration for concomitant injuries, one should repair extraperitoneal bladder injuries, as this will reduce the complication rate
   e. A suprapubic catheter is always necessary when repairing a bladder injury

7. The anatomic urethral segment that is most often injured concomitantly with a pelvic fracture is:
   a. Pendulous
   b. Bulbar
   c. Membranous
   d. Prostatic
   e. Fossa navicularis

8. When urethral injury is suspected in a trauma patient (i.e., blood at the meatus with inability to urinate), which is the appropriate next step?
   a. Retrograde urethrogram
   b. Catheter placement
   c. Cystoscopy with attempt at wire placement
   d. Operative exploration with urethroplasty
   e. Observation

9. When repairing a urethral distraction defect following a pelvic fracture urethral injury, the technical factor associated with the best long-term outcomes with lowest risk of recurrence is:
   a. Using a 12-suture anastomosis
   b. Complete excision of all fibrous scar tissue
   c. A 28Fr luminal caliber on both urethral ends
   d. Shorter operative time
   e. Surgery at a low-volume surgical center

10. The best initial management of a stable patient with a gunshot wound to the scrotum and no concomitant injuries is:
    a. Scrotal ultrasound to confirm injury
    b. Immediate exploration and repair
    c. MRI of the scrotum
    d. Observation
    e. Retrograde urethrogram



Case Studies

CASE 1

In 2006, an active duty soldier sustained a straddle injury and a bulbar urethral stricture developed over several months. He underwent an anastomotic urethroplasty, which remained patent for 4 years. However, in 2010 his stricture recurred and he failed two DVIUs and a dorsal inlay buccal mucosa graft (BMG), which failed immediately. He then had a repeat ventral onlay BMG urethroplasty. He presented 4 years later with epididymitis and complaints of obstructive voiding. His retrograde urethogram is pictured (Case Fig. 15.1).

1. The best approach to treating this patient's stricture is:
   a. DVIU
   b. Scrotal skin flap urethroplasty
   c. Split-thickness skin graft urethroplasty
   d. Repeat BMG urethroplasty
   e. Excision and primary anastomosis (EPA) urethroplasty

The patient underwent a reoperative EPA, with excellent urethral patency as shown in the VCUG Case Fig. 15.1, and to date has not experienced recurrence.

Case Figure 15.1

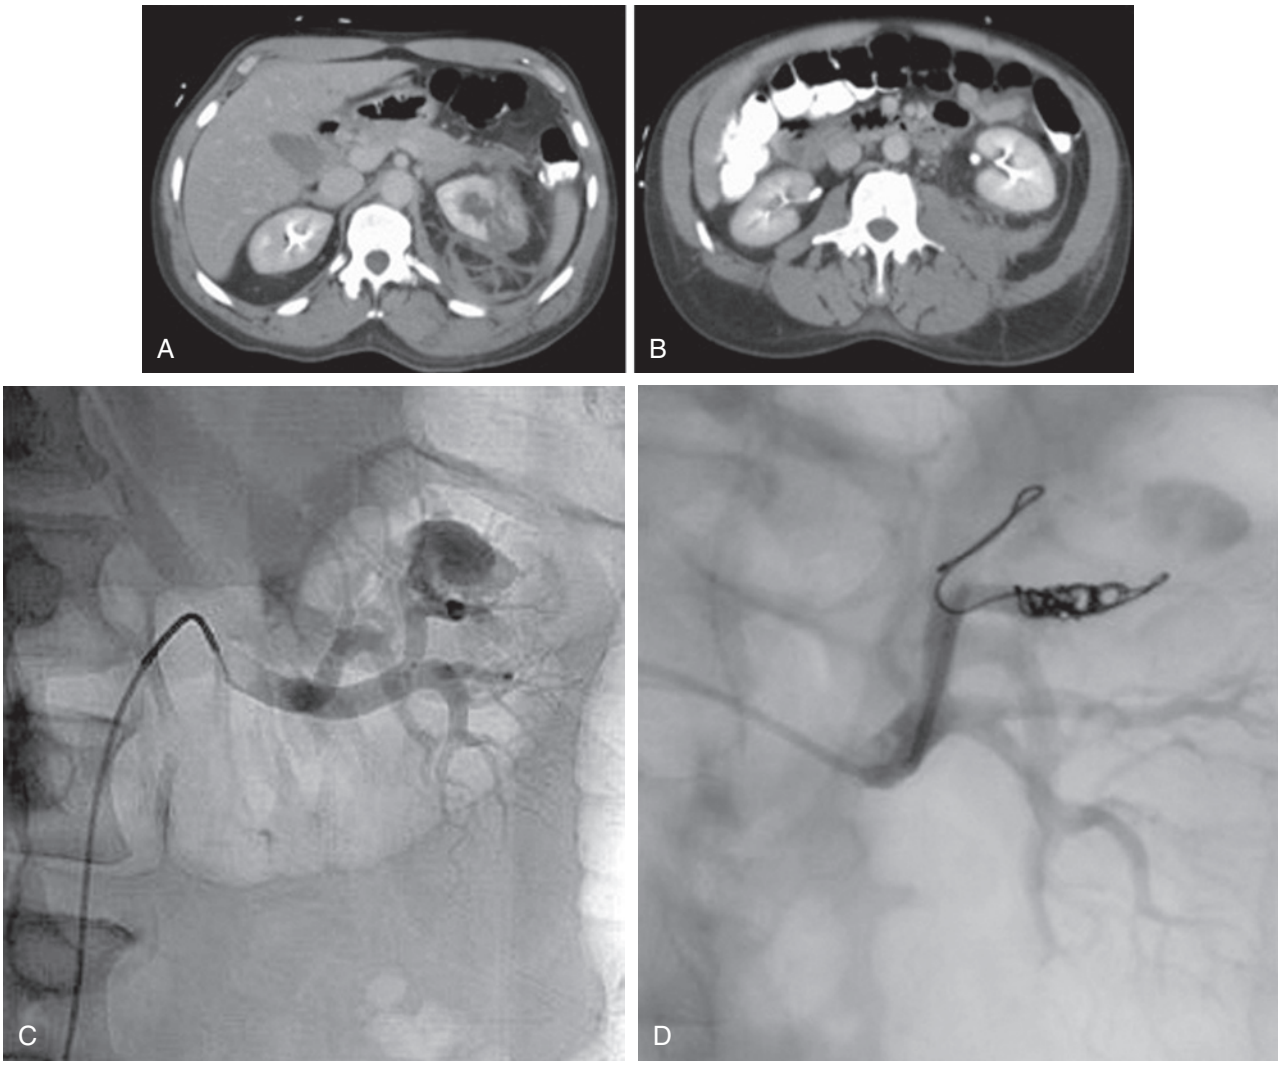
2. What is the success rate of EPA urethroplasty in this patient?
   a. <25%
   b. 26–50%
   c. 51–75%
   d. >75%
   e. 0%

3. What is the success rate of DVIU or dilation in this patient?
   a. <25%
   b. 26–50%
   c. 51–75%
   d. >75%
   e. 0%

CASE 2

A 51-year-old man was stabbed by his wife in the left flank. He was hemodynamically stable, and his urinalysis showed no red blood cells. His CT scans is in Case Fig. 15.2.

He had a grade 3 renal laceration with no urinary extravasation. He was clinically stable and discharged home on hospital day 3.



He then returned later the same day with gross hematuria. Hematocrit was 24%. Repeat CT scan with delayed images were largely unchanged, with no extravasation of contrast from either vascular or urinary structures. Over the course of 12 hours, his hematocrit dropped to 21%, and though he remained hemodynamically stable, an arteriogram was performed.

1. What is the diagnosis?
   a. Renal cell carcinoma
   b. Missed renal artery injury
   c. Pseudoaneurysm
   d. Missed collecting system injury
   e. Renal infection

2. What is the treatment for posttraumatic pseudoaneurysm?
   a. Open exploration
   b. Endovascular embolization
   c. Ureteroscopy and cauterization
   d. Observation
   e. Endovascular stenting

Answers

1. **c.** Injury to the kidneys is the most common genitourinary trauma encountered, accounting for 24% of traumatic abdominal solid organ injuries.
2. **b.** The current American Urological Association guidelines on urotrauma now advocate for noninvasive management of any patient with a renal injury who is hemodynamically stable, and compulsory intervention (either endovascular or surgical) in unstable patients with poor response to resuscitation. Contrast-enhanced CT scanning, with delayed images, remains the most common method for evaluating both vascular and collecting system trauma.
3. **c.** In patients with a persistent urine leak on repeat imaging (48 hours later), or with complications such as enlarging urinoma, fever, pain, ileus, fistula, or infection, urinary drainage with an internalized ureteral stent should be performed.
4. **d.** In cases where ureteral injury is suspected, intravenous contrast-enhanced axial imaging with delayed films is recommended, or direct visualization during laparotomy if no preoperative imaging is available.
5. **d.** Either a stent or percutaneous nephrostomy (if a stent cannot be placed) can divert the urine from a partial or delayed presentation of a ureteral injury, with a definitive repair at a later date, when the patient has recovered from the acute trauma.
6. **d.** While extraperitoneal bladder ruptures are typically managed with urethral catheter drainage alone, if the patient is undergoing a laparotomy for concomitant injuries, complication rates are lower if the bladder is repaired during the operation.
7. **c.** Injuries of the posterior urethra are typically "disruption" type injuries, usually occurring in conjunction

Case Figure 15.2

with multisystem trauma such as motor vehicle accidents, falls, or industrial accidents. These injuries are almost always encountered in conjunction with fracture of the anterior pelvic ring or pubic diastasis, with the degree of displacement correlated to a higher risk of urethral injury. Conversely, only 10–15% of pelvic fractures are associated with urethral injury.

8. **a.** In all patients suspected of a urethral injury due to blood at the meatus, inability to pass a catheter, perineal or penile hematoma, or high riding bladder on imaging, a retrograde urethrogram should be performed for evaluation of the urethra.
9. **b.** Following a pelvic fracture distraction injury, the resultant hematoma is replaced by fibrous scar tissue. The most important step in ensuring success of a posterior urethroplasty is complete excision of this scar tissue.
10. **b.** Ultrasound is the modality of choice in evaluating for testicular injury. The most common specific finding is loss of testicular contour with heterogeneous parenchymal echotexture. Early exploration and repair should be undertaken to prevent complications arising from rupture of the tunica albuginea. In cases where the initial trauma is penetrating in nature, immediate exploration is recommended to reduce complications.

CASE 1

1. **d.** Given that he has failed two BMG urethroplasties, his risk of recurrence and oral complications is higher should another BMG be harvested. DVIU has a dismal success rate in this setting, and the other choices of substitution urethroplasty are suboptimal. Excellent success rates of revision surgery with EPA have been demonstrated, and particular attention must be given to complete excision of the scarred tissue, as this was likely the cause of the previous failures.
2. **d.** If the surgeon adheres to the principles of complete scar excision and precise mucosal apposition of healthy urothelial edges, the expected results can approach those of primary EPA urethroplasty, even in the reoperative setting.

3. **a.** In fact, current literature suggests that having failed two dilations renders DVIU completely ineffective (0%) in maintaining urethral patency.

CASE 2

1. **c.** The patient's axial imaging did not suggest injury to either the collecting system or vasculature, and as he has gross hematuria at this time, a pseudoaneurysm is the most likely diagnosis.

2. **b.** One of the benefits of arteriography for the evaluation of renal trauma is that intervention can be performed in the same setting. By selectively embolizing bleeding vessels, the remaining renal parenchyma can be spared. Open exploration would likely result in nephrectomy due to intraoperative hemorrhage, and endoscopic methods and observation would be ineffective.

   The patient underwent coil embolization of the pseudoaneurysm and recovered with preservation of his left kidney and renal function.

Chapter 16 Questions and Answers

KEY POINTS

1. Obesity is a substantial, growing problem with broad medical impact.
2. Obesity has and important pathophysiologic impact on many urologic diseases.
3. Surgery in obese patients introduces unique issues which should be addressed to optimize outcomes.

In the decades obesity has quickly become a major worldwide problem. Worldwide, obesity has more than doubled since 1980, with estimates of nearly 2 billion people being at least overweight. In the United States, it is estimated that more than one-third of adults are obese and a staggering two-thirds of adults are at least overweight. Some estimates suggest that nearly 1 in 5 deaths in the United States can be attributed to obesity.[1] The incidence of obesity has nearly tripled in just over 50 years and continues to increase.[2] Fig. 16.1 illustrates the actual and predicted prevalence of obesity through 2030. It has been suggested that if the prevalence of obesity continues to rise at the current pace it could ultimately lead to a decline in life expectancy, which has not taken place in the last 2 centuries.[3]

The health implications of obesity are enormous, as obesity is a well-established risk factor for a number of chronic conditions, including type 2 diabetes and cardiovascular disease. In addition, obesity contributes to the increased incidence of death from several malignancies. Largely as a result of these multiple comorbid conditions, medical care comes at a significantly increased economic cost for the obese. In 2006, medical costs for an obese patient were $1429 higher, or 42% more, than that of a normal-weight patient.[4]

The World Health Organization (WHO) defines the terms *overweight* and *obese* as excessive fat accumulation presenting a risk to health. The most commonly used anthropometric measure of obesity is body mass index (BMI), which is a weight (in kilograms) divided by the square of height (in meters). The assumption of BMI is that adiposity is not reliant on height. The WHO has defined a BMI greater than 25 as overweight and greater than 30 as obese. The WHO classification of BMI is listed in Table 16.1. The validity of BMI has been supported by multiple studies that have shown correlation to densitometry estimates of body fat composition.[5] BMI may be a less reliable measure of central obesity, and as a result measures of waist-to-hip ratio and waist circumference have been used in several epidemiologic studies. Using BMI as a measure of obesity is certainly not perfect, but it is easily calculated and by far the most commonly used standard.

As the prevalence of obese patients continues to increase, so will the number of obese patients seeking urologic care. Compounding the issue is that obesity can increase the risks of several urologic diseases, including kidney cancer, aggressive prostate cancer, urolithiasis, and lower urinary tract symptoms (LUTS). More now than ever urologists must be aware of the challenges associated with caring for and operating on overweight and obese patients.

Condition-specific Considerations

MALIGNANT UROLOGIC DISEASE

Obesity as a risk factor for cancer first garnered attention as a result of a number of epidemiologic studies in the 1970s–1980s. Obesity has been linked to the development of a number of malignancies, most notably colon, breast (postmenopausal women), endometrial, esophageal, and kidney cancer. It has been estimated that 15–20% of all cancer deaths in the United States can be attributed to overweight and obesity.[6]

The biologic mechanisms linking obesity to cancer are not well understood, but likely involve the alterations obesity causes in metabolism and endocrine activity, as well as to peptide and steroid hormone production. Insulin resistance and hyperinsulinemia resulting from increased

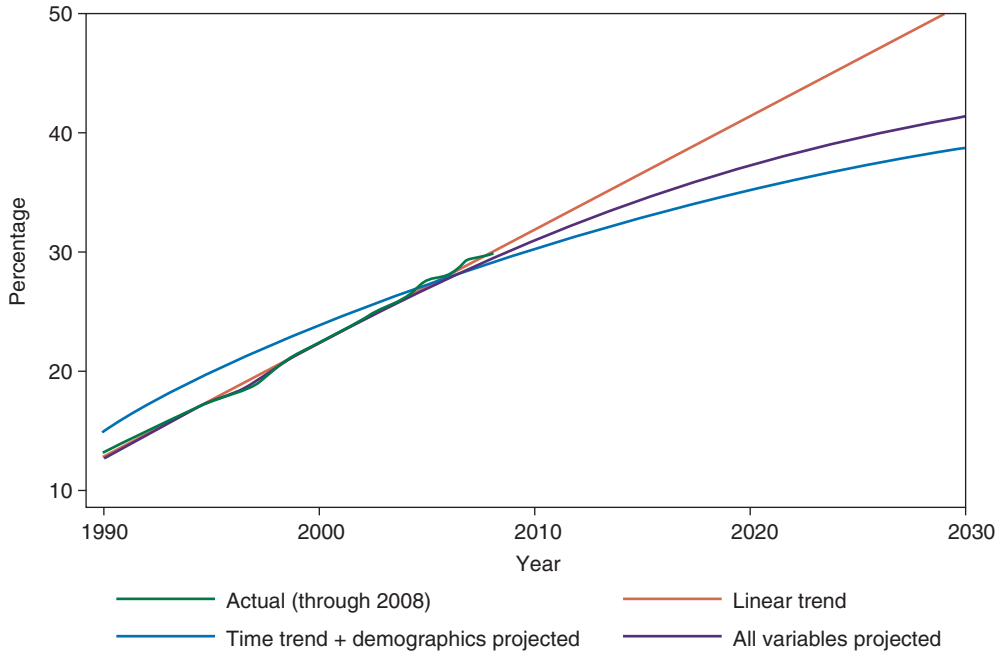

Figure 16.1 Actual and predicted prevalence of obesity (BMI ≥30) (From Finkelstein EA, et al. Obesity and severe obesity forecasts through 2030. American Journal of Preventive Medicine 2012;42.6:563-70.)

Table 16.1 The International Classification of Adult Underweight, Overweight and Obesity According to BMI

Classification	BMI(kg/m²)
Underweight	<18.50
Severe thinness	<16.00
Moderate thinness	16.00–16.99
Mild thinness	17.00–18.49
Normal range	18.50–24.99
Overweight	≥25.00
Pre-obese	25.00–29.99
Obese	≥30.00
Obese Class 1	30.00–34.99
Obese Class 2	35.00–39.99
Obese Class 3	≥40.00

(Adapted from WHO, 1995, WHO, 2000, and WHO 2004. World Health Organization. Obesity: preventing and managing the global epidemic. No. 894. World Health Organization, 2000.)

circulating levels of free fatty acids may play an important role in the development of several cancers. Insulin promotes synthesis of the hormone insulin-like growth factor 1 (IGF1), which has been shown to promote cell proliferation and inhibit apoptosis.[7] Additional support for hyperinsulinemia as a risk factor for cancer development lies in the association of many cancers with type 2 diabetes, which is typically associated with long-term insulin resistance and hyperinsulinemia.

Beyond the association with aggressive disease, obesity has a major influence on the surgical approach to urologic malignant disease. Commonly performed surgical procedures are found to be more difficult and complex among the obese, with an increased risk of perioperative complications, incomplete resection, and poor oncologic outcomes.

PROSTATE CANCER AND RADICAL PROSTATECTOMY

Obesity is a condition that can have a dramatic effect on sex hormones, specifically raising estrogen levels through increased aromatase activity and thus lowering testosterone levels. It is a logical step to think obesity may have an effect on the incidence of an androgen sensitive malignancy such as prostate cancer. Links between obesity and other sex hormone related malignancies, such as postmenopausal breast cancer and endometrial cancer, have been more clearly defined, but the data on prostate cancer and obesity are not as clear.

Several meta-analyses have been performed in regard to obesity and prostate cancer incidence with conflicting results. Some have found a weak positive correlation,[8] while others have found no significant effect.[9,10] As one might expect, the studies included in these analyses vary greatly in their findings, whether harmful or protective. Largely due to the heterogeneity of these findings and the lack of a consensus effect, prostate cancer has not typically been listed among malignancies in which obesity has a significant role.[5,11]

While overall incidence of prostate cancer may not be associated with BMI, there is a growing body of evidence that obesity is linked to particularly aggressive prostate cancer. A meta-analysis by MacInnis et al. found obesity increased risk for advanced disease with a relative risk (RR) of 1.12 (95%, CI 1.01–1.23) for every 5-unit increase in BMI.[8] Similarly, Discacciati et al. found an increased risk of advanced disease, RR = 1.09 (95%, CI 1.02–1.16), for every 5-unit increase in BMI while actually observing a protective effect in localized disease, RR = 0.94 (95%, CI 0.91–0.97).[12] This dual effect on localized and aggressive disease may help explain why no obvious relationship has emerged in regard to total incidence. An elevated risk of

aggressive disease, however, may help explain the association with increased risk of prostate cancer mortality in the obese. Calle et al. found a 34% increased risk of dying from prostate cancer with a BMI greater than 35 in a prospectively followed group of more than 900,000 people.[6] Similarly, in a meta-analysis performed by Cao et al., each 5 kg/m^2 unit increase in BMI increased risk of death from prostate cancer by 15%.[13]

Outcomes after radical prostatectomy seem to corroborate the notion that obesity may be associated with more aggressive disease. A multi-institutional review found obesity was associated with higher-grade tumors, a trend toward more positive surgical margins, and higher biochemical failure rates.[18] Similarly, data from the CaPSURE database showed increasing BMI was associated with biochemical recurrence, with very obese patients 1.69 times more likely to recur than normal-weight patients.[19] In addition, obese patients are less likely to regain urinary continence and sexual function after radical prostatectomy.[20–22]

Technical Considerations

Obesity can compromise both open and robotic-assisted prostatectomy techniques. In the case of open surgery, the depth of the incision compromises visibility and manual dexterity and limits the ability to expose neurovascular structures and the membranous urethral complex. A number of techniques have been implemented to improve apical exposure, including pubic osteotomy, but in general, when performing prostatectomy on obese patients, a generous incision, use of a multi-bladed fixed retractor, and surgical magnification are useful.

While robotic-assisted surgical techniques as compared to open surgery may allow better exposure of the deep pelvis and increased dexterity, obesity negatively impacts the technique as well. Obese patients are often unable to tolerate the steep Trendelenburg position due to increased airway pressure, diaphragmatic elevation, and difficulty with ventilation. Upon docking, arm movement can be made difficult by the presence of a large, protuberant abdomen, similarly limiting the reach of instruments to the deep pelvis. In these cases, careful port position selection, below the level of the most protuberant abdomen, can be helpful.

In approaching obese patients with prostate cancer, a recommendation for preoperative weight loss is reasonable, provided the patient's disease risk is not deemed to be excessive, risking progression upon delaying surgery. In general, patients who would benefit from radical prostatectomy have time for consideration of weight loss. If weight loss cannot be achieved, then alternative therapeutic approaches might be considered.

KIDNEY CANCER, NEPHRECTOMY, AND PARTIAL NEPHRECTOMY

Kidney cancer, specifically renal cell carcinoma, is one of the malignancies more firmly established as being associated with increased risk in the obese. The majority of epidemiologic studies have identified obesity as increasing the risk of renal cancer in a directly proportionate manner. Some have shown a greater risk for cancer in obese women compared to men, while others have shown a similar effect regardless of sex. A meta-analysis in 2001 of 11 studies found a relative risk of 1.06 and 1.07 for men and women, respectively, for each unit increase in BMI. This corresponds to a relative risk of 1.84 for an obese patient compared to a normal-weight patient.[23] In prospectively following more than 900,000 people, Calle et al. found that increased BMI correlated to an increased risk of death from kidney cancer of up to 70% in patients with BMIs greater than 35.[6] Hypertension and diabetes, both of which are commonly associated with obesity, are also established risk factors for kidney cancer. Despite possible confounding factors, obesity has been shown to increase risk of kidney cancer independent of hypertension.[24,25] With the majority of evidence showing a positive association, The International Agency for Research on Cancer, a part of the World Health Organization, has included kidney cancer among malignancies linked to obesity.

Like prostate cancer, obesity may have a large impact on how kidney cancer is surgically treated. This is an important point because more than half of patients undergoing surgery for kidney cancer will be at least overweight. The data are mixed on how obesity affects outcomes given the particular approaches for kidney surgery. Some data suggest obese patients have increased complications regardless of approach.[26] In the advent of laparoscopic surgery, obese patients were reported to have increased complications[26,27] and obesity was regarded as a relative contraindication to minimally invasive surgery. As experience increased, multiple reports showed similar outcomes among obese and nonobese patients.[28–30] Romero et al. compared open and minimally invasive partial nephrectomy in obese and nonobese patients and found obese patients undergoing open surgery had longer operative times, more blood loss, longer clamp times, increased complications, and longer hospital stays than did nonobese patients. In contrast, obese patients undergoing laparoscopic surgery had similar outcomes compared to nonobese patients except for greater blood loss.[31] A report using the National Surgical Quality Improvement Program from 2005 to 2012 showed patients undergoing laparoscopic partial nephrectomy had fewer overall complications than those undergoing open partial nephrectomy for all BMI categories, but the difference was largest for the morbidly obese, 22.2% versus 9.2%.[32] Robotic surgery has lowered some of the technical hurdles of laparoscopic partial nephrectomy, and many regard robotic partial nephrectomy as the procedure of choice for small renal masses. Obese patients undergoing robotic partial nephrectomy have similar outcomes compared to nonobese patients with the exception again of greater blood loss.[33,34]

Technical Considerations

In approaching the obese patient for renal tumor surgery, patient positioning is a critical consideration. Weight distribution during flank position can lead to increased risk of nerve injury, rhabdomyolysis, and compartment syndrome. Specific considerations for positioning are covered in Chapters 9, 31, and 37. In general, careful padding of the upper extremity; fixation of the arms, chest and pelvis; and avoidance of excessive flex can minimize positioning-related injuries. Elevation of the kidney rest should, likewise, be avoided to minimize pressure on the dependent muscles of the flank. In positioning the patient, either in full flank or

semi-oblique positions, the pelvis should be sufficiently rotated to distribute weight on the hip rather than the gluteal or presacral muscle compartments.

Mobilization of the kidney in the obese patient can present a unique challenge due to the abundance of perinephric fat and pericolic fat, as well as the depth of incision in the case of open surgery. Often fat surrounding the kidney can be inflamed, hypervascular, and adherent to the renal capsule. It is critical that the surgeon conduct the operation by first identifying critical anatomic structures surrounding the kidney, thereby minimizing the risk of inadvertent injury, and facilitating ultimate kidney mobilization for radical or partial excision. In the case of partial excision of the kidney, removal of excessive outer perinephric fat can aid in increasing mobility of the kidney during manipulation if partial nephrectomy is contemplated.

The decision for open versus laparoscopic renal surgery techniques is highly surgeon dependent. As in the case of other surgical procedures, open nephrectomy in the obese will likely require larger incisions, deeper exposure, and risk of perioperative morbidity as outlined below. Laparoscopic surgery should only be undertaken in the obese in the hands of experienced surgeons who can ensure that operative times are not excessive, in order to minimize the risk of positioning-related complications and pulmonary morbidity.

BLADDER CANCER

There is a general lack of evidence for a link between obesity and the incidence of bladder cancer. Several large epidemiologic studies fail to show an association between the two,[35–37] but there are limited data to support an association. Koebnick et al., using the NIH-AARP Diet and Health Study of nearly 500,00 people, found a positive correlation between BMI and bladder cancer with a relative risk of 1.28 (95%, CI 1.02–1.61) in those with the highest BMI.[38] Additionally, a meta-analysis of 11 cohort studies found a modestly increased risk of bladder cancer in the obese with a relative risk of 1.09 when controlled for smoking.[39] More recently, a systematic review of the literature by Cantiello concluded there is no consensus effect of BMI on the incidence of bladder cancer.[40] Perhaps more importantly, Calle et al. found no association between obesity and the risk of dying from bladder cancer in a cohort of more than 900,000 people.[6]

While there may not be consensus on whether obesity plays a role in the development of bladder cancer, there is evidence treatment is impacted in terms of outcomes and complications. In nonmuscle invasive bladder cancer, studies suggest obese patients have higher risks of recurrence, progression, and mortality.[41,42] In patients undergoing radical cystectomy, the obese have higher readmission rates, increased blood loss, and more complications,[43–45] specifically postoperative ileus[46] and parastomal hernia.[47,48] There are conflicting data regarding the impact of obesity on survival after radical cystectomy. In a multicenter review of over 4000 patients, Chromecki et al. found BMI >30 was associated with a higher risk of disease recurrence as well as disease-specific and overall mortality.[49] Other reports found no association.[50,51] Some reports suggest obese patients actually do better than normal-weight patients following radical cystectomy,[52,53] consistent with the "obesity paradox," or protective effect of obesity observed in a number of chronic conditions. Few would argue to advocate for increased levels of obesity for better outcomes after cystectomy; however, perhaps those with lower BMI, malnourishment, and lean muscle wasting are at greater risk. In a single institution series of patients undergoing radical cystectomy, Psutka et al. observed a protective effect in increased BMI, which was lost when adjusting for sarcopenia.[53]

Technical Considerations

Considerations for cystectomy in the obese patient are similar to those for prostatectomy. Exposure through wide incision and adequate retraction is essential, as is identification of critical vascular structures in the pelvis, prior to bladder mobilization. Urinary diversion can be particularly challenging in obese patients, owing to a thick, fat mesentery with limited mobility. Wide mesenteric incisions, to maximize bowel mobility, along with careful selection of bowel segment are essential. In forming a stoma, the Turnbull loop technique can be utilized if the bowel does not reach skin easily, as discussed in Chapter 45, but extending the distal mesenteric incision line may offer the most aid in lengthening of the segment.

LOWER URINARY TRACT SYMPTOMS

Obesity is a well-established risk factor for development of benign prostatic hyperplasia (BPH) and LUTS. In a longitudinal study of VA patients in 1985, Glynn et al. noted only BMI was a significant predictor of BPH.[54] More than a decade later, Hammarsten et al. found prostate size correlated with several components of metabolic syndrome, including not only obesity but also hyperinsulinemia, hypertension, and dyslipidemia.[55] Additional data have suggested BPH may be a consequence of metabolic syndrome, specifically from increased insulin levels.[55,56] Excess abdominal fat, or central obesity, is particularly recognized as a core component of metabolic syndrome. Correspondingly, Giovannucci et al. found that central obesity as measured by waist circumference was predictive of LUTS.[57] Multiple additional studies confirm this association.[56,58,59] In addition to being at higher risk for urinary symptoms, data suggest that patients with central obesity do worse following surgery for LUTS/BPH. Gacci et al. recently showed patients with a waist circumference greater than 102 cm are less likely to symptomatically improve, specifically in regard to storage symptoms after surgery.[60]

ERECTILE DYSFUNCTION

Sexual function is generally negatively impacted in the obese,[61] and erectile dysfunction (ED) is no exception. Obesity, and central obesity in particular, has been linked to ED in several studies.[62–64] ED is known to be multifactorial in origin, with vascular-, neurologic-, and endocrine-related etiologies. Obesity can have profound effects on each of these factors so an association with ED is not particularly surprising. Diabetes, of which obesity is a risk factor, can lead to microvascular compromise as well as autonomic neuropathy. Obesity is known to lower levels of testosterone and increase estrogens. Overweight and obese patients have

been estimated to have between a 1.5 and 3 times increased risk of developing ED.[65] Treatment of ED in the obese may be particularly difficult, especially in diabetics because pharmacologic therapy in these patients is not as effective. In a randomized trial, Esposito et al. demonstrated lifestyle changes and weight loss improved sexual function in up to one-third of obese men with ED.[66]

These observations are important when counseling men undergoing radical prostatectomy as the increased risk of ED in the obese population likely influences recovery of erections following surgery.

UROLITHIASIS

As the prevalence of obesity has dramatically increased in recent years, so has the prevalence of stone disease.[67] Epidemiologic studies have increasingly linked the two conditions. Using data from the Nurses' Health Study I and Health Professionals Follow-Up Study, Curhan et al. reported an increased risk of stone formation with higher BMI in women but not men.[68] A later report using the same datasets, in addition to the Nurses Health Study II, found BMI was associated with increased risk of kidney stone formation in both men and women, with obese men having a 1.33 and obese women having a 1.9–2.09 times increased risk of those with BMIs from 21 to 22.9. Moreover, weight gain itself was associated with increased risk of kidney stone formation, as was central obesity measured by waist circumference.[69] Reasons for increased risk of stones with obesity are likely multiple and associated with various components of metabolic syndrome. Hyperinsulinemia and resultant insulin resistance are associated with impairments in renal ammonium production,[70] with obese and diabetic patients shown to form more acidic urine.[71,72] Low urinary pH is an important risk factor for uric acid stones, but defects in renal acid handling may also lead to hypocitraturia.[73] Hyperinsulinemia can lead to increased urinary calcium excretion,[74] and both hypocitraturia and hyperinsulinemia increase the risk for calcium oxalate stones.

Obesity may further play an important role in which surgical treatment modality is chosen for stones. Current European Association of Urology guidelines state morbid obesity is an indication for open stone surgery, but few are eager to perform such procedures due to associated morbidity. Extracorporeal shock wave lithotripsy (ESWL) seems less effective in the obese.[75,76] Issues with ESWL in the obese may include poor fluoroscopic targeting and increased skin to stone distance.[75,77,78] In a systematic review of seven studies, Aboumarzouk et al. found a stone-free rate of 87.5% in patients with a mean BMI of 42.2 undergoing flexible ureteroscopy.[79] In expert hands, percutaneous nephrolithotomy (PCNL) in the obese has similar stone-free rates (SFR) with minimal complications,[80–84] although potentially with increased operative times and more radiation exposure.[84] A prospective review of 5803 patients from the Clinical Research Office of the Endourological Society (CROES) database showed PCNL could be done safely in the obese but resulted in lower SFR and more repeat procedures.[85] Several factors make PCNL challenging in the obese. From an anesthetic perspective, the prone position can compromise respiratory function and venous return, particularly in the obese.[86] Standard instrumentation and techniques may need modification due to the anatomy of the obese patient and increased skin to stone distance. Several strategies are suggested to improve success, including use of extra-long nephroscopes, long access sheaths, or suture tails to allow burying of sheaths within the subcutaneous fat.[83,87] Regardless of approach, surgical treatment of stones in the obese requires both surgeon experience and the thoughtful analysis of all available options (Table 16.2).

Table 16.2 Impact of Obesity on Urologic Conditions

	Increased Risk	Impact on Treatment
Prostate cancer	Overall: ↔ Aggressive disease: ↑	■ Higher risk of recurrence ■ Less likely to regain continence and sexual function
Kidney cancer	↑↑	■ Minimally invasive surgery may result in fewer complications
Bladder cancer	↔	■ May have worse outcomes after treatment for NMIBC ■ Blood loss, ileus, readmissions may be increased ■ Late complications such as parastomal hernia and ureterointestinal stricture may be increased
Lower urinary tract symptoms	↑	■ Surgery may not be as effective, specifically in regard to storage symptoms
Erectile dysfunction	↑	■ Oral agents may be less effective in those with diabetes
Urolithiasis	↑↑	■ ESWL less effective ■ PCNL may be challenging

NMIBC, non-muscle invasive bladder cancer; ESWL, extracorporeal shockwave lithotripsy; PCNL, percutaneous nephrolithotomy

Conclusions

Obesity has become a major medical problem that continues to grow. It has important associations with a number of chronic medical conditions. In urology, obesity is most strongly associated with increased risk of kidney cancer and is also linked to aggressive prostate cancer, urolithiasis, LUTS, and ED. Surgery in the obese is associated with higher risk of positioning complications, wound complications, and venous thromboembolism. Additionally, obese patients may have worse outcomes following some procedures such as prostatectomy. These risks, along with surgeon expertise and experience, should be carefully considered prior to surgery on the obese patient.

Chapter 16 Questions

1. According to current data, the prevalence of which urologic disease is least associated with obesity?
   a. Advanced prostate cancer
   b. Bladder cancer
   c. Kidney cancer
   d. Urolithiasis
   e. Lower urinary tract symptoms

2. Which peripheral nerve is most likely to be injured perioperatively?
   a. Ulnar nerve
   b. Peroneal nerve
   c. Brachial plexus
   d. Obturator nerve
   e. Femoral nerve

3. The mainstay of treatment for well leg compartment syndrome is:
   a. Fluid resuscitation
   b. Antibiotics
   c. Intermittent compression devices
   d. Fasciotomy
   e. Anticoagulation

4. All of the following comorbidities have been associated with obesity except:
   a. Obstructive sleep apnea
   b. Type 2 diabetes
   c. Risk of stroke
   d. Coronary artery disease
   e. Ureteropelvic junction obstruction

5. Obese patients may be less likely to resolve which symptoms after surgery for lower urinary tract symptoms (LUTS)?
   a. Storage symptoms
   b. Emptying symptoms
   c. Storage and emptying symptoms
   d. None, they do just as well as the nonobese
   e. Surgery for LUTS in the obese is contraindicated

6. Which closure method is best to reduce the rate of incisional hernia?
   a. Large bite interrupted with a braided suture
   b. Small bite running with a monofilament suture
   c. Large bite running with a braided suture
   d. Small bite interrupted with a monofilament suture
   e. Large bite running with a monofilament suture

7. Which of the following is/are risk factors for the development of well leg compartment syndrome?
   a. Lithotomy position
   b. Trendelenburg position
   c. Hypotension
   d. Obesity
   e. All of the above

8. Reasons for increased stone formation in the obese include:
   a. Impairments in renal ammonium production
   b. Hypocitraturia
   c. Increased urinary calcium excretion
   d. Decreased urinary pH
   e. All of the above

9. According to recent estimates, approximately what proportion of the US population is obese?
   a. ⅓
   b. ⅔
   c. 1/2
   d. 1/10
   e. 4/5

Answers

1. **b.** While prostate cancer has not been formally listed as a disease for which obesity has a significant role, obesity has been linked, in many studies, with an increased risk of advanced prostate cancer. The World Health Organization lists kidney cancer as a malignancy related to obesity. Both urolithiasis and lower urinary tract symptoms are linked to obesity, while bladder cancer has never been shown to have a link.
2. **e.** The ulnar nerve is most commonly injured and is an increased risk in the obese. The ulnar nerve is vulnerable to compression in the cubital tunnel at the elbow and protection requires support of the arm and careful padding of the elbow.
3. **d.** Compartment syndrome is a rare and potentially catastrophic complication requiring prompt clinical diagnosis and treatment. When this occurs in a nontraumatized, otherwise healthy lower limb, it is termed *well leg compartment syndrome* (WLCS). Measurement of intracompartmental pressures (ICP) confirms diagnosis, and the general consensus is that ICP within 20 mm Hg of diastolic is an indication for fasciotomy.
4. **e.** Ureteropelvic junction obstruction has not been linked to obesity, while all other listed operative comorbidities are observed with greater frequency among obese patients.
5. **a.** In addition to being at higher risk for urinary symptoms, data suggest that patients with central obesity do worse following surgery for LUTS/benign prostatic hyperplasia. Gacci et al. recently showed that patients with a waist circumference greater than 102 cm are less likely to symptomatically improve, specifically in regards to storage symptoms after surgery.
6. **b.** Meta-analyses have shown a running technique with long-lasting monofilament suture reduces incisional hernia rates. Additionally, a running technique taking small bites of 5 mm every 5 mm reduced the rate of incisional hernia in a recent randomized prospective clinical trial.
7. **e.** Obesity, intraoperative hypotension, steep Trendelenburg position, and lithotomy position are all associated with various forms of lower extremity compartment syndrome.
8. **e.** Reasons for increased risk of stones with obesity are likely multiple and associated with various components of metabolic syndrome. Hyperinsulinemia and resultant

insulin resistance are associated with impairments in renal ammonium production, with obese and diabetic patients shown to form more acidic urine. Low urinary pH is an important risk factor for uric acid stones, but defects in renal acid handling may also lead to hypocitraturia. Hyperinsulinemia can lead to increased urinary calcium excretion, and both hypocitraturia and hyperinsulinemia increase the risk for calcium oxalate stones.

9. **a.** In the United States, it is estimated that more than one-third of adults are obese and a staggering two-thirds of adults are at least overweight.

Chapter 17 Questions and Answers

KEY POINTS

1. Lithogenic urinary changes occur during pregnancy.
2. When encountering nephrolithiasis during pregnancy, conservative measures should be initially considered. If surgery is indicated and/or necessary, options include temporary drainage with ureteral stent or nephrostomy tube placement, or definitive therapy with ureteroscopy. Shock wave lithotripsy is contraindicated in pregnancy.
3. If imaging is necessary for a pregnant patient, ultrasound is a simple and inexpensive test that may provide important information. If non-diagnostic, MRI is also considered safe to use in pregnancy. The use of computerized tomography exposes both mother and unborn child to ionizing radiation; its role continues to evolve.
4. Urinary tract infections are common in pregnancy, and the most frequent bacterial cause is Enterobacter.
5. Urologic malignancies are rare in pregnancy. If they are present and warrant treatment, both open and laparoscopic approaches have been reported to be successful.

Introduction

Although surgery is a mainstay of urologic practice, in the pregnant patient it introduces a myriad of challenges due to both the presence of the developing unborn child and the requisite physiologic changes induced in the mother. The unborn child, during critical periods of rapid development, may be particularly vulnerable to adverse effects induced by urologic disease, its diagnosis, and therapeutic interventions.

Management of common urologic problems, diagnostic options, therapeutic concerns, and the potential complications that may be encountered may all therefore be significantly altered in this unique population. Herein, we shall review underlying concerns for the pregnant patient; implications for diagnosis of pertinent urologic disease; surgical considerations for open, laparoscopic, and endoscopic surgery during pregnancy; and complications specific to the pregnant population.

The Pregnant Patient

Although select urologic problems such as placenta percreta are truly unique to the pregnant patient, the most commonly encountered urologic issues in pregnant patients are, in fact, common urologic problems. The complexities of their diagnosis and management arise from issues of the pregnancy itself. Therefore it is imperative to begin with a review of concerns specific to the expectant mother.

PHYSIOLOGIC CHANGES DURING PREGNANCY

The fetus subjects the mother to a host of metabolic demands, and both temporary and evolving physical alterations, all of which may affect surgical and anesthetic concerns. Although a comprehensive review of these alterations would be prohibitive in this context, a brief review of important points is presented.

Cardiovascular Considerations

To accommodate growing requirements for oxygen and nutrition delivery, cardiac output increases by an estimated 30–50%. The vasodilating effects of prostacyclin and progesterone in addition to the low vascular resistance of the placenta cause a reduction in systemic vascular resistance, contributing to increased cardiac output. This is augmented further by increases in both heart rate and stroke volume as pregnancy progresses.[1,2]

Of particular clinical importance, this new elevated baseline cardiac output can be threatened through otherwise innocuous surgical positioning. By the second trimester, the gravid uterus emerges more prominently from the pelvis and can cause clinically significant compression of the inferior vena cava in the supine and lithotomy positions, with resultant acute drop in venous return and cardiac output. Hence, standard supine and lithotomy positions should be avoided in favor of right-sided elevation of 15–20 degrees to accomplish a left lateral tilt, thereby reducing uterine compression of the vena cava and optimally preserving cardiac output.[2]

Respiratory Considerations

Several competing alterations will affect respiratory and airway considerations in the pregnant patient. The enlarging gravid uterus ascends from the pelvis and – in concert with pregnancy-related weight gain – can exert mechanical restriction on respiration. These combined effects may result in a subsequent decline in functional residual capacity. Offsetting these mechanical concerns, early in the first trimester both respiratory rate and tidal volume increase. These changes lead to increased minute ventilation and address increasing maternal and fetal oxygen requirements.[1] A clinically pertinent effect of the increased minute ventilation is observation of a mild respiratory alkalosis, attenuated by increased renal bicarbonate secretion.[2]

Airway management is complicated by anatomic changes of pregnancy. The aforementioned weight gain of pregnancy increases the difficulty of intubation. Furthermore, edema of the oropharynx, larynx, and trachea may limit endotracheal tube placement and increase risk of bleeding and trauma related to establishment of an airway. Finally, concerns regarding decreased reliability of the gastroesophageal sphincter lead to increased risk of regurgitation and aspiration.[3]

Hematologic Considerations

Blood volume increases throughout pregnancy, ultimately increasing up to 40–50% by term.[1,4] Because the expansion of plasma outpaces the increase in red blood cell volume, there is a resultant dilutional anemia associated with pregnancy.[4] Additionally, a leukocytosis up to 15,000 WBC per microliter may be encountered during normal pregnancy, thereby potentially raising a false concern for systemic infection.[1] Finally, pregnancy is considered a hypercoagulable state due to increased fibrinogen, factor VII, VIII, X, and XII and decreased fibrinolysis, increasing the risk of thromboembolic events.[1,4,5]

Renal Considerations

There is a physiologic 30–50% increase in glomerular filtration rate during pregnancy. At the tubular level, there is a subsequent increase in urinary excretion of calcium and uric acid, which are both potential promoters of stone formation.[6] Additionally, urine pH is typically elevated, potentially related to increased urinary bicarbonate excretion to compensate for the aforementioned respiratory alkalosis. Increased excretion of citrate and thiosulfate, putative inhibitors of stone formation, is thought to offset the effects of the hypercalciuria.[7]

At the macroscopic level, mechanical compression by the gravid uterus at the level of the pelvic brim leads to dilation of the ureter and renal pelvis. This is most pronounced on the right side, with right greater than left dilation seen in 86% of imaging in one retrospective study.[8] The differential lateralization is likely related to both typical dextrorotation of the uterus as well as protective cushioning of the left ureter provided by the sigmoid colon. Besides mechanical events, hormonal effects also contribute with a suspected progesterone-mediated decrease in ureteral peristalsis.[7]

ETHICAL CONSIDERATIONS FOR UROLOGIC SURGERY DURING PREGNANCY

The previous section highlights some of the many unique physiologic changes due to pregnancy. The source underlying all of these changes is the developing child in utero. Herein also lies the critical challenge of urologic care of the pregnant patient – diagnostic and therapeutic decisions may directly affect not only the patient but also her child. Medical decision making for the pregnant patient is therefore complicated by concerns on many levels, from the patient's concerns regarding her health and the health of her child, the practitioner's attempts to maximize benefit while minimizing risks, and practical concerns regarding medico-legal risks.

In most instances, sound medical judgment aimed at taking the best care of the mother will result in taking the best care of the child. Similarly, it has been proposed that the interests of the mother will typically converge with the interests of her child.[9]

Challenging dilemmas may arise from maternal–fetal conflicts, in which either maternal actions or refusal to undergo tests or procedures directly endanger the fetus.[10] Fortunately, such conflicts do not typically arise in the context of maternal urologic disease covered here. Nevertheless, it has been recommended that due to the wide variety of motivations for such conflicts, it is critical to open a dialogue with the patient to discern the conflict, alleviate concerns, and improve the understanding of risks and benefits so as to preserve and strengthen the doctor–patient relationship.[10] The American College of Obstetrics and Gynecology (ACOG) issued a committee opinion on maternal decision making in 2005, recommending that first and foremost, the patient's autonomy in decision making should be respected. ACOG further argues against coercive legal action when these decisions fail to agree with medical recommendations, as such action would deny the mother's autonomy, potentially criminalize informed decisions, and fail to acknowledge that the medical knowledge underlying our recommendations remains imperfect.[9]

In summary, the cornerstone of medical decision making for the pregnant patient should be based on the well-informed mother understanding the relative risks and benefits of proposed interventions. These risks and benefits apply to both her and her child, recognizing the inherent limitations in medical knowledge. When conflicts arise, further counseling may divulge underlying concerns, and consultation with involved stakeholders including the patient, her family, the obstetric team, and the hospital ethics committee if needed may allow an informed and appropriate resolution.

Urologic Disease During Pregnancy

UROLITHIASIS

Kidney stones rightfully evoke significant concern for incapacitating pain. As such, they represent a source of significant anxiety. When coupled with the concerns of pregnancy, anxiety can rapidly mount for the patient, her family, and her medical providers. Symptomatic renal colic prompting admission increases the risk of preterm premature rupture of membranes and nearly doubles the risk of preterm delivery.[11,12] Unfortunately for all involved parties, urolithiasis during pregnancy is not an uncommon clinical scenario.

Epidemiology

Renal colic secondary to urolithiasis is considered the most common cause of nonobstetric hospitalization in the pregnant patient.[13] Widely varying estimates suggest that up to 1:200 women may suffer renal colic during pregnancy.[14] Gravid stone formers are most likely to be Caucasian.[11,12] Of those suffering stones during pregnancy, the majority will present in the latter half of gestation.[11,15]

The majority presenting with stones during pregnancy were not previously identified stone formers, but rather first-time stone formers.[11] Among those who are affected by urolithiasis during pregnancy, their subsequent risk of recurrent stone formation remains to be defined.

Etiology of Stone Disease During Pregnancy

A myriad of potential etiologic factors in stone formation during pregnancy have been proposed. Physiologic changes of urine chemistry increase the lithogenicity of urine during pregnancy. In particular, maternal hypercalciuria, hyperuricosuria, and elevated urine pH are all well-recognized pro-lithogenic changes during gestation.[6] The alkaline urine dramatically reduces solubility of calcium phosphate, which is reflected in the fact that approximately 75% of stones in pregnancy are calcium phosphate.[16] Despite substantial predisposition to stone formation, it is reassuring to remember that most women do not have stones during pregnancy, a fact attributed to the physiologic protection in the form of increased urinary inhibitors of stone formation including citrate.[6,7,14]

It has been hypothesized that stagnant urine in a hydronephrotic system may contribute to stone formation.[17] Thus the aforementioned "physiologic" hydronephrosis of pregnancy may be causative or coincidental to stone formation during pregnancy. As previously noted, direct external impingement upon the ureter by the enlarged uterus at the level of the iliac vessels is oft considered a primary means for mid- and proximal ureteral dilation. Ureteral dilation may additionally be a result of progesterone-induced relaxation of ureteral smooth muscle.[18] It is important to note that this dilation may obfuscate both diagnosis of ureterolithiasis and the differentiation of obstructing stone from unrelated loin pain during pregnancy.

Diagnosis of Stones During Pregnancy

The diagnosis of urolithiasis remains an imperfect art. The abdominal and loin pain of renal colic – as well as their associated nausea and emesis – are not unique to nephrolithiasis. Indeed, a large retrospective review confirmed clinical signs and symptoms alone are often inadequate to predict obstructing stones during pregnancy.[19] Even among women hospitalized for suspected acute renal colic during pregnancy, stone was confirmed in only 29%.[20] This clinical experience underscores the challenge of accurate diagnosis despite the availability of powerful diagnostic tools and enhanced imaging techniques. Attempting to predict the 29% of pregnant women with a confirmed stone diagnosis,

Figure 17.1 Ultrasound shows an obstructing right proximal ureteral stone in a pregnant patient.

Figure 17.2 Low-dose CT scan demonstrates a small left ureteral stone (arrow) in a pregnant patient.

this study found left-sided hydronephrosis >10 mm as the only significant predictor on multivariable analysis.[20] This emphasizes the confusion caused by frequent right-sided hydronephrosis and underscores the fact that the ubiquity of right-sided renal pelvic dilation in later gestation reduces the utility of ultrasound.

Nevertheless, with widespread prenatal use confirming its safety profile, ultrasound (US) remains the cornerstone of diagnostic imaging during pregnancy (Fig. 17.1). No adverse effects to mother or child have been identified. With neither ionizing radiation nor intravenous contrast administration, US is widely accepted as appropriate for use during pregnancy.

In the setting of a markedly dilated ureter, the sonographer may be able to follow the ureteral course and identify an obstructing ureteral stone, although this is the exception as opposed to the rule. Transvaginal ultrasound may allow visualization of distal ureteral stones between the transducer and the bladder when located near the ureterovesical junction. Finally, functional information may be inferred from Doppler US measurements of systolic and diastolic renal arcuate arterial blood flow. An increased renal resistive index has been utilized to successfully differentiate nonobstructive hydronephrosis of pregnancy from hydronephrosis due to ureteral obstruction.[19,21]

Although computerized tomography (CT) has clearly emerged as preferred imaging for urolithiasis in the general population, concerns regarding fetal radiation exposure continue to limit its use in pregnancy (Fig. 17.2). Advocates for CT, however, point out that its accuracy outperforms both US and magnetic resonance imaging (MRI), and radiation doses can be reduced to levels considered below the threshold for inducing fetal anomalies (Fig. 17.3).[22,23]

Management of Stone Disease in Pregnancy

An accurate diagnosis is of great importance, as symptomatic urolithiasis has been linked to maternal and fetal morbidity.[12,24] Definitive diagnosis of a ureteral stone may clarify management options but is often elusive in the parturient. In the absence of endoscopic inspection or CT demonstration, it is often impossible to confirm a ureteral stone. Therefore conservative options remain attractive in order to reduce occurrence of unnecessary surgical interventions (Fig. 17.4). As in the general population, in the absence of absolute indications to intervene one may pursue a course of active surveillance to assess for stone passage.

Medical expulsive therapy (MET) with alpha-blockers is an increasingly embraced adjunctive therapy aimed at increasing stone passage rate. To date, there has been only one study specifically reporting upon MET with tamsulosin during pregnancy. This retrospective study of 27 pregnant patients receiving tamsulosin to expedite passage of presumed ureteral stones specifically assessed perinatal outcomes.[25] In this cohort study, subjects were matched not for predictors of stone passage (e.g., stone size or stone location) but rather for risk factors for adverse neonatal outcomes (tobacco use, prematurity, or small for gestational age). Thus, stone passage was not a primary outcome and the trial was not designed to assess for this. Nevertheless, they observed a 24% increased stone passage rate in the MET group and reported that there was no statistically significant difference in perinatal outcomes. There were two cases of sudden infant death syndrome in the MET group and none in the control group, although the authors noted that there was no obvious mechanistic explanation for this, and the difference was not significant ($p = 0.11$).[25]

If conservative management is not indicated (e.g., uncontrollable pain or nausea, bilateral obstruction or unilateral obstruction of a solitary functioning kidney with subsequent worsening renal function) or if attempts at conservative management have failed, surgical intervention may be considered. These maneuvers include temporizing options including ureteral stent or nephrostomy tube placement, as well as definitive ureteroscopic stone removal. Shock wave

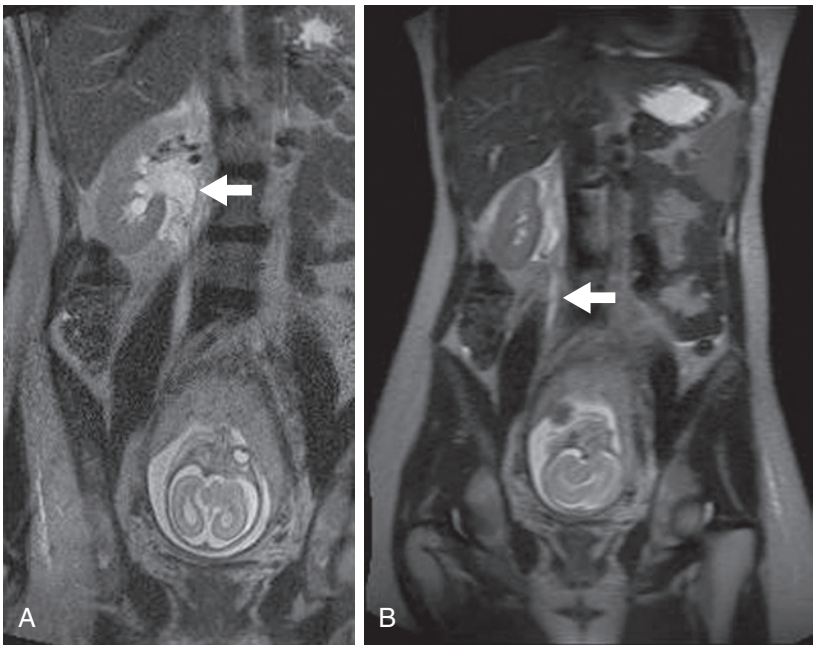

Figure 17.3 MRI of a pregnant patient with right renal colic. A, T2-weighted MRI without contrast reveals right hydronephrosis (arrow). B, Filling defect noted on HASTE MRI without contrast in the right proximal ureter later confirmed to be a 5-mm ureteral stone.

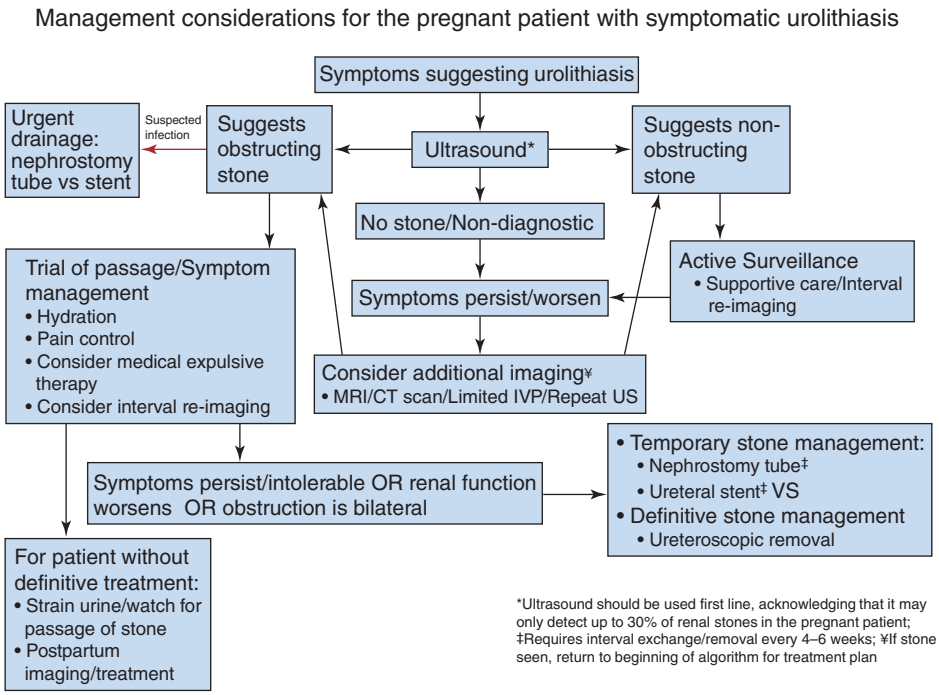

Figure 17.4 Management considerations for the pregnant patient with symptomatic urolithiasis.

lithotripsy (SWL) is contraindicated during pregnancy due to concerns of catastrophic fetal injury from shock wave injury.

COMPLICATIONS

In light of concerns of the effect of the gravid habitus on ureteroscopic maneuverability, a meta-analysis of reports of ureteroscopy during pregnancy was performed, identifying an overall 8.3% risk of endoscopic complications, Clavien grades 1–3, which did not differ from rate of endoscopic complications in the nonpregnant population.[26]

However, arguably the most noteworthy problem encountered in the surgical treatment of stones during pregnancy – accelerated stent encrustation – is not typically labeled a postoperative "complication" at all. As a result of the aforementioned physiologic changes to urine chemistry during pregnancy, aggressive accelerated stent

encrustation must be anticipated in this population. Since the earliest reports of stent use in pregnancy, rapid encrustation has been repeatedly encountered, often complicating stent removal or exchange.[27] Similarly, accelerated encrustation of nephrostomy tubes may be encountered. The best management is truly prevention, with recommendation for maintenance of excellent hydration and planned stent exchange every 6–8 weeks. Despite proactive preventative strategies, encrustation may still occur in this high-risk population. In order to reduce risk of ureteral injury or avulsion, only gentle attempts at extraction of a suspected encrusted stent should be pursued, and the attempts should be abandoned if resistance is encountered. Temporizing strategies may be employed, including placement of an adjacent, "tandem" stent to allow upper tract drainage and provide additional ureteral dilation. Additionally, one may place a nephrostomy tube to ensure drainage. In either case, the encrusted stent will require more extensive intervention in the postpartum period for extraction, including SWL of proximal encrustations, ureteroscopic lithotripsy, and/or percutaneous nephrolithotomy and extraction.[28] Additionally, others have reported ureteroscopic lithotripsy of the offending stone and stent encrustations during pregnancy to free the entombed stent and reduce the symptomatic burden as expeditiously as possible.[29]

URINARY TRACT INFECTIONS

Urinary tract infections (UTIs) remain one of the most frequently diagnosed and treated infections among women. Pregnancy increases the risk of contracting a urinary infection, the diagnosis of which is associated with adverse outcomes for both the mother and the fetus. As these infections may be encountered perioperatively and the urologist will be called upon to manage these issues, a brief review is presented. Special considerations for the pregnant woman include the role of screening for asymptomatic bacteriuria – an often otherwise benign condition in most populations – and antibiotic selection that is mindful of potential fetal effects. In the following section we review the epidemiology of urinary tract infections and their diagnosis, management, and treatment.

Epidemiology and Risk Factors of Urinary Tract Infections During Pregnancy

UTIs represent a significant public health burden; over 10 million ambulatory visits and nearly 1 million emergency department visits in the United States are attributed to UTIs annually.[30,31] Women bear the majority of these infections, and pregnancy itself is an independent risk factor for UTIs. Other risk factors for UTIs include diabetes, sexual intercourse, urologic instrumentation, history of UTIs in childhood, functional/anatomic abnormalities of the urinary tract, etc.

UTIs are the most common bacterial infection occurring during pregnancy.[32] Several normal physiologic changes occur during pregnancy that may contribute to an increased risk of UTI. These include dilation of the urinary tract, compression of the bladder by the growing uterus, urinary stasis and increased reflux, and changes to the urine itself, which may favor bacteriuria[33–35]

UTIs may be categorized anatomically into broad categories of cystitis if confined to the lower tract (including asymptomatic bacteriuria) and pyelonephritis if the UTI involves the upper urinary tract. Of particular importance, pregnancy increases the risk of cystitis progressing to pyelonephritis by 40%.[33,34]

Implications of Urinary Tract Infections and Asymptomatic Bacteriuria During Pregnancy

UTIs during pregnancy are associated with both maternal morbidity and adverse outcomes for the fetus including preterm birth and low birth weight.[34] In fact, several professional organizations recommend both screening for and treating even asymptomatic bacteriuria during pregnancy, including the U.S. Preventative Task Force (USPTF), the American College of Obstetricians and Gynecologists (ACOG), and the American Academy of Family Physicians.[34,36] Due to these recommendations screening is implemented in the vast majority of obstetric care.

Asymptomatic bacteriuria (ASB) is defined as $\geq 10^5$ colony forming units of a single bacterium per milliliter of urine in two urine samples.[37] ASB is diagnosed in approximately 5% of pregnant women.[38] Considered a benign condition for nonpregnant patients, ASB during pregnancy increases the risk of maternal pyelonephritis, preterm delivery, and low fetal birth weight.[33,39–41] A recent Cochrane review confirmed that antibiotic treatment of ASB reduced incidence of low birth weight but not preterm deliveries.[42] The USPTF recommends first trimester screening with a urine culture, although a positive urinalysis without culture should still receive proper treatment.[36] Following treatment for ASB, a follow-up culture should confirm effective treatment, with consideration for prophylactic treatment for the remainder of the pregnancy.[41]

Pyelonephritis due to ASB in pregnancy has decreased significantly in the setting of routine screening; however, it remains a significant health burden being diagnosed in 1–2% of pregnant women.[43] Pyelonephritis is a clinical diagnosis, and urine culture is the diagnostic test of choice. Blood cultures are inconsistently positive in pregnancy and official recommendations are not in place for routine blood cultures per a recent Cochrane review.[44] The majority of patients are admitted to the hospital and treated with IV fluids and empiric antibiotics until urine cultures are finalized. There is no established standard duration of treatment; however, a 7–14 day course is the most often recommended.[34] Follow-up cultures should confirm effective eradication of the infection. The bacteria most often responsible for UTIs in pregnancy are outlined in Table 17.1.

Table 17.1 Prevalence of Bacteria[33,34,115]

Pathogen	Prevalence
Enterobacteriaceae (including *E. coli*)	63–85%
Coagulase negative staphylococcus	15%
Klebsiella	8–11%
Group B streptococcus	2–10%
Staphylococcus aureus	8%

Table 17.2 Antibiotic Therapy in Pregnancy[33,34,42,43,45,46,115,116]

Antibiotic	Indication	Notable Side Effects	Comments
Amoxicillin	Asymptomatic bacteriuria (ASB)		First-line treatment
Cephalexin	ASB		First-line treatment
Aminoglycosides	Urinary tract infection (UTI), ASB	Should be avoided in the first trimester for being nephrotoxic and neurotoxic; otherwise most commonly prescribed	Streptomycin should specifically be avoided for potential damage to hearing
Fosfomycin	UTI, ASB	GI disturbances	Only requires 1 dose, data are new and limited
Nitrofurantoin	UTI, ASB	Teratogenic (?), avoid in first trimester and in the 40th week	Frequently used for lower UTIs; second-line treatment for ASB
Cephalosporins	UTI, ASB, pyelonephritis		Commonly used; avoid ceftriaxone at end of pregnancy for risk of kernicterus; any cephalosporin for pyelonephritis
Penicillin/derivatives	UTI, ASB, pyelonephritis		Commonly used; amoxicillin/clavulanic acid is second-line treatment for ASB; ampicillin + gentamicin for pyelonephritis
Sulfonamides	UTI, but generally avoided	Avoid in first trimester (?) and in the 40th week; trimethoprim requires folic acid supplementation	
Macrolides	Contraindicated except for serious or life-threatening infections resistant to other treatments	GI disturbances; teratogenic (?), increase in spontaneous abortions (?)	Conflicting data
Fluoroquinolones	Contraindicated except in symptomatic UTIs resistant to other treatments	Interferes with fetal cartilage development	
Tetracyclines	Contraindicated after 5 months	Discolored teeth in 2nd/3rd trimester	
Carbapenams	UTI, ASB		Use for patients with allergy to penicillin/cephalosporin
Aztreonam	UTI, ASB		Use only for severe allergy to beta-lactams
Glycopeptides	UTI, ASB		Limited data; consider infectious disease involvement
Miscellaneous –Daptomycin –Clindamycin –Polymyxins –Metronidazole	UTI, ASB		 –Use if benefits > risks –Review route for sexually transmitted infection treatment –Use with caution and monitor closely –Avoid topically

Management of Urinary Tract Infections During Pregnancy

It is important to consider both the mother and the fetus when selecting antibiotic therapy. As this remains a dynamic topic, consider consultation with a pharmacist and an obstetrician to assist with antibiotic selection and dosage. Local antibiograms and susceptibility should also be examined. Treatment duration generally increases based on the severity of the infection. Classic recommendations suggest 3–7 days of therapy for ASB or cystitis and up to 14 days for pyelonephritis.[34] A recent Cochrane review evaluated the duration of treatment for ASB and concluded that more data are needed and the recommendation is a standard course until these data are available.[39]

Most antimicrobials can cross the placenta; thus, care must be taken to avoid teratogens. Of note, as of June 2015 the FDA no longer uses the classic letter categorization for labeling these drugs. Instead, drugs are now classified for their phase of care including pregnancy and lactation, as well as for concerns regarding reproductive potential. Commonly used antibiotics are displayed in Table 17.2. Specific considerations are detailed in the following section.

Nitrofurantoin, often used to treat urinary infections in nonpregnant women, has been a source of controversy during pregnancy. A meta-analysis incorporating over 90,000 pregnant women receiving nitrofurantoin during the first trimester reported conflicting results. Analysis limited to cohort studies demonstrated no association of the antibiotic with major malformations in the offspring. However, analysis of the case-control studies showed a 22% increased odds for major malformations.[45] This has been refuted in other large population-based studies, and the ACOG currently does not recommend against nitrofurantoin in the first trimester in the setting if other antimicrobials are unavailable.[33]

Similar concerns exist for trimethoprim-sulfamethoxazole (TMP-SMX), and as such, many avoid this antibiotic in both the first trimester and final week of pregnancy. In addition, as a folic acid antagonist, any gravid woman taking TMP-SMX should also receive a folic acid supplement.[33]

Fosfomycin is emerging as a potentially safe and effective option during pregnancy; however, data are limited. A review of three randomized control trials of fosfomycin trometamol for both asymptomatic bacteriuria and lower UTIs showed that a single dose of fosfomycin had similar efficacy compared to cefuroxime and amoxicillin/clavulanic acid for the treatment of both conditions in pregnant women.[46]

UTIs and their treatment during pregnancy remain a dynamic topic. Poor maternal and fetal outcomes are associated with UTIs, and screening for asymptomatic bacteriuria is now the standard of care. Recommendations for specific antimicrobial agent and duration of treatment should come from a multidisciplinary team including a urologist, obstetrician, and pharmacist. Follow-up test of cure is important and women who fail to clear their infection should remain on prophylactic antibiotics for the remainder of their pregnancy.

UROLOGIC TUMORS

The diagnosis of urologic malignancy during pregnancy is a rare occurrence; published literature is limited mostly to case reports. However, when suspected it is important for the urologist to understand presentation, evaluation, and treatment of urologic cancers in the gravid patient.

Epidemiology

Of an estimated 810,170 annual cancer diagnoses in women, approximately 5% arise from the urinary tract.[47] The largest cohort study to examine the incidence of malignancy among pregnant women took place in the early 1980s and identified a rate of approximately 2.35/10,000 women.[48] Of note, other than cancer, pregnancy is the only condition in which the natural immune system is altered to allow tolerance.[49] Several studies have examined whether or not pregnancy itself is a risk factor for malignancies and have generally concluded that pregnancy does not increase the risk of malignancy.[50–52]

Renal Tumors

Renal cell carcinoma (RCC) is the most common renal tumor diagnosed in the pregnant patient.[53] Additionally angiomyolipoma, oncocytoma, and Wilm's tumor have been reported.[54–57]

Identification of a renal mass is more challenging in a gravid female patient. Hematuria may be mistaken for vaginal bleeding, hypertension may be attributed to preeclampsia, the gravid body habitus limits the physical exam, and cross-sectional imaging is less frequently employed during pregnancy.

However, once a renal mass is identified, the decision between intervention and observation is dependent on the size and stage of the mass, the suspected histopathologic subtype, and the pregnancy trimester. Treatment early in pregnancy subjects the developing fetus to risk for miscarriage or teratogenicity, whereas delaying treatment in favor of extending the pregnancy may subject the mother to risk of tumor growth or metastasis.

Successful radical nephrectomies have been reported during early pregnancy with the pregnancy continued to completion with delivery of a healthy infant.[58,59] However, it has been suggested that based on the slow growth rate of small early-staged RCCs, surgical intervention may be delayed until fetal lungs have matured at the end of the second trimester, early third trimester, or even until the postpartum period.[53] If delayed until the third trimester, one may consider concomitant nephrectomy and cesarean delivery, although in most cases the nephrectomy can be performed without having to induce labor.[60–62] A single case report described a patient who elected conservative management, although over the gestation her mass tripled in size, ultimately metastasizing and leading to death 1 year after delivery of a healthy infant.[63] Although clearly unusual, this case report underscores the need to consider the potential aggressiveness of malignancy rather than automatically deferring treatment until postpartum.

Angiomyolipomas (AMLs) are the second most common renal mass diagnosed in pregnancy.[58] Most AMLs are asymptomatic but when symptoms develop they include hematuria, flank pain, a palpable mass, and rarely hemorrhage. Size matters for these lesions; tumors >4 cm are more likely to rupture. As such, the feared complication of these tumors due to their high vascularity is spontaneous bleeding and/or hemorrhage. Treatment options in a pregnant patient are similar to those offered to the general population and include observation, embolization, or nephrectomy. Case reports have documented successful treatment of AMLs in pregnancy by all three options.[64–70]

Adrenal Tumors

Adrenal incidentalomas may be identified on ultrasound. If small in character and nonfunctioning these should be managed with observation.[53] Surveillance of these lesions has been recommended as they may represent undiagnosed pheochromocytomas.[71]

Pheochromocytoma in pregnancy has been well described. Incidence is estimated to be 1/54,000 pregnancies.[72] This was previously a morbid diagnosis carrying a fetal mortality rate >50%.[72] With advances in early diagnosis and appropriate treatment the mortality rates are nearly 0% for the mother and approximately 15% for the fetus.[54] Confounding its diagnosis are ambiguous symptoms; hypertension alone is often the only warning sign. Other classic symptoms may include headaches, dizziness, nausea and vomiting, vision changes, and palpitations. The hypertension may initially be attributed to eclampsia in a pregnant patient; however, pheochromocytoma is distinguished by its episodic hypertension presenting earlier in pregnancy and a lack of proteinuria.[73] Plasma or urine catecholamines should be obtained if clinical suspicion arises. As in the nonpregnant patient, MRI is the first-line imaging modality for evaluation and localization of suspected pheochromocytoma.[54]

Pheochromocytoma is treated with surgical excision, with attention to perioperative control of hypertension with a combination of alpha and beta blockade.[53] Similar to RCC, intervention may depend upon gestational age. Reports have noted first trimester fetal mortality rates as high as 40%.[74,75] Later in the third trimester, one may

consider resection of the tumor and simultaneous cesarean section.[76–78] Laparoscopic excision of pheochromocytoma during pregnancy has been reported with excellent outcomes.[79] Delivery without treatment of the tumor is potentially treacherous due to the increased autonomic activity for the patient. Indeed, delivery method itself is controversial for this specific neoplasm. Data show that maternal mortality is increased for vaginal delivery versus cesarean.[80]

Adrenocortical carcinomas may also present in pregnancy. These aggressive malignancies carry a poor prognosis. A case report has documented successful excision via laparoscopic adrenalectomy.[81] These adrenal tumors may be functioning or nonfunctioning; if they secrete glucocorticoids they may cause Cushing's syndrome. Alternatively, if they secrete aldosterone, they may present as preeclampsia with hypokalemia.[81] Four cases of maternal adrenal tumors resulting in fetal virilization have been reported.[82] In all four of these cases the maternal malignancy was not discovered until after delivery of the child.

Bladder Tumors

Case reports of bladder cancer in pregnancy extend back to the 1920s.[54] Often heralded by hematuria, diagnosis may be delayed due to misattribution to vaginal bleeding, reported in up to 22% of cases.[83] If concern arises for intravesical abnormality, cystoscopy can be performed safely in the pregnant patient.[48] In addition, transurethral resection can be safely performed in pregnancy acknowledging the mass effect of the uterus on the bladder.[54,83–85] Depending on the size of the mass, a staging and/or metastatic evaluation may be necessary.

Several other rare bladder tumors have been identified. Leiomyoma is a benign tumor that may present in the bladder. Four cases have been documented in pregnant patients.[86] Cystoscopy, ultrasound, MRI, and tissue biopsy are important in the work-up to differentiate from its malignant counterpart, leiomyosarcoma.[87] In pregnant patients with histologically confirmed leiomyoma, due to the benign nature of the diagnosis, surgical resection may be delayed until the postpartum period.

Ureteral Tumors

Ureteral cancer has been documented in pregnancy in two case reports.[81] More commonly, benign lesions of the ureter may present as ureteral filling defects during pregnancy, including urolithiasis and malakoplakia.

Urethral Tumors

Urethral carcinomas are another rare urologic cancer. A case report from the 1970s described a woman with a urethral adenocarcinoma that was treated with surgical excision and radiotherapy following normal vaginal delivery of her child.[88] There are several benign urethral lesions; these may increase in size during pregnancy. No emergent treatment is necessary.[89] Finally, leiomyomas of the urethra have been documented in three pregnant patients; all three were treated successfully with surgical excision.[90]

Urachal Tumors

Two case reports of urachal carcinoma diagnosed in pregnancy have been published.[91,92] One presented as abdominal pain; the other as hematuria. The first case resulted in a normal term delivery after surgical excision. The second case resulted in cystectomy along with hysterectomy in the first trimester of pregnancy due to lymph node involvement.

Imaging Considerations During Pregnancy

Although diagnostic imaging is a daily part of urologic practice, concerns regarding potential adverse fetal effects of medical radiation limit utilization of studies employing ionizing radiation during pregnancy. Radiation effects can be broadly characterized as either deterministic or stochastic effects. The latter are randomly induced events including genetic mutations and carcinogenesis, and these do not have a recognized "threshold" dose. Nevertheless, it continues to be debated whether the typical medical radiation doses associated with current diagnostic imaging increases the risk of developing childhood cancer.[93] The ACOG issued guidelines for diagnostic imaging during pregnancy and estimated that after 1–2 rad fetal radiation exposure, the risk of childhood leukemia may be elevated to 1/2000 from a baseline of 1/3000 (an absolute excess of 1/6000 children).[94]

Deterministic effects, however, are direct tissue effects from the radiation that may manifest as fetal demise (particularly if prior to implantation), or mental retardation, microcephaly, growth retardation, or congenital malformations if radiation exceeds threshold exposures. These risks are highest during the first and second trimesters when organogenesis and brain development are underway and thus most susceptible to radiation damage.[95] Nevertheless, neither fetal anomalies nor pregnancy loss was associated with radiation exposure less than 5 rad, which is well in excess of the exposure of typical diagnostic imaging.[94] In order to better assess potential fetal exposure, consultation with the institutional radiation physicist may allow appropriate dosimetry calculations.

Avoidance of ionizing radiation by using imaging techniques such as US or MRI obviates the aforementioned concerns regarding both stochastic and deterministic fetal radiation effects and the associated fetal harm. In practice, these should be considered first-line imaging options when feasible, although they are limited in particular capabilities, including diagnosis of urolithiasis. However, with guidance provided by the ACOG, patients can be counseled that medically indicated diagnostic imaging with plain films and CT may be performed within acceptable fetal exposure thresholds.

Surgical Considerations During Pregnancy

The decision to operate on the parturient must weigh the risks of untreated disease if intervention is deferred or withheld against the risks of the intervention to both the mother and her unborn child. The ACOG has issued a committee statement reassuring that no currently used anesthetic agents have teratogenic effects at standard concentrations.

Box 17.1 Recommendations for Nonobstetric Surgery During Pregnancy

Preoperative Recommendations
- Indicated surgery should not be denied based on pregnancy.[96]
- Medical decision making must respect autonomy of the mother.[9]
- Obstetric consultation should be obtained perioperatively (preoperatively if maternal condition allows).[96,100]
- Nonurgent surgery should be performed in second trimester if possible.[96]
- Surgery should be performed at an institution with obstetric and neonatal care.[96]
- Assess pre- and postoperative Doppler fetal heart rate.

Anesthetic Recommendations
- Currently used anesthetic agents have not demonstrated teratogenic effects in humans at standard concentrations.[96]
- Fetal heart rate monitoring may assist in intraoperative anesthetic assessment.
- End-tidal capnography should be utilized during laparoscopic surgery.[100]
- Patient should be positioned with right side elevated (left lateral tilt) to reduce vena caval compression.[100]

Intra- and Postoperative Surgical Recommendations
- For laparoscopic access, adjustments should be based on fundal height and prior incisions.[100]
- For laparoscopic procedures, insufflations pressures of 10–15 mm Hg can be used.[100]
- Pneumatic compression devices and early postoperative ambulation should be utilized.[100]

Box 17.2 Perioperative Fetal Monitoring

General Considerations

Have qualified individual available to interpret fetal monitoring
Have obstetric provider available if monitoring suggests need for urgent/emergent delivery

Pre-Viable Fetus

Obtain preoperative and postoperative fetal heart rate to assess fetal well-being

Viable Fetus

Perform simultaneous fetal heart rate and contraction monitoring pre- and postoperatively
Consider intraoperative fetal monitoring if:

fetus is viable
operative field physically allows monitoring
an obstetrician/provider with obstetric surgical privileges is available to intervene if fetal indications are noted
nature of operation would allow interruption of procedure for emergency delivery
patient consents to possible emergency delivery

(Adapted from ACOG Committee Opinion No. 474: nonobstetric surgery during pregnancy. Obstet Gynecol. 2011;117(2 Pt 1):420-1.)

ACOG additionally offers guidance regarding nonobstetric surgery in the pregnant patient. Advocating for both mother and child, ACOG recommends that indicated surgery should never be denied based on the pregnancy, although elective surgery should be postponed until postpartum. Nonurgent surgery should occur in the second trimester if possible, at which time both spontaneous abortion and preterm contraction are least likely.[96] These recommendations are summarized in Box 17.1.

SURGICAL POSITIONING

Due to the tendency for the dextrorotated gravid uterus to compress the inferior vena cava (IVC), left uterine displacement maximizes venous return and preserves cardiac output. This can be accomplished with left lateral decubitus positioning when possible, or left lateral tilt by elevating the right hip/flank. In procedures in which intraoperative radiographic imaging may be required, a radiolucent roll should be used for these purposes.

PERIOPERATIVE FETAL MONITORING

Guidelines for perioperative fetal monitoring are based upon fetal viability as well as the planned surgical intervention. Prior to fetal viability, fetal monitoring is limited to pre- and postoperative Doppler ascertainment of fetal heart rate. Once viability has been achieved, simultaneous fetal heart rate and contraction monitoring should be performed pre- and postoperatively. When the surgical field allows and the procedure could be safely interrupted if prompted, intraoperative fetal monitoring may be of use as signs of fetal distress could inform improved patient positioning, surgical or anesthetic maneuvers, or need for emergent delivery. A summary of fetal monitoring recommendations and conditions when intraoperative monitoring is appropriate are noted in Box 17.2.[96]

Open Versus Laparoscopic Approaches

No prospective trial has directly assessed the choice of laparoscopy versus laparotomy when surgical intervention is required during pregnancy. A review of over 2 million singleton pregnancies from the Swedish Health Registries assessed fetal outcomes after maternal intrapartum surgery. Compared to the general population, there was no difference in rate of fetal malformations among those undergoing intrapartum laparotomy (1522) or laparoscopy (2181), although they were more likely to be delivered before 37 weeks and to weigh less than 2500 g. Between the two surgical approaches there was no difference in cumulative infant survival or rate of fetal malformation.[97] Choice of surgical approach should therefore be dictated by surgeon experience and anticipated surgical exposure requirements.

In addition to the well-recognized advantages of laparoscopic surgery related to reduced pain and expedited convalescence, improved visualization has been suggested to reduce the need for uterine manipulation.[98] Initial concerns of laparoscopy included risk of inadvertent uterine injury. Uterine puncture, insufflation, and trocar placement with incidental fetoscopy resulting from laparoscopy at 19 weeks have been reported. This case report noted successful management via suture closure of the uterine puncture site, with subsequent preterm delivery at 32 weeks due to premature rupture of membranes.[99] Although the child was reported alive and well at 1 year, this highlights the importance of careful selection of laparoscopic access in this

population. Additional physiologic concerns included fetal acidosis from CO_2 absorption as well as decreased placental perfusion resulting from pneumoperitoneum. However, a comprehensive review from the Society of American Gastrointestinal Endoscopic Surgeons concluded that laparoscopic surgery could safely be performed in all trimesters of pregnancy. They noted that, although it had been recommended to maintain insufflation pressures below 12 mm Hg, insufflation to a standard 15 mm Hg has been performed without increased adverse maternal–fetal events. They therefore proposed that CO_2 insufflation between 10 mm Hg and 15 mm Hg can be safely used for laparoscopy during pregnancy, but also recommend intraoperative maternal end-tidal capnographic monitoring. Additional recommendations include adjusting abdominal access site based on fundal height, left lateral decubitus positioning to reduce caval compression, and intra- and postoperative pneumatic compression devices as well as early ambulation due to hypercoagulability during pregnancy.[100]

ENDOSCOPIC

The lithotomy position should be modified with the above-noted left lateral tilt to reduce caval compression. As endoscopic cases would allow obstetric intervention if needed, fetal monitoring should be employed when indicated. For cystoscopy and transurethral resection of bladder tumor, extrinsic impression on the bladder from the gravid uterus should be anticipated, but otherwise the procedures should not otherwise differ from the nonpregnant patient. For ureteroscopic procedures, ureteroscope access to the ureter can typically be obtained in the same fashion, with flexible ureteroscope available if required to access mid- and proximal ureteral location or to navigate ureteral tortuosity. If lithotripsy is required, the holmium:YAG laser is advocated as the preferred tool given small diameter fibers without energy transmission to mother or fetus, reduced retropulsion compared with pneumatic devices, and maximal safety margin of available lithotripsy devices.[101]

Ureteroscopy is typically performed with image guidance in the nonpregnant patient. Concerns regarding fetal radiation exposure have prompted a number of alternative strategies. Ureteroscopy solely under endoscopic visualization without image guidance has been promoted, although limited fluoroscopy was required when resistance to wire or scope passage was encountered.[101] Alternatively, sparing fluoroscopy can be used, with lead shielding placed beneath the patient's pelvis (between the C-arm x-ray tube and the uterus), or above the pelvis for easier access in which case the C-arm must be inverted.[102,103] Ultrasound guidance can also be utilized to monitor safety wire passage and maintenance within the renal pelvis, ureteroscopic position, and stent deployment, eliminating the need for fluoroscopy.[104]

Complications Related to Pregnancy

PRETERM LABOR/PRETERM DELIVERY

Preterm labor has been clearly associated with general surgical interventions during the third trimester, occurring in 82% of third trimester patients versus 26% of second trimester patients in a 2001 series from the University of California at San Francisco. No fetal loss was reported in this series, although preterm delivery occurred in 16% of those undergoing third trimester interventions.[105] A small series of 11 patients undergoing laparoscopic general surgical procedures in the third trimester demonstrated 18% incidence of preterm labor.[106] Although we lack specific reports of preterm labor from open or laparoscopic urologic procedures, one may reasonably extrapolate these risks from the general surgical literature. A multiinstitution report of 46 ureteroscopic procedures during pregnancy revealed a 10% incidence of preterm labor among patients undergoing ureteroscopy in the third trimester. One of the two was managed with tocolytics and rest, and the other progressed to preterm delivery (5%).[107] In light of such accumulated experience, the ACOG has recommended that nonurgent surgery ideally be performed in the second trimester when preterm contractions are least likely, emphasizing that any such surgery should be performed at an institution with obstetric services readily available.[96]

INVASIVE PLACENTAL ATTACHMENT

Placental chorionic villi typically attach to the endometrium; however, a recent 2015 update suggests that in 1/700 live births pathologic attachment beyond the endometrium may occur.[108] Of those with abnormal placental attachments, 81% may attach to the myometrium (placenta accreta), 12% may invade into the myometrium (placenta increta), and 7% invade through the myometrium to other pelvic structures (placenta percreta).[109] Although abnormal placental attachment can often be identified on prenatal ultrasound to prompt cesarean and possible hysterectomy, it was suspected prior to delivery in only 53%.[108,109]

The reported risk of unintentional urinary tract injury during delivery in the setting of abnormal placentation is estimated at 29%, although it may be as high as 63% when the abnormal placenta is not diagnosed antenatally but rather identified incidentally at time of surgery.[110] When urologic injury occurred, the bladder was affected most commonly (76%), followed by ureter (17%), genitourinary fistula (5%), and combined bladder and ureter (2%). In nonemergent cesarean delivery, a bladder-first approach involving formal bladder distension and dissection from the uterus before commencing with cesarean delivery has been advocated to reduce the risk of unintentional bladder injury. Additionally, this meta-analysis confirmed that preoperative temporary bilateral ureteral stent placement significantly reduced the risk of urinary tract injury (6% vs 33%, $p = 0.01$).[110]

Placenta percreta – the most severe abnormal placentation – has a reported 72% incidence of urologic complications. Due to potential invasion into the bladder, partial cystectomy was required in 44%.[111] Ultimately 4% had resultant reduced bladder capacity. Of note, despite the invasive nature of this condition, cystoscopy was not found to be useful in preoperative diagnosis in the 12 of 54 patients in whom it was performed. Gross hematuria, however, was identified in 31% and was thus advocated as a more useful tool to suggest the presence of placenta percreta and prompt further evaluation with ultrasound or

MRI. Finally, this review identified three (5.5%) maternal deaths and 14 (26%) fetal deaths associated with placenta percreta.[111]

UROLOGIC TRAUMA DURING DELIVERY

Although perineal trauma is common during vaginal delivery, surgically urgent urologic trauma is rarely associated with vaginal childbirth. However, case reports have identified at least four instances of intraperitoneal bladder rupture without concomitant uterine perforation following vaginal delivery.[112] In each case, patients presented with abdominal pain, ileus or abdominal distension, and elevated serum creatinine. The authors propose prolonged fetal pressure against the dome of the distended bladder during forceful contractions may have allowed pressure necrosis to develop. They recommend a high index of suspicion, with cystogram if needed to confirm diagnosis.

Urinary tract injury requiring urgent surgical repair is more clearly associated with cesarean delivery. The bladder is the most common site of injury, comprising 97% of urinary tract injury in the largest recent study.[113] Contemporary studies have estimated the incidence of urologic trauma injury at cesarean delivery at 0.3%.[113,114] The incidence was noted to markedly rise to 5% in the setting of urgent hysterectomy at time of cesarean.[113] Repeat cesarean more than tripled the odds of bladder injury (OR 3.82, 95% CI 1.62–8.97), although this may have been largely attributable to failed attempt at vaginal birth after cesarean.[114]

When encountered, repair of bladder lacerations and distal ureteral injuries should proceed as per standard protocols, reviewed in depth in dedicated chapters in this text.

Conclusions

Urologic disease and its management are altered by pregnancy. Physiologic and anatomic changes may affect the urinary chemical milieu, collecting system dilation, risk of stones, and infection. Furthermore, these changes and concerns regarding the rapidly developing fetus may limit our diagnostic options and their utility. Complications of childbirth may also induce urologic injury. Nevertheless, the well-informed urologist, harnessing the expertise of obstetricians, neonatologists, and anesthesiologists, may utilize current urologic surgical techniques in the service of both the patient and her child.

Chapter 17 Questions

1. When planning surgical positioning for a pregnant patient, it is most important to consider:
   a. Dependent edema of her extremities – try to keep her hands and legs elevated
   b. Increased blood pressure relative to systemic vasodilation – ask anesthesiologist to monitor closely
   c. Urethral hypermobility
   d. Increased risk of postoperative ileus
   e. Potential compression of the inferior vena cava (IVC) by the growing uterus

2. A 34-year-old recurrent calcium oxalate stone former presents with her typical symptoms of renal colic. She mentions that she is 10 weeks pregnant. You counsel her that:
   a. No matter what size her kidney stone is, having a nidus for infection in her urinary tract increases her own risk of infection in pregnancy and the risk of harm to the fetus; she should have this endoscopically removed in the second trimester
   b. She should undergo stone protocol CT to confirm that a stone is present
   c. She is at increased risk of pyelonephritis based on her history and pregnancy; you order a urine culture and start her on prophylactic antibiotics to decrease her risk of pyelonephritis
   d. She may consider elect conservative management including hydration and oral pain medication for the time being, knowing that she has successfully passed stones in the past and that being pregnant should not interfere with this process
   e. She should have stent placement later this afternoon; you want to avoid further dilation of her urinary tract. You will place her on prophylactic antibiotics and will have the stent removed as soon as she passes the stone

3. Which of the following physiologic changes most frequently contributes to increased stone formation in pregnancy?
   a. Decreased urine pH
   b. Decreased excretion of uric acid
   c. Increased excretion of calcium
   d. Compression of the IVC
   e. Ascending bacteriuria

4. Third trimester surgical intervention as opposed to observation is most likely warranted for which of the following incidental findings?
   a. 2-cm fat-containing renal mass
   b. 5-mm mid renal calyceal stone
   c. 3.5-cm adrenal mass with normal serum catecholamines
   d. 2-cm solid renal mass
   e. 2.5-cm adrenal mass with elevated urinary catecholamines

5. The first-line imaging technique to assess for suspected urolithiasis in pregnancy is:
   a. Ultrasound
   b. Intravenous pyelogram
   c. CT scan
   d. MRI
   e. Plain abdominal film

6. On routine follow-up of urine culture results you reach out to one of your young female patients. In clinic the previous week she had a urine dipstick positive for bacteria, white blood cells, and leukocyte esterase; you started her on a standard course of Bactrim 2 days prior. Culture results show that she is growing pan-sensitive *E. coli*, and when you call to tell her to continue her course as prescribed she informs you that her symptoms have improved, she feels well, and she just had a positive pregnancy test. You:
   a. Congratulate her and advise her to continue the original prescription
   b. Tell her that due to her hypervolemic vascular state she will need fewer days of treatment but the antibiotic choice is still correct
   c. Instruct her that cephalosporins are preferred over trimethoprim and sulfa during pregnancy and switch her antibiotic accordingly
   d. Tell her that she is at increased risk of progressing to pyelonephritis and that you will thus need to admit her for intravenous antibiotic administration
   e. Tell her that the pregnancy itself likely confounded her urinalysis and that she can stop taking the antibiotics immediately; she should follow-up with her obstetrician for future urine culture

7. Which of the following is the most common organism to cause a urinary tract infection (UTI) in pregnancy?
   a. *Klebsiella*
   b. Group B strep
   c. *Pseudomonas*
   d. *E. coli*
   e. *Candida*

8. You are called to assess a 32-year-old pregnant female in the emergency room for hematuria. She is in her third trimester of pregnancy. She presented after finding "bright red blood" in the toilet after urination. Urinalysis in the ED was positive for large blood; she is otherwise stable. Your initial assessment includes:
   a. Bringing an ultrasound machine to the bedside to assess for hydronephrosis or other obvious abnormality to the urinary tract
   b. Verifying that the bleeding is from the urinary tract and not vagina; you begin with a pelvic exam assisted by an obstetrician
   c. Ordering kidney, ureter, and bladder (KUB) investigations; you are concerned that she may have nephrolithiasis as this is the most common urologic diagnosis in pregnancy. You assure her that the radiation effects from x-ray at this stage of pregnancy are minimal
   d. Sending a urine sample for culture, starting her on antibiotics, and admitting her to the hospital with a consult to the obstetrician

e. Ruling out pathology in her bladder; you perform bedside cystoscopy to rule out bladder or urethral lesion knowing that this is safe and tolerated in pregnancy

9. While all pregnant females should take a folic acid supplement, you especially ensure that they take the folate if they are being treated with which antibiotic?
   a. Penicillin
   b. Trimethoprim-sulfamethoxazole
   c. Isoniazid
   d. Cephalexin
   e. Doxycycline

10. Which of the following is the best first-line antibiotic for treating a UTI in a pregnant patient with an anaphylactic penicillin allergy?
    a. Fosfomycin
    b. Doxycycline
    c. TMP-SMX
    d. Nitrofurantoin
    e. Gentamicin

Case Study

A 26-year-old woman presents to her obstetrician with right flank pain. She is pregnant, at 17 weeks' gestation. Her pregnancy was complicated by hyperemesis gravidum limited to the first trimester; otherwise she has no significant prior medical history. She is afebrile. Screening urinalysis in the first trimester was normal. Urinalysis today reveals 18 RBCs/hpf. No leukocytes or bacteriuria are seen.

1. The most likely diagnosis is:
   a. Pyelonephritis
   b. Left renal stone
   c. Right ureteral stone
   d. Right ureteral tumor
   e. Placenta increta

2. The most reasonable initial diagnostic study is:
   a. Low-dose CT
   b. Fat-suppression MRI
   c. Doppler ultrasound with determination of renal resistive indices
   d. Diuretic renal scan
   e. Transvaginal ultrasound

3. She initially declines any further investigation after her pain is controlled. She returns to the ER 3 days later with increased flank pain, now accompanied by nausea. An ultrasound was obtained (Case Fig. 17.1). A presumptive diagnosis of right ureteral stone is made. She elects to proceed with ureteroscopy. Which is the most appropriate strategy for perioperative fetal monitoring?
   a. No fetal monitoring required at 17 weeks' gestation
   b. Obtain preoperative fetal heart rate only
   c. Obtain postoperative fetal heart rate only

Case Figure 17.1

   d. Obtain pre- and postoperative fetal heart rate
   e. Obtain intraoperative fetal monitoring with obstetrician on stand-by to perform emergency delivery if needed

Answers

1. **e.** While all choices may be considered, the most influential one on intraoperative hemodynamics would be compression of the IVC by the growing uterus. Positioning of the pregnant patient should reflect this concern.
2. **d.** Most studies suggest the majority, or at least a significant minority, of pregnant women with stones will pass them if provided with adequate hydration and symptom management. Choices a and e both involve procedures that, based on the clinical scenario provided, are not warranted this early. Choice b is incorrect because the imaging tool that should be used first in pregnancy is ultrasound, particularly in the first trimester. Choice c is incorrect as current evidence does not support the presence of a stone in this situation increasing her risk of pyelonephritis, nor would empiric antibiotics be indicated at this time.
3. **c.** Several studies have examined pathophysiology of urinary changes and stone formation in pregnancy, and the common finding is an increase in urinary excretion of calcium.
4. **e.** Choice a is suggestive of an angiomyolipoma, and surgical intervention is not recommended until the size is >4 cm. Choice b is a relatively small stone that should be offered a trial of conservative management before surgical intervention. Choice c is likely an adrenal adenoma based on the absence of elevated catecholamines and may be safely observed. Choice d is a clinical T1a renal mass that should be monitored closely and would benefit from further exploration including possible biopsy and/or partial nephrectomy. Based on its relatively small size there is no need for urgent surgical intervention during the third trimester of pregnancy.

Choice e is a functional adrenal neoplasm that puts this patient at increased risk of hemodynamic instability, especially during labor, which should be proactively treated.

5. **a.** This is the only option that puts the patient and fetus at minimal risk and is recommended as the first-line imaging tool for the pregnant patient.
6. **c.** Trimethoprim-sulfamethoxazole is less desirable in pregnancy due to potential harm to the fetus; hence a is also incorrect. Choices b, d, and e are incorrect as the pregnant state will not alter either required antibiotic duration, administration, or urinalysis results.
7. **d.** *E. coli* is the most common organism to cause a UTI regardless of pregnant state.
8. **b.** Before performing any further intervention or diagnostic technique it is most important to determine the source of bleeding. The entire work-up depends on the source of the bleeding and to avoid unnecessary procedures and potential harm to the mother/fetus, bleeding source confirmation is essential.
9. **b.** Trimethoprim-sulfamethoxazole interferes with the folic acid synthesis pathway, and supplemental folic acid should be encouraged in the pregnant patient taking this antibiotic to prevent neural tube defects.
10. **d.** Cephalosporins are considered minimal risk in pregnancy but with a history of anaphylaxis to penicillin and the 10% cross-reactivity of cephalosporins to penicillins, the next best choice with the least amount of harm to the fetus is nitrofurantoin.

CASE STUDY

1. **c.** With right flank pain, pathology on the left can be ruled out. With a urinalysis positive only for blood and not infection, the likely diagnosis is urolithiasis. While a tumor may also present with gross hematuria, it does not usually cause pain and the incidence is much lower than stones.
2. **c.** Given the history and likely diagnosis of ureteral stone, the most useful and appropriate diagnostic test in a pregnant patient is ultrasound.
3. **d.** Fetal heart rate should be assessed both before and after the procedure. Ureteroscopy has been safely performed in pregnancy, and the risk of harm to the fetus is low. Intraopertaive fetal monitoring with an obstetrician on stand-by to perform emergency delivery should be considered after fetal viability, which currently is later than 17 weeks.

Chapter 18 Questions and Answers

KEY POINTS

1. Complications in female-to-male gender confirmation surgery include urethral stricture, meatal stenosis, urethrocutaneous fistula, and persistent vaginal cavity.
2. Complications in male-to-female gender confirmation surgery are less common and include neovaginal stenosis, rectoneovaginal fistula, neovaginal prolapse, and meatal stenosis.
3. Wound healing is compromised by decreased blood flow to urethral anastomotic sites, making reconstructive procedures less likely to be successful.
4. Use of vascularized tissue flaps is an important principle in reconstruction of post–gender confirmation surgery complications.

Introduction

The prevalence of gender dysphoria is approximated to be about 355 per 100,000 persons, and 9.8 per 100,000 seek affirmation surgery.[1] Transition to the new gender involves several lifestyle, pharmaceutical, and surgical steps. While many surgeons who perform gender confirmation surgeries are plastic surgeons, it is important that urologists are involved in the preoperative, intraoperative, and postoperative care.[2] Gender confirmation surgery involves a balance of aesthetic and functional goals, and urologists are often asked to manage the urologic complications.

Complications of female-to-male (FTM) gender confirmation surgery include urethral stricture, urethrocutaneous fistula, meatal stenosis, and persistent vaginal cavity. Wound healing is impaired due to poor vascularity at the urethral anastomotic site and the tip of the neophallus. Male-to-female (MTF) gender confirmation surgery has fewer reported complications, which include neovaginal stenosis, rectoneovaginal fistula, and meatal stenosis. The urologist must be knowledgeable of the unique anatomic considerations during primary surgery as well as during management of complications. Local or regional flaps for vascular support may be needed to provide a durable outcome. This chapter reviews etiology,

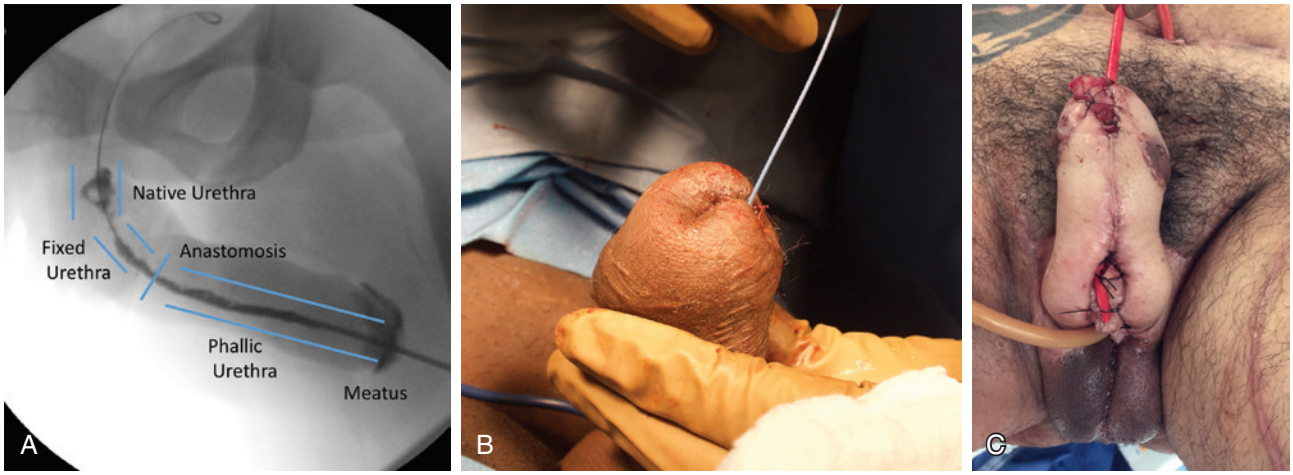

Figure 18.1 A, The urethral anatomy of the neophallus in female-to-male patients is divided into five segments: native, fixed urethra, anastomotic urethra, phallic urethra, and meatus. B, Patient with meatal stenosis after phalloplasty. C, Patient with anastomotic stenosis who underwent creation of urethrostomy at the junction of the phallic and fixed urethra.

diagnosis, and management of complications of gender confirmation surgery.

Complications Specific to Female-to-Male Gender Confirmation Surgery

Voiding from a standing position is an important goal of over 98% of patients seeking FTM gender confirmation surgery.[3] Standing to void can be achieved with the construction of a neourethra with both metoidioplasty and phalloplasty.

URETHRAL STRICTURE AND URETHROCUTANEOUS FISTULA

Etiology

Understanding the anatomy of the neophallic urethra is paramount in managing complications. The urethra is divided into five segments from proximal to distal as follows: native (female) urethra, fixed urethra, anastomotic urethra, phallic urethra, and meatus[4,5] (Fig. 18.1A). The fixed urethra is formed after lengthening of native urethra using local vaginal or labial flaps, regional flaps, and skin or mucosal grafts.[4,6] The anastomotic urethra is the portion where the fixed urethra and phallic urethra are connected. The phallic urethra is constructed using prelamination, or tube-in-tube techniques.[4,6] The anastomotic urethra is the most common site of urethral stricture.

The rate of urethral stricture after phalloplasty is reported to be from 25% to 58%.[2,7,8] Urethral stricture occurs in the anastomotic urethra in 41%, phallic urethra in 28%, meatus in 15%, fixed urethra in 13%, and multifocal in 8%.[5] The most common etiologic factor is ischemia. At the level of the meatus, contracture of neourethral tissue and neophallic skin can cause meatal stenosis (Fig. 18.1B). One series reported a mean urethral stricture length of 3.6 cm (range 0.5–15 cm).[5]

Urethrocutaneous (UC) fistula is the most common urethral complication from FTM gender confirmation surgery and is reported in 22–75% of radial forearm free flap phalloplasties.[9,10] Fistulas are usually associated with a urethral stricture and typically occur just proximal to it.[7] Most common locations are the point of urethral anastomoses between the native urethra and fixed urethra, and between the fixed urethra and phallic urethra.[7,11] The anastomotic point between the fixed urethra and phallic urethra is compromised due to attenuated vasculature of the free flap. The phallic urethra is typically narrower than the fixed urethra as a result of primary construction or contraction, which causes relative obstruction of urinary flow and resulting fistula.[7] Most UC fistulas will require surgical repair.[12]

Diagnosis

Most common symptoms for patients with urethral stricture are obstructive, including weak stream, urinary hesitancy, straining to void, and incomplete emptying. Symptoms of urethral stricture and/or UC fistula may be recurrent urinary tract infection, dysuria, or suprapubic discomfort. Review of any available operative report of the gender confirming surgery will help with understanding of the anatomic reconstruction. Physical examination may reveal palpable scar or induration at the site of stricture. Any signs of cellulitis should be noted and may be a sign of local infection, abscess, or concomitant UC fistula. Fluctuance may be noted in cases of UC fistula or abscess. Suprapubic tenderness or fullness may be signs of urinary retention that are critical to note. Urethral strictures must be repaired as long-standing obstruction may result in chronic infections, sepsis, bladder stones, and renal insufficiency. Diagnostic assessment is done using retrograde urethrogram and/or voiding cystourethrogram to assess the location and length of stricture as well as presence of UC fistula. Examination under anesthesia may be necessary given the complex anatomy. Cystoscopy should be performed in a retrograde fashion as well as antegrade if there is an existing suprapubic tube.

Treatment

If the patient has urinary retention or severe obstructive symptoms, the urine should be diverted. Foley catheter placement generally requires endoscopy and placement of a small-caliber catheter over a wire. Placement of a suprapubic tube may be helpful by resolving the acute clinical problem and as an aid in surgical planning and treatment. The suprapubic tube should be placed away from the vascular anastomosis of the neophallus, which is typically lateral to the neophallus. If the vascular anastomosis is unknown, image-guided placement or open catheter placement may be safer. Placement of a 16Fr or larger suprapubic tube facilitates performing antegrade cystoscopy for assessment of the urethral anatomy at the time of diagnostic evaluation and surgical treatment. For optimal treatment planning, review of prior surgeries and understanding of the vascular anatomy of the existing flap are paramount.

Examination under anesthesia is done with retrograde and antegrade cystoscopy to determine stricture length and location and presence of fistula. Sometimes the neourethra is narrower than the native urethra and is unable to accommodate the 16Fr flexible cystoscope. A flexible ureteroscope may be used in these cases to directly visualize the urethra. Contrast injection through the scope can be used to perform a retrograde urethrogram using fluoroscopy.

Repair of UC fistula involves closure of the fistula and reinforcement using flaps or grafts. The possibility of use of grafts or flaps while performing urethroplasty or fistula repair should be discussed with the patient. More than one stage may be needed for durable repair. Patients should be made aware of the risk of vascular damage and partial or total loss of the neophallus. If the patient does not wish to urinate from the tip of the neophallus, a perineal urethrostomy (Fig. 18.1C) is a reasonable option.

General anesthesia is used in these cases with the endotracheal tube taped to the side opposite the proposed site of buccal mucosa graft harvest. The patient is positioned in a low lithotomy position as it provides access to the genitalia, suprapubic area, and bilateral thighs for possible regional flaps. A guidewire is placed through the fistula and visualized via the cystoscope; this aids in dissection of the fistula tract. Stay sutures placed at the edges of the fistula tract help in dissection and excision of the tract. The urethral opening is closed in several nonoverlapping layers. A local or regional fasciocutaneous flap or labial fat pad flap from the neoscrotum may be used for vascular support (Figs. 18.2A and B).

If the UC fistula is associated with a urethral stricture, it should be repaired at the same time. Options for treatment of urethral stricture include direct vision internal urethrotomy (DVIU), single-stage anastomotic urethroplasty, single-stage substitution urethroplasty, staged urethroplasty, and perineal urethrostomy. Due to the lack of corpus spongiosum and compromised blood supply, urethral dilation and DVIU have an overall failure rate of 88% in this population.[8] However, for strictures of 3 cm or less, it may be a reasonable option. In one study, the success rate of first DVIU was reported to be 44%, with an additional 13% success rate after a second DVIU at a median follow-up of 51 months.[11] More than two endoscopic procedures were not successful.

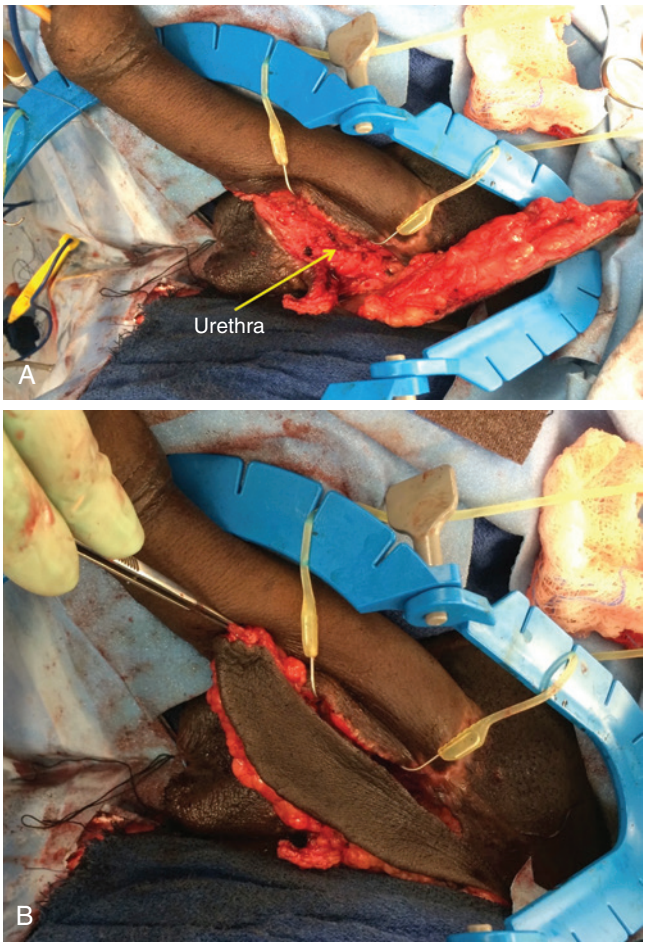

Figure 18.2 A, Fasciocutaneous flap harvested from the patient's medial thigh for ventral coverage of a urethral defect. B, Fasciocutaneous flap used for coverage and to provide support for ventral buccal mucosa graft.

One-stage anastomotic urethroplasty techniques include nontransecting urethroplasty using the Heineke-Mikulicz principle, excision and primary anastomosis, buccal mucosa graft urethroplasty, or pedicle flap urethroplasty. In a Heineke-Mikulicz nontransecting anastomotic urethroplasty, the stricture is incised vertically and closed horizontally resulting in a wider lumen.[5] Excision and primary anastomotic urethroplasty is done when the strictured segment of the urethra is less than 2–3 cm long. The stricture is excised, healthy ends spatulated, and primary anastomosis done. The success rate of excision and primary anastomotic urethroplasties has been reported to be about 57% in neophallus patients; low success rates are attributed to decreased blood supply and inability to maximally mobilize tissue.[13]

One-stage substitution urethroplasty is performed when the stricture is longer and not amenable to anastomotic repair. Several flaps or grafts have been used including fasciocutaneous flap, bladder mucosa, and buccal mucosa grafts.[8,14] A dorsal inlay approach is preferred over ventral onlay due to the better vascular bed on the dorsal surface. In traditional native dorsal inlay urethroplasty, the urethra is mobilized circumferentially. However, in neophallic urethroplasty, circumferential mobilization is not recommended as it may

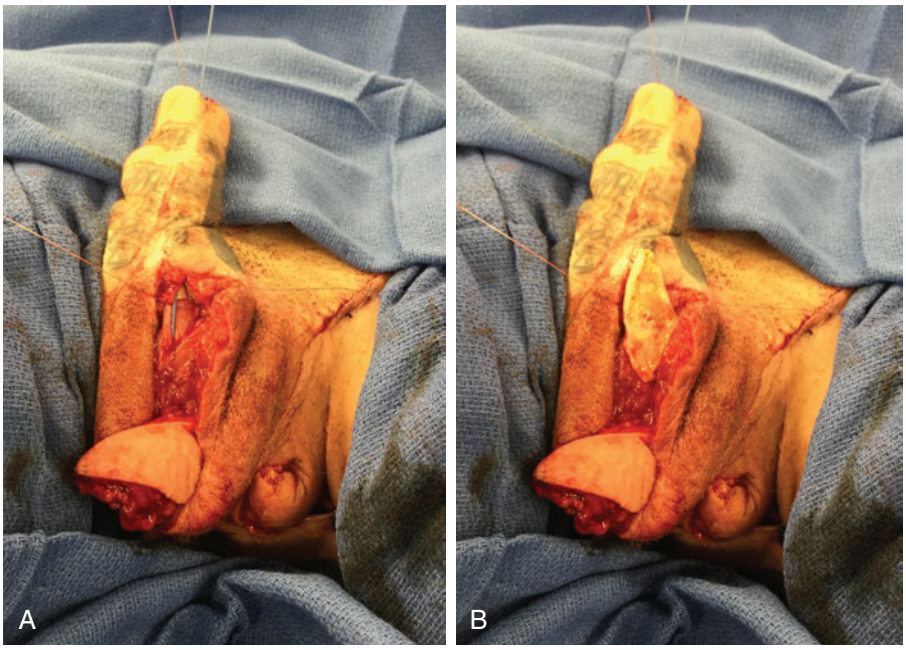

Figure 18.3 A, Neophallus with stricture of the anastomotic urethra. Urethrotomy is made ventrally. B, Buccal mucosa graft is placed ventrally, and a fasciocutaneous flap is moved over for coverage of the graft.

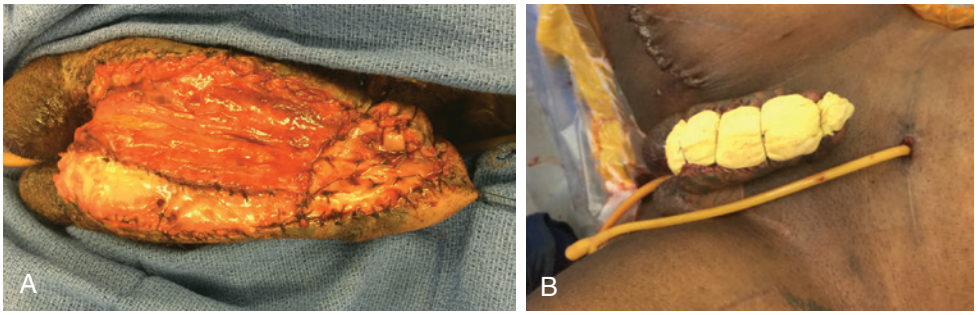

Figure 18.4 A, First-stage urethroplasty using buccal mucosa graft. B, Bolster dressing is placed over the graft for 1 week until the graft takes.

compromise the blood supply to that portion of the urethra. Instead, after the urethra is opened, a ventral urethrotomy on the dorsal surface is made and the graft placed on the dorsal surface, followed by closure of the ventral urethrotomy. In the perineal or neoscrotal area, overlapping double-face grafts can be used (Figs. 18.3A and B). Dorsal inlay is done as described. In addition, a ventral onlay graft is placed and covered with a labial fat pad from the neoscrotum or a gracilis flap. As in urethroplasty for natal males, buccal mucosa graft is the graft of choice for substitution urethroplasty for two main reasons: (1) presence of pan-laminar vascular plexus and (2) nonkeratinized epithelium used in a wet environment.

A two-stage substitution urethroplasty may be done for long or recurrent strictures. The urethra is opened ventrally. A buccal mucosa graft is placed to widen the urethral plate (Figs. 18.4A and B). Six months later, the urethra is tubularized and the neophallus is closed. This technique has the highest success rate (70%) as reported in a large neophallus urethroplasty study.[13]

Perineal urethrostomy is another option if the patient does not have a desire to urinate in a standing position. The fixed urethra is opened and approximated to the perineum to expose the native urethral meatus (see Fig. 18.1C). Despite the approach, stricture recurrence rates remain high at 60%,[5] and multiple procedures may be necessary.[7] Urinary incontinence is not an uncommon problem in these patients. This is due to urine trapping in the fixed and phallic urethra.[15] Lifelong follow-up on bladder function is important due to the high risk of bladder dysfunction given the prevalence and recurrence of urethral strictures.[2]

PERSISTENT VAGINAL CAVITY

Etiology

Many FTM patients undergo vaginectomy as a part of their gender confirmation surgery. However, if there is a distal urethral stricture, the back pressure of urine causes urine to leak from the fixed urethra into the obliterated vaginal cavity (Fig. 18.5A). Incomplete vaginectomy predisposes to this condition. A collection of fluid in this cavity leads to obstructive symptoms, urinary incontinence, and recurrent urinary tract infections.

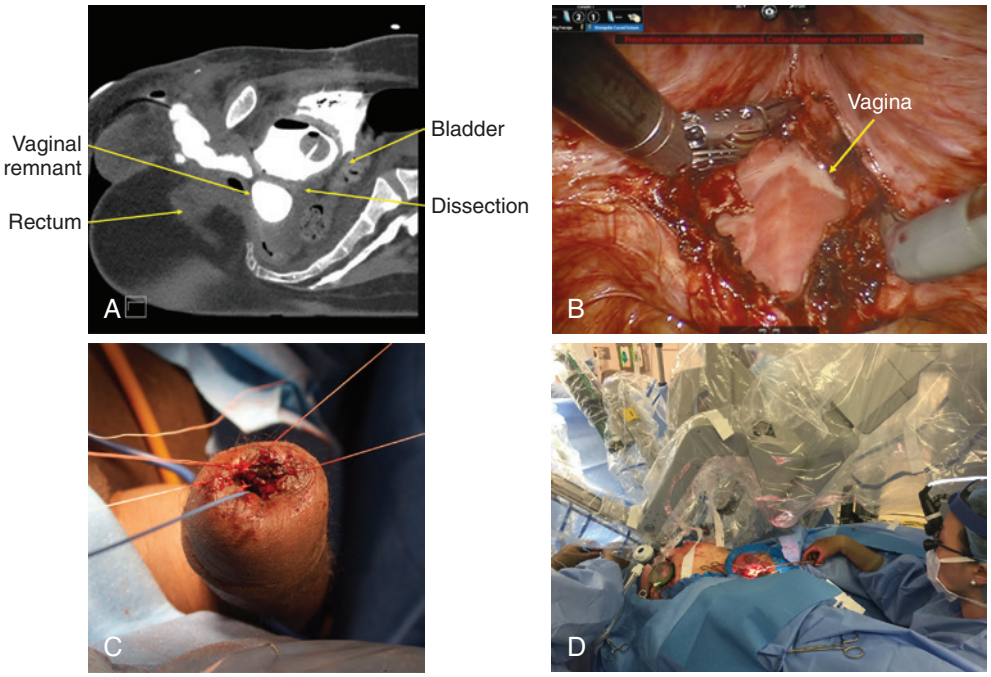

Figure 18.5 A, CT scan showing urine leaking into a cavity that is the remnant of the vagina. B, Image of robotic-assisted laparoscopic excision of the remnant vaginal cavity. C, Appearance of meatus after meatal reconstruction. D, The addition of the robotic technique to the standard perineal approach allows for intraabdominal deep pelvic dissection, helping to identify neighboring structures.

Diagnosis

If a persistent vaginal cavity is present, retrograde urethrogram and voiding cystourethrogram will reveal extravasation from the urethra and filling of a cavity. Examination under anesthesia and cystoscopy will help confirm the findings and aid in surgical planning.

Treatment

When a persistent vaginal cavity is found, it must be completely excised and the remaining space obliterated. The transabdominal robotic-assisted laparoscopic approach has been used to facilitate complete removal of the remaining vaginal epithelium (see Fig. 18.5B).

MEATAL STENOSIS OF NEOPHALLUS URETHRA

Etiology

The urethral meatus can become stenosed in about 15% of neophallus patients due to contraction of skin and the neourethra; blood flow may also be compromised at this point.[5]

Diagnosis

Diagnosis is made by physical examination. Retrograde urethrogram may be done if urethral stricture is suspected in the rest of the neourethra. Alternatively, cystoscopy is done at the time of reconstruction to assure that the rest of the urethra is normal.

Treatment

Meatal stenosis is treated with meatotomy if the rest of the urethra is uninvolved. The patient should be advised that this may result in mild hypospadias. To avoid the appearance of hypospadias, we incise the meatus in a ventral as well as dorsal fashion, excise the dense scar, and spatulate the opening (Fig. 18.5C).

Male-to-Female Gender Confirmation Surgery Complications

Surgeries for MTF gender confirmation consist of penectomy, clitoroplasty, labioplasty, orchiectomy, and vaginoplasty. While some patients undergo orchiectomy first, often all of these procedures are completed in the same surgical setting.[16] The most common technique for creating a neovagina utilizes the skin of the existing genitalia.[17] The penile skin inversion technique uses the foreskin and scrotal skin to create the vagina, and the glans penis is formed into the neoclitoris.[18] For those patients whose genital skin is not sufficient, a skin graft from the abdomen may be used to supplement.[19] Some surgeons have suggested using intestine (sigmoid, ileum, jejunum) as a substitute for genital skin. This technique's benefits include natural lubricant from the intestinal mucus secretion, no need to use hair baring skin or concern with hair regrowth, potentially a decreased need to dilate the neovagina because there are no skin grafts (scar shrinkage), and the natural caliber of the intestine.[20] However, this procedure is not without complications including stenosis at the bowel to skin anastomosis and the need to reconstruct the intestine, which can lead to risks of adhesions, bowel obstruction, bowel leak, and fistulas.[21]

The operative field for MTF surgery is the groin and perineum. The deep perineal dissection between the rectum

and the prostate can be more complicated. Experience with other procedures involving this deep perineal dissection, such as for perineal prostatectom, or posterior urethroplasty, may be useful. Additionally, depending on the patient's complication, the surgical planes may have been manipulated with resulting inflammation, scarring, and infection, making the operation more challenging.

Male-to-female procedures generally have fewer complications than FTM, likely due to the fact that less urethral reconstruction is required for this surgery. In a systematic review by Horbach et al. from a total of 12 studies, which included 1461 patients who underwent penile skin inversion, they found vaginal depth loss in 7%, meatal stenosis in 5%, neovaginal prolapse in 2%, and rectovaginal fistula in 1%.[22] The authors reported that these complications were able to be repaired with an average of one additional surgery, although follow-up was poor. Sigurjonsson et al. reviewed 205 of their MTF surgeries and found that 2% required additional surgeries for rectovaginal fistula, resection of retained corporal tissue, or meatoplasty.[23]

Most often the penile inversion vaginoplasty is performed through a single perineal incision. The surgeon uses the perineal incision to free the perineal body (central tendon) and continue the dissection, often bluntly, into a space anterior to Denonvilliers fascia and posterior to the prostate. This technique ultimately creates a vagina in the shape of a cone, which requires vaginal dilations to prevent closure.[7]

NEOVAGINAL FISTULA

Etiology

A fistula can form between the neovagina and neighboring structures resulting in rectovaginal and vesicovaginal fistula. While it has been thought that predisposing conditions like diverticular disease, ulcerative colitis, and Crohn's disease may increase the risk for intestinal fistula formation, a study of 1082 patients who underwent MTF surgery did not identify any risk factors. However, all 25 women who developed a fistula required at least one additional surgery. [24] While fistulas are uncommon, 1–2% in select series, these fistulas are caused during the neovaginal dissection, specifically at the most apical aspect.[17,21] All women required a surgical intervention. It is in this location that the surgeon encounters the prostate and posterior urethra. While one needs to be mindful of the rectum at all points in the case, this is the location where trying to define a plane posterior to the prostate is most difficult.[25] Operating deep in the perineum can be difficult, and even with modifications like rectal packing or a rectal speculum, injury to neighboring structures may be incurred.[26] An injury to the rectum that is recognized during the procedure should be repaired with a tension-free, multilayer closure followed by a low residue diet, without the need for diverting colostomy. Retrospective reviews have noted that rectovaginal fistulas are most likely caused by an unrecognized rectal injury, often with thermal or blunt dissection. These patients present with discharge from the vagina that is often brown or green and a comment of passing gas, or even stool, from the neovagina. Patients with vesicovaginal fistulas will present with urine drainage from the vagina, recurrent urinary tract infections, or pneumaturia.

Diagnosis

As stated earlier the diagnosis of a fistula can be made based on patient symptoms. If symptoms are suspected, a cystogram or a barium enema study can help to identify the fistula. In the case of vesicovaginal fistulas, cystoscopy is often not helpful because the tract may not be visible.

Treatment

All identifiable fistulas should be repaired with either primary closure or advancing a flap of local tissue (advancement flaps or pedicled flaps) for coverage.[24] Several authors have suggested a pedicled inferior gluteal artery fasciocutaneous flap because of its robust vascular supply and ability to be used throughout the perineum.[21,23,27] The location of the fistula determines if it can be repaired via a perineal approach or if it requires abdominal access. We find the use of the robotic-assisted laparoscopic approach with the interposition of omentum helpful in this regard. The decision to perform fecal diversion for a rectal fistula either with temporary colostomy or ileostomy is dependent on patient-specific characteristics and the expertise of the surgeon. Centers of excellence use these techniques when there is a very large fistula or gross stool spillage.[24,28,29]

STRICTURE OF NEOURETHRA OR MEATAL STENOSIS

Etiology

The anterior urethra (penile/bulbar) is separated from the corpora cavernosa, and the proximal urethra is then sutured circumferentially at the base of the neoclitoris. Meatal stenosis may occur due to compromised vascularity to the neomeatus. In a study of 66 patients who underwent MTF gender confirmation surgery, 5% were found to have meatal stenosis, and in a study of nearly 70 patients, 13% required surgical treatment.[27,28]

Diagnosis

The diagnosis is made based on patient symptoms. Meatal stenosis is typically characterized by a deflected urinary stream or by an increase in lower urinary symptoms including frequency, urgency, and dysuria or stranguria.[29] If symptoms are present, physical exam confirms the diagnosis.

Treatment

While a meatoplasty can be a straightforward case for most urologists, one needs to be aware that if the urethra cannot be identified, the patient will require urinary diversion with a suprapubic tube. It is prudent to have fluoroscopy or ultrasound in the operative suite during complicated urethral stricture repair. When performing the meatoplasty, one needs to be sure to have healthy urethral mucosa everted to the skin.

NEOVAGINAL STENOSIS OR ATRESIA

Etiology

When the vaginoplasty is performed through a single perineal incision and uses an inverted penile skin flap

technique, the resulting neovagina is shaped like a cone, which requires dilations to prevent closure. The timing to initiate dilations and the frequency of dilations is surgeon and center specific, but it is not uncommon for a patient to dilate 1–2 times a day. If a patient does not dilate or decreases the frequency of dilations, the neovagina may eventually contract to a diameter that causes pain with penetration. This creates a negative cycle where painful dilations are increasingly painful, which leads to a further decrease in dilations and eventual stenosis. Neovaginal stenosis can also be problematic because the tissue that lines the canal is skin and requires an opening to allow dead skin cells, sweat, and hair to leave. With neovaginal stenosis, bacteria thrive and an abscess can form.[30] Falcone et al. found neovaginal stenosis in 5.8% and atresia in 2.9% of their patients.[28]

Diagnosis

History and physical examination aid in the diagnosis of this complication. Patients relay a history of difficulty dilating as deeply as before, or a more painful dilation. Patients rarely present with vaginal atresia. Physical exam shows a narrower neovaginal canal than on previous examination. Because the narrowing usually starts in the most apical aspect of the canal, physical examination may not identify a change in depth, but the patient states that she can no longer pass the dilator as far as she did before. The contraction of the lumen may not occur in a uniform manner in a proximal to distal fashion, and there may be multiple areas of narrowing throughout the vagina.

Treatment

The first step in treatment is prevention, and if the neovagina is able to be formed as a cylinder and not a cone, not only is the need for dilation decreased but the complications of stenosis are decreased as well. We employ a transabdominal robotic-assisted laparoscopic approach to facilitate the dissection between the prostate and the rectum (similar to a robotic-assisted radical prostatectomy) and are able to connect to our perineal incision (Fig. 18.5D). This confirms an equal diameter for the entire length of the neovagina.

If patients present with stenosis a surgical procedure should be performed to relax the tension. We find that an incision perpendicular to the line of stress opens the tissue. The amount of incisions is determined in the operating room. If there is significant contracture, additional reconstructive techniques may be needed including rotational flaps. Depending on the amount of reconstruction that is performed, a vaginal stent may be placed postoperatively. Intestinal vaginoplasty is an option for complete vaginal atresia.

NEOVAGINAL PROLAPSE

Etiology

One of the most difficult and confusing aspects of the penile skin inversion vaginoplasty is how to best affix the apex of the vagina. Techniques include fixation to the sacrospinous ligament or fixture to local tissues. Authors in favor of sacrospinous ligament fixation state that it is the strongest tissue in the pelvis, and they note that this ligament has been used in vaginal vault and uterovaginal prolapse surgery for years.[31,32] Disadvantages to this procedure are risks of injury to the ureter, pudendal vessels, and nerves. Additionally, the sacrospinous ligament changes the vaginal axis to be directed to one side (right or left), making sexual intercourse difficult.[33] Because of these concerns some surgeons have suggested fixture of the neovagina at three points to local tissues, sparing the rectum, which ensures that the neovagina stays in normal orientation. A German group utilized fibrin glue for fixation of the neovagina in order to induce local scarring of the tissue.[34]

Prolapse can be understood as movement of the neovagina out of the perineal canal, which results in poor patient satisfaction with both the external aesthetic appearance and sexual intercourse. The patient may first notice prolapse after dilations as a sensation of the neovagina being pulled out of the canal.

Diagnosis

Patients will present to the surgeon's office with a complaint of their neovagina "falling out." Physical exam will demonstrate a mobile apex or side, and one will also notice some aspect of the neovagina protruding out of the canal.

Treatment

An exam under anesthesia will assist the surgeon to fully evaluate the location(s) of prolapse of the neovagina. We have been referred cases where prolapse is associated with flap necrosis. This requires significant debridement of the neovagina and additional skin grafts or flaps to repair. If the prolapse is distal, a dissection of the neovagina can be performed and tissues can be resuspended with 2-0 polydioxanone suture. If the prolapse is proximal or apical we recommend performing transabdominal exposure. In this approach, the posterior peritoneum is opened and the plane between the prostate and rectum is developed. The apex of the neovagina is suspended proximally and sutured circumferentially to ensure sufficient fixation and a normal vaginal axis.

Conclusions

Gender confirmation surgery is a challenging surgical endeavor. The expertise of urologists is important to ensure the best functional and aesthetic outcomes. The optimal approach to these complex cases is thorough preoperative planning to minimize postoperative complications. The management of postoperative complications often requires more than one surgical technique due to inflammation, scarring, infection, and compromised blood supply. The urologist is knowledgeable in the unique genital and urethral anatomy and the plastic surgeon is well versed in use of local flaps and grafts, thereby making a team approach desirable for initial gender confirmation surgery as well as management of complications.

Chapter 18 Questions

1. Complications of female-to-male (FTM) gender confirmation surgery include all the following EXCEPT:
   a. Urethral stricture
   b. Urethrocutaneous fistula
   c. Persistent vaginal cavity
   d. Meatal stenosis
   e. Neophallus prolapse

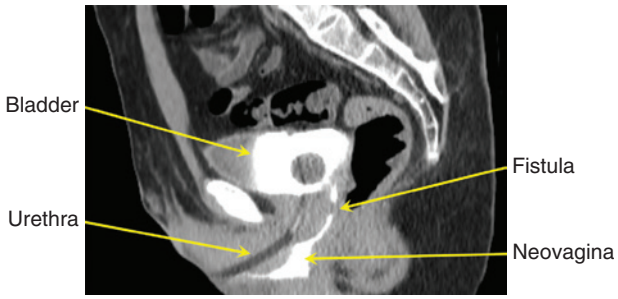
2. Complications of male-to-female (MTF) gender confirmation surgery include all the following EXCEPT:
   a. Neovaginal prolapse
   b. Persistent vaginal cavity
   c. Meatal stenosis
   d. Neovaginal atresia
   e. Neovaginal fistula

3. The neophallic urethra has five parts from proximal to distal as follows:
   a. Native, anastomotic, fixed, phallic, meatal urethra
   b. Native, phallic, anastomotic, fixed, meatal urethra
   c. Native, fixed, anastomotic, phallic, meatal urethra
   d. Native, meatal, phallic, anastomotic, fixed urethra
   e. Native, anastomotic, phallic, meatal, fixed urethra

4. Which neourethral segment is most susceptible to stricture?
   a. Fixed urethra
   b. Meatus
   c. Phallic urethra
   d. Anastomotic urethra
   e. Native urethra

5. Which of the following is the most common complication of FTM gender confirmation surgery?
   a. Urethrocutaneous (UC) fistula
   b. Oral pain from harvest of buccal mucosa for neourethra
   c. Meatal stenosis
   d. Persistent vaginal cavity
   e. Neophallus atresia

6. All of the following maneuvers aid in repair of the rectovaginal or vesicovaginal fistula EXCEPT:
   a. Bowel diversion in cases of gross spillage in rectovaginal fistulas
   b. Use of local tissue advancement flaps
   c. Use of pedicle flaps
   d. Wide excision of fistula
   e. Use of omentum interposition



7. Which of the following is NOT a disadvantage of affixing the neovagina to the sacrospinous ligament?
   a. Risk of injury to pudendal nerves
   b. Orientation of vaginal axis to the right or left
   c. Risk of injury to ureter
   d. Risk of injury to pudendal vessels
   e. Poor aesthetic appearance

8. A FTM transgender patient presents with lower urinary tract symptoms (LUTS) and post-void dribbling per urethra. Voiding cystourethrogram confirms a patient neophallic urethra, but also identifies a collection of contrast distal to the bladder that empties on delayed films. What is the underlying pathology, and how should it be treated?
   a. Postsurgical fistula, catheter drainage
   b. Persistent vaginal canal, surgical excision
   c. Persistent vaginal canal, catheter drainage
   d. Postsurgical fistula, surgical excision
   e. No intervention needed

9. A MTF with lower urinary tract symptoms (LUTS) physical exam (transvaginal) identifies an enlarged prostate, and post-void residual is 87 mL. Cystoscopy shows an enlarged prostate with bilateral tissue ingrowth without a median lobe. Bladder has minor trabeculations with normal urethral sphincter coaptation. Initial treatment for this patient should include:
   a. GreenLight photovaporization
   b. Transurethral resection of prostate
   c. Either GreenLight photovaporization or transurethral resection of prostate
   d. Neither GreenLight photovaporization nor transurethral resection of prostate
   e. Increased fluid intake

Case Study

A 37-year-old MTF transgender patient presented with urinary incontinence 6 months after penile inversion vaginoplasty. She described dribbling from neovagina only after dilation. No stress incontinence. On physical exam, the neovagina accommodated two fingers at the introitus; however, approximately ⅔ of the way into the neovagina there was a circumferential area of scar that narrowed the lumen. She was found to have a 0.5-cm fistula between the neovagina and the bladder on cystoscopy. Vaginoscopy was performed, which confirmed a thick band of scar tissue. CT cystogram identified the fistula as well (Case Fig. 18.1). The decision was made to formally repair the urethroneovaginal fistula and perform a revision vaginoplasty with skin graft supported by a pedicled muscle flap. The fistulous tract between the neovagina and the bladder was dissected free. The bladder was closed with interrupted sutures. We started the skin graft harvest by excising skin down to rectus fascia (Case Fig. 18.2). A split-thickness skin graft was created and divided. The skin graft was modeled into a neovagina over a 20-mL syringe (Case Fig. 18.3). After dissecting out the apex of the neovagina, we inset the graft, which was supported by a rectus muscle flap (Case Fig. 18.4). A vaginal stent was fashioned using a 20-mL syringe with the plunger removed, which was then wrapped in Xeroform gauze. Abdominal skin was closed with the help of plastic surgery (Case Fig. 18.5). The Foley catheter and vaginal stent were removed on postoperative day 10 (Case Fig. 18.6). The patient was most recently seen at 10-month follow-up and was engaging in sexual activity without pain or difficulty without requiring dilations.

Case Figure 18.3

Case Figure 18.4

Case Figure 18.5

Case Figure 18.6

1. Which of the following flaps or grafts are NOT used to create a neovagina?
   a. Stomach mucosa
   b. Sigmoid colon mucosa
   c. Penile skin
   d. Scrotal skin
   e. Abdominal skin

2. Urinary incontinence at time of neovaginal dilation is characteristic of which diagnosis?
   a. Urinary stress incontinence from damage to the external urinary sphincter during vaginoplasty
   b. Urge incontinence due to pudendal nerve damage
   c. Fistula between urethra and neovagina
   d. Vesicovaginal fistula
   e. Mixed stress and urge incontinence

3. Which of the following treatment options is most suitable for treatment of complete neovaginal stenosis?
   a. Perpendicular incisions to release the scar
   b. Local rotational flaps
   c. Intestinal vaginoplasty
   d. Prevention of scar formation by employing a transabdominal approach
   e. Use of abdominal skin graft for repair

Answers

1. **e.** a–d are possible complications from FTM gender confirmation surgery. e is incorrect; neovaginal, not neophallus, prolapse is a possible complication in MTF gender confirmation surgery.
2. **b.** Persistent vaginal cavity is a possible complication in FTM gender confirmation surgery where incomplete resection of the vagina results in a potential cavity that is susceptible to infections and/or fistula. The other options are potential complications from MTF gender confirmation surgery.
3. **c.** The urethra is divided into five segments from proximal to distal as follows: native (female) urethra, fixed urethra, anastomotic urethra, phallic urethra, and meatus. The fixed urethra is formed after lengthening of native urethra using local vaginal or labial flaps, regional flaps, and skin or mucosal grafts. The anastomotic urethra is the portion where the fixed urethra and phallic urethra are connected. Phallic urethra is constructed using prelamination, tube-in-tube techniques, and pedicle flaps. Meatus is the most distal urethral opening.
4. **d.** Anastomotic urethra is the most common site of neourethral stricture due to lack of adequate blood supply to this portion.
5. **a.** UC fistula is the most common urethral complication from FTM gender confirmation surgery and is reported in 22–75% of radial forearm free flap phalloplasties. Oral pain (b) is a rare complication after harvest of buccal mucosa. Meatal stenosis (c) is reported in 15% of cases, and persistent vaginal cavity (d) is uncommon. A neophallus does not typically undergo atresia; a neovagina may undergo stenosis or atresia more commonly.
6. **d.** The fistula does not need to be excised widely. It may be closed primarily with use of local flaps or omentum for vascular supply as well as interposition between suture lines. Bowel diversion may be used in cases of large rectovaginal fistulas or gross spillage.
7. **e.** All of the other choices (a–d) are disadvantages of affixing the neovagina to the sacrospinous ligament. It does not result in poor aesthetic appearance; therefore that is not a potential disadvantage.
8. **b.** This patient has a persistent vaginal canal. While all FTM patients should undergo vaginectomy and an obliteration of the remaining space as part of their gender confirmation surgery, an incomplete resection will cause a pooling of urine during voiding similar to a urethral diverticulum. After voiding has completed, this collection of urine will drain out causing LUTS symptoms and recurrent urinary tract infections. If a persistent vaginal canal is identified, we advocate for a transabdominal robotic-assisted laparoscopic approach for its removal.
9. **d.** The treatment algorithm of LUTS in transgender (MTF) patients should follow standard clinical practice with a trial of medication: alpha-blockers, with or without 5-alpha-reductase inhibitors, and possibly anticholinergic medication (if the LUTS symptoms are more consistent with urgency). Endoscopic evaluation is essential to confirm urethral strictures or injury to the urethral sphincter, which can happen during dissection of the genitourinary diaphram to form the neovagina. Initial endoscopic management by either GreenLight photovaporization or transurethral resection of prostate may be too aggressive, and the patient's symptoms may be managed by medical therapy alone.

CASE STUDY

1. **a.** The rest of the options listed have been used in construction of a neovagina.
2. **d.** Leakage at time of dilation is characteristic of vesicovaginal fistula, as the dilation opens up the fistula tract. A fistula between the urethra and neovagina would result in changes in urine flow, but not urinary incontinence.
3. **c.** When extensive neovaginal stenosis is present, intestinal vaginoplasty offers a definitive repair. For mild to moderate scarring, perpendicular incisions to release the scar (a) or local rotational flaps (b) may be used. Choice d is a preventative measure that should be considered during the initial vaginoplasty surgery. Grafts (choice e) are typically not used for repair but may be considered for a smaller stenotic area if there is a fasciomuscular flap for vascular supply.

19 Complications of Genitourinary Surgery in the Irradiated Pelvis

KARL COUTINHO and CHRIS M. GONZALEZ

CHAPTER OUTLINE

The Effects of Radiation on Wound Healing
Preoperative Evaluation and Patient Selection
Hyperbaric Oxygenation
General Intraoperative Considerations
Urethral Stricture
Rectourethral and Colovesical Fistula
Bladder Neck Contracture
Conclusions
Chapter 19 Questions and Answers

KEY POINTS

1. Radiation induced tissue ischemia, decreased tensile strength, increased scar formation, and inhibition of neovascularization all contribute to surgical complications in the previously irradiated patient.
2. Patient optimization through smoking cessation, improved nutritional status, and improved glycemic control may improve outcomes after surgery in the previously irradiated field.
3. Endoscopic management of radiation induced urethral strictures may increase the complexity of these strictures, prolong disease duration, and has a high rate of failure.
4. The keys to preventing complications in post radiation urologic surgery are multilayer, watertight, tension free closures with the interposition of healthy tissue.
5. Fecal diversion is mandatory prior to repair of post radiation rectourethral and colovesical fistulas.

Radiation therapy is an accepted primary and adjuvant treatment for a significant number of genitourinary, colorectal, and gynecologic malignancies. Within urology, external beam radiation therapy, brachytherapy, proton beam therapy, and other radiation modalities have become cornerstones in the treatment of prostate cancer, the most common nonskin-related malignancy amongst American men, with the second highest cancer-related mortality.[1] While efficacious in the treatment of prostate and other malignancies, radiation therapy can present unique and demanding challenges to the urologist due to its effects on surrounding genitourinary structures. In a retrospective series analyzing 964 patients, Dean and Lytton found a 2.5% incidence of urologic complications resultant from pelvic radiation after a 5- to 10-year follow-up.[2] In another retrospective study of 10,709 patients who received pelvic radiation for gynecologic malignancies, Maier and colleagues found a 1.24% incidence of severe urologic complications of which radiation cystitis (49%), urinary fistula (26%), and ureteral stenosis (25%) were most common. Most of these patients (88%) required a urologic procedure for which complication rates were significantly higher when compared to nonirradiated patients.[3]

This chapter describes the etiology, diagnosis, and perioperative management of common radiation-related complications of the lower urinary tract.

The Effects of Radiation on Wound Healing

To understand the complications of surgery in the previously irradiated field, it is important to discuss the pathophysiologic effect of radiation on tissue and wound healing. The process of wound healing begins at the moment of injury and is classically divided into four phases: hemostasis, inflammation, proliferation, and maturation.[4] Each stage is predictable in its onset and mediated by the interactions of numerous cell-signaling molecules in a sequential cascade. This complex process of healing can be interrupted directly or indirectly at several stages by the effects of radiation. The direct effects of radiation on cell proteins and DNA leads to inhibition of cell replication, or cell death through instability or apoptosis. The indirect effects of radiation involve the excitation of intracellular molecules and the generation of free radicals that in turn damage genetic material, signaling mechanisms, and other cell components.

Radiation's effect on the cell signaling molecules in the wound-healing cascade has been studied in a large and growing field of research. Radiation-induced alterations in the expression of several cell-signaling molecules have been documented in both human and animal models. These include interferon-γ (IFN-γ), transforming growth factor

beta (TGFβ), vascular endothelial growth factor (VEGF), nitric oxide (NO), and tumor necrosis factor (TNF), as well as a variety of interleukins (IL) and matrix metalloproteinases (MMPs). The downstream effects of these alterations include disorganization of extracellular matrices; impairment of neovascularization and cell migration; and disordered collagen deposition leading to compromised blood supply, tensile strength, and the inability to recover from subsequent insults,[5–8] all contributing to surgical complications in the irradiated field. The severity of these effects is dependent on a variety of factors, most importantly the total dose of radiation, dose per fraction, and surface area of the treatment field.[4,9,10] Individual sensitivity to radiation may also vary and has been shown to play a part in determining the extent of radiation-induced injury.[11–13]

Preoperative Evaluation and Patient Selection

An important step to improve surgical outcomes in the previously irradiated patient is minimization of risk factors for poor wound healing such as tobacco use, hyperglycemia, and poor nutritional status. Whenever possible these issues should be addressed preoperatively through patient counseling, referrals to specialists, or changes in medication.

Diabetic control can be assessed preoperatively though serum hemoglobin A1C (HbA1c) testing. Retrospective studies have identified increased length of stay and worsened surgical outcomes in diabetic patients with HbA1c levels at 7% or greater.[14–17] While the implications of rapid correction of HbA1c have been debated, and no widely accepted preoperative "cutoff" guidelines exist, diabetic control should be assessed via serum glucose and HbA1c testing in order to facilitate preoperative counseling regarding outcomes, especially in the previously irradiated patient. If the situation permits, referrals to diabetic nutritionists and endocrinologists should be pursued in order to maximize glycemic control preceding surgery.

Combustible tobacco use is a significant inhibitor of wound healing, necessitating cessation when at all possible prior to surgery. Smoking decreases oxygen levels in tissue, impairs cell migration, decreases neovascularization, and increases the presence of inflammatory mediators. This has been shown to result in increased rates of wound dehiscence, increased healing time,[18] worse cosmetic outcomes of surgical scars,[19] reduced skin graft take,[20] increased rates of postsurgical infections,[21] and increased overall complication rates.[22] With tenuous tissue characteristics already present in irradiated tissue fields, the impact of smoking greatly increases the risk for poor outcomes following surgery. Sørensen and colleagues have shown that smoking cessation results in restoration of tissue oxygenation and blood flow within 1 day, and restoration of inflammatory cell functions within 4 weeks.[23] This short timeline of reversal makes smoking cessation counseling a necessary step in the perioperative management of not just previously irradiated, but all urologic patients.[24]

Optimization of nutritional status is an important step in achieving good surgical outcomes. Several studies show improvements in surgical outcomes and complication rates with better preoperative nutritional status as measured by serum albumin and validated tools such as the Nutritional Risk Classification, or Nutritional Risk Screening 2002.[25–28] Enteric supplementation is universally preferred in patients who can tolerate it. However, studies evaluating the impact of short course (~10-day) preoperative enteric supplementation on postoperative complications and outcomes have yielded conflicting results.[29,30] Similarly, meta-analyses of studies on preoperative parenteral nutrition were also indeterminate as to its actual impact on outcomes.[31–33] Still, the European Society for Clinical Nutrition and Metabolism (ESPEN) guidelines suggest that there may be a benefit to preoperative short-term (7- to 10-day) parenteral nutrition prior to surgery in a select group of severely malnourished patients unable to sustain enteral supplementation. The American Society for Clinical Nutrition and Metabolism (ASPEN) recommends nutritional supplementation only when enteral intake is impaired. Although consensus is lacking, an assessment of nutritional status through albumin measurement, combined with patient characteristics through a nutritional screening tool, would allow the urologist to properly advise patients on their individual risk of complications related to poor nutrition.

Hyperbaric Oxygenation

Hyperbaric oxygenation (HBO) represents a potential perioperative therapy for carefully selected patients with a history of radiation. HBO has been used for over three decades in the treatment of post-radiation complications of head and neck cancers[34,35] and has been well explored in the treatment of radiation cystitis.[36] A recent meta-analysis on the use of HBO for a variety of surgical procedures, including pelvic surgery, suggests that preoperative HBO may reduce wound breakdown, infection, fistula formation, and flap loss after surgery in the irradiated patient.[37] Mechanisms of action discussed in this meta-analysis include stimulation of angiogenesis, reduction of fibrosis, improved tissue oxygenation, and stimulation of stem cells and stem cell derivatives.

In a small series of patients with a history of complications from pelvic radiation for gynecologic, bladder, and spinal malignancies, Pomeroy and colleagues showed a reduction in radiation-related post-surgical complications in patients treated with HBO prior to planned pelvic surgery.[38] Patients underwent 30 HBO "dive" sessions at 2.0 atmospheres prior to bladder augmentation, urinary diversion, or palliative resection of recurrent pelvic tumor, followed by 10 sessions postoperatively. The authors noted fewer radiation-related complications in these patients, which they attributed to the stimulation of angiogenesis and promotion of wound healing. Although limited by its size, this study indicates a possible role for pre- and postsurgical HBO therapy in reducing surgical complications in the previously irradiated patient.

General Intraoperative Considerations

The hallmarks of the irradiated surgical field are a paucity of reliable tissue planes, an abundance of scar tissue, and

tissue atrophy. Preoperative stents, catheters, or wires (through fistula tracts or small strictures) are useful in the identification of relevant genitourinary structures while operating in irradiated fields; the authors recommend their placement whenever possible. Additionally, the inhibition of collagen content remodeling seen with radiation leads to a decrease in tissue tensile strength.[39] As a result, maneuvers such as "sweeping" and other blunt dissection techniques may result in tissue damage rather than a separation of planes. Sharp dissection under visualization is key throughout any case in an irradiated field, with care taken to establish and reestablish anatomic landmarks during the procedure. Bony landmarks are most reliable, as they do not change post-radiation; however, palpation may be difficult in some areas due to patient size and fibrotic scar tissue.

General principles for wound closure in an irradiated field are shown in Box 19.1. A watertight closure of the urinary tract in multiple layers should be completed with irradiated tissue. The integrity of such closures should be tested via irrigation intraoperatively and reinforced if necessary. In situations where tissue integrity of the genitourinary tract is questionable, as in most post-radiation cases, the diversion of urine through urethral or suprapubic catheterization, or percutaneous nephrostomy drainage is prudent in order to maintain a dry anastomosis and prevent fistula formation and wound breakdown. Fecal diversion is mandatory in a post-radiation enteric fistula to the urinary tract, and should be performed prior to urologic repair. In cases of urinary diversion, a stepwise approach to "un-diversion" is advisable with replacement of catheters if urine leak is suspected. Often this process can take several weeks or months due to the slow healing nature of irradiated tissue. While algorithms have been described for periodic assessment and un-diversion,[40] there are no established guidelines for fecal un-diversion. Most studies, however, advocate waiting at least 3–6 months post successful repair.[41,42] In cases of rectal sphincter involvement or damage, consideration of a permanent diverting colostomy should be considered. Following fistula repair, fecal un-diversion should be attempted last, after urinary un-diversion and a period of observation to ensure proper closure of the urinary tract. Premature fecal un-diversion holds the risk of contamination, infection, and potential wound breakdown in the already tenuous irradiated field.

The interposition of nonradiated, healthy tissue into the irradiated field can be challenging and may be determined by the surgical approach. With perineal surgery, access to gracilis flaps, labial flaps, tunica vaginalis, or dartos tissue flaps should be considered. During transabdominal procedures the omentum is a reliable source of healthy tissue for interposition. Proper mobilization of a tension-free flap based on the right gastroepiploic artery allows for extension of the omentum as far inferiorly as the proximal urethra and should be utilized liberally in transabdominal procedures. Kulkarni and colleagues have described laparoscopic mobilization of omentum during the perineal approach for posterior urethroplasty.[43] In this series of patients undergoing repair of complex and re-do pelvic-fracture–associated urethral injury, omentum was mobilized inferiorly through a peritoneal incision and placed between the prostate and rectum. However, due to the close proximity of the rectum and the difficulty of dissection in this area, the use of omentum through this approach should be considered a last resort if no other healthy tissue is available.

Wound closure of the abdominal cavity and perineum is as crucial to operative success as any other factor in post-radiation surgery. A large retrospective analysis of 160 previously irradiated patients undergoing abdominoperineal resection of the rectum (APR) with perineal wound closure found that the rate of major wound complications more than doubled in patients with a history of pelvic radiation as compared to patients who did not receive radiation preoperatively (41% vs 19%, $p < 0.02$).[44] The rate of fascial dehiscence with major abdominal surgery for both irradiated and nonirradiated patients ranges from 1% to 6%,[45,46] with an average mortality of 25%.[47] While retrospective reviews have not associated prior radiation with an increased risk of abdominal dehiscence,[48] there is a lack of data in this patient population. The use of retention sutures to prevent postoperative abdominal-wall fascial dehiscence is controversial and has not been proven to provide benefit at the cost of greater patient discomfort and local complications at the suture site.[49] Abdominal binders may reduce pain postoperatively;[50] however, similar to the use of retention sutures, there is a lack of evidence to support the use of abdominal binders to prevent seroma formation or reduce the rates of wound dehiscence. Further information on abdominal wound closure is covered in detail elsewhere in this book.

Box 19.1 General Surgical Principles in the Irradiated Pelvis

1. Watertight closure of the urinary system
2. Interposition of healthy tissue
3. Multilayer closure of the GU tract
4. Tension-free wound closure
5. Appropriate diversion of the fecal and urine streams for fistulas

Urethral Stricture

Santucci and colleagues estimated the incidence of male urethral stricture disease to be about 0.6% of the general population.[51] Radiation therapy, through any modality, has been shown to increase this incidence. Among those who have had pelvic radiation, the incidence of urethral stricture increases from 1.7% to as high as 5.2% for those receiving combination brachytherapy and EBRT.[52,53] Overall, urethral strictures are most commonly associated with EBRT.[54] The pathophysiology of urethral stricture in the post-radiation patient is related to chronic oxidative stress subsequently leading to vascular damage, ischemia, and poor wound healing of the surrounding tissue.[55] The resulting fibrosis of the corpus spongiosum leads to urethral stricture formation, which can present several years following the completion of therapy, and is typically found in the bulbar urethra extending to the prostate.[56] Endoscopic management of these strictures, regardless of location and the type of intervention, carries a high rate of recurrence, upward of 50–60%.[56,57] Additionally, repeat endoscopic procedures

have been shown to increase the complexity and length of a stricture.[58]

The first step in management of the post pelvic radiation urethral stricture is the diagnosis of stricture length and location via a retrograde urethrogram (RUG). A suprapubic tube may be necessary in patients with obliterative urethral strictures. In these situations, antegrade cystoscopy and concomitant retrograde urethrogram can define a stricture's length and location (Fig. 19.1).

Urethroplasty in the irradiated pelvis can be a challenge due to tissue fibrosis and obliterated surgical planes of dissection. Utilization of a suprapubic cystostomy assists the surgeon in identifying the proximal extent of the urethral stricture which extends to the prostatic urethra during perineal dissection. It is advisable to start dissection distally, where the urethra is less affected by pelvic radiation, continuing proximally once the proper tissue planes are identified. As previously described, the typical bulbomembranous location of most radiation-induced strictures requires proximal dissection to the prostatic urethra.[55,59] Once proximal dissection is achieved, resection of necrotic tissue at or to the prostate may be necessary in order to expose healthy mucosa for an anastomosis. Surgical instruments such as a pituitary rongeur have been utilized to accomplish prostatic resection.[60] The Capio device (Boston Scientific, Massachusetts) has proven useful in the authors' experience to deliver anastomotic sutures to the prostatic urethra when conventional suture placement is not feasible. This device, often used in female prolapse surgery, allows passage and suture capture in limited space and operates at oblique angles, which makes it ideal to capture prostatic or bladder mucosa through the perineum.

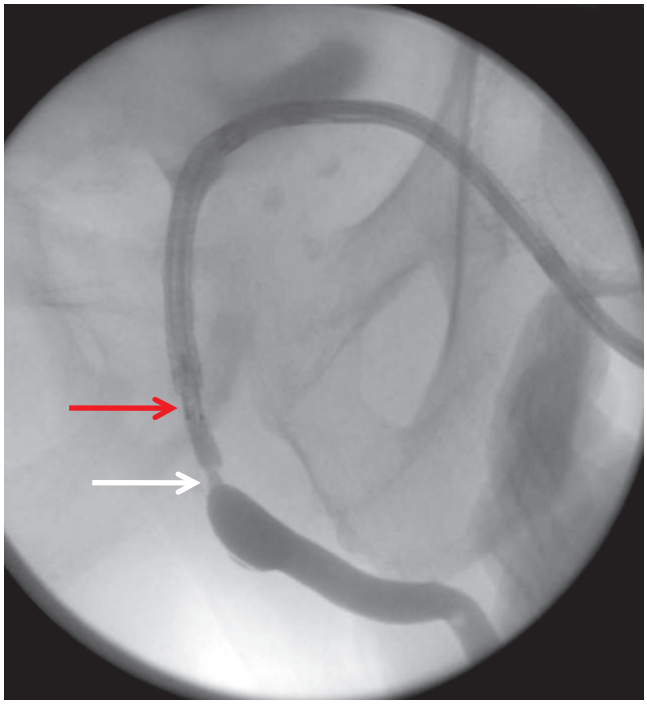

Figure 19.1 Simultaneous antegrade and retrograde urethrogram ("up-and-down-ogram") using a flexible cystoscopy though the suprapubic tract. The white arrow denotes stricture and the red arrow denotes the cystoscope.

Grafts or fasciocutaneous flaps may be utilized for the repair of lengthy post-radiation urethral strictures, with good results seen in small series.[61] However, graft uptake in the irradiated perineum can be somewhat tenuous due to the often fibrotic and avascular resection bed. Buccal mucosa appears to be the most ideal graft in these situations due to its thin lamina, good vascularization, and remote location away from the irradiated field. For excision and primary anastomosis (EPA), surgical maneuvers such as splitting of the corpora, re-routing the urethra around the corpora, or resection of the pubic bone have been described, but are rarely necessary once adequate mobilization of the proximal and distal urethra have been achieved.

Data evaluating the efficacy of urethroplasty specifically in post-radiation patients are limited to retrospective case series with limited follow-up. Nonetheless, acceptable outcomes following urethroplasty for post-radiation urethral strictures have been reported.[54,55,61] In one multi-institutional retrospective series of 72 men with radiation-induced strictures EPA was the predominate technique used. The average stricture length was 2.4 cm in this cohort, with most strictures located in the bulbar or bulbomembranous urethra.[60] Overall success was 70% in these men at an average of 2.9 years' follow-up. Stricture recurrence in this series was associated with stricture length >2 cm and treatment center.[54,60] Substitution urethroplasty in this series was reported on six patients; four patients with a graft and two with a flap. Mean stricture length in these men was 4.3 cm. Stricture recurrence was reported in one of these patients after 7 months.

In cases of relatively short (<3 cm) recurrent bulbar urethral strictures in the irradiated pelvis, repeat EPA should be considered in order to excise as much surrounding ischemic spongiosum as possible. Aggressive mobilization of the urethra is necessary and is feasible in the proximal bulbar urethra. In lengthier stricture recurrences, pedicled fasciocutaneous genital skin flaps may be more successful than graft substitution due to the added benefit of the flap retaining its own blood supply as compared to a graft placement into an irradiated host bed. Overall in irradiated patients, several studies have demonstrated successful outcomes using perineal, scrotal, or penile skin as both flaps and grafts, as well as gracilis muscle as a carrier for grafts.[60,62]

Urinary incontinence is a potential complication following bulbomembranous urethroplasty in the irradiated pelvis. In one series the onset of new postoperative urinary incontinence was 36–50%; however, 20% of these patients (3/15) experienced spontaneous resolution of their incontinence 4 weeks after surgery.[60] If incontinence does not resolve, an artificial urethral sphincter can be offered.[54,60,61]

As in nonirradiated patients, it does not appear that erectile function is significantly altered following urethroplasty in men with previous pelvic radiation.[60]

Rectourethral and Colovesical Fistula

The development of rectourethral (RUFs) or colovesical fistulas (CVFs) are troublesome complications seen in the post-radiation prostate cancer patients. While historically

associated with surgical injuries during rectal or prostate surgery, an increasing number of patients have been reported with radiation-induced fistula. The incidence of RUF after radiation ranges from 0.2%[63] to as high as 2.9%[64] in patients receiving multimodality radiation therapy for prostate cancer. Lane and colleagues reported that since 1998, 50% of reported cases of RUF involved pelvic radiation (mainly EBRT, brachytherapy, or combination), as opposed to 3.8% prior to 1998.[41] No matter what the approach, the repair of these fistulas can be tedious and difficult. Surgical planning and a multidisciplinary approach are necessary for a successful outcome.

Common signs and symptoms of RUF and CVF include fecaluria, urine per rectum, recurrent urinary tract infection (UTI), pelvic pain, and hematuria.[40] Patients with prior radiation have been reported to have a higher incidence of wound infection, transfusion requirements, and increased time to fecal un-diversion as compared to nonirradiated patients.[65] Identification and localization of RUF and CVF involve history, physical exam, imaging, and endoscopy. Physical examination includes evaluation of the perineum for cutaneous tracts, as well as digital rectal exam to palpate the fistulous tract and determine its distance from the anal verge. The fistula tract will generally feel firm and fibrotic on rectal exam. Computed tomography with triple infusion (oral, intravenous, and rectal contrast), followed by cystoscopy with retrograde urethrogram and cystogram, is recommended to localize the fistula and plan the reconstructive approach (Fig. 19.2). Cystoscopy has a high sensitivity (80–100%) for fistula diagnosis within the bladder and allows for measurement of the size and location of the fistula in relation to the ureteral orifice, prostate, bladder neck, and external urinary sphincter.[66] Small fistula tracts may not be visible, but can present as bullous edema of the urothelium, seen with raised erythematous edges (Fig. 19.3). Larger fistula can present on cystoscopy with an easily identifiable tract into the rectum (Fig. 19.4). Biopsy of the fistula tract during cystoscopy is recommended if there is a suspicion of malignancy. Anoscopy or colonoscopy is also useful in surgical planning and should be performed by appropriate specialists in order to identify the enteric fistula location and size.

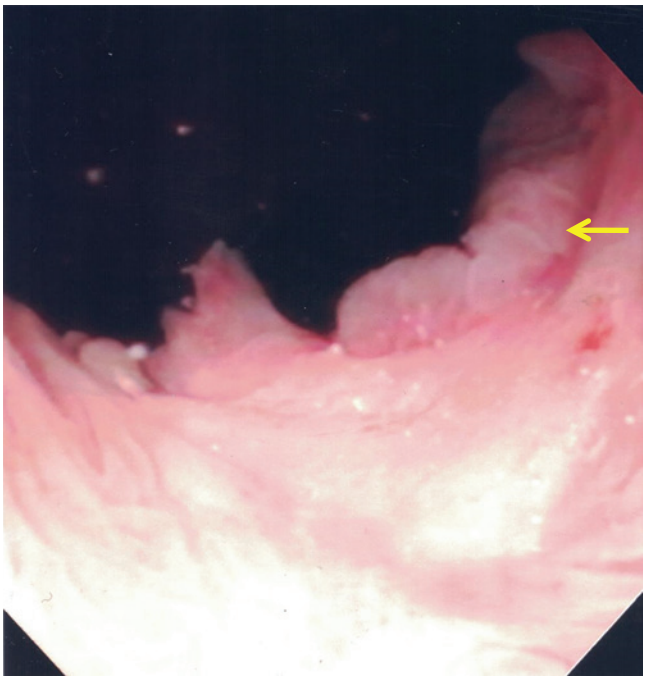

Figure 19.3 A rectourethral fistula seen on cystoscopy with raised, bullous, mucosal edges and erythema (arrow).

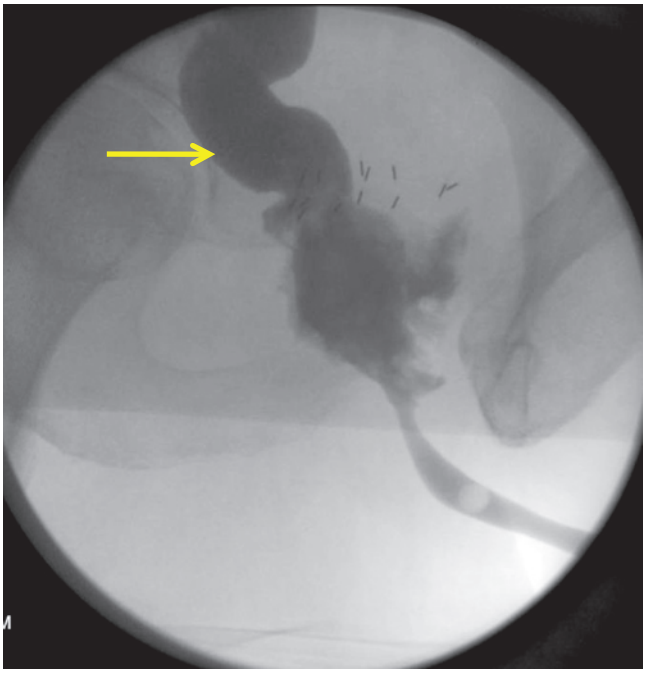

Figure 19.2 Appearance of a rectourethral fistula on retrograde urethrogram. Contrast is seen filling the rectum (arrow), with brachytherapy seeds noted in the prostate.

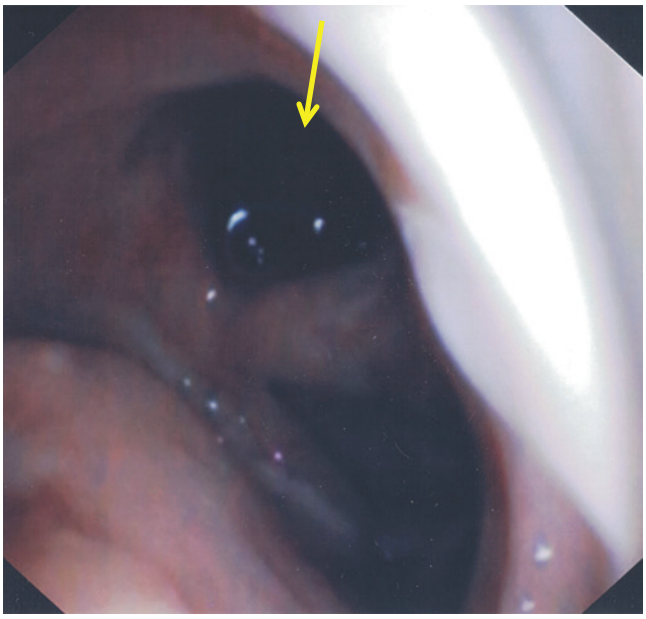

Figure 19.4 A large rectourethral fistula noted on cystoscopy with a clear view of the rectal mucosa (arrow) seen from the lumen of the urethra.

In the previously irradiated patient, fecal diversion in conjunction with urinary diversion is mandatory. Temporary suprapubic urinary diversion is useful for two reasons: It allows the diversion of urine away from the fistula, and it allows "urethral rest" in order to evaluate the patient for concurrent urethral stricture formation. One study puts the incidence of concurrent urethral strictures at 30% in patients with RUF.[42] Although conservative management with both urinary and fecal diversion has been successful in some patients with small, less fibrotic fistulas,[67] it is rarely successful in our experience with post-radiation RUF or CVF. Furthermore, HBO therapy has not been shown to reduce the need for surgical management.[68] Assessment of a patient's functional and health status is key, as operative management tends to be more complex with a longer postoperative recovery in the irradiated patient.[65] The location of these fistulas can range from the bladder to the bulbar urethra, highlighting the need for both cystoscopy and radiologic imaging to fully assess the extent of disease. Preoperative ureteral stenting can be considered prior to repair of fistulas that appear to be in close proximity to the ureteral orifices, especially in post-prostatectomy patients.

Options for management of radiation-induced RUF and CVF depend on the location, size, and etiology of the fistula. Due to the rarity of these fistulas, combined with their heterogeneity in type and patient characteristics, there are little data on the standard approach to surgical management. Prior to incision, placement of a small catheter or guidewire may aid in identification of the fistula tract.[69] Surgical approaches to the fistula include trans-sphincteric, transanal, transperineal, or transabdominal. General surgical principles necessary to achieve the best outcomes for a fistula in a previously irradiated pelvis are shown in Box 19.2. While some studies have noted worse outcomes of fistula repair in post-radiation or cryotherapy patients,[70,71] Whick and colleague's meta-analysis of all available RUF patients undergoing repair showed comparative success rates (90%) for irradiated and nonirradiated patients alike, with the exception of patients who underwent transanal repair. A transabdominal approach was most commonly utilized in previously irradiated patients undergoing RUF repair (74.4%). However, direct comparison of groups in this case series was difficult as operative approaches and postoperative permanent fecal and urinary diversion rates were significantly different for irradiated and nonirradiated patients. Additionally, 25% and 42.5% of irradiated patients were unable to have their fecal and urinary diversions reversed after RUF repair, respectively, as compared to only 4% of nonirradiated patients.[72] Similar to urethral stricture repair, urinary incontinence was not uncommon after RUF repair (up to 71% in one cohort of both irradiated and nonirradiated patients).[73] For those patients with moderate-to-severe urinary incontinence following RUF repair, successful treatment with AUS implantation has been reported.[73,74]

The transphincteric approach was developed circa 1960 by English surgeon Aubrey York Mason, for whom it is now commonly named. Utilizing this approach, the patient is placed in a prone jackknife position (Fig. 19.5). An incision is made from the anal verge to the coccyx, allowing dissection through subcutaneous tissue with exposure of the posterior rectal wall. The posterior rectal wall is opened, exposing the anterior rectal wall and fistula tract. This dissection requires careful division and reapproximation of the rectal sphincter.[75] With proper technique, the risk of postoperative fecal incontinence is negligible.[76,77] The York Mason approach was described for RUF repair in 1969 by both Kilpatrick and Mason.[78] This approach is beneficial in providing excellent visualization of proximal RUF and CVF fistulas near the bladder neck. Closure can be accomplished in three layers (urothelium, interposed mucosa, and rectal wall), and this approach is generally well tolerated with relatively limited recovery time. However, interposition of healthy tissue between the urinary tract and rectum is limited to tissue immediately adjacent to the fistula, which may also be damaged from prior radiation. Interposition of distant healthy tissue such as a gracilis flap requires a separate perineal incision, which increases operative morbidity. While good results have been shown for many iatrogenic RUFs, the York Mason approach has a higher rate of recurrence with radiation-induced strictures (4/7 patients recurred in one study) and larger diameter fistulas and is, therefore, not recommended for complex post-radiation RUF, re-do RUF repair, or post-radiation fistulas greater than 2 cm.[79]

The transanal approach to RUF repair involves dilation and circular retraction of the anus, allowing exposure of the fistula tract through the dilated anal canal. The fistula tract can then be excised and a flap of rectal mucosa is closed over the tract. The transanal approach is well tolerated and has the benefit of avoiding disruption of the rectal sphincter.[80,81] However, exposure is difficult for proximal

Box 19.2 Surgical Principles for Rectourethral Fistula Repair in the Irradiated Pelvis

1. Prior fecal and urinary diversion
2. Identification of the fistula tract through adequate exposure
3. Complete excision of the fistula tract and pathologic analysis of tissue
4. Interposition of healthy tissue
5. Multilayered closure of the fecal and urinary streams

Figure 19.5 Prone jackknife positioning.

fistulas, and this technique does not allow for healthy tissue interposition. Meta-analysis of outcomes after fistula repair demonstrated a higher rate of surgical repair failure for the transanal approach when compared to other approaches.[72] Therefore complex or irradiated RUF using a transanal approach should be avoided.

The perineal approach is well represented in literature, especially amongst urologists. Two recent studies utilizing the transperineal approach for RUF amongst patients with previous pelvic radiation and ablative therapy demonstrated successful fistula closure rates of 76.9% and 100% at mean follow-up times of 15.6 and 11.4 months, respectively. In both studies all patents underwent fecal diversion preoperatively, and most (38% and 100% in each study, respectively) underwent tissue interposition during the perineal approach. In these studies, the most common interposed tissue was gracilis muscle (9/20 patients combined), followed by dartos (2/20), and a rectus muscle flap (1/20).[42,73]

During the transperineal approach, the patient can be placed in either a lithotomy or prone jackknife position. A U-shaped incision is made in the perineum, and dissection is carried proximally between the urethra and rectum until the fistula tract is encountered and excised and the surrounding rectal and urethral mucosa closed. Exposure of rectal fistulas involving the proximal urethra or bladder may be difficult with this approach, especially in obese patients. Management of the urethral defect is through primary closure or, for larger urethral defects, graft onlay.[73] Benefits of the perineal approach include the familiar dissection for the urologist as well as the ability to interpose a variety of tissue sources between the bowel and urinary tract suture lines including gracilis muscle, genital skin, or tunica vaginalis. Dartos muscle interposition during the perineal approach is possible; however, a higher rate of failure has been reported, most likely due to the fact that the dartos tissue also resides within the irradiated field.[82] Gracilis muscle interposition has been utilized most successfully in post-radiation patients with the perineal approach as this tissue is robust, well vascularized, and located outside of common radiation field limits.[71,73] The use of synthetic grafts such as AlloDerm has also been described with successful outcomes in radiotherapy- and cryotherapy-induced fistulas.[83]

The transabdominal approach is recommended for more anatomically proximal fistulas or when simultaneous bowel resection, prostatectomy, or other related procedures may be necessary. While more invasive than other approaches, a lower midline incision allows for excellent exposure of CVF after opening the anterior bladder wall. Access to the omentum allows for ample tissue interposition during repair. In meta-analysis, the transabdominal approach provided the best rates of success for radiation- or ablative-therapy-induced RUF repair, with a failure rate of only 6.9% (2/29 patients).[72]

Bladder Neck Contracture

Bladder neck contracture (BNC) is a complication most commonly reported in the post–radical prostatectomy patient; however, BNC after radiation therapy is notably different from posttraumatic or postsurgical etiologies. Often these contractures can present years after treatment and are thought to be a result of microvascular injury causing progressive, chronic ischemia, fibrosis, and necrosis.[84–87] Multimodal therapy for prostate cancer, which includes any form of radiation, has been associated with higher rates of BNC and a higher risk of failure of endoscopic treatment.[88–90] Patient characteristics, such as active cigarette smoking, hypertension, diabetes, and coronary artery disease, have also been linked to a higher rate of BNC development after prostatectomy in cohorts that included patients with prior pelvic radiation, emphasizing the importance of patient counseling.[91,92]

After clinical signs and symptoms present, such as difficulty with urination and high post-void residual, the diagnosis of BNC can be confirmed via cystoscopy or RUG (Fig. 19.6). In-office urethral dilation has been described with postprostatectomy BNC, with the best outcomes in patients compliant with intermittent self-catheterization protocols to maintain bladder neck patency.[93] However, these outcomes are reported in cohorts where the etiology of BNC is previous transurethral resection of prostate or radical prostatectomy without adjuvant radiation. There are little data to determine if post-radiation strictures respond similarly.

Various modalities such as the cutting loop, hot knife, cold knife, and laser have all been described for post prostatectomy and post-radiation BNC, with varying degrees of efficacy.[94–97] Recent data have demonstrated good outcomes using balloon dilatation followed by deep lateral bladder neck incisions with a hot knife at the 3- and 9-o'clock positions into perivesical fat.[92] The majority of patients in this study (78%) had failed previous attempts at endoscopic management before attempting bladder neck incision. Over a 5-year period, 50 patients underwent deep lateral incisions of their BNC with a 72% success rate at a mean follow-up of 12.9 months. Success of the procedure was defined as passage of a flexible cystoscope without the need for further procedures. Again, this cohort was primarily

Figure 19.6 Retrograde urethrogram of a bladder neck contracture after radical retropubic prostatectomy.

patients who developed BNC after radical prostatectomy (35/50, 70%) or TURP (13/50, 26%), with a limited number of patients who underwent prostatectomy with adjuvant radiotherapy (2/50, 4%). Nonetheless this approach can be considered for endoscopic management of a BNC in the previously irradiated pelvis.

Intralesional injection of mitomycin C after cold knife bladder neck incision has been reported in the nonirradiated, post–radical prostatectomy, recurrent-BNC population with a 72% success rate after a single treatment at median follow-up of 12 months.[98] However, in a multi-institutional trial of 55 patients, of which 25% had prior radiation therapy for prostate cancer, success after a single treatment was lower at 58% at a median follow-up of 9 months.[99] In this same study, four patients were reported to have experienced serious adverse effects (Clavien IIIb) from mitomycin including osteitis pubis, bladder necrosis, and RUF. Of note, three out of these four patients had prior radiation therapy, and all three irradiated patients required eventual cystectomy and urinary diversion. Similar adverse effects including bladder and perivesical fat necrosis have been described in other mitomycin trials.[100] Steroid injection following holmium laser BNC incision has been described with success rates of 83% at a mean follow-up of 24 months in a cohort of post–radical prostatectomy patients, most of whom (79%) had recurrent BNC.[101]

More study is needed to determine the role of steroid or mitomycin injection following BNC endoscopic incision.

Open bladder neck reconstruction has been reported, almost exclusively in the nonirradiated, postprostatectomy population.[102,103] The surgical approach is determined by the patient's anatomy and extent of fibrosis. The key to a successful repair is adequate exposure of the bladder neck during reconstruction. Exposure has been described through perineal, abdominal, transpubic, or a combination of approaches depending on the extent of the contracture and other individual patient characteristics. In one series of four patients with postprostatectomy BNC reconstruction, two patients underwent pubectomy with bladder neck reconstruction completed with a penile skin onlay flap in one, and reconstruction of an anterior bladder neck tube in another. Transpubic exposure allowed for rectus muscle flap and omental interposition to cover each repair, respectfully. A third patient, the only one to have received previous radiation, underwent a perineal approach due to a long stricture involving the anterior urethra. In this case, a penile fasciocutaneous flap was used to complete a combined onlay urethroplasty with bladder neck repair. The last patient underwent a combined abdominal and perineal approach with excision and end-to-end primary anastomosis. At a mean of 33.8 months, all patients had a patent urethra, although one required a single dilatation after surgery. All patients were incontinent after their procedure, and two underwent successful placement of a staged AUS.[103]

A combined abdominal and perineal approach was described in a series of six patients with obliterated BNC after multiple attempts at endoscopic intervention.[102] In this series, abdominal and perineal approaches were used to mobilize the bladder neck distally and the bulbomembranous urethra proximally for a tension-free end-to-end anastomosis. All patients received simultaneous AUS placement, and three patients received bladder augmentation with ileum. Five patients were voiding adequately at a mean follow-up of 24 months, with one patient requiring intermittent self-catheterization. Almost all patients were continent at last follow-up, with one patient requiring one pad daily. Only one patient had erosion of the AUS cuff, requiring replacement. Of note was that none of these patients had previous radiation exposure. In the authors' experience men with recalcitrant BNC following radical prostatectomy, adjuvant XRT, and failed endoscopic management (Fig. 19.7) are best approached with a simultaneous abdominal and perineal approach. It is important to assess bladder capacity prior to reconstruction in these patients as those with a capacity less than 200 mL will require bladder augmentation as well, or urinary diversion. In this combined approach the pubic bone is resected through the transabdominal approach for exposure to the bladder neck and to allow for anastomosis of the mobilized urethra to the bladder neck (Fig. 19.8A, B). Staged AUS for urinary incontinence is planned 4–6 months following this procedure, as all are incontinent of urine. In men with recalcitrant BNC following radiation treatment to the prostate, a retropubic approach to the bladder neck provides adequate exposure for excision of the BNC and creation of an anterior bladder wall advancement flap. Preoperative evaluation must demonstrate a bladder capacity of at least 250–300 mL in these patients for development of an appropriately sized anterior bladder wall advancement flap.

In patients with recalcitrant BNC not amenable to bladder neck reconstruction, bladder neck closure with concurrent creation of a catheterizable stoma with bladder augmentation has been described with acceptable outcomes.[88] Urinary diversion with or without cystectomy represents another option for patients who are not candidates or who do not desire bladder neck reconstruction.

Conclusions

Surgery in the previously irradiated pelvis presents a unique challenge for urologists. In addition to dealing with the many complications of radiation damage to the tissues, the risk of surgery is considerably higher even in the absence of discernible complications. When performing routine procedures on the prostate, bladder, and lower ureters following radiation, one must be attentive to the condition of the tissues. Even when normal in appearance, it is likely that vascularity, pliability, and healing are compromised, thus resulting in a higher likelihood of leak, stricture, and need for reoperation. Identification of healthy tissue, minimization of excessive mobilization (thereby disrupting already fragile vascularity), and interposition of healthy tissues are all essential operative strategies for achieving good outcomes. In utilizing specialized techniques, good outcomes can clearly be achieved. In dealing with strictures, fistulas, or badly damaged bladders as a consequence of radiation injury, one must recognize that there is a high likelihood of treatment failure with conservative or minimal surgical approaches. Surgical reconstruction with a low threshold for diversion in cases of refractory disease processes, may be prudent.

Chapter 19 Questions

1. Perioperative hyperbaric oxygenation has been shown to do which of the following in the previously irradiated patient?
   a. Reduce fibrosis
   b. Stimulate stem cell and stem cell derivatives
   c. Improve tissue oxygenation
   d. Reduce wound breakdown
   e. All of the above

2. Which of the following is TRUE regarding perioperative nutritional support?
   a. Parenteral supplementation is preferred over enteral nutrition in patients with poor nutrition status
   b. Serum sodium and glucose levels are the most useful blood tests to determine nutritional status
   c. The American Society for Clinical Nutrition and Metabolism (ASPEN) recommends nutritional supplementation only when enteral intake is impaired
   d. Nutritional status has not been shown to have any impact on wound healing
   e. Nutritional screen tools have not been validated for clinical use in screening preoperative patients

3. Place these steps of the wound healing cascade in the correct order:
   a. Hemostasis, maturation, inflammation, and proliferation
   b. Proliferation, inflammation, hemostasis, and maturation
   c. Hemostasis, inflammation, proliferation, and maturation
   d. Inflammation, hemostasis, maturation, and proliferation
   e. Hemostasis, proliferation, inflammation, and maturation

4. Radiation has all of the following effects on treated tissue, EXCEPT:
   a. Disorganization of extracellular matrices
   b. Increased cell migration
   c. Reduction in tissue tensile strength
   d. Impairment of neovascularization
   e. Disordered collagen deposition

5. The perineal approach to rectourethral fistula repair allows easy access to all of the following tissues useful for interposition EXCEPT:
   a. Gracilis muscle
   b. Tunica vaginalis
   c. Dartos muscle
   d. Omentum
   e. Penile skin

6. Which surgical approach to rectourethral fistula repair is NOT recommended in the previously irradiated patient?
   a. Transanal approach
   b. Abdominal approach
   c. York Mason approach
   d. a and c only
   e. a and b only

7. Which of the following is TRUE regarding the surgical treatment of post-radiation fistula?
   a. Pelvic MRI is the most sensitive test for the diagnosis of rectourethral fistula
   b. The incidence of concurrent urethral stricture in patients with rectourethral fistulas is as high as 30%
   c. Cystoscopy has poor sensitivity in the diagnosis of colovesical fistula
   d. Un-diversion of the GI tract should be attempted before urinary un-diversion in the post–rectourethral fistula repair patient
   e. On digital rectal exam, a fistula tract will feel spongy and soft

8. Which of the following is TRUE regarding open bladder neck reconstruction of a recalcitrant bladder neck contracture in a man following radical prostatectomy and adjuvant radiation therapy?
   a. Bladder neck reconstruction should be the first step in managing post-radiation bladder neck contractures
   b. Bladder capacity must be 200 mL or less in order to develop a sufficient bladder advancement flap for bladder neck reconstruction
   c. Bladder neck reconstruction is almost always associated with postoperative urinary incontinence
   d. Exposure of the anterior urethra is the key step in a successful open bladder neck reconstruction
   e. AUS placement is not recommended after open bladder neck reconstruction due to the risk of erosion

9. Which of the following is FALSE regarding endoscopic management of post-radiation urethral strictures?
   a. Endoscopic management of these strictures carries a recurrence rate upward of 50–60%
   b. Repeat endoscopic procedures have been shown to reduce the complexity of strictures and shorten disease duration
   c. Cystoscopic evaluation and retrograde urethrogram are the recommended initial diagnostic studies to determine stricture location and length
   d. Antegrade cystoscopy and injection of contrast through a suprapubic tract is useful in determining the length of obliterative urethral strictures
   e. All of the above

10. Which of the following complications is least associated with urethroplasty in the post-radiation patient?
    a. Urinary tract infection
    b. New onset urinary incontinence
    c. New onset erectile dysfunction
    d. Hematuria
    e. Dysuria

11. The most common location for post-radiation urethral stricture formation is at the:
    a. Bulbomembranous urethra
    b. Bladder neck
    c. Fossa navicularis
    d. Penile urethra
    e. Prostatic urethra

Case Study 1

A 52-year-old man with a history of prostate cancer treated with brachytherapy and external beam radiation therapy 6 months prior to presentation has a 1-week history of dysuria and urine per rectum. A retrograde urethrogram was performed.

1. What is the next step in the management?
   a. Rectourethral fistula repair through the perineal approach
   b. Fecal diversion
   c. Hyperbaric oxygenation
   d. Fulguration of fistula tract
   e. Observation

Case Study 2

A 60-year-old man with a history of prostate cancer treated with external beam radiation therapy 6 years ago presents with slow urinary stream and dysuria. A retrograde urethrogram is shown.

1. The next step is:
   a. Suprapubic tube drainage
   b. Urethroplasty with buccal mucosa graft
   c. Excision and primary anastomosis
   d. Direct visualization internal urethrotomy
   e. Transurethral incision of the bladder neck

Answers

1. **e.** A recent meta-analysis on the use of HBO for a variety of surgical procedures, including pelvic surgery, suggests that preoperative HBO may reduce wound breakdown, infection, fistula formation, or flap loss after surgery in the irradiated patient. Mechanisms of action discussed in this meta-analysis include stimulation of angiogenesis, reduction of fibrosis, improved tissue oxygenation, and stimulation of stem cells and stem cell derivatives.
2. **c.** The European Society for Clinical Nutrition and Metabolism (ESPEN) guidelines suggest that there may be a benefit of preoperative short-term (7–10 day) parenteral nutrition prior to surgery in a select group of severely malnourished patients unable to sustain enteral supplementation. The American Society for Clinical Nutrition and Metabolism (ASPEN) recommends nutritional supplementation only when enteral intake is impaired. Although consensus is lacking, an assessment of nutritional status through albumin measurement, combined with patient characteristics through a nutritional screening tool, would allow the urologist to properly advise patients on their individual risk of complications related to poor nutrition.
3. **c.** The process of wound healing begins at the moment of injury and is classically divided into four phases: hemostasis, inflammation, proliferation, and maturation. Each stage is predictable in its onset and mediated by the interactions of numerous cell-signaling molecules in a sequential cascade.
4. **b.** This complex process of healing can be interrupted directly or indirectly at several stages by the effects of radiation. Direct effects of radiation on cell proteins and DNA lead to inhibition of cell replication, or cell death through instability or apoptosis. Indirect effects of radiation involve the excitation of intracellular molecules and the generation of free radicals that in turn damage genetic material, signaling mechanisms, and other cell components. Radiation-induced alterations in the expression of several cell-signaling molecules have been documented in both human and animal models. The downstream effects of these alterations include disorganization of extracellular matrices; impairment of neovascularization and cell migration; and disordered collagen deposition leading to compromised blood supply, tensile strength, and the inability to recover from subsequent insults, all contributing to surgical complications in the irradiated field.
5. **d.** A number of healthy tissues are available for interposition when operating through the perineum, but as the peritoneal cavity is not entered directly, the omentum is not accessible without an alternate incisional approach.
6. **d.** While good results have been shown for many iatrogenic RUFs, the York Mason approach has a higher rate of recurrence with radiation-induced strictures (4/7 patients recurred in one study), and larger diameter fistulas, and is therefore not recommended for complex post-radiation RUF, re-do RUF repair, or post-radiation fistulas greater than 2 cm. With the transanal approach, exposure is difficult for proximal fistulas, and this technique does not allow for healthy tissue interposition. Meta-analysis of outcomes after fistula repair demonstrated a higher rate of surgical repair failure for the transanal approach when compared to other approaches. Therefore complex or irradiated RUF using a transanal approach should be avoided.
7. **b.** One study puts the incidence of concurrent urethral strictures at 30% in patients with RUF. Although conservative management with both urinary and fecal diversion has been successful in some patients with small, less fibrotic tissue, it is rarely successful in our experience with post-radiation strictures.
8. **c.** In limited reports of bladder neck reconstruction for contraction following radiation, patients are uniformly incontinent following the procedure. For this reason, simultaneous artificial urinary sphincter placement is usually utilized.
9. **b.** The first step in management of the post–pelvic radiation urethral stricture is the diagnosis of stricture length and location via a retrograde urethrogram (RUG). A suprapubic tube may be necessary in patients with obliterative urethral strictures. In these situations antegrade cystoscopy and concomitant retrograde urethrogram can define a stricture's length and location. Endoscopic management of these strictures, regardless of location and the type of intervention, carries a high rate of recurrence, upward of 50–60%. Additionally, repeat endoscopic procedures have been shown to increase the complexity of strictures and prolong disease duration.

10. **c.** Urinary incontinence is a potential complication following bulbomembranous urethroplasty in the irradiated pelvis. In one series the onset of new postoperative urinary incontinence was 36–50%; however, 20% of these patients (3/15) experienced spontaneous resolution of their incontinence 4 weeks after surgery. If incontinence does not resolve, an artificial urethral sphincter can be offered. As in nonirradiated patients, it does not appear that erectile function is significantly altered following anterior urethroplasty in men with previous pelvic radiation.
11. **a.** The pathophysiology of urethral stricture in the post-radiation patient is related to chronic oxidative stress subsequently leading to vascular damage, ischemia, and poor wound healing of the surrounding tissue. The resulting fibrosis of the corpus spongiosum leads to urethral stricture formation, which can present several years following the completion of therapy, and is typically found in the bulbar urethra extending to the prostate.

CASE STUDY 1

1. **b.** The retrograde urethrogram and cystogram picture clearly demonstrate an enteric fistula to the lower urinary tract. Given this patient's prior history of radiation, fecal diversion is mandatory and the first step in management, prior to repair. Consideration should also be given to suprapubic drainage of the urine away from the fistula. While hyperbaric oxygenation has been shown to aid wound healing and prevent fistula formation in the previously irradiated field, it is not a treatment option for an active fistula. Fulguration of the fistula tract is unlikely to be successful given the patient's prior radiation and the extent of the fistula as evidenced by the amount of extravasated contrast. Observation will not improve the patient's condition.

CASE STUDY 2

1. **b.** The retrograde urethrogram demonstrates a relatively long post-radiation urethral stricture best managed with graft interposition. Excision and primary anastomosis is best reserved for men with strictures <2 cm. Endoscopic management via direct visual internal urethrotomy has been shown to have a high rate of recurrence in men with previous pelvic radiation and may increase the complexity of strictures and prolong disease duration. Transurethral resection of the bladder neck would not address this patient's urethral stricture. Suprapubic drainage is not necessary in this case as the patient is voiding and there is no indication of urinary retention.

SECTION IV

Complications of Ambulatory Urologic Procedures

20 Prostate Biopsy Complications

MEENAKSHI DAVULURI and STACY LOEB

CHAPTER OUTLINE

Introduction
Prostate Biopsy Complications and Factors Influencing Complications
Bleeding Complications
Infectious Complications
Lower Urinary Tract Symptoms and Acute Urinary Retention
Erectile Dysfunction
Pain
Mortality
Complications of Alternative Biopsy Technique: Transperineal Biopsy
Methods to Decrease Complication Risks
Management of Complications
Conclusion
Chapter 20 Questions and Answers

KEY POINTS

1. Prostate biopsy complications can range from minor complications such as pain, mild hematuria, and hematochezia to severe infectious complications including sepsis, and very rarely death.
2. Bleeding is the most common complication, but usually self limiting. The discontinuation of aspirin pre-biopsy does not appear to significantly impact post-biopsy bleeding.
3. The rise in infectious complications is likely due to an increase fluoroquinolone resistance that has been demonstrated in recent studies. Various antibiotic regimens have been proposed, but it is important for institutions to look at their local antibiogram.
4. Patient risk factors that increase chance of post-biopsy infection include immunosuppression, diabetes mellitus, recent antibiotic use, and foreign travel.
5. There appears to be no significant difference in complications when comparing between standard TRUS biopsy and transperineal template guided biopsy.
6. Patient education regarding potential complications is critical for early recognition and treatment of post-biopsy complications.

Introduction

It has been estimated that 1 million transrectal ultrasound-guided biopsies (TRUS-bx) are performed annually in the United States. These biopsies are done by insertion of an ultrasound probe into the rectum. A biopsy needle is then used to take samples of prostate tissue in a systematic manner. The 2016 National Comprehensive Cancer Network Guidelines recommend sampling 12 cores for initial and repeat prostate biopsy.[1] Although anteriorly directed biopsies are not recommended routinely, additional transition zone biopsies may be considered in the repeat biopsy setting.

Recent improvements in magnetic resonance imaging (MRI) technology are leading to a substantial shift to targeted prostate biopsy. This can be performed several ways including MRI-TRUS fusion, cognitive co-registration, or in-gantry MRI-targeted biopsy.

There are several known significant major and minor complications associated with prostate biopsy (Table 20.1). Minor complications include pain, lower urinary tract symptoms, urinary retention, infection, and self-limited bleeding. There is also a possible link to erectile dysfunction. Major complications are uncommon but include hemorrhage, sepsis and, very rarely, death. Additionally, this procedure can be associated with significant anxiety and discomfort for the patient.

Prostate biopsy complications have been increasingly recognized in recent years and are an important consideration when weighing the benefits and harms of prostate cancer screening. For this reason, the risk of complications is now included in some risk calculators designed to help patients weigh the pros and cons for prostate biopsy decisions.[2]

Prostate biopsies are also performed in other clinical scenarios, such as active surveillance and evaluation for local recurrence after treatment. The complications associated with this procedure will be discussed in detail including prevention strategies and management of complications (Table 20.2).

Prostate Biopsy Complications and Factors Influencing Complications

BLEEDING COMPLICATIONS

Bleeding is the most common complication associated with TRUS-bx and includes hematuria, rectal bleeding, and hematospermia.

Visible hematuria is reported in 10–84% of cases; however <1% is severe enough to require catheterization and hospitalization.[3] More than 90% of men reported that hematuria was not a significant burden.[4] Most hematuria resolves within 3 days; however, for 22% of patients it may persist for a longer period.[5] This is associated with a larger prostate and transition zone volume. Additional factors that increase the risk of hematuria are pre-biopsy enemas and use of anticoagulation.[5,6] Repeat biopsies and needle size are not associated with increased hematuria.[3] There are conflicting data on whether the number of cores sampled impacts hematuria severity or duration.[3]

Rectal bleeding is observed in 1.3–45% of cases.[3] Usually patients consider this minor with <2.5% of cases considered moderate or severe.[4] Factors influencing the risk of rectal bleeding include number of cores sampled and use of anticoagulation. As with hematuria, needle size does not appear to impact risk of rectal bleeding.[3]

The frequency of hematospermia after biopsy varies widely in the literature, with reported rates of 1.1–93%.[3] However, hematospermia is also transient and resolves with repeated ejaculation. The reported median duration is 12–20 days or approximately eight ejaculations, although this also varies.[3,7,8] Patients should be counseled on the specific risk of hematospermia as social factors and cultural barriers could prevent patients from seeking medical attention if this occurs. Factors increasing the risk of hematospermia are larger prostate volume, previous transurethral resection prostate (TURP), and the number of cores sampled.[3]

It is important to note that while the majority of bleeding complications are self-limiting, in rare cases significant hematuria or rectal bleeding can be life threatening. Patients should be appropriately counseled on these risks as part of the informed consent process for prostate biopsy.

The impact of anticoagulation on bleeding is a concern for many urologists. Comparison of patients on aspirin and off aspirin has not been associated with any difference in significant bleeding events. However, patients on aspirin do seem to notice that minor bleeding may have a longer duration than for patients not on anticoagulation.[3,9] Current practice recommendations have concluded that it is therefore safe to continue antiplatelets during prostate biopsy.[10]

There are fewer data on the effects of anticoagulants such as warfarin and clopidogrel.[3] Additionally the impact of newer anticoagulation drugs such as factor X inhibitors rivaroxaban and apixaban have not been well-studied in this context, and the risk of serious complications is unknown.[10]

Table 20.1 Potential Side Effects/Complications of Prostate Biopsy

Pain/Anxiety

Urinary Side Effects
- Lower urinary tract symptoms
- Acute urinary retention
- Hematuria

Sexual Side Effects
- Hematospermia
- Reduction in sexual function

Bowel Side Effects
- Hematochezia

Infectious Complications
- Urinary tract infection
- Sepsis

Death (rare)

INFECTIOUS COMPLICATIONS

Some well-documented risks of prostate biopsies include infectious complications such as urinary tract infection, bacteremia, sepsis, and, in rare cases, death. The risk of hospitalization due to infection ranges from 0% to 6.3%.[3] Data from SEER-Medicare showed that men undergoing prostate biopsy had a 2.26 greater risk of 30-day hospitalization for infection compared to randomly selected controls.[11] Furthermore, there has been a plethora of data showing a significant increase in hospitalization rates over time in the United States and globally.[11–13]

Table 20.2 Influencing Factors, Treatment, and Prevention of Prostate Biopsy Complications

Complication	Influencing Factors	Treatment	Prevention
Hematuria	■ Anticoagulation ■ Number of cores	Observation, may require catheterization and continuous bladder irrigation	■ Discontinuation of anticoagulation (except aspirin)
Infection	■ Fluoroquinolone-resistant *E. coli* ■ Comorbidities, recent travel, recent antibiotic use	Antibiotics	■ Proper sterilization tactics ■ Screening for risk factors ■ Knowledge of local antibiogram ■ Rectal swabs
Urinary retention	■ Prostate size and volume	Urethral catheterization	■ Periprocedural alpha-blockers
Erectile dysfunction	■ Anxiety from prostate cancer diagnosis	Observation, medical management	■ Appropriate counseling

This is thought to be due to increased prevalence of fluoroquinolone-resistant *Escherichia coli* worldwide, with up to 37% of *E. coli* isolates being flouroquinolone resistant in parts of Asia.[14] This has also been reported in the African continent as well as parts of Europe.[15,16] It has been shown that foreign travel is an independent risk factor for post-biopsy infection and sepsis, with approximately a six times increased risk of fluoroquinolone-resistant *E. coli* for patients who recently traveled abroad.[17] Additionally, recent antibiotic use increases the risk of post-biopsy infection, as antibiotics can cause a change in normal bowel flora.[3,17]

It has been shown that a particular *E. coli* strain, ST131, has demonstrated an increased resistance to fluoroquinolones worldwide. A small number of studies have isolated this strain as a significant contributor to the increased rate of sepsis associated with prostate biopsies in recent years. Up to 35% of patients who suffered from post-biopsy sepsis grew this *E. coli* strain.[18]

Other patient-specific factors shown to increase the risk of prostate biopsy infections include comorbid medical conditions such as diabetes and conditions with immunosuppression.[3] These patients at baseline are more prone to infections and sepsis and should undergo further counseling on the increased risks prior to proceeding with prostate biopsy. Diabetic patients should additionally be counseled on the importance of glucose control and compliance with medical therapy.

Factors such as age, prostate specific antigen (PSA), and prostate volume do not appear to be associated with an increased risk of infection. However, there has been a reported five-fold increased risk of developing sepsis if preprocedure WBC was greater than 11.2 /μL.[19] Certainly any patients with a symptomatic urinary tract infection should undergo testing and treatment for that prior to prostate biopsy.[10]

Procedural factors may also increase the risk of infectious complications. There are documented instances of infections related to contaminated ultrasound gel and improper processing of the equipment.[20]

Finally, the impact of repeat biopsies on the risk of infection has received significant attention, since approximately 38% of US men with a negative biopsy undergo another biopsy within 5 years.[21] This is also germane in light of recent increases in the use of active surveillance, with an estimated 40–50% of low-risk men in the United States choosing conservative management as of 2013.[22,23] More recent data from Sweden reported higher rates of active surveillance, with 2014 rates of 91% of very-low-risk, 74% of low-risk, and 19% of intermediate-risk patients diagnosed nationwide.[24] In the major prospective active surveillance programs, the frequency of repeat prostate biopsy ranges from annual to every 5 years.[25] As this strategy increases globally, this can be expected to increase the number of patients continuing to have repeated prostate biopsies over the course of many years after their diagnosis.

Whether men undergoing repeat biopsy have greater risks has been previously studied. Data from SEER-Medicare reported that, although performing repeat biopsies increases the chance of patients experiencing a complication in a cumulative way, the actual repeat biopsy procedure had a similar risk of serious infectious complications compared to the initial biopsy procedure.[26] A recent series from the Prostate Cancer Research International Active Surveillance (PRIAS) study reported infection after 2.5% of biopsies.[27] Biopsy number was not a significant independent predictor of infectious complications. However, it is noteworthy that patients experiencing a complication were less likely to undergo their next protocol-recommended biopsy. The risks of serial prostate biopsy are an important component of patient counseling regarding active surveillance.

LOWER URINARY TRACT SYMPTOMS AND ACUTE URINARY RETENTION

In the immediate postprocedure period, patients may experience symptoms such as dysuria in approximately 6–25% of cases.[3] These symptoms are usually transient and resolve.

The risk of acute urinary retention is 0.2–1.7% following transrectal prostate biopsy, although higher rates have been reported following transperineal biopsy.[3] The use of alpha-blockers such as tamsulosin has been shown to produce a statistically significant decrease in International Prostate Symptom Score (IPSS).[28] Therefore these can be prescribed to patients who may be at higher risk for urinary retention, although premedication is not necessary for every patient.

Factors that have been shown to increase the risk of urinary problems after biopsy include larger prostate size, ratio of transition zone volume to total prostate volume, and higher IPSS scores.[5,6] There does not appear to be a correlation between the number of biopsy cores taken or the number of repeat serial biopsies performed and LUTS.[3,27]

ERECTILE DYSFUNCTION

There are mixed data regarding the impact of prostate biopsy on erectile dysfunction. The most common measure of erectile dysfunction post-biopsy is the International Index of Erectile Function (IIEF).

The exact etiology of erectile dysfunction after biopsy is unknown, but it may be due to inflammation in the immediate post-procedure period as well as minor damage to the neurovascular bundle from needles.[3] There has been some speculation that a component of erectile dysfunction may be related to the psychological impact of concerns about cancer or receiving a prostate cancer diagnosis.[29] It has been shown that 19% of men who underwent a negative prostate biopsy were more worried about prostate cancer and had a moderate to severe impact on sexual function compared to 10% of age-matched control patients.[30] Another study showed that men who underwent TRUS-bx and received a positive prostate cancer diagnosis had a lower post-biopsy IIEF score compared to those men who had a negative prostate biopsy.[31]

However, studies that have established a baseline of erectile function prior to biopsy have shown that IIEF scores return to normal within 6 months.[32] While there may be a transient short-term increase in erectile dysfunction after a single biopsy, most patients return to baseline after an initial prostate biopsy.[33] Factors that have been associated with the risk of erectile dysfunction include periprostatic local anesthetic nerve block and the psychological impact of the anxiety associated with prostate cancer diagnosis.[3] Factors that have not been show to impact erectile dysfunction after biopsy include PSA, prostate volume, and number of cores.[3]

Another factor that has been associated with the risk of erectile dysfunction is biopsy number. In particular there is concern as to whether repeated biopsies performed during active surveillance could increase the risk of erectile dysfunction. In the Johns Hopkins active surveillance program, there was a reduction in sexual function scores on later transrectal prostate biopsies.[34] Similarly, a recent study from the United Kingdom found that erectile function scores returned to baseline 6 months after the first transperineal sector biopsy, but had not fully returned to baseline at 6 months after the second transperineal sector biopsy.[33] Other active surveillance studies did not find a significant relationship between repeated prostate biopsy with erectile dysfunction.[35] It is important to recognize that during the course of active surveillance patients are also aging and may experience changes in other risk factors as well, making it difficult to isolate the effects of repeated prostate biopsies.[36] Nevertheless, this possible issue should be discussed with men considering active surveillance, particularly since preservation of sexual function is one of the reasons patients may opt to defer radical treatment.

PAIN

Use of analgesia has been shown to reduce pain during prostate biopsy. Factors worsening pain include anorectal compliance, number of biopsy cores, younger age, and anxiety.[3,37] Pain can be a significant barrier for men requiring a repeat biopsy, with up to 18% of men reporting they would refuse repeat biopsy.[38] There are multiple options for prostate biopsy anesthesia, ranging from local options such as lidocaine gel and periprostatic nerve block, to sedation and general anesthesia. Combined approaches to anesthesia are also possible, such as combining gel and periprostatic nerve block, or sedation plus periprostatic nerve block.[39]

There has also been investigation into other simple techniques to reduce pain and anxiety with prostate biopsy. A recent study showed that waiting an additional 5 minutes after administering periprostatic nerve block did not significantly reduce pain.[37] However, simple maneuvers like patient positioning also may affect the level of pain, and listening to music is another optional technique to reduce anxiety.[40]

MORTALITY

The risk of death after prostate biopsy is extremely small, likely due to careful patient selection for prostate biopsy. Some studies have even shown a lower risk of overall mortality within a 30-day period among men undergoing biopsy compared to controls from the population.[11] However, the risk of death after prostate biopsy is significantly higher in patients who develop sepsis,[11] highlighting the importance of prevention and effective management for infection in this population.

During the preprocedure, informed consent and the need for prompt follow-up with a health-care provider if the patient experiences any symptoms should be discussed thoroughly. Understanding where and how these patients with complications present can also be crucial in timely management of TRUS biopsy complications.

Complications of Alternative Biopsy Technique: Transperineal Biopsy

Transperineal biopsy (TP-bx) is an alternate prostate biopsy strategy in which the rectum is avoided completely and samples are taken by accessing the prostate through the perineum. Overall, there does not appear to be a significant difference in total complication rates between TP-bx and ultrasound-guided TRUS-bx, although the profiles may differ slightly. Similar to TRUS-bx, TP-bx may be associated with pain, hematuria, urinary retention, infection, and possibly erectile dysfunction. Additionally there have been reports of scrotal swelling and perineal ecchymosis, which self-resolve.[3]

A possible advantage of TP-bx is the decreased infectious complications rate, as the rectum is avoided with this approach.[41] This can be a significant factor for patients at higher risk of infection. The 2016 AUA White Paper lists this as an optional strategy for prevention of infection.[10] However, TP-bx often involves a greater number of cores, which increases the risk of urinary retention. As discussed earlier, periprocedural alpha-blockers may be used to reduce this risk.

Overall, the European Association of Urology (EAU) guidelines state that both TUS-bx and TP-bx are acceptable strategies for prostate biopsy, and a recent review by the Australian guidelines panel concluded that there is a lack of evidence to determine whether the transperineal or transrectal approach is more effective in preventing adverse events.[42,43] The risks and benefits of both methods can be discussed with the patient.

Methods to Decrease Complication Risks

Since most bleeding after prostate biopsy is minor and short in duration,[4] there has been debate over the necessity of discontinuing anticoagulation. Important factors to consider include the indication for use and type of anticoagulant.[3] Because the frequency of serious bleeding complications is extremely low, the 2016 American Urological Association (AUA) White Paper and EAU guidelines suggest that TRUS-bx is safe without stopping aspirin beforehand, though there are fewer data available regarding other anticoagulants such as warfarin and clopidrogel.[10,42]

Fig. 20.1 summarizes important steps in the prevention of infectious complications. The first step is to ensure that proper cleaning and sterilization practices are being used for all equipment. Reusable prostate needle guides require cleaning then heat sterilization.[10] The American Institute of Ultrasound in Medicine has published guidance regarding the specific processing of reusable ultrasound transducer probes.[44]

All patients with an upcoming prostate biopsy should be screened for risk factors, including comorbidities, recent medications, hospitalizations, and foreign travel.[10] Antibiotic prophylaxis has been shown to reduce the risk of bacteriuria, bacteremia, and clinical infections, and routine

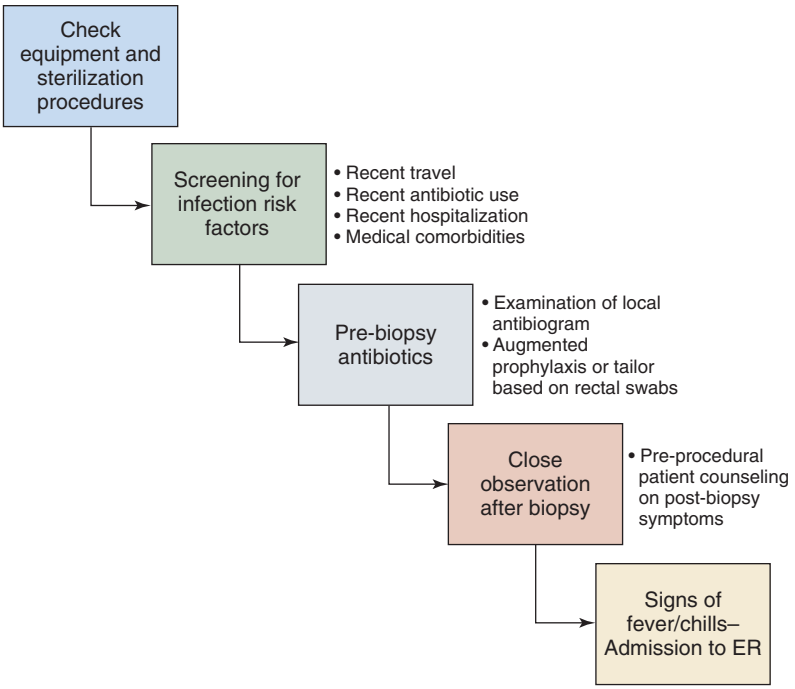

Figure 20.1 Flowchart of steps for prevention and evaluation of biopsy-related infection.

antimicrobial prophylaxis is recommended for all prostate biopsies by multiple international guidelines.[45] The AUA Best Practice Policy Statement on Urologic Surgery Antimicrobial Prophylaxis recommends a duration of less than 24 hours for prostate biopsy prophylaxis.[45] Longer duration antibiotic use has not been shown to reduce infections and could promote resistance.

The choice of antimicrobial agents recommended for prostate biopsy includes fluoroquinolones, first-/second-/third-generation cephalosporins, and trimethoprim-sulfamethoxazole.[45] An alternative is IM/IV aminoglycoside or aztreonam. While fluoroquinolone antibiotics remain the most commonly prescribed for prostate biopsies worldwide,[46] increasing fluoroquinolone resistance has led to a search for alternative options.[47]

With respect to empiric prophylaxis, the 2016 AUA White Paper recommends examining the local antibiogram to choose the best option within those offered in the AUA guidelines. It also presents the options of antibiotic augmentation (e.g., fluoroquinolone plus cephalosporin, aminoglycoside, amikacin, or fosfomycin) or targeted prophylaxis.[10]

Performing a rectal swab culture prior to biopsy and giving targeted prophylaxis are alternative options for reducing the risk of infection with fewer total antibiotics.[48] However, rates of resistance on rectal swab cultures are substantially higher than the rate of clinical infections. The cost-effectiveness of this practice in an average-risk population requires further study since the overall event rate of serious infectious complications is low. However, this option should be offered to high-risk patients, defined as those with previous antibiotic exposure or known resistance in the past, those who undertake frequent international travel, health-care workers, or immunosuppressed patients. Finally, consultation with infectious disease service is recommended for immunocompromised patients.[10]

The use of bowel preparation as a way to decrease infections has been studied as well. Results are mixed with some studies showing that it could half the rate of infection[49] and others showing no impact on post-biopsy complication rates.[6] The differences in these findings can be attributed to various uses of antibiotics, various end points for infection, and geographical differences in patient population. Various bowel preparations have been compared, including simple phosphate enemas, laxatives, and polyethylene glycol. No specific bowel preparation has been shown to be superior.[6,50,51] Overall it does not appear that bowel prep decreases the rate of infectious complications significantly, and prophylactic antibiotics appear to be sufficient.[3,6]

Men with lower urinary tract symptoms should be screened for infection prior to biopsy,[10] and periprocedural alpha-blockers may be prescribed for high-risk patients to prevent urinary retention. Men should be told to void after the biopsy while still in the clinical setting, and the post-void residual urine volume can be measured if the patient has difficulty. If the patient is unable to void, a Foley catheter may need to be placed to relieve the acute symptoms of urinary retention. The patient may follow up in clinic for a trial of void after 1–2 days.

All patients undergoing biopsy should be counseled preemptively to seek prompt medical attention if issues develop at home. In particular, patients should present to the emergency department for fevers and chills. Although some complications can be managed as an outpatient,[52] this general practice allows appropriate evaluation and triage.

Management of Complications

Intervention or hospitalization is rarely required for bleeding after prostate biopsy. Significant gross hematuria can be

managed with clot irrigation and external traction for a compressive effect, as well as cystoscopy and coagulation for refractory cases.[10]

Patients often experience rectal bleeding at first postural change to a standing position or upon first attempt at bowel movement. Much of this may reflect evacuation of bleeding that occurred during the biopsy rather than active bleeding. Evacuation of clots may lead to a vasovagal reaction and presyncope/syncope resulting in potential traumatic injury. As such, men who do not have active bleeding during the biopsy should be observed for a period of time in the recumbent, then seated position to determine if active bleeding is present. Gentle manual distraction of the anal sphincter upon removal of the probe will often demonstrate the presence of blood in the rectum. In such cases, a long gauze packing can be generously lubricated and advanced into the rectum for purposes of rectal packing and tamponade. The packing should be left in place for 3–5 minutes and removed. Serial packings can be employed as necessary until bleeding is stopped. In our experience, this technique with manual pressure is quite effective and has the added advantage of soaking up any blood already present in the rectosigmoid lumen.

In the rare event that massive rectal bleeding occurs the treatment options include rectal balloon tamponade, endoscopic adrenaline injection or sclerotherapy, or direct vessel clipping.[3] If rectal bleeding continues, the patient can be admitted and undergo consultation with general surgery, interventional radiology, and/or gastroenterology.[10]

There has been no proven technique that can be used intraprocedurally or postprocedurally to decrease bleeding rates significantly. Holding pressure with biopsy probe in the needle tracts postprocedurally has been attempted but no significant changes in bleeding have been reported.[53] Therefore knowledge regarding management of these complications postprocedurally is important.

Vasovagal reaction with potential syncope due to rectal manipulation/distention and bladder pressure can occur during the biopsy, immediately after, or even at delayed intervals up to 1–2 hours after the procedure. Patients should be encouraged to come to the biopsy having eaten some food earlier in the day, and should maintain good hydration status. Patients experiencing nausea, diaphoresis, or dizziness during the procedure (indicative of vasovagal response) should be managed by cold compress placement and blood pressure monitoring. If symptoms persist, the rectal ultrasound probe should be removed until the patient's symptoms improve. Following the biopsy, patients should be observed for a minimum of 30 minutes to ensure they are feeling well. Persistent symptoms of nausea, lightheadedness, diaphoresis, or sensation of rectal or bladder fullness should prompt longer observation until resolution.

Patients who present with a fever following biopsy should be evaluated promptly since timely intervention is essential to prevent worsening. Patients should be evaluated for the presence of sepsis, to avoid progression to septic shock. Fever, accompanied by chills or rigors, should result in hospitalization for intravenous antibiotics rather than outpatient oral medications.

Management of patients with severe infection should include aggressive fluid resuscitation and initial broad-spectrum antibiotic coverage (third-generation cephalosporin and aminoglycoside) after urine and blood cultures are taken. The AUA White Paper states that oral Bactrim should not be used if bacteremia is suspected.[10] Antibiotic management can be tailored later as necessary based on culture results. If hypotensive or tachycardic, patients should be admitted to a monitored setting. Urinary retention should be ruled out and, if present, gentle catheterization or suprapubic cystostomy should be considered. In the very sick patient, urethral catheter and rectal exam should be avoided due to the risk of secondary bacteremia from prostate manipulation.

Most urinary symptoms after prostate biopsy resolve spontaneously. Retention post-biopsy may require catheterization and alpha-blockers. Patients should be asked to void before departure following biopsy, and in cases of concern, post-void residual should be monitored. If patients call with persistent irritative symptoms, frequency, or urgency after biopsy, in addition to ruling out infection, retention should NOT be discounted.

Conclusion

The risk of prostate biopsy complications is an important factor in discussions with patients considering diagnostic biopsy, as well as biopsies performed for restaging in men with a diagnosis of prostate cancer. Most prostate biopsy complications are minor, with the most common being bleeding. Hematuria, hematochezia, and/or hematospermia may occur but typically resolve spontaneously over time without intervention. Infection after transrectal prostate biopsy has increased in frequency despite the standard use of antimicrobial prophylaxis. This is thought to be due to an increasing frequency of fluoroquinolone resistance in the population. These complications may be potentially life-threatening, requiring prompt evaluation and management. To reduce the risk of infection, equipment must be sterilized in accordance with guidelines, and patients should be screened for risk factors including co-morbidities and exposures that might increase the risk of harboring resistant bacteria. Augmented or targeted antimicrobial prophylaxis, or alternate biopsy techniques such as a transperineal approach, can be considered to reduce infection risk. Pain with prostate biopsy can be effectively reduced with anesthetics and, possibly, anxiety reduction techniques. Lower urinary tract symptoms are typically transient, but periprocedural alpha-blockers may be prescribed to reduce the risk of acute urinary retention for patients with significant prostate enlargement and those undergoing transperineal prostate biopsy. Changes in erectile function after a prostate biopsy have also been reported; while mostly transient, the potential impact of multiple repeat biopsies on erectile function requires further study. All patients undergoing prostate biopsy must be informed about the potential complications of the procedure.

Chapter 20 Questions

1. Which of the following complications has been occurring with increasing frequency in recent years?
   a. Urinary retention
   b. Hematuria
   c. Erectile dysfunction
   d. Infection
   e. Hematospermia

2. Which of the following factors is associated with an increasing risk of biopsy infection?
   a. Increased number of cores
   b. Increased number of overall TRUS biopsies done
   c. Increasing prevalence of fluoroquinolone resistance
   d. The use of rectal swabs before TRUS biopsies
   e. Increased prevalence of repeat TRUS biopsies being done

3. Which of the following techniques has been used to try to decrease infection after prostate biopsy?
   a. Use of rectal swab to tailor prophylactic antibiotics
   b. Rectal cleansing with povidone-iodine before TRUS biopsy
   c. Expanding antimicrobial regimen
   d. Rectal prep including enemas preprocedurally
   e. All of the above

4. Which is the most common complication after biopsy?
   a. Minor bleeding
   b. Urinary retention requiring catheterization
   c. Hemorrhage
   d. Sepsis
   e. Erectile dysfunction

5. Which of the following has been shown to decrease the risk of acute urinary retention/LUTS symptoms after transperineal biopsy?
   a. Expanded antimicrobial prophylaxis
   b. Use of alpha-blockers
   c. Use of smaller gauge biopsy needle
   d. a and b
   e. None of the above

6. Which of the following statements about biopsy preparation is FALSE?
   a. Patients should have informed consent before biopsy
   b. All patients should receive antimicrobial prophylaxis before transrectal biopsy
   c. Use of anesthetic agents reduces pain with biopsy
   d. Fluoroquinolones are the most common antibiotics prescribed for prostate biopsy
   e. Aspirin must always be discontinued before prostate biopsy

7. Which antibiotics are NOT among the options for empiric prostate biopsy prophylaxis according to the AUA Best Practice Policy?
   a. Fluoroquinolones
   b. Aminoglycosides
   c. Nitrofurantoin
   d. Cephalosporins
   e. Trimethoprim-sulfamethoxazole

8. Which of the following complications is usually minor and self-limited?
   a. Hematospermia
   b. Hematuria
   c. Hematochezia
   d. All of the above
   e. None of the above

9. Which of the following patient factors increases the risk of biopsy infections?
   a. Diabetes
   b. Immunosuppression
   c. Recent foreign travel
   d. Antibiotic use
   e. All of the above

10. Compared to transrectal biopsy, transperineal prostate biopsy may reduce the risk of the following complications:
    a. Infection
    b. Perineal ecchymosis
    c. Urinary retention
    d. Scrotal swelling
    e. All of the above

Case Studies

CASE 1

A 58-year-old male patient presents with an elevated PSA and suspicious lesion on MRI.

1. Which risk factors should be evaluated in this patient as part of the pre-biopsy evaluation?
   a. Comorbid medical conditions
   b. Recent illness and antibiotics
   c. History of urinary tract infection or retention
   d. All of the above
   e. None of the above

Upon further questioning, the patient mentions that he had an infection after a previous prostate biopsy 3 years ago.

2. Which statement about repeat prostate biopsy is TRUE?
   a. A greater number of biopsies increases the cumulative risk of experiencing a complication
   b. The repeat biopsy procedure has a greater risk of infection than the initial biopsy procedure
   c. Repeat biopsy is associated with a greater risk of death
   d. Alpha-blockers are always used for repeat biopsy
   e. There is an increased risk of urinary retention associated with repeat prostate biopsies

The patient is concerned about having infection with this biopsy.

3. What is a possible strategy to reduce the risk of prostate biopsy infection?
   a. Use transperineal approach
   b. Augmented prophylaxis
   c. Targeted prophylaxis using rectal swab culture
   d. Screening for risk factors such as recent travel, hospitalizations, antibiotic use, and co-morbidities
   e. All of the above

CASE 2

A 67-year-old male patient with a past medical history of hypertension and type II diabetes mellitus calls the office complaining of fever, chills, and nausea. He underwent a prostate biopsy the previous day with fluoroquinolone prophylaxis.

1. What is the appropriate management?
   a. Recommend patient go to the emergency room for further evaluation
   b. Prescribe antibiotics over the phone and have patient come to office the next day for urinalysis and culture
   c. Observation as this can be a common occurrence post-biopsy
   d. Recommend that the patient get in touch with his primary care physician as his symptoms are likely not related to the prostate biopsy
   e. None of the above

The patient presents to the emergency department.

2. What should be done as part of initial management?
   a. Blood culture
   b. Urine culture
   c. Start broad-spectrum antibiotics
   d. All of the above
   e. None of the above

The patient is hospitalized and cultures grow fluoroquinolone-resistant *E. coli*. His fever gradually resolves and he is discharged on culture-specific oral antibiotics. Two days later he calls the office concerned after seeing blood in his ejaculate.

3. What is the correct advice regarding hematospermia?
   a. Full hematuria workup is required with cystoscopy and CT urogram
   b. Hematospermia suggests the presence of sepsis
   c. Most cases are transient and will resolve with subsequent ejaculations
   d. Immediate medical attention is needed for hematospermia after biopsy
   e. Hematospermia is an uncommon event after prostate biopsy

Answers

1. **d.** The risk of infection after prostate biopsy has increased recently, whereas the frequency of other complications has remained relatively stable.
2. **c.** Fluoroquinolones are historically the most commonly used antibiotics for prostate biopsy, and resistance has increased recently, resulting in an increase in infectious complications.
3. **e.** Rectal swab cultures, rectal cleansing, expanded antibiotic prophylaxis, and rectal prep are all techniques that have been employed in an effort to reduce the frequency of infection after biopsy.
4. **a.** Minor bleeding in the urine, stool, and/or ejaculate is the most common complication after biopsy and is usually self-limiting.
5. **b.** Prescribing alpha-blockers periprocedurally has been shown to reduce the risk of acute urinary retention after transperineal biopsy. None of the other strategies has been shown to help with this.
6. **e.** Prostate biopsy may be performed on aspirin, which has not been associated with an increased risk of serious bleeding complications.
7. **c.** Fluoroquinolones, aminoglycosides, cephalosporins, and trimethoprim-sulfamethoxazole are all options for prostate biopsy prophylaxis, whereas nitrofurantoin is not.
8. **d.** Bleeding complications are frequent after prostate biopsy but are usually minor and self-limiting.
9. **e.** Diabetes, immunosuppression, recent foreign travel, and recent antibiotic use can all increase the risk of infection after biopsy.
10. **a.** Transperineal biopsy is associated with minimal risk of infectious complications by avoiding the rectum. However, it may have other complications such as perineal ecchymosis, urinary retention, or scrotal swelling.

CASE 1

1. **d.** The patient's full medical history should be assessed before biopsy including comorbidities, recent illnesses and antibiotic use that could increase the risk of resistance, and a history of urinary tract infection or retention.
2. **a.** Although the repeat biopsy itself has a similar risk of infection and retention, the more biopsies a patient undergoes the greater the cumulative risk of experiencing a complication. Alpha blockers are not required to be used in every repeat biopsy but can be used to help decrease the risk of urinary retention of patient has experienced that complication previously.
3. **e.** Changing the approach to transperineal, giving augmented antibiotic prophylaxis, rectal swab cultures, and engaging the patient in a thorough history to evaluate particular risk factors are all strategies that can assist in decreasing risk of infection with biopsy.

CASE 2

1. **a.** Patients with signs or symptoms of infection after biopsy should proceed directly to the emergency room since prompt evaluation is essential.
2. **d.** A patient presenting with infection after prostate biopsy should have prompt evaluation with blood and urine cultures and initiation of broad-spectrum antibiotics.

3. **c.** Hematospermia is a common complication after prostate biopsy but is usually minor and resolves spontaneously with repeated ejaculation. Therefore, immediate medical attention is not needed. Low dose aspirin has not been shown to significantly worsen bleeding complications associated with prostate biopsies including hematospermia. However, the impact of other anticoagulation such as warfarin, clopidogrel, and factor X inhibitors is unclear. Hematospermia is not a definitive sign of sepsis.

Urine Leak/Renal Pelvis Perforation
Injury to Intraabdominal Organs
Tumor Seeding
Complications of Antegrade Stents
Conclusion
Chapter 21 Questions and Answers

KEY POINTS

1. Upper tract drainage can be achieved by retrograde ureteral stent placement, percutaneous nephrostomy tube placement or antegrade stent placement.
2. Retrograde stent placement can be complicated by stent symptoms, urinary tract infection or sepsis, wire-related complications, stent migration, encrustation, fragmentation or failure, periureteral fluid collection, adjacent organ injury or fistula formation.
3. Percutaneous nephrostomy tubes can be complicated by tube dislodgement/leakage, urinary tract infection or sepsis, issues related to patient prone positioning, adjacent organ injury, hemorrhage, urine leak, and tumor seeding.
4. Antegrade ureteral stents are usually a two-step process, and their complications are a combination of the two above mentioned procedures.

Introduction

Upper urinary tract (UUT) obstruction is a common urologic condition that can be caused by extrinsic or intrinsic processes. Causes of both types of obstruction are diverse. Extrinsic obstruction may be caused by regional malignancy or retroperitoneal fibrosis, while intrinsic obstruction may be caused by kidney stones, stricture disease, intrinsic neoplasm, or other causes. Drainage of UUT obstruction may be elective, urgent, or emergent depending on the clinical scenario. In general, urgent/emergent procedures are required for obstruction in the setting of infection, bilateral obstruction or blockage of a solitary renal unit, or refractory symptoms such as intractable pain or vomiting.

Drainage procedures can be either internal or external. For the former, "double J" ureteral stents (DJS) were first described by Zimskind in 1967[1] and have since become widely used in urology. For the latter, percutaneous nephrostomy (PCN) drainage was first described by Goodwin in 1955[2] and was first used to drain an infected obstructed system in 1976.[3] There are advantages and disadvantages to each of these procedures, and appropriateness varies by clinical scenario.

In this chapter, we review indications for different types of UUT drainage procedures, and the possible complications of these procedures, with the goal of prevention and rapid effective management.

Surgical Decompression of the Urinary Tract

INDICATIONS FOR RETROGRADE URETERAL STENTS

Retrograde ureteral stents are placed for diverse types of ureteral obstruction, or prophylactically to prevent obstruction after manipulation of the genitourinary (GU) tract. Stents are used to temporize blockage with refractory symptoms, signs of infection, or renal functional compromise, until definitive treatment can be provided. Patients with obstruction and infection should always be decompressed to relieve obstruction prior to UUT manipulation to avoid precipitating urosepsis.

Ureteral stents are commonly used for intrinsic causes of blockage, such as stone disease, ureteral strictures, ureteral tumors, or papillary necrosis. However, stents may also be used for extrinsic processes, for example, retroperitoneal fibrosis (RPF) or regional malignancy. Progressive local processes (for example, malignancy) may render internal drainage less effective over time; however, ureteral stents may still be a useful short-term strategy. Many patients will benefit from chronic internal urinary drainage, especially with relatively stable chronic obstruction due to malignancy or scar tissue, with contraindications to more definitive management (e.g., UUT reconstruction).

DJS, also known as double pigtail stents, are often placed at the conclusion of a ureteroscopic procedure for stones, biopsy, or other manipulations to prevent obstruction from ureteral edema or bleeding. DJS may be used to passively dilate the ureter following ureteroscopy or shock wave lithotripsy, to facilitate passage of stone fragments after stent removal. In the setting of concern for iatrogenic ureteral injury during ureteroscopy, a stent may be left for a longer period of time (e.g., 4–6 weeks) to enable further healing around a buttressed ureter. DJS are placed after UUT reconstruction such as pyeloplasty, reimplant, or ureteroureterostomy to reduce the likelihood of obstruction from ureteral edema and to promote antegrade flow to prevent leakage. Duration of stent placement after these procedures varies depending on provider and local practice patterns. Occasionally stents are placed for flank pain in the setting of equivocal obstruction to determine if pain improves with internal drainage.

"Single J" stents are used during urinary diversion surgery to ensure drainage from the UUT following ureteral implantation, for instance, into an ileal conduit. These are temporary, until they fall out or are removed after a certain interval after surgery.

Finally, ureteral stents may be placed perioperatively for patients undergoing colorectal, gynecologic, or retroperitoneal surgery to enable identification of the ureters intraoperatively with the goal of avoiding iatrogenic injury. These temporary stents are generally 5Fr "open ended" or Pollack catheters that are secured to the Foley catheter and removed at the conclusion of the case or when the Foley is removed.

In patients with bleeding diathesis or active anticoagulation requiring urgent decompression, internal drainage is preferred to external drainage to mitigate the risk of bleeding from percutaneous tube placement.

INDICATIONS FOR NEPHROSTOMY TUBES

Percutaneous nephrostomy (PCN) tubes are placed for more selective indications than are DJS, as retrograde drainage is often preferred due to the lack of an external tube and drainage bag.[4,5] Obstruction is the primary indication for PCN, comprising 85–90% of indications.[6] Indications for PCN include failed internal stenting (inability to place retrograde stent or obstruction despite stenting), obstructive urosepsis (to reduce manipulation of the GU system and possible worsening of clinical infection),[7] patient's preference (e.g., severe stent-related morbidity such as flank pain or irritative symptoms), or for bulky or progressive local malignant processes in which DJS are considered likely to fail.

PCNs may be placed in anticipation of percutaneous nephrolithotomy (PCNL) with strategic placement in a certain calyx to enable direct and/or safe access to the stones of interest, or to enable a percutaneous intervention for an UUT tumor (e.g., antegrade resection or ureteroscopy). Uncommonly, PCNs are used for administration of UUT chemotherapy (e.g., mitomycin or Bacillus Calmette-Guerin [BCG]) for treatment of recurrent or high-grade, noninvasive urothelial cancer.

PCNs may be placed for diagnostic purposes as well. A PCN affords the option of an antegrade contrast study of the UUT that can delineate renal and/or ureteral anatomy for surgical planning (e.g., for stricture disease) or to assess healing of a reconstructed system. PCN can be used for a Whitaker test to assess for UUT obstruction with an equivocal nuclear renal scan. Finally, PCNs may be placed for flank pain and equivocal obstruction to determine if there is relief of symptoms with external drainage.

INDICATIONS FOR ANTEGRADE URETERAL STENTS

Ureteral stents may be placed in antegrade fashion when retrograde stenting is not feasible (e.g., from an impacted stone or with anatomic distortion within an ileal conduit). Patients require percutaneous access for this procedure. Antegrade stenting may enable stent placement in the setting of malignant extrinsic obstruction when retrograde stenting may not be feasible. Chitale et al. reported only a 21% success rate of retrograde stenting, compared to 96% for a two-staged antegrade approach for obstruction due to malignant pelvic disease,[8] with other studies reporting a success rate for antegrade stent placement of up to 88%.[9,10]

It is important to underscore that comparative data for DJS versus PCN for different obstructive indications are generally retrospective and prone to selection bias. Given the absent level 1 evidence, the use of internal verus external drainage for UUT obstruction is often individualized to the patient, with the exception of clear indications for one type of procedure (e.g., PCN for active urosepsis with obstruction).

Complications of Stents

STENT SYMPTOMS

The most common issue related to indwelling DJS is stent morbidity. These symptoms may include flank pain,

abdominal pain, irritative voiding symptoms, bladder spasms, and gross hematuria. Stent symptoms can range from mild to debilitating. In one study of 120 patients with indwelling ureteral stents, 80% of patients experienced bothersome symptoms and 40% reduced work capacity. The most commonly experienced symptoms were pain (80%), and frequency, urgency, or dysuria (60%). Additionally, 40% of patients also reported sexual dysfunction. The authors reported that stent-related symptoms led 40% of patients to seek the assistance of family members in their routine daily activities and 20% to seek medical assistance.[11]

Stent position can exacerbate related symptoms. In particular, incomplete distal curls, distal curls crossing the midline of the bladder, or proximal curls located in a calyx are associated with a higher degree of stent symptomatology.[12,13]

Management of stent morbidity includes ruling out a more significant process, such as urinary tract infection or stent malposition with obstruction. Urine culture, with or without empiric antibiotic treatment, and imaging, such as abdominal x-ray (KUB), can be considered to evaluate these issues. Diverse oral medications can be used to treat stent pain or irritative symptoms such as analgesics, anticholinergics, phenazopyridine, and alpha-1 adrenoreceptor blockers.[14,15] Tamsulosin has been shown to reduce stent-related symptoms in prospective comparative studies.[16,17] A recent randomized study showed that tamsulosin plus tolterodine had no increased reduction of stent morbidity versus tamsulosin alone.[18] Intravesical agent instillations (ketorolac and oxybutynin) have been studied and shown to decrease pain compared to placebo; however this treatment remains uncommon.[19] Other more invasive treatments for stent pain have been studied, including ropivacaine injection around the ureteral orifice, which was shown to potentially decrease pain and voiding symptoms in one study.[20] In another study, botulinum toxin A was injected around the ureteral orifice and was shown to improve postoperative pain and decreased narcotic requirements.[21]

If ureteral stent symptoms are not able to be controlled, hospitalization with intravenous pain control, early removal, or placement of percutaneous nephrostomy tubes can be considered. Finally, given high rates of stent morbidity, thought should be given to the indication for stenting in the first place, and duration of stenting, to reduce patient suffering. While there are data suggesting that stenting after uncomplicated ureteroscopy is not necessary,[22,23] and American Urological Association (AUA) guidelines consider stenting optional after these procedures, provided certain criteria are met (e.g., absence of ureteral injury, normal anatomy, normal renal function),[24] it is common for stents to be placed routinely in patients to avoid the risk of postoperative obstruction. A reasonable approach to stenting is to use a tether to enable easier removal (obviating the need for office cystoscopy) within several days of a procedure; however, this may generate fear of inadvertent dislodgment.[25] Ultimately additional research is needed to improve stent design and pharmacologically reduce morbidity to improve the patient experience related to these procedures.

URINARY TRACT INFECTION/SEPSIS

If ureteral stents are placed in the setting of known urinary infection or sepsis, appropriate antibiotic coverage with culture-specific or broad-spectrum antibiotics is the standard of care. If stent placement is performed without clinical suspicion for infection, a culture should be sent preoperatively if possible; otherwise the American Urological Association Best Practice Statement for antibiotic prophylaxis recommends fluoroquinolone or trimethoprim-sulfamethoxazole (TMP-SMX) as first-line and first-/second-generation cephalosporins, aminoglycoside with or without ampicillin or amoxicillin/clavulanate as second-line prophylactic agents, with consideration of local resistance patterns.[26] Obstruction and infection can readily lead to urosepsis, and while decompression is essential to mitigate risks, instrumentation itself can precipitate bacteremia and hemodynamic instability. Indeed, Flukes et al. reported that 12% of patients with obstructed infected kidney required ICU admission before intervention, and another 6% deteriorated after retrograde intervention, necessitating hemodynamic support in the ICU.[27]

Risk factors for UTI associated with ureteral stents that are in place more chronically include longer duration of stent retention, presence of certain comorbid systemic diseases (diabetes mellitus, chronic renal failure, and diabetic nephropathy), and female gender.[28] Stents removed within 30 days of insertion have a lower risk of UTI compared with those removed after 90 days (6.8% vs 28.6%, respectively). Interestingly, the stent colonization rate was much higher in longer duration stents (64.9% vs 20.5%, respectively).[28]

PERIURETERAL FLUID COLLECTION (STERILE OR INFECTED)

During ureteral stent placement, extravasation of fluid can occur by two mechanisms – either by direct instrument damage (perforation) or indirectly by increased fluid pressure (rupture) (Fig. 21.1). Patients may experience flank pain, fever, and/or ileus, or they can be asymptomatic.[29]

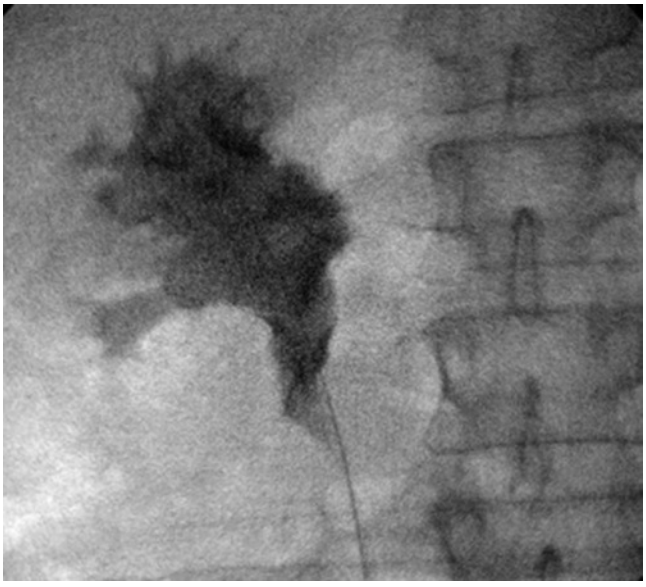

Figure 21.1 Contrast extravasation during retrograde ureteral stent placement.

These events are generally apparent via retrograde pyelography at the time of intervention; however, if there is postoperative concern, cross-sectional imaging will show a fluid collection, which can contain urine, blood, contrast, or irrigation fluid. In rare cases, stone fragments can migrate into this collection, which may be insignificant or may create an abscess in the setting of infection.

Treatment for periureteral collections typically involves a longer duration of ureteral stenting to encourage antegrade urine flow and buttress the injured ureter. If a patient has worsening symptoms or is clinically infected, a percutaneous drain may be required. Intravenous antibiotics and inpatient observation may be required depending on the clinical scenario. If there is persistent urinary drainage into a periureteral collection, proximal diversion of the urine via nephrostomy tube drainage is indicated. Unless there is a foreign body or abnormal tissue such as in prior radiation therapy, a ureteral perforation should heal within 2–4 weeks of ureteral stenting.

WIRE-RELATED COMPLICATIONS

There are many different types of wires available for retrograde stent placement (e.g., hydrophilic, hybrid wires, stiff wires). It is preferable to use a wire with a flexible tip to minimize intrarenal injury and risk of bleeding/perforation, especially in the setting of anticoagulated patients. It is also important to ensure that the wire is placed intraluminally rather than submucosally. If significant resistance is encountered during wire placement, the wire should be removed and replaced. Placing a 5Fr catheter over the wire can help confirm that the wire is in the correct position based on lack of resistance and ability to perform a retrograde contrast injection. Placing a wire past an impacted stone may increase the risk of submucosal placement or perforation, and judicious use of a flexible tip catheter, including an angled tip when necessary, monitoring with fluoroscopy, and knowing when to halt attempts at retrograde access can help to reduce these risks.

There is one report of significant intraperitoneal bleeding after stent placement. A patient developed hemorrhagic shock after uneventful stenting, which led to exploratory laparotomy with splenectomy to find and control the source of bleeding, which was intraoperatively identified as a 6-mm renal upper pole puncture. The article emphasized the importance of ensuring the wire is placed correctly with the flexible tip first to avoid trauma from a rigid wire.[30]

If there is significant urinary tract bleeding from mucosal injury/wire trauma, we recommend placing the retrograde stent and monitoring the patient closely. Any bleeding diathesis should be reversed if possible. Continuous bladder irrigation may be needed depending on degree of hematuria.

STENT MIGRATION

Ureteral stents can migrate proximally into the kidney or distally into the bladder (Fig. 21.2). Rates of stent migration reported in literature range from 8% to 9%.[31,32] The etiology is thought to be an incorrectly sized stent (if migration occurs in a delayed fashion) or technical error (during surgery, when the distal end of the stent is pushed too far and becomes intraureteral).

Management includes stent removal and reinsertion for distal migration, and ureteroscopic removal and reinsertion for proximal migration. The latter can be challenging depending on the caliber of the ureter. Several types of graspers and baskets can be used to retrieve the distal end of the stent and to reposition the stent. If this cannot be safely accomplished, "tandem" stenting can be performed to enable ureteral dilation to allow retrieval of the migrated stent at a later point (1–2 weeks).

ADJACENT ORGAN INJURY/STENT EROSION

A rare complication of ureteral stents is erosion into adjacent vascular structures or organs and development of fistulas. Arterio-ureteral fistulas are rare but life threatening. Risk factors include previous cancer surgery/radiotherapy (54%), vascular surgery (31%), and known aneurysm or pseudoaneurysm of the iliac artery (38%).[33] Often, patients present only with massive hematuria. If hemodynamic compromise ensues, mortality rates are reported to be up to 23%, with delayed diagnosis being associated with worsened outcomes.[34,35] Diagnosis can be confirmed with angiography, and management includes a combined approach comprising urology, vascular surgery, and interventional radiology. The preferred approach is stenting of the involved artery; however, options also include ligation, repair, or embolization of the involved vascular structure. The ureter is generally treated conservatively with stenting and/or nephrostomy drainage, and delayed reconstruction may be needed.[33]

Ureteral stents can also erode into the venous system. These events have included erosion and migration via renal, iliac, or ovarian veins into the vena cava and even the right ventricle.[36–38] One patient with a ureteral stent in her right heart had only mild back pain and suprapubic discomfort after voiding.[37] When the stent migrates to the right

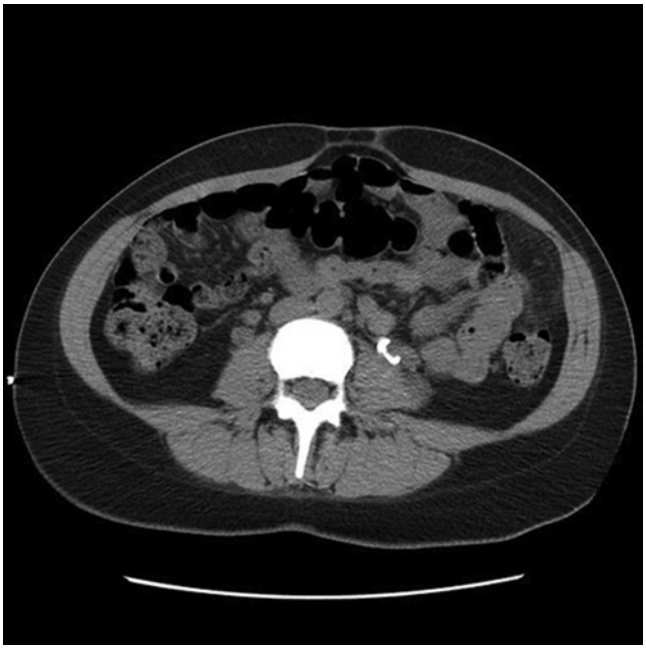

Figure 21.2 DJS with proximal curl in proximal ureter.

ventricle, open heart surgery may be necessary to remove it.[38] When stents are placed into or erode into veins, initially there can be hematuria,[38] or there may be no initial symptoms with large bleeding encountered upon stent removal.[39]

There are reports of stent erosion into adjacent organs, such as the colon[40] or vagina,[41] leading to fistulization. These are very rare events and require stent removal and possible reconstructive surgery. Erosion into the uterus has been reported with antegrade stenting.[42]

STENT ENCRUSTATION

Underlying metabolic conditions, urinary supersaturations, pregnancy, and increased indwelling stent times increase the likelihood of stent encrustation. One study showed encrustation rates of 9.2% at <6 weeks and up to 76.3% at >12 weeks.[43] Another study reported encrustation rates of 26.8% at less than 6 weeks, 56.9% at 6 to 12 weeks, and 75.9% at more than 12 weeks.[44] Encrustation can occur on the distal intravesical portion of the stent, along the intraureteral portion, or on the proximal curl within the renal pelvis. Vigilance regarding the timing of stenting is needed when treating patients who are particularly lithogenic or pregnant, and exchange should occur up to every 4–6 weeks depending on the clinical circumstance.

Diagnosis can be made at the time of cystoscopy, when encrustation is visualized and stent cannot be extracted with the aid of a grasper in the standard transurethral fashion. The diagnosis can also be made using noncontrast CT. Plain x-rays are not recommended, because they may miss minor (but removal-complicating) encrustations.

Attempting to cystoscopically remove an encrusted stent with excessive force can lead to fracturing of the stent or avulsing or intussuscepting the ureter. The management strategies for an encrusted stent therefore include extracorporeal shock wave lithotripsy, cystolithalopaxy, manual scraping of the encrustations from the stent by extraction through a ureteral access sheath, ureteroscopy with intracorporeal lithotripsy, percutaneous nephrolithotomy, and open or laparoscopic pyelolithotomy and/or cystolithotomy. The exact approach depends on burden and the location of encrustation. Often, patients will need more than one procedure.[45–48]

There may be instances in which a stent cannot be removed due to low volume encrustation, and ureteroscopy adjacent to the stent cannot be performed due to narrow anatomy. A second or "tandem" stent can be considered adjacent to the indwelling stent, with staging of the procedure to enable further ureteral dilation and retrograde fragmentation of encrustation in the future.

If a significant ureteral injury occurs during attempted stent removal, such as avulsion or intussusception, a percutaneous nephrostomy tube is generally required with consideration of acute or delayed ureteral reconstruction.

STENT FRAGMENTATION

While stents are designed of sturdy material, there is a risk of stent fragmentation. This may occur from overzealous use of the laser contiguous with the stent or spontaneously.[49] For the former, care in lasing adjacent to an indwelling stent can obviate this issue. The latter is a rare event, but there are published series of spontaneous fragmentation.[49] Plain x-ray, as well as computerized tomography, can diagnose stent fragmentation. It can also be diagnosed at the time of surgery, when an incomplete stent is extracted from the ureter. Management strategies include removal of fragments endoscopically, either retrograde from the bladder or ureter, or percutaneously if needed.

RETAINED STENT

Retained stents can present a significant clinical problem. These stents are at risk for encrustation and can be challenging to remove (see section on encrusted stents for more detail). Retained stents that become encrusted may increase the risk of ureteral injury and can lead to renal atrophy.[48] All patients undergoing stent placement should be counseled that stents are temporary and require exchange or removal to avoid complications. This information should also be provided in paper form for counseling and medicolegal reasons. Stent registries have been used to track patients to reduce the likelihood of retained stents.[50] There are various formats of stent registries in use, ranging from manual handwritten "card" systems, computer based with automatic reminders to providers, to even automatic letter and cellular phone texting reminders to patients.[50–52]

INADEQUATE RELIEF OF OBSTRUCTION/HYDRONEPHROSIS

Ureteral stents may not adequately relieve obstruction, whether the primary process is benign or malignant. Stent failure rates of up to 6% have been reported for urolithiasis.[32] Stent failure rates are greater, however, with malignant extrinsic obstruction, with obstruction rates as high as 44% within 30 days[53,54] and 58% with longer follow-up.[55] Stent failure can be diagnosed by increased hydronephrosis, worsened kidney function despite absent other causes, or clinical suspicion. Management may include stent exchange and monitoring, placement of tandem stents, placement of a metallic stent that can be more resistant to extrinsic compression, or more proximal diversion (percutaneous nephrostomy tube placement). Benign extrinsic compression (e.g., retroperitoneal fibrosis) can also lead to stent failure.

METAL STENTS

When conventional ureteral stents fail, metal stents have been used for long-term drainage in an effort to avoid percutaneous nephrostomy tubes and improve the patient's quality of life. Compared to polymeric ureteral stents, metal stents preserve patency under a greater degree of extrinsic compression and have longer indwelling times necessitating fewer stent changes (up to 12 months). However, they are associated with a high rate of migration (up to 81%), stone encrustation (23%), and obstruction resulting from hyperplastic reaction (up to 60%).[56,57] Tumor ingrowth has also been reported. Metal stents are used mostly for malignant obstruction. One small study reported 100% patency rate (mean follow-up 8.5 months) in patients with malignant obstruction, but only 44% with benign obstruction.[58] A study with longer follow-up (median 15

months) reported 62% patency rate for malignant obstruction.[59] Retrospective studies have shown that metallic stents may not perform better than regular stents in preventing obstruction, particularly in patients with locally invasive prostate cancer;[60] however, there are insufficient data to draw a definitive conclusion. The higher cost of metallic stents raises the question of cost-effectiveness, which requires additional investigation.

Complications of Nephrostomy Tubes

COMPLICATION OF PRONE POSITIONING

Patients undergoing PCN placement are typically placed in a prone position to enable access to the flank. This positioning may be problematic for some patients. For instance, patients with contractures or severe morbid obesity may require modified positioning or additional padding. Ventilatory difficulty for those with severe obesity should be anticipated. For those for whom PCN placement is occurring under sedation, a modified supine position can be used to maintain access to the airway. Prolonged prone positioning should be avoided to prevent neuromusculoskeletal injuries.[61]

TUBE COMPLICATIONS

Urinary leakage around a PCN is uncommon (1%), but may present a hygiene issue.[62,63] First, tube position should be confirmed; this can be done by checking for the presence of urine in the tubing, flushing/aspirating the PCN, or imaging. CT may show the tube in the collecting system, and an antegrade contrast study is most definitive. Skin infection adjacent to the tube is rare as well (1%) and can be treated with oral antibiotics.[62]

Tube dislodgment can be a significant problem. Reported rates of dislodgement range widely from 1% to 36%.[63,64] Pigtail catheters are generally used, and the tube is secured to the skin via permanent sutures and other adherent devices, to reduce the risk of dislodgment. Obesity and precariousness of the tube within the kidney may lead to dislodgment with movement.[62] Replacement of the tube via rewiring or a new access is typically needed.[6]

Catheter occlusion occurs in up to 6% of PCNs and can be managed with irrigation, re-wiring or re-insertion. [62,63] Care must be taken to secure the tubing and drainage bag to a patient's clothing and to avoid excessive traction, both of which are key to avoiding dislodgement.

UTI/SEPSIS

Sepsis can occur following PCN placement due to bacteremia from the procedure, or from incipient urosepsis in the setting of obstruction and infection. The incidence of septic complications with PCN placement is reported as being ~2%, but varies based on the clinical scenario.[64,65] In the setting of pyonephrosis, this incidence rate rises to 7–9%.[66,67] Incidence of symptomatic urinary-tract infection or pyelonephritis ranges from 2.5% to 14%.[63,68] Because the PCN is a foreign body, the incidence of infection increases to 27% in patients with long-term tube placement (at least one PCN change).[68] Changing the PCN every 6–12 weeks for chronic tubes may reduce the risk of clinical infection. Periprocedural prophylaxis with culture-specific antibiotics may decrease the risk of procedure-induced infection.

PLEURAL COMPLICATIONS

Placement of a PCN may be complicated by injury to nearby structures, including the pleura (Fig. 21.3). The incidence of pleural complications (i.e., pneumothorax, empyema, hydrothorax, hemothorax) is reported to be 0.1–0.2%.[67] Patients can exhibit signs of pulmonary compromise or hemodynamic instability (e.g., hemothorax). These complications are diagnosed by imaging (such as chest radiography or CT scan). Management depends on the patient's clinical status. For example, stable patients with small volume pneumothorax/hydrothorax can be managed with observation. For respiratory distress in the setting of a pneumothorax, a pigtail pleural catheter can be placed. If a patient is in more significant distress or there are signs of infection, tube thoracostomy can be used. In severe cases (for example, hemothorax from lacerated intercostal vessels), thoracoscopy or thoracotomy may be required. If pleural infection develops, a large bore chest tube is needed with consultation by thoracic surgery.

HEMORRHAGE, HEMATURIA/CLOT COLIC

Hemorrhage is the most common local complication of PCN placement (Fig. 21.4). Venous bleeding is usually self-limited and stops with tamponade effect. Arterial bleeding is more severe and results most commonly from renal artery branches or intercostal arteries. To minimize the risk of injury to the intercostal arteries, access should be obtained

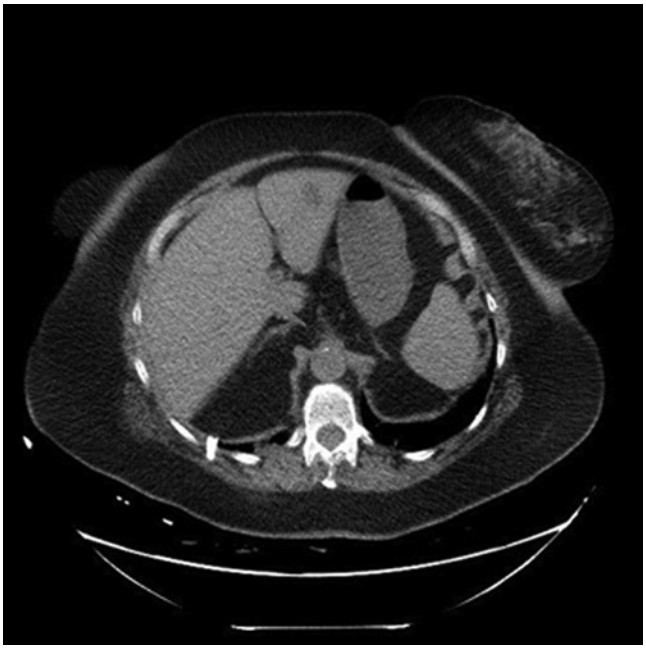

Figure 21.3 Transpleural percutaneous nephrostomy tube.

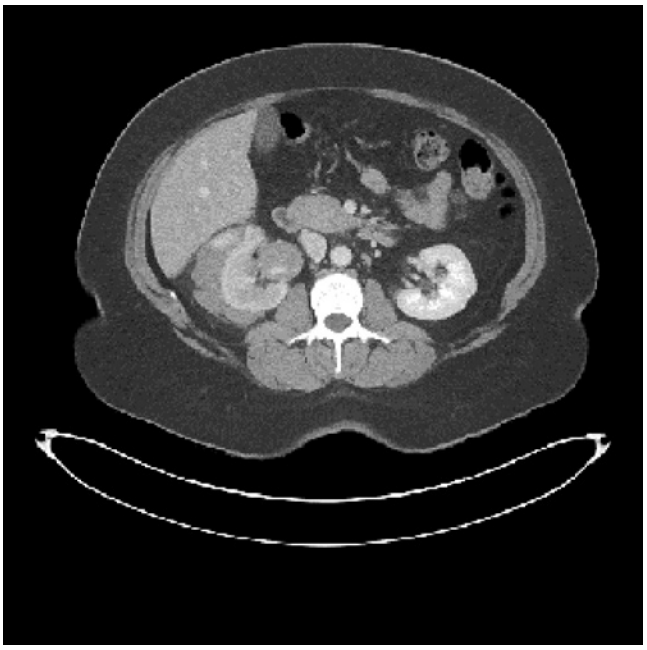

Figure 21.4 Perirenal hematoma and extravasation after unsuccessful percutaneous nephrostomy tube placement.

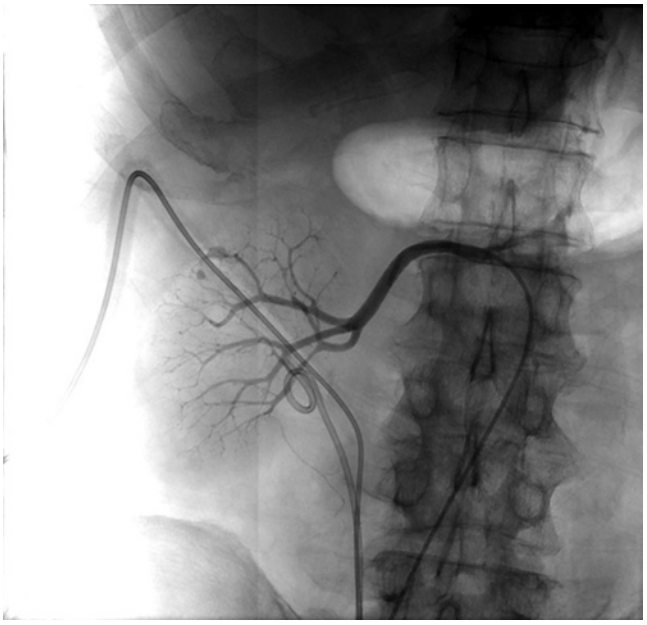

Figure 21.5 Renal arterial angiogram demonstrating pseudoaneurysm at site of nephroureteral stent.

directly above the rib and in the avascular Brodel's line on the posterolateral kidney. Entry to the collecting system should occur at a calyx rather than the infundibulum. Arterial injury can lead to hematoma, pseudoaneurysm (Fig. 21.5), or a fistula. Hematuria causing clot colic and catheter blockage occurs in 0.5–6.5% of patients.[64] Hemorrhage requiring transfusion occurs in 0.5–4% of patients.[64,65,68] Vascular injury necessitating embolization or nephrectomy is reported in 0.1–1% of patients.[63,67] Severe persistent gross hematuria or perinephric hemorrhage related to arterial bleeding associated with hemodynamic changes requires selective angioembolization as the first-line intervention.

If there is profuse bleeding from the nephrostomy tract refractory to tamponade from the PCN, a Kaye tamponade catheter can be placed in the tract and balloon inflated for additional tamponade effect. This may be therapeutic or temporizing until further management. If the bleeding is severe, or in the case of arteriovenous fistulas, first-line treatment involves selective renal artery embolization.[69] This allows for nephron preservation, compared to nephrectomy. Nephrectomy is the option of last resort for refractory bleeding.

URINE LEAK/RENAL PELVIS PERFORATION

Renal pelvic injuries can occur during tract dilatation or catheter insertion in 1–2% of cases.[62,70] This may lead to perinephric urinoma formation. Treatment is usually continued renal drainage only (via properly positioned PCN and/or indwelling stent). Surgical correction is rarely needed, but may be necessary if the injury is severe or shows no evidence of healing after 6 weeks.[70] Ensuring the absence of a foreign body, such as the PCN abutting or protruding through the fistulous tract, is necessary to ensure healing occurs.

One study reported asymptomatic retroperitoneal urine extravasation at a rate of between 4.5% and 6.5%.[64] This usually reabsorbs and is treated with urinary tract drainage and observation.

INJURY TO INTRAABDOMINAL ORGANS

Other organs that may be injured during percutaneous access include liver, gallbladder, bowel, and the spleen. Bowel injury is the most common intraabdominal injury and occurs in 0.2%[67] to 0.5%[64] of PCN placements. The colon is the most frequently injured portion of the bowel, though small bowel (e.g., duodenum) injury is also possible.[71] Jejunal injuries have been reported as complications of nephrolithotomy, but not nephrostomy itself.[72] Small bowel injury from PCN may lead to small bowel obstruction,[73] though the complication of greatest concern is perforation. Timely diagnosis is crucial. Signs and symptoms of bowel injury include pneumaturia, fecaluria, fever, diarrhea, hematochezia, and peritonitis. If bowel perforation is intraperitoneal, surgical repair is required. If the perforation is extraperitoneal and the patient is stable, the injury may be treated conservatively.[74,75] Also, if access to the colon is inadvertently performed without extravasation, this should be treated conservatively. Conservative treatment entails a ureteral stent and Foley catheter (or a second percutaneous nephrostomy tube) to drain the urinary tract and positioning of the original nephrostomy tube into the colonic lumen.[75] After 7–10 days, contrast is injected to verify no communication between the colonic tube and the urinary tract, and the colon tube can then be safely removed.

TUMOR SEEDING

Tumor seeding is a rare complication of percutaneous drainage in patients with high-grade urothelial cancer,

with several case reports in the literature.[76,77] Careful access to minimize trauma and number of accesses to the kidney can help to reduce the risk of this complication. Retrograde access is preferred when feasible for this disease process to reduce the likelihood of seeding.

Complications of Antegrade Stents

Some patients require antegrade placement of a DJS, for example, based on inability to place one in retrograde fashion or after a percutaneous procedure. Antegrade stenting can be done as a one-stage or two-stage procedure (with initial establishment of percutaneous access). One-stage tubeless PCNs have been described to have an 88% success rate;[78] however, the majority of antegrade stenting is done in a two-stage fashion.[42]

Overall, complications of antegrade stent placement are similar to those of retrograde stenting. There is a single report of ureterovaginal fistulization during antegrade stent placement that results from a silent ureteral perforation. Rao et al. reported ureteral perforation with unrecognized extra-anatomic stent placement in 3% of antegrade stent attempts, all with delayed manifestations (retroperitoneal abscess, urinoma, ureterorectal fistula, ureterovaginal fistula).[42]

Conclusion

Upper tract drainage can be achieved by multiple ways: percutaneous nephrostomy, retrograde or antegrade stenting. All three methods are generally safe, and effective in the appropriate patient. Complications may occur, but can be minimized with careful technique, proper patient selection, and early recognition.

Chapter 21 Questions

1. In order to avoid the intercostal vessels, percutaneous nephrostomy access should be obtained:
   a. Between the ribs in Brodel's line
   b. Directly above the rib in the posterolateral kidney
   c. Directly below the rib in the posterolateral kidney
   d. Directly above the rib in the posteromedial kidney
   e. 0.5 cm below the rib in the posteromedial kidney

2. One day after nephrostomy tube placement, the patient presents with abdominal pain and gas in his nephrostomy tube. He is afebrile and hemodynamically stable. CT scan reveals an extraperitoneal colonic perforation. The management is:
   a. Exploratory laparotomy with perforation repair
   b. Repositioning of the tube into the colon
   c. Ureteral stent, Foley, and repositioning of the tube into the colon
   d. Ureteral stent, Foley catheter, and removal of the nephrostomy tube
   e. Removal of the nephrostomy tube followed by perforation repair

3. Three days after left ureteroscopy with laser lithotripsy, the ureteral stent is uneventfully removed in clinic. Two days later the patient presents with left back and abdominal pain, ileus, and fevers to 102.5°F. A CT scan is done that shows a large periureteral collection. The next step in management is antibiotics and:
   a. Left percutaneous nephrostomy tube
   b. Left ureteral stent
   c. Left percutaneous nephrostomy tube and left ureteral stent
   d. Percutaneous drain
   e. Percutaneous drain and left ureteral stent

4. A ureteral stent was placed for unilateral hydronephrosis; however, during the procedure it was pushed too far into the ureter and it is no longer visible in the bladder. The ureter is too narrow to accommodate a ureteroscope. What is the next step?
   a. Using a piranha grasper to retrieve the distal end
   b. Using a ureteral dilator to dilate the ureter to enable access to the migrated stent
   c. Percutaneous nephrostomy tube, with antegrade stent retrieval on the same day
   d. Percutaneous nephrostomy tube, with antegrade stent retrieval in 1 week
   e. Tandem stent, followed by return to the operating room in 1 week to retrieve the stent

5. Shortly after left PCN placement, a 56-year-old male develops shortness of breath. His vitals signs are: T 36.5°C, HR 120, BP 115/67, saturation 80% on room air. The saturation increases to 86% with 10L nasal cannula. In addition to applying more oxygen, what is the next step?
   a. Observation
   b. Chest x-ray followed by tube thoracostomy
   c. CT chest angiography
   d. Transfusion of 1 unit of blood and chest CT
   e. Removal of nephrostomy tube and placement of occlusive dressing over the site

6. A 69-year-old female has bilateral ureteral obstruction caused by ovarian cancer, which has been managed with indwelling polymeric ureteral stents. The stents get exchanged every 3 months, with minimal encrustation. They were last changed 30 days ago. Today, she presents to the hospital with creatinine increase (from 1.5 to 2.6), and right-sided flank pain. A CT scan reveals both stents in appropriate position, moderate hydronephrosis on the left, severe hydronephrosis on the right, and increase in size of her pelvic mass. The patient is scheduled to start chemotherapy the next day. What is the next step in her urologic management?
   a. Bilateral ureteral stent exchange for polymeric stents
   b. Bilateral ureteral stent exchange for metallic stents
   c. Right PCN tube
   d. Left metallic stent and right PCN tube
   e. Bilateral PCNs

7. A 45-year-old woman with unilateral retroperitoneal fibrosis managed with right-sided ureteral stent exchanged every 6 months has been lost to follow-up for 14 months. Abdominal x-ray reveals the stent in the appropriate position, with no encrustations visible on the x-ray. The patient should be scheduled for the following:
   a. Extracorporeal shock wave lithotripsy
   b. Routine cystoscopy with stent exchange
   c. Cystoscopy with stent exchange, possible ureteroscopy with laser lithotripsy, and possibility of a staged procedure
   d. Ureteroscopy with laser lithotripsy, with possibility of a staged procedure
   e. CT scan of the abdomen and pelvis

8. Risk factors for urinary tract infection with chronic ureteral stents include:
   a. Increased duration of stent retention, chronic renal failure, male gender
   b. Female gender, diabetes mellitus, chronic renal failure
   c. Increased duration of stent retention, obesity, diabetes mellitus
   d. Diabetic nephropathy, dialysis, age >65
   e. Female gender, age >65, obesity, chronic renal failure

9. The following ureteral stent positions have been shown to exacerbate stent symptoms:
   a. Incomplete distal curl
   b. Distal curl crossing the midline of the bladder
   c. Proximal curl in the upper pole
   d. a, b, and c
   e. a and b

10. During ureteroscopy for a 5-mm distal ureteral stone, significant resistance is encountered in the midureter with a guidewire. The next step is:
    a. Removing and replacing the wire
    b. Removing the wire, turning it around, and using the back stiffer end
    c. Placing a 5Fr open-ended catheter over the wire and performing a retrograde contrast injection
    d. a or b
    e. a or c

Case Study 1

A 53-year-old man presents to the ED with 3 days of fever and back pain. He reports a history of poorly controlled diabetes, hypertension, and kidney stones. His temperature is 38.3°C, heart rate is 110, blood pressure is 90/50, and respiratory rate is 20. On exam, he is diaphoretic and ill-appearing. He has right costovertebral angle tenderness. His labs show WBC 22 and a serum creatinine of 2.4. He is given resuscitative fluids, and a noncontrast CT scan is obtained that reveals a 2.9-cm right renal pelvis stone with severe hydronephrosis and perirenal stranding.

1. What is the next step in management?
    a. Admit for broad-spectrum antibiotics and observation
    b. Percutaneous nephrostomy tube placement
    c. Retrograde ureteral stent placement
    d. Antegrade ureteral stent placement
    e. Percutaneous nephrolithotomy

He undergoes percutaneous nephrostomy tube placement and improves clinically. Urine and blood cultures grow *Escherichia coli* and he is placed on culture-specific antibiotics. Three weeks later, he is brought to the OR for PCNL. This is uncomplicated; however, in the PACU gross blood begins to drain from the nephrostomy tube, and the patient is noted to be hypotensive to 80/30.

2. What is the next step in management?
    a. Send a CBC
    b. Monitor vital signs continuously
    c. Send to interventional radiology for angioembolization
    d. Clamp the nephrostomy tube
    e. Return to operating room for exploration

The patient stabilizes, and a hemoglobin returns with a value of 7.5. The patient is given 2 units of packed red blood cells (PRBC). However, he develops recurrent hypotension and his repeat hemoglobin is 7.9.

3. What is the next step in management?
    a. Repeat transfusion of 2 units PRBC
    b. Admit to the ICU for monitoring
    c. Angioembolization
    d. Emergent nephrectomy
    e. Remove the nephrostomy tube

Case Study 2

A 43-year-old woman presents to the ED with abdominal pain. She has a history of kidney stones. Her pain radiates to the right groin. She denies fever or chills. She is afebrile with stable vital signs. Her exam shows some sensitivity on the right flank. She appears uncomfortable. A noncontrast CT scan shows a 3-mm proximal ureteral stone with proximal collecting system dilation. Her labs are normal with a serum creatinine of 1.0. She elects for a trial of passage, but on follow-up she continues to have pain and a renal ultrasound shows persistent hydronephrosis. She is brought to the OR for ureteroscopic management. Cystoscopy is performed, and a hybrid guidewire is advanced through the ureteral orifice with fluoroscopic guidance. The wire will not traverse the area of the known stone and buckles underneath.

1. What is the next step in management?
    a. Wake the patient and send for a percutaneous nephrostomy tube
    b. Perform ureteroscopy without a safety wire
    c. Wake the patient and refer for shock wave lithotripsy
    d. Use an angle-tip hydrophilic guidewire to traverse the stone
    e. Use the stiffer (back) end of the Sensor wire to traverse the stone

The angle-tip wire is also unable to traverse the area of stone. A retrograde pyelogram is performed that shows the following (Case Fig. 21.1):

2. What is the next step in management?
    a. Wake the patient and send for a percutaneous nephrostomy tube
    b. Perform ureteroscopy without a safety wire
    c. Wake the patient and refer for shock wave lithotripsy
    d. Place a periureteral drain
    e. Use the stiff (back) end of the wire

Case Figure 21.1

The patient obtains a percutaneous nephrostomy tube. Two weeks later, she is brought for ureteroscopy, which is uncomplicated. A double J stent is placed and the nephrostomy tube is removed. She returns to the ED that night with severe flank pain. She has no fever and has stable vital signs.

3. What is the next step in management?
   a. Give Flomax and oral narcotics for symptom control
   b. Give antibiotics for presumed pyelonephritis
   c. Reassurance
   d. CT scan with IV contrast
   e. KUB to confirm adequate position of the stent

Answers

1. **b.** To avoid intercostal vessels, obtain access directly above the rib in Brodel's avascular line (posterolateral kidney).
2. **c.** Since the patient is hemodynamically stable, he can be managed conservatively with ureteral stent, Foley catheter and repositioning of the tube into the colon. If he was unstable, or if the perforation was intraperitoneal, then the perforation would need to be repaired.
3. **e.** The patient had a ureteral perforation with urinary extravasation that became infected; he requires both a ureteral stent (to encourage antegrade urine flow and buttress the injured ureter), as well as a percutaneous drain of the infected collection.
4. **e.** In the case of proximal migration of a ureteral stent, the end can be grasped with a basket or grasper to try to retrieve and reposition the stent. However, in this case, since the ureter is too narrow to accommodate the ureteroscope, tandem stenting should be used to decompress and enable passive dilation of the ureter.
5. **b.** The patient likely has a pleural complication. The next step is imaging (to distinguish between the different types of pleural complications). Given patient's respiratory distress, he will need a tube thoracostomy after imaging.
6. **e.** The patient's ureteral stents have failed in the setting of enlarging pelvic mass. Given her rise in creatinine, she needs bilateral PCNs to help maximize renal function.
7. **c.** Imaging is not reliable in predicting the ease of removal of a retained stent. Although no encrustations are visible on imaging, the stent may still be encrusted, and patient should be counselled accordingly about possible need for ureteroscopy with laser lithotripsy and possibility of a staged procedure.
8. **b.** The risk factors for urinary tract infection with chronic ureteral stents are the following: female gender, diabetes mellitus, chronic renal failure, diabetic nephropathy and longer duration of stent retention.
9. **e.** Stent positions that exacerbate stent symptoms are the following: incomplete distal curl, distal curl crossing the midline of the bladder and proximal curls located in a calyx.
10. **e.** When significant resistance is encountered, the wire can either be removed or replaced, or a retrograde contrast injection can be performed. Never use the back (stiff) end of a wire, as this can lead to perforation.

CASE STUDY 1

1. **b.** Patient is presenting with urosepsis and needs emergent decompression. PCN is the preferred option given patient's hemodynamic instability. If interventional radiology is unavailable, retrograde ureteral stent can also be attempted. Antegrade ureteral stent is not appropriate in this scenario. Percutaneous nephrolithotomy will likely be necessary in the future given large stone burden.
2. **d.** The patient is actively bleeding. The first step is to "apply pressure", in this case clamp the nephrostomy tube that is draining gross blood. Only then should a CBC be sent and vital signs monitored.
3. **c.** The patient has persistent bleeding. He will likely require more blood products, and possibly a higher level of care (such as the ICU), however the most important step is trying to control the source of bleeding with angioembolization. Nephrectomy is used if angioembolization fails. Removing the nephrostomy tube will likely only exacerbate the bleeding.

CASE STUDY 2

1. **d.** The first step is using a glide-wire. Never use the stiff back end of a wire, this will increase the risk of ureteral perforation. If the area cannot be traversed with a glide-wire, then a percutaneous nephrostomy can be discussed with patient. The stone is likely too small for shockwave lithotripsy. Ureteroscopy without a safety wire in the setting of impacted stone is not recommended.
2. **a.** The figure shows contrast extravasation after attempted wire placement. The wire was never able to traverse the stone. The next step is placement of a percutaneous nephrostomy tube. Ureteroscopy without a wire is contraindicated especially in the setting of a perforation. Never use the stiff back end of a wire, this will only exacerbate the ureteral perforation.
3. **e.** Reassurance, Flomax and oral narcotics should be used only after adequate position of the stent is confirmed. This can be done with KUB, renal US, or a non-contrast CT scan. Pyelonephritis is unlikely given lack of fevers.

Chapter 22 Questions and Answers

KEY POINTS

1. The local and systemic inflammatory toxicities of bacille Calmette-Guérin (BCG) are usually short-lived and can be managed symptomatically.
2. Prevention of systemic absorption and infectious toxicity of BCG relies on healing of the bladder wall and avoidance of trauma at the time of instillation.
3. Prompt recognition and treatment of BCG sepsis is essential, given its potential for mortality.
4. Mitomycin C (MMC) is the least likely absorbed intravesical chemotherapeutic agent, given its molecular weight.
5. Toxicity of MMC is usually related to irritation of the bladder and resolves with time. Nonetheless, instillation should be avoided in the setting of bladder perforation, large resection defects, or ureteral orifice resection.
6. Although MMC is frequently given perioperatively, BCG should not be given until bladder wall healing is achieved following transurethral resection.
7. Valrubicin and gemcitabine are newer agents with efficacy in BCG-refractory disease and mild toxicity profiles primarily limited to local, irritative symptoms.

Nearly 80% of newly diagnosed bladder cancers represent nonmuscle invasive urothelial carcinoma (i.e., stage Ta, stage T1, or carcinoma in situ [CIS]).[1] Numerous intravesical agents may be used in the management of these cancers. Thus, specific knowledge of the toxicity of these agents is imperative for the practicing urologist.

Intravesical Immunotherapy

BACILLE CALMETTE-GUÉRIN

Bacille Calmette-Guérin (BCG) is used for patients with stage T1 tumors, CIS, or stage Ta tumors of high grade. Originally introduced for this indication by Morales and colleagues in 1976, BCG is now accepted as the most efficacious of the intravesical agents.[2–4] Numerous studies demonstrate that the use of BCG reduces the risk of disease recurrence and progression.[5–8]

BCG's mechanism of action involves creating an inflammatory reaction in the bladder by means of live, attenuated mycobacteria.[9–12] For this reason, the rate of local side and systemic side effects is high. The primary cytokines released following intravesical BCG administration are interferon-γ (IFN-γ) and interleukin 2 (IL-2); therefore, many of the systemic side effects noted with BCG are similar to those seen with the systemic administration of cytokines.[13,14] The primary cytokine-related side effects of BCG often do not occur until the third or fourth instillation, a finding suggesting cumulative cytokine release with increasing exposure to the antigen.

Traditionally, BCG was given in 6 weekly instillations, although numerous studies indicate a significant benefit

from maintenance therapy as opposed to induction therapy alone.[15–17] The largest of these studies was the Southwest Oncology Group (SWOG) trial, which randomized 550 patients with recurrent Ta, T1, or CIS to receive either induction alone or induction and maintenance using 3-week treatments given at 3, 6, 12, 18, 30, and 36 months. Median time to disease recurrence was 35.7 months in the group without maintenance and 76.8 months in the maintenance group. At 5 years, the recurrence-free rate was 41% and 60%, respectively.[15] Maintenance therapy, however, was not well tolerated; only 16% of the 243 patients completed all eight scheduled maintenance courses over 3 years.

Low-dose BCG was proposed as a means of decreasing toxicity and improving tolerance.[18–20] A large randomized trial compared 500 patients treated with a BCG dose of either 27 mg (1/3 dose) or 81 mg and found no statistically significant difference in recurrence or progression between the two groups.[18] The investigators reported a significant reduction in toxicity in the low-dose group. A subsequent study from the same group demonstrated that BCG 27 mg (1/3 dose) is superior to BCG 13.5 mg (1/6 dose) with regards to disease recurrence and equivalent with regards to side effects.[20]

A shorter duration of maintenance therapy has been suggested as another approach to reduce BCG toxicity.[21,22] A noninferiority, randomized study of 1355 patients compared 1/3-dose BCG with full-dose BCG and 1 year of maintenance with 3 years of maintenance therapy using a primary outcome of disease recurrence.[21] One-third–dose BCG was not found to be inferior to full-dose BCG. In high-risk patients (i.e., T1 or grade 3), 3 years of maintenance with full-dose BCG reduced disease recurrence as compared to 1 year of maintenance with full-dose BCG, but there was no difference in disease progression or survival. This benefit from 2 additional years of maintenance with full-dose BCG was not observed in intermediate-risk patients. There was no significant difference in toxicity by either reducing the dose or the duration of maintenance.[22]

Numerous strains of BCG are widely used: TICE, Connaught, RIVM, Armand Frappier, Pasteur, and Tokyo. In a large meta-analysis, Lamm and colleagues found no difference among the different strains in terms of clinical efficacy or side effects.[14] Other studies have suggested that efficacy varies with strain, but there is currently insufficient evidence for specific recommendations.[2,3,23]

OVERVIEW OF COMPLICATIONS

Although BCG is generally well tolerated, every urologist should be familiar with the expected and unexpected adverse effects. Soloway and associates reviewed 234 patients referred from community urologists and found significant numbers of patients treated for Ta G1 disease, a pathologic stage and grade in which one must seriously consider whether the side effects of BCG outweigh the small benefit in treatment of typically indolent disease.[24]

A distinction should be made between expected side effects and true complications of BCG therapy (Table 22.1). Local and systemic toxicities can be divided into immune-mediated or infection-mediated complications. Local toxicities are generally treatable and unavoidable symptoms. Some degree of local toxicity is experienced by virtually all patients, although the reported incidence in contemporary series ranged from 27% to 90% depending on sample size,

Table 22.1 Frequency of Bacille Calmette-Guérin Complications

Study (year)	No. Patients	Induction Dose	Maintenance Dose	Irritative Voiding Symptoms	Fever	Sepsis	Death
Pagano et al (1991)[118]	126	75 mg Pasteur, 6 wk	Monthly × 1 yr, every 4 mo × 1 yr	30%	17%	0%	0%

dose and regimen, and definition of local toxicity.[14,25,26] Although many investigators believe that a strong correlation exists between BCG toxicity and efficacy, this link has never been proven in clinical trials.[27]

Systemic complications are uncommon, and >95% of patients will tolerate the treatment well. In a review of 2400 cases, Lamm and colleagues found that fever >103°F was the most severe adverse event (2.9%).[28] Other systemic complications include granulomatous changes, sepsis, pneumonitis, hepatitis, arthralgias, and cutaneous manifestations. Although major adverse reactions are unusual, it is important that the urologist recognize, diagnose, and treat these conditions early. When these complications are diagnosed and treated appropriately, virtually all patients recover from them with no long-term sequelae.

In an attempt to reduce side effects and improve tolerability, isoniazid (INH) has been tested as a prophylactic adjunctive treatment with BCG. A study by Vegt and associates did not show any reduction in local or systemic reactions when INH was used prophylactically.[26] In addition to not providing any protection against reactions to BCG, INH was associated with a significantly higher risk of developing abnormal hepatic transaminase levels. More recently, ofloxacin was given in a randomized multicenter trial to 115 patients undergoing BCG treatment.[29] Prophylactic ofloxacin was found to decrease the incidence of moderate-to-severe adverse events, which many investigators believe cause patients to discontinue treatment. No negative effect on efficacy was reported in the ofloxacin-treated group.

SPECIFIC COMPLICATIONS

We generally categorize the side effects of BCG as local, inflammatory, or infectious. Management and prevention of these side effects depend on the timing of BCG administration and the early recognition of symptoms.

Local Toxicity

The most commonly seen local toxicity of BCG is cystitis-like irritative voiding symptoms, reported in ≤90% of patients.[30,31] Severe symptoms typically occur after the third instillation when lymphokine release causes the maximal inflammatory response. Consideration should always be given to secondary bacterial infection, and a negative urine culture should be obtained before further BCG administration. If a urinary tract infection (UTI) is present, it should be treated and BCG should be delayed until 1 week after resolution of the infection.[32]

Most local symptoms subside within 2 to 3 days of administration, but in severe cases, symptoms can persist for several weeks after completion of therapy. Management should include local analgesics such as phenazopyridine and anticholinergics if severe bladder overactivity is noted.[32] However, further study regarding anticholinergics is required, as a recent randomized study did not demonstrate improvement in urinary symptoms with oxybutynin.[33] BCG dose reduction may be considered on follow-up administration, but unless the problem is severe, doses should not be withheld on the basis of local irritative symptoms alone. These patients may also benefit from treatment with quinolones, though it is unclear if quinolones will reduce further efficacy. Ofloxacin 200 mg given twice after each BCG instillation was found to reduce toxicity and improve compliance with BCG therapy. Antituberculosis therapy (e.g., isoniazid, rifampin) has not demonstrated efficacy in the prophylactic setting. We have generally avoided quinolones during BCG administration, and monitored urine cultures on a routine basis to determine the need for antibiotic therapy.

Gross hematuria occurs in 1–34% of patients receiving BCG.[31,34] It is usually self-limiting and most commonly occurs after the second or third dose. Urine culture should be obtained. Further BCG administration should be delayed until resolution of hematuria.[32] If hematuria does not resolve after 2 to 3 weeks of observation, repeat cystoscopy is indicated to exclude the possibility of recurrent tumor.

Inflammatory Toxicity

Flulike symptoms, such as low-grade fever <101.3°F, often accompany the irritative voiding symptoms. Malaise, myalgia, and low-grade fever typically last 24 to 48 hours. Treatment with acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) is typically successful. In many cases, we have used prophylactic acetaminophen administered at the time of BCG instillation if patients have previously demonstrated such toxicity upon administration. In our experience, the likelihood of inflammatory toxicity may increase with increasing exposure to BCG, and it is rare for patients to have substantial symptoms within the first few doses of induction. Over time, if administered as maintenance therapy, inflammatory toxicity may increase, and dose reduction can be an effective strategy when symptoms become severe. If no resolution is noted after 48 hours, or symptoms are severe and refractory to simple maneuvers, consideration should be given to antituberculosis therapy with two or more agents until symptoms resolve.[32]

Infectious Toxicity

High fever (>102–103°F) or shaking chills suggests fever resulting from systemic absorption and warrants empiric treatment with antituberculosis therapy. Failure to treat or delay in diagnosis can result in a progression to sepsis and mortality.

Sepsis typically occurs in <4% of patients.[31] In patients who develop BCG sepsis, therapy must be immediate and aggressive. More than 10 deaths have been attributed to BCG sepsis, and the rate is estimated to be 1 death for every 12,500 patients treated with intravesical BCG. The classic presentation is a patient with history of traumatic catheterization who presents with fever, chills, hypotension, and mental confusion. Respiratory failure, hepatomegaly, jaundice, leukopenia, and disseminated intravascular coagulopathy can occur. Although BCG sepsis generally occurs soon after instillation, a delayed onset several months after BCG therapy is possible. Results of culture are typically negative for mycobacteria, and treatment must be started based on clinical suspicion.

Management includes cessation of intravesical BCG, consultation with an infectious disease specialist, and administration of INH, rifampin, ethambutol, fluoroquinolones, and high-dose corticosteroids.[32] Empiric coverage of gram-negative organisms and/or *Enterococcus* can also be considered. Lamm proposed that BCG sepsis is, in part, the result of a delayed-type hypersensitivity reaction, and

for this reason the administration of 40 mg prednisolone may improve survival.[34] Whereas corticosteroids and fluoroquinolones may be discontinued after the resolution of symptoms, antituberculosis agents should be continued for a minimum of 6 months. Addition of a fourth antituberculosis drug can be considered in severe cases. Of note, BCG strains are not sensitive to pyrazinamide. The use of cycloserine has previously been proposed by some investigators for systemic BCG absorption. Although the use of this agent has shown a survival advantage in mice, it appears to be ineffective against currently used BCG strains and thus is not recommended.[35–37]

Prevention of Systemic Absorption

Numerous factors may contribute to the risk of systemic absorption. Most commonly, traumatic catheterization, a nonhealing resection site, and unrecognized UTI are the leading suspects.

During catheterization of a patient for BCG instillations, any difficulty or trauma should raise concern. At least seven reported deaths have resulted from systemic BCG infection after traumatic catheterization.[31] At the time of instillation, atraumatic catheterization is essential. If traumatic catheterization does occur, BCG therapy should be withheld for 1 week.[32] A history of significant urethral stricture may be a contraindication to BCG therapy. In these patients, the stricture disease should be treated definitively prior to initiating intravesical therapy.

On rare occasions, a patient can be treated with a catheter in place. Following catheterization, the BCG is instilled and the catheter is left capped for 2 to 3 hours, depending on the patient's bladder capacity. Caution must be exercised to ensure that the patient does not have poor compliance or detrusor instability, which may result in high intravesical pressure and systemic absorption. Such individuals may not be appropriate candidates for BCG therapy if they also have poor bladder capacity. BCG should not be administered in the setting of known muscle-invasive or necrotic bladder cancer.

BCG instillation should be performed by gravity, not by pressurized instillation. Generally, a syringe with the piston removed can be attached to the catheter and used as a reservoir for gravity-driven instillation.

Following tumor resection, it is recommended to withhold BCG for 2 weeks.[32] We have found an interval of 2 to 3 weeks with resolution of hematuria is usually sufficient to allow healing without affecting therapeutic outcome. In patients with a large resection bed, flexible cystoscopy can be used to ensure healing, and the presence of residual tumor, before BCG instillation. Gross hematuria or significant microscopic hematuria should have resolved before instillation. Periodic urine culture is useful to identify UTI. Symptoms alone may not be helpful for identification of UTI because most patients experience some irritative voiding symptoms.

Granulomatous Complications

Granulomatous prostatitis is reported to occur in 1–27% of patients receiving BCG therapy, depending to some degree on the treatment regimen.[31] The true incidence of this complication is likely much higher and was found to be as high as 40% among patients undergoing biopsy in one study.[38] Granulomatous prostatitis is usually discovered incidentally on digital rectal examination in patients with or without an elevated prostate-specific antigen (PSA) level. In the small percentage of patients who are symptomatic (6%), Lamm and associates noted that these patients usually present with acute prostatitis or urinary retention.[39] Biopsy is needed to rule out cancer, and once the diagnosis is made, asymptomatic patients can be observed. Symptomatic disease warrants cessation of BCG instillations and treatment with INH 300 mg/day and rifampin 600 mg/day for 3 to 6 months and high-dose fluoroquinolones and corticosteroids until symptoms resolve.[32,37,40]

It is wise to obtain a PSA level before BCG therapy. This test should be performed at a time distant from lower tract instrumentation. If test results are normal, PSA need not be measured until 1 year following BCG instillation. In individuals undergoing maintenance therapy, we determine the PSA level immediately before the 12-month maintenance dose. Prostate nodules and elevated PSA are common in men undergoing BCG therapy. Given the frequent instrumentation, rises in PSA level are difficult to interpret. We have found multiparametric prostate MRI to be invaluable in this setting as it often distinguishes between inflammation, BCG granuloma, or regions suspicious for prostate cancer. One may give a course of INH for 2 to 3 months to assess the cause of PSA elevation. If the BCG treatment was given in the remote past, the urologist should proceed directly to biopsy on the basis of PSA or abnormal exam.

More infrequently, granulomatous epididymo-orchitis or even granulomatous balanoposthitis can occur.[41] Patients with granulomatous epididymo-orchitis generally present with local induration and pain. Local symptoms may be accompanied by fever or leukocytosis. A diagnosis of bacterial infection should be excluded, as epididymo-orchitis in the setting of BCG therapy is often caused by gram-negative bacteria.[32] Treatment is with INH and rifampin for 3 to 6 months and fluoroquinolones and steroids until symptoms resolve. Some cases may proceed to abscess formation requiring orchiectomy for definitive treatment. Granulomatous balanitis can present with erythematous nodules on the glans and should be treated with antituberculosis therapy.[37]

Granulomatous hepatitis and pneumonitis represent systemic infection and occur in <1% of patients treated with BCG.[31] Granulomatous hepatitis presents with typical signs and symptoms of hepatitis, such as fever, jaundice, and anorexia. Granulomatous pneumonitis presents with general malaise, shortness of breath, and fever >101°F. One death has been reported from granulomatous hepatitis and BCG sepsis.[42] A full fever workup that includes elevated liver enzymes and a chest radiograph or CT scan are needed to delineate the diagnosis. Liver biopsy is required to confirm the presence of granulomatous hepatitis. Hospitalization, fluid resuscitation, and acetaminophen are essential. INH and rifampin are given for 3 months with ethambutol added for severely ill patients. The incidence of hypersensitivity reaction from BCG is unclear, but investigators have reported that some granulomatous reactions result from an immune rather than an infectious process.[30,43,44] Although no controlled studies have been conducted of steroid therapy in BCG-infected patients, preliminary data reveal that prednisolone (40 mg/day) may be added in unremitting conditions, as in the case of BCG sepsis.[45–47]

Granulomatous reactions also occur in the bladder.[47,48] Contracted bladder occurs in <1% of patients, but patients receiving maintenance therapy may be at higher risk, and some investigators have advocated use of prophylactic INH to decrease the likelihood of this complication. Management of contracted bladder consists of hydrodistention and withholding of BCG.[32] If conservative measures fail, cystectomy may be required.[49] Ureteral obstruction may occur secondary to edema or inflammation of the orifice and is reported in <0.3% of patients. CIS and vesicoureteral reflux are probably predisposing factors.[50] This rare complication may require ureteral stenting or percutaneous drainage to relieve the obstruction.[32]

Granulomatous reactions of the bone and bone marrow may rarely occur. Osteomyelitis of the vertebral bodies has been reported. Patients can present with back pain or even motor weakness.[51] The presence of cytopenia should arouse suspicion of bone marrow involvement. Treatment is with antituberculosis therapy and cessation of BCG therapy.[52]

Arthralgic Complications

Arthralgia and arthritis are some of the rare severe complications associated with BCG therapy. Joint involvement occurs in approximately 0.5% of cases.[31] Arthritis usually occurs ≤2 weeks after the last instillation, whereas arthralgias can appear within a few days of instillation and become more severe with further instillations.[53] Arthritis may occur within the complex of Reiter syndrome.[54] The symptoms may resolve with NSAID treatment. If symptoms persist, administration of antituberculosis drugs and steroids should be considered.[40]

Arthralgias with associated skin rash likely indicate an allergic reaction to BCG. Treatment begins with NSAIDs and antihistamines. Refractory or severe symptoms require discontinuation of BCG and use of INH, rifampin, quinolones, and steroids.[32]

Rare Complications

Penile edema and meatal ulceration have been reported with and without lymph node enlargement.[55] A 3-month course of INH and rifampin therapy should be given. Cutaneous complications of BCG therapy are rare, but penile edema and meatal ulceration suggest the possibility of local spillage.[56] Other rare reported complications include nephrogenic adenoma, immune complex glomerulonephritis, choroiditis, cardiac toxicity, suppurative lymphadenitis, mycotic aneurysm, aortoduodenal fistula, lupus vulgaris, and musculoskeletal lesions.

CONTINUING THERAPY AND MAINTENANCE

Patients experiencing mild local and systemic inflammatory side effects can be safely continued on an unmodified dose of BCG. In individuals experiencing severe local side effects or systemic toxicity lasting >48 hours, we recommend withholding the dose until symptoms have resolved and then resuming treatment with a lower dose of BCG (1/3, 1/6, 1/12, or 1/100 dilution) to reduce the severity of symptoms.[32,57] Evidence suggests that 1/3 dilutions are the minimum effective dose in maintenance.[18,20] In our practice, however, we have occasionally reduced the dose to 1/6 or 1/12, transiently, with later a attempt to increase the dose back to a 1/3 dose. In general, prophylactic use of INH is not indicated unless the clinician suspects systemic absorption of the organism. Prophylactic ofloxacin 200 mg given twice following each BCG instillation is a reasonable option to reduce side effects.[29] We have always been concerned that quinolones have the potential to reduce efficacy given their cytotoxic effect on the BCG organism.

In patients with high fever or severe local symptoms, once the symptoms resolve, the clinician should rule out obvious reasons for systemic absorption such as traumatic catheterization, bladder wall ulceration, or timing in relation to transurethral resection. Individuals who have experienced severe systemic illness or sepsis should not receive further BCG therapy.

Numerous studies have shown that long-term maintenance therapy is associated with a poor rate of compliance, ranging from 16% to 65.5%.[58–61] In comparison with nonmaintenance regimens, patients undergoing maintenance therapy clearly have a greater incidence of side effects, and compliance seems directly related to the duration and total number of instillations.[59] Most treatment cessations are secondary to local or regional symptoms of irritation. Although low-grade fever is common and increases in incidence with successive maintenance doses, this complication has not been found to be associated with cessation of therapy.[62] Recent evidence suggests that in patients without high-risk cancer, 1 year of maintenance therapy is effective and thus might be an option in patients with intolerable side effects.[21] Alternatively, we have used a modified regimen of administration at 3, 6, 12, 18, 24, 36, 48, and 72 months. Anecdotally, this regimen has been better tolerated.

In follow-up, we have generally chosen to perform cystoscopy no sooner than 3 months following BCG administration, in part because of the high likelihood of ongoing bladder wall inflammation, but additionally because of the need for an adequate period to allow therapeutic efficacy, particularly in the setting of CIS. BCG inflammation can take on several appearances, but typically is demonstrated as a patch of raised, friable erythema, or bullous edema, in the dome of the bladder. Similar findings, located at the previous site of resection, are commonly observed as well. Use of cytology, and biopsy if cytology is abnormal, can differentiate apparent BCG inflammation from persistent urothelial cancer. In cases of normal cytology, deferral of maintenance BCG for 6 weeks with repeat inspection can be considered prior to biopsy.

PURIFIED PROTEIN DERIVATIVE CONVERSION

Routine purified protein derivative (PPD) skin testing prior to administering intravesical BCG is unnecessary, as most patients in the United States are at low risk for active tuberculosis infection.[63] A positive PPD test without evidence of active disease is not a contraindication to intravesical BCG. PPD positivity may in fact be encouraging, as patients with prior immunity to BCG as demonstrated by a positive PPD may have improved recurrence-free survival without experiencing greater toxicity.[64,65]

PPD conversion to a positive test result occurs in approximately 34% of patients previously treated with intravesical BCG and should not be considered a complication of

BCG therapy.[66] Although favorable responses to treatment have been shown to occur more frequently in patients with PPD conversion, this factor has not been shown to be a reliable indicator of either prognosis or tolerance of therapy.[31,67]

CONTRAINDICATIONS

Classic contraindications to BCG therapy include human immunodeficiency virus (HIV) infection, leukemia, lymphoma, organ transplantation, pregnancy, breast-feeding, active tuberculosis, and intractable UTIs.[68] In severely immunocompromised patients, there is a theoretical concern for increased risk of systemic BCG toxicity. However, limited evidence has demonstrated efficacy and safety in some of these patient groups.

Yossepowitch and colleagues evaluated the use of BCG induction therapy in 24 "immunocompromised patients" with lymphoma, chronic obstructive pulmonary disease, or steroid therapy and found a response rate of 58% overall; only a single patient experienced a self-limited febrile illness (≤39.3°C for 48 hours after his third BCG cycle).[69]

BCG therapy has been safely given in several small studies of patients with renal transplants.[70–73] Some investigators utilized prophylactic antituberculosis drugs and adjusted immunosuppressive doses due to possible drug interactions.[70,71] Herr and colleagues administered an induction course of BCG in 45 immunosuppressed patients, including those with organ transplants, cancer treated with chemotherapy, or corticosteroid use.[73] Transplant patients experienced higher rates of treatment failure, recurrence, and progression. No patients in this cohort developed bacterial or BCG sepsis. Thus, they concluded that intravesical BCG is effective and safe in these immunocompromised patients. Caution should still be practiced when considering intravesical BCG in immunocompromised patients, as there is only preliminary evidence suggesting its safety. Severely immunocompromised patients should not undergo BCG therapy.

There are scarce data regarding the use of intravesical BCG in patients with HIV.[72] Only two such patients were identified, one of whom with a CD4+ lymphocyte count of 10/mm^3 developed interstitial pneumonitis following BCG therapy.[74,75] In patients with HIV well-controlled with medications, BCG therapy might be safe but is yet unproven.[63]

No contraindication exists for BCG therapy in patients with valvular heart disease, prosthetic heart valves, or orthopedic hardware. Appropriate antibiotic prophylaxis for bacterial endocarditis should be administered in these patients before urethral instrumentation is undertaken but is not necessary for simple urethral catheterization during BCG instillation.[63]

Another area of debate is transmission of BCG by sexual intercourse. Even though no cases of sexual transmission have been reported, use of a condom is generally advised during sexual intercourse for 1 week after BCG therapy.

BCG may be given to patients with vesicoureteral reflux without significant risk of complication.[76] Some investigators have advocated resection of the ureteral orifices to induce reflux before BCG therapy to increase the proportion of urothelium in contact with BCG. Only one case of necrotic pyelonephritis has been reported. When patients do develop severe febrile reactions to BCG, consideration should be given to BCG pyelonephritis or renal abscess.

INTERFERONS

Interferons (IFNs) are proteins with antiviral, antiproliferative, and immunomodulatory properties. Three classes of IFNs are recognized:[77] IFN-α, IFN-β, and IFN-γ derive from leukocytes, fibroblasts, and lymphocytes, respectively. IFNs stimulate macrophages for antigen presentation, promote cytokine release, enhance natural killer cell activity, and indirectly activate T and B lymphocytes.[78]

The best studied IFN is IFN-α. When it is used alone, this agent is well tolerated, with minimal local inflammatory effects or low-grade fever.[79] Efficacy depends on dose (range, 10 million to 100 million U). IFN-α is less effective and more expensive than BCG, and therefore its primary use is in salvage intravesical therapy for BCG-refractory tumors.[58,80,81] In patients with CIS and BCG treatment failure, the complete response to IFN-α is 15–20% at 1 year, with a durable response rate of 12% by 2 to 3 years.[26]

COMPLICATIONS

Most side effects of IFN are the result of the systemic inflammatory response generated by lymphokine release. Acute IFN toxicity consists of flulike symptoms, which occur in 0–27% of patients and include chills, fever, headache, malaise, and myalgia.[79,82] Chronic toxicities include fatigue, weight loss, and anemia. Some patients (0–10%) develop local cystitis and hematuria.[17] Most adverse events resolve with expectant management within 24 to 48 hours of onset or on discontinuation of therapy. Acetaminophen can be used as a supportive agent to reduce fever and myalgia. Although treatment is generally symptomatic, dose reduction can aid in the completion of therapy.

O'Donnell and colleagues conducted a phase II randomized trial comparing IFN alfa-2b with BCG and found systemic side effects in 5.3% of patients.[80] The use of low-dose BCG showed a trend toward decreased severe inflammatory and infectious events.

Although most toxicities associated with intravesical IFN are mild, transient, and completely reversible on discontinuation of therapy, these symptoms can occasionally interfere with patient compliance and completion of therapy. Dose reduction (25 or 10 million U, if necessary) offers a potential means of continuing therapy.

INTRAVESICAL CHEMOTHERAPY

Intravesical chemotherapy is an important class of therapeutics for treatment of Ta and T1 bladder carcinoma. The most commonly used drugs are mitomycin C (MMC), epirubicin, doxorubicin, valrubicin, and gemcitabine. Intravesical chemotherapy can usually be administered immediately following transurethral resection. Given the high molecular weight of chemotherapeutic drugs, the risk of absorption is low; consequently, systemic toxicity is of smaller concern than with BCG. Local symptoms due to irritation are most prevalent, and few side effects are immunologically mediated. As such, the side effects of individual agents are

commonly related to the drug itself. Furthermore, the use of intravesical chemotherapy precludes the risk of sepsis and death associated with BCG therapy.

MITOMYCIN C

Mitomycin C is an antibiotic chemotherapeutic alkylating agent that acts by inhibiting DNA synthesis.[83,84] Because of its high molecular weight, MMC is not easily absorbed and has a lower incidence of systemic reactions. This agent has been used in 20- to 60-mg doses for 8 weeks, although the usual dose is 40 mg in 40 mL of saline or water intravesically for 8 weeks followed by monthly maintenance therapy for 1 year in most studies. Table 22.2 summarizes the different schedules of intravesical MMC therapy and their associated side effects.

Chemical cystitis, the most common side effect of MMC therapy, has an incidence of 3–33%.[85,86] Genitourinary toxicity occurs even with a single dose of perioperative MMC, with one study reporting symptoms in 28% of 116 patients receiving MMC following tumor resection.[87] Symptoms generally respond to phenazopyridine and anticholinergics, but ≤3% of patients may require discontinuation of therapy because of severe cystitis.[67] Common symptoms include dysuria, suprapubic discomfort, and urinary frequency and urgency. UTI should be ruled out before palliative therapy is instituted; before discontinuation of therapy, consideration should be given to reducing the dose. Toxicity partly depends on the dose administered, but cystitis can occur even at low doses.

The incidence of dermatologic toxicity with MMC ranges from 4% to 12% in most series. Contact dermatitis may result from a delayed hypersensitivity reaction or direct contact of the drug with the skin.[88] Delayed hypersensitivity as a cause was postulated after deGroote and colleagues reported on six patients, all of whom developed rash after their second instillation, a finding suggesting that MMC sensitization was required for the dermatitis to occur. Contact dermatitis can manifest as an eczema-like desquamation of the skin of the palms, soles of the feet, perineum, chest, and face. Other investigators have reported a generalized rash.[67,89] There is a report of penile gangrene secondary to MMC contact dermatitis that ultimately required penectomy.[56] Contact dermatitis due to allergic reaction may rarely present with associated eosinophilic cystitis, causing severe voiding symptoms that usually necessitate cessation of MMC therapy.[90]

Dermatologic toxicity may be prevented by careful cleansing of the hands and genitals after voiding. When a rash does arise, MMC therapy is generally discontinued, though topical steroids can sometimes suppress the reaction sufficiently to continue therapy.[88] In most cases, repeat treatment results in recurrence of the dermatitis. Some investigators have suggested skin testing patients with a 0.1% MMC petroleum patch to observe whether a systemic response occurs, but this approach has not gained favor.[91]

Myelosuppression after intravesical MMC therapy is rare but has been reported by multiple investigators.[92] In general, patients appear to have coexisting risk factors for leukopenia, thus making it difficult to assess the causative

Table 22.2 Toxicity of Intravesically Administered Mitomycin C

Study (year)	No. Patients	Induction Dose	Dose Frequency	Chemical Cystitis	Bladder Capacity Reduction	Contact Dermatitis	Leukopenia	Thrombocytopenia

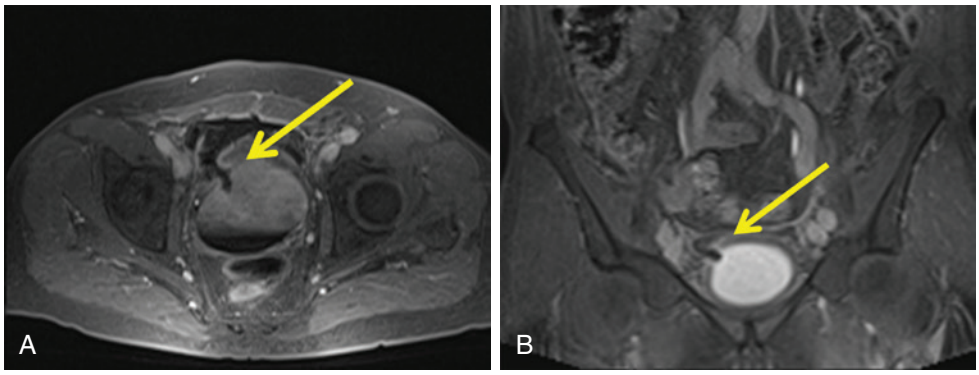

Figure 22.1 Magnetic resonance imaging urogram of a patient with severe pelvic pain following perioperative mitomycin instillation. A, On axial imaging a perivesical phlegmon with fat necrosis extending to an apparent breach in the bladder well is noted (see arrow). B, On urographic phase, coronal section unrecognized extravesical bladder perforation is noted with fat necrosis extending into the bladder lumen with layering of lipid in the bladder (see arrow).

factor. Myelosuppression is rare enough that routine monitoring is not necessary. If myelosuppression occurs, intravesical MMC should be stopped and white blood cell count should be monitored.

A relatively infrequent complication of MMC instillation is bladder contracture.[86] Although a reduction in bladder capacity has been reported by numerous investigators, interpretation of the finding is difficult because in most cases, pretreatment bladder capacity is not measured. In patients with a severe reduction in bladder capacity, it appears that MMC administration at the time of resection is the major risk factor, and the most likely contributor is extravasation. Selecting patients carefully based on the extent and depth of resection, and particularly avoiding administration in the setting of perforation, may decrease the risk.

Contraindications to MMC instillation include suspected bladder perforation during tumor resection, pregnancy, and previous allergic reaction or severe adverse reaction to MMC. MMC may cause peritonitis, abdominal or pelvic pain, fibrosis, and necrosis if bladder perforation and extravasation occur.[93–95] Affected patients may suffer from chronic pelvic pain or require surgical reconstruction.[96] Urologists must constantly be aware of the depth of transurethral resection, and if perforation is suspected, MMC should be withheld until a cystogram is done to confirm bladder integrity. In rare instances, extravasation may be a direct effect of MMC-induced transmural muscle necrosis.[94] Allergic reactions generally manifest as the aforementioned skin rashes or, rarely, as eosinophilic cystitis.[90]

In patients with severe cystitis symptoms with or without pelvic pain, cross-sectional imaging is indicated to rule out extravesical or bladder wall necrosis, bladder fistula, or pelvic abscess (Fig. 22.1). Cystoscopy typically demonstrates severe inflammation, with bullous edema, surface necrosis of the urothelium, and punctate hemorrhage surrounding sites of resection (Fig. 22.2), often as a concentric ring at the dome of the bladder. In cases of bladder wall fistula to the surrounding perivesical fat, the actual fistula may not be seen, but droplets of fat are often observed floating in the bladder. In these cases, simple observation with administration of pain medication, urinary analgesics, and, when needed, antimuscarinic agents is a reasonable first course. Healing can take several months in cases of bladder fistula,

Figure 22.2 Cystoscopic view of severe mitomycin reaction in a patient administered perioperative mitomycin following resection of a papillary bladder tumor. Local reaction with bullous, hemorrhagic edema surround the resection bed.

but severe cystitis will generally resolve within 3 months. Transurethral resection of necrotic tissue can be considered in cases of secondary infection or when large amounts of necrotic debris are noted in the bladder, but caution must be exerted to avoid overt perforation. Additional intravesical therapy, particularly BCG, should be withheld until complete resolution of cystitis and healing of the bladder in cases of fistula. Upon healing, a stellate scar will be visible at the site of the previous fistula and, depending upon the amount of bladder wall necrosis and perivesical fibrosis, bladder function or compliance can be affected. Secondary bladder augmentation is rarely required, and generally should be avoided until a prolonged cancer-free interval is noted. Visual inspection of the bladder previously treated with mitomycin will often demonstrate multifocal telangiectasias as a result of bladder wall healing (Fig. 22.3).

THIOTEPA

Thiotepa was used in the past for nonmuscle invasive bladder cancer at high-risk for recurrence due to tumor multifocality, frequent recurrence, or high-grade disease associated with urothelial atypical cancer or CIS. The drug was appealing because of its low cost, but it lost appeal because of the availability of anthracycline compounds and of the relatively higher risk of systemic absorption and myelosuppression. Unlike MMC, thiotepa has a low molecular weight, which allows as much as one-third of the drug to be absorbed through the urothelium when it is retained in the bladder for 3 hours.[84] Because of the low molecular weight, the high rate of absorption, and the potential for bone marrow suppression associated with thiotepa, the treating physician should be extremely cautious when administering this agent (Table 22.3).

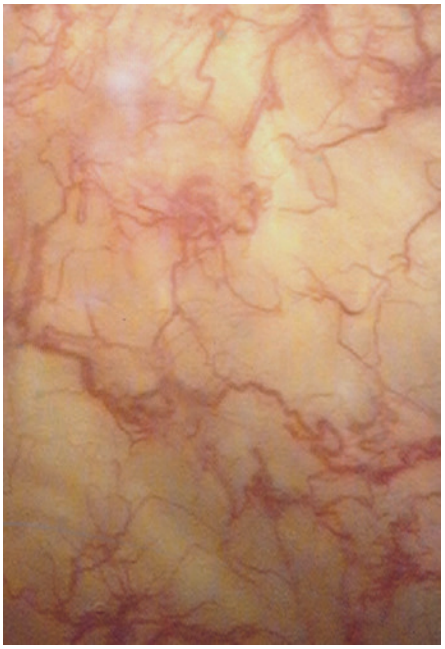

Figure 22.3 Cystoscopic appearance of the urothelium in a patient previously administered mitomycin for nonmuscle invasive bladder cancer. The urothelium is well healed with a hypervascular pattern consisting of multiple telangiectasias.

DOXORUBICIN, EPIRUBICIN, AND VALRUBICIN

Doxorubicin, epirubicin, and valrubicin are anthracycline antibiotics. Doxorubicin is used primarily for pTa and pT1 tumors for treatment and prophylaxis. BCG is superior for the treatment of CIS, but doxorubicin may be used in patients who cannot tolerate BCG. Because of its large molecular weight, doxorubicin is minimally absorbed and has few systemic complications. Local toxicity, however, is far more common (Table 22.4).

Chemical cystitis manifesting as dysuria, frequency, urgency, and suprapubic pain is seen in 13–56% of patients.[84] Management involves symptomatic care and urine cultures to rule out bacterial infection. Local treatment with phenazopyridine or anticholinergics provides relief of mild symptoms.

Systemic side effects are uncommon and occur in <5% of patients in most series. Rare systemic side effects include gastrointestinal upset, fever, and rare hypersensitivity reactions. In very rare reported instances, hypersensitivity reactions manifested with tachypnea and bronchospasm and were treated with diphenhydramine; in one case, subcutaneous epinephrine was required.[97,98]

Epirubicin is similar to doxorubicin but has become more popular, especially in Europe, because of comparable or improved efficacy and decreased toxicity relative to doxorubicin. Numerous investigators have verified the efficacy of epirubicin in the treatment of superficial bladder cancer.[99–104] Theo and colleagues randomized 168 patients to either 50 mg epirubicin or 81 mg BCG for CIS.[99] The clinical response rate was equivalent for the two agents; however, time to tumor recurrence after initial clinical response was longer in patients treated with BCG than in those treated with epirubicin (5.1 vs 1.4 years). A higher rate of CIS recurrence was noted with epirubicin than with BCG therapy (45% vs 16%).[99] In the epirubicin-treated

Di Lorenzo et al (2010)[114]	40	2000 mg/50 mL	Twice weekly × 6 wk; weekly × 3 at 3, 6, 12 mo	15%	3% (fever) 5% (neutropenia, thrombocytopenia) 5% (rash)
Addeo et al (2010)[115]	109	2000 mg/50 mL	Weekly × 6 wk; monthly × 1 yr	9.2%	6% (rash)
Skinner et al (2013)[112]	55	2000 mg/100 mL	Weekly × 6 wk; monthly × 1 yr	62%	2% (neutropenia)
Sternberg et al (2013)[113]	69	2000 mg/100 mL	Twice weekly × 6 wk	40%	10% (rash) 3% (fever) 3% (infection) 1% (thrombocytopenia)

group, systemic toxicity was very rare and mild, ranging from skin rash to general malaise. Both local and systemic side effects were more commonly observed in the BCG-treated group. Due to these side effects, 26 patients stopped treatment in the BCG group, as opposed to only eight patients in the epirubicin group.

Valrubicin is a semisynthetic analog of doxorubicin. It has demonstrated antitumor activity in the treatment of superficial bladder cancer and superior efficacy with lower risk of contact and cardiac toxicity compared to doxorubicin in animal models.[105] Valrubicin has gained FDA approval for its role in BCG-refractory CIS in patients who are not candidates for cystectomy. Local bladder symptoms due to valrubicin are mild and rarely cause early cessation of therapy. Symptoms such as urinary frequency, urgency, and dysuria occurred in approximately 50–60% of patients in the two largest studies.[106,107] Other less common side effects include UTI, asthenia, urinary retention, and foul-smelling urine with or without passing of tissue.

GEMCITABINE

Gemcitabine is a pyrimidine analog that inhibits DNA synthesis through insertion into the DNA sequence and inhibition of ribonucleotide reductase, which prevent downstream DNA polymerization and nucleotide synthesis, respectively.[108] In patients with advanced or metastatic bladder cancer, systemic administration of gemcitabine has proven efficacious and to be well-tolerated.[109,110] Several studies have demonstrated that an induction course of intravesical gemcitabine is effective in treatment-naïve and BCG-refractory disease.[108,111–113]

BCG-refractory disease treated with gemcitabine has a relatively high rate of recurrence at 1 year of follow-up, even with 1 year of maintenance therapy.[111,112] However, this represents a group that is difficult to treat and would otherwise be relegated to cystectomy. In a randomized study of 80 patients who previously failed one course of BCG, patients treated with gemcitabine had a reduced rate of recurrence relative to those treated with BCG, after 1 year of maintenance therapy of each drug.[114] Another randomized study of 120 patients with BCG-refractory disease demonstrated that gemcitabine was more efficacious and less locally toxic than MMC.[115]

Intravesical gemcitabine is extremely well-tolerated, allowing high rates of completion with therapy. Side effects are summarized in Table 22.5. Local urinary symptoms occur in 10–40% of patients and are generally mild. One

study evaluating a maintenance regimen of gemcitabine found mild local toxicity in 62% of patients; however, there was no increase in toxicity with higher numbers of instillations.[112] Although there are no studies evaluating their efficacy in this setting, anticholinergics and phenazopyridine can be utilized to alleviate local symptoms. Systemic toxicity is rare but can include infection, dermatitis, fever, neutropenia, and thrombocytopenia.

Conclusions

The management of nonmuscle invasive bladder cancer is greatly aided by the use of intravesically administered adjuvant therapies. The use of these therapies is generally safe, and with precautions, such as careful techniques of administration, patient selection, and patient observation, long-term sequelae should be minimal. Thorough knowledge of the individual toxicity profile of each agent is essential for the practicing urologist. Although various agents carry different risks of toxicity, adherence to the standard treatment principles of intravesical therapy, outlined in this chapter, will minimize the likelihood of complications.

Chapter 22 Questions

1. Which dilution of the standard bacille Calmette-Guérin (BCG) dose reduces toxicity without compromising efficacy?
   a. 1/2 dilution
   b. 1/3 dilution
   c. 1/6 dilution
   d. 1/12 dilution
   e. 1/100 dilution

2. Which drug can be used prophylactically to reduce adverse effects of intravesical BCG?
   a. Corticosteroids
   b. Isoniazid (INH)
   c. Ofloxacin
   d. Rifampin
   e. Nonsteroidal antiinflammatory drugs (NSAIDs)

3. What is the most common adverse effect of BCG therapy?
   a. Fever
   b. Irritative voiding symptoms
   c. Skin rash
   d. Pneumonia
   e. Sepsis

4. Which of the following is an appropriate first-line treatment for BCG sepsis?
   a. INH, rifampin, ethambutol, prednisone, cycloserine
   b. INH, rifampin, prednisone
   c. Rifampin, pyrazinamide, prednisone
   d. INH, rifampin, ethambutol, prednisone, ciprofloxacin
   e. INH alone

5. Perioperative intravesical mitomycin C (MMC) is planned for a patient following transurethral resection of bladder tumor. After an extensive resection, bladder perforation is suspected. Which of the following is the most appropriate next step?
   a. Withhold mitomycin until a cystogram can be performed
   b. Proceed with intravesical MMC
   c. Proceed with intravesical gemcitabine
   d. Proceed with a lower dose of intravesical MMC
   e. Leave the catheter for 24 hours and then administer MMC

6. Which of the following is *not* a contraindication to intravesical BCG?
   a. Hematuria
   b. HIV/AIDS
   c. Positive purified protein derivative (PPD) skin test
   d. Traumatic catheterization
   e. Transurethral resection within 1 week

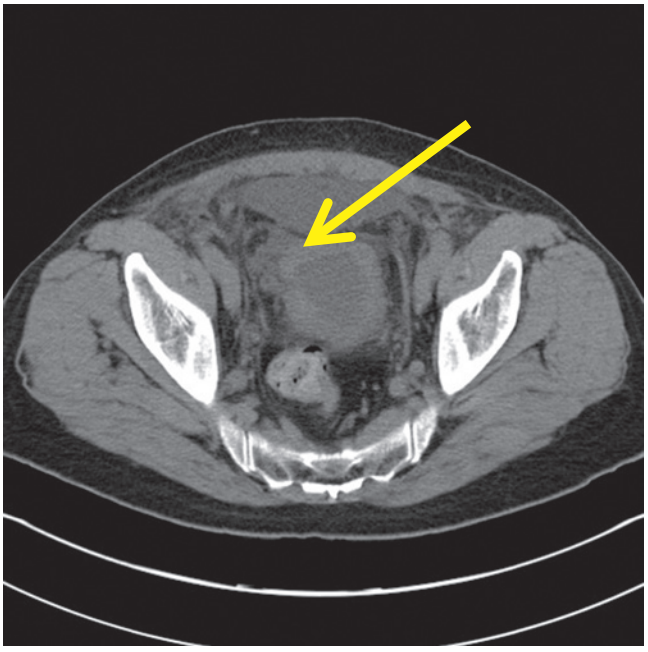
7. Which adverse effect of intravesical MMC can be immune-mediated?
   a. Cystitis
   b. Myelosuppression
   c. Bladder contracture
   d. Skin rash
   e. Fistula

8. For which indication does valrubicin have FDA approval?
   a. BCG-refractory carcinoma in situ (CIS)
   b. BCG-refractory papillary tumors
   c. Muscle invasive bladder cancer
   d. Treatment-naïve CIS
   e. Upper tract CIS

9. A 70-year-old man undergoing BCG maintenance therapy presents with fever and left testicular pain. Which of the following is the most likely diagnosis?
   a. Granulomatous epididymo-orchitis
   b. Testicular torsion
   c. Bacterial epididymo-orchitis
   d. Granulomatous prostatitis
   e. Testicular tumor

10. After undergoing an instillation of BCG, a patient experiences a fever of 101.1°F for 8 hours. What is the best next step in management?
    a. INH, rifampin, ethambutol, prednisone
    b. Acetaminophen
    c. Ofloxacin
    d. Withhold further BCG therapy
    e. Admission to hospital

Case Study 1



1. A 63-year-old man with a 3-cm papillary bladder tumor undergoes a transurethral resection of the tumor with plan for perioperative administration of intravesical mitomycin (Case Fig. 22.1). There is visible thinning of the bladder wall, with no evidence of perforation. The next step is:
   a. Proceed with planned mitomycin administration
   b. Proceed with reduced-dose mitomycin administration
   c. Delay mitomycin administration for 24 hours
   d. Withhold mitomycin
   e. Cystogram prior to mitomycin administration

2. Following administration of mitomycin, the patient develops severe dysuria within 72 hours. He notes right lower quadrant abdominal pain, urinary frequency, and urgency. He denies fever or chills. CT scan is shown (Case Fig. 22.2). The next step is:
   a. Pain medication, urinary analgesic, and antimuscarinics
   b. Intravenous antibiotics, bowel rest
   c. Cystoscopy, bladder debridement
   d. Catheter drainage
   e. Exploration and bladder repair

3. Nine months following resection, the patient's symptoms have largely dissipated. He reports mild urinary frequency without dysuria or pain. He is noted to have multifocal papillary recurrence. At time of resection, no perforation is noted. Pathology demonstrates

Case Figure 22.1

Case Figure 22.2

high-grade pTa urothelial cancer with focal CIS. The next step is:
a. Continued surveillance
b. Intravesical mitomycin administration
c. Cystogram followed by mitomycin administration
d. BCG induction therapy
e. Cystectomy

Case Study 2

1. A 60-year-old woman is administered induction BCG following the diagnosis of high-grade nonmuscle invasive bladder cancer. Following administration of the fourth dose, she experiences fever of 100.8°F, severe muscle aches, and fatigue persisting for 18 hours. The next step is:
   a. Antipyretics, analgesics, supportive care
   b. Quinolone antibiotics
   c. Discontinue BCG
   d. Intravenous antibiotics
   e. Intravenous antibiotics and antituberculous agents

2. Given a favorable response to BCG, a maintenance regimen is initiated. After the second dose of the third maintenance cycle, the patient develops severe, persistent dysuria and pelvic pain. Urine culture and cytology are negative. Cystoscopy is consistent with severe BCG inflammation, and biopsy shows no cancer. After 4 weeks of supportive care, symptoms persist without great improvement. The next step is:
   a. Analgesics and antimuscarinics
   b. Cystoscopy and resection of ulcerations
   c. Intravenous antibiotics
   d. Antituberculous agents
   e. Cross-sectional imaging

3. After a course of antituberculous agents for 3 months, the patient's symptoms largely resolve. She is noted to have persistent urinary frequency without pain. Evaluation reveals a reduced bladder capacity of 120 mL, with poor bladder compliance. Urine culture, cytology, and cystoscopy are normal. The next step is:
   a. Bladder biopsy
   b. Full-dose maintenance BCG
   c. 1/3-dose maintenance BCG
   d. Full-dose maintenance BCG with catheter in place
   e. Cessation of BCG therapy

Answers

1. **b.** Three studies from the CUETO group evaluated varying doses of BCG. Initially, it was demonstrated that 27 mg BCG (1/3 dilution) provides an equivalent reduction in disease recurrence and progression and less toxicity compared to 81 mg BCG. A subsequent study found that 13.5 mg (1/6 dilution) was inferior to 27 mg BCG. Another study from the EORTC-GU group confirmed that 1/3-dose has comparable efficacy to full-dose BCG.
2. **c.** Ofloxacin 200 mg given twice after each BCG instillation was found to reduce toxicity and improve compliance with BCG therapy. Antituberculosis therapy (e.g., INH, rifampin) has not demonstrated efficacy in the prophylactic setting. Corticosteroids are an important component of treatment for systemic BCG toxicity (e.g., BCG sepsis). NSAIDs are often used to treat systemic inflammatory toxicity of mild severity.
3. **b.** Irritative voiding symptoms, similar to those of cystitis, occur in 27–90% of patients treated with BCG. These symptoms usually arise after the third instillation and are the most common reason for early cessation of treatment. Treatment is with phenazopyridine or anticholinergics. If severe, consider dose reduction, prophylactic quinolones, or cessation of BCG therapy.
4. **d.** BCG sepsis should be managed with cessation of BCG therapy and administration of INH, rifampin,

ethambutol, corticosteroids, and quinolones. Addition of gram-negative coverage and another antituberculosis agent can be considered. Cycloserine and pyrazinamide are ineffective against some BCG strains and are thus not appropriate. BCG sepsis may be caused in part by a delayed-type hypersensitivity reaction, which explains the role for prednisone in its management.

5. **a.** Due to its high molecular weight, MMC is generally not absorbed systemically. In the setting of bladder perforation, however, MMC may cause peritonitis, pelvic pain, fibrosis, and necrosis. If MMC is absorbed into the extravesical space, bladder contracture and chronic pain may result. If there is concern for bladder perforation, MMC should be withheld until bladder integrity can be confirmed. Similarly, in cases of extensive resection, a post-instillation inflammatory response can be quite severe and prolonged. In these cases, caution should be exercised, and if there is any concern, the dose withheld to avoid prolonged toxicity.
6. **c.** Patients with a positive PPD can safely undergo BCG therapy as long as there is no active infection with tuberculosis. In fact, intravesical BCG may be more effective in patients with prior PPD positivity. Severely immunocompromised patients, including those with HIV/AIDS, should not receive BCG. However, there is some evidence suggesting BCG is safe in patients with renal transplant, corticosteroid use, leukemia, or lymphoma. After transurethral resection, 2 weeks should pass before administering BCG. Traumatic catheterization warrants waiting 1 week before giving BCG. Hematuria should resolve before BCG is administered.
7. **d.** MMC is believed to cause skin rashes through two mechanisms: direct contact or delayed hypersensitivity. Thus, steroids can be used in the treatment of MMC-induced rash, though further treatment often must be discontinued due to recurrence of the rash. The remaining side effects of MMC are due to the direct toxicity of the drug.
8. **a.** Valrubicin is FDA-approved to treat BCG-refractory CIS and is especially important in patients who are not candidates for cystectomy. Gemcitabine has also demonstrated efficacy in this patient group.
9. **c.** Granulomatous epididymo-orchitis is a rare complication of BCG therapy. Typical presentation is local induration and pain in the testis with possible fever or leukocytosis. Bacterial infection should be excluded with urine culture, as this is a more common cause of epididymo-orchitis even in the setting of BCG therapy. Granulomatous epididymo-orchitis should be treated with INH, rifampin, steroids, and fluoroquinolones.
10. **b.** Low-grade fever (<101.3°F) is common during BCG therapy. It typically lasts 24 to 48 hours and can be treated with acetaminophen or NSAIDs. If the fever persists for greater than 48 hours or increases in severity (>102°F), BCG sepsis may have developed and antituberculosis therapy is warranted.

CASE STUDY 1

1. **e.** In cases of bladder wall thinning, even small perforations can lead to extravesical extravasation of mitomycin, secondary necrosis, and fistula formation. As such, prior to administration of mitomycin, a distention cystogram to rule out extravasation is wise. Withholding mitomycin is not unreasonable, but given the benefits, and initial treatment plan, proceeding with administration is desirable, if possible. Reducing mitomycin dose, or delaying dose for a short period of time, would not prevent extravasation if perforation is present.
2. **a.** The CT demonstrates a breach in the bladder wall with likely extravasation of mitomycin to the surrounding perivesical fat. Local inflammation is noted, without extension to the peritoneal space or local organs. In this case, as there is no urinary extravasation, a catheter does not need to be placed, and is likely to exacerbate local irritative symptoms. Supportive care and time will likely resolve the symptoms and allow healing, though this may require months for resolution.
3. **d.** While it is safe to proceed with administration of intravesical mitomycin upon bladder healing, despite previous complications, in this case the high-grade nature of the tumor and the presence of CIS make BCG induction a more rational approach, with greater likelihood of therapeutic efficacy. It is important to note that the administration of mitomycin does not preclude later BCG induction, but delayed healing of the bladder wall, and/or complications from mitomycin administration, may delay BCG instillation.

CASE STUDY 2

1. **a.** Systemic inflammatory symptoms commonly associated with BCG administration include low-grade fever, muscle aches, and chills that may start within 8 hours of administration and persist for 1–2 days. These symptoms are generally self-remitting, do not require BCG dose reduction, and can be managed by supportive care only. High fever, rigors, or hypotension, if occurring within hours of administration, should prompt emergent evaluation with suspicion for bacterial sepsis or systemic BCG absorption.
2. **d.** Severe local symptoms are common after administration of intravesical BCG, particularly after the patient has been sensitized to the mycobacterium through previous administration. Usually these symptoms are self-remitting if they are inflammatory in nature. Most will resolve in 2–3 days, allowing for repeat administration the following week. In those cases in which the symptoms persist for longer, a dose can be withheld, and upon readministration, dose reduction can be carried out. If symptoms persist, despite supportive care, for longer than 2–3 weeks, granulomatous cystitis should be considered and empiric antituberculous therapy should be implemented to prevent systemic dissemination and/or chronic bladder damage. Bladder biopsy may demonstrate granulomatous inflammation, but should primarily be used to rule out refractory, progressive malignancy, if suspected. Even if no granulomatous inflammation is noted on biopsy, empiric therapy should be considered on the basis of high clinical suspicion.
3. **e.** Given the history of BCG infection and granulomatous cystitis, additional BCG should not be considered in this patient, particularly given the absence of residual cancer. If recurrence were to be noted, alternate intravesical therapy, or cystectomy, should be considered.

Chapter 23 Questions and Answers

KEY POINTS

1. Ablation therapy is being used with increasing frequency for renal masses.
2. Complication rates of renal mass ablation compare favorably to extirpative nephron-sparing surgery.
3. Patient and tumor selection are the most important factors to prevent complications.
4. The most common complications after percutaneous renal mass ablation are minor and include pain or paresthesia and asymptomatic hematomas.
5. Urinary tract injury is the most common major injury after radiofrequency or microwave ablation and is often managed with ureteral stenting or percutaneous drains.
6. Hemorrhage is the most common major injury after cryoablation. Larger tumors can be embolized preoperatively to limit the risk of hemorrhage.

Introduction

With the rise in diagnosis of incidental small renal masses, a shift in management of renal cell carcinoma (RCC) has emerged. Most notable is the increased utilization of nephron-sparing techniques. A recent publication based on the National Inpatient Sample showed that from 2005 to 2007 there was a 25% and 20% relative increase in the use of thermal ablation (TA) and partial nephrectomy (PN), respectively, while the use of radical nephrectomy (RN) had a 7% relative decrease.[1]

In 2009, the American Urological Association's (AUA) *Guideline for the Management of the Clinical Stage 1 Renal Mass* stated that for T1a renal lesions PN and RN are considered a standard of care (highest grade). TA is considered an option (lowest grade) for healthy patients and a recommendation (middle grade) for unhealthy patients. This conclusion, appropriate at the time of publication, stemmed from outcomes with increased risk of local recurrence and shorter follow-up.[2] More recent publications have improved our understanding of TA outcomes.

Psutka et al. reviewed 185 patients with cT1 RCC undergoing percutaneous radiofrequency ablation (RFA), with a median follow-up of 6.4 years.[3] They demonstrated 5-year cancer-specific survival (CSS) of 99% and local recurrence-free survival (LRFS) of 95%. Evaluating laparoscopic cryoablation (CA), 142 patients with cT1 RCC and a median follow-up of 92 months had 5-year CSS of 97% and LRFS

of 87%.[4] Given the indolence of many of the tumors, the CSS survival data are not surprising considering what we know about active surveillance in this population. More important, however, is the focus on local control. More recent studies, specifically focused in the RFA literature, have demonstrated that with refined preoperative tumor selection we can improve LRFS outcomes to approach those of partial nephrectomy.[5–7] With longer follow-up and improved oncologic outcomes, we anticipate increased utilization of ablative techniques in the management of renal masses. Therefore a thorough understanding of complications is critical to achieving excellent oncologic efficacy while minimizing morbidity.

Based on the aforementioned 2009 AUA Guideline, the morbidity of RFA and CA compares favorably with that of laparoscopic PN (LPN), a referent standard, in the context that LPN patients had similar sized tumors and were younger and, presumably, healthier.[2] To understand in further detail, the following chapter reviews the mechanism of action of ablative technologies, along with the prevention, frequency, and management of complications. Although RFA and CA are the most popular modalities used, newer modalities, including microwave ablation (MWA) and irreversible electroporation (IRE), are also discussed.

Prevention of Complications

Many factors play into complication risk during and after ablation. Most important is choosing appropriate patients who have a high probability of success with a low risk of complications. However, there are instances where higher-risk patients or tumors have ablation as a solitary option. In this scenario adjunct procedures, such as preoperative angioembolization, hydrodisplacement, and cold pyeloperfusion can help minimize complications.

PATIENT SELECTION

Patient selection plays the largest role in preventing complications. While it is generally understood that larger tumors, tumors closer to renal sinus, and tumors close to important structures are most at risk of complications, quantifying that risk can be difficult.

The RENAL nephrometry score (Radius, Exophytic/Endophytic, Nearness to the collecting system or sinus, Anterior/posterior and Location relative to polar lines) was developed to standardize renal tumor size, location, and depth[8] and has been shown to correlate with complications after PN.[9] Subsequent work by Schmit and colleagues compared RENAL nephrometry scores to complication rates in patients undergoing percutaneous ablation (RFA or CA).[10] In 627 patients (751 tumors) there was a significant association between higher RENAL nephrometry score and major complication (≥Clavien III) risk, with low- (RENAL 4–6), moderate- (RENAL 7–9), and high-complexity (10–12) major complication rates of 3.4%, 5.4%, and 15.9%, respectively ($p < 0.001$). Overall, major complications occurred in 7.8% of CA, but only 2.7% of RFA. They did not do independent analysis on type of TA, and, therefore, their finding might be dominated by CA alone. Similar results correlating RENAL nephrometry score and CA complications were also confirmed in another series.[11]

In contrast, Seideman et al. found no association between RENAL nephrometry score and risk of complications in 199 RFA procedures (2.0% Clavien grade III–IV).[12] They argued that additional factors related to the type of TA could affect complication risk. For example, most CA probes and some RFA probes must puncture through the tumor, while the RFA probe used in their series deploys small 25G tines into the tumor, potentially minimizing trauma. Other potential reasons why no association was seen could be that the standard RENAL nephrometry score does not capture size differences between tumors that are generally <4 cm. A more discerning tool might be the modified RENAL nephrometry score, which has shown improved correlation with oncologic outcomes.[6]

Specifically evaluating laparoscopic CA, Lagerveld et al. differentiated risk factors for both intraoperative and postoperative complications.[13] They concluded that intraoperative complications are significantly associated with tumors >3.5 cm, which appears to predict complications better than RENAL nephrometry score. Regarding postoperative complications, only the N (nearness to collecting system) portion of the RENAL nephrometry score was predictive of complications.

Both RFA and CA can be used to treat exophytic as well as completely endophytic renal masses. Selection of the approach (laparoscopic versus percutaneous) depends on tumor location, patient's health status, and the surgeon's expertise. At our center, we use TA to treat tumors of <3–4 cm that typically have a peripheral component allowing percutaneous access. Laparoscopic or robot-assisted TA is rarely recommended. We believe the energy source chosen should be based on physician preference, and we solely use RFA given our comfort and experience with the modality. More endophytic tumors might have the benefit of ice ball monitoring with CA, although outcome differences have not been reported in the literature.

Historically, contraindications to percutaneous TA have included tumors adjacent to the renal pelvis or ureter, or near important structures (bowel, liver, spleen, etc.). However, more advanced work with hydrodisplacement has made these relative contraindications.

PREOPERATIVE ANGIOEMBOLIZATION

Initially described to minimize the heat-sink effect in RFA,[14] preoperative tumor angioembolization has more recently been utilized to limit complications with CA. CA carries an increased risk of hemorrhage, especially in larger tumors, due to renal capsule fracture. In addition, unlike RFA, freezing of a tumor does not have inherent coagulative effects and likely causes a local coagulopathy with regard to platelet function.[15] Woodrum and colleagues embolized 40% (4/10) of tumors ≥5 cm that underwent CA.[16] The decision to undergo embolization was based on central involvement of the tumor, number of probes needed to treat the tumor, and tumor vascularity. There was no difference in mean tumor size between the embolization group (6.2 cm) and the no embolization group (5.7 cm, $p = 0.26$). Mean hematoma volume in patients who underwent preoperative embolization was 18 mL, compared to 357 mL in patients

who did not ($p < 0.001$). Clinically, this translated into no blood transfusions in the embolization group, and one transfusion (17%) in the no embolization group. This study was retrospective and small, but certainly suggests that utilizing preoperative embolization in large tumors can decrease the risk of hemorrhage. Further work on embolization from the same institution shows increased utilization in larger tumors: 15% of cT1b patients[17] and 58% of cT2 patients underwent preoperative embolization.[18]

Similar results were found by Miller et al., who reviewed their small series of 21 tumors.[19] Four tumors (mean 4 cm) were treated preablation with embolization and had no complications. In contrast, the remaining 17 tumors (mean 3.6 cm) had an 83% complication rate, including a 41% hemorrhage rate. Although their study lacked granularity with regard to blood transfusions, they concluded preablation embolization reduces the risk of hemorrhage.

We do not use angioembolization in our practice, as we prefer to treat larger tumors that might benefit from angioembolizaiton prior to CA with either partial or radical nephrectomy. If thermal ablation is performed in a larger tumor (>3–4 cm), we prefer to use RFA as it is coagulative, precluding the need for angioembolization.

HYDRODISPLACEMENT

All forms of TA risk injury to nearby structures, and it is generally accepted that structures within 1 cm of a renal lesion are most at risk. Colon is most commonly involved, but abdominal wall, small intestine, ureter, and psoas muscle are also encountered. Hydrodisplacement prior to ablation was first described by Farrell and colleagues, who used sterile water to displace bowel prior to RFA (Fig. 23.1).[20] This technique involves fine needle placement in a plane between the tumor and structure, with instillation of fluid. Typically, 5% dextrose or sterile water are used, although iodinated contrast material has been described to better illuminate the infusion on cross-sectional imaging.[21] It is best to avoid saline if performing RFA due to the risk of ionic transmission of energy.

The type of thermal ablation should not affect the success of hydrodisplacement; studies have shown 96% success (50 of 52) prior to CA[22] and 96% success (53 of 55) prior to RFA.[23] More contemporary series have demonstrated that hydrodisplacement was used prior to 12–14% of RFA procedures.[24,25] It is less frequently described in CA series, except in procedures involving large (cT1b/cT2) tumors, where it was used 35–42% of the time.[17,18]

In our experience, tumors that lie in close proximity to critical structures often gain enough separation just by positioning the patient prone or lateral decubitus. Hydrodisplacement is infrequently needed, but often successful when used. We find the greatest success when displacing colon or small intestine. The ureter can be more difficult to move; tumors in close proximity to the ureter are more commonly referred for partial or radical nephrectomy.

PYELOPERFUSION

For tumors that lie close to the ureter or collecting system, prior investigations have looked at retrograde ureteral infusion of cold fluid. The first description of this technique during RFA was by Wah and colleagues in 2005.[26] They published a case report with retrograde infusion of 5% dextrose solution cooled to 6°C at a pressure of 80 cm of H_20 for a 2-cm centrally located tumor. The infusion was through a 7F pigtail catheter placed endoscopically into the renal pelvis and subsequently removed 48 hours after the procedure. Just as in hydrodisplacement, a nonionic solution was used due to theoretical concerns about energy transmission. The patient recovered well without any collecting system or ureteral damage.

They followed this initial investigation by publishing results of their pilot study, comprising 17 patients with 19 tumors that were within 1.5 cm of the ureter.[27] No complications occurred, and no patients developed urinary fistulas

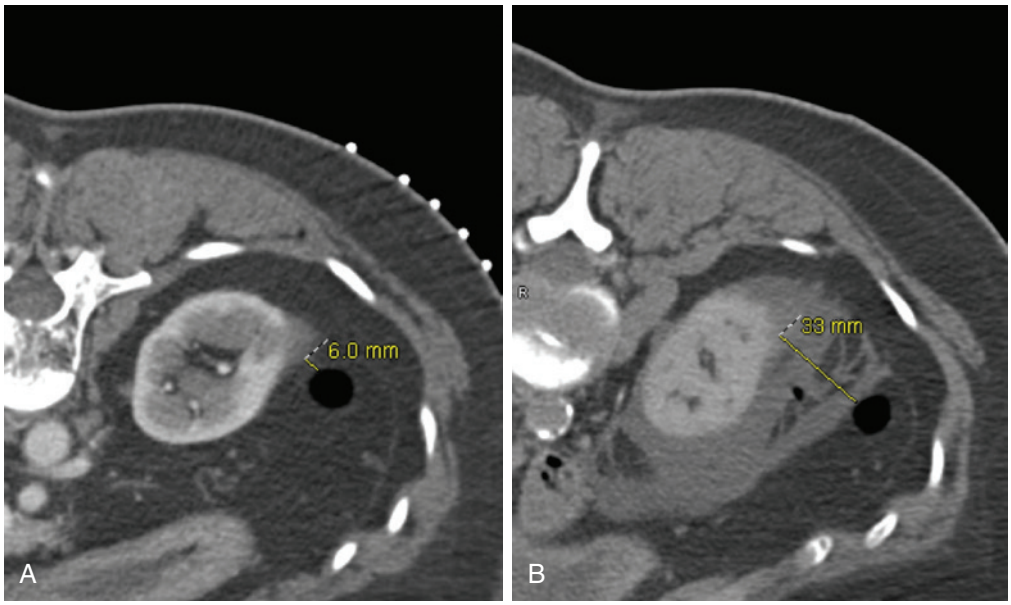

Figure 23.1 CT scan showing left colon pre- (A) and post- (B) hydrodisplacement with D5 water away from renal mass.

or ureteral strictures. Although there is the potential to cause a heat sink with cold pyeloperfusion, there were no local recurrences during their follow-up period. The most recent series by Wah et al. utilized this technique in 6.2% (13/210) of RFA procedures.[24]

Complications of Ablation

RADIOFREQUENCY ABLATION

Radiofrequency ablation can be performed either laparoscopically or percutaneously. The main difference with respect to complications relates to the need to mobilize colon and/or small intestine and expose the tumor to perform the ablation laparoscopically. These portions of the procedure have expected risks that are no different than a laparoscopic radical or partial nephrectomy. Specifically related to the ablation portion of the procedure, most complications are related to thermal injury.

The 2009 AUA Guideline meta-analysis lists major urologic complications including hemorrhage requiring transfusion or other intervention, urinary leak or fistula, and loss of kidney function, among others. The major RFA complication rate was 6% (range 4.4–8.2%), not significantly different than CA.[2] Comparing studies is often difficult due to different terminology, different grading criteria, and lack of granularity. A contemporary list of RFA studies with complications are summarized in Table 23.1. Ranges for minor Clavien grade I complications, grade II complications, and major grade III–V complications were 5–19%, 1–8%, and 2–10%, respectively. Specific complications are discussed below.

Mechanism of Action

Radiofrequency ablation uses a monopolar alternating electrical current using the frequency within the radio segment of the electromagnetic spectrum. The current flows between the grounding pad and the RFA probe. Heat is generated as a result of ionic agitation of the tissue around the probe, and cell death is achieved when the temperature within a tumor and a small rim of the surrounding tissue rises to 60°C. High temperatures produce occlusion of the microvasculature and destruction of the cellular cytoskeleton, causing tissue ischemia and impaired DNA replication, and ultimately resulting in a predictable zone of coagulation necrosis around the radiofrequency electrode.[28]

During RFA tissue temperatures generally reach >100°C. In addition to causing cell death, heating also has inherent coagulant properties to limit the risk of hemorrhage.

Urinary Tract Injury

Typically, the most common major injury with RFA is to the urinary tract, either the collecting system or ureter (Fig. 23.2). In a porcine model, Brashears et al. demonstrated that after causing direct damage to the collecting system, four of seven RFA procedures resulted in urinary fistula. In contrast, after 15 direct cryoablation procedures to the collecting system not a single fistula developed.[29]

Table 23.1 Complications of Radiofrequency Ablation

Study (year)	No. Patients/ Procedures	Approach	Tumor Size (mean, cm)	Hydrodisplacement	Pyeloperfusion	Clavien I	Clavien II	Clavien III/IV	Blood Transfusion	Urinary Tract Injury

Atwell et al. (2012)[15]	–/254	Perc	2.1	–	–	13 (5.1%)	3 (1.2%)	9 (3.5%)	–	6 (2.4%)

Perc, percutaneous; Lap, laparoscopic

Although most urinary tract injuries lead to major complications, studies have described minor complications including a single episode of urine leak (0.9%)[30] and two ureteral strictures (1.0%)[24] managed conservatively. More commonly, injury to the urinary tract is a grade III complication as it requires either ureteral stenting or percutaneous drainage, and has been described in 1.7–4.8% of cases.

Hemorrhage

As stated before, the risk of bleeding after RFA is low given the coagulative properties of heating tissue. However, many studies describe minor Clavien grade I complications of perinephric hematoma after RFA (Fig. 23.3) without subsequent transfusion, up to 14.5% of cases.[31] More importantly, the need for blood transfusion (grade II) or subsequent angioembolization (grade III) is an infrequent event in most RFA series (0–1.6%).

Figure 23.2 Delayed phase of CT showing urine leak after radiofrequency ablation of right renal mass.

Pain/Neuropathy

A common minor grade I complication after RFA is pain or neuropathy. Baker et al. noted the correlation between pain after RFA and distance of the renal tumor to body wall musculature.[32] Reports of significant pain or nerve injury were made in most series, with the highest incidence in 3.9% of cases.[15] However, as described in their report, 90% of these patients had resolution of their symptoms within 6 months.

Pneumothorax

Pneumothorax in RFA is typically either related to the probe traversing the pleural cavity, or diaphragmatic injury during laparoscopy. Seideman et al. described a single case of pneumothorax that required needle decompression (grade III, 0.5%),[12] while most other series described minor grade I pneumothoraces that were managed conservatively (up to 4.8%).[31]

Other

Damage to colon or small intestine are rare complications of RFA. In the contemporary studies listed, only one patient (1.6%) experienced a duodenal perforation, which was reported by Balageas et al.[31]

CRYOABLATION

Like RFA, contemporary cryoablation (CA) is performed either laparoscopically or percutaneously, and complications due to laparoscopic CA are related to mobilization of the colon and nearby structures and exposure of the tumor. In this section, we focus on complications specific to the ablation itself.

The 2009 AUA Guideline meta-analysis lists major urologic complications from CA of 4.9% (3.3–7.4%), not significantly different than from RFA.[2] Like RFA, major complications analyzed in this meta-analysis include hemorrhage requiring blood transfusion and/or interventions and urinary tract injury. With CA, and as many highlighted studies show, the most concerning complication is the risk

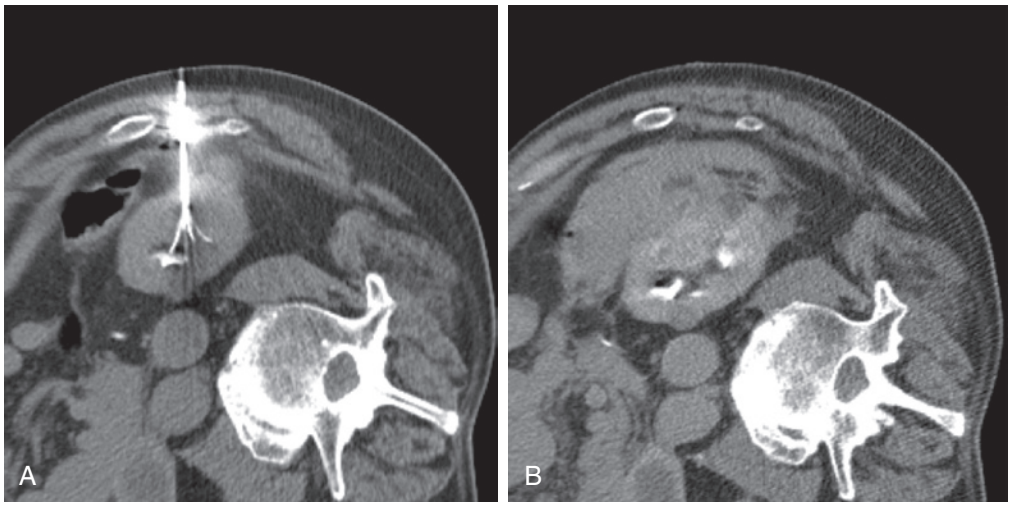

Figure 23.3 CT demonstrating probe placement during radiofrequency ablation of left renal mass (A), and perinephric hematoma on immediate postablation imaging (B).

Table 23.2 Complications of Cryoablation

Study (year)	No. Patients/ Procedures	Approach	Tumor Size (mean, cm)	Preoperative Embolization	Hydrodis-placement	Clavien I	Clavien II	Clavien III/IV	Blood Transfusion	Urinary Tract Injury

of hemorrhage due to ice ball–induced renal capsule fracture and local coagulopathy.

A contemporary list of CA studies is listed in Table 23.2. For the purposes of summarizing these findings, the 2015 studies by Atwell et al.[17] and Moynagh et al.[18] are excluded because of the size of the tumors treated being discordant from general practice. Minor grade I complications were reported in up to 11% of cases, while grade II complications were reported in 1–15% of cases. Major complications (Clavien grade III or IV) ranged from 1% to 5% in most series.

Mechanism of Action

Cell death secondary to rapid severe freezing occurs by several mechanisms. Extracellular ice formation results in movement of water out of the cell and leads to changes in intracellular pH, protein denaturation, and mechanical disruption of the plasma membrane followed by intracellular ice formation.[33] Delayed tissue effects are caused by injury to the microvasculature resulting in tissue hypoxia, endothelial cell damage, edema, platelet aggregation, and thrombosis, and these delayed tissue effects culminate in coagulative necrosis.[34] Apoptosis and gene-regulated cell death have also been identified as other mechanisms of tissue disruption following freezing.[35]

It is generally accepted that a temperature of −40°C must be achieved to ensure cytotoxic effects of CA. Animal studies have shown that a double freeze cycle creates a larger cryolesion as compared to a single freeze.[36] It is not clear whether passive thawing between freezing cycles has greater tissue effects than active rapid thawing. However, it is generally accepted that a double freeze-thaw cycle with ice ball extension beyond the tumor margin should be used in clinical practice.

Hemorrhage

Some studies did not report the incidental finding of an asymptomatic perinephric hematoma, due to its low clinical significance. In those that did, the highest reported rate was 6.6% in the percutaneous series by Zargar et al.[37] For

percutaneous series the frequency of blood transfusion in the setting of a retroperitoneal hematoma ranged from 0.7% to 3.2% as noted by Atwell et al.[15] For laparoscopic CA most studies ranged from 1.4% to 2.5%, although Larcher et al. reported an 8% blood transfusion rate in their series of 174 patients.[38]

Even more concerning is the rate of angiography with possible embolization for patients with significant hemorrhage. Atwell et al. reported that 3.2% of patients undergoing percutaneous cryoablation required angiography due to Clavien grade III hemorrhage.[15]

Urinary Tract Injury

In contrast to RFA, the risk of urinary tract injury after CA is considerably lower. Zargar et al. reported one patient (0.4%) with urine leak requiring stent placement after undergoing laparoscopic cryoablation.[37] Breen et al. reported a slightly higher rate in their percutaneous CA series of 2.0% (n = 3) in their 153 patients.[39]

Pneumothorax

Although rare, Breen et al. reported a 2.6% (n = 4) rate of pneumothorax managed conservatively in their percutaneous series of 153 patients,[39] and Blute et al. noted a 3.6% rate (n = 5) in their percutaneous series of 139 patients.[11] Clinically significant pneumothoraces requiring chest tubes were recorded in 0.7% of a laparoscopic series[37] and 1.3% of a percutaneous series.[39]

Other

Pain and/or nerve injury was a fairly rare complication of CA, reported in only 0.6% of procedures by Atwell and colleagues. Regarding the rare complication of tumor track seeding, that same series only reported one case (0.3%).[15] No other large contemporary series reported track seeding.

Injury to colon or small intestine is relatively rare and was reported in 2.2% (n = 3) of patients by Blute et al.[11] All three were managed conservatively with no long-term complications. Kim et al. reported a single patient (0.7%) who had a duodenal and ureteral injury managed only with percutaneous drains.[40]

MICROWAVE ABLATION

Like the other thermal modalities discussed, microwave ablation (MWA) can be performed laparoscopically or percutaneously. This section focuses on complications related to the modality itself.

MWA is a heating technology so major complications can be viewed similarly to RFA. As one of the newer ablative technologies, all of the current literature is based on single-center series of <100 patients. In addition, many clinicians are learning this newer technology. Therefore one must take into account patient and tumor selection (size, location, depth) in assessing complications listed.

Seven studies were selected for review (Table 23.3). Number of patients per study ranged from 10 to 65, with most tumors cT1a. Studies had various methods of reporting tumor location and depth, so comparison of complication rates between studies is not feasible. Minor grade I, grade II, and major grade ≥III complication rates were 7–20%, 2–3%, and 2–20%, respectively.

Mechanism of Action

The utilization of electromagnetic microwaves to generate heat was popularized with the domestic microwave oven in the 1960s. The technology stems from using radiofrequency waves (900–2500 MHz) to induce oscillation of water molecules in tissue, leading to heat formation. Early MWA systems struggled with bulky coaxial cables because of inadvertent heat and power loss. The antenna also risked increased power loss as its diameter decreased in size, bringing concerns about treatment efficacy. Newer generation microwave machines utilize gas or liquid cooled antennae that help to minimize power loss, with a resultant increase in tissue temperature and ablation zone size.[41]

Unlike RFA, which relies on the conduction of electrical current through tissue, electromagnetic microwaves can propagate irrespective of tissue conductance. One notable area of clinical relevance is in dealing with tissue charring. With RFA if tissue is heated too quickly char forms, increasing tissue impedance and limiting ablation size. With MWA, tissue can be heated quickly and with much higher temperatures. This makes MWA cycles considerably shorter than RFA, with higher temperatures.[41]

Multiple microwave probes can be used simultaneously and act synergistically, similar to CA, which gives the potential to treat larger tumors.[42] With respect to the kidney, higher treatment temperatures can also potentially better overcome the risk of heat sink seen with other ablation modalities.[41]

Hemorrhage

Similar to RFA, heating tissue with electromagnetic waves provides inherent coagulative properties to limit the risk of hemorrhage. Hematoma and blood transfusion were only encountered in the study by Moreland et al., which treated 53 patients with percutaneous MWA.[43] The one patient who required a blood transfusion (1.9%) had a delayed bleed on postoperative day 10, likely due to resumption of anticoagulation medication from an underlying comorbidity. No other study reported bleeding complications, and we conclude that in this early phase of study MWA has a low risk of hemorrhage when treating small renal masses.

Urinary Tract Injury

Urinary tract injury was the most frequent major complication encountered (1.5–20%). The high complication rate noted in Castle et al. (20%) relates to their small series, larger tumor size (mean 3.65 cm), and tumor depth with 50% of the tumors abutting the urinary tract. The complications included one patient who developed a postoperative urinoma, and another patient who had a retained foreign object, likely from the microwave needle, causing ureteropelvic junction obstruction and subsequent radical nephrectomy.[44] Two other studies described patients with urinary fistula, one (1.5%) resolved without any further treatment[45] and one (2.1%) that ultimately led to a nephrectomy due to abscess formation.[46]

Other

Most complications related to microwave ablation were minor (Clavien grade I). Reviewed studies demonstrated the most frequently reported complication of flank site pain and

Table 23.3 Complications of Microwave Ablation

Study (year)	No. Patients/ Tumors	Approach	Tumor Size (mean, cm)	Hydrodisplacement	Clavien I	Clavien II	Clavien III/IV	Blood Transfusion	Urinary Tract Injury
Moreland et al. (2014)[43]	53/55	Perc	2.7 (median)	20 (38%)	4 (7.5%)	1 (1.9%)	0	1 (1.9%)	0
Yu et al. (2014)[45]	65/69	Perc	2.7	–	0	2 (3.1%)	0	0	1 (1.5%)
Horn et al. (2014)[47]	14/15	Perc	2.0	–	0	0	1 (7.1%)	0	0
Guan et al. (2012)[46]	48/48	28 Lap/20 open	3.1	–	4 (8.3%)	1 (2.1%)	1 (2.1%)	0	1 (2.1%)
Castle et al. (2011)[44]	10/10	3 Perc/7 Lap	3.65	–	2 (20%)	–	2 (20%)	0	2 (20%)
Bai et al. (2010)[56]	22/23	Lap	2.8	–	4 (18.2%)	0	0	0	0
Carrafiello et al. (2010)[57]	12/12	Perc	2.0	–	1 (8.3%)	0	0	0	0

or numbness (8.3–18.2%), likely due to thermal injury to musculature or retroperitoneal nerves.

The only other notable complication in this early collection of studies was a single pseudoaneurysm identified immediately after ablation that required embolization.[47] These authors noted that of the 14 patients undergoing ablation, this was the largest tumor in their series (3.9 cm). Arteriovenous fistulas and pseudoaneurysms are known, but not well understood, risks of nephron-sparing procedures and likely relate to microvascular procedural trauma. To our knowledge, this is the only report of pseudoaneurysm after microwave ablation and further literature will better define its accepted risk.

IRREVERSIBLE ELECTROPORATION

Mechanism of Action

Since the 1970s researchers have utilized low-voltage electrical current to induce reversible poration in cellular membranes, which can aid in drug delivery and gene therapy. More recent investigations by Rubinsky and colleagues augmented the impulses and recognized that a higher voltage and a greater number of impulses can lead to irreversible electroporation and subsequent apoptosis. What they found was a reproducible, relatively nonthermal area of tissue necrosis.[48] Given the decreased risk of thermal injury, irreversible electroporation (IRE) has a different complication spectrum compared to the other forms of thermal ablation.

Overview of Complications

The first study to describe human applications of IRE for RCC utilized the technology prior to curative extirpation in five subjects.[49] The only intraoperative complication was a single case of supraventricular extrasystole. The electrical impulses are gated to an electrocardiogram to prevent cardiac arrhythmias, so it is unclear the etiology of this finding. No postoperative complications were noted.

At the time of publication, there is only one manuscript describing outcomes after percutaneous IRE for small renal masses.[50] Trimmer et al. published their series of 20 renal masses undergoing IRE, with mean tumor size of 2.2 cm. They described seven minor (Clavien grade I) complications and no major complications. The most common complication was seen in three patients with postoperative urinary retention (15%), likely related to anesthesia. Two patients required increased pain control (10%). The last two patients (10%) had small asymptomatic retroperitoneal hematomas that were noted on immediate postprocedure imaging and required no further management. No blood transfusions, urinary tract injuries, or delayed complications occurred. Prior animal models have shown that IRE spares connective tissue structures, thereby limiting potential damage to nerves, vasculature, and collecting system.[51] This might explain the lack of complications in this initial small series, although larger series are needed to confirm this finding.

Managing Complications of Ablation

HEMORRHAGE

Most perinephric hematomas following percutaneous ablation are diagnosed using the immediate postablation imaging done to document the adequacy of ablation. These are usually small and often are not clinically relevant. However, severe hemorrhage can occur. Significant bleeding causing hemodynamic instability can be treated by selective embolization of the bleeding vessel. Patients with large hematomas but stable vital signs can be treated conservatively with strict bed rest and frequently repeated blood counts. Specifically related to CA, injecting a hemostatic agent into the cryoprobe tract following ablation can lower the risk of hemorrhage.

Bleeding after laparoscopic CA is frequently due to premature needle extraction and renal parenchymal fractures, which can be prevented by ensuring that cryoneedles enter the tumor at a right angle. It is important to wait until the thawing is complete before attempting to remove the cryoneedle to avoid large cracks in the tumor or renal parenchyma. If bleeding occurs, hemostatic agents can be placed into the defect and are often sufficient to achieve hemostasis. As stated previously, hemorrhage following laparoscopic

RFA is uncommon because RFA effectively coagulates the vessels within the tumor and a rim of normal parenchyma.

URINARY TRACT INJURY

Urine leaks following ablation result from either direct calyceal puncture or unintended extension of the ablation zone into the collecting system. If urine leak is suspected, CT of the abdomen with IV contrast is usually diagnostic and will show contrast extravasation into a perinephric urinoma. In patients with renal insufficiency or contrast allergy, antegrade or retrograde pyelography can help establish the diagnosis. Treatment consists of draining the collecting system percutaneously or with a ureteral stent for 4 to 6 weeks as most leaks will seal by that time.

A ureteral stricture or ureteropelvic junction obstruction is typically diagnosed clinically by flank pain, or hydronephrosis on imaging. Significant obstruction can be managed acutely with a ureteral stent or percutaneous nephrostomy tube. Long-term cure with a pyeloplasty or ureteroureterostomy, depending on the location of the obstruction, can be done 6 weeks after ablation. We prefer to remove ureteral stents for at least 4 weeks prior to reconstruction to avoid significant periureteral inflammation. Percutaneous nephrostomy tubes can be used instead for patients with symptomatic obstruction prior to surgery.

PAIN OR PARESTHESIA AT THE PROBE INSERTION SITE

With CA, pain or paresthesia occurs secondary to cryoinjury to the sensory nerves at the body surface. The entire cryoneedle is cooled during CA; therefore, care must be taken to avoid freezing the skin at the insertion site. Placement of a warm, saline-soaked gauze around the cryoneedle is usually sufficient to prevent freezing of the skin. With RFA, the active portion of the probe is positioned within the kidney, but injury to the sensory nerves in the skin is possible if they are within the ablation zone. Track ablation is usually the final step of percutaneous RFA. It is used to decrease bleeding and prevent tumor seeding. The generator is activated as the probe is slowly withdrawn through the renal parenchyma and the perinephric fat. It is important to deactivate the generator before withdrawing the probe beyond Gerota's fascia because thermal injuries to psoas muscle can result in pain and paresthesias. Most of these are self-limited and will resolve after a few days. However, significant sensory or motor deficits may require a neurologic consultation.

INJURIES TO ADJACENT ORGANS

Injuries to the bowel and other adjacent organs are some of the most serious complications of renal ablation. Fortunately, as shown above, these complications are rare. During laparoscopic ablation, colon is usually reflected off the kidney before ablation. If the probe is positioned correctly and monitored carefully bowel injury should never be an issue. As a general rule, for percutaneous ablation the presence of bowel within 1 cm of the ablation zone that cannot be manipulated with changes in patient position or hydrodisplacement should preclude treatment.

CT of the abdomen and pelvis with oral contrast has very high sensitivity for diagnosis of a bowel injury and should be obtained immediately if suspected. If CT is indicative of a bowel perforation, an immediate exploration with bowel repair and/or resection is often necessary.

Pneumothorax can result from inadvertent lung injury during percutaneous insertion of an ablation probe. The diagnosis is made with a chest radiograph. Small pneumothoraces can be followed with repeated chest radiographs, and treatment with supplemental oxygen is frequently sufficient. However, large expanding pneumothoraces or those causing respiratory compromise will require a chest drain for resolution.

Conclusions

Both percutaneous and laparoscopic approaches with multiple ablation modalities are used to effectively treat renal masses with increasing frequency. Incidence of complications is favorable when compared to extirpative nephron-sparing surgery. Proper patient selection, careful preoperative planning, and meticulous technique will ensure excellent cancer control with minimal morbidity.

Chapter 23 Questions

1. Which of the following renal mass characteristics is generally not a risk factor for ablation complications?
   a. Larger tumors
   b. Exophytic tumors
   c. Tumors close to renal sinus
   d. Tumors close to ureteropelvic junction
   e. None of the above

2. Literature has shown that RENAL nephrometry score correlates with complication risk for which treatment modality(ies)?
   a. Cryoablation
   b. Radiofrequency ablation
   c. Microwave ablation
   d. Irreversible electroporation
   e. Both a and b

3. Which adjunct preoperative procedure will decrease the size of retroperitoneal hematoma after cryoablation?
   a. Hydrodisplacement
   b. Pyeloperfusion
   c. Angioembolization
   d. Blood transfusion
   e. None of the above

4. Important structures within ___ cm of a renal mass should undergo hydrodisplacement prior to ablation.
   a. 1
   b. 2
   c. 3
   d. 4
   e. 5

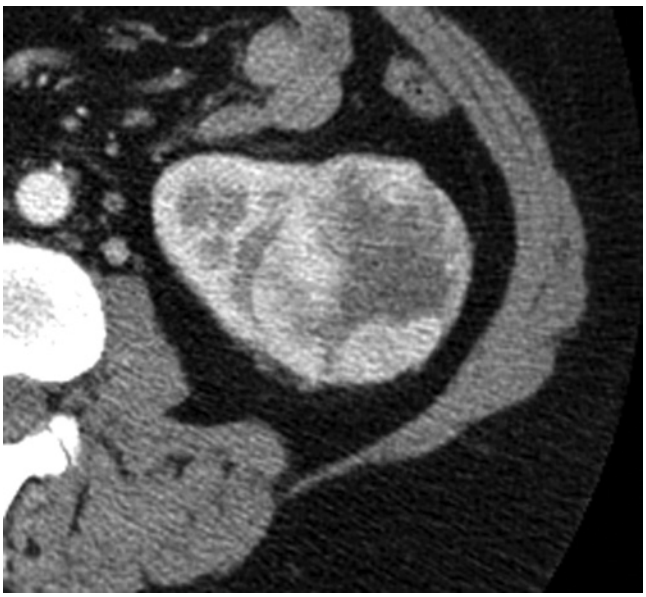
5. Which type of fluid should be used for retrograde pyeloperfusion during thermal ablation?
   a. NaCl
   b. Lactated Ringers
   c. D5 H_2O
   d. Iodinated contrast
   e. Both a and b

6. Urinary tract injury is the most common major complication for which modality(ies)?
   a. Radiofrequency ablation
   b. Cryoablation
   c. Microwave ablation
   d. Irreversible electroporation
   e. Both a and c

7. Which of the following ablation modalities has the highest rate of blood transfusion?
   a. Radiofrequency ablation
   b. Cryoablation
   c. Microwave ablation
   d. Irreversible electroporation
   e. Both a and b

8. Which of the following is not a management option for postablation hemorrhage?
   a. Serial blood counts
   b. Bed rest
   c. Blood transfusion
   d. Percutaneous drain
   e. Angioembolization

9. Ureteral stents for urine leaks following ablation therapy should be kept in place for what length of time?
   a. 1 day
   b. 2 days
   c. 1 week
   d. 2 weeks
   e. 6 weeks



10. Renal mass distance from body wall musculature has been shown to correlate with postprocedural pain in which modality?
    a. Radiofrequency ablation
    b. Cryoablation
    c. Microwave ablation
    d. Irreversible electroporation
    e. None of the above

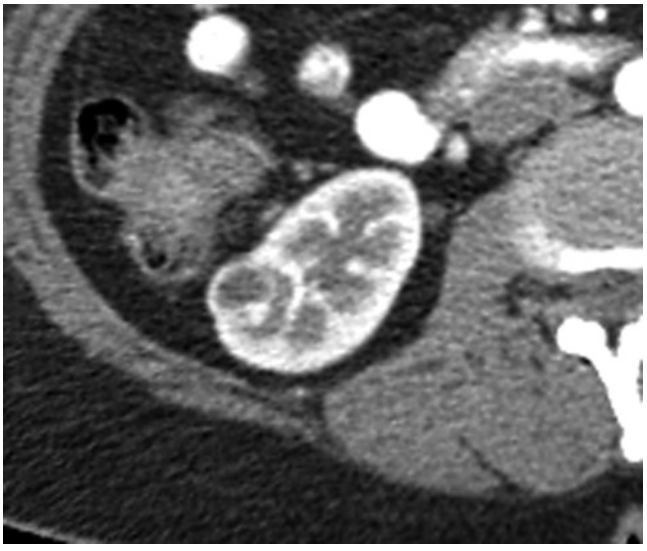
Case Studies

CASE 1

A 65-year-old unhealthy male with a 6-cm left renal mass extending into the renal sinus presents to your office (Case Fig. 23.1). His comorbidities make him a high-risk candidate for extirpative surgery. After a discussion of treatment options, he elects to proceed with percutaneous cryoablation.

1. Which of the following preablation procedures has been shown to limit the size of retroperitoneal hematoma?
   a. Blood transfusion
   b. Ureteral stent placement
   c. Pyeloperfusion
   d. Angioembolization
   e. Overnight admission with bed rest

Case Figure 23.1



2. To limit the risk of skin freezing, what should be done prior to performing cryoablation?
   a. Body warmer
   b. Warm gauze surrounding cryoprobe
   c. Increase room temperature
   d. Only freeze to O°C
   e. Skin freezing is not a risk of cryoablation

3. Postoperatively the patient develops mild hematuria and flank pain. His hemoglobin decreases from 13 g/dL to 10 g/dL. His vital signs remain stable. A stat CT scan is performed and demonstrates a large retroperitoneal hematoma. Repeat hemoglobin and vital signs remain stable. What is the best next step?
   a. Bed rest
   b. Serial blood counts
   c. Angioembolization
   d. Open exploration
   e. Both a and b

4. The following morning, his urine becomes bright red and his flank pain worsens. His hemoglobin is now 7 g/dL. What is the best next step?
   a. Bed rest
   b. Serial blood counts
   c. Angioembolization
   d. Open exploration
   e. Both a and b

CASE 2

A 79-year-old healthy woman with a 1.5-cm right anterior renal mass in a solitary kidney presents to clinic (Case Fig. 23.2). She underwent left radical nephrectomy for renal cell carcinoma 15 years ago. You review the films and note that the tumor comes close to a calyx, and the right ascending colon is approximately 0.5 cm from the edge of the renal mass. Her creatinine is 1.8 mg/dL. After extensive discussion, she elects to proceed with percutaneous radiofrequency ablation.

Case Figure 23.2

1. What is the most common risk of her radiofrequency ablation (RFA) procedure?
   a. Small retroperitoneal hematoma
   b. Pneumothorax
   c. Track seeding
   d. Colon injury
   e. Urinary tract injury

2. Which of the following adjunct procedures should be performed prior to RFA?
   a. Preoperative embolization
   b. Ureteral stent placement
   c. Hydrodisplacement of ascending colon
   d. Pyeloperfusion
   e. None of the above

3. After successful RFA, she is discharged home the same day. She presents to the ER 1 week later with a temperature of 38.5°C and flank pain. You are concerned that she has a urine leak. What is the best next step?
   a. Computed tomography of the abdomen and pelvis with contrast
   b. Retroperitoneal ultrasound
   c. Magnetic resonance imaging of the abdomen and pelvis with contrast
   d. Cystoscopy with retrograde pyelogram
   e. Observation

4. For what period of time should she have urinary tract drainage?
   a. 1 day
   b. 1 week
   c. 2 weeks
   d. 6 weeks
   e. 26 weeks

Answers

1. **b.** Large tumors are a risk factor for bleeding complications. Tumors close to renal sinus risk bleeding and urinoma. Tumors close to the ureteropelvic junction risk ureteral stricture. An exophytic tumor, independently, is not a risk factor for complications.
2. **a.** Prior literature has shown that cryoablation complications correlate with RENAL nephrometry score, while radiofrequency ablation results are equivocal. Microwave ablation and irreversible electroporation complications have not been evaluated compared to RENAL nephrometry score.
3. **c.** Prior literature has demonstrated that angioembolization prior to cryoablation decreases the risk of retroperitoneal hematoma postoperatively.
4. **a.** One cm is considered the safe cutoff for nearby structures prior to thermal ablation. Hydrodisplacement would be the procedure of choice if a critical structure is less than 1 cm from the tumor.
5. **c.** Because of the potential to conduct current during radiofrequency ablation, non-ionic fluids should be used. Iodinated contrast would also not be ideal as it would appear on peri-ablation computed tomography,

which could distort probe placement. Therefore, D5H20 would be the best choice.

6. **e.** Injury to the urinary tract is the most common complication after both types of heat-driven thermal ablation. The most common major complication after cryoablation is bleeding.
7. **b.** Due to the bleeding complications related to cryoablation, it has the highest rate of post-operative blood transfusion.
8. **d.** Managing a patient with post-ablation hemorrhage should include bed rest, serial blood counts, and blood transfusions. In severe cases, angioembolization might be needed. Placing a percutaneous drain into a retroperitoneal hematoma would expand the potential space of the hematoma and is counterproductive to the tamponade the retroperitoneum provides.
9. **e.** Ureteral stents for retroperitoneal urine leak should be left in at a minimum of 4 weeks. Therefore, the best answer here is 6 weeks.
10. **a.** The distance from body wall musculature to the renal mass has been shown to correlate with pain after radiofrequency ablation.

CASE 1

1. **d.** For large renal masses prior to cryoablation, angioembolization has been shown to limit the size of retroperitoneal hematoma.
2. **b.** Skin freezing is a minor but common complication of cryoablation. Placing a warm gauze around the cryoprobe at the level of the skin will help to limit the risk of skin freezing.
3. **e.** For a stable patient with a retroperitoneal hematoma, bed rest and serial blood counts are an appropriate first step, with blood transfusions only as indicated for symptomatic anemia or blood counts below threshold levels. Mild hematuria and flank pain are expected post-operative symptoms, so angioembolization or emergent open exploration are too aggressive management strategies at this point, regardless of the size of the hematoma.
4. **c.** With more significant hematuria and a dropping blood count, this is now an indication to proceed with a more aggressive intervention. Angioembolization would be the preferred next step of the options provided.

CASE 2

1. **a.** The most common risk (both minor and major) of radiofrequency ablation is a small retroperitoneal hematoma. Pneumothorax, track seeding, and colon injury are all rare complications. Urinary tract injury would be the most common major injury.
2. **c.** Given the less than 1 cm proximity of the ascending colon, hydrodisplacement would need to be performed.
3. **d.** Given her elevated creatinine of 1.8, a cystoscopy with retrograde pyelogam would be the best choice.
4. **d.** If a urine leak is seen on retrograde pyelogram, ureteral stent drainage should be in place for 4–6 weeks. Leaving a Foley catheter for the first 24–48 hours would be a reasonable adjunct move to ensure decompression of the urinary system.

Chapter 24 Questions and Answers

KEY POINTS

1. Cryotherapy causes tissue destruction by freezing, and can cause lower urinary tract symptoms (LUTS) in a fashion similar to that seen after other prostate surgeries like transurethral resection of the prostate (TURP) or laser prostatectomy.
2. In order to optimize results, and minimize the complication rates, careful patient selection is necessary.
3. The incidence of complications is higher in the salvage cryoablation group as compared to the primary cryoablation group.
4. It is challenging to treat large prostate glands. Neo-adjuvant androgen deprivation therapy for size reduction of such glands may help with reduction of gland size but not with oncological outcomes.
5. Erectile dysfunction is one of the commonest complications of prostate tissue ablation, and is multifactorial in etiology.
6. Urethral warming reduces the risks of urethral slough, strictures, pain and incontinence with cryoablation.
7. Saline injection in the layers of the Denonvilliers fascia to cause a separation between the prostate and rectum may reduce the incidence of rectal injuries and fistulas in cryoablation.

Introduction

According to the Surveillance, Epidemiology, and End Results (SEER) Program data, the estimated number of new cases of prostate cancer in 2015 was 220,800, with an estimated death in 27,540 patients. Of the 10,018 patients from a CaPSURE study published in 2004, patients with prostate cancer underwent treatment with either brachytherapy, external beam radiation therapy, or cryoablation in 10.1, 12, and 2.8%, respectively.[1] The number of patients undergoing brachytherapy has since increased, and approximately 30% of patients undergoing radiation therapy will develop a biochemical failure or recurrence. Since salvage radical prostatectomy is a challenging procedure with high morbidity rates, the drive toward minimally invasive treatment of recurrent prostate cancer is increasing. Prostate cryoablation is now a reasonably well-established option for residual or recurrent cancer after primary nonexcisional treatment of prostate cancer. Experience with cryoablation has shown this to be minimally invasive and convenient, requiring short hospital stays, with many centers discharging patients the same day of the procedure. These features make the procedure an attractive choice, and the pool of patients has now been expanded to include even primary cases, in the nonsalvage setting.

Mechanisms of Tissue Injury and Causes of Complications

Prostate tissue ablation causes cell death by causing irreversible injury from nonphysiologic temperatures that are

not considered compatible with cell survival. In cryoablation cell damage is caused by intracellular ice formation, altered permeability of the cell membrane, and loss of cellular integrity. Factors that are important are intracellular ice formation, the final temperature achieved, and the rate of cooling.[2] Intracellular ice formation is very important and can be achieved either through multiple (double or even triple) freeze/thaw cycles[2] or by ensuring the right combination of cooling rate and end-point temperature.

In order to achieve optimal results, a good balance needs to occur between adequate freezing of tissues that need to be destroyed and cryoprotection of tissues that should not be frozen. This requires an accurate mapping of the extent of cancer, since a patient could potentially be cured without the risks of complications, if all of his cancer could be completely destroyed without any collateral damage. Focal cryoablations have lower complication rates compared to total cryoablation, and the incidence of incontinence, erectile dysfunction (ED), and fistula rates were higher in patients undergoing total cryoablation as compared to focal ablation (incontinence 13% vs 0%, ED 71% vs 100%, and fistula 4% vs 0%).[4]

Unfortunately focal ablations often undertreat cancers, since prostate cancer is known to be multifocal (79.5% of radical prostatectomy specimens),[5] and various studies have shown that biopsy often does not accurately map out the true extent of the disease. Many cancers are also found to be very close to the urethra, and one study reported that 66% of cases had foci of cancer within 5 mm of the urethra,[5] while another study showed actual urethral involvement in 17% of cases.[6] Also, apical cancers were seen in almost three-fourths of cases (74%) cases, and these tumors were more likely to be closer to the urethra.[6] Technical modifications aimed at reducing the cryo-injury to the urethra could cause undertreatment of these cancers, and many cryoablation failures typically occur in areas that get undertreated, like the prostate apex and the seminal vesical (SV).

Optimal cancer treatment thus requires a balanced approach, and the first step to minimizing complications would be to select patients appropriately.

Patient Selection

Appropriate case selection can go a long way in preventing (or minimizing) complications. In the absence of good diagnostic modalities that allow us to pinpoint the extent and sites of cancer in the prostate, we continue to rely on whole gland (or hemigland) ablation for cure.

The first aim of the treatment is to cure the patient of the cancer, and therefore it is essential to select patients with organ-confined disease. Patients with extraprostatic disease or those with SV involvement will have disappointing outcomes, since they will either have residual cancer or the ablation will have to be so aggressive and extensive that they will have higher risks of more serious complications.

Studies have confirmed this in the setting of primary cryoablation for clinical T3 disease with higher rates of biochemical failure than that after radical prostatectomy (RP) or radiation therapy (RT) in similar groups (biochemical failure seen in 48–52%[7,8]) and higher rectourethral fistula rates.[7]

For patients being considered for primary ablation, one should follow accepted parameters that define higher risk disease like prostate-specific antigen (PSA) levels, PSA velocities, biopsy parameters including volume of cancer, and Gleason scores. Patients with Gleason scores 8 or greater, tumor stage ≥T3, or those suspected of having LNI should be offered treatment, but with the knowledge that data on the use of cryoablation in these settings are not robust, although results from published series demonstrate effectiveness for high-grade disease.[7]

For patients undergoing salvage treatment, similar parameters have been studied. The following guidelines used for salvage radiation[9] have often been extrapolated for use in the salvage cryoablation setting: demonstration of localized recurrence with no evidence of distant metastases, time to recurrence after primary therapy of >2 years, PSA levels <10 ng/mL, PSA doubling time of >6–9 months, and a life expectancy >5–10 years.

In an effort to standardize the inclusion criteria for patients undergoing prostate focal therapy as part of clinical trials, a study panel has suggested the following criteria: PSA <15 ng/mL, clinical stage T1c–T2a, Gleason score 3 + 3 or 3 + 4, life expectancy of more than 10 years, and any prostate volume.[10]

DIAGNOSIS OF LOCALIZED RECURRENCE FOR PATIENTS UNDERGOING SALVAGE PROSTATE ABLATION

Dynamic magnetic resonance imaging (MRI) using diffusion-weighted imaging (DWI) or dynamic contrast-enhanced (DCE) MRI, and MR spectroscopy (MRS) can be used for assessment of local recurrence of prostate cancer. Combinations of DCE-MRI and DWI have a higher efficacy in detecting recurrence after RT.[11] Multiparametric (mp) MRI also has greater accuracy than T2-weighted imaging alone, for the detection of recurrent prostate cancer after RT.[12] Final confirmation of local recurrence is achieved through a prostate biopsy.

Prostate Biopsy

Doing targeted zonal or hemigland ablations when possible can help to minimize the risks of complications. However, it is important to map out the exact extent of the disease. Prostate biopsies are necessary, but there is a discordance between a conventional transrectal ultrasound (TRUS) guided biopsy and final pathology after radical prostatectomy. True unilateral cancer after radical prostatectomy was noted in only 28–29.3% of patients.[13,] In the lobe classified as benign on prostate biopsy, 5% cases even had T3 tumors noted after RP.[13,14]

More extensive biopsies and template saturation biopsies may be indicated for patients being considered for focal or hemiablative therapies, although data to support superiority of template biopsy remain limited.

MRI fusion biopsy is another technical advancement and has been included in the list of recommendations for the workup of patients undergoing focal therapy as part of clinical trials.[10] MRI with ultrasound fusion biopsy, identified 30% more high-risk cancers and 17% fewer low-risk cancers.[15] However, even with this advancement in technology, it is still possible for cancer to remain undetected on

an mpMRI, as exists the possibility of missing the target lesion on a fusion biopsy possibly from technical errors.[16]

Imaging and Other Tests for Staging

Conventionally, nuclear imaging with bone scans, computed tomography (CT) scans, and MRI have been used to assess the stage of the disease. The chances of these studies being negative even when there is occult metastases is high when the PSA is under 10 ng/mL, and many patients selected for either primary or salvage cryoablation have lower PSAs. The overall staging accuracy using current MRI protocols seems to be around 71–72%.[17] Studies using MRI have also shown that when a patient has either extraprostatic extension or SV involvement that is suspected on MRI, the chances of micro-metastases in lymph nodes as small as 0.8–1 cm in size is higher, especially when used in conjunction with other staging nomograms.[18] Micrometastases to lymph nodes could be predicted with a sensitivity and specificity of 100% and 65.2% for tumors that were T3a or more and 88.9% and 94.6% for T3b tumors using MRI.[17]

Thus, there may be a role for a pelvic lymph node dissection (PLND) in all patients suspected of having T3a disease or more on MRI. PLND can be done either by the conventional open technique or by laparoscopic or robotic-assisted laparoscopic technique. A conventional PLND may miss 13% of metastases that can occur outside of the drainage area,[19] and extended lymph node dissections may need to be done in selected cases. This may need to include the presacral nodes.[19]

Bone scans have a limited utility because of lower diagnostic yields in asymptomatic patients with PSA <10 ng/mL. The incidence of positive bone scans is higher with higher PSA levels, rising from 8% for PSA levels between 20 and 50 ng/mL to 40% for PSA >50 ng/mL.[20] MRI-DWI and 11C-choline PET/CT have also been shown to be useful for detecting bone metastases.[21] NaF PET/CT using 18F-sodium fluoride has shown some promise in detecting bone metastases from prostate cancer; whole-body DWI showed a higher specificity but lost some sensitivity when compared to 18F-NaF PET/CT.[22] It is possible that DW whole-body imaging may, in the future, be used to aid in the detection and/or follow-up of bone metastatic prostate cancer.

Operative Considerations

TECHNICAL ADVANCES IN TECHNOLOGY THAT HELP TO REDUCE COMPLICATIONS

Today's third-generation cryoablation devices have incorporated many technological advances that make the tissue injury more precise and controlled, thus reducing collateral damage. The first of these modifications is the use of an argon–helium gas combination to produce the freeze–thaw cycle. The use of multiple fine 17G cryoprobes can ensure delivery of well-controlled iceballs of 8–10 mm diameter, and improved glandular destruction has been shown to occur using a 6–8-probe technique compared to a 5-probe technique.[23] The use of transrectal ultrasound (TRUS) to monitor the iceball was developed by Onik et al.[24] and enabled a more accurate assessment of the extent of the "cryolesion." In order to decrease the effects on the urethra and minimize urethral slough a urethral warming device was later developed.[25] Efforts to minimize injury to the rectum were also described. Onik et al. found that raising the handle of the TRUS probe pushed the tip of the probe against the posterior rectal wall, thereby pulling the rectum off the prostate.[25] Developing further on this, Onik et al. subsequently created a mechanical separation between the rectum and prostate by injecting saline through the layers of the Denonvilliers fascia around the mid and apical regions of the prostate.[23]

TECHNICAL CONSIDERATIONS

Based on our experience with cryoablation, we feel that patients with uncontrolled bleeding diathesis or those on anticoagulant therapy can have significant bleeding and must be taken off these medications prior to surgery. These medicines can be resumed within 24–48 hours after the procedure or after the urine clears, whichever is earlier. A complete preoperative assessment includes a fitness for anesthesia. Many centers commonly do these procedures under general anesthesia, because of the ease, and often per patient's choice, but in patients with anticipated intubation difficulties, the procedure may be done under spinal anesthesia, and this choice is often run by the anesthesiology team. A limited bowel preparation may be used to ensure a rectum free of fecal matter at the time of the procedure, although we have not found this to be necessary or to add value and therefore use bowel preparations selectively. Antibiotics are used at the time of induction of anesthesia. Patients with tight urethral strictures may need an internal urethrotomy prior, since a Foley catheter is required to drain the bladder, and during the procedure a urethral warmer catheter is also used. Tight anal stenosis or a previous abdomino-perineal resection ending up with a closed anal orifice preclude placement of the transrectal probe. Transrectal ultrasound monitoring of the procedure is then not possible, and such patients are better managed by other modalities.

Patients with a very large prostate gland need multiple probes and are at risk for undertreatment. Neoadjuvant androgen deprivation therapy (NADT) may be useful in reducing the size of the gland (a mean reduction of 35% was noted) and a reduction of tumor volume by 50% that can occur within 2 months of therapy, although this rarely downstages the disease.[26] A more recent study with the use of NADT in men undergoing primary cryoablation showed that there were no significant differences in outcomes or complications between the groups except for patients in the intermediate-risk group, who showed better 5-year disease-free status.[27] We usually limit whole-gland treatment to patients with glands of 80 g or smaller and have also had good success with downsizing using luteinizing hormone-releasing hormone (LHRH) agonist therapy for 6 months in patients in whom the treatment delay is not believed to be consequential.

Our practice is to use two freeze–thaw cycles and monitor the ice ball formation with transrectal ultrasound. Temperature sensors are used at the apex, external sphincters, and neurovascular bundle (NVB). We also use the Onik maneuver of injecting saline between the layers of the

Denonvilliers fascia in order to cause a zone of separation between the prostate and the rectum (Fig. 24.1). After the procedure patients are discharged home the same day with a catheter, and we remove the catheter in 1 week.

Complications

Complications after prostate tissue ablation occur due to thermal damage to the prostate and surrounding tissues and are similar in patients undergoing cryoablation. They present as troublesome lower urinary tract symptoms or incontinence, sexual dysfunction, and/or as injury or damage to adjacent organs/tissue. The complication rates have been reported in a variable manner in the literature. The maximum variability seen is in the way ED and incontinence are reported. It is not uncommon for ED to be reported only in the group of patients who were previously potent before the initiation of treatment. The International Index of Erectile Function (IIEF-15) and the shortened version the Sexual Health Inventory for Men (SHIM) are two standardized questionnaires that are used, but these have limited utility in men who are not sexually active. A lot of variability is also noted in the way incontinence is reported, and this causes difficulties in comparison of results among studies. With prostate cancer, it is also important to consider the concept of "trifecta," since the biochemical progression-free survival (BPFS) is also important. It is technically possible to have a lower complication rate, as can be seen with focal ablation, and the tradeoff would be a higher BPFS.[4]

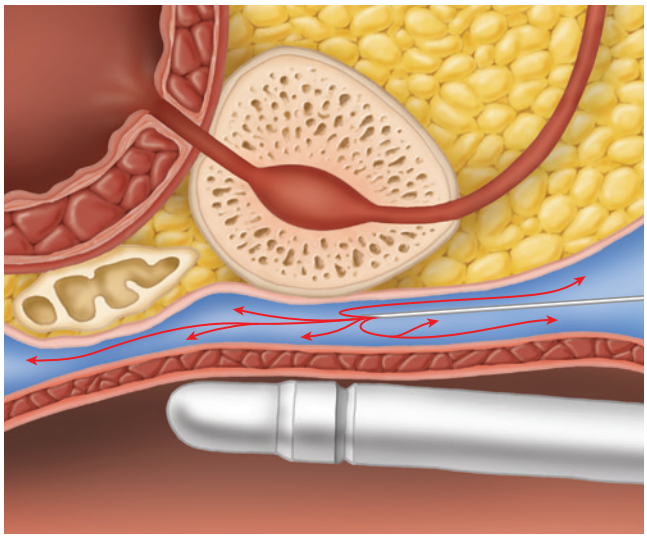

Figure 24.1 Saline hydrodissection into the space between Denonvilliers fascia and anterior rectal wall.

COMPLICATIONS OF CRYOABLATION

We queried the Cryo Online Data Registry (COLD) in addition to a review of literature for complications. As of December 6, 2015, the COLD registry had data from 39 sites, and 10 of these were academic centers. Records of 6771 cases were available, and of these 4102 patients underwent primary whole-gland ablation, and another 1011 patients had primary partial ablation. The remaining cases were either salvage whole/partial ablations or repeat ablations.

Commonly Seen Complications

Erectile Dysfunction

INCIDENCE. Erectile dysfunction was one of the most commonly seen side effects of cryoablation. The incidence of ED varies from 23.1% to 98.1% of primary series and 50–100% of salvage cryoablation series (Tables 24.1 and 24.2). The incidence is lowest for focal primary ablations[28] but highest for salvage total ablations.[29] In spite of a general

***Data being analyzed for a future journal manuscript. TURP, transurethral resection of the prostate; OIU, optical internal urethrotomy; COLD, cryo online data registry; LUTS, lower urinary tract symptoms.

lack of standardization for the assessment of ED, many studies currently used standardized questionnaires like the SHIM or IIEF for assessment and follow-up after treatment. The reported incidence depends on the way ED is defined. Most studies report ED only in men who were potent prior to therapy. There are currently no studies that have looked at what constitutes a significant change in the SHIM score in order to be classified as ED. Studies have often used terms like erection sufficient for intercourse,[30] or vaginal penetration, and this is sometimes used in conjunction with the SHIM (IIEF-5) scores; one study also required potency to be classified as a score of 3 or more for Question 2 of the IIEF-5 questionnaire[28] as evidence of potency. However, for erectile function to be meaningful, patients should have the ability to get an erection (assisted or unassisted with phosphodiesterase 5 inhibitors [PDE5I]) and should be able to maintain this through sexual intercourse.

ETIOLOGY AND PATHOGENESIS. The cause of ED is multifactorial, with the precipitating factor being the cryo-injury to the neurovascular bundles. It is important to understand that many patients with prostate cancer have multiple other medical conditions that could have an impact on erectile function prior to any treatment. The Baltimore Longitudinal study has shown hypogonadal testosterone levels to increase with age and ranged from approximately 20% in men over 60 years to over 50% in men over 80 years.[31] Many patients also have hypertension requiring antihypertensive medication, and this could be complicated by the presence of diabetes and preexisting peripheral vascular disease in some patients. After cryoablation, the cause of ED is multifactorial. Studies have demonstrated a neurogenic and vasculogenic component. The direct effect of freezing the cavernous nerve has been studied in the animal model, and the authors showed decreased cavernous pressure response to nerve stimulation at 1 month but a somewhat recovered response at 3 months after the initial freezing.[32] A study found that the incidence of ED was higher when two freeze–thaw cycles were used instead of one (92% vs 77%).[30] Another study looking at the vascular component assessed cavernosal artery velocities after induction of artificial erection using prostaglandin, PGE1. The study showed the possible role of a vascular injury due to cryoablation, by demonstrating a blunted response with an overall lower peak flow velocity that also took a longer time to achieve in all of the 9/15 patients who developed ED after cryoablation.[33]

MANAGEMENT. Recovery of erectile function can be seen as late as 2–3 years after treatment. One study reported an

average recovery time of 16.4 months[34] while another reported that spontaneous recovery of erectile function occurred with time, with 47% of patients able to have sexual intercourse at 3 years, and recovery seen in one patient as late as 5 years.[35] Penile rehabilitation should be started early, and patients should be advised to be persistent. A trial of phosphodiesterase 5 inhibitors (PDE5I) alone, followed by combination therapy with PDE5I and vacuum erection device often helps. A study on penile rehabilitation after cryoablation noted improvement in results with a protocol consisting of the use of a vacuum device without constriction ring to attain an erection for 10 minutes a day and regular use of oral medication for ED.[36] Penile prosthesis should be a consideration for the motivated patient with persistent ED even after a 2–3 years of penile rehabilitation.

Perineal and/or Rectal Pain

INCIDENCE. Perineal and/or rectal pain has been described to occur in 0–11% after primary cryoablation and 4–44% after salvage cryoablation. This entity has been variably recorded and is not mentioned in many reports on primary cryoablation. However, when this complication occurs, it can be a significant problem. It was described as a cause of dissatisfaction among patients undergoing salvage cryoablation and was noted to occur in 44% of patients in one series; it was a big quality of life problem in 41% and interfered with regular activities in 38%.[30]

ETIOLOGY AND PATHOGENESIS. Many cases are probably related to prostatic and urethral or periurethral inflammation. Symptoms could mimic severe forms of prostatitis, and the pain is often described as burning; it could be associated with frequent bowel movements or rectal irritation.[37] There could be an association of this symptom with urethral slough. Higher incidence of perineal pain was noted when a urethral warming catheter was not used (70% vs 34%), and this group of patients also had more severe symptoms and were twice as likely to use narcotic pain medications.[30] Many cryosurgeons believe that excessive freezing duration in the anterior probes is a cause, so we usually limit freeze time on anterior probes to 8 minutes.

MANAGEMENT. Initial management is conservative with emphasis on symptomatic treatment. Nonsteroidal antiinflammatory drugs and acetaminophen should be tried as first line of treatment, with use of narcotic pain medications being reserved for more severe cases. Alpha blockers may be tried. Use of warm sitz baths and a donut/pillow has also been described.[30] TUR of the necrotic material can hasten recovery of pain,[37] but given the higher incidence of incontinence after transurethral resection of the prostate (TURP) following cryoablation, patients should be carefully selected based on demonstration of persistent slough or necrotic material on cystoscopy.

Urinary Retention

INCIDENCE. Urinary retention after cryoablation is seen in 0–6% after primary ablation and 0–21.4% after salvage cryoablation. From our recent COLD data, 10% of patients after primary cryoablation and 19% after salvage cryoablation had some form of retention lasting beyond the 1-week catheterization time. Incidence can change depending on the definition of retention and how soon after the cryoablation it is assessed. Urinary retention lasting more than 4 weeks was found in 29% in one older study.[37] Lower urinary tract symptoms worsen after cryoablation and will continue to improve over a period of time. The IPSS score and bother score worsen over the first 6 months but return to baseline in 12 and 18 months, respectively.[38] However, patients requiring an indwelling catheter for bladder drainage 4–6 weeks after the procedure should be considered to have a retention episode.

ETIOLOGY AND PATHOGENESIS. Urethral and prostatic inflammation and prostate swelling[39] are considered to be causative mechanisms.

MANAGEMENT. Many retention episodes are transient and require an indwelling Foley catheter for bladder drainage until the swelling resolves. After two failed voiding trials, a decision must be made regarding the next steps. Some patients can be managed with medical therapy and will void but continue to have >150 mL postvoid residual urine on a bladder sonogram. If these patients do not develop urinary tract infections or have evidence of worsening renal function, they can be closely observed for a few months. Clean intermittent self-catheterization is also an alternative, and of the patients who developed retention in the primary and salvage series of the COLD data, 16% and 18%, respectively, were managed this way; approximately 12% and 23%, respectively, underwent TURP. However, there is risk of the intermittent catheter damaging the urethra and creating a fistula, so we often limit this use to the primary treatment setting and do not advise patients to self-catheterize after salvage therapy. Suprapubic catheter placement is also an option, and some authors have used this mode of drainage after patients fail a second voiding trial.[39]

Tissue Slough

INCIDENCE. This complication has been variously reported, and many publications have omitted to mention the exact incidence. The overall incidence will be difficult to determine since all patients do not get diagnostic cystoscopies to assess for this, and often this is either a patient-reported symptom, or incidentally detected during a TURP, or cystoscopy for other reasons. The incidence also depends on the generation of machine used for cryotherapy and the use of urethral warmers. In primary ablation series, slough is described to occur in 0–6.7% cases, but in the salvage series it is reported in 1.1–55% (Table 24.2), and one series published in 1995 reported an incidence of 55%.[40] Cohen reported a 14–16% incidence in the pre-2001 era using the older machines, and this was in contrast to the 2% incidence noted after 2001.[41]

ETIOLOGY AND PATHOGENESIS. The tissue necrosis and sloughing are direct responses to the freezing of the prostate and the prostatic urethra. It is seen a few weeks after the cryoablation and can present with the patients complaining of passing tissue pieces or mucoid material or debris[37] after catheter removal. In other patients it may present with obstruction and is often the leading reason for a TURP in this setting. When done in this setting the TURP is reported to be more challenging since the normal anatomic landmarks are distorted, and this can results in over-resection.[42] The risk of incontinence, therefore is very high. The use of a urethral warmer catheter offers protection against tissue slough,[30,42] but in the study no significant relationship was

noted with the number of freeze–thaw cycles or number of probes used.[30]

MANAGEMENT. Tissue slough often presents with obstruction. Initial management should be conservative, with catheterization, with use of antibiotics and alpha blockers as indicated. A transurethral resection of the slough has a high incontinence rate. However, no studies have compared cases undergoing TURP with matched controls managed conservatively to determine the true fate and incidence of incontinence in this group managed conservatively (once the tissue debris from the prostatic urethra and/or sphincter gets passed out, and the area gets replaced with fibrosis). However, TURP may eventually be found to be necessary, and some advocate doing a limited TURP, to create a channel, and recommend that this should be done at least 3 months after the cryoablation.[42] We and most others with experience feel that TURP should be withheld until at least 12 months post treatment, especially in the salvage setting.

Less Commonly Seen Complications

Incontinence

INCIDENCE. Again, plagued by variations in definition, incontinence is reported in 1.6–9.5% of primary series and 5.5–91.3% for salvage cryoablation series (0% for focal salvage cryoablation). In a report by Bahn et al., when incontinence was defined as any leakage of urine 15.9% were considered incontinent, but when the definition was refined to include those who used any pads, the rate dropped to 4.3%.[34] The incontinence rates have also reduced in recent years with improving technology. Incontinence rates of 8.2% were noted by Cohen in the pre-1996 era using first- or second-generation machines, but this dropped to 3.2% in the 1996–2001 era and later to 0% in the post-2001 era with the use of third-generation machines.[41]

ETIOLOGY AND PATHOGENESIS. The mechanisms of incontinence after cryoablation are similar to those seen after radiation therapy or radical prostatectomy. When the prostate is ablated the change in the anatomy, damage to the external sphincter mechanism, and new-onset bladder overactivity contribute to incontinence. Compromised vascular supply to the sphincter due to microvascular damage from radiation may result in poorer healing after cryoablation and could explain the higher incontinence rates in salvage cryoablation.[42] Urge incontinence possibly from overactive bladders may be seen in up to 80% of patients having long-term incontinence.[39] Resection of the slough is also a good predictor of incontinence, and in one study all patients who were incontinent for more than 6 months had previously had a transurethral resection of the slough.[43] In another series 13 of the 15 patients who developed obstruction became incontinent either after a TURP or after spontaneous passage of slough.[42] Use of urethral warmers has been described to result in a lower rate or severity of incontinence.[30,42]

MANAGEMENT. Recovery of continence can sometimes be a slow process, and in one study, the average time to continence was 6.1 months.[34] When the predominant symptoms are suggestive of bladder overactivity, appropriate therapy with anticholinergic agents helps to decrease the incontinence. Stress urinary incontinence can be managed by sphincter strengthening exercises and physiotherapy. When such conservative measures fail, use of collagen injections or even artificial urinary sphincters has been described.[30]

Rectal Fistula

INCIDENCE. Rectal fistula rates were higher in the salvage cryoablation series. The incidence of rectal fistulas is 0–1.3% in pooled primary ablation series and 0–11.1% in the salvage cryoablation series. On review of the COLD data, rectal fistulas were noted in 1% for primary whole-gland and 2.8% for salvage whole-gland ablation.

ETIOLOGY AND PATHOGENESIS. Rectal fistulas occur when tissue freezing extends to involve the whole thickness of the rectal wall, and in the earlier series, inadequate visualization of the iceball in relation to the sagittal view of the rectal wall, due to shortcomings in imaging and ultrasound machines, may have been partly responsible for this.[41] With improvement in technology the fistula rates are now lower. Compromised tissue characteristics of irradiated tissues may be responsible for the higher fistula rates in salvage ablation series. Operator skills could also be an important factor, and an experienced surgeon has lower fistula rates. Cohen noted that most of the fistulas occur in the first 25 cases of most surgeons' series,[41] when the surgeon is still in his or her learning curve.

MANAGEMENT. Rectal fistulas often come to attention because patients complain of passing urine per rectum or a form of persistent watery diarrhea. An index of suspicion is required in order to identify cases who need to be subjected to more testing, since some rectal irritation and frequent bowel movements can be seen in the initial phase in some patients with perineal pain syndromes.[37] Some patients present with classical symptoms of the fistula and can have recurrent urinary tract infections or pneumaturia. Sectional imaging with contrast often shows loss of tissue planes at the site of communication, a retrograde urethrogram may show extravasation (Fig. 24.2), and a

Figure 24.2 Post-salvage cryotherapy urethrogram showing contrast extravasation.

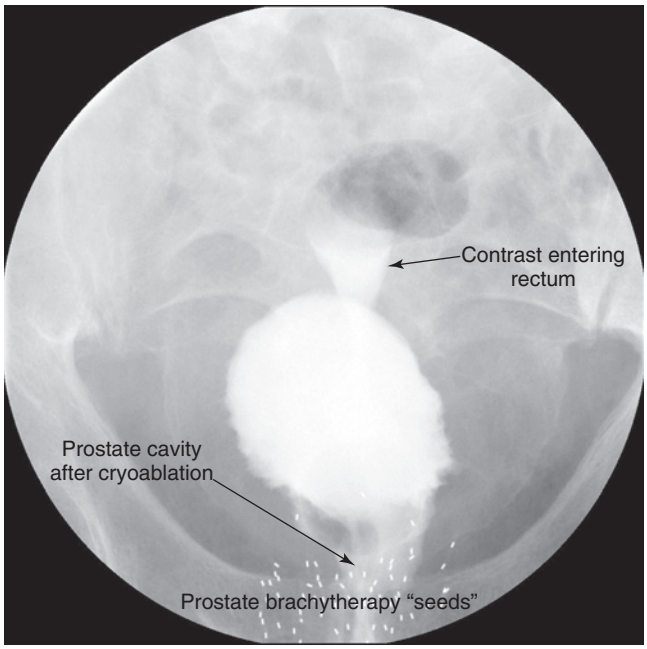

Figure 24.3 Post-salvage cryotherapy cystogram showing contrast material present in the rectum suggesting uethro-rectal fistula. (With permission from Kim IW, Herts BR, Jones JS. Rectourethral fistula after salvage cryotherapy for prostate adenocarcinoma; J Urol. 2013; Feb; 189(2):699-700.doi:10.1016/j.juro.2012.10.132.Epub 2012 Nov 10.)

conventional cystogram will show flow of contrast into the rectum (Fig. 24.3). A CT cystogram can substitute for the two investigations and has good accuracy in detecting these fistulas.

Some cases can be managed by extended catheter drainage, and spontaneous closure of the fistula with up to 3 months of catheter drainage alone has been described.[37] In our experience and also when we are consulted from other facilities for this problem, we do recommend the use of a Foley catheter for 6–12 weeks as the first-line intervention. From our center, we have also reported on a patient following salvage therapy who was managed with a suprapubic catheter and fecal diversion whose fistula closed spontaneously, and the patient underwent fecal undiversion 15 months later.[44]

Some fistulas, especially in the salvage setting are more difficult to treat and may not close spontaneously. All patients should get a urinary diversion, and a suprapubic catheter drainage is often a better option since the catheter is not traversing through the area of the fistula. In a study on rectourethral fistulas, fecal diversion was also required in 59% of patients.[45] If the fistula does not close spontaneously, some patients will go on to develop membranous urethral strictures, and this may need to addressed at the time of the repair.[46] In a study, nonirradiated patients or those with small fistulas considered to be low risk for recurrence were treated by a posterior transanosphincteric transrectal approach.[45] More complex fistulas have been managed by the use of a gracilis muscle interposition flap, or rarely even pelvic exenteration.[45] In their series, Hanna et al. noted that fecal undiversion should be offered only after careful review of the patient's progress. With this approach, 100% of their patients undergoing fecal undiversion had no complications, but 45% of patients with complex radiation-induced fistulas developed a "noncompliant rectum or anosphincteric dysfunction" and ended up having a permanent colostomy.[45] At our institution we have reported on a multidisciplinary approach involving urology and colorectal surgery. The series reported on the use of a transperineal approach with gracilis muscle interposition for the repair, including repair of membranous urethral strictures and the use of a buccal mucosa graft, supported by the corpus spongiosum and gracilis muscle flap. Notably, most of the patients in that series had fistulas related to treatments other than cryoablation.[46]

Bladder Neck Contractures/Urethral Strictures

INCIDENCE. This is seen in 3.3% of cases in the primary ablation group and 0–28% in the salvage group (Table 24.2).

ETIOLOGY AND PATHOGENESIS. Strictures and bladder neck contractures are direct results of freezing, tissue slough, infections and irritation from the catheter, and subsequent scarring and fibrosis. The use of a urethral warming device has been shown to reduce the incidence of tissue slough.[30,42]

MANAGEMENT. Urethral stricture should be managed depending on the location, length, and degree of spongiofibrosis. Bladder neck contractures can be managed by bladder neck incisions. Bulbar urethral strictures can be managed by internal urethrotomy. Membranous urethral strictures can be managed by dilatation or urethrotomy; however, the risks of incontinence are higher. Longer segment strictures may need to be treated by urethroplasty.

Rare or Anecdotal Complications

Other rarer complications have been described in an inconsistent manner in the literature. Some of these could be directly related to the procedure but others, such as a single patient death,[40] transient ischemic attack (one patient – 2%), and cerebrovascular accident (one patient – 2%),[37] may not be directly related or specific to the procedure. Acute renal failure was reported in two patients,[40] and ureteral obstruction and hydronephrosis have been described in 2%[37] to 36% in very small series, but not in any large contemporary series[40] of patients, and could be from damage to the trigone or ureteral orifices during the cryoablation. One patient in each of these series had bilateral hydronephrosis and required percutaneous nephrostomies.[37]

Penile tingling/numbness was noted in 2.6%[47] and 10%[3] and can be managed conservatively. Scrotal hematoma was noted in 5%,[37] and scrotal edema was seen in eight (7.5%) patients in one study,[39] but some degree of scrotal swelling was described to have occurred in all (100%) patients in another small series.[48] Urethrocutaneous fistula occurred in one patient and was managed by long-term suprapubic tube.[37] Hematuria was reported in four patients (3.77%) in a study.[39]

Infective complications were noted in a few patients: epididymitis was seen in three patients in one small study,[40] testicular abscess in one case,[35] one case each of prostatic abscess,[49,50] and one case each of a delayed presentation of a prostatic abscess.[39,51] Urosepsis was seen in two patients,[40] and osteitis pubis was noted in 3% of cases in one series.[50]

Conclusions

Prostate tissue ablation is increasingly being used in the primary setting. In the COLD database, 4109 patients had primary cryoablation for prostate cancer.

Impotence is very commonly seen after prostate cryoablation. The etiology is multifactorial. Impotence as a complication is, however, better accepted by the patient than incontinence. Incontinence is a troublesome complication, but its incidence is declining. Rectal fistula is one of the most dreaded complications and can be technically difficult to manage. With further improvements in imaging and in tissue ablation technology, BPFS may continue to improve, and the complication rate may continue to decrease.

Chapter 24 Questions

1. Factors affecting degree of tissue injury using cryotherapy include which of the following?
   a. Final temperature
   b. Rate at which final temperature was achieved
   c. Number of freeze–thaw cycles
   d. All of the above
   e. None of the above

2. Using multiple (two to three) freeze–thaw cycles, the appropriate temperature to cause adequate tissue destruction is:
   a. −40°C
   b. −25°C
   c. −19°C
   d. −15°C
   e. −8°C

3. The commonest sites of cancer recurrence after cryoablation of the prostate are the following:
   a. Apex and seminal vesical (SV)
   b. Apex and midgland
   c. Base and SV
   d. Apex only
   e. Transition zone

4. Techniques that can minimize urethral slough and urethrorectal fistula following cryoablation of the prostate include which of the following?
   a. Use of TRUS to monitor the iceball
   b. Use of urethral warmer catheterization during the procedure
   c. Hydro-distention of the space between the rectum and the prostate
   d. All of the above
   e. None of the above

5. The most common complication encountered following prostate cryoablation is:
   a. Fistula
   b. Erectile dysfunction
   c. Slough
   d. Urinary retention
   e. Sepsis

6. Transurethral resection of the prostate (TURP) as a treatment option for patients who had failed conservative treatment for slough following salvage cryoablation of the prostate should be withheld at least ___ post treatment:
   a. 3 months
   b. 6 months
   c. 9 months
   d. 12 months
   e. 6 weeks

7. Management of urinary retention following salvage cryoablation of the prostate includes all of the following EXCEPT**:**
   a. Urethral catheterization
   b. Medical therapy
   c. Clean intermittent self-catheterization
   d. TURP
   e. Continuing medical management for enlarged prostate

8. Patients with urethra-rectal fistulas following cryoablation may present with:
   a. Recurrent urinary tract infection
   b. Watery diarrhea
   c. Pneumaturia
   d. All of the above
   e. None of the above

9. Mechanism of urge incontinence after cryoablation of the prostate:
   a. Compromised vascular supply to the sphincter
   b. TUR of the slough
   c. Bladder overactivity
   d. Fistula
   e. None of the above

10. Post cryoablation ED may be due to:
    a. Cryo-injury of the neurovascular bundle
    b. Hypogonadal testosterone level
    c. Preexisting medical comorbidities
    d. All of the above
    e. None of the above

Case Studies

CASE 1

A 65-year-old male was diagnosed with cT2, Gleason 4 + 3 = 7 prostatic adenocarcinoma on a standard 12-core prostate biopsy. After discussion, he opted to undergo treatment with brachytherapy. Patient's nadir PSA was achieved 2 years out of treatment at 0.6 ng/mL. He was scheduled for annual PSAs, and 4 years out of the treatment his PSA was 1.3 ng/mL. A decision was made to do the PSA every 6 months, and his PSAs over the next 2 years were 1.6, 1.9, 2.5, and 3.3 ng/mL. He was now 71 years old and a discussion 6 months back at a PSA of 2.5 included Phoenix criteria of BF and treatment options. The patient wanted to wait at that time, but now his wife wants him to strongly consider salvage cryoablation.

1. The next step in the management would be:
   a. Advise against salvage treatment and schedule for androgen deprivation therapy
   b. Schedule for a transrectal ultrasound-guided biopsy, and biopsy should include biopsy of seminal vesicles
   c. Refer for salvage external beam radiation therapy
   d. Monitor PSA every 3 months for another 2 years
   e. Repeat brachytherapy

A transrectal ultrasound-guided biopsy including biopsy of the SV revealed Gleason 3 + 4 = 7 prostate adenocarcinoma with benign SV. After discussion of treatment options, the patient elected to undergo whole-gland salvage cryotherapy.

He presented with progressive irritative voiding symptoms 4 months after undergoing salvage cryotherapy.

2. Which of the following is the least likely cause of symptoms?
   a. Infectious etiology like cystitis or prostatic abscess
   b. Anatomic abnormality like urethral stricture or bladder neck contracture
   c. Tissue slough
   d. Rectoprostatic fistula
   e. Urinary tract infection

3. Which of the following is not an appropriate next step?
   a. Urine culture followed by antibiotics
   b. Preparation for a cystoscopy
   c. Low-dose chemoprophylaxis and return to clinic in 6 months
   d. Consider for imaging for bladder or prostatic urethral stones and/or fistula
   e. CT cystogram

CASE 2

A 73-year-old man with a PSA of 6.2 ng/mL was found to have a Gleason score 3 + 4 = 7 prostate cancer and opted to undergo cryoablation. His Foley catheter was removed 1 week after the procedure, but later that evening the patient returned to the ER and was catheterized for a returned volume of 800 mL. He was seen in the office a few days later and started on tamsulosin. One week later he underwent a trial of voiding and was able to void. Another week later he called with complaints that his stream had been weak all along, and now was having frequency and some urgency and nocturia, along with some perineal pain/discomfort and was also passing some tissue pieces in the urine intermittently.

1. At this point in time the most likely primary problem is:
   a. Urinary tract infection
   b. Tissue slough
   c. Urethral stricture
   d. Prostatic abscess
   e. Bladder stone

A bladder scan is done, and patient is in retention with over 700 mL in the bladder. A Foley catheter is placed, and the patient returns after another week and fails yet another trial of voiding.

2. Which of the following is not considered a good option at this point in time?
   a. Reinsert Foley catheter
   b. Suprapubic tube placement
   c. Clean intermittent self-catheterization
   d. TURP
   e. Cystolithotripsy

3. A suprapubic catheter is placed, and a few months later the patient is taken up for a TURP. What procedure-specific complication must the patient be warned about?
   a. Urinary incontinence
   b. Recurrent urinary tract infections
   c. Recurrent bladder stones
   d. Erectile dysfunction
   e. Regrowth of adenoma

Answers

1. **d.** Factors affecting the degree of tissue injury during cryoablation of the prostate include the final temperature and the rate at which it is achieved, as well as the number of freeze–thaw cycles used.
2. **c.** A temperature of −40°C was shown to cause adequate cell destruction. However, using a newer technique during cryoablation either through multiple (double or even triple) freeze thaw cycles, that keep cells at subzero temperatures for a longer time or by ensuring the right combination of cooling rate (25°C/min) plus end point temperature, cell death can be achieved at a higher temperature of −19°C.
3. **a.** Most of the local recurrence after cryoablation of the prostate occurs in the prostate apex and the SV as they are usually undertreated.
4. **d.** The hydro-distention technique using saline injection to separate the rectal wall from the prostate during cryosurgery has markedly decreased the incidence of urethra rectal fistula following the operation. Moreover, the use of TRUS to monitor the iceball and urethral warming device decreases the effects on the urethra and minimize urethral slough.
5. **b.** ED is the most commonly encountered complication following cryoablation of the prostate and is due to the effect of freezing that causes damage to the neurovascular bundles. However, other medical conditions may contribute to the development of ED prior to any treatment.
6. **d.** Following salvage cryoablation of the prostate, the incidence of incontinence and urinary retention rates increase. Spontaneous resolution occurs in half of the patients within 1 year, especially with the use of urethral warmer. Most of the authors recommended withholding incontinence treatment and TURP until at least 12 months post salvage cryotherapy.
7. **c.** Self-intermittent catheterization may damage the urethra and create fistula, especially in the salvage setting, and so should be avoided.
8. **d.** Rectal fistulas following cryoablation of the prostate may present with passing urine per rectum or a form of persistent watery diarrhea. Some patients present with classical symptoms of the fistula and can have recurrent urinary tract infections or pneumaturia.
9. **c.** Overactive bladder presents with urge incontinence following cryoablation of the prostate. Urge incontinence from overactive bladders may be seen in the majority of patients having long-term incontinence.
10. **d.** ED is multifactorial; the precipitating factor is the cryo-injury to the neurovascular bundles. Multiple other medical conditions including preexisting DM that could have an impact on erectile function prior to

any treatment. The hypogonadal testosterone levels also increase with age, which may contribute to ED following cryoablation of the prostate.

CASE 1

1. **b.** A biopsy confirmation of recurrence is necessary before planning salvage cryoablation. The biopsy should exclude an SV recurrence, as these case are not suitable for salvage cryoablation.
2. **c.** Tissue slough is seen earlier in the course after cryoablation and more often presents with retention or difficulty in voiding.
3. **c.** This could potentially delay the diagnosis. A physical examination was done followed by a cystoscopic evaluation, and this revealed findings suggestive of a rectourethral fistula. A cystogram showed active communication between the bladder and rectum. The patient underwent bowel diversion with loop sigmoid colostomy and urinary diversion with suprapubic tube placement for the rectourethral fistula. Contrast enema 8 months after diversion showed resolution of the fistula, the patient was able to void normally, and the suprapubic tube was removed. Repeat barium enema revealed a small pocket of contrast at the area of injury but no fistula. The patient underwent reversal of both diversions 15 months after the original presentation and is doing well.

CASE 2

1. **b.** Tissue slough can present this way.
2. **d.** Most clinicians would not consider a TURP until at least 3 months out of the procedure.
3. **a.** Patients undergoing TURP after cryoablation are at risk for urinary incontinence and should be warned about this.

Complications of Post Transurethral Resection of Bladder Tumor Intravesical Chemotherapy
Conclusions
Chapter 25 Questions and Answers

KEY POINTS

1. Equipment should be inspected by the surgeon and nursing team prior to its use to ensure proper selection and good working order.
2. Depending on the type of diathermy selected, all irrigant solutions are suitable for use with transurethral resection of bladder tumors (TURBT), each with its unique advantages and limitations.
3. A thorough preoperative evaluation, including anesthesia and subspecialty referral when indicated, will optimize patient health and lessen the likelihood of complication.
4. Documentation of a negative urine culture is recommended prior to TURBT.
5. Careful patient positioning and padding can prevent severe lower extremity nerve injury and lasting disability.
6. Office-based, flexible cystoscopy can assist in planning a successful procedure by providing a resection map. Tumor located on the anterior wall, on the lateral walls, at the dome, in a diverticulum, or involving the ureteral orifice may require special equipment or additional anesthetic considerations.
7. Bleeding is the most common complication associated with TURBT. Depending on its severity, it can be managed with continuous bladder irrigation through a 3-way catheter (using saline, alum, or Amicar), repeat endoscopic fulguration, open surgery, or arterial embolization.
8. Perforation increases the risk of numerous other complications including bleeding, infection, TUR syndrome, and possible disease spread. Careful planning, appropriate equipment

selection, diligent attention to operative technique, and effective communication between the surgical, anesthesia, and nursing teams lessen the likelihood of perforation occurring.

9. TUR syndrome can be a lethal complication. Prompt identification and management are critical. Transferring the patient to a monitored setting (ICU) is often appropriate.
10. Resident involvement in TURBT can increase operative time and readmission rates but does not seem to increase overall complication or reoperation rates.
11. Post-TURBT intravesical chemotherapy is contraindicated with known bladder perforation. Intravesical Bacillus Calmette-Guerin (BCG) is absolutely contraindicated in the immediate postoperative setting.
12. Staff responsible for administering, monitoring, and disposing of intravesical chemotherapeutics must understand how to maintain a safe working environment for themselves and their patients.

Introduction

Transurethral resection is not only the initial treatment for bladder tumors but also provides tissue for the pathologic evaluation of tumor stage and grade, making this procedure both therapeutic and diagnostic. This chapter will discuss strategies to reduce perioperative complications and maximize patient outcomes. Since transurethral resection of bladder tumors (TURBT) shares many techniques and hazards with transurethral resection of the prostate (TURP), we will refer to the excellent discussion in Chapter 26 at several points.

General Considerations

The vast majority of patients who undergo TURBT have already had office-based cystoscopy. This gives the surgeon an opportunity to not only note the location, number, and appearance of bladder lesions, but to also look for possible barriers to successful resection such as problems with mobility (hip/knee range of motion) and urethral/bladder access (phimosis, stenosis, stricture). These findings should be relayed to the operating room scheduler in a timely fashion to ensure that the appropriate personnel, equipment, and operating room time are available.

Surgical Instrumentation

The equipment used for TURBT is nearly identical to that for TURP. A full list of the mandatory and optional equipment is provided in Table 25.1. A dedicated cystoscopy suite is an excellent way to centralize all the necessary equipment and ensure that the operating table is both maneuverable and compatible with lithotomy stirrups and C-arm fluoroscopy. A variety of urethral catheters should also be on hand for postprocedure bladder drainage including conventional Foley and coude catheters, as well as three-way catheters for continuous bladder irrigation (CBI or Murphy drip).

All instrumentation should be maintained regularly so that worn or ill-fitting parts can be serviced. The nursing staff and surgeon should inspect the set-up prior to starting the case to confirm that the necessary equipment has been picked and that any contingency items are immediately available. This step may seem to add time to the procedure but it is far riskier to proceed only to find out that an urgently needed item is broken or was mislabeled during processing and is therefore not on hand. It is the surgeon's ultimate responsibility to confirm the good working order of his/her equipment, and a preprocedure check should become as much of a habit as the "right patient/right site" preoperative verification for patient safety.

Table 25.1 Equipment Necessary for Transurethral Resection of Bladder Tumor

Equipment Required	Optional Equipment
Endoscopic sheaths (20F, 24F, 28F, deflecting)	Urethral sounds
Resecting loops	Evacuators (Toomey, Ellik, Creevy)
Roller ball	Urethral access catheter
Right-angle electrodes	Contrast
Marberger cold-cup biopsy forceps	Fluoroscopy
Generator with grounding pad	
Lens (30-degree and 70-degree)	
Camera and light source	
Irrigation tubing and irrigant	
Water-soluble lubricant	
Specimen cups	

Irrigating Solutions

Copious amounts of the surgeon's irrigant of choice must be readily available. An experienced nursing team, the members of which understand that any loss of visibility not only prolongs the procedure but also increases the likelihood of an adverse event, is invaluable.

Since the bladder does not readily absorb its contents, the use of sterile water is safe, unlikely to result in hemolysis or hyponatremia (transurethral resection (TUR) syndrome), and yields outstanding endoscopic visualization. In a comparison of glycine and sterile water use for the resection of superficial bladder tumors, the two solutions were found to be equally effective and sterile water was less expensive.[1] However, for long resections of large, hypervascular tumors, changing to an iso-osmotic fluid should be considered. Bipolar resectoscopes allow for the use of normal saline as the irrigant, lessening the risk of hyponatremia.[2]

Sorbitol, mannitol, and glycine are all suitable options but each has a metabolic profile that must be considered (see Chapter 26 for detailed discussion). Sorbitol is metabolized to glucose and can result in hyperglycemia, making it

a less desirable choice for diabetic patients. Mannitol, an osmotic diuretic, can cause intravascular fluid shifts if absorbed further, exacerbating hyponatremia. Lastly, ammonia is a metabolic breakdown product of glycine, which can increase the risk of hyperammonemia and resultant encephalopathy in patients with poor hepatic function. Bladder perforation, which will be addressed later in this chapter, is an absolute contraindication to continued resection regardless of the irrigant being used.

Patient Preparation

The National Surgical Quality Improvement Program (NSQIP) has laid an important foundation for the development of surgical risk–reduction strategies. Recently, Matulewicz and colleagues used the NSQIP data from 2006 to 2012 to examine postoperative complications stratified by TURBT duration. They adjusted for patient age, tumor size, comorbidities, and American Society of Anesthesiologists (ASA) classification. They found that the incidence of complications increased with operative duration. For cases longer than 90 minutes in duration the complication rate was 11.3%. Complications included mortality, myocardial infarction, sepsis/septic shock, venous thromboembolism (VTE), and reintubation/respiratory failure.[3] Hollenbeck and colleagues also used NSQIP data to specifically identify risk factors for adverse outcomes following TURBT.[4] They found that the presence of disseminated bladder cancer, weight loss (≥10%), low serum albumin, elevated serum creatinine, dependent functional status, and emergent case status were significant preoperative predictors of adverse outcomes. Perioperative predictors included postoperative hyponatremia and the need for intraoperative blood transfusion. In another study, McLaughlin and colleagues reported on a pilot study that examined the risk factors associated with 30-day morbidity in a non–Veterans Affairs urology setting (including open, laparoscopic, and endoscopic procedures).[5] Not surprisingly, the authors found that patients who have comorbidities such as heart disease (hypertension, angioplasty, myocardial infarction, congestive heart failure); lung disease (dyspnea, asthma, chronic obstructive pulmonary disease); diabetes (with or without end organ damage); cancer (second nonmetastatic solid tumor initially treated within 5 years, prior chemotherapy); laboratory abnormalities (anemia, elevated blood urea nitrogen [BUN]); and poor operative risk scores (Charlson comorbidity index score, American Society of Anesthesiologists' physical status class 3–5) or who underwent longer procedures or required intraoperative blood transfusion were much more likely to suffer a complication within the first 30 days of surgery. Due to the epidemiology of bladder cancer, patients undergoing TURBT are likely to have one, if not several, of the risk factors identified in the two studies above.

PREOPERATIVE EVALUATION

Maximizing patient health status preoperatively is always beneficial. Attention to cardiopulmonary status, renal function, and identifying any issues with coagulation are of specific concern. Following a detailed history and physical examination, correspondence with a patient's primary care provider and consultation with an anesthesiologist can help identify areas for optimization before TURBT. Preoperative EKG, chest x-ray, and laboratories (complete blood count [CBC], prothrombin time [PT]/partial thromboplastin time [PTT]/ international normalized ratio [INR], chemistry-14 or comprehensive metabolic panel) allow the patient to be referred for evaluation by a specialist if needed.[6] Blood bank cross matching may need to be considered in select cases.

MEDICATION COUNSELING

Patients will need to be counseled about which medications (prescription, over-the-counter, and supplements) they should discontinue, how long they must abstain preoperatively, and when it is safe to resume their usual regimen. Special attention must be paid to patients with diabetes or hypertension to ensure euglycemia and normotension in the perioperative period.

The preoperative planning for patients taking anticoagulants (warfarin, dabigatran, apixaban, edoxaban, heparin, etc.) and antiplatelet agents (clopidogrel, prasugrel, ticagrelor, ticlopidine, cilostazol, aspirin, NSAIDs, etc.) requires careful coordination with the prescribing provider. Some patients, such as those with artificial heart valves, cardiac stents, or hypercoaguable states, may need to be admitted and heparinized to mitigate the risk of clot formation (see Chapter 4). Postoperatively, determining when patients should resume their usual anticoagulation/antiplatelet regimen will require weighing the risks of bleeding against those of thrombus formation.

URINE CULTURE AND ANTIBIOTIC PROPHYLAXIS

A documented negative urine culture is recommended prior to transurethral surgery. Any suspicion of infection should result in immediate culture, appropriate antibiotic therapy, and rescheduling the procedure until the urine has been documented to be sterile on repeat culture. Preoperative antibiotic prophylaxis, usually with a cephalosporin, sulfamethoxazole-trimethoprim, or a fluoroquinolone, is recommended.[9] Of note, prescribers should be aware of the July 2016 black box warning issued by the US FDA regarding fluoroquinolone antibiotics. This warning did not address the use of fluoroquinolones as presurgical prophylaxis, but the potential risk from this class of drugs should be weighed when selecting a preoperative antibiotic. Second-line options include aminoglycosides, ampicillin, or a cephalosporin. The antibiotic choice should be altered in the case of an allergy or certain other aspects of the patient's medical history, including documented UTI with resistance to that agent, artificial heart valve, joint replacement, etc.[9] Antibiotic prophylaxis is recommended for 24 hours unless the patient has a positive urine culture indicating therapy should be extended.[9]

Anesthesia and Positioning

ANESTHESIA

Selecting the appropriate anesthetic regimen is a collaborative process involving the patient, anesthesiologist, and

surgeon. For TURBT, the choice is between regional (spinal or epidural) and general (laryngeal mask or endotracheal tube) anesthesia. If a regional approach is chosen, the anesthesiologist should be prepared to deepen the patient's sedation, and even intubate if needed, to prevent the patient from coughing or bucking during the procedure. Sudden movement can result in significant complications, such as imprecise resection, hemorrhage, and bladder perforation. If the tumor is located laterally in the bladder, general anesthesia is appropriate because a paralytic can be given to eliminate leg adduction should current from the resecting loop stimulate the underlying obturator nerve.[10–12] Similarly, injection of 30 mL of local anesthetic as an obturator block can significantly decrease nerve sensitivity and adductor strength.[13–22]

PATIENT POSITIONING

Proper positioning is a fundamental aspect of any procedure performed in the lithotomy position. The surgeon, anesthesiologist, and nursing team should concur that all bony prominences are adequately padded and that the legs are secured within the stirrups to ensure minimal risk of nerve injury (Table 25.2). The patient should be appropriately covered to prevent hypothermia and its sequelae (impaired drug metabolism, prolonged emergence from anesthesia, coagulopathy, postoperative discomfort)[23] as a significant amount of body heat can be lost ambiently and through the irrigating fluid used intraoperatively. Warming the irrigant or using a warming blanket/forced air device can be beneficial in longer cases. Since patients with malignancy have an increased risk of venous thromboembolism, sequential compression devices (SCDs) are applied to the lower extremities for all cases that may last more than 1 hour, although many surgeons choose to use them for even shorter cases.[24] It is critical to have the SCDs in place and functioning prior to induction, when the risk of DVT increases.

Surgical Approach

RESECTION

As mentioned earlier, the information gathered during office-based flexible cystoscopy can aid in the planning of TURBT. Adjustments in equipment selection and technique may need to be made based on the size, location, and number of tumors seen (Figs. 25.1 and 25.2 and Table 25.3).

Table 25.2 Nerve Injury due to Lithotomy Positioning[110]

Nerve Injured	Physical Deficit	Caused by
Sciatic	Inability to flex knee	Excessive external hip rotation
Femoral	Inability to flex hip or extend knee	Excessive external hip rotation
Common peroneal	Foot drop (loss of dorsiflexion)	Compression of lateral knee at proximal fibula

(From Gonzalgo M. Bladder cancer: Superficial. In: Parsons J, Wright E, eds. The Brady Urology Manual. London: Informa Healthcare; 2006.)

DIFFUSE CARCINOMA IN SITU

The initial standard therapy for *carcinoma in situ* (CIS) is intravesical therapy with attenuated Mycobacterium bovis Bacillus Calmette-Guérin (BCG).[25] If CIS is believed to involve extensive segments of the bladder, representative biopsies with hemostatic fulguration are preferable to

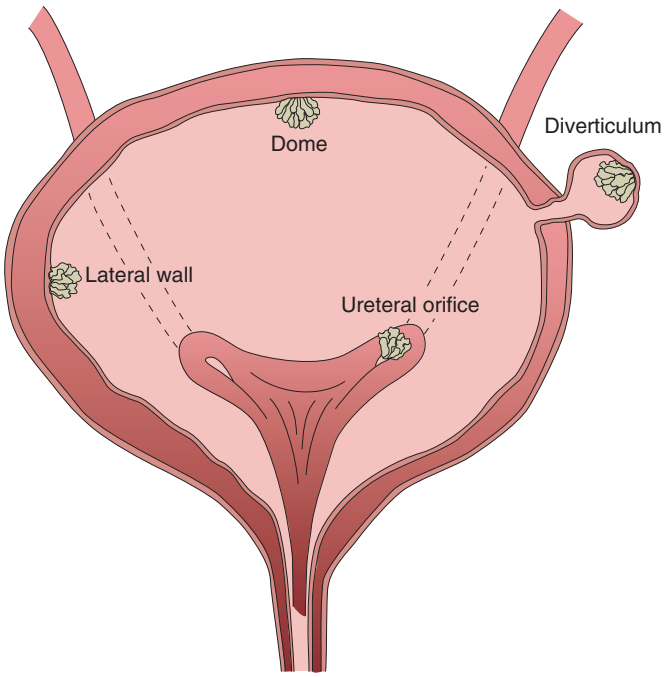

Figure 25.1 Office-based flexible cystoscopy allows the surgeon to map out the location of tumors and plan an appropriate resection. High-risk or challenging resection areas include the dome (perforation), lateral walls (obturator reflex), and ureteral orifice (obstruction).

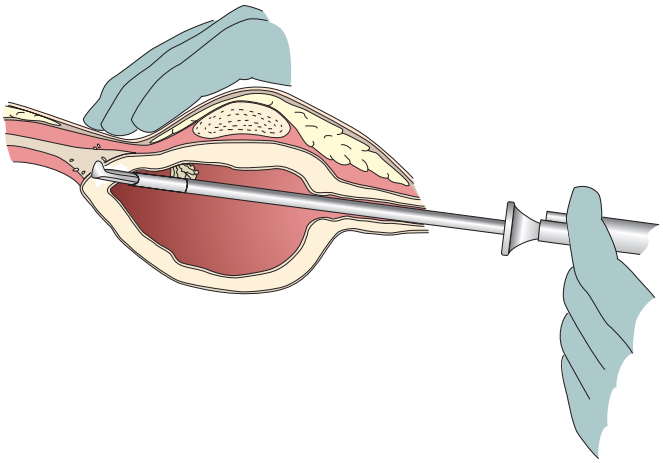

Figure 25.2 Resecting a tumor on the anterior wall of the bladder can be facilitated by using one's nonoperative hand to apply downward suprapubic pressure (anterior to posterior) to bring the area of interest into view. Care must be taken to control the end of the resectoscope at all times; the dome of the bladder can be perforated resulting in potential bowel injury.

Table 25.3 Challenging Bladder Tumor Locations

Location	Unique Risks	Preventative Measures
Ureteral orifice	Ureteral stricture	Resect with cutting current, use only pinpoint cautery
Bladder dome	Poor visualization Risk of perforation	Use continuous flow sheath Do not overdistend the bladder
Lateral wall	Obturator reflex	Do not overdistend bladder Decrease cut/coagulation current settings Obturator nerve block or general anesthesia with paralysis
Diverticulum	Risk of perforation	Do not resect too deeply

cauterizing large swaths of the bladder mucosa. Extensive use of electocautery over a large surface area can result in bladder contracture.[26] Recently, hexaminolevulinate (HAL) has begun to be used in combination with blue-light cystoscopy. This was approved for use in the United States in 2010, and since then experts recommend considering blue-light cystoscopy for assessment of CIS in patients with positive urine cytology, but negative white-light cystoscopy findings.[27]

TUMOR INVOLVING THE URETERAL ORIFICE

A tumor near or involving the ureteral orifice poses the challenge of obtaining complete resection and adequate hemostasis while preserving the caliber of the intramural ureter. Resecting with a purely cutting current and the judicious use of pinpoint cautery (with a right-angle cautery electrode) at the lowest effective setting for hemostasis make ureteral stricture unlikely.[28–32] If postoperative flank pain develops, a renal ultrasound can be performed to evaluate for hydroureteronephrosis. If present, a percutaneous nephrostomy tube can be placed. Tumor location at the ureteral orifice should not deter appropriate endoscopic management.

Reflux of urine into the upper tracts, which may occur with ureteral stenting (either anterograde or retrograde) or via vesicoureteral reflux following resection of the ureteral orifice, has been shown to increase the risk of seeding and tumor occurrence in the ureter and renal pelvis in some retrospective studies.[33–36] Conversely, Solsona and colleagues found no significant difference in upper tract recurrence patterns when refluxing and nonrefluxing patients were studied post-TURBT.[37] Regardless, close follow-up and monitoring for bladder as well as upper tract recurrence are advisable. Patients who symptomatically reflux after TURBT have been successfully managed with the endoscopic injection of bulking agents.[38] Surgical reimplantation of the refluxing ureter is also possible.

TUMOR ON THE ANTERIOR SURFACE

Resecting a lesion on the anterior surface of the bladder can be facilitated by using one's nonoperative hand to apply downward suprapubic pressure (compressing the anterior wall toward the posterior wall) on a bladder only partially filled with irrigant to allow better visualization of the tumor.[10,28]

TUMOR AT THE DOME

Resection at the bladder dome is challenging because of its anatomic relationships. It is the furthest point from the trigone, making visualization difficult; the more irrigant used to clear away blood the further the point of interest travels from the resectoscope. A continuous flow resectoscope sheath can be especially useful in this situation. Additionally, bowel can overlie the dome and be injured by transmural current from aggressive electrocautery. Lastly, the elderly in general, and postmenopausal women in particular, have significantly thinner bladder walls, making perforation an even greater concern. Taking care not to overdistend the bladder and paying meticulous attention to resection technique and depth are important when working at the dome.

TUMOR AT THE LATERAL WALL

In addition to the anesthetic options discussed above, there are several techniques the surgeon can employ to lessen the likelihood of a complication stemming from the inadvertent stimulation of the obturator nerve during resection of a laterally located tumor. Preventing overdistention, decreasing the cutting/coagulation current settings, and the use of intermittent cautery can lessen the incidence of adductor contraction.[10,14,39] The endoscopic injection of local anesthetic into the tumor base can also deliver an obturator nerve block if a percutaneous attempt was not made preoperatively.[39] Lastly, use of a bipolar resecting system restricts the flow of current to between the two electrodes of the resecting loop thus decreasing stimulation of the obturator nerve.[40,41]

TUMOR IN BLADDER DIVERTICULA

It is critical to remember the anatomic differences of bladder diverticula; by definition, they lack the muscularis propria layer making them thinner and much easier to perforate. This aspect can also make the pathologic staging of lesions within diverticula more difficult. Golijanin and colleagues from Memorial-Sloan Kettering Cancer Center have put forth post-TURBT staging and treatment recommendations based on their experience.[42] They suggest that conservative treatment is appropriate when the tumor is confined to the diverticula, it can be resected in its endoscopic entirety, and the patient is agreeable to close follow-up. For large or high-grade tumors, transurethral biopsy followed by partial cystectomy may be more prudent than attempting complete transurethral resection.[43]

RESTAGING TRANSURETHRAL RESECTION OF BLADDER TUMORS

American Urological Association (AUA) guidelines and European Association of Urology (EAU) guidelines recommend repeat resection for all patients with lamina propria invasion without muscularis propria present in the specimen.[44,45] In addition, EAU guidelines recommend restaging

in all T1 tumors as well as all high-grade Ta tumors.[44] According to AUA guidelines, repeat resection is considered for patients with high-grade Ta bladder cancer and T1 tumors with muscularis propria in the specimen.[45]

Restaging TURBT is typically performed 6–8 weeks following initial resection. Richstetter and colleagues found that residual tumor was found in 38% of restaging TURBT specimens.[46] The risks of restaging TURBT are similar to the risks of initial TURBT and include anesthetic risk, bleeding, perforation, potential delay of definitive therapy, and increased difficulty with future therapies such as cystectomy.[47]

"RADICAL" TRANSURETHRAL RESECTION OF BLADDER TUMORS FOR MUSCLE INVASIVE BLADDER CANCER

Bladder preservation surgery for select patients with bladder cancer is an option. This can be achieved with combined chemoradiation. The patients undergoing this approach must be willing to undergo lifelong surveillance cystoscopy, multiple TURBTs, and possible intravesical therapy. Recurrent T1 or T2 disease with restaging indicates that patients should not undergo bladder preservation. Candidates for bladder preservation are limited to those who are not surgical candidates due to comorbidities or those who refuse cystectomy.[48]

MONOPOLAR VERSUS BIPOLAR ELECTROCAUTERY

Both bipolar and monopolar electrocautery can be used for transurethral resection of bladder tumors. A recent study retroactively compared monopolar versus bipolar TURBT. The study examined perioperative complications in monopolar versus bipolar TURBT. They found that bipolar TURBT was associated with a lower incidence of bladder injury, with slightly shorter postoperative length of hospitalization and lower costs.[49] In contrast, Venkatramani and colleagues found that bipolar transurethral resection was not superior to monopolar with regard to obturator reflex, bladder perforation, or hemostasis.[50] However, other authors have reached the opposite conclusion.[40,41]

REDUCING CAUTERY ARTIFACT

While typically not considered a complication, excessive cautery artifact is both counterproductive and preventable. Cold-cup biopsies can be obtained prior to resection or fulguration. Adjustment of the resectoscope's power to the lowest effective setting combined with the preferential use of pure cutting current also aids the pathologist in his or her grading/staging evaluation.[26] Alternatively, obtaining hemostasis via fulguration after adequate specimens have been obtained helps to preserve the microscopic appearance of the samples. There are differing opinions on whether use of bipolar energy decreases the degree of cautery artifact when compared to monopolar resection.[50,51]

USE OF LASERS

Several different types of lasers have been used to treat bladder cancer, including neodymium-YAG, argon, potassium titanyl phosphate (KTP), and holmium-YAG.[52–55] The neodymium-YAG was found to be equally as effective as conventional TURBT in a prospective randomized trial, making it the laser of choice for some surgeons. Since laser energy vaporizes or coagulates the tissue it contacts, cold-cup biopsies should be performed prior to using the laser to resect a suspicious lesion. Likewise, determining tumor depth or muscular invasion is not readily possible with this type of resection, making patients with papillary, low-grade tumors the most appropriate population for this technology.[56]

A recent meta-analysis reviewed seven randomized control trials to evaluate transurethral laser therapy for nonmuscle invasive bladder cancer. The study demonstrated decreased obturator reflex, decreased bladder perforation, and decreased length of stay for laser therapy compared to TURBT.[57] Yang et al. also performed a retrospective analysis of laser vaporization versus TURBT and demonstrated that phosphate laser vaporization for nonmuscle invasive bladder cancer resulted in fewer perioperative complications and lower recurrence.[58] The most significant complication of laser use is the transmural passage of energy resulting in the perforation of an adjacent structure, such as an overlying loop of bowel, but this risk is low.[1,59,60]

Complications of Transurethral Resection of Bladder Tumors

Nearly all patients with bladder cancer will undergo TURBT at least once, making it the most common surgical therapy for this disease.[61] In studies of postoperative resource use, patients who have had TURBT often need additional medical services and readmission at higher rates than similar patients receiving other ambulatory procedures.[62,63] It is incumbent on all urologists to review their practice patterns in order to lessen the complications associated with this procedure.

OVERALL MORBIDITY AND MORTALITY

While TURBT is typically a safe and well-tolerated procedure, urologists must be mindful of the morbidity (5.1%[39] to 43.3%[64]) and mortality rates (0.8%[65] to 1.3%[64]) reported in the literature.

MECHANICAL DIFFICULTIES

The list of possible mechanical failures or difficulties that can occur during TURBT is myriad. The surest way to minimize this frustrating event is by carefully examining the selected equipment prior to initiating the procedure. Clear, timely communication between the surgeon and operative team (anesthesia and nursing) regarding unexpected findings, the need for replacement, additional or specialized equipment, or any adjustments in the estimated operative time can help increase efficiency and patient safety.

PROBLEMS OF INSTRUMENT INTRODUCTION

Barriers to effective transurethral surgery such as phimosis, meatal stenosis, or urethral stricture should be noted during

flexible office cystoscopy. If an operative intervention is needed to correct one of these conditions prior to TURBT, the surgical consent form should be amended and the necessary additional equipment selected. The techniques for circumcision, meatal dilation/meatoplasty, and optical internal urethrotomy (OIU) are described in greater detail in Chapter 26 and other surgical texts.[66] If for some reason office cystoscopy has not been performed prior to TURBT, the surgical consent should reflect the possible need for additional interventions.

POSTOPERATIVE BLEEDING

Postoperative bleeding is the most frequently reported complication of TURBT with rates ranging from 2% to 13%.[39,64,67] Intraoperative or postoperative bleeding is typically associated with large tumors and extensive or complex resections.[39,68] Careful examination of all resected areas under little to moderate distention is important so as not to miss small vessels temporarily tamponaded by a distended bladder. Unfortunately, coughing or bucking by the patient on emergence from general anesthesia can cause a significant increase in blood pressure resulting in a loss of hemostasis. Prompt management (removal of stimulus, sedation, or antihypertensives) can decrease systemic blood pressure and allow clot formation. If symptomatic hypotension or tachycardia ensues that does not respond to a fluid bolus, transfusion of packed red blood cells (PRBC), laboratory work (CBC, PT/PTT/INR, basic metabolic panel), and resuscitative measures are indicated.

Insertion of a transurethral catheter is common post-TURBT. Choosing a three-way catheter (20–24F) enables the use of CBI in the recovery room, if needed. It is critical to include orders for scheduled and PRN manual irrigation with 60–120 mL of normal saline via a 60-mL catheter-tipped syringe to remove any sediment or small blood clots that may have formed. The relatively small lumens of the inflow and outflow tracts in a three-way catheter, even in a large 24F catheter, can become clotted off easily and can lead to iatrogenic bladder perforation if the bladder continues to fill but is unable to drain. Continuous bladder irrigation should only be gravity fed; it must never be attached to an IV pump. Additionally, CBI is contraindicated with a bladder perforation. Titrating the flow for pink urine is usually adequate to limit clot formation. All nursing staff caring for a patient on CBI must be oriented to the apparatus and must strictly monitor and record the amount of irrigant instilled and returned and understand how to calculate urine output (total output − irrigant instilled = urine output).

If the degree of postoperative hemorrhage is significant and results in physiologic changes (hypotension, tachycardia) despite fluid resuscitation or repeated transfusions, returning the patient to the operating room for clot evacuation and fulguration is advisable. If hemorrhage is still uncontrollable, conversion to open cystectomy or embolization of the internal iliac artery by interventional radiology/vascular surgery may be necessary.[69–72] Selective and superselective embolization techniques have since been developed in the attempt to minimize potential morbidity.[73–75] In summary, the surgeon should first consider taking the patient back to the operating room for hemostasis. After determining that this is not advisable, other measures may be utilized.

BLEEDING DUE TO UNRESECTABLE DISEASE, RADIATION, OR CHEMOTHERAPY

Significant hematuria in an oncology patient, regardless of cause, will often result in urologic consultation. The urologist should also be familiar with intravesical agents that are commonly used to manage hemorrhagic cystitis due to unresectable tumor, prior external beam radiation, or chemotherapy treatment. Some of these patients may be poor operative candidates, making intravesical treatments valuable temporizing measures.

Use of a 1% alum solution (50 g of aluminum ammonium sulfate or aluminum potassium sulfate dissolved in 5 L sterile water)[76] functions as an astringent by causing protein precipitation and vasoconstriction.[77] This can be delivered in the same manner as saline CBI. The alum will cause a precipitate to form, so manual irrigation via a piston syringe (60-mL catheter-tipped syringe) will be required to ensure adequate outflow. Aluminum absorption is possible, especially if large portions of the bladder have been resected. Signs of aluminum toxicity, which is more likely in patients with renal dysfunction and can be fatal, include lethargy, confusion, seizures, and metabolic acidosis.[76,78] Alum irrigation should be stopped immediately and bloodwork (serum aluminum level) sent.

Chapter 26 discusses the use of intravenous and oral aminocaproic acid (Amicar; an inhibitor of plasminogen activators, which interferes with fibrinolysis) in the management of post-TURP bleeding. The same regimen can be employed post-TURBT or mixed as a solution for use with CBI. It is important to rule out disseminated intravascular coagulation (DIC) as the source of bleeding by evaluating the patient's platelet count and fibrinogen level prior to initiating aminocaproic acid therapy.[79]

Instillation of intravesical formalin has been used to manage refractory hematuria due to advanced bladder cancer and hemorrhagic cystitis due to external beam radiation or cyclophosphamide chemotherapy.[80] Formalin causes protein denaturation and precipitation in the bladder mucosa resulting in blood vessel occlusion.[81] This treatment should not be considered first-line therapy, and it is not advisable to use it in the immediate postoperative period because absorption is possible. Pretreatment cystography is recommended to evaluate for reflux and bladder integrity.[76] Complications, both local and systemic, include bladder contracture, urinary incontinence, vesicoureteral reflux, ureteral stricture and obstruction, acute tubular necrosis, vesicovaginal or enterovesical fistula formation, myocardial injury, and bladder rupture.[82–90] Bladder fibrosis with reduced capacity and resultant urinary frequency is a common side effect.[76]

BLADDER PERFORATION

Bladder perforation is one of the most significant complications associated with TURBT. It can result in numerous sequelae including hemorrhage, TUR syndrome, infection, the need for urgent open surgery, tumor spillage, peritonitis, and death.[64,91] Mindful assessment of inflow and outflow

irrigant volumes during extensive resection may prompt the recognition of serious occult bladder perforations. Bladder perforation typically occurs extraperitoneally, which can usually be managed with drainage via a large caliber urethral catheter (20–24F) for 7–14 days with a cystogram prior to removal. For large intraperitoneal perforations, surgical repair should be performed. This should be performed especially if tumor resection is incomplete and the risk of tumor spillage is high. Drain placement by interventional radiology may be required if there is a large amount of extravasated irrigation fluid.

The incidence of post-TURBT perforation may be underestimated. In a prospective study, Balbay and colleagues performed cystography after TURBT in a series of 36 patients with suspected bladder cancer.[92] They found contrast extravasation in 58.3% of their patients, compared to other series reporting perforation in only 1–5% of cases.[39,93,94] The significance of subclinical perforations detected by cystography is unclear. In an editorial accompanying the Balbay report, Soloway raises concerns about the oncologic efficacy of "radical TUR," meaning that resecting to the point of perforation, even if done deliberately, poses a risk to the patient from tumor spillage.[92] Regardless, one must be cognizant of a possible bladder perforation when performing aggressive resections.

Skolarikos and colleagues attempted to determine the impact of bladder perforation during TURBT on extravesical tumor recurrence by examining the records of over 3400 patients.[93] They found the incidence of perforation to be only 1% and identified several risk factors associated with extravesical tumor recurrence. The most significant risk factor was the need for an open surgical repair of the perforation, followed by the bladder defect being located intraperitoneally, and the tumor size being in excess of 3 cm.[93] They also noted that patients with extravesical disease after perforation repair fared far worse than the rest of the cohort. In contrast, other studies examining outcomes after TURBT-associated perforation did not detect an increase in extravesical disease frequency or poorer outcomes.[39,95]

Golan and colleagues performed a retrospective review of TURBTs performed at their institution from 1996 to 2008. They identified 15 patients who required open surgical repair of their bladder perforation. They found that bladder perforation requiring open surgical repair is more likely to occur in elderly patients with posterior wall tumors who had prior TURBTs and prior intravesical instillations.[96]

While rare, it seems plausible that perforation during TURBT can lead to extravesical disease, which carries with it a dismal prognosis. It is unclear if perforation should prompt consideration of systemic treatment in an attempt to mitigate any increased risk of soft tissue seeding.[93] Additionally, the use of postresection intravesical chemotherapy is contraindicated in the presence of perforation. The loss of the demonstrated risk-reduction benefit of postoperative intravesical chemotherapy combined with a theoretical increase in disease progression due to perforation reinforces the severity of this complication.

TRANSURETHRAL RESECTION SYNDROME

While TUR syndrome is covered in-depth in Chapter 26, there are several differences in its etiology and presentation that should be considered when this complication arises after TURBT. Post-TURBT hyponatremia is usually due to bladder perforation and the extravasation/extravesical absorption of irrigant fluid, in contrast to absorption across open prostatic venous sinuses during TURP. Since the irrigant is not being directly introduced into the patient's circulatory system and must be absorbed across the peritoneum, the initial presentation may be delayed. Dorotta and colleagues report a case series of four such events and noted that the time to serum sodium nadir was 2–9 hours[91] compared to 1–6 hours[97–100] following prostatic resection. Hyponatremia, intravascular hypovolemia with an increase in total body water, hypotension, oliguria, acute renal failure, metabolic acidosis, and mental status changes are all described in TURBT syndrome.[91]

Early detection, rapid assessment, and immediate treatment are critical when faced with this complication. Management is nearly identical to that for TURP syndrome described in Chapter 26. The procedure should be halted, a bladder catheter left in place, "STAT" serum chemistries sent, and resuscitation with normal saline started. The patient's sodium deficit should be calculated and serial measurements made to ensure the proper rate of correction. Use of hypertonic saline poses the risk of central pontine myelinolysis caused by rapid electrolyte and fluid shifts in the brain, and requires consultation with specialists such as in nephrology or critical care medicine. Diuretics (e.g., furosemide) can facilitate hemoconcentration but should only be used in a euvolemic patient. Drainage of the peritoneum or retroperitoneum can be accomplished via an open surgical procedure with simultaneous repair of the bladder perforation or by placement of a percutaneous drain under ultrasonic guidance by interventional radiology; surgical repair of the bladder can then be performed at a later date once the patient has been stabilized. Transferring the patient to a monitored setting such as an intensive care unit is advisable.

INFECTION

Dysuria is common after transurethral bladder surgery, so patients may have difficulty differentiating the expected symptoms from infection. Likewise, a dipstick urine analysis will be difficult to interpret. A short course of postoperative prophylaxis with oral antibiotics is reasonable until the bladder mucosa has had an opportunity to heal.[9] A suspected infection should be cultured immediately. Empiric antibiotics can be started and tailored to the sensitivities once they are available.

URINARY RETENTION

Instrumentation, anesthesia (general, spinal, or epidural), and postoperative narcotics can all lead to acute urinary retention, especially in men. While many patients are discharged from the hospital or surgical center with a catheter in place, most who undergo resection of superficial and/or small to medium lesions may not require an indwelling Foley. Recovery room orders should clearly indicate that patients must void adequately prior to discharge (specify both a volume and the time in which it must be passed), otherwise a urethral catheter should be inserted and an

office voiding trial performed. Men who take alpha-1 antagonists or 5α-reductase inhibitors should continue on their medications at the usual prescribed dose. Urinary retention that occurs weeks to months post-TURBT should be investigated with cystoscopy to evaluate for urethral stricture, bladder neck contracture, or tumor recurrence and managed appropriately.

THE EFFECT OF TRAINEE PARTICIPATION ON TRANSURETHRAL RESECTION OF BLADDER TUMOR COMPLICATIONS

Transurethral resections of bladder tumor are frequently done in an academic setting and involve residents or fellows who are learning to perform the procedure. Nieder and colleagues prospectively evaluated all TURBTs performed in part by residents or fellows under direct attending supervision. Intraoperative complications were evaluated. Of the 173 TURBTs performed at their institution there were 10 complications including four patients with hematuria requiring transfusion, six extraperitoneal perforations, and two intraperitoneal perforations. This was a complication rate of 5.8%, which is comparable to other studies that did not include residents.[94]

In contrast, Allard and colleagues performed an analysis of all transurethral surgeries (including both TURPs and TURBTs) in the NSQIP user files.[101] They assessed the effect of trainee involvement comparing post graduate year (PGY) 1-2, PGY 3-4, PGY 5, and above versus attending-only resections. In multivariate analysis they found that resident involvement increased the operative time and hospital readmissions within 30 days. Resident involvement was not associated with increased overall complications or need for reoperation.[101]

Complications of Post Transurethral Resection of Bladder Tumor Intravesical Chemotherapy

Several series have shown that intravesical chemotherapy (e.g., mitomycin c) administered in the immediate postoperative period provides a significant reduction in cancer recurrence (50% at 2 years) for patients with superficial disease.[102–105] It is recommended that patients receive such treatment within 6 hours of resection unless there is suspicion of bladder perforation or the patient has an allergy to the chemotherapeutic agent of choice.[106]

The common side effects of intravesical chemotherapy include irritative voiding symptoms consistent with cystitis (dysuria, frequency, and hematuria).[107] All of the agents currently used can result in fibrosis and contracture of the bladder, usually due to chronic exposure, and thiotepa has been shown to cause bone marrow suppression if absorbed.[108] Operating room and postanesthesia care unit staff must also be educated regarding the safe administration, monitoring, and disposal of intravesical chemotherapy agents and supplies. Intravesical BCG is absolutely contraindicated in the postoperative setting; use of this agent can result in systemic sepsis (BCG-osis) and death. BCG should not be given until the bladder epithelium has been allowed to heal for at least 14 days and gross hematuria has resolved.[109]

Conclusions

Transurethral resection of bladder tumor continues to play an integral role in the management of bladder cancer. Careful preoperative preparation, attention to operative technique, and diligent postoperative monitoring and follow-up will help decrease the risk of morbidity and mortality while maximizing patient benefit.

Chapter 25 Questions

1. At the start of your first case, a transurethral resection of bladder tumor (TURBT), no current is produced when the resectoscope foot pedal is pressed. Which of the following actions should you take?
   a. Confirm that the patient is appropriately grounded
   b. Check that the electrocautery generator is plugged in/properly connected
   c. Ensure that the resectoscope is properly connected to the generator
   d. Confirm that the irrigant being used is not saline
   e. All of the above

2. You are performing a TURBT on a man with a tumor in the expected location of the right ureteral orifice (UO). The left ureteral orifice is clearly visible. Which of the following options is most appropriate?
   a. Have the anesthesia team give a diuretic, such as furosemide, in an attempt to see urine effluxing from the right UO
   b. Attempt blind catheterization of the obscured UO with a Bentson guidewire
   c. Resect the tumor using pure cutting current
   d. Abort the procedure and order an intravenous pyelogram (IVP) to better define the anatomy
   e. Do not resect the tumor but instill intravesical chemotherapy instead

3. Which of the following laboratory studies is mandatory prior to TURBT?
   a. Liver function tests (LFTs)
   b. Complete blood count (CBC)
   c. Basic metabolic panel/Chem-7
   d. Urine culture
   e. Coagulation studies (PT/PTT/INR)

4. When endoscopically managing a tumor located on the anterior wall of the bladder, the surgeon should do which of the following to facilitate resection?
   a. Apply anterior-to-posterior suprapubic pressure with the nonoperative hand
   b. Increase the height of the irrigant fluid in order to maximally distend the bladder
   c. Increase the electrocautery current settings
   d. Select a larger resectoscope loop
   e. Perform "blind" resection (i.e., without direct visualization of the tumor)

5. Four hours after the completion of a large, deep, complex TURBT, you are called by a nurse in the ambulatory surgery center about your patient. He reports that your patient is lethargic and clumsy with an altered mental status. Which of the following should be done immediately?
   a. Evaluate the patient
   b. Obtain STAT serum chemistries
   c. Confirm the type of irrigant used during the resection
   d. Review the patient's history and recent medications administered
   e. All of the above

6. An elderly woman who underwent a TURBT for tumor at the bladder dome complains of significant abdominal pain shortly after the procedure. Which of the following studies is most helpful in ruling out a serious complication?
   a. Renal ultrasound
   b. Cystogram
   c. CBC
   d. Abdominal free air series
   e. Repeat cystoscopy

7. At the completion of a TURBT, there is some oozing from the resection bed but hemostasis appears adequate. During emergence from anesthesia, the patient "bucks" against the endotracheal tube and his blood pressure increases significantly. In the PACU frank blood is draining from the Foley catheter. Irrigation with normal saline is initiated but the bleeding persists, eventually resulting in hemodynamic instability. The best course of action is:
   a. Place the Foley catheter on tension
   b. Instill Amicar intravesically
   c. Overdistend the bladder with saline to tamponade the bleeding vessels
   d. Take the patient back to the OR for repeat cystoscopy/clot evacuation/fulguration
   e. Perform an angiogram to localize the bleeding

8. When resecting a tumor on the lateral wall of the bladder, the risk of sudden leg adduction (obturator reflex) can be lessened by which of the following?
   a. General anesthesia with the use of a paralytic
   b. Preoperative percutaneous obturator nerve block
   c. Endoscopic (pre-TURBT) injection of the tumor base with local anesthetic
   d. Use of intermittent electrocautery during resection
   e. All of the above

9. Which of the following is a contraindication to immediate post-TURBT intravesical chemotherapy, such as mitomycin C?
   a. Tumor resected from multiple areas within the bladder
   b. Planned re-TURBT in 2 weeks for additional staging information
   c. Patient age >80 years
   d. Suspected small perforation when the deep resection margin was biopsied
   e. Outpatient surgery status (patient is to be discharged the day of surgery)

10. Informed consent for TURBT should include which of the following risks:
    a. Bleeding
    b. Infection
    c. Bladder perforation
    d. Need for additional surgery/procedures/treatments
    e. All of the above

Case Studies

CASE 1

You are managing a 73-year-old woman who has undergone one previous TURBT for superficial bladder cancer that was resected in its endoscopic entirety. She returns to your clinic after spending the winter in Florida; she recently had an episode of gross hematuria but did not seek medical attention or contact your office. Her urinalysis is positive for microscopic hematuria but negative for signs of infection. Office cystoscopy reveals recurrent disease at the dome, a larger tumor on the left lateral wall, and several papillary fronds near the left ureteral orifice.

1. What course of action would you suggest to your patient?
   a. Intravesical BCG
   b. Renal ultrasound
   c. Intravenous gemcitabine/cisplatin systemic chemotherapy
   d. Transurethral resection of the bladder tumors in the operating room
   e. Bladder biopsy only

This patient undergoes the appropriate preoperative evaluation and is consented for TURBT with intravesical chemotherapy. She does not have significant cardiovascular or pulmonary disease. The anesthesiologist contacts you to see if you have a preference regarding the type of anesthetic he uses.

2. You reply:
   a. The anesthesia team can choose the method they feel is best
   b. Let the patient decide
   c. General anesthesia
   d. Conscious sedation
   e. Spinal anesthesia

You suggest that general anesthesia be used so that a muscle relaxant (paralytic) can be used to prevent stimulation of the obturator nerve during the resection of the left lateral wall tumor. Alternatively, a percutaneous obturator nerve block could be performed preoperatively or local anesthetic could be infiltrated into the base of the tumor endoscopically.

You decide to resect the tumor at the dome first. This is facilitated by applying downward suprapubic pressure (anterior to posterior) with your nonoperative hand. Once the resection is complete, a cold-cup biopsy of the deep margin is obtained and submitted separately to pathology.

3. Which of the following is most accurate with regard to managing the several small papillary fronds around the left ureteral orifice?
   a. Do not treat this area surgically because it could result in ureteral obstruction
   b. Use cold-cup biopsy forceps to remove the tumors and focal electrocautery to fulgurate the tumor base
   c. Resect the entire ureteral orifice using a blended cutting/coagulating current
   d. Fulgurate the area copiously with a high level of coagulating current and then place a retrograde ureteral stent
   e. Attempt to pass an access catheter into the ureter at the conclusion of the case to ensure the ureteral orifice is open

You now turn your attention to the largest tumor located on the left lateral wall. The tumor is fairly vascular and it takes longer than anticipated to resect it completely and obtain hemostasis even though you have been using sterile water as the irrigant. At the conclusion of the procedure you place a three-way Foley catheter for continuous bladder irrigation because of your concern for clot retention. The total procedure time is now over 1.5 hours.

4. In this setting, what intravesical chemotherapy should be used?
   a. BCG
   b. Thiotepa
   c. Mitomycin C
   d. Gemcitabine
   e. No intravesical therapy

The nurses from the ambulatory care unit call to inform you that the patient has not been making adequate urine. They were concerned that her Foley was clotted so they have been vigorously irrigating her catheter by hand with a 60-mL catheter-tipped syringe. When you review the nursing flowsheets you see a sizeable discrepancy between the volume of saline placed into her bladder and what has been documented in the Foley bag. Her abdomen is obviously distended, and she states that she feels bloated. She is mentating appropriately.

5. To investigate the most likely cause of these findings you should:
   a. Obtain a KUB x-ray
   b. Order a CT scan of the abdomen and pelvis
   c. Perform flexible cystoscopy at the bedside
   d. Obtain a cystogram
   e. Obtain an ultrasound

The diagnostic evaluation reveals a perforation at the dome, likely caused by the deep biopsy performed after the tumor was resected, with extravasation of contrast into the peritoneum.

6. The next steps to take include:
   a. Ensure adequate bladder decompression, stop intravesical irrigation
   b. Emergent surgery
   c. Obtain STAT laboratory studies, specifically serum sodium
   d. Monitor the patient closely for signs of TURBT-syndrome
   e. All of the above

CASE 2

Two hours after completing cystoscopy, biopsies, and fulguration of several erythematous bladder lesions in a

68-year-old diabetic man who has a 50-pack/year history of cigarette smoking, you are notified that your patient is febrile to 39.2°C, tachycardic, and hypotensive.

1. You next:
   a. Evaluate the patient
   b. Review his preoperative laboratory studies
   c. Confirm that he received the ordered preoperative antibiotic prophylaxis
   d. Perform urine culture if it was not performed preoperatively
   e. All of the above

You note that his procedure was originally scheduled for 1 month ago. His case was cancelled because the patient was ill with a viral upper respiratory infection. His urinalysis was negative 2 weeks prior to that date but another more recent sample was never sent. Ciprofloxacin 400 mg IV was administered, as ordered, prior to the procedure.
When you evaluate the patient he is pale, diaphoretic, tachycardic, and complaining of chills. His blood pressure is 84/54 mmHg but he is alert and oriented.

2. Appropriate management includes:
   a. Fluid resuscitation and transfer to an appropriate setting for monitoring
   b. Blood and urine cultures
   c. Broad-spectrum intravenous antibiotics
   d. Admit patient for observation
   e. All of the above

Answers

1. **e.** Each of the options above is a common point of equipment malfunction resulting in a loss of current.
2. **c.** Resecting a tumor at the ureteral orifice should be performed carefully with a pure cutting current with the goal of removing all suspicious tissue. The patient should be monitored closely for signs/symptoms of ureteral obstruction or symptomatic vesicoureteral reflux.
3. **d.** While each of these tests may be indicated in many if not most patients, documenting that the patient has sterile urine prior to undertaking transurethral surgery is mandatory.
4. **a.** Applying suprapubic pressure with one's nonoperative hand in the anterior-to-posterior direction over a partially filled bladder can bring a tumor on the anterior wall into view.
5. **e.** TURBT syndrome is a severe complication that must be recognized and managed promptly.
6. **b.** A suspected bladder perforation is best assessed by a cystogram.
7. **d.** Post-TURBT hemorrhage that results in hemodynamic instability is best managed in the operating room by repeat cystoscopy, clot evacuation, and fulguration.
8. **e.** Stimulation of the obturator nerve during TURBT can result in imprecise resection, increased bleeding, and bladder perforation. Appropriate preprocedure planning based on tumor location can minimize this risk.
9. **d.** Bladder perforation is a contraindication to intravesical chemotherapy. BCG is *never* used in the immediate postoperative setting due to the risk of absorption, sepsis, and death.
10. **e.** While TURBT is a commonly performed and usually well-tolerated procedure, it is associated with risks ranging from bleeding, infection, and bladder perforation.

CASE 1

1. **d.** Resection is indicated, in the setting of recurrent superficial bladder cancer, prior to consideration of any form of intravesical therapy. Given the described presence of tumor in the dome, and a large tumor in the lateral wall of the bladder, the resection in the operating room is most appropriate, and more likely to be efficacious than office resection. Bladder biopsy prior to resection would not alter management in this setting. Ultrasound to rule out hydronephrosis would only be indicated if obstruction is suspected.
2. **c.** General anesthesia should be used so that a muscle relaxant (paralytic) can be used to prevent stimulation of the obturator nerve during the resection of the left lateral wall tumor. Alternatively, a percutaneous obturator nerve block could be performed preoperatively or local anesthetic could be infiltrated into the base of the tumor endoscopically.
3. **b.** Since there are only a few frond-like tumors near the UO, they can be removed with the biopsy forceps and hemostasis obtained with focal electrocautery. If the UO was involved extensively, resecting the tumor with a pure cutting current is appropriate. Postoperatively, a percutaneous nephrostomy tube could be employed if ureteral obstruction occurred.
4. **e.** Bleeding that requires the use of continuous bladder irrigation (CBI, also known as a Murphy drip) is a contraindication to intravesical chemotherapy. BCG should never be used in the immediate postoperative setting.
5. **d.** Given the presence of decreased urethral catheter output and return of irrigant, along with increasing abdominal distention, an intraperitoneal bladder rupture at the site of dome resection should be considered. This may have been the result of undetected perforation at the time of resection, secondary perforation at the time of clot retention in the recovery room, or overly aggressive irrigation. In this setting, a cystogram would be he most likely to demonstrate the presence of a perforation, along with its size and location. A CT scan of the abdomen can be informative, and might demonstrate urinary ascites in this case, but it would not likely be diagnostic without a distention cystogram performed simultaneoulsy (CT cystogram would also be an acceptable test to consider).
6. **e.** This patient is at risk for TURBT syndrome, peritonitis, and up-staging of her disease. The sterile water irrigant used during the resection, as well as the normal saline from the postoperative CBI, will need to be removed from the peritoneal space and the bladder defect repaired. This can be accomplished through either an open or laparoscopic approach, based on the

experience and preference of the surgeon. The patient should be consented for emergency surgery and returned to the OR as soon as possible.

CASE 2

1. **e.** It is critical to ensure that the patient's urine is sterile prior to undergoing any transurethral surgery whenever possible.
2. **e.** Urosepsis must be promptly identified and aggressively managed. Sepsis can trigger other complications such as demand-mediated myocardial ischemia, renal failure, coagulopathy, etc.
