26 Complications of Endoscopic Procedures for Benign Prostatic Hyperplasia

TRACY MARIEN, MUSTAFA KADIHASANOGLU, and NICOLE L. MILLER

CHAPTER OUTLINE

Introduction
Nonspecific Complications of Endoscopic Procedures for BPH
Intraoperative
- Intraoperative Bleeding
- Transurethral Resection Syndrome
- False Urethral Passage
- Injury to the Bladder or Ureteral Orifices
- Injury Beyond the Prostate
- Challenges to Initiating Treatment

Postoperative
- Postoperative Bleeding
- Infection
- Urinary Incontinence
- Urethral Stricture
- Bladder Neck Contracture
- Meatal Stenosis
- Retrograde Ejaculation
- Erectile Dysfunction
- Need for Retreatment

Miscellaneous
Conclusions
Chapter 26 Questions and Answers

KEY POINTS

1. While there are multiple ways to approach the surgical management of benign prostatic hyperplasia (BPH), endoscopic techniques are by far the most common.
2. Endoscopic techniques to manage BPH include transurethral microwave therapy (TUMT), transurethral needle ablation (TUNA), prostatic urethral lift (PUL), transurethral resection of the prostate with monopolar or bipolar energy, bipolar vaporization of the prostate, transurethral incision of the prostate (TUIP), laser vaporization of the prostate, and laser enucleation of the prostate.
3. Complications of endoscopic BPH surgery that patients should be counseled on preoperatively include bleeding, transurethral resection syndrome, infection, injury to adjacent structures such as the bladder or ureteral orifices, urinary incontinence, urethral stricture, bladder neck contracture, meatal stenosis, erectile dysfunction and retrograde ejaculation.
4. Overall, the incidence of most of these complications is quite low with the exception of retrograde ejaculation which occurs at a rate of 50% or higher with many approaches. TUIP, PUL, TUNA, and TUMT preserve ejaculatory function at a higher rate.
5. It is essential to understand the risk of surgical complications by procedure type and adequately counsel patients as to these risks as part of a shared decision making process. Knowledge of landmarks, excellent technique, and careful patient counseling will minimize complications, result in excellent outcomes, and increase patient satisfaction.

Introduction

Benign prostatic hyperplasia (BPH) is one of the most common diseases of aging men. Fifty percent of men between the ages of 51 and 60 years old have pathologic benign prostatic hyperplasia.[1] Surgical treatment options for BPH include open, laparoscopic, endovascular, and endoscopic techniques. Open and laparoscopic simple prostatectomy techniques have the disadvantages of being more invasive, with a higher risk of blood loss, and the need for prolonged catheterization and hospitalization.[2–5] These approaches are reserved for very large prostates, typically greater than 80–100 g. Recently, prostatic arterial embolization has gained some interest as a minimally invasive approach to the management of BPH.[6] Further studies are necessary to validate the effectiveness and durability of this approach.

Endoscopic techniques comprise the most common approach for the surgical management of BPH. These endoscopic procedures include monopolar and bipolar transurethral resection of the prostate (TURP) (mTURP and bTURP, respectively), bipolar vaporization of the prostate (BVP) using the mushroom electrode, laser vaporization/ablation, laser enucleation of the prostate, transurethral incision of the prostate (TUIP), transurethral microwave therapy (TUMT), transurethral needle ablation therapy (TUNA), and prostatic urethral lift (PUL). Techniques such as interstitial laser coagulation and transurethral ethanol injection are antiquated, rarely performed, and will not be reviewed here. This chapter will focus on the prevention and management of complications following the aforementioned endoscopic procedures for BPH. When reviewing laser vaporization procedures or photovaporization of the prostate (PVP), the discussion will focus on GreenLight laser (Boston Scientific, Marborough, MA), also known as the potassium titanyl phosphate (KTP) laser, as it is the most utilized laser for this approach. Similarly, in terms of enucleation procedures, this chapter will focus on holmium laser enucleation of the prostate (HoLEP). The safety and efficacy of thulium and diode lasers for prostatic enucleation are currently being studied and compared to HoLEP. The rates of well-studied complications are reported in Table 26.1 and Table 26.2.

Table 26.1 Perioperative Complications

	Blood Transfusion	TUR Syndrome	Capsular Perforation
mTURP	1.5–20%[32,34,62,97–100]	1.8–21%[32,34,97,98]	2.7–16.7%[34,97,100]
bTURP	0–2.7%[33,34,99–102]	0%[32,33,97]	7.1%[97]
HoLEP	0–1.8%[45,51,62,98,103]	0–6.1%[45,51,63,98]	1.5–9.6%[45,51]

Nonspecific Complications of Endoscopic Procedures for BPH

INTRAOPERATIVE

Intraoperative Bleeding

The prostate is a highly vascular organ and some degree of bleeding is expected during any surgical approach to BPH. Hemorrhage is the main cause of surgical vision loss, which can lead to prolonged operative time, capsular perforation, fluid absorption, and excessive use of irrigation fluids, all of which are risk factors for transurethral resection syndrome (TURS) and sepsis.[7] The risk of bleeding increases with larger prostate size, longer operative time, increasing tissue resected, general anesthesia, positive urine culture, indwelling catheter, and the use of antiplatelet therapy or anticoagulation.[7–12] While several older series have demonstrated less blood loss with regional anesthesia, the mechanism for this is not well understood.[13,14] The rate of blood transfusion following endoscopic BPH surgery is low and depends on the type of procedure performed (see Table 26.1). A meta-analysis comparing HoLEP and TURP found a lower transfusion rate in those undergoing prostatic enucleation.[15]

Several steps can be taken preoperatively to decrease the risk of excess bleeding and potential blood transfusion. First, platelet count and coagulation panel are obtained and any abnormalities addressed preoperatively. Assessing for preoperative anemia will aid in counseling the patient on the risk of perioperative blood transfusion. A type and screen should be sent preoperatively to facilitate timely transfusion if necessary. Second, if the patient is taking antiplatelet therapy or anticoagulants, a discussion must take place with his primary care provider (PCP) as to whether it is safe to hold and/or bridge these medications. If the procedure must be done on antiplatelet or anticoagulants, then laser and bipolar techniques have been shown to provide the best hemostasis.[16–18] Men undergoing PVP and bTURP have less bleeding, need for blood transfusions, and postoperative clot retention compared to those undergoing monopolar TURP in some series.[19,20] Preoperatively, the patient is carefully counseled on the risk of bleeding. If

Table 26.2 Postoperative Complications[20,32–34,45,51,62–64,77,82,88–91,94,97–174]

	Urinary Tract Infection	Urethral Stricture	Bladder Neck Contracture	Stress Incontinence	Retrograde Ejaculation	Erectile Function		Retreatment

PUL	2.9–12.12%	0%	0%	0%	0%	0%	nwd	1.9–20%

bTURP, bipolar TURP; BVP, bipolar vaporization of the prostate; HoLEP, Holmium laser enucleation of the prostate; mTURP, monopolar TURP; nwd, not well described; PUL, prostatic urethral lift; PVP, photoselective vaporization of the prostate; TUIP, transurethral incision of the prostate; TUMT, transurethral microwave therapy; TUNA, transurethral needle ablation

the risk of bleeding is high due to medical comorbidities and/or the need to remain on blood thinners, medical therapy or management with catheterization may be more prudent. The use of 5α-reductase inhibitors prior to TURP has not consistently been shown to reduce blood loss or the need for transfusion, and thus this approach in an attempt to reduce perioperative bleeding is not recommended by the AUA guidelines.[21–25]

Intraoperative techniques to prevent bleeding complications include avoiding capsular perforation and entry into venous sinuses where bleeding is difficult to control. Additionally, controlling bleeding vessels as they are encountered and aiming for a shorter operative time will result in less blood loss. If electrocautery is being used some advocate first fulgurating all of the friable mucosa with the button electrode to prevent bleeding from this friable tissue prior to loop resection of adenoma.[26]

When significant intraoperative bleeding is encountered, the best way to obtain hemostasis, decrease blood loss, and avoid the need for a staged procedure is to advance the scope into the bladder and slowly pull it back into the prostatic fossa to identify the bleeding vessels and fulgurate or laser. If arterial bleeding is directed straight at the lens, an optimal angle to visualize the bleeding stump must be found to achieve hemostasis.[12] Simultaneous digital rectal manipulation may help to expose vessels over the prostate floor.[12] Venous bleeding is usually dark red and may be found in areas of capsular perforation.[12,27] Small venous bleeders can be controlled with direct pressure from a three-way Foley catheter. Excessive coagulation is avoided in areas of capsular perforation to decrease the risk of aggravating this defect. Hemostasis is assessed at the end of the case with the bladder minimally full, irrigation flow off, and patient normotensive. Hypotension at the end of the procedure can mask arterial bleeding. Blood work can be performed intraoperatively as well to monitor for anemia if there is concern for significant blood loss.

Transurethral Resection Syndrome

TURS is a serious and potentially life-threatening complication of mTURP as one of the requirements of monopolar resection is the use of hypotonic fluid, typically glycine or sorbitol. TURS occurs with early perforation of the capsule and venous sinuses resulting in the absorption of hypotonic solution and a dilutional hyponatremia. These patients can be confused and disoriented and may experience nausea, vomiting, seizures, blurred vision, bradycardia, and hypotension. The incidence of mild-to-moderate TURS has decreased during the last few decades from 0.5–8% to 0–1.4% secondary to the use of saline irrigant with laser and bipolar techniques.[9,28–35] Several meta-analyses of monopolar and bipolar resection have reported a significant decrease in TURS, with no patient developing TURS following bTURP.[19,36]

TURS may be seen from as early as 15 minutes after the start of resection and up to 24 hours postoperatively.[37,38] Hyponatremia can be very severe and result in significant morbidity and even mortality at a rate up to 50% when the sodium concentration drops below 120 mEq/L.[39] Hyponatremia and hypoosmolality result in acute cerebral or bronchial edema secondary to large absorption of fluid and expansion of extracellular fluid. TURS most commonly occurs when 1.5% glycine is used as the irrigant fluid during mTURPs. This irrigant is nonconductive, nonhemolytic, and hypotonic with an osmolality of about 220 mmol/L irrigant. Excessive absorption of glycine solution results in TURS in 5–20% of mTURPs.[40]

The best way to prevent TURS is to avoid endoscopic procedures using hypotonic solutions. If mTURP must be performed, then it is important to avoid deep resections and extravasation, which will increase the amount of fluid absorbed. If a venous sinus is opened or capsular perforation has occurred, hemostasis is achieved and the procedure aborted. When performing mTURP, even if capsular perforation or major venous sinuses are not encountered, the procedure is generally limited to 60–90 minutes in order to minimize the amount of fluid absorbed and decrease the risk of TURS. Therefore, if a larger prostate is approached with TURP, the patient is counseled that he may need to be treated in a staged manner and if the prostate is very large, a simple prostatectomy can be considered if mTURP is the only endoscopic surgical option. During the procedure, anesthesia may periodically send blood gases to check electrolytes and the procedure may be aborted if the serum sodium is low.

Besides limiting operative time and selecting patients with smaller prostate volumes, another method to prevent TURS includes minimizing irrigant fluid pressure.[40,41] Techniques that have been described to decrease fluid pressure at the time of TURP include the standard use of a continuous flow resectoscope that allows drainage out of the scope (Iglesias), suprapubic fluid evacuation using a Reuter's trocar or via suprapubic catheterization, and intermittent drainage of irrigant fluid.[37,40] Irrigation fluid is always kept on gravity and not placed under pressure. The urologist can also attempt to monitor fluid absorption. This is done by calculating the difference between irrigation fluid used and the volume of fluid that drains from the resectoscope and into the collection bag. Accurate measurement of fluid absorption may be challenging given the mixture of blood and urine and the inevitable spillage of irrigant fluid onto the floor.

It is prudent to monitor the serum sodium postoperatively for TURS for all men undergoing endoscopic BPH treatments when hypotonic fluids such as glycine are used. If serum sodium is only mildly decreased (about 5 mEq/L) on postoperative lab work and the patient is asymptomatic, then no specific therapy is indicated. If renal function is normal, then the hyponatremia will correct with the natural excretion of excess water. If there is concern for pulmonary congestion, a loop diuretic can be given. The management of patients with symptomatic hyponatremia is variable depending on the severity. For patients with severe hyponatremia, low serum osmolality, and/or cerebral edema, hypertonic saline can be considered. Hypertonic solution reduces cerebral edema and replaces urinary sodium losses that result from the osmotic diuresis that occurs with glycine, mannitol, or sorbitol. This osmotic diuresis perpetuates hyponatremia and results in hypotension secondary to hypovolemia.

Hypertonic saline can initially be administered as a 100-mL bolus of 3% saline, giving 51 mEq of sodium, which will increase serum sodium by 2–3 mEq/L. If

symptoms do not improve, 100-mL boluses can be given one to two more times in 10-minute intervals.[42] Given the acute onset and short duration of hyponatremia in patients following endoscopic BPH surgery, rapid correction of hyponatremia and hypoosmolality is generally safe, unlike in those with chronic hyponatremia who are at risk for central pontine demyelination with rapid correction of serum sodium. For patients with hyponatremia and normal serum osmolality, hypertonic saline has not been shown to be beneficial and actually there have been reports of delayed osmotic demyelination.[43] Hemodialysis (HD) can rapidly correct hyponatremia, osmotic abnormalities, and volume status. HD may be preferred in those with chronic kidney disease, marked hyponatremia without significant osmolality abnormalities, or those with severe neurologic symptoms.[44] Ultimately, nephrology should be consulted as well to assist with the management of symptomatic electrolyte abnormalities, fluid overload, or refractory hyponatremia.

False Urethral Passage

A false urethral passage is an iatrogenic defect somewhere along the course of the urethra. This complication probably occurs more frequently than is reported in the literature. One series reported this complication in 0.5% of men undergoing endoscopic surgery for BPH.[45] This can happen with blind urethral catheter insertion and cystoscope placement. At the time of endoscopic BPH treatment, a false urethral passage may occur if the resectoscope is inserted haphazardly and if inadequate lubrication is used. To avoid this complication, place the scope under direct vision using a visual obturator instead of a blind obturator, especially if any resistance is noted with an attempt at blind insertion. On insertion of the scope, if narrowing or stricturing of the urethral lumen is noted, then the scope can be passed over a catheter or a wire to ensure that it follows the natural lumen and does not go off-course creating a false urethral passage. Additionally, urethral dilation can be performed prior to scope placement to facilitate successful passage. The Foley catheter may be left in place for a few more days postoperatively in the setting of a significant false passage.

Injury to the Bladder or Ureteral Orifices

Injury to the bladder or ureteral orifices is rare but can occur if one is not careful.[46] Using a surgical table with radiologic capabilities is ideal to allow for cystogram and ureteral stent placement if these complications do occur. Bladder perforation has been described for all types of endoscopic BPH procedures and can occur from perforation with the scope, with Ellik evacuation of prostate chips, laser application or transurethral resection beyond the prostate, and at the time of morcellation with enucleation procedures.[46,47] Several case reports describe bladder rupture at the time of TURP related to the ignition of flammable gases created by electrical activity during resection.[48–50]

On initial cystourethroscopy, landmarks are identified including the ureteral orifices. Generally, the ureteral orifices are located between 4–5 o'clock (patient's left side) and 7–8 o'clock (patient's right side) over the trigonal ridge on endoscopic evaluation. Sometimes, when there is significant intravesical tissue – especially from a large median lobe – identification of the ureteral orifices may be very difficult and even impossible. Additionally, on initial inspection the bladder is characterized not only with regard to the presence of trabeculation, stones, diverticula, and mucosal lesions, but also bladder capacity as morcellating in a smaller capacity bladder can be more challenging and potentially dangerous.

Injury to the ureteral orifice has been reported to occur in 0–2% of patients undergoing various endoscopic procedures for BPH.[46,51] Some have suggested suprapubic cystoscopy to help identify the ureteral orifices in some cases, though this technique is rarely employed today.[52] Knowledge of ureteral orifice location relative to the bladder neck will decrease the risk of injury. The ureteral orifices will be closer to the bladder neck when the bladder is underfilled. Familiarity with equipment is essential to avoid complications including where a side-firing laser will penetrate tissue to avoid accidently firing past the bladder neck and causing bladder or ureteral orifice injury. Depending on the degree of ureteral orifice injury, placement of a ureteral stent may be considered to prevent stenosis. If there is concern the ureteral orifice was injured, but the opening cannot be identified, the patient can be monitored for symptoms of obstruction postoperatively. Imaging with renal ultrasound or computerized tomography may be necessary. If hydronephrosis is present, placement of a ureteral stent, nephrostomy tube, or nephroureteral stent can relieve the obstruction. Agents such as indigo carmine, methylene blue, and fluorescein can be used to dye the urine and aid with localization of the ureteral orifice if it is not completely obstructed at the time of cystoscopy.

Bladder injury can also occur if resection, ablation, or vaporization is performed within the bladder. This may happen if visualization is obscured secondary to bleeding, inadequate irrigation, and/or broken equipment. If hemostasis is adequate and visualization is poor, check the irrigation flow and equipment. The irrigant bags can be raised to increase the flow of gravitational irrigation. Sometimes, the outflow port of the continuous flow resectoscope can be obstructed with clot, which will limit the inflow of irrigant. This can usually be fixed by flushing the outflow port.

With enucleation procedures, removal of prostatic tissue is achieved through morcellation. Morcellator injury of the bladder occurs when engagement of the bladder with the morcellator blades is not recognized. Sometimes the bladder mucosa is just engaged by the suction mechanism of the morcellator and not the blades themselves. Superficial bladder mucosal injuries without perforation have been reported in 0.7–5% of cases and bladder perforation in 0–1.5% of cases.[51,53] Anecdotally, the risk of morcellation injury increases with poor visualization, large adenoma in a small capacity bladder, inadequate anesthesia resulting in patient motion during morcellation, and surgeon inexperience. In order to decrease the risk of morcellator injury, it is recommended that both ports of the resectoscope be used as "inflow" ports with irrigation fluid running continuously through both. This allows for adequate distension of the bladder for safe morcellation. If visualization is poor secondary to bleeding, some describe leaving the adenoma in the bladder and coming back 1–2 days later to morcellate when there is better visibility and the tissue is less firm.[54] Some advocate for morcellating the enucleated adenoma in the prostatic fossa to avoid bladder injury.[55] Others recommend a "mushroom" technique where the prostatic lobes

are enucleated but left attached at the bladder neck and then electroresected.[56] This technique is not employed by most urologic surgeons performing HoLEP who have access to a tissue morcellator.

If the bladder becomes engaged in the blades of the morcellator, morcellation ceases. The morcellator is left in place, while the suction is relieved by opening the hinged gate of the roller ball. This will release the bladder from the morcellator blades. Next, examine the bladder carefully. If it was only engaged and not actually cut, proceed with morcellation, and take care to correct whatever caused the bladder to become engaged in the blades. If there is concern for bladder perforation, perform a cystogram on the table to assess for extravasation. If extraperitoneal injury occurred, obtain hemostasis, place a catheter, and abort the procedure. Come back in 1–2 weeks after the bladder has healed to complete the morcellation and or treatment of BPH. If an intraperitoneal bladder injury occurs, then immediate cystotomy repair is recommended. This is typically performed with exploratory laparotomy, though laparoscopic repairs have been reported.[49] In the case of enucleation procedures, the remainder of the adenoma can be extracted from the bladder via the cystotomy prior to repair. A drain should be placed outside the bladder at the time of cystotomy repair.

Injury Beyond the Prostate

Endoscopic BPH procedures can all be complicated by capsular perforation, undermining of the bladder neck, and rarely though potentially morbid, rectal injury. As previously described, capsular perforation (Fig. 26.1) can result in increased fluid absorption and TUR syndrome and potentially erectile dysfunction (ED) secondary to neurovascular bundle injury.

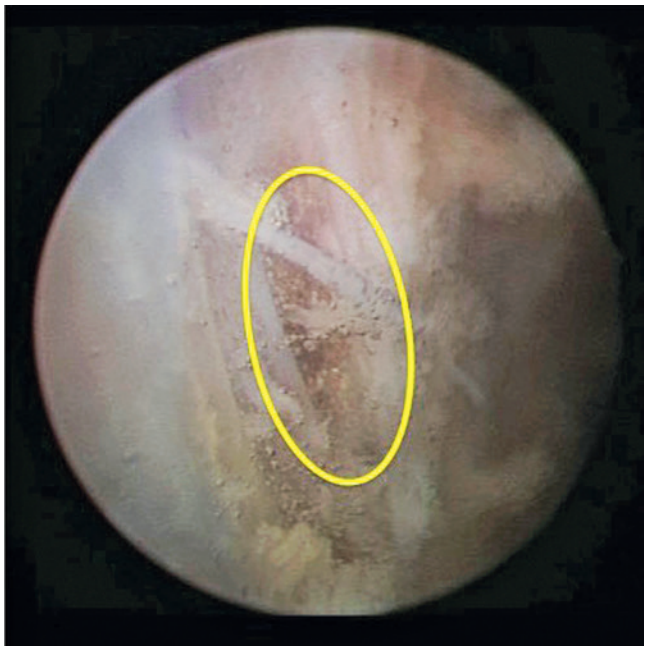

Figure 26.1 Capsular perforation. Small perforation in the prostatic capsule encircled.

In men with significant BPH, it is not uncommon to have prostatic adenoma protruding under the bladder neck and approaching the trigone. This adenoma must be carefully resected, enucleated, or vaporized to avoid undermining and/or perforation. Depending on the extent of undermining and/or perforation, there is the potential to injure the ureters as they insert into the bladder. If significant undermining of the trigone occurs, place the urethral catheter over a wire, otherwise it will likely preferentially pass into this defect, possibly worsening this injury. If the patient fails a voiding trial postoperatively, consider replacing the catheter cystoscopically over a wire, or at least using a coude catheter.

Rectal injury at the time of endoscopic BPH surgery is an incredibly rare but very serious and morbid complication. This can happen when the surgeon carries the treatment plane too far posteriorly. One French study reported their experience with four rectal perforations that occurred at the time of transrectal ultrasound-guided PVP of the prostate in two cases, TURP in one case, and TUIP in another in a series of 450 patients.[57] Rectal injury was managed with either colostomy or primary closure. Ultimately two patients died from this complication and two others were doing well at 1-year follow-up. History of prior BPH surgery, prostatitis, and/or prostatic/rectal abscesses may also increase the risk of this injury. If a rectal injury is noted, abort the procedure and consult a colorectal or general surgeon immediately. Bowel diversion and urinary diversion with suprapubic catheter drainage may be required.

Challenges to Initiating Treatment

At times there are barriers to treatment, which represent situations where the procedure cannot proceed due to some physical obstacle. These difficult situations include patients with phimosis, meatal stenosis, urethral stricture, intraoperative priaprism/penile erection, and excessive urethral length that prohibit passage of the resectoscope into the bladder. We will briefly discuss these situations and how to manage them to facilitate endoscopic BPH treatment.

Phimosis occurs in adult uncircumcised men most commonly when the distal prepuce skin develops scar tissue from chronic inflammation. The scarred tissue loses its elasticity and, if severe, may not allow for retraction of the foreskin beyond the glans of the penis, obscuring visualization of the urethral meatus and prohibiting scope placement. A thorough examination of the phallus and meatus prior to BPH surgery will identify this pathology preoperatively and allow for appropriate counseling and surgical preparation. A dorsal slit may be required to facilitate scope placement and BPH treatment. Circumcision at the time of the operation or on a date prior to BPH surgery may also be considered.

Meatal stenosis identified preoperatively allows for patient counseling for meatal dilation and meatotomy at the time of BPH surgery. Meatal dilation can be facilitated with Van Buren sounds. An Otis urethrotome is an excellent tool to perform meatotomy and will be discussed later in the section describing ways to prevent postoperative meatal stenosis. It is not uncommon to identify concurrent urethral stricture disease in those men with BPH who may have undergone urethral instrumentation for management and diagnosis of BPH. In some cases, the scope can be gently passed through the narrowed urethral segment over a wire or catheter so

as to maintain the lumen. For a more robust stenosis, dilation over a wire with a balloon or sequential urethral dilators with filiforms and followers is usually effective.

Priapism is defined as a persistent erection of the penis not associated with sexual stimulation or desire. Penile erections at the time of transurethral surgery occur in 0.1% to 1% of cases.[58,59] Transiently ceasing stimulation in some cases will return the phallus back to a flaccid state. These series all found that a single dose of phenylephrine given intracorporeally resulted in successful detumescence and allowed for completion of the endoscopic procedure.[58,59] We recommend starting with a dose of 100 to 200 µg of phenylephrine.

Due to significant urethral and penile length, especially in the setting of very large and long prostates or malleable penile prostheses, a resectoscope may not reach the bladder. In these cases, an extra-long resectoscope can be used if available. Another option is to perform a perineal urethrostomy and insert the scope through this opening.[60,61] A perineal urethrostomy can be created by passing a van Buren sound down to the bulbar urethra and incising down onto it. Once the van Buren sound is visible, place stay sutures in the urethra and pass the resectoscope into the bladder for BPH treatment. At the conclusion of the procedure, a Foley catheter is placed into the bladder and the perineal urethrostomy is closed in several layers over the catheter. The catheter is left indwelling for at least 1–2 weeks and a pericatheter retrograde urethrogram (RUG) or RUG following catheter removal is performed to ensure the urethra has healed.

POSTOPERATIVE

Postoperative Bleeding

The rate of postoperative bleeding and hematuria following endoscopic BPH procedures is variable. Some degree of postoperative hematuria is expected following these procedures. However, significant bleeding and hematuria resulting in clot urinary retention and the need for hand irrigation, continuous bladder irrigation (CBI), blood transfusions, and surgical intervention with cystoscopy, clot evacuation, and fulguration is rare. The need for postoperative clot evacuation and fulguration for the management of clot retention ranges from 0% to 2.2%.[51,62–64]

The best way to prevent postoperative bleeding is to obtain excellent hemostasis at the time of surgery. The prostatic fossa is evaluated at the end of the procedure with the bladder minimally full, irrigation fluid off, and any bleeders noted controlled. The patient should be normotensive at the time of evaluation, as hypotension can mask bleeding. Blood thinners and antiplatelet agents are held postoperatively when deemed safe by the patient's PCP.

When significant postoperative bleeding is encountered, many patients can be managed conservatively with hand irrigation, CBI, and serial hemoglobin/hematocrit levels. CBI through a large bore three-way catheter (20–24Fr) helps to stop the bleeding secondary to pressure of the urethral catheter across the resection bed, contraction of the prostatic capsule and prostatic peripheral zone, and vasoconstriction.

Some have reported reduction in postoperative bleeding following TURP by placing the catheter on traction and effectively compressing the prostatic fossa, achieving hemostasis with pressure.[65] Depending on the size of the prostate and amount of tissue resected, one must be sure an adequate amount of fluid is placed in the balloon to avoid migration into the fossa. Others describe digital compression via the rectum on the prostate to tamponade bleeding vessels.[12] If hematuria does not improve with these conservative measures and/or there is significant acute blood loss anemia, evaluation of platelet count and coagulation panel are necessary. Some series have reported severe bleeding associated with disseminated intravascular coagulation following endoscopic BPH treatment.[54] Some patients may require blood transfusions and observation in an intensive care unit with appropriate monitoring and supportive measures. If bleeding persists, ultimately cystoscopy with clot evacuation and fulguration may be required. Some case reports describe the rare need for angiography and embolization when bleeding is refractory to cystoscopy and fulguration.[66]

Infection

Urinary tract infections (UTIs) can occur following any endoscopic urologic treatment and can manifest as a lower UTI, pyelonephritis, prostatitis, prostatic abscess, epididymitis, and/or urosepsis. Patients with indwelling urethral catheters, on intermittent catheterization, with incomplete bladder emptying, prior history of UTI, and diabetes mellitus are at higher risk for bacterial colonization and postoperative infections.[67] One prospective study looking at patients without indwelling urethral catheters or on intermittent catheterization and sterile urine preoperatively reported a 26% rate of postoperative bacteriuria, which was associated with an operating time of greater than 52 minutes and disconnection of the closed urinary drainage system.[68]

In order to prevent postoperative UTIs, a preoperative urine culture is sent and if positive the patient treated with a course of culture-specific antibiotics. The urine culture can be repeated to assure clearance of the bacteria. For patients with negative preoperative urine cultures, AUA guidelines recommend perioperative coverage with fluoroquinolones, trimethoprim-sulfamethoxazole, aminoglycoside ± ampicillin, first- or second-generation cephalosporins, or amoxicillin/clavulanate.[67] However, given the black box warning placed on fluoroquinolones by the Food and Drug Administration in 2016 secondary to the risk of serious side effects, including debilitating tendon injuries, this antibiotic class should be used only when there are no other reasonable alternatives. A course of preoperative antibiotics can be considered in patients with an indwelling catheter or on intermittent catheterization and negative preoperative urine culture, as these patients are at high risk of being colonized with bacteria. It is our practice to change the catheter in the office and send urine for culture from the new catheter. A meta-analysis found that a short course of antibiotics may be superior compared to a single-dose regimen to prevent postoperative UTI.[69] We often extend the course of postoperative antibiotics in patients with positive preoperative urine culture and/or urinary retention requiring an indwelling catheter or intermittent catheterization.

If the patient develops a UTI postoperatively, he can be managed with empiric broad-spectrum antibiotics followed

by a course of culture-specific antibiotics once the urine culture finalizes. Given the black box warning of and rising antimicrobial resistance to fluoroquinolones, including in men with UTIs and prostatitis, alternate empiric antibiotic is preferred.[70] If they are stable, reliable, and have minimal medical co-morbidities they can likely be managed on an outpatient basis. However, patients who are elderly often have significant medical comorbidities, and any signs of sepsis should prompt admission and close monitoring. A Foley catheter may be placed for maximal drainage if systemic infection is suspected.

Rarely an inflammation of the pubic bone can occur following endoscopic BPH surgery. Pubic symphysitis has been described in 0.297% of patients following TURP.[71] This is thought to be secondary to infection, trauma, or impaired blood flow and possibly related to preoperative instrumentation and capsular perforation with sinus or fistula formation. Clinically, these patients complain of severe pain in the pubic region and groin with difficulty walking about 1 month following surgery. A minority present with fevers as well. On physical exam these patients are tender over the pubic bone and groin. MRI and CT imaging may be useful diagnostic adjuncts. Temporary catheterization, supportive measures, and a long course of antibiotics (at least 4 weeks) resulted in complete resolution of symptoms in one series of 12 patients.[71]

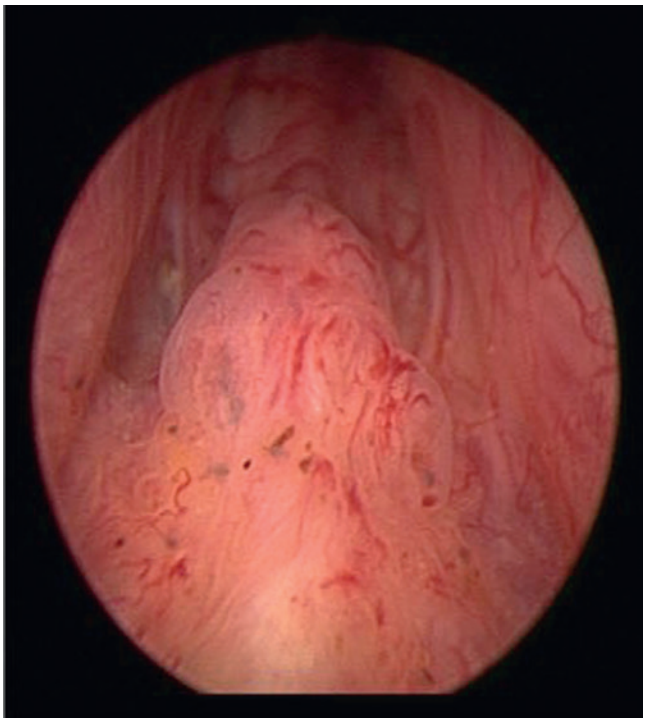

Figure 26.2 Verumontanum.

Urinary Incontinence

Men may experience both stress urinary incontinence (SUI) and/or urge urinary incontinence (UUI) following endoscopic BPH procedures. Transient SUI is not uncommon following most bladder outlet obstruction (BOO) procedures. However, long-term SUI is related to sphincter injury at the time of BPH treatment or preexisting intrinsic sphincter deficiency, which is impossible to determine in the setting of prostatic obstruction. The rate of long-term SUI following endoscopic BPH surgery ranges from 0% to 2.2% (see Table 26.2). In order to prevent long-term SUI the urologist must be cognizant of the location of the external urethral sphincter at all times. The verumontanum (Fig. 26.2) is used as a landmark of the external urinary sphincter, which is an omega-shaped rhabdosphincter. Resection or laser ablation/vaporization distal to the verumontanum should be avoided to prevent injury to the sphincter. For enucleation procedures the laser energy can be reduced when incising the mucosa near the apex of the prostate and blunt enucleation implemented preferentially in this region.

While they are not well studied in men undergoing prostate surgery for benign disease, Kegel exercises are known to improve postoperative urinary incontinence following radical prostatectomy. One series reported a continence rate of 95% versus 65% at 6 months follow-up after radical prostatectomy ($p < 0.001$) favoring those performing postoperative pelvic muscle floor training with Kegel exercises.[72] Many urologists encourage their patients to perform Kegel exercises following endoscopic BPH surgery. For long-term SUI not responsive to pelvic muscle floor training, treatment options include penile compression devices, urethral sling, or artificial urethral sphincter. If the patient is not that bothered, he may elect to use incontinence pads. Cystoscopy is performed prior to surgical intervention to rule out strictures or bladder neck contracture (BNC) that would require treatment before incontinence surgery. If the patient's incontinence is not clearly stress based on history and exam, urodynamic evaluation may be considered prior to surgical intervention.

Irritative lower urinary tract symptoms (LUTS) develop with BPH secondary to long-standing BOO causing detrusor hypertrophy, bladder-wall thickening, and bladder dysfunction. When the obstruction is relieved, some men can develop de novo UUI or exacerbation of preexisting UUI. Some series have found improvement in detrusor overactivity in 30–62% of men following TURP.[73–75] If symptoms persist, medical therapy with anticholinergics, a β_3-adrenergic agonist, or botulinum toxin injections can be trialed.

Urethral Stricture

Urethral stricture can occur anywhere along the urethra following endoscopic management of BPH. The rate of postoperative urethral stricture ranges between 0% and 10% (see Table 26.2). Possible mechanisms leading to urethral stricture following BPH surgery include trauma from resectoscope insertion and monopolar current leakage secondary to insufficient insulation. While one series comparing bTURP versus mTURP noted a significantly higher rate of urethral strictures in the group of men with prostates greater than 70 g undergoing bTURP and contributed this to the differences between bipolar and monopolar energy, a meta-analysis comparing bTURP versus mTURP found no difference in the rate of postoperative urethral stricture.[19,76] This meta-analysis actually found an association of larger prostate size and incidence of postoperative urethral stricture. The authors recommend that larger prostates be treated with HoLEP or simple prostatectomy to avoid this complication. Prostate size and surgical time

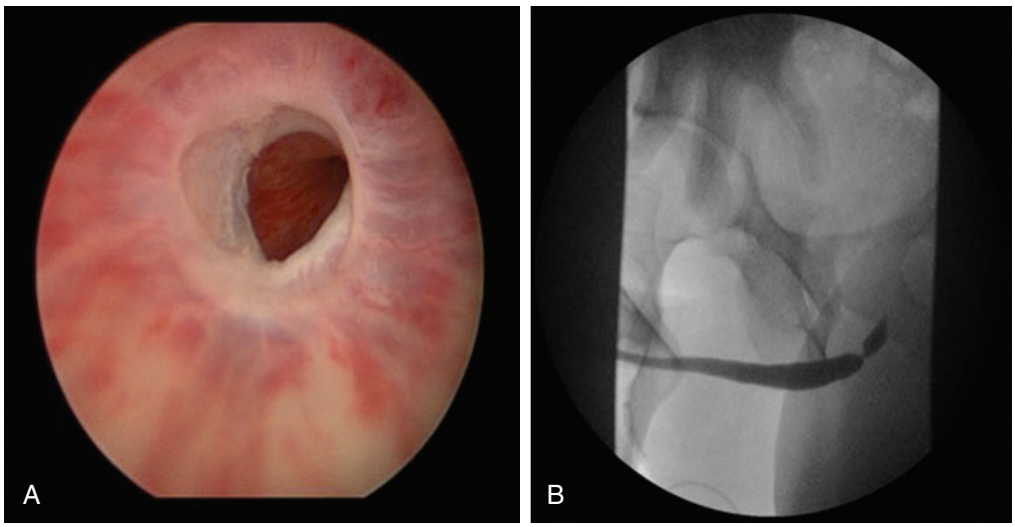

Figure 26.3 Urethral stricture. A, Bulbar urethral stricture on cystoscopy. B, Short bulbar urethral stricture on retrograde urethrogram. (Photographs courtesy of Dr. Douglas F. Milam, MD.)

for HoLEP have not been associated with risk of urethral stricture.[77]

Several studies comparing the size of the resectoscope and postoperative urethral stricture have found an association with larger scope diameter and increased risk of urethral stricture.[78,79] One series evaluating different scope diameters (24Fr vs 26Fr) reported a significantly higher rate of bulbar urethral strictures (11.4% vs 2.9%, $p = 0.018$) with the larger scope.[78] A higher rate of urethral stricture has also been reported in men undergoing retreatment versus primary therapy for BPH (3.3% vs 1.5%, $p = 0.043$).[80] Series localizing urethral stricture report that most occur in the bulbar urethra.[32,78]

Some older series found that patients whose bladders were drained with a suprapubic tube (SPT) following TURP had a lower rate of urethral stricture compared to those drained transurethrally (17% vs 4%).[81] However, in contemporary practice, SPTs are rarely placed at the time of endoscopic BPH treatment unless there is a high risk of permanent urinary retention postoperatively. Other older series also found lower postoperative rates of urethral stricture when prostate resection was performed through a perineal urethrostomy instead of transurethrally.[60] Again – this is rarely performed today unless the resectoscope cannot reach the prostate. To prevent postoperative urethral stricture, great care must be taken to atraumatically insert the resectoscope at the time of surgery. Also, consideration should be given to selecting HoLEP for larger glands and using the smallest diameter resectoscope necessary to perform the procedure safely.

Urethral stricture may be suspected when a patient who initially reported significant improvement in voiding symptoms following a bladder outlet procedure begins to complain of obstructive urinary symptoms. He will likely have a reduction in his urinary flow rate and possibly an elevation in his post-void residual (PVR). Cystoscopy will identify the location and severity of the stricture, and if further characterization is necessary a RUG to help determine stricture length can be performed (Fig. 26.3).

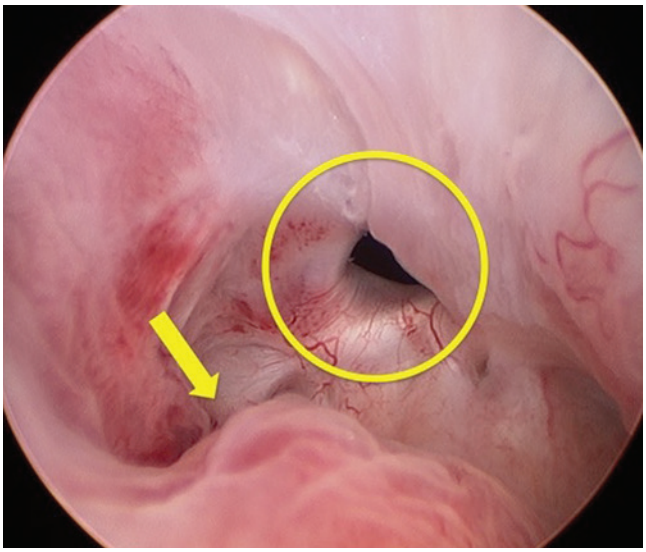

Figure 26.4 Bladder neck contracture. The bladder neck contracture is encircled. The yellow arrow is pointing to the verumontanum. (Photograph courtesy of Dr. Douglas F. Milam, MD.)

Treatment options for postoperative urethral stricture include dilation with sequential or balloon dilators, direct vision internal urethrotomy, urethroplasty, or, in severe cases, perineal urethrostomy. Chronic catheterization is also an option.

Bladder Neck Contracture

BNCs are scar tissue at the bladder neck that can develop following treatment of BPH as well as following radical prostatectomy performed for prostate cancer (Fig. 26.4). The rate of BNC varies by procedure (see Table 26.2). The cause of BNC following endoscopic BPH surgery is attributed to excessive use of cautery around the bladder neck. Pinpoint fulguration is recommended to avoid this complication. Anecdotally, some have found that BNCs following

HoLEP tend to present within the first 6 months after surgery whereas BNC following TURP can present anywhere from 8 months to 36 months postoperatively.[77]

Patients with smaller prostates (<30 mL) and absence of bladder stones are at higher risk of developing BNC following BPH surgery.[82] No difference has been found in the rate of BNC between mTURP and bTURP.[19] A prophylactic bladder neck incision following TURP has been shown to decrease the incidence of BNC postoperatively (12% vs 6%, p = 0.000) with no patient developing BNC if a transurethral incision of the bladder neck was performed and the prostate was greater than 30 g.[82] BNC can be treated with dilation, incision, or transurethral resection. The success rate of endoscopic BNC treatment ranges from 72% to 73%, with a greater than 80% patency rate when a steroid injection is given following incision of the BNC.[83] Rarely patients may require bladder neck reconstruction or even urinary diversion. Chronic catheterization or suprapubic tubes are also an option for surgical failures or in the event the patient is unfit medically.

Meatal Stenosis

Meatal stenosis is a narrowing of the urethral meatus that can be congenital or occur following instrumentation secondary to scar tissue. Meatal stenosis can coexist with fossa navicularis strictures as well. The cause of postoperative meatal stenosis following endoscopic BPH surgery is thought to be secondary to local tissue ischemia from pressure of the scope in a patient with a somewhat narrow meatus at the time of surgery. The rate of postoperative meatal stenosis following endoscopic BPH surgery ranges from 0.8% to 3.7%.[51,84–87] If meatal narrowing or frank meatal stenosis is encountered at the onset of the procedure, Van Buren sounds can be used to calibrate the urethral diameter and for urethral dilation as well. If significant narrowing is encountered, then meatotomy is recommended to prevent pressure necrosis during the case. Meatotomy can be performed with an Otis urethrotome or cold knife incision.[51] Additionally, frequent lubrication of the scope may also help to reduce friction and ischemia at the meatus.

Retrograde Ejaculation

Retrograde ejaculation is when semen is redirected into the bladder instead of out of the urethra. Normally the bladder neck contracts via sympathetic stimulation directing the semen out of the urethra at the time of ejaculation. Retrograde ejaculation or anejaculation can occur both from sympathetic nerve damage at the time of retroperitoneal lymph node dissection or use of alpha-blockers for BPH, as well as from surgery on the prostate and bladder neck. The rate of retrograde ejaculation is quite variable following endoscopic BPH procedures (see Table 26.2) and is best preserved following PUL, with multiple series reporting a 0% rate of retrograde ejaculation.[64,88,89] TUIP also has a relatively low rate of retrograde ejaculation, at 28–35%.[90,91]

Some have studied ways to preserve ejaculatory function following TURP and HoLEP with varying success. The rate of antegrade ejaculation with apical tissue preservation at the time of TURP has been reported to be as high as 90.8%, with comparable improvements in voiding symptoms to standard TURP at 3-month follow-up.[92] However, attempts to preserve the ejaculatory region and ejaculation at the time of HoLEP have been less successful.[93] Patients should be counseled on the risk of retrograde ejaculation with endoscopic treatment of BPH. If maintaining ejaculation is important to the patient, possibly secondary to a desire to maintain fertility, then a procedure with a lower rate of retrograde ejaculation may be best suited for him. He may even want to consider banking his sperm prior to surgery if the ability to father a child later is desired.

Erectile Dysfunction

Studies reviewing the risk of ED following the treatment of BPH have generally found no significant differences between preoperative and postoperative sexual function in terms of intercourse satisfaction and desire.[94] Several series have found mixed outcomes, with some patients reporting improvement in erectile function following BPH treatment and others reporting some decrease in sexual function. Improvement in sexual function may be related to cessation of 5α-reductase inhibitors and alpha-blockers postoperatively. Some series have found an association with postoperative ED and intraoperative capsular perforation.[95,96] This may be secondary to neurovascular bundle injury. Avoiding capsular injury and the cessation of BPH medications may improve erectile function and prevent ED postoperatively.

Need for Retreatment

The goal of endoscopic BPH surgery is to create an open outlet and remove all BPH adenoma. However, in most cases, some BPH tissue in the transition zone is left in order to avoid the complications associated with capsular perforation and deep resection. Over time, benign adenoma can grow back and cause recurrent obstruction and symptoms. Incomplete tissue removal is also possible, especially in the setting of larger glands. Inadequate resection is more frequent in the anterior prostatic fossa.

The rate of retreatment following endoscopic BPH surgeries varies based on procedure type (see Table 26.2). One series on PVP reported an 11% reoperation rate at 3-year follow-up, where reoperation was necessary in glands only greater than 80 mL.[34] Need for retreatment or additional BPH surgery has been reported in 1.9–20% of PUL procedures (see Table 26.2). At the time of TURP, the investigators found that the monofilaments securing the PUL instantly melt and are not an impediment to resection of prostatic tissue.[88] The best way to avoid retreatment is to remove as much adenoma as is safe and possible at the time of endoscopic BPH treatment. In the setting of adenoma regrowth or incomplete treatment, HoLEP has been shown to be safe and effective, with similar improvement in flow rates, PVRs, and symptom scores in men undergoing primary treatment, and just slightly higher rates of clot retention (4.7% vs 1.8%, p = 0.01) and urethral stricture (3.3% vs 1.5%, p = 0.043) in those undergoing retreatment.[80]

MISCELLANEOUS

PUL is an endoscopic treatment for BPH that places permanent implants into the prostate to retract the lateral lobes and expand the urethral lumen. One series reported a 2.1% rate of implant encrustation when the device was inadvertently delivered such that a portion of it was exposed inside

the bladder.[64] Unrecognized this could result in bladder stones, recurrent UTIs, hematuria, and LUTS. To avoid this complication, the surgeon must place the implant no closer than 1 cm to the bladder neck and ensure appropriate angulation.[64] At the end of the procedure the bladder is inspected to assess for exposed implants, and if found they can be removed with endoscopic forceps.

Conclusions

Many minimally invasive endoscopic treatment options exist for BPH. Fortunately, major complications are rare. More common minor complications such as UTI and perioperative bleeding can be minimized with appropriate preoperative workup and management of medications. Postoperative complications such as undesirable retrograde ejaculation can be avoided in many cases with appropriate procedure selection. Most complications can be managed conservatively, though others, including clot retention, urethral stricture, and urinary incontinence, may require further operative intervention to alleviate.

Chapter 26 Questions

1. Which transurethral BPH procedure has the lowest rate of retrograde ejaculation?
   a. Transurethral resection of the prostate
   b. Transurethral incision of the prostate
   c. Photovaporization of the prostate
   d. Holmium laser enucleation of the prostate
   e. Prostatic urethral lift

2. Which of the following does NOT decrease the risk of postoperative urethral stricture following endoscopic BPH surgery?
   a. Smaller resectoscope caliber
   b. Use of monopolar instead of bipolar energy for TURP
   c. Suprapubic tube insertion instead of indwelling urethral catheter postoperatively
   d. Atraumatic insertion of the resectoscope
   e. Larger prostate size

3. Which is NOT a risk factor associated with increased risk of bleeding at the time of transurethral BPH surgery?
   a. Patient age
   b. Prostate size
   c. Longer operative time
   d. Surgical approach
   e. Anticoagulation

4. If treatment of BPH is carried distal to this structure the patient is at increased risk of this complication (Case Fig. 26.1):
   a. Urethral stricture
   b. Rectal injury
   c. Bladder neck contracture
   d. Stress urinary incontinence
   e. Urge urinary incontinence

Case Figure 26.1

5. Where in the urethra is the most common place to develop a urethral stricture following transurethral BPH surgery?
   a. Fossa navicularis
   b. Penile urethra
   c. Bulbar urethra
   d. Membranous urethra
   e. Prostatic urethra

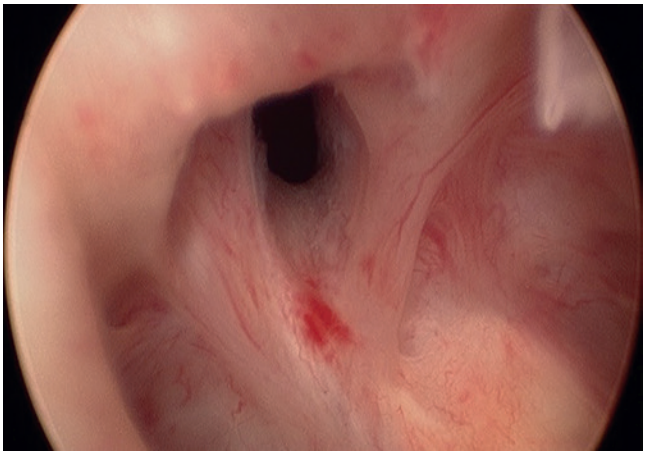
6. Which of the following is NOT associated with TUR syndrome?
   a. Hypertension
   b. Cerebral edema
   c. Blurred vision
   d. Confusion
   e. Seizures

7. All of the following can be done at the time of transurethral BPH surgery when a smaller meatus is encountered to reduce the rate of postoperative meatal stenosis, EXCEPT:
   a. Meatal dilation with sounds
   b. Meatal balloon dilation
   c. Use a smaller resectoscope
   d. Meatotomy
   e. Steroid cream

8. Which factor is NOT associated with increased risk of morcellator injury to the bladder?
   a. Obesity
   b. Smaller bladder size
   c. Experience level
   d. Poor visualization
   e. Inadequate anesthesia and patient movement during surgery

9. Which of the following is NOT part of the treatment algorithm for TUR syndrome?
   a. Hypertonic saline
   b. Hemodialysis
   c. Nephrology consultation
   d. Colloid intravenous fluids
   e. Loop diuretic

10. Which measure is NOT recommended by the AUA guidelines committee to decrease the risk of bleeding at the time of endoscopic BPH treatment?
    a. Hold anticoagulants prior to surgery if medically safe
    b. Send a coagulation panel prior to surgery
    c. Start the patient on finasteride prior to BPH surgery
    d. Check the platelet count
    e. Treatment of preoperative urine culture with antibiotics



Case Studies

CASE 1

A 68-year-old male underwent TURP 8 months ago. He had an excellent stream initially postoperatively. However, he

now reports having a weak stream and sensation of incomplete emptying. His PVR is elevated from 10 mL at his 2-month postoperative visit to 215 mL and his maximum urinary flow is now 5 mL/s, which is down from 23 mL/s. His American Urological Association Symptom Index (AUASI) is 21, up from 5. His urine dip today is negative for leukocyte esterase or nitrite and has five red blood cells.

1. What is your next step?
   a. Reassure the patient that this is normal and continue routine follow-up
   b. Treat him with a course of antibiotics and recheck his symptoms, urinary flow, and PVR in 1 month
   c. Obtain an abdominal US
   d. Perform cystoscopy
   e. Send urine for cytology

Case Figure 26.2 (Image courtesy of Dr. Douglas F. Milam.)

2. You perform cystoscopy and you see this (Case Fig. 26.2). What is your diagnosis?
   a. Meatal stenosis
   b. Prostate cancer
   c. Urethral stricture
   d. Recurrent BPH
   e. Bladder neck contracture

CASE 2

A 71-year-old male with multiple medical comorbidities, including coronary artery disease with prior coronary stents, lumbar disc disease with history of laminectomy, and symptomatic BPH, desires HoLEP. He has a 170-mL prostate on transrectal ultrasound measurement. A cystoscopy done prior to HoLEP was significant for trilobar prostatic hypertrophy and a trabeculated, small bladder. Video urodynamics had been performed given his history of laminectomy and showed bladder outlet obstruction with good detrusor function, a maximum urinary flow of 7.6 mL/second after voiding 158 mL, and a bladder capacity of 195 mL. He is cleared by his cardiologist to undergo HoLEP but must remain on aspirin 81 mg daily through the procedure. The enucleation part of the procedure is uncomplicated except for some diffuse oozing likely related to antiplatelet therapy. The morcellation portion of the procedure is more challenging. Anesthesia notes that they are having trouble ventilating the patient. The patient is normotensive and develops bradycardia.

1. What are you most concerned is going on?
   a. TUR syndrome
   b. Perforation of the prostatic capsule
   c. Extraperitoneal bladder injury
   d. Intraperitoneal bladder injury
   e. Significant blood loss and symptomatic anemia

2. Which of the following is NOT a risk factor for bladder injury during morcellation of prostatic adenoma?
   a. Small capacity bladder
   b. Poor visualization
   c. Inadequate anesthesia
   d. Obesity
   e. Surgeon experience

3. Which of the following would NOT have decreased the risk of bladder injury in this patient?
   a. Medical management instead of surgery for BPH
   b. Pause morcellation and use the laser to improve hemostasis
   c. Abort morcellation and extract the enucleated tissue via a cystostomy
   d. Perform staged morcellation at which time there will be less bleeding and the tissue will be softer and easier to morcellate
   e. Switch from gravity to pressurized irrigation

Answers

1. **e.** Prostatic urethral lift has the lowest rate of retrograde ejaculation (Case Table 26.1).
2. **b.** A meta-analysis compared mTURP and bTURP and did not find any association between energy type and postoperative urethral stricture.
3. **a.** All factors except age have been associated with increased risk of bleeding.
4. **d.** This structure is the verumontanum and the marker for the urethral sphincter. Resection, enucleation, and vaporization distal to this structure risk injury to the sphincter and stress urinary incontinence.
5. **c.** Most series of endoscopic BPH treatment describe urethral stricture predominantly occurring in the bulbar urethra.
6. **a.** Cerebral edema, blurred vision, confusion, and seizures are all associated with TUR syndrome.
7. **e.** Steroid cream is not a treatment option for intraoperative meatal narrowing or stenosis.
8. **a.** Smaller bladder size, surgeon experience, inadequate visualization, and patient movement are all risk factors for bladder injury during morcellation.
9. **d.** Hypertonic saline, loop diuretics, hemodialysis, and nephrology consultation are measures that may be required to manage TUR syndrome. Colloid intravenous fluids are not used to treat this complication.
10. **c.** Per the AUA guidelines, insufficient evidence exists to recommend the use of 5α-reductase inhibitors to decrease blood loss at the time of endoscopic BPH surgery.

Case Table 26.1 Postoperative Complications[20,32–34,45,51,62–64,77,82,88–91,94,97–174]

	Urinary Tract Infection	Urethral Stricture	Bladder Neck Contracture	Stress Incontinence	Retrograde Ejaculation	Erectile Function		Retreatment
						Worse	Better	
mTURP	2–13.5%	1.1–10%	1.1–12%	1.1–2.2%	57–86%	28%	23%	0–4%
bTURP	0–10.5%	0.8–2%	0–6.6%	0–2.5%	4.5–66.6%	2.2–17%	10.1–28.2%	0–9.4%
HoLEP	0–3.2%	1.7–4.1%	0.4–3.9%	0.7–1.7%	74–78%	11–12%	3–7%	0–1.4%
PVP	0–17%	0–5.1%	0–7.4%	0.8%	49.9%	10%	20%	4.3–11%
BVP	2.4–10%	0–6.8%	0–8%	0–11.7%	59.2–82%	12–13%	nwd	0–43%
TUIP	0–9%	2.4–21.5%	0–2.1%	0–11%	0–35%	0–6.25%	12.5%	4–34.8%
TUMT	0–33%	0–2%	0%	0%	0–22.2%	0–9%	0–15.2%	2.2–32%
TUNA	4–14%	0–1.5%	nwd	0–1.5%	0–15%	0–3%	nwd	9.75–31%
PUL	2.9–12.12%	0%	0%	0%	0%	0%	nwd	1.9–20%

bTURP, bipolar TURP; BVP, bipolar vaporization of the prostate; HoLEP, Holmium laser enucleation of the prostate; mTURP, monopolar TURP; nwd, not well described; PUL, prostatic urethral lift; PVP, photoselective vaporization of the prostate; TUIP, transurethral incision of the prostate; TUMT, transurethral microwave therapy; TUNA, transurethral needle ablation

CASE 1

1. **d.** Based on history, urinary flow, and PVR, this patient sounds like he has developed a recurrent bladder outlet obstruction.
2. **e.** This patient has a bladder neck contracture (BNC). This can be treated with incision of the BNC in the operating room.

CASE 2

1. **d.** The patient is unlikely to be symptomatic from blood loss given normal BP and lack of tachycardia. Additionally, blood loss would likely not cause difficulty with ventilation. Given the use of normal saline irrigant at the time of HoLEP, this patient is at low risk to develop TUR syndrome. Perforation of the prostatic capsule and an extraperitoneal bladder injury would not illicit this response. However, an intraperitoneal bladder injury would result in irrigant filling the peritoneal cavity, causing increased abdominal pressure and cephalad shift of the diaphragm, limiting tidal volume. Peritoneal stretch from the intraabdominal accumulation of fluid can cause a vasovagal type response and the patient can become bradycardic.
2. **d.** No study or anecdotal experience has reported an increased risk of bladder injury at the time of morcellation in obese patients.
3. **e.** If no surgery is performed (a) then no bladder injury will occur in this patient with a small capacity bladder and large prostate, who is on antiplatelet therapy and at high risk for complications. Improving hemostasis and visualization will decrease the risk of complications related to the morcellator (b). If the bladder is too small to safely morcellate this large enucleated adenoma, then open cystotomy should be pursued (c). Anecdotally, some have reported staging morcellation when the tissue was difficult to morcellate secondary to visibility or just tissue quality. By staging the procedure, hemostasis should improve and the tissue will be softer and easier to morcellate (d). The irrigant inflow into the resectoscope should never be placed on pressure (e). If anything this may increase the risk of bladder injury/rupture as the outflow will not be able to keep up with the amount of fluid going into the bladder.

27 Complications of Ureteroscopic Surgery

JUSTIN B. ZIEMBA and BRIAN R. MATLAGA

CHAPTER OUTLINE

Introduction
Patient Selection
Renal and Ureteral Stones
Upper Urinary Tract Strictures
Upper Urinary Tract Urothelial Carcinoma
Contraindications
Preparation
Preoperative Assessment
Perioperative Preparation
Technique of Upper Urinary Tract Endoscopy
Cystoscopy and Initial Upper Urinary Tract Access
Negotiating the Obstruction
Maintaining Access
Entry of the Ureteroscope
Endoscopy
Intraoperative Complications
Ureteral Bleeding
Low-grade Ureteral Injury
High-grade Ureteral Injury
Failure and Conversion
Instrument Failure
Early Postoperative Complications
Infectious Complications
Cardiopulmonary Complications
Other Complications
Late Postoperative Complications
Ureteral Stricture
Retained and Encrusted Ureteral Stents
Conclusions
Chapter 27 Questions and Answers

KEY POINTS

1. Complications of ureteroscopy (URS) are rare.
2. Prevention of complications is the best management.
3. Appropriate patient selection, case preparation, and technique will help to minimize the potential for complications.
4. Always bypass the level of obstruction and establish access to the upper urinary tract with a wire prior to addressing any pathology.
5. Always visualize the actions of your instruments and energy sources, and never force the scope or instrument.
6. If a ureteral injury is suspected, then it is acceptable to abort the procedure, place a ureteral stent, and then return for a second session at a later date.
7. Postoperative complications are often minor and can be managed conservatively.

Introduction

Endoscopic surgery for the diagnosis and treatment of disorders of the upper urinary tract is an important minimally invasive tool in the urologists' armamentarium. Since 1929, when Young and McKay[1] documented the use of a cystoscope to perform a ureteropyeloscopy in a child, and with Marshall's first use of a flexible passively deflecting fiberoptic ureteroscope in 1964,[2] ureteroscopy (URS) has continued to progress.

Contemporary indications for URS now include the evaluation and treatment of many conditions of the upper urinary tract including ureteral and renal stone disease, strictures of the ureter, ureteropelvic junction (UPJ) obstruction, intrarenal strictures or calyceal diverticulum, and select upper urinary tract urothelial cell carcinoma (UCC).[3–6] Even with the greatly increased range of indications for URS, the rate of complications has steadily decreased. This change is partly the result of technologic advances such as the development of smaller ureteroscopes, improvements in energy sources with the holmium laser, and the use of smaller endoscopic tools such as guidewires, access sheaths, graspers, and baskets.[3–5] In addition, the skill level of urologists has significantly improved in part because URSs comprise index cases for resident education within the United States.[3]

Despite the now routine use of URS, complications do still occur. In an analysis for the Clinical Research Office of the

Endourological Society (CROES) URS Global Study Group, the observed stone-free rate in 11,885 patients was 85.6% with a very low overall postoperative complication rate of 3.5%, with the most common complication being fever (1.8%).[4] It should be noted that the majority of the complications described in the literature are based on analyses from renal and ureteral stone surgery. Nevertheless, the information can and should be applied to all cases where URS is used. To prevent complications, the best management remains appropriate case preparation with proper selection of the patient, technique, and postoperative care. In this chapter, we discuss the indications for URS, describe the techniques used to perform URS to prevent complications, and identify the possible intraoperative and postoperative complications with strategies to successfully recognize and manage them.

Patient Selection

RENAL AND URETERAL STONES

URS has become the de facto gold standard for the treatment of stones at all locations within the ureter.[5–7] In the kidney, stones up to an aggregate size of 2.0 cm have become routine indications for URS, especially in the lower pole.[7] Larger renal stones may also be addressed with URS but have lower stone-free rates, often require more than one session, and should therefore typically be reserved for percutaneous nephrolithotomy.[7–9]

UPPER URINARY TRACT STRICTURES

Strictures in the ureter, at the UPJ, and intrarenal abnormalities like a calyceal diverticulum are also amenable to URS in selected cases. In the ureter, endoscopic management of strictures is generally limited to those that are nonischemic, nonradiation induced, benign, less than 1.5 cm in length, with minimal ipsilateral hydronephrosis, good renal function, and without prior failed endoscopic attempts.[10] Similarly, for UPJ obstruction, endopyelotomy can be successful for strictures less than 2 cm in length, in the absence of ipsilateral severe hydronephrosis, ipsilateral renal function greater than 25%, and without a crossing accessory renal artery, which is an absolute contraindication.[11] It is also particularly effective as a salvage option following recurrence after an open or laparoscopic repair.[11] Last select intrarenal abnormalities like calyceal diverticulum can be addressed with URS, especially when located in an anterior calyx in the upper or midpole with or without a small associated stone.[12]

UPPER URINARY TRACT UROTHELIAL CARCINOMA

In the management of upper urinary tract UCC, URS is an important modality for both diagnosis and treatment. A diagnostic biopsy can be performed with URS, which is important for determining tumor grade and in treatment planning, especially for those patients with a solitary kidney or considering renal-sparing management.[13] URS ablation of the tumor is an acceptable elective treatment option for patients if the tumor burden can be successfully treated endoscopically and provided they meet strict criteria such as unifocal disease or small volume multifocal disease, small tumor size, low-grade histology on biopsy, noninvasive imaging characteristics, and the ability of the patient to submit to close postoperative surveillance.[13]

Contraindications

As described, appropriate patient selection for each indication is critical to successful treatment but also to prevent complications. Once the patient is appropriately selected for URS, the only absolute contraindication to proceeding is active, untreated infection.[6,7] Therefore, prior to URS all patients must undergo at least a urinalysis with microscopy, but preferably a urine culture.[6–9,14] If the urinalysis suggests infection, or the patient has a culture-proven urinary tract infection, then this must be treated prior to endoscopy.[6,7]

A relative contraindication is an uncorrected bleeding diathesis or ongoing anticoagulation therapy, which cannot be safely discontinued.[7] Despite this, it is still possible to perform URS in these situations, as long as the risks and benefits are clearly discussed with the patient and the medical team prior to proceeding.

Preparation

PREOPERATIVE ASSESSMENT

As with any surgical intervention, appropriate careful preparation is mandatory. In the anticipation of URS, the first step in patient preparation is a history and physical exam. A biochemical evaluation with serum and urine laboratory tests may also be carried out, and as stated previously, a urinalysis or a urine culture is the minimum standard.

Once this is completed, then depending on the pathology to be evaluated or treated, it is often necessary to proceed with an imaging study. For patients suspected of having nephrolithiasis, a noncontrast CT (NCCT) is the recommended first-line imaging modality for an adult nonpregnant patient.[15] However, a renal bladder ultrasound (US) may be an alternative with an NCCT reserved if a stone is suspected in the setting of acute flank pain.[14] For a patient with a ureteral stricture or UPJ obstruction, then a contrast-enhanced CT with delayed, excretory phase imaging (CT urography) to opacify the urinary tract is recommended. This is particularly important for the diagnosis of an upper urinary tract UCC, where CT urography is the recommended first-line imaging modality.[13,16,17] Alternative imaging strategies include MR urography if a patient has an absolute or relative contraindication to a CT, such as with an iodinated contrast allergy.[13,16]

After the diagnosis is made based on history, physical exam, laboratory tests, and imaging studies, then a discussion regarding the appropriateness of URS in the context of the patient's pathology, comorbidities, and provider's skill with URS should be conducted. If URS is selected, then depending on local or regional practice patterns, a preoperative medical evaluation for fitness for anesthesia can be performed.

PERIOPERATIVE PREPARATION

Once in the operating room, but prior to the start of the procedure, appropriate antimicrobial prophylaxis is necessary. A single preoperative dose[7,18] or duration of less than 24 hours is sufficient.[19] The antibiotic should be tailored to preoperative cultures, local resistance patterns, or based on guideline recommendations.[8,19] The timing of administration relative to scope insertion/incision should reflect the pharmacokinetics of the agent selected, which is particularly important for the fluoroquinolones that need to be given 120 minutes prior to incision (as opposed to 60 minutes for most other drugs).[19]

Prophylaxis to prevent thromboembolic events is an important consideration for all surgical patients. In the recent CROES URS Global Study Group, the rate of thromboembolic events was 0.02%.[4] This is an exceedingly rare complication and, therefore, the recommendation is against pharmacotherapy or mechanical prophylaxis, other than early ambulation for patients at very low risk.[20] However, individual patient factors should be taken into consideration, especially if the risk is high, and then pharmacotherapy or mechanical prophylaxis should be strongly considered.[20] It should be noted that despite these recommendations intermittent pneumatic compression is often still used in routine clinical practice.

Appropriate patient positioning is a vital component of the pre-procedure preparation. It provides for both patient and provider comfort. In the majority of instances URS is performed in the dorsal lithotomy position. This position, especially in thin patients and in those undergoing prolonged procedures, can result in neuropraxia, most often to the peroneal nerve, and compartment syndrome, which can lead to rhabdomyolysis.[21,22] Therefore it is important that the patient is appropriately positioned with all pressure points padded, the joints not hyperextended, and adequate perfusion is permitted and maintained to the extremities.[21] Of course, there is no substitute for close clinical monitoring during prolonged cases, especially in those patients at risk.[21]

Last appropriate preparation does not rest solely with the urologist. A coordinated effort is required from all members of the operating room team. Formal preprocedural briefings are becoming routine and have been demonstrated to improve inter-team collaboration,[23] prevent complications, and enhance patient outcomes. Furthermore, centers with a high case volume for URS have increased stone-free rates with decreased retreatment, readmission, and complication rates.[24] This is likely a surrogate for the presence of integrated, coordinated processes surrounding the preoperative, intraoperative, and postoperative care of patients after URS.

Technique of Upper Urinary Tract Endoscopy

CYSTOSCOPY AND INITIAL UPPER URINARY TRACT ACCESS

The initial step of upper urinary tract endoscopy is to perform a proper cystoscopy. This allows for examination of the bladder for concomitant pathology. Once the cystoscopy is complete and no lower urinary tract intervention is deemed necessary, then access to the upper urinary tract may be performed. This starts with identification and intubation of the appropriate ureteral orifice.

This step is most often performed with a guidewire. There are several available on the market of varying diameters and several with a hybrid technology. We prefer to use a hybrid 0.038″ straight Sensor PTFE-nitinol guidewire with hydrophilic tip. We feel that this hybrid wire combines the flexible, delicate tip of a nitinol hydrophilic wire, which is useful for bypassing points of obstruction, with the security and strength of a nitinol core PTFE-coated wire for instrument passage. Thus, it has the theoretical advantage of preventing the use of multiple different wire types.

NEGOTIATING THE OBSTRUCTION

The wire is then advanced under fluoroscopic guidance up to the point of obstruction or, if possible, passed into the renal pelvis (Fig. 27.1). If resistance is met during advancement of the wire, then a 5Fr open-ended ureteral catheter can be placed over the wire up to the point of resistance. The wire can then be removed. A retrograde pyelogram can be performed through the catheter to outline the ureter and collecting system in order to identify the area of concern (Fig. 27.2). If there is complete obstruction on the retrograde pyelogram, then an alternative access to the upper urinary tract may be necessary, such as a percutaneous access.

However, if this is not the case, then there are several strategies to negotiate the wire past the level of obstruction. If the issue is kinking of the wire, then the 5Fr open-ended ureteral catheter can be left in place to provide additional support. If, however, the wire continues to kink or coil, then the next step is to try a hydrophilic guidewire, which has the nitinol core of the guidewire but with a lubricated coating allowing for ease of passage and flexibility. These can be either straight or angled. By using these wires, it is often possible to bypass areas of narrowing or tortuosity not amenable with the standard or hybrid guidewire. It should be kept in mind that serial unsuccessful attempts at wire passage across an area of obstruction can lead to further injury, complicating future management. Therefore, if this is encountered, then it is reasonable to abort the procedure and consider alternative access to the upper urinary tract or decompression with percutaneous access.

MAINTAINING ACCESS

If a hydrophilic guidewire is used and placed into the collecting system, then this wire should be exchanged for the stiffer guidewire prior to instrument or URS placement. This can be done with a 5Fr open-ended ureteral catheter placed above the level of obstruction under fluoroscopic guidance. As stated previously, the hydrophilic guidewire has lubricity and is flexible, making it prone to migrating if used for manipulation. Once a guidewire is situated in the kidney, above the level of obstruction, then it is possible to proceed with endoscopy. However, if turbid or purulent urine is encountered at this, or any point, then it is mandatory to

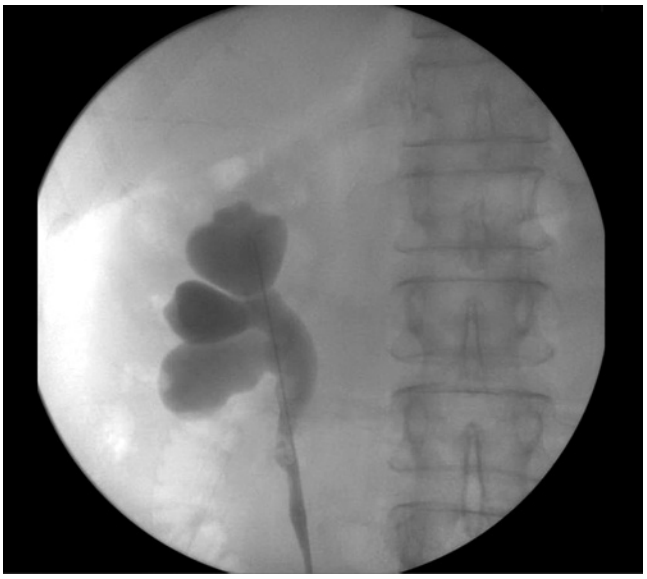

Figure 27.1 A large proximal ureteral stone is visualized with proximal moderate hydronephrosis. It was possible for a guidewire to be placed past the stone into the renal pelvis. To prevent complications, the level of obstruction should always be passed with a wire prior to advancing the ureteroscope.

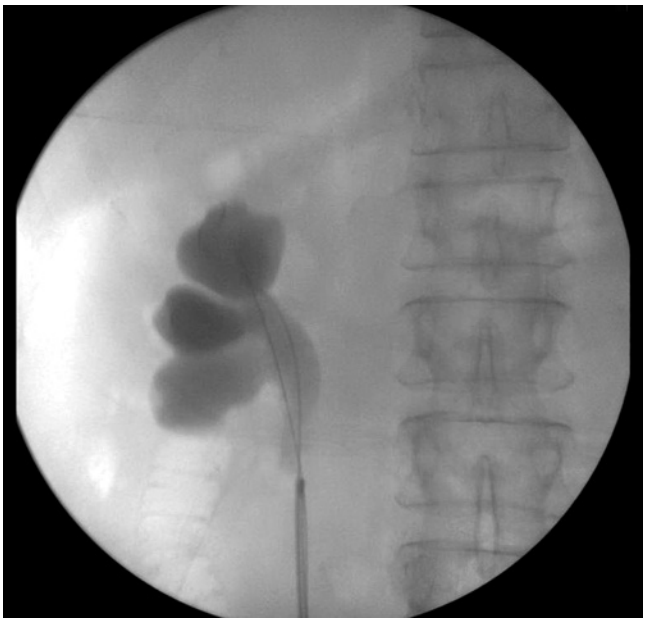

Figure 27.3 Working and safety guidewires were placed into the renal pelvis. Over the working wire, the ureteroscope is advanced into the collecting system. The safety wire remains in place. If complications do occur, a safety wire will provide persistent access to the renal collecting system for ureteral stent placement.

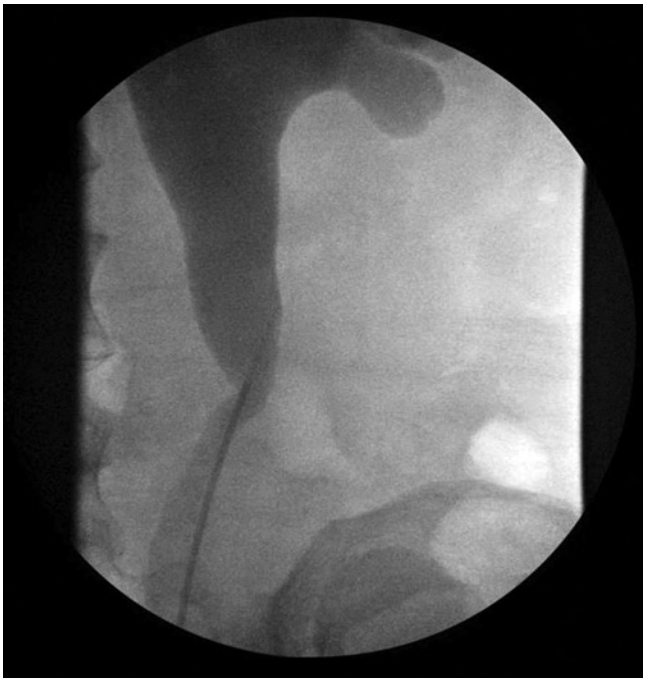

Figure 27.2 The placement of a wire in the renal pelvis was attempted, but resistance was met in the mid- to proximal ureter. The wire was exchanged for a 5Fr open-ended ureteral catheter. A retrograde pyelogram was performed, which demonstrated moderate hydroureter with a kink in the mid- to proximal ureter and proximal moderate-to-severe hydronephrosis. Once the anatomy was outlined, the 5Fr open-ended ureteral catheter was exchanged for a guidewire, and this kink was bypassed with placement of the wire in the renal pelvis. To prevent complications, the ureteral anatomy should be defined with a retrograde pyelogram, if resistance is met during initial wire placement.

abort the remaining procedure, place a ureteral stent for decompression, and then treat accordingly with appropriate antibiotics.[8,9]

Although a single wire may suffice, it is often prudent to place a second, safety wire to ensure access to the collecting system at all times, especially in the event of ureteral injury (Fig. 27.3). This is often done using a dual-lumen ureteral access catheter or an 8/10Fr dilator/sheath set. This is placed over the original, working wire into the distal ureter, and then a second, safety wire is placed through the device into the collecting system under fluoroscopic guidance. Both devices are also useful for gently dilating the ureteral orifice and intramural ureter to later accommodate the URS.

ENTRY OF THE URETEROSCOPE

If a rigid URS is required, which we typically limit to the distal one-third of the ureter below the crossing of the iliac vessels in men and the mid- to proximal ureter in women, then placement of a second wire can be done under direct visualization. A nice strategy is to place the second wire through the scope as the scope is advanced up the ureter, thereby "railroading" the scope between the two wires. Each wire acts to straighten and stent open the ureter as the scope passes by for improved visualization.

If a flexible URS is used, then either an instrument, such as a ureteral access sheath, or the URS itself can be advanced over the wire. This is usually done under fluoroscopic guidance. We prefer to use a ureteral access sheath for larger stone burdens (>1.0–1.5 cm), as they have demonstrated improved entry/reentry of the scope, decreased intrarenal pressures, as well as a suggestion of improved clinical

outcomes with a lower stone-free rate and reduced infectious complications but without increasing the rate of ureteral injury.[25,26]

At any point, if the instrument or scope cannot be advanced due to a narrowed ureter, then the options include serial or balloon dilation of the ureter or placement of a ureteral stent with a plan to return for a second attempt at ureteroscopy.[27] Typically, the distal ureter or a short segment of the ureter is dilated, only up to 12Fr. In our practice, we advocate for placement of a ureteral stent (Fig. 27.4) over ureteral dilation. This will allow for passive dilation of the ureter. A repeat attempt at access in a delayed setting is successful in the vast majority of cases.[28] We do not recommend using serial or balloon dilators, as we feel this is associated with a relatively high complication rate,[29] although it does involve the need for a second surgery.

ENDOSCOPY

Once the scope reaches the point of the pathology (stone, stricture, or tumor), then work can begin. The actual procedure will depend on the problem to be addressed. However, irrigation is a key component of all upper urinary tract procedures. Proper irrigation will allow for maximal visualization to facilitate safe and effective performance of the procedure. Saline should always be used for irrigation with URS due to the risk of hyponatremia with hypotonic solution.[9] There are advocates for both passive and active irrigation systems. Active (hand pump) irrigation systems reportedly have an increased risk of stone migration[30] with a suggestion of increased risk of pyelovenous and pyelolymphatic backflow, which can lead to infectious complications. We prefer to use a passive irrigation system with pressure bags. However, we acknowledge that for challenging cases with poor visualization it may be necessary to use an additional active irrigation mechanism to improve the field of view.

Intraoperative Complications

The overall rate of intraoperative complications is very low (Table 27.1). In the contemporary CROES multicenter, multinational clinical registry of URS, the rate was 5.5% in over 11,000 patients.[4] All of these were related to the ureter.

Figure 27.4 A wire was placed into the collecting system. The advancement of the ureteroscope up the ureter over the wire was attempted, but it could not be advanced past the distal ureter. The wire was exchanged for a 5Fr open-ended ureteral catheter and a retrograde pyelogram was performed. This demonstrated a very narrow caliber ureter, which was only approximately 5Fr in diameter. Therefore it would not accommodate the ureteroscope. A ureteral stent was placed for passive dilation of the ureter with plans to return for a delayed ureteroscopy.

Table 27.1 Intraoperative Complications of Ureteroscopic Surgery and Management

Complication	Risk Factor[a]	Etiology	Rate[b]	Management
Ureteral bleeding	Multiple ureteral locations Low-volume center	Dilation Misfired energy Mucosal injury	1.4%	Observation Ureteral stent
Ureteral erosion or false passage	Unknown	Wire placement Scope manipulation Misfired energy Instrument deployment Stone removal	Unknown	Observation Ureteral stent
Ureteral perforation	Midureteral location Low-volume center	Wire placement Scope manipulation Misfired energy Instrument deployment Stone removal	1.0%	Ureteral stent
Ureteral intussusception or avulsion	Low-volume center	Entrapped stone removed with excessive force	0.1%	Nephrostomy tube Delayed repair

Impact of case volume on outcomes of ureteroscopy for ureteral stones: the Clinical Research Office of the Endourological Society Ureteroscopy Global Study. Eur Urol. 2014 Dec;66(6):1046-51.)

([b]Adapted from de la Rosette J, Denstedt J, Geavlete P, et al. The Clinical Research Office of the Endourological Society Ureteroscopy Global Study: indications, complications, and outcomes in 11,885 patients. J Endourol. 2014 Feb;28(2):131-9.)

Several factors were also shown to modify the risk of intraoperative complications.[5,24,26] However, preoperative ureteral stent placement was not one of them. In fact, there was no difference in intraoperative complications with or without pretreatment ureteral stent placement in either renal or ureteral stones.[31]

A grading system developed by the American Association for the Surgery of Trauma exists for traumatic injuries.[32] This ranges from contusion (grade I) to complete transection with extensive devitalization (grade V).[32] However, this is not applicable to iatrogenic injuries. Instead, a specific classification system was developed for injury from URS.[33] In this scale, damage to the ureter ranges from wall petechiae (grade 0) to mucosal erosion (grade 1) to perforation with or without advential preservation (grade 2 and 3) to total avulsion (grade 4) (Fig. 27.5).[33] Although this continuum when divided as either low grade (grade 0 and 1) or high grade (grade 2, 3, and 4) is useful as a framework with which to discuss iatrogenic ureteral injuries from URS, it is rarely used clinically.

URETERAL BLEEDING

Bleeding was the second most common complication in the CROES registry at only 1.4%.[4] However, it was more common when stones were treated in multiple locations (2.5%) as compared to only a single location in the proximal (0.9%), mid- (1.3%), or distal (1.3%) ureter.[5] Similarly, case volume also influenced the rate. Low-volume centers had more than twice the rate as high-volume centers (2.5% vs 0.9%).[24] Minor bleeding can occur during ureteral dilation, due to misfired energy from a laser, or at sites of pathology, such as along the mucosa of an impacted stone or from a papillary urothelial tumor. Additionally, wires advanced too far can pierce the collecting system and enter the renal parenchyma, leading to minor bleeding. The rate of

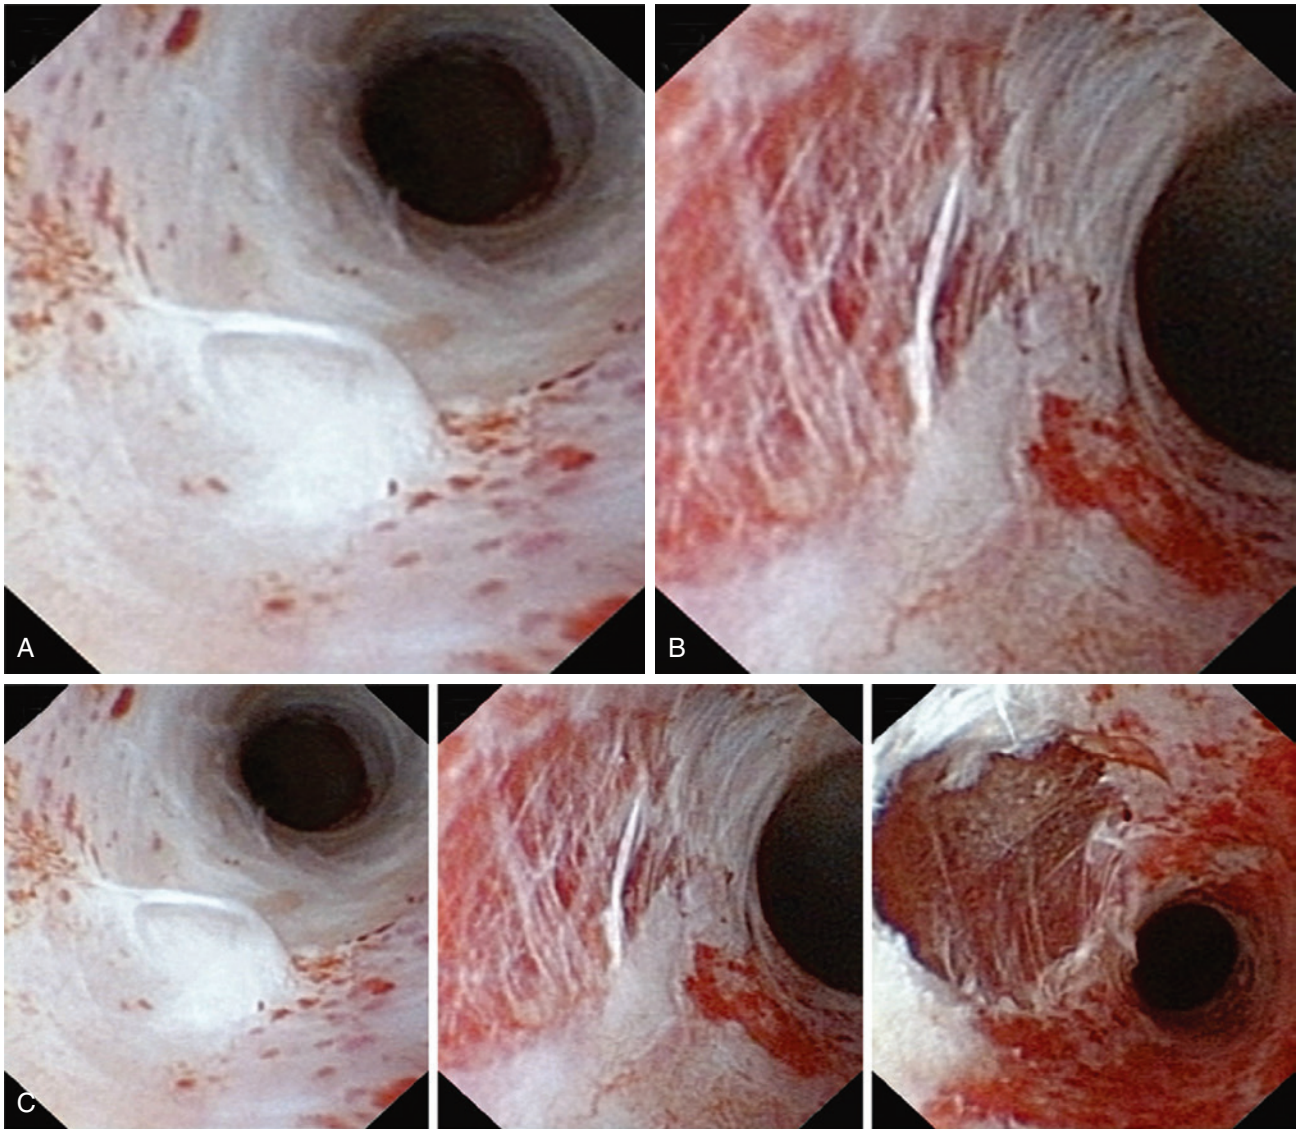

Figure 27.5 Part A demonstrates ureteral mucosal erosion (grade 1). Part B shows ureteral perforation with adventitial preservation (grade 2). Part C displays ureteral perforation without adventitial preservation where periureteral fat is visible (grade 3). Prompt recognition of these injuries is key with ureteral stent placement to facilitate healing. (Adapted from Traxer O, Thomas A. Prospective evaluation and classification of ureteral wall injuries resulting from insertion of a ureteral access sheath during retrograde intrarenal surgery. J Urol. 2013 Feb;189(2):580-4.)

subcapsular hematoma is estimated at 0.36–0.4%.[34,35] This minor bleeding is usually self-limited. However, it can reduce visibility if it enters the collecting system, and active irrigation may be necessary for a short period of time. More extensive bleeding is very rare, although it can occur, especially from a large papillary urothelial tumor, or following endopyelotomy for a UPJ obstruction with rates as high as 8–9%.[36,37] Rare causes of massive ureteral bleeding include endometriosis and ureteroarterial fistulas.[38] If bleeding is severe and persistent or visualization is poor, then it is prudent to abort the procedure and place a ureteral stent. This is usually sufficient to tamponade the bleeding. However, it may be necessary to consider further intervention such as angioembolization[37] or, rarely, nephrectomy in select situations. A blood transfusion after ureteroscopy is very rare, estimated at only 0.2%.[4]

LOW-GRADE URETERAL INJURY

Low-grade ureteral injuries consisting of either a contusion with wall petechiae, a superficial mucosal erosion, or false passage are likely very common during URS. However, the exact incidence is unknown. In a multi-institutional cohort, there were a total of 311 (86.6%) patients who experienced a low-grade ureteral injury after URS with the use of a ureteral access sheath.[33] The reporting of this complication is absent from other studies, particularly the comprehensive CROES URS registry.[4] Nevertheless, as it is commonly encountered in routine clinical practice, recognition and treatment are still important. The mucosal erosion typically occurs during wire placement, scope manipulation, misfired energy, instrument deployment, or stone removal. After the injury, it is still possible to complete the procedure, but extra care must be taken not to convert a mucosal erosion to a perforation. This can best be avoided by moving the action of the procedure away from the site of injury. This is especially true if stone fragmentation is undertaken, as stones displaced outside the ureter are associated with the later development of ureteral strictures.[39] Furthermore, if at all possible, the site of injury should not be crossed repeatedly, as is common practice with basket stone removal. At the conclusion of the procedure, or if there is concern for a worse ureteral injury, then it is reasonable to abort the procedure and place a ureteral stent. The late development of a ureteral stricture after URS is very rare, with a contemporary reported rate of only 0.3%.[4]

HIGH-GRADE URETERAL INJURY

High-grade ureteral injuries, although potentially devastating, are now increasingly rare. These include ureteral perforation, intussusception, and avulsion. As stated previously, perforation involves injury to all layers of the ureter with either the adventitial or the periureteral fat containing the area of damage. The perforation, as with mucosal erosion, can occur with wire placement, scope manipulation, misfired energy, instrument deployment, and stone removal. The current accepted rate of perforation is 1%.[4] It is more common in midureteral locations (1.6%) than in the proximal (1.1%), distal (0.7), or multiple locations (1.1%).[5] Similarly, a low-volume center is associated with an increased rate as compared to a high-volume center (2.3% vs 0.8%, respectively).[24] Surprisingly, the rate was not changed with or without use of a ureteral access sheath (1.2%).[26] Once a perforation is identified, then the procedure should be aborted and a ureteral stent should be placed. The procedure can then usually be accomplished in a delayed fashion after several weeks with ureteral stent drainage. Again, the late development of a ureteral stricture is very rare.[4]

Intussusception is also a rare event where the mucosa telescopes inward, folding in on itself, and separating from the underlying stroma. This is often associated with antegrade or retrograde basket stone removal, where the stone entrapped within the basket is too large to be removed from a narrowed, unaccommodating ureter.[40] The force of removal shears the ureteral mucosa, pulling it inward with the basket. This is one reason why blind basketing is prohibited.[6] The exact incidence of this complication is unknown, as it is likely not reported separately from avulsion.

Ureteral avulsion is the most feared and devastating complication of URS. Thankfully, it is exceedingly rare. It is reported to occur in only 0.1% of cases.[4] The location of treatment (proximal, mid, distal, or multiple locations) does not seem to influence the rate of avulsion.[5] However, case volume does. The rate was over 12 times higher in low- as compared to high-volume centers (0.5% vs 0.04%).[24] Similarly to intussusception, ureteral avulsion typically occurs when a stone too large to be removed is engaged within a basket and then excessive force is used to remove it. During removal, the ureter becomes entrapped, tears from its attachments, and then is externalized with the basket and scope as they are withdrawn. If this is recognized, then the procedure must be aborted immediately. Another possible complication related to intussusception and avulsion is the "scabbard effect," where the proximal scope, which is larger in diameter than the tip, becomes wedged in the narrower distal ureter, resulting in friction and dissociation of the mucosa. This is similarly observed when small stone fragments get trapped along the length of the scope.

For intussusception, avulsion, and the scabbard effect, proper technique is the best prevention. When stone removal is undertaken, the mucosal wall must always be visualized. If resistance is met at any point, then further removal must be aborted. The ureter should then be inspected for integrity. Again, blind basketing without direct visualization should be avoided,[6] and excessive force should never be used. If, however, intussusception or avulsion does occur, then placement of a ureteral stent is likely not possible, nor will it provide for adequate drainage as the ureter is completely devascularized. Therefore, it is prudent to urgently place a nephrostomy tube. Formal open or laparoscopic surgical repair will be required. The type of repair will depend on the location and extent of the injury, comorbid medical conditions, and the experience of the surgeon.[40] The repairs range from simple ureteroneocystotomy to psoas hitch or Boari flap to ileal interposition to autotransplantation or nephrectomy.[40] Therefore we do not advocate for immediate repair but rather a delayed approach for time to adequately discuss the options with the patient.

FAILURE AND CONVERSION

Failure is defined as an inability to access the ureter or stone during initial treatment. Both failure and conversion are

reported as complications in modern series with overall rates of 1.6% and 0.1%, respectively.[4] There is evidence that stone location and procedure volume do influence the rates. Failure is more common in a proximal (2.8%) location than in a mid- (1.9%), distal (0.7%), or at multiple (0.7%) locations.[5,41] Similarly, it is more common in low- as compared to high-volume centers (2.3% vs 1.5%).[24] This was also observed for the rate of conversion (0.4% vs 0.01%).[24] Although both failure and conversion are listed as complications, in certain circumstances they should be viewed as appropriate treatment, especially if further attempts at ureteroscopy would lead to injury.

Instrument Failure

Instrument failure can include any piece of equipment necessary to safely and adequately perform URS. This can be the ancillary equipment such as the operating room table, positioning devices, and fluoroscopy unit; the endoscopic tools such as the laser generation unit, laser fiber, and stone retrieval basket; and the scope itself. However, we will focus only on the endoscopic tools, particularly the stone retrieval basket, and the scope. The exact rate of endoscopic tool failure and/or breakage is not known. It is likely not all that common, but it is important to be familiar with strategies should it occur. Scope durability, however, is well defined and quantifiable, which allows for appropriate planning and preparation.

Stone Retrieval Basket Failure. The stone retrieval baskets used for URS are now miniaturized to 1.9Fr for improved irrigation, tipless to prevent mucosal abrasions, and composed of nitinol, allowing for maximal flexibility without compromising strength.[42] In fact, they are the only basket recommended by current EAU guidelines for stone extraction.[7] Despite their clinical utility, the baskets remain susceptible to damage, especially when laser energy is directly applied.[43] Therefore when a basket is broken, it should be immediately disengaged from the stone. The basket can then be withdrawn into the scope or, if not possible, then carefully withdrawn out of the ureter under direct visualization.[40] It is imperative to always be cognizant of the end of the basket and the damaged or disrupted tine to prevent its catching on the ureter.[40]

The other possible scenario involving a basket is if it is used to grasp a stone larger than the ureter will accommodate for removal. As stated previously, this is the condition where ureteral intussusception or avulsion can occur if excessive force is applied. Typically, the basket will be able to be disengaged from the stone, but sometimes this is not possible. In this case, one strategy is to disassemble the basket. Usually, the external end of the basket housing can be unscrewed (or the basket wire itself cut), which allows the outer sheath of the basket to be removed through the scope while the internal basket wires remain in place. This often increases the opening diameter of the basket wires, facilitating disengagement from the stone. If this occurs, then it can be removed through the scope with the stone left in place.

If this does not disengage the basket from the stone, then two additional strategies are possible. The first is to pass a 200-micron laser fiber through the working channel alongside the dissembled basket. The stone can then be fragmented in situ while engaged within the basket. Once the stone is in pieces less than 2–3 mm, the basket can usually be separated from the stone and removed. When employing this strategy, it is important to know that irrigation through the scope will be minimal and also that maneuverability of the scope must be limited as it is still engaged to the basket and stone. The alternative option is to remove the scope entirely over the disassembled basket and then reinsert it alongside the basket up to the level of the stone.[40] The laser can then be introduced and the stone fragmented, allowing for safe basket removal. In fact, a proprietary basket, termed the "Escape" basket, is a 1.9Fr device specifically designed to engage the stone and then allow passage of a 200-micron laser fiber through the basket to facilitate fragmentation of the stone.[44]

Scope Damage and Durability. Damage to the URS is primarily localized to degradation of the lens/fiber optic bundle, channel perforation, or loss of deflection. In a survey of the four major URS manufacturers (ACMI, Olympus America, Karl Storz, and Richard Wolf) in 2005, repairs to the URS were to the working channel, shaft of the scope, deflection mechanism, and the eyepiece in 52%, 27%, 15%, and 8% of cases, respectively.[45] The mechanism was attributed to the laser in 42% of the cases with damage to the working channel, 20% of the cases with damage to the body of the shaft, 20% of the cases with damage to the optical fibers, and 45% of the cases with damage to the deflection mechanism.[45] Other top causes for the damage at each site included instrument insertion/extraction, extreme bending, sterilization, and storage.[45]

By understanding the common mechanisms of damage to the URS, strategies aimed at preventing or mitigating them can be designed and implemented to improve the longevity of each scope. In particular, avoiding firing of the laser in close proximity to the tip of the scope or within the working channel will prevent damage to the fiberoptic bundles and working channel. Similarly, not deploying endoscopic devices when the scope is at extreme degrees of deflection will also preserve the working channel.

Durability represents the number of repairs over the total number of cases performed. In a contemporary series with a modern third-generation fiber-optic URS model (Olympus URF P5), all 643 cases at a single ambulatory surgical center in the United States were examined during a 3-year period (2011–2014).[46] There were 31 repairs performed on the four flexible URSs for an average of 21 procedures between repairs.[46] With the new fourth-generation digital URS there is a suggestion of even superior durability. In a retrospective analysis at a single institution with a single surgeon using a single model of digital URS (Storz Flex-Xc) from 2012–2013, the three scopes were able to be used for 96, 151, and 159 cases, respectively, prior to repair.[47]

Durability varies by scope manufacturer, practice location, surgeon, sterilization technique/team, and case mix. Therefore, it is important to have an understanding of the average durability of your scope. This will allow for proper inventory so that in every case, a clean, functional scope is always available. In our experience, this is best achieved through standardization of staff, processes, and equipment in consultation with manufacturer representatives. The recent introduction of a single-use (disposable) digital

ureteroscope into the market provides an alternative option that eliminates many of the issues related to durability and reprocessing and, thus, may increase the value of the procedure.

Early Postoperative Complications

In the contemporary CROES multicenter, multinational clinical registry of URS, the rate of postoperative complications was 3.5% in over 11,000 patients (Table 27.2).[4] Of these patients, 78% (2.8% of the total population) experienced a low-grade complication (Clavien Grade I or II) and 19% (0.62% of the total population) experienced a high-grade complication (Clavien Grade III, IV, or V).[4] The causes of death in the Clavien V group (five patients, or 0.02% of the total population) were sepsis, pulmonary embolism, cardiac arrest, multisystem organ failure, and fatal arrhythmia.[4]

INFECTIOUS COMPLICATIONS

Fever was the most common immediate postoperative complication, with a rate of 1.8%.[4] Documented urinary tract infection was rare, with a rate of 1.0%, and progression to sepsis was even rarer, with a rate of 0.3%.[4] There was a single documented death related to sepsis.[4]

As infectious complications are common after URS, it is important for the practicing endourologist to know how to prevent, recognize, and treat them. According to guideline recommendations, a preoperative urine microscopy or culture is necessary, and all bacteriuria and UTI should be treated prior to URS.[6,8] Antibiotic prophylaxis is indicated. A single preoperative dose[7,18] or duration of less than 24 hours is sufficient.[19] The antibiotic should be tailored to preoperative cultures, local resistance patterns, or based on guideline recommendations.[19] The timing of administration relative to scope insertion/incision should reflect the pharmacokinetics of the agent selected, which is particularly important for the fluoroquinolones that need to be given 120 minutes prior to incision (as opposed to 60 minutes for most other drugs).[8,19] Despite these guideline recommendations,[7,19] a recent analysis of the CROES URS registry demonstrated no difference in fever or UTI for those patients receiving as compared to those patients not receiving perioperative antimicrobial prophylaxis for both renal (fever: 2.2% vs 2.2%; urinary tract infection: 1.6% vs 1.1%) and ureteral (fever: 1.1% vs 0.5%; urinary tract infection: 0.6% vs 0.4%) stones.[48] The risk factors identified for the development of infectious complications included female gender, Crohn's disease, anticoagulation use, increasing stone burden, and an ASA score greater than II.[48] Although this study does challenge accepted recommendations, we still advocate for a single dose of antimicrobial prophylaxis prior to scope insertion, which is not continued postoperatively.

Of all the infectious complications, sepsis is the most feared, and if it is not recognized early it has a high mortality.[49] Sepsis is a systemic response to probable or documented infection, and severe sepsis is sepsis plus end-organ dysfunction or tissue hypoperfusion.[49] Early recognition is key. Therefore all urologists should be familiar with the evaluation and treatment of sepsis, which can occur during manipulation of an obstructed, infected urinary system. Current guidelines recommend initial fluid resuscitation, bacterial cultures prior to starting antimicrobial therapy, imaging to confirm the potential source of infection, administration of antibiotics within the first hour with activity against all likely pathogens and tissue penetration against

Table 27.2 Early Postoperative Complications: Prevention and Management

Complication	Rate[a]	Prevention	Management
Bleeding	0.4%	Sound endoscopic technique	Observation Ureteral stent
Bladder spasms	0.4%	Avoid ureteral stent placement	Remove ureteral stent Anticholinergics Alpha-blockers
Fever	1.8%	Negative baseline urinalysis or culture Single-dose antimicrobial	Antimicrobials
Urinary tract infection	1.0%	Negative baseline urinalysis or culture Single-dose antimicrobial	Antimicrobials
Sepsis	0.3%	Negative baseline urinalysis or culture Single-dose antimicrobial	Fluid resuscitation Antimicrobials Cultures Imaging Source control
Venous thromboembolic	0.02%	Early ambulation Mechanical or pharmacologic in high-risk patients	Early recognition Anticoagulation
Cerebrovascular	0.02%	Preoperative medical evaluation	Early recognition
Acute myocardial infarction	0.01%	Preoperative medical evaluation	Early recognition
Death	0.02%	Preoperative medical evaluation	Early recognition

([a]Adapted from de la Rosette J, Denstedt J, Geavlete P, et al. The Clinical Research Office of the Endourological Society Ureteroscopy Global Study: indications, complications, and outcomes in 11,885 patients. J Endourol. 2014 Feb;28(2):131-9.)

the likely source, and early (<12 hours) source control.[49] In the setting of URS, if sepsis is recognized, then the procedure should be immediately aborted, cultures obtained, and a ureteral stent or percutaneous nephrostomy placed for immediate decompression.

CARDIOPULMONARY COMPLICATIONS

These are the rarest complications in the immediate postoperative period. In the recent CROES URS Global Study Group, the rates of venous thromboembolic events, cerebrovascular accident/transient ischemic attack, and acute myocardial infarction were 0.02%, 0.02%, and 0.01%, respectively.[4] Although rare, these complications can be devastating. Therefore prevention remains the best strategy. For venous thromboembolic events, guidelines recommend against routine pharmacotherapy or mechanical prophylaxis, other than early ambulation for patients at very low risk.[20] However, individual patient factors should be taken into consideration, especially if the risk is high, and then pharmacotherapy or mechanical prophylaxis should be strongly considered.[20] Despite these recommendations, intermittent pneumatic compression is often still used in routine clinical practice. To prevent cerebrovascular events, it is important to manage patients' risks with optimization of their medical comorbidities in consultation with a primary care physician or cardiologist prior to URS.

OTHER COMPLICATIONS

These include bleeding and bladder spasms. For both, the reported rate is 0.4%.[4] The majority of bleeding is likely clinically insignificant as the need for a blood transfusion after URS is very rare.[4] Bleeding is usually self-limited and, if not, then can often be controlled with a ureteral stent alone. As for bladder spasms, this is likely an under-reported complication. These can originate from the procedure itself but are more commonly associated with the postoperative indwelling ureteral stent. One way to avoid these symptoms is to not place a ureteral stent. According to current guidelines, placement of a ureteral stent is optional after uncomplicated URS.[6,7,9] Despite this recommendation, in the CROES URS registry, over 80% of cases had a ureteral stent inserted.[4] If a ureteral stent is left in place, both alpha-adrenergic antagonists and anticholinergics have demonstrated efficacy in reducing stent-related symptoms, although it is unclear if one is superior to the other or if a combination is beneficial.[50,51]

Late Postoperative Complications

In the contemporary CROES multicenter, multinational clinical registry of URS, the readmission rate within 3 months was 8.4% (Table 27.3).[4] When the reason was identified, it was due to flank pain (1.1%), ureteral stent discomfort (0.9%), and ureteral obstruction (0.5%).[4] The majority of these can be managed conservatively. Ureteral stricture, on the other hand, can be devastating, often requiring formal open or laparoscopic surgical revision. Thankfully, this late complication is very rare, with a reported rate of only 0.3%.[4]

Table 27.3 Late Postoperative Complications: Prevention and Management

Complication	Rate[a]	Prevention	Management
Readmission	8.4%	Sound endoscopic technique	Early recognition variable
Ureteral stricture	0.3%	Sound endoscopic technique	Postoperative imaging Endoscopic dilation or incision Open or laparoscopic repair
Encrusted/ retained ureteral stent	Unknown	Avoid ureteral stent placement Patient counseling Ureteral stent registry	Postoperative imaging Endoscopic removal

([a]Adapted from de la Rosette J, Denstedt J, Geavlete P, Keeley F, Matsuda T, Pearle M, et al. The Clinical Research Office of the Endourological Society Ureteroscopy Global Study: indications, complications, and outcomes in 11,885 patients. J Endourol. 2014 Feb;28(2):131-9.)

URETERAL STRICTURE

Ureteral stricture formation likely results from injury to the mucosa and underlying lamina propria leading to vascular compromise, fibrosis, and ultimately luminal narrowing. The mechanism by which the injury occurs is varied. It can be iatrogenic due to perforation from wire placement, scope manipulation, misfired energy, instrument deployment, or stone removal. It can also be due to the impacted stone itself. In one historical series, there was an observed ureteral stricture rate of 24% in the setting of perforation at the site of an impacted stone.[52] Furthermore, all the stones were impacted for greater than 2 months, suggesting that not only perforation but also duration of impaction was a risk factor for ureteral stricture formation.[52] However, in a more contemporary series, the rate of ureteral stricture formation was significantly lower at only 7.8%. None of the traditional risk factors, including stone size, presence of impaction, duration of impaction, site of impaction, or mucosal injury/perforation was associated with ureteral stricture formation.[53] Furthermore, registry data have demonstrated that ureteral stricture formation is not associated with stone location[5] or the use of a preoperative ureteral stent.[31] Ureteral access sheaths also do not appear to increase overall postoperative complications.[26] Despite these conflicting reports, prevention remains the best solution. Therefore sound endoscopic techniques as previously described always should be followed to prevent injury to the ureter and thus avoid development of a ureteral stricture.

Although rare, detection of a ureteral stricture is important, especially in the setting of silent obstruction. According to current guidelines, postoperative imaging to confirm removal of the stone and resolution of hydronephrosis is recommended.[15] This should be performed first with a renal ultrasound and then subsequent imaging, depending on the modality of treatment and the findings.[15] Although the rate of ureteral stricture formation is rare, and silent obstruction in this setting is even rarer, a recent analysis

demonstrated the possible cost-effectiveness of routine imaging as opposed to imaging only for symptoms following URS.[54] In this analysis, opportunistic imaging only after the development of symptoms resulted in a $130 savings per patient but at the risk of loss of up to two kidneys per 100 patients.[54] Therefore the authors concluded that the minimal cost increase for routine postoperative imaging was justified as it prevented renal unit loss.[54]

After a ureteral stricture is identified, then the type of repair will depend on the location and extent of the injury, comorbid medical conditions, and experience of the surgeon.[40] Endoscopic management of strictures is generally limited to those that are nonischemic, nonradiation induced, benign, less than 1.5 cm in length, with minimal ipsilateral hydronephrosis, good renal function, and without prior failed endoscopic attempts.[10] If endoscopic repair is not an option, then formal open or laparoscopic surgical repair may be required. These repairs include simple ureteroneocystotomy, psoas hitch or Boari flap, ileal interposition, autotransplantation, and rarely nephrectomy.[40]

RETAINED AND ENCRUSTED URETERAL STENTS

The optimal duration a ureteral stent remains indwelling should be the shortest possible period of time that is deemed safe for the patient. Ureteral stents themselves are associated with complications, including irritative voiding symptoms, infection, hematuria, migration, encrustation, obstruction, and renal unit loss.[55] In an early analysis of modern ureteral stents, encrustation occurred in 9.2%, 47.5%, and 76.3% at less than 6 weeks, 6 to 12 weeks, and greater than 12 weeks, respectively.[56] Even in stents that remained in place for less than 3 months, a 30% rate of luminal occlusion was cited, but the incidence of clinical obstruction was noted to be only 4%.[56] Therefore to completely eliminate the risk of stent-related complications, a ureteral stent should not be placed after routine URS, as recommended by current guidelines.[6,7,9] If, however, a ureteral stent is placed, then appropriate patient counseling is necessary to ensure timely follow-up for removal. Additionally, a ureteral stent registry may also be valuable to ensure adequate tracking and provide reminders to staff. Patient noncompliance is a commonly cited risk factor,[55] and these patients should be given extra attention in follow-up.

When a ureteral stent becomes encrusted, removal requires complex, often multiple endoscopic procedures.[55,57,58] However, prior to any removal, it is recommended that the patient undergo a CT scan to document the degree of stone burden on the proximal and distal curl.[57] Once the stone burden is quantified, the distal curl should be addressed first, often with cystolitholapaxy. Once this is completed, then the proximal curl can be managed. Both URS and percutaneous approaches are acceptable, but the choice of procedure will depend on the ability of the URS to be placed alongside the encrusted stent and also the quantity of stone to be removed.

Conclusions

Although URS is commonly employed across an increasing range of indications, complications are becoming rarer. When they do occur they are often minor and can be treated conservatively. To minimize the potential for complications, proper patient selection, case preparation, and sound endoscopic technique are all critical. When an intraoperative complication does occur, early recognition, and then appropriate management, usually with abortion of the procedure and placement of a ureteral stent, is sufficient. Early and late postoperative complications, although rare, can be serious, especially the development of infection and stricture, and therefore appropriate follow-up is necessary after the procedure.

Chapter 27 Questions

1. Prior to any endoscopic procedure of the upper urinary tract the minimum preoperative laboratory evaluation in all patients should include which of the following?
   a. Urinalysis with microscopy or urine culture
   b. Basic metabolic panel
   c. Complete blood count
   d. Coagulation panel
   e. Serum calcium

2. You have just completed a time-out for patient safety prior to starting a routine ureteroscopy for a 5-mm midureteral stone. What medication should you ensure is administered prior to scope insertion?
   a. Antimicrobial prophylaxis
   b. Mannitol
   c. Methylene blue
   d. Lasix
   e. Heparin

3. In the course of a ureteroscopy for removal of a 7-mm proximal ureteral stone, you begin by placing a wire into the ureteral orifice. However, as you advance the wire up the ureter under fluoroscopic guidance you encounter resistance at the proximal ureter. Which one of the following would be an appropriate next step?
   a. Use excessive force to drive the wire past the area of resistance
   b. Exchange the wire for a ureteral catheter and perform a retrograde pyelogram
   c. Convert the procedure to a percutaneous nephrolithotomy
   d. Convert the procedure to a shockwave lithotripsy
   e. Abort the procedure

4. You are consulted by the emergency department to see a patient with a 1-cm obstructing distal ureteral stone with resultant moderate hydronephrosis. The patient's only complaint is persistent flank pain. You elect to proceed with ureteroscopy and laser lithotripsy. At the start of the case, you place a guidewire into the ureteral orifice, and there is an immediate return of purulent material. Which one of the following would be an appropriate next step?
   a. Proceed with ureteroscopy and laser lithotripsy
   b. Place a ureteral stent and delay ureteroscopy
   c. Abort the procedure without urinary drainage
   d. Convert the procedure to a percutaneous nephrolithotomy
   e. Convert the procedure to a shockwave lithotripsy

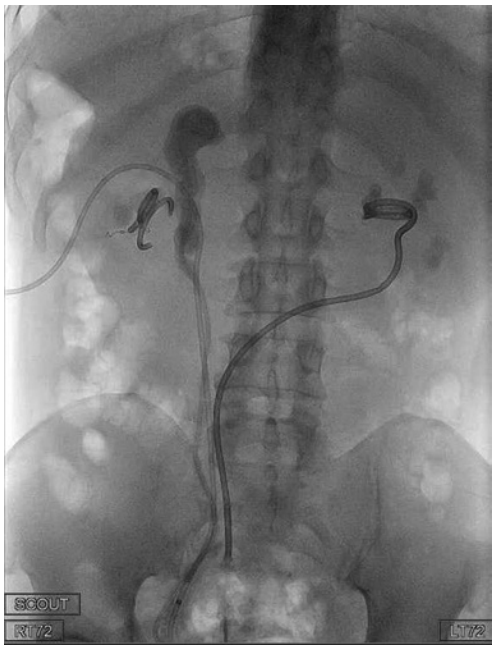
5. You would like to approach an 8-mm lower pole renal stone with ureteroscopy and laser lithotripsy. You start the case by placing both a working and safety guidewire into the renal collecting system without issue. However, as you attempt to advance the ureteroscope over the working wire and into the distal ureter you meet resistance. The scope cannot be advanced. Which one of the following would be an appropriate next step?
   a. Use excessive force to drive the ureteroscope past the area of resistance
   b. Place a ureteral stent for passive dilation and delay ureteroscopy
   c. Abort the procedure without urinary drainage
   d. Convert the procedure to a percutaneous nephrolithotomy
   e. Convert the procedure to a shockwave lithotripsy

6. What is the contemporary reported rate of ureteral stricture development after ureteroscopy?
   a. 1.5%
   b. 1%
   c. 0.5%
   d. 0.3%
   e. 2.0%

7. You are performing ureteroscopy for an 8-mm midureteral stone. You visualize the stone, and it appears partially impacted in the ureteral mucosa. You begin with laser lithotripsy. After several minutes, you notice a ureteral perforation with periureteral fat visible. You have a safety wire in place. Which one of the following would be an appropriate next step?
   a. Terminate ureteroscopy and place a ureteral stent
   b. Complete ureteroscopy with laser lithotripsy but without fragment extraction
   c. Complete ureteroscopy with laser lithotripsy and fragment extraction
   d. Convert the procedure to a percutaneous nephrolithotomy
   e. Convert the procedure to a shockwave lithotripsy

8. You have successfully performed laser lithotripsy on a 1-cm renal pelvis stone. The stone is now in several fragments in the renal pelvis. You proceed to remove the fragments with a nitinol basket. After engaging one of the fragments, you withdraw the basket into the ureter, but it becomes entrapped in the proximal ureter. You cannot disengage the basket from the stone. Which one of the following would be an appropriate next step?
   a. Use excessive force to move the basket past the area of entrapment
   b. Disassemble the external basket housing and then attempt to disengage it from the stone
   c. Terminate ureteroscopy and place a ureteral stent
   d. Convert the procedure to a percutaneous nephrolithotomy
   e. Convert to an open ureterolithotomy

9. What is the contemporary reported rate of postoperative complications from ureteroscopy, and which one is the most common?
   a. 3.5%; Fever
   b. 3%; Urinary tract infection
   c. 2.5%; Sepsis
   d. 0.6%; Ureteral stricture
   e. 1.0%; Death



10. You are called into the operating room by your colleague who encountered a complication during ureteroscopy. When you enter the operating room, you

recognize the ureteroscope, the basket containing a stone fragment, and the ureteral mucosa all externalized per urethra. You are concerned about a ureteral avulsion. Which one of the following would be an appropriate next step?
a. Immediate surgical exploration with primary repair
b. Immediate cystoscopy with ureteral stent placement
c. Immediate percutaneous nephrostomy tube
d. Immediate nephrectomy
e. Immediate abortion of the procedure without urinary drainage

Case Studies

CASE 1

A 53-year-old gentleman presents to your clinic to re-establish care after undergoing bilateral ureteroscopy for bilateral renal stones approximately 1 year prior by another provider. He states that he had bilateral ureteral stents placed after the procedure, but he never returned to have them removed. He is currently asymptomatic without flank pain. You obtain point-of-care labs in your office, and these are significant for a creatinine of 1.2 mg/dL and a urinalysis positive for leukocytes. You order a kidney-ureter-bladder x-ray. This is shown below (Case Fig. 27.1).

Case Figure 27.1

1. What complication following ureteroscopy is depicted in this image?
   a. Retained and encrusted ureteral stent
   b. Ureteral stricture
   c. Emphysematous pyelonephritis
   d. Urethral stricture
   e. Horseshoe kidney

You discuss with the patient that surgical intervention is necessary to remove both the residual renal stones and retained ureteral stents.

2. What additional study would be the most appropriate prior to proceeding with surgical intervention?
   a. Computed tomography
   b. Renal ultrasound
   c. Retrograde pyelogram
   d. Intravenous pyelogram
   e. Magnetic resonance imaging

You successfully perform a staged bilateral percutaneous nephrolithotomy removing his retained ureteral stents and clearing his renal stone burden. However, at the end of the procedure, you again place bilateral ureteral stents to facilitate urinary drainage. You plan on removing these in the office in 1 week.

3. To prevent a repeat complication from retained, encrusted ureteral stents what strategy would be the most appropriate to ensure timely removal and appropriate follow-up?
   a. Ureteral stent registry
   b. Allowing the patient to schedule follow-up
   c. Informing the patient that ureteral stents were placed
   d. Keeping the patient in the hospital until scheduled ureteral stent removal
   e. Ordering a medical alert bracelet for the patient

CASE 2

A 66-year-old woman presents to your office with a 1-cm left-distal ureteral stone without hydronephrosis detected incidentally on a CT scan performed for back pain. You discuss her options for treatment, and she elects to proceed with a left ureteroscopy and laser lithotripsy. You perform this without complication. You place a temporary ureteral stent, which is removed in the office 1 week later.

1. According to current professional guidelines, you should routinely perform which study after ureteroscopy?
   a. Renal ultrasound
   b. Basic metabolic panel
   c. Complete blood count
   d. 24-hour urine collection
   e. Urinalysis

You obtain a renal ultrasound approximately 6 weeks after ureteroscopy. The renal ultrasound demonstrates moderate-to-severe left hydronephrosis without evidence of a shadowing renal or ureteral calculus. You elect to proceed to the operating room for a left retrograde pyelogram to determine the etiology of the hydronephrosis. This is shown in Case Fig. 27.2.

2. What complication following ureteroscopy is depicted in this image?
   a. Retained ureteral stent
   b. Persistent ureteral calculus
   c. Ureteral stricture
   d. Ureteral avulsion
   e. Retained foreign body

Case Figure 27.2

3. In contemporary series, what risk factors are associated with the development of a ureteral stricture after ureteroscopy?
   a. Stone location
   b. Placement of ureteral stent prior to ureteroscopy
   c. Ureteral access sheath usage
   d. Manufacturer of ureteroscope
   e. None of the above

Answers

1. **a.** According the AUA Guidelines, one of the only absolute contraindications to proceeding with ureteroscopy is an active or untreated urinary tract infection. Therefore all patients need at least a urinalysis, preferably a urine culture to document no evidence of infection prior to the procedure. All the other choices can be obtained depending on local practice patterns but are not required.
2. **a.** According to the AUA Best Practice statement, ureteroscopy is an upper urinary tract procedure, and thus should receive antimicrobial prophylaxis prior to incision. The specific antibiotic depends on several factors, including local resistance patterns, but should cover common uropathogens. All the other medication choices can be given in select circumstances but are not required for every patient.
3. **b.** B is the only answer that is reasonable at this stage of the procedure. There is likely obstruction at the point where the wire met resistance. However, at this point, you do not know the reason for the resistance. Prior to any further manipulation, it is reasonable to perform a retrograde pyelogram to better assess why the wire met resistance. It may be as simple as a kink in the ureter. Using excessive force to drive the wire past the area of resistance is not reasonable and can lead to development of a false passage. It may be reasonable to abort the procedure for the future, but at this point you still do not have all the information. Therefore it is more reasonable to perform a retrograde pyelogram prior to aborting. For the same reason the procedure should not be converted to percutaneous nephrolithotomy. The procedure should also not be converted to shockwave lithotripsy if there is a blockage at that position in the ureter. Therefore once again a retrograde pyelogram should be performed first.
4. **b.** According to the AUA Guidelines, if purulent material is expressed after accessing the ureter, then infection is present, and immediate urinary drainage with abortion of the procedure is the accepted standard practice. All the other options would result in either continued manipulation of the urinary system with an increased risk of systemic inflammatory response syndrome or sepsis or would not drain the urinary system.
5. **b.** There are cases where the ureter will not accommodate the diameter of the ureteroscope. In this case, the options are active dilation with either serial dilation or balloon dilation. However, this is not one of the answer choices. Therefore the other option is placement of a ureteral stent with a return for a re-attempt at ureteroscopy at a later date. Successful access of the ureteroscope after passive dilation with a ureteral stent is almost always successful. The other options are reasonable, but if your desired approach is ureteroscopy, then this is the only option listed that is acceptable.
6. **d.** According to the CROES database, the contemporary reported rate of a ureteral stricture after ureteroscopy is now 0.3%. The other options are not what is currently reported in the literature.
7. **a.** If a ureteral perforation is witnessed, then the generally accepted standard practice is to abort the procedure and place a ureteral stent. By aborting the ureteroscopy and placing a ureteral stent, you prevent further injury to the area. The ureteral stent will facilitate healing of the area. All the other options are not reasonable, as they could lead to further injury to the area or do not involve placement of a ureteral stent to facilitate healing of the area.
8. **b.** This is the next step to allow the basket to be disengaged from the stone. Once the external basket housing is dissembled, the basket tines will separate. Typically, this will free it from the stone. Using excessive force can result in a ureteral avulsion. Terminating the procedure and placing a ureteral stent is not feasible until the basket is removed. Converting the procedure to a percutaneous nephrolithotomy is technically possible, but the next step is not, as you have not tried to dissemble the basket first. A similar rationale exists for not converting to an open ureterolithotomy.
9. **a.** This is the only answer with the correct percentage associated with the correct complication. Fever is the most common early complication. All the other complications with their associated risk are listed in Case Tables 27.1 to 27.3.
10. **c.** This is the most feared and devastating complication of ureteroscopy: ureteral avulsion. Thankfully, this is

Case Table 27.1 Intraoperative Complications of Ureteroscopic Surgery and Management

Complication	Risk Factor[a]	Etiology	Rate[b]	Management
Ureteral bleeding	Multiple ureteral locations Low-volume center	Dilation Misfired energy Mucosal injury	1.4%	Observation Ureteral stent
Ureteral erosion or false passage	Unknown	Wire placement Scope manipulation Misfired energy Instrument deployment Stone removal	Unknown	Observation Ureteral stent
Ureteral perforation	Midureteral location Low-volume center	Wire placement Scope manipulation Misfired energy Instrument deployment Stone removal	1.0%	Ureteral stent
Ureteral intussusception or avulsion	Low-volume center	Entrapped stone removed with excessive force	0.1%	Nephrostomy tube Delayed repair

([a]Adapted from Perez Castro E, Osther PJ, Jinga V, et al. Differences in ureteroscopic stone treatment and outcomes for distal, mid-, proximal, or multiple ureteral locations: the Clinical Research Office of the Endourological Society Ureteroscopy Global Study. Eur Urol. 2014 Jul;66(1):102-9; and Kandasami SV, Mamoulakis C, El-Nahas AR, et al. Impact of case volume on outcomes of ureteroscopy for ureteral stones: the Clinical Research Office of the Endourological Society Ureteroscopy Global Study. Eur Urol. 2014 Dec;66(6):1046-51.)
([b]Adapted from de la Rosette J, Denstedt J, Geavlete P, et al. The Clinical Research Office of the Endourological Society Ureteroscopy Global Study: indications, complications, and outcomes in 11,885 patients. J Endourol. 2014 Feb;28(2):131-9.)

Case Table 27.2 Early Postoperative Complications: Prevention and Management

Complication	Rate[a]	Prevention	Management
Bleeding	0.4%	Sound endoscopic technique	Observation Ureteral stent
Bladder spasms	0.4%	Avoid ureteral stent placement	Remove ureteral stent Anticholinergics Alpha-blockers
Fever	1.8%	Negative baseline urinalysis or culture Single-dose antimicrobial	Antimicrobials
Urinary tract infection	1.0%	Negative baseline urinalysis or culture Single-dose antimicrobial	Antimicrobials
Sepsis	0.3%	Negative baseline urinalysis or culture Single-dose antimicrobial	Fluid resuscitation Antimicrobials Cultures Imaging Source control
Venous thromboembolic	0.02%	Early ambulation Mechanical or pharmacologic in high-risk patients	Early recognition Anticoagulation
Cerebrovascular	0.02%	Preoperative medical evaluation	Early recognition
Acute myocardial infarction	0.01%	Preoperative medical evaluation	Early recognition
Death	0.02%	Preoperative medical evaluation	Early recognition

([a]Adapted from de la Rosette J, Denstedt J, Geavlete P, et al. The Clinical Research Office of the Endourological Society Ureteroscopy Global Study: indications, complications, and outcomes in 11,885 patients. J Endourol. 2014 Feb;28(2):131-9.)

now extremely rare. After ureteral avulsion there is no longer a viable ureter remaining. Therefore primary repair, ureteral stent placement, and abortion of the procedure without urinary drainage are not reasonable options. Immediate nephrectomy is theoretically an option. However, given the devastating nature of the injury and the inability of the patient to participate in the decision making while under anesthesia, it is reasonable to proceed directly with nephrectomy. Since this is not a life-threating emergency, an alternative is to place a nephrostomy tube to allow for urinary drainage. This will allow appropriate shared decision making with patient in a delayed fashion.

CASE 1

1. **a.** The imaging demonstrates bilateral stents, one in each kidney. Surrounding the proximal curl of each stent is

Case Table 27.3 Late Postoperative Complications: Prevention and Management

Complication	Rate[a]	Prevention	Management
Readmission	8.4%	Sound endoscopic technique	Early recognition variable
Ureteral stricture	0.3%	Sound endoscopic technique	Postoperative imaging Endoscopic dilation or incision Open or laparoscopic repair
Encrusted/ retained ureteral stent	Unknown	Avoid ureteral stent placement Patient counseling Ureteral stent registry	Postoperative imaging Endoscopic removal

([a]Adapted from de la Rosette J, Denstedt J, Geavlete P, Keeley F, Matsuda T, Pearle M, et al. The Clinical Research Office of the Endourological Society Ureteroscopy Global Study: indications, complications, and outcomes in 11,885 patients. J Endourol. 2014 Feb;28(2):131-9.)

stone material. The imaging does not show a ureteral stricture, which usually cannot be demonstrated without contrast. Emphysematous pyelonephritis is a gas-forming infection of the renal parenchyma. There is no evidence of gas around the kidneys. A urethral stricture would not be demonstrated on a plain x-ray. Similar, there is no suggestion of an isthmus on this imaging, which is characteristic of a horseshoe kidney.

2. **a.** A CT is the best imaging study, since it will clearly demonstrate kidney stone and will also provide anatomic information for operative planning. The other imaging modalities will provide you with more information than a plain x-ray, but none is superior to a CT to identify both stone and anatomy.
3. **a.** Several studies have demonstrated the effectiveness of a ureteral stent registry in preventing the "forgotten ureteral stent." Allowing the patient to schedule follow-up is reasonable, but there are patients who will not schedule that follow-up. Informing the patient that ureteral stents were placed should always be done, but this alone will not prevent patients from being lost to follow-up. Keeping the patient in the hospital for 1 week is not practical. Ordering a medical alert bracelet is an option, but again, that will only remind the patient, and he or she can still be lost to follow-up.

CASE 2

1. **a.** According to the AUA Guidelines, a renal US is recommended after ureteroscopy. This is to ensure clearance of all residual stone fragments and detect silent obstruction. All the other options are reasonable to perform if clinically indicated but are not required.
2. **c.** This image demonstrates a ureteral stricture. There is a narrowing and then a transition point with proximal hydroureter. These findings are classic for a ureteral stricture. A retained ureteral stent, foreign body, or persistent ureteral calculus would be visible as a filling defect. The clinical scenario is not suggestive of a ureteral avulsion. However, on retrograde pyelogram this would demonstrate extravasation of contrast.
3. **e.** Although each of these was once thought to be related to the development of a ureteral stricture, recent studies have suggested otherwise. It is now accepted that none of these factors either increases (stone location or ureteral access sheath) or decreases (prior ureteral stent placement) the risk of a ureteral stricture after ureteroscopy.

Chapter 28 Questions and Answers

KEY POINTS

1. Hemorrhage, the most common complication of percutaneous renal surgery (PRS), can occur intraoperatively or postoperatively. It is usually managed conservatively with blood transfusion if needed. If more profound bleeding is encountered, angiographic evaluation or open exploration may be required.
2. In patients with delayed postoperative bleeding, one should have a high index of suspicion for an arteriovenous fistula or pseudoaneurysm. This complication can be managed conservatively in most cases, although patients in whom conservative management fails should be treated with angiography and selective embolization.
3. Perforation of the collecting system should be suspected if perirenal or renal sinus fat is visualized during endoscopy. When perforation is recognized, the procedure should be terminated, and a nephrostomy tube should be left in place.
4. Tumor seeding is a potential but rare complication of percutaneous resection of urothelial carcinoma. It can be minimized by proper selection of patients with low-grade, noninvasive tumors.
5. The lung and pleura are the perirenal structures at greatest risk of injury. Intraoperative fluoroscopy of the chest is recommended at the end of PRS to rule out obvious hydrothorax or pneumothorax. Postoperative chest radiography is not required unless patients develop signs of pulmonary compromise.
6. Patients at higher risk for colonic injury include patients with congenital anomalies such as horseshoe kidneys, colon distention, or previous colon surgery. Preoperative CT imaging should be performed to evaluate for retrorenal colon.
7. In a stable patient, colonic perforation is managed by retraction of the nephrostomy tube into the colon, placement of an indwelling ureteral stent and Foley catheter, use of broad-spectrum antibiotics, and institution of a low-residue diet. This approach allows healing in the majority of cases.
8. Negative preoperative urine culture results do not predict negative stone or pelvic urine culture results. Therefore, it is recommended to start patients on antibiotics (i.e., fluoroquinolones, nitrofurantoin) 1 week preoperatively if there is suspicion of an infected or infection-

based (struvite, carbonate apatite) stone. There are few data at this time to recommend long-term postoperative antibiotics.

9. Multiple positioning methods are possible for PRS, with each position having varied reported advantages and disadvantages. No matter the positioning chosen, careful padding of all pressure points and avoidance of overextension of joints can decrease the risk of positioning-related injuries.
10. The effects of PRS on renal function appear minimal. Many patients undergoing percutaneous nephrolithotomy (PCNL), particularly for staghorn calculi, have deterioration of their renal function over time, although this is likely due to their stone disease.

Percutaneous renal surgery (PRS) is commonly employed to treat a variety of urologic conditions, from stone disease to upper tract urothelial carcinoma. Despite increasing surgical experience and advances in technology, complications can still occur. Prompt recognition of complications along with timely treatment can minimize the impact. This chapter reviews the spectrum of complications that can occur during and after PRS. Diagnosis, treatment, and preventive measures are presented.

Hemorrhage

INTRAOPERATIVE HEMORRHAGE

Patients undergoing PRS are at risk for significant intraoperative bleeding and subsequent blood transfusion. The transfusion rates from various contemporary series have ranged from 1% to 34%.[1–7] Several factors have been shown to be associated with an increased risk for transfusion. These include surgical technique, surgeon experience, preoperative anemia, advanced patient age, increased stone surface area, and the need for multiple tracts.[4,6,8] Intraoperative complications such as infundibular tear or pelvic wall tear have been shown to significantly increase blood loss. Other factors that have been shown to predict increased blood loss during PRS include diabetes, longer operating time, and increased parenchymal thickness.[6,8]

Proper preoperative workup of the patient is necessary to decrease risks of intraoperative hemorrhage. Perioperative use of anticoagulation is a controversial topic and should be discontinued in the proper time frame to allow the anticoagulant effect to wear off whenever possible. However, with the increased use of anticoagulants, studies are now being performed to evaluate the safety in performing PRS while on anticoagulation. Current evidence demonstrates that some medications such as aspirin, which were typically stopped in the perioperative period, need not necessarily be witheld. Leavitt and colleagues performed a retrospective review of 321 patients showing that perioperative use of aspirin is not associated with higher rates of bleeding complications.[9] While there is no guideline for management of these medications at this time, proper discontinuation and administration of other anticoagulation therapies allow for successful PRS without an increase in bleeding or thromboembolic complications.[10,11] Lange and associates evaluated the safety and efficacy of perioperative removable inferior vena cava filter placement in patients who were at significant risk for a venous thromboembolic event, allowing for complete discontinuation of these medications; bleeding and thrombotic complications were absent, although this may not be a satisfactory option in all patients.[12]

Operative technique is a modifiable risk factor, and certain principles, if followed, can help to reduce the risk of significant blood loss. For the prone approach, the collecting system should be accessed through a posterior calyx along the direction of the infundibulum. This technique avoids the blood vessels that course adjacent to the infundibulum.[13] The posterior calyx that provides the most direct access to the targeted stone should be chosen. Once access is established, the tract should be dilated only up to the peripheral aspect of the collecting system. Care should be taken not to dilate the tract too far medially because this increases the risk of pelvic wall tear and injury to the hilar vessels. Stoller and colleagues reported that renal pelvic perforation is a risk factor for excessive blood loss.[4]

The impact on blood loss by the method of tract dilation is controversial. Davidoff and Bellman found that the use of balloon dilators was associated with significantly less blood loss and lower transfusion rates when compared with the Amplatz serial dilators.[14] More recently, the Endourological Society Percutaneous Nephrolithotomy Study Group found that balloon dilation and larger sheath size were associated with bleeding and transfusion risk, although on multivariate analysis only sheath size remained significant.[15] Another series demonstrated that Alken serial dilators were associated with significantly greater blood loss than were either balloon dilators or Amplatz dilators.[6] Turna and colleagues reported that Amplatz serial dilators were associated with significantly greater blood loss compared with balloon dilation.[8] However, Osman and associates reported on 300 patients who had tracts dilated with Alken dilators, none of whom required a transfusion.[16] Other investigators have found no difference in blood loss among methods of dilation, including a one-shot dilation with a 25- or 30Fr Amplatz dilator.[4,17,18] Additional experimental techniques for tract creation and dilation are under investigation, including a method utilizing bipolar plasma vaporization of the renal tissue for tract formation, which was noted to be safe and effective in decreasing operative blood loss.[19]

Once access is obtained and the tract is dilated, a working sheath is often placed. Tract and sheath size appear to be one of the strongest risk factors for operative blood loss, but regardless of tract size, care must be taken to keep the working sheath in the collecting system to limit parenchymal bleeding.[20] Excessive torquing of rigid instruments through the working sheath may injure renal parenchyma and vasculature and therefore should be avoided. Flexible nephroscopy or placement of additional nephrostomy tracts should be performed instead, as demonstrated by Lam

and colleagues.[21] These investigators reported that the use of multiple tracts and flexible instruments decreased transfusion rates for their patients undergoing percutaneous nephrolithotomy (PCNL) in the treatment of staghorn calculi. Accessing the appropriate calyx, or using multiple access tracts when appropriate, can reduce the amount of blood loss and the number of complications.[22–24] Care must also be taken when removing stone fragments through an access sheath because sharp fragments can tear the sheath. Further manipulation of the fragments and sheath can lead to significant bleeding.[25]

When access is achieved and the working sheath is in place, it is not unusual for some bleeding to continue. However, if bleeding is such that visibility is compromised, certain measures should be taken. First, the surgeon should assess the position of the working sheath. If the end of the sheath has withdrawn into the parenchyma, simply repositioning the sheath back into the collecting system may correct the problem. If this maneuver does not correct the problem, or if the sheath is not malpositioned to begin with, then other interventions need to be undertaken. Inflation of a 30Fr dilating balloon in the tract for 10 to 20 minutes with subsequent placement of a large nephrostomy tube (24–28Fr) usually controls the bleeding. If bleeding persists, the nephrostomy tube should be clamped for 2 to 3 hours to allow the blood to clot and tamponade the injured vessel(s). Administration of mannitol may hasten this process by causing renal swelling within the capsule that may help tamponade vessels along the nephrostomy tract.[4,26] The nephrostomy tube is left to straight drainage when unclamped if the patient has no signs of continued bleeding.

If these maneuvers are unsuccessful, a specialized nephrostomy tamponade catheter can be inserted (Kaye, Cook Medical, Spencer, IN).[27] This catheter has a peripherally located balloon that is inflated in the nephrostomy tract while urine drains through the inner core. The catheter is typically left inflated for 2 to 4 days. The aforementioned measures are usually successful in controlling bleeding from peripheral vessels along the nephrostomy tract. Significant bleeding can also arise from injury to the main renal vein, and this bleeding can be controlled using a tamponade approach. Gupta and colleagues reported successful management of this complication in four patients by inflating a Council balloon catheter adjacent to the point of venous injury.[28] Additionally, Millard and associates noted the success of a hemostatic "sandwich" method whereby two nephrostomy tubes are left, one with the balloon inflated within the collecting system and the second inflated just under the skin within the tract; the region between the balloons was injected with hemostatic sealant with excellent hemostasis.[29] When these measures fail, or when significant arterial injury is suspected, then one should proceed expeditiously to renal angiography with selective embolization.

Antegrade Endopyelotomy

Percutaneous endopyelotomy has the additional risk of bleeding when the ureteropelvic junction (UPJ) is incised. DiMarco and colleagues reported a transfusion rate of 1.3% in their series of antegrade endopyelotomy.[30] In cases involving secondary UPJ obstruction or ectopic kidneys, preoperative imaging with computed tomography (CT) or magnetic resonance angiography is recommended to delineate vascular anatomy. Some investigators advocate the use of endoluminal ultrasonography (US) for this purpose.[31,32] Hendrikx and associates reported the use of endoluminal US, which detected 15% more crossing vessels than CT angiography and concluded that its use better prevents bleeding complications.[32] When significant hemorrhage arises from the incised UPJ, a 24Fr balloon should be inflated across the area and left in place for 10 minutes. If bleeding persists once the balloon is deflated or the patient becomes hemodynamically unstable, the balloon is reinflated, and renal angiography should be performed with embolization if possible. Rarely, open surgical exploration with possible nephrectomy may be necessary if the previous measures fail.

Tubeless Percutaneous Renal Surgery

Nephrostomy tube–free, or tubeless PRS, has become more prevalent over the past 10 years. The reported advantages of tubeless PRS are decreased pain and speedier recovery leading to decreased length of stay.[33,34] The transfusion rates for tubeless PRS have been reported to be approximately 5%, while the rate of stone clearance has been reported to range from 83% to 93%.[33,35,36] Success has been shown in cases with supracostal access and for larger stone burdens, although patients with continued bleeding at the end of the procedure should have a nephrostomy tube left in place to control and monitor bleeding.[33,36,37]

Certain techniques have been applied to tubeless PRS to minimize blood loss and the risk for transfusion. Jou and associates performed electrocauterization of bleeding points along the nephrostomy tract and inside the collecting system.[38] These investigators found that this method leads to a significantly lower transfusion rate. They were able to obtain a bloodless tract in 33.7% of patients, and these patients were left without a nephrostomy tube. When bleeding persists, these investigators advocate leaving a nephrostomy tube in place.

Hemostatic fibrin glue can be placed in the nephrostomy tract to aid in hemostasis. Shah and associates reported on the use of Tisseel Vapor Heated Sealant (Baxter AG, Vienna).[39] They prospectively compared patients who underwent tubeless PRS with Tisseel sealant placed in the tract at the end of the case to those without Tisseel sealant. These investigators found no significant difference in the change in hematocrit between the two groups, and other groups have duplicated this result as well.[40] Of note, a small prospective trial of tract closure methods showed that patients who underwent tract instillation of a gelatin matrix hemostatic sealant noted an initial increase in postoperative pain.[41] Additionally, care must be taken to avoid injecting the Tisseel sealant into the collecting system because it can form a solid clot that could possibly obstruct the collecting system.[42] A meta-analysis was performed to review the safety and efficacy of hemostatic agent use in tubeless PRS; overall these agents were noted to be safe although costly and not significantly beneficial.[43]

POSTOPERATIVE HEMORRHAGE

Patients continue to be at risk for significant bleeding for the first several weeks postoperatively.[5,7,44] Most patients who bleed postoperatively can be managed conservatively, but approximately 1% will require invasive treatments.[5,7,14,44] If bleeding occurs with the nephrostomy tube in place, the

(B, C courtesy of Dr. Brian Eisner.)

measures discussed earlier may be employed, although it should be noted that large-bore nephrostomy tubes (>18Fr) are associated with lower bleeding complications than small-bore tubes.[45] If significant bleeding from the tract is encountered after removal of the tube, digital tamponade should be performed with subsequent placement of a tamponade catheter or large nephrostomy tube under fluoroscopic guidance. If a nephrostomy tube is placed, it should be clamped. The patient should then be placed on bed rest and transfused as needed. Renal angiography with selective angioembolization should be performed on patients who continue to require blood transfusions or who become hemodynamically unstable.

Delayed bleeding often occurs approximately 1 to 3 weeks postoperatively.[5,7,44] When angiography is performed on these patients, the most common causes of bleeding are laceration of a segmental artery, arteriovenous malformation, pseudoaneurysm, and arteriovenous fistula.[1–3,5,7,46] Renal angiography with selective embolization is highly effective in treating these lesions (Fig. 28.1).[5,7,44] The nephrostomy tube must sometimes be removed so that the bleeding site may be localized during these procedures. When renal angiography and embolization are unsuccessful, open surgical exploration with vascular repair or nephrectomy may be necessary. El-Nahas and colleagues reported on 39 (1.3%) of 2909 patients (3878 PCNL procedures) over a 10-year period who had severe perioperative bleeding requiring renal angiography and embolization.[7] Twenty-nine of these patients had severe bleeding before discharge, where the other 10 patients developed bleeding after discharge at a mean of 6.3 days. Renal angiography with selective embolization was successful in treating 36 of the 39 patients. The other three patients required exploration, and one required nephrectomy. These investigators identified upper calyx puncture, solitary kidney, staghorn stone, multiple punctures, and operator inexperience as significant risk factors for severe bleeding.[7] In another large series, Srivastava and colleagues identified stone size as the only significant risk factor predicting these serious vascular complications.[5] A similar series noted that tubeless surgery was associated with postoperative bleeding as well.[47]

Kessaris and colleagues reported that 17 of 2200 patients (0.8%) who underwent PRS over a 10-year period required angiography and embolization for uncontrolled significant bleeding.[44] Twenty-four percent of these patients presented in the immediate postoperative period (<24 hours), 41% in the early postoperative period (2–7 days), and 35% in the late postoperative period (>7 days). Superselective or selective angiographic embolization of such lesions, using Gianturco coils, absorbable gelatin sponges, or platinum microcoils, is generally quite successful. This study reported success in 15 of 17 such cases with selective or superselective embolization.[44,46] Failures of angioembolization have been related to the number of percutaneous access sites, more than two bleeding sites found on angiography, and use of gelatin sponge alone for embolization.[48]

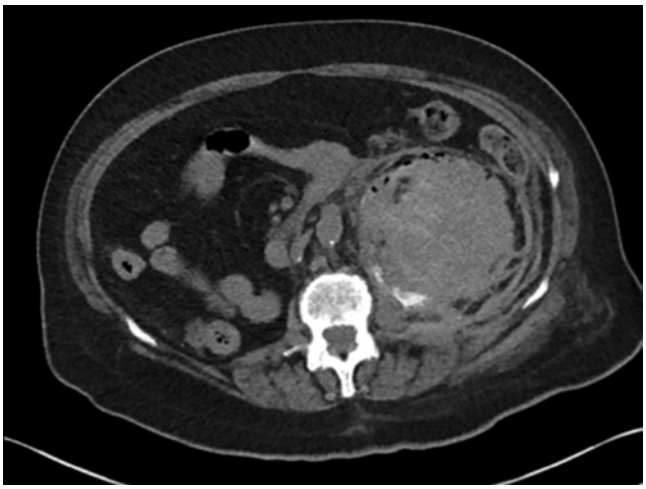

Figure 28.2 Perinephric/subcapsular hematoma displacing the left kidney after attempted percutaneous nephrostomy tube placement by interventional radiology.

Another cause of perioperative bleeding after PRS is perinephric hemorrhage (Fig. 28.2). This complication should be suspected in patients who have decreasing hemoglobin with clear urine draining from both the nephrostomy tube and the bladder. Perinephric hemorrhage can occur in cases with difficult access or in cases with thin parenchyma where bleeding occurs extrarenally, rather than into the collecting system. Malpositioning of the working sheath outside the renal parenchyma is another possible cause.

"Sandwich therapy" with shock wave lithotripsy and subsequent second-look PCNL is another potential risk

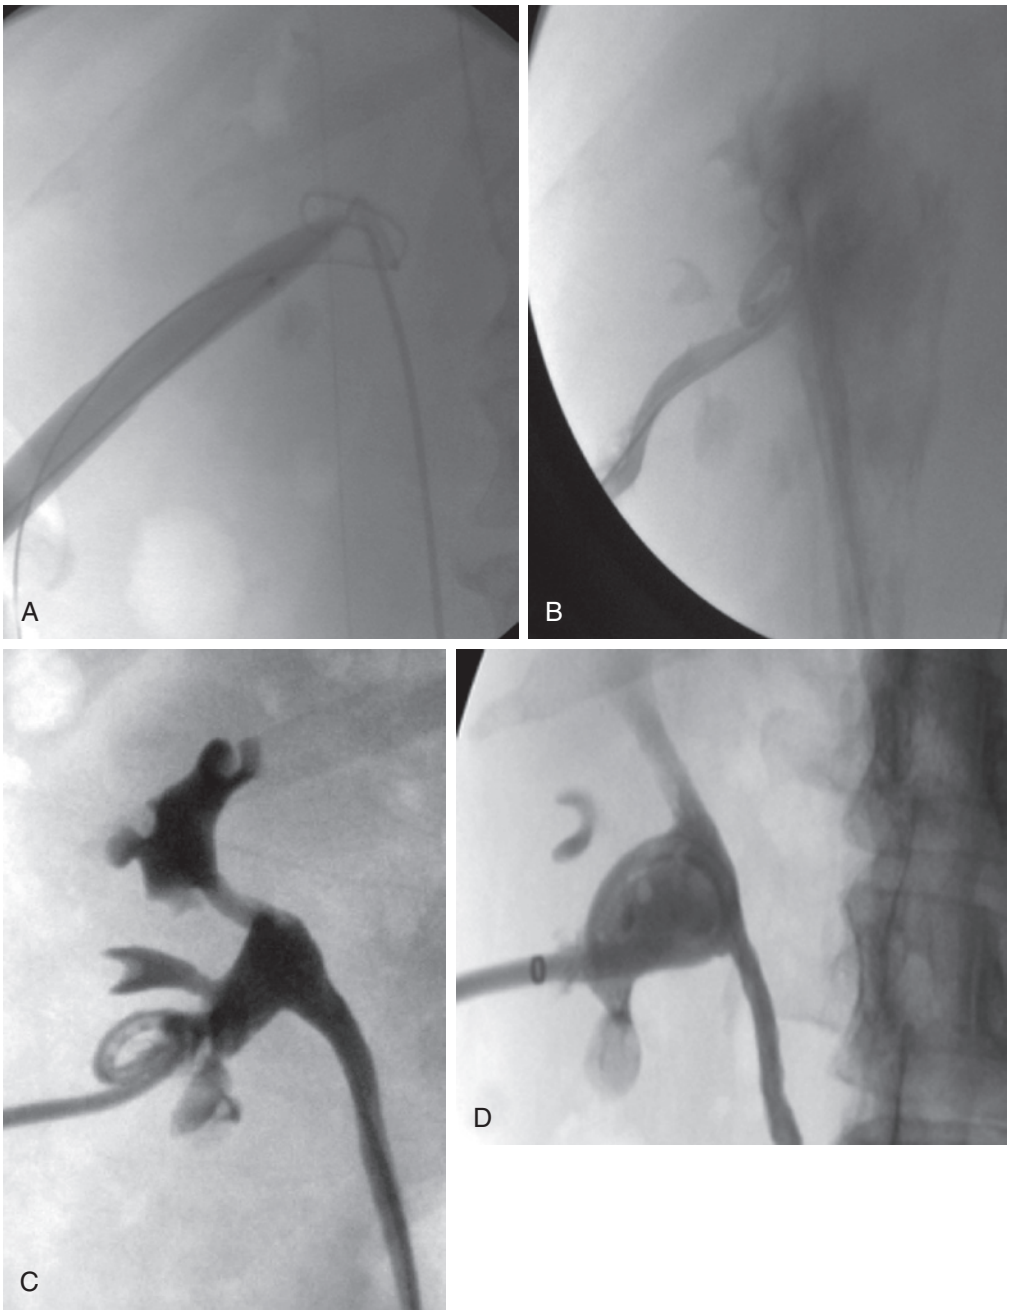

Figure 28.3 Renal pelvis injury/perforation with extravasation. A, Initial access with balloon dilator with wires in position. B, Perforation noted intraoperatively as nephrostogram demonstrates extravasation. C, Postoperative nephrostogram after 36 hours confirms healing of the renal pelvis. D, Nephrostogram at 1 week upon removal of nephrostomy tube shows complete resolution of extravasation. (Courtesy of Dr. Brian Eisner.)

factor. In these situations, subcapsular or perinephric hemorrhage caused by shock wave lithotripsy may be exacerbated by further tract and collecting system manipulation. Patients in whom this is suspected should be evaluated with CT scan. This situation can typically be treated conservatively with monitoring of hemoglobin, serial physical examinations, hemodynamic parameters, and imaging as needed because the bleeding is usually confined to the retroperitoneal space. Affected patients should be treated with blood transfusions as needed, and rarely exploration may be required if hemodynamic instability cannot be controlled or if bleeding is persistent.

Collecting System Injuries

PERFORATION AND EXTRAVASATION

Perforation of the collecting system can occur any time during PRS (Fig. 28.3). When the working sheath is located outside the collecting system secondary to perforation, large amounts of fluid can extravasate. Additionally, newer access methods including micropercutaneous nephrolithotomy may introduce a significant increase in renal pelvic pressure leading to perforation.[49] Lee and associates reported that perforation with extravasation occurred in

7% of 582 cases of PCNL.[50] Perforation should be suspected if perirenal or renal sinus fat is visualized, if other perirenal structures are visualized, or if the patient's abdomen or flank becomes distended. Large amounts of fluid can quickly accumulate in the retroperitoneal space or, less commonly, the abdominal cavity. This fluid can cause difficulties in ventilating the patient during the procedure, electrolyte and hemodynamic abnormalities secondary to fluid absorption, and ileus postoperatively.[51]

CT- or US-guided percutaneous drainage of the fluid is sometimes necessary if the patient is having respiratory distress, if prolonged ileus does not resolve spontaneously, or if infection of the fluid is suspected. Once perforation is recognized, serious consideration should be given to terminating the procedure. If the procedure is nearly completed, it may be possible to complete it with low-flow irrigation, provided the patient remains stable. Concerns that arise when the procedure is continued are stone migration outside the collecting system and tumor cell spillage during percutaneous resection of urothelial carcinoma, both discussed later in this chapter. Once the procedure is terminated, a nephrostomy tube should be left in place. Most perforations heal in 72 hours, but it may be prudent to wait 7 days and perform a nephrostogram to confirm closure of the perforation before going back to complete the stone extraction or tumor removal. On rare occasions, open surgical repair or nephrectomy may be necessary.[50,52] This complication can be limited by paying close attention to proper access and dilation techniques (e.g., preventing sheath placement significantly beyond the balloon or sequential dilator, preventing dilation of and avoiding access sheath placement through narrow infundibuli), by taking care to keep the working sheath in the collecting system, by judicious stone fragmentation, and by fluoroscopic monitoring of nephrostomy tube insertion and removal.

URETERAL AVULSION

Ureteral avulsion is an extremely rare complication of PRS. It is most commonly caused by attempts at basketing of large, impacted ureteral stones, but it can also occur with dilation or incision of the UPJ and tumor resection.[50,53] Additionally, a "scabbard" injury can occur rarely when performing antegrade ureteroscopy (typically in cases where the ureter has not been pre-stented or is narrow at baseline and with greater risk when using a semirigid ureteroscope in a retrograde manner) where the ureteroscope is down the ureter; the proximal shaft of the scope is larger in caliber than the tip, therefore the proximal shaft may be tight in the ureter. When removing the scope, the tissue adheres to the scope and can lead to an injury in that region of the ureter where the scope is trapped. If this is occurring, very gentle removal of the scope is needed, and occasionally injection of lubrication via the scope or adjacent to the scope down the ureter can allow the ureteroscope to be removed safely. This can also theoretically occur if larger fragments or a high volume of fragments are left adjacent to the ureteroscope as the ureteroscope is advanced distally to treat additional stones. The friction in the ureter with these fragments as the ureteroscope is removed can give resistance, and great care is needed to gently remove the scope to avoid an avulsion type of injury.

This complication mandates prompt open surgical exploration, although, when necessary, nephrostomy tube drainage may be used as a temporizing measure to allow stabilization of the patient. Occasionally, a percutaneous drain will need to be inserted into the potential urinoma if the nephrostomy tube alone is not able to adequately drain the majority of the urine produced by the affected kidney. This complication can be avoided by making sure stones are fragmented into pieces small enough to be removed by an extraction device, as well as by adhering to proper endopyelotomy, endoureterotomy, and resection techniques. Furthermore, when dealing with a narrow ureter that is unable to handle the capacity of a ureteroscope, safe dilation techniques are possible, or placement of a ureteral stent with return to the operating room several days later after passive dilation has likely occurred.

EXTRARENAL AND EXTRAURETERAL STONE FRAGMENT MIGRATION

Extrarenal and extraureteral stone fragments are generally not of any clinical consequence, provided the urine and stone are not infected and the stone is far enough from the collecting system and ureter not to cause periureteral inflammation with subsequent stricture formation (Fig. 28.4).[54,55] Intraperitoneal migration of stone fragments has also been reported; in this case open extraction was performed with success in order to prevent further peritoneal complications.[56] Endoscopic retrieval should not be attempted in most cases because this may enlarge the perforation. The occurrence of this complication can be minimized by avoiding collecting system perforation or, if one has occurred, recognizing it and stopping the procedure, as well as applying proper stone removal techniques.

STRICTURE

The development of a stricture following PRS occurs rarely, with a reported incidence of <1%. The most commonly affected segments are the proximal ureter and the UPJ.[1,2] Strictures can form as a result of inflammation secondary to stone impaction or from procedural trauma including intracorporeal lithotripsy and periureteral urine and/or stone extravasation. Patients who have undergone previous cutaneous urinary diversion and undergo PRS for proximal ureteral calculi may be at increased risk for stricture formation because of an intense inflammatory response (obliterative pyeloureteritis) that may be secondary to infection and other local factors.[57] Ureteral strictures can be asymptomatic, and patients undergoing PRS should be routinely evaluated for this complication with postoperative imaging.[58] Most ureteral strictures that develop after PRS can be managed with endourologic techniques, provided the stricture is <1 cm and is not in a radiated field. However, open or laparoscopic reconstruction may be required in patients with more extensive strictures or in patients in whom an endoscopic approach has failed.

INFUNDIBULAR STENOSIS

Infundibular stenosis is a rare complication that can occur after PRS.[2,59,60] Parsons and colleagues reported a

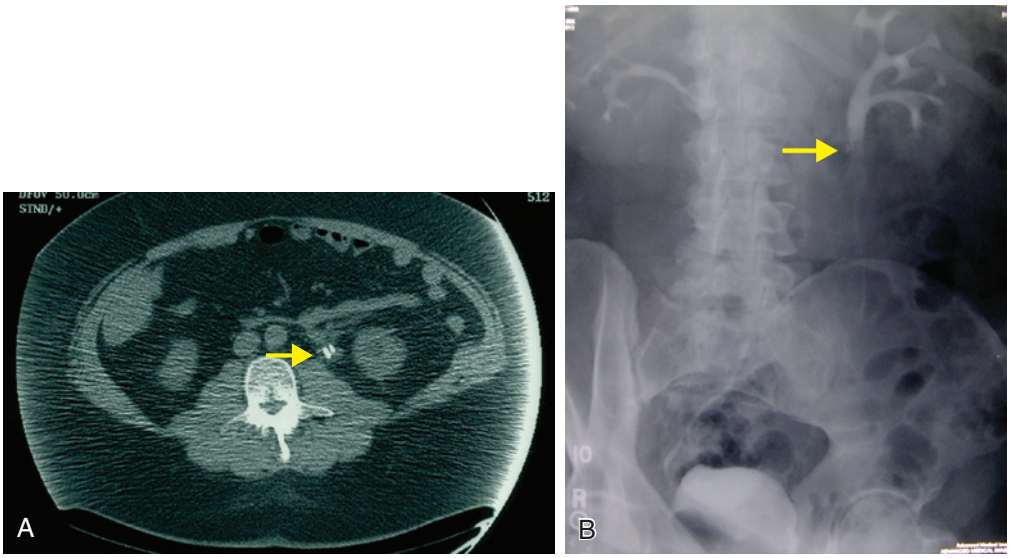

Figure 28.4 Left extraureteral stone. A, CT scan postoperatively demonstrates a stone fragment (arrow) adjacent to the ureteral stent in the region of the proximal ureter. B, Postoperative intravenous pyelogram reveals that the stone fragment lies adjacent to the left proximal ureter causing mild extrinsic compression (arrow) but no significant hydronephrosis and drainage of contrast material distally. (Courtesy of Dr. Joshua Wein and Dr. Rupa Patel.)

2% incidence following PCNL.[61] They identified prolonged operative time, large stone burden requiring multiple procedures, and extended postoperative nephrostomy tube drainage as independent risk factors for this occurrence. These investigators postulated that factors that increase local inflammation could include prolonged instrumentation or the use of large amounts of energy to break up stones. This complication is usually detected in the first year after PRS. Goel and associates noted a case of the formation of an excluded calyx, which was seen 2 weeks post PRS in a patient presenting with fevers, obstructed upper pole, and nonvisualization of this calyx on excretory urography.[62] This was treated with nephrostomy placement and eventual antegrade creation of neo-infundibulum with holmium:YAG laser. Infundibular stenosis should be managed endourologically, as in the above case, with open surgery reserved for those in whom this approach fails. For patients who are asymptomatic without evidence of impaired renal function, close observation is an option.

RETAINED FOREIGN BODIES

On occasion, a piece of equipment used in a percutaneous procedure can break off in the renal collecting system. This can occur during any stage of the procedure, including during postoperative renal embolization.[63] Lynch and associates reported on a piece of plastic drape that was translocated into the collecting system during tract dilation, while Kaba and colleagues noted the migration of a 2-cm fragment of ureteral catheter that was found on fluoroscopy to have migrated into the left lung, possibly intravascularly.[64,65] Instruments should be inspected periodically during and at the end of procedures to ensure that nothing is broken or missing. Every effort should be made to find the foreign body and remove it because it can act as a nidus for stone formation or infection or cause a granulomatous reaction within the kidney.

The foreign body can usually be extracted with a rigid or flexible nephroscope and graspers or a basket. Fluoroscopy can aid in removal of the foreign body if it is radiopaque. If the foreign body is discovered after nephrostomy tube removal, a retrograde ureteroscopic approach can be performed. If this fails, percutaneous extraction may be necessary. This complication can be limited by replacing instruments before instrument fatigue develops. Careful manipulation of wires, laser fibers, other lithotripter devices, baskets, and tubes can also minimize the incidence of this complication. Postoperatively, the tips of nephrostomy tubes, such as Malecot catheters, may become entrapped in the collecting system as a result of the ingrowth of fibrous and inflammatory tissue. If this occurs, it can be managed using a ureteroscopic approach or the creation of a new nephrostomy tract and endoscopic removal of this tissue.[66]

TUMOR SEEDING

Tumor seeding of the nephrostomy tube tract is a potential but rare complication of percutaneous resection of urothelial carcinoma. It has been reported after resection of poorly differentiated, locally invasive disease.[67] More commonly, it has been noted in association with percutaneous drainage of an obstructed system in patients with urothelial carcinoma.[68–70] Numerous series have performed percutaneous resection without evidence of tract seeding with long-term follow-up.[71–74] This complication can be minimized by proper selection of patients with low-grade, noninvasive tumors. Special care should be taken to maintain proper position of the working sheath, to perform the procedure with low-pressure irrigation, to have low-pressure postoperative drainage with properly sized nephrostomy

tubes, and to decrease operative times in these patients, when possible.

NEPHROCUTANEOUS FISTULA

Nephrocutaneous fistula formation is a rare occurrence after PRS.[75] It is usually caused by distal obstruction secondary to ureteral edema, obstructing stone, blood clot, or stricture. Delayed development of nephrocutaneous fistulas has been reported to occur in patients with genitourinary tuberculosis.[76] Fibrin glue has been used to assist with healing of the fistula, although this is usually unnecessary; relief of the distal obstruction by either placement of a ureteral stent or removal of stone usually allows the fistula to close without additional treatment at the fistula site.[77]

INJURY RESULTING FROM ENERGY SOURCES

The continued advances in design of lithotripsy and ablative energy sources have aided the performance of PRS. Although these advances have improved efficacy and safety, the potential for energy-related complications should not be underestimated. Intracorporeal damage from these sources can range from minor to extensive. To avoid these complications, the surgeon should have a thorough knowledge of each energy source before it is used.

Ultrasonic lithotripsy is a commonly used energy-source technique for PCNL.[53] Collecting system or ureteral perforation can occur with this device, especially if excessive pressure is applied to these tissues. The probe can become clogged with debris, thus causing overheating that could result in thermal injury. As mentioned earlier, a piece of the lithotripter can break off. A single case report noted that the tip of an ultrasonic lithotripter broke off and migrated to the left pulmonary artery.[78]

As a result of the development of newer devices with better safety profiles, electrohydraulic lithotripsy is used less frequently for PCNL.[79] The most common complications associated with electrohydraulic lithotripsy are perforation of the collecting system and bleeding, which are managed as previously described.

The holmium laser is commonly used for lithotripsy, for incision of strictures, and for the ablation of upper tract tumors. Although the laser has been shown to have an excellent safety profile, complications can still occur.[80] These include hemorrhage, perforation of the collecting system, and thermal injury. Investigators have also reported that heat generated from the laser can interact with hydrogen gas and can generate an explosion in the collecting system that leads to perforation and hemorrhage.[81] These complications can be minimized with careful technique and use of appropriate energy settings, which have not been standardized at this time. The typical energy settings during PCNL range from 0.5 to 3.0 joules and from 6 to 30 hertz, with a single study showing that higher power energy settings were associated with an increased risk of injury as 6/38 patients were found to have proximal ureteral stricture postoperatively.[82]

Pneumatic lithotripters and hybrid devices (pneumatic and US) are also used during PCNL.[83–85] A small risk of perforation and hemorrhage also exists with these devices.

Electrocautery and electroresection are used during PRS for resection of tumors and to control bleeding. The patient should be properly grounded to prevent thermal burns. Only nonconductive materials should be in contact with the collecting system and ureter to prevent current dispersal that could lead to thermal injury. Maintaining proper orientation with respect to adjacent vascular structures can minimize the risk of hemorrhage. When electrocautery or electroresection is performed, sterile glycine is typically used as irrigant, with an associated risk of fluid absorption and secondary hyponatremia. Maintaining the lowest possible irrigation pressures and limiting resection time can minimize this risk. Bipolar electrocautery devices can instead be used with sterile saline irrigation, thereby reducing the risk of hyponatremia from fluid absorption.

Injury to Adjacent Structures

LUNG AND PLEURA

The lung and the pleura are the perirenal structures most at risk of injury during PRS.[1,2] The incidence of intrathoracic complications has been reported to be between 0.3% and 15.3%.[86–90] These complications include pneumothorax, hydrothorax, hemothorax, and nephropleural fistulas (Fig. 28.5). They occur more commonly with supracostal access when compared with infracostal access.[86,88,89,91] Hopper and Yakes studied 43 randomly selected patients with CT imaging during maximal inspiration and expiration and predicted that during maximal expiration the pleura and lung would be traversed 86% of the time on the right and 79% of the time on the left with a supra–11th rib approach.[92] These investigators also predicted that the pleura and lung would be traversed 29% of the time on the right and 14% on the left with a supra–12th rib approach. These rates are higher than those noted clinically, with reported rates ranging from 3.3% to 15.3% for supracostal approaches, although one series did report hydrothorax in three of four cases performed with supra–11th rib access.[86–88]

Munver and colleagues analyzed their experience with supracostal access for PRS.[89] Of 300 total access tracts, 98 (32.6%) were supracostal, and of these 73.5% were supra–12th rib and 26.5% were supra–11th rib. The overall complication rate for supracostal access was 16.3% (supra–11th rib, 34.6%; supra–12th rib, 9.7%), significantly higher than the rate of 4.5% for subcostal approach in the same series. Seven of the eight intrathoracic complications in this report occurred during supracostal access, including six complications during supra–11th rib access. In a more recent series, Lojanapiwat and Prasopsuk reported a significantly greater incidence of hydrothorax with supra–12th rib access than with subcostal access (15.3% vs 1.4%), while el-Karamany noted a 10% incidence of hydrothorax with supracostal access.[88,93]

Studies have suggested that different operative positions may alter the risk of pleural injury, with a prone-flexed position displacing the kidney caudally and decreasing the need for supracostal access.[94] Additionally, the supine position allowed for subcostal upper calyceal access when the kidney

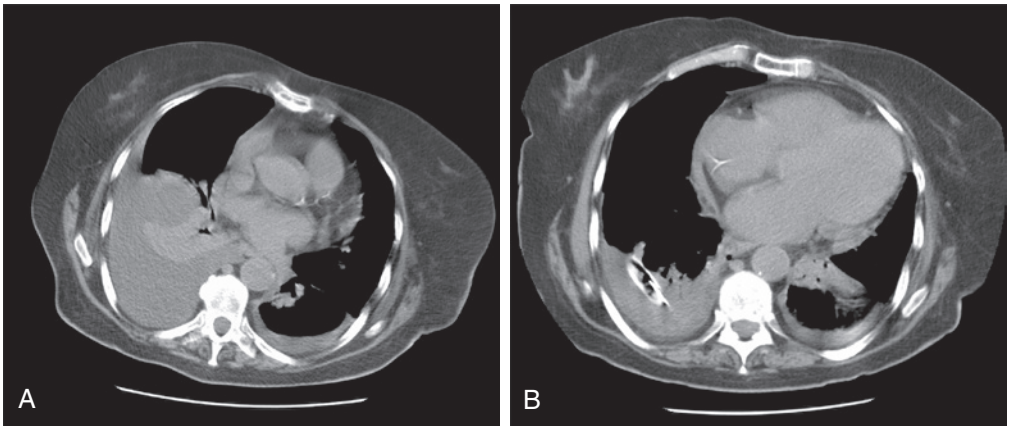

Figure 28.5 Hydrothorax. A, Chest CT scan demonstrates right hydrothorax. B, Hydrothorax was managed with tube thoracostomy. (Courtesy of Dr. Dean Assimos.)

was displaced with a lung inflation technique, avoiding possible intrathoracic complications.[95]

A working sheath should be used with a supracostal approach to provide a barrier to the influx of fluid and air into the pleural cavity if the parietal pleura is violated. Routine intraoperative chest fluoroscopy is recommended at the termination of PRS to evaluate for obvious hydrothorax or pneumothorax, and routine postoperative chest radiography is not required if results of fluoroscopy are normal and the patient has no signs of pulmonary compromise.[96] Preoperative CT imaging during expiratory and inspiratory phases with coronal, sagittal, and three-dimensional reformats may be used in preoperative planning of access tracts to avoid intrathoracic complications.[97]

Patients with small-volume, asymptomatic hydrothorax or pneumothorax can be observed. When patients exhibit signs of pulmonary compromise or become unstable, aspiration or tube thoracostomy may be required, although recent studies show that small-bore thoracostomy tubes may perform as well for drainage as traditional chest tubes.[98] In cases of PRS for struvite stones, if hydrothorax occurs, it is prudent to place a chest tube to prevent development of empyema from potentially infected irrigation fluid and urine. Rarely, thoracoscopy or formal thoracotomy may be required if the foregoing interventions fail or if complex pleural effusion or empyema develops.[99]

Nephropleural fistula can manifest intraoperatively, immediately postoperatively, or 1–2 weeks postoperatively. In the immediate postoperative period, this complication should be suspected if thoracic fluid persists despite tube thoracostomy drainage. Delayed nephropleural fistula should be suspected in patients who have undergone PRS and who present with shortness of breath with or without flank pain. The diagnosis is best made with retrograde pyelography. Treatment consists of draining the pleural fluid with tube thoracostomy and decompressing the collecting system with a ureteral stent or nephrostomy tube.[91]

The intercostal vessels can be lacerated during supracostal access, with resulting hemothorax. Tube thoracostomy and open surgical thoracotomy may be necessary if this complication occurs. To minimize the risk, access should be obtained directly above the rib to avoid the intercostal vessels.

COLON

Colonic perforation is a rare complication of PRS, reported in <1% of cases.[50,53,100–102] The likely reason for this low incidence is that the colon is rarely retrorenal. Hadar and Gadoth and Sherman and colleagues analyzed the relationship of the kidney and colon on CT scan and found that the colon was retrorenal in approximately 0.6% of individuals.[103,104] Patients at higher risk for colonic injury include those with congenital anomalies such as horseshoe kidney and other forms of renal fusion and ectopia, as well as those with colonic distention resulting from jejunoileal bypass, partial ileal bypass, neurologic impairment, and "institutional" bowel. Other proposed risk factors are lower pole puncture, left-sided procedure, previous colonic surgery, older age, and female sex.[100,105] El-Nahas and associates reviewed their experience with 5039 PCNL procedures to try to identify risk factors for colonic perforation.[101] These investigators reported 15 colonic perforations (0.3%). The only significant risk factors identified on multivariate analysis were older patient age and the presence of horseshoe kidney. Although there was concern that supine PCNL was a risk factor for colonic injury, this has not been borne out in the literature, with a similar proportion of colon injury in supine PCNL (0.5%).[106] Preoperative CT scan is recommended for PRS, and this should allow for detection of retrorenal colon in the majority of cases, and CT guidance can be used to direct percutaneous access in these patients.[107] Of note, given that patients often undergo percutaneous access in the prone position, there is some concern about the utility of preoperative supine CT for PRS planning. Chalasani and colleagues performed preoperative CT scans on patients in a prone position and found increased rates of retrorenal colon (16.2% of 265 kidneys), which is significantly higher than previous estimates of retrorenal colon, suggesting the value of preoperative prone CT scanning for operative planning.[108]

Early recognition and diagnosis of colonic perforation are of critical importance. Serious infectious complications can occur when diagnosis or management is delayed. Signs of colonic perforation include passage of gas or feculent material through or around the nephrostomy tube, intraoperative diarrhea or hematochezia, and peritonitis.[100,101,105,109] These

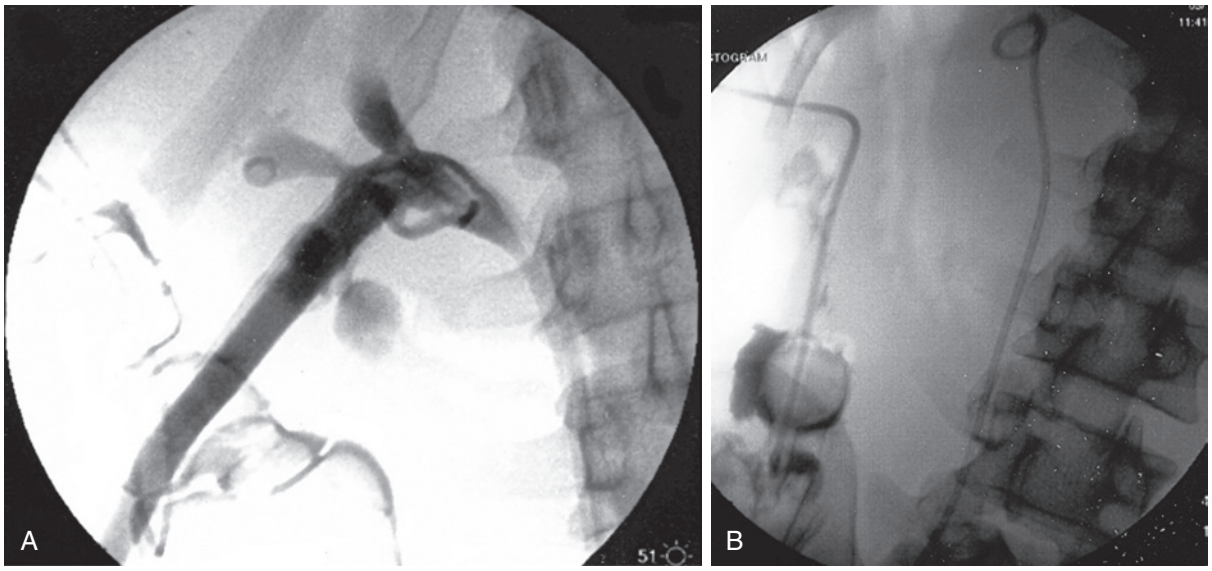

Figure 28.6 Colon injury. A, Postoperative nephrostogram demonstrates contrast within the large intestine. B, The nephrostomy tube was removed, and the colon tube was placed in addition to an indwelling ureteral stent and Foley catheter. The patient healed without complications, and the colon tube was removed 7 days later, when a cologram confirmed no evidence of fistula.

patients usually present with fever. Patients can present after the nephrostomy tube is removed with feculent material draining from the nephrostomy site.[110] Some investigators recommend antegrade nephrostogram at the end of the procedure to evaluate for colonic perforation.[101]

In the majority of cases, colon injuries can be managed conservatively if the perforation is retroperitoneal and the patient does not have signs of sepsis or peritonitis (Fig. 28.6).[101,111] An indwelling ureteral stent and Foley catheter should be placed and the nephrostomy tube should be pulled back into the colon, although some have suggested that placement of an indwelling ureteral stent may not be necessary and withdrawal of the nephrostomy tube into the colon is sufficient.[100] The patient should be administered broad-spectrum antibiotics and placed on a low-residue diet. A contrast study should be performed through the colostomy tube in 7 to 10 days, and the tube should be removed if no evidence of nephrocolic fistula is noted.[112,113] Open surgical management is required in patients with transperitoneal perforation, peritonitis, or sepsis and in those in whom conservative management has failed. Delay in diagnosis may increase the need for open surgical management.[101]

SMALL INTESTINE

The second and third portions of the duodenum are adjacent to the lower pole and pelvis of the right kidney and may be injured during PRS, although this complication is very uncommon.[114] Such an injury may occur during percutaneous access, if the renal pelvis is perforated during dilation, during placement of the working sheath, or during stone removal or tumor excision. This complication should be suspected if intestinal mucosa and contents are visualized, and it is usually diagnosed when contrast material is seen in the duodenum during intraoperative or postoperative nephrostogram. Surgical exploration is required in the majority of cases, specifically with large perforations or in patients with signs of sepsis or peritonitis. Patients with small injuries who are clinically stable can be managed conservatively. Conservative management includes antibiotics, nasogastric suction, and parenteral hyperalimentation. The nephrostomy tube should be positioned correctly in the collecting system to ensure adequate drainage or withdrawn into the bowel lumen with separate urinary drainage. A nephrostogram and an upper gastrointestinal radiograph study are performed 10 to 14 days following the injury to assess for closure of the fistula.

LIVER, GALLBLADDER, AND SPLEEN

The liver is rarely injured during PRS. Hopper and Yakes studied the relationship between the liver and kidney and reported on the risk of liver injury with different access approaches.[92] These investigators reported that the risk of injury with an 11th–12th rib intercostal approach was minimal. The risk increased to 14% for a 10th–11th rib approach during inspiration. Hepatomegaly increases the risk of injury to the liver, and for these patients, CT-guided access should be considered to minimize this risk. If injury to the liver is diagnosed postoperatively, the nephrostomy tube should be left in place for 7 to 10 days to allow for maturation of the tract. After this time, the tube can be carefully removed, but if high-volume bleeding is noted, the tube should be reinserted immediately. Additionally, fibrin products can be instilled through the tract to improve hemostasis. Retrograde placement of an internalized ureteral stent at the time of nephrostomy tube removal may aid in preventing the development of a renobiliary fistula. Injury to the gallbladder can also occur during access, with similar risk factors to liver injury. Patients present with signs of peritonitis with or without septic shock, are typically diagnosed during laparoscopy/laparotomy, and treatment consists of cholecystectomy in all cases.[106,115]

Splenic injury is very uncommon during PRS, likely because of the spleen's cephalad position.[116,117] Hopper and Yakes also analyzed the relationship between the kidney and spleen and noted that the spleen should not be at risk of being traversed with an 11th–12th rib supracostal approach during expiration, but the risk during inspiration was 13%.[92] This risk increased to 33% when a 10th–11th rib approach was used. In patients with splenomegaly, the risk is even higher. Injury to the spleen can cause significant internal bleeding and, in some cases, hypovolemic shock. The diagnosis is established with CT or US. Although some patients with splenic laceration can be managed nonoperatively (with bedrest, maintaining tube tamponade, close hemodynamic monitoring, and rarely splenic embolization), most patients require splenectomy.[1,2,106,117]

LYMPHATICS

Perforation of the collecting system during PRS may cause disruption of adjacent lymphatics that could lead to chyluria.[118] Management of this complication consists of optimizing urinary drainage and maintaining the patient with total parenteral hyperalimentation until the chyluria resolves. If this occurs in a delayed fashion, a low fat, medium-chain triglyceride diet can be trialed. Somatostatin may aid in the treatment of these cases.[119] If chyluria persists, sclerotherapy can also be attempted with retrograde instillation of silver nitrate or povidone-iodine.[120,121] For further refractory cases, renal pedicle lymphatic ligation can be performed.[122,123]

Medical Complications

INFECTION AND SEPSIS

It is mandatory for all patients with urinary tract infections to be treated with the appropriate antibiotic therapy before they undergo PRS because of the risk of bacteremia and sepsis from the extravasation of bacteria into the pyelovenous or pyelolymphatic channels. Antibiotic therapy for patients with urinary tract infections should be initiated at least 1 week before the procedure. The use of prophylactic antibiotics in patients with sterile urine culture is controversial, although many urologists will similarly place patients on 1 week or more of preoperative antibiotic prophylaxis despite a negative urine culture. Mariappan and associates reported on the use of prophylactic antibiotics in patients with stones >2 cm or pelvicalyceal dilation with negative urine cultures.[124] These investigators found that in these patients, prophylaxis with 1 week of ciprofloxacin significantly decreased the risk of urosepsis after PRS; similar results were found with nitrofurantoin prophylaxis in subsequent studies.[125] Other studies comparing patients with negative preoperative urine culture who received either single-dose antibiotics in the operating room or continuation of antibiotics until the nephrostomy tube was removed found no difference in rates of postoperative fever, bacteriuria, or bacteremia.[126–129]

Negative preoperative urine cultures do not preclude patients from developing bacteremia or urosepsis. Rao and colleagues demonstrated that patients without bacteriuria may still develop bacteremia and endotoxemia.[130] This is likely because negative urine culture results do not predict negative pelvic urine or stone culture results.[131] Margel and colleagues found that 25% of patients with a negative urine culture result had a positive stone culture result.[132] In these patients, the most common organisms found in the stone culture were gram-positive organisms; *Enterococcus* was reported in 42% of the cultures. In another study, Mariappan and colleagues found that bladder urine culture results were positive in only 5.6% of patients, whereas 42.6% of patients had positive results of pelvic urine or stone cultures.[133] These investigators also found that positive results of pelvic urine and stone cultures were associated with a significantly greater risk for urosepsis than were positive results of bladder urine cultures. It has been shown that stone culture results more frequently correlate with the causative pathogen in the setting of postoperative urosepsis when compared to preoperative urine culture.[134] It is important to send renal pelvis urine and stone for culture during PCNL to help predict and guide therapy in the event of urosepsis.

Multiple studies have attempted to qualify which patients are at increased risk for postoperative urosepsis given preoperative parameters to better guide the use of antibiotic prophylaxis. In addition to the aforementioned positive urine and stone cultures, studies have also pointed toward increased stone burden, history of recurrent urinary infections, and urine cultures with multidrug-resistant bacteria as risk factors for postoperative urosepsis.[135–137]

Purulent urine may be unexpectedly encountered at the time of accessing the collecting system. When this occurs, it is sensible to delay treatment, leave a nephrostomy tube in place to drain the collecting system, culture the fluid, and give the patient appropriate antibiotic therapy. Even with these precautions, patients can still develop urosepsis when the stone is eventually treated.[138]

Sepsis has been reported in 0.6% to 1.5% of patients undergoing percutaneous stone removal, which can be secondary to bacteremia and/or endotoxemia.[1,2,53] Patients should be monitored closely after surgery for signs or symptoms of systemic infection, including changes in vital signs, mental status, and laboratory values. Although postoperative leukocytosis and fevers are common, significant elevations in these values may be a sign of postoperative sepsis in patients after PRS; other tests such as lactate levels and procalcitonin may assist in early diagnosis of postoperative sepsis.[139–141] These patients should be aggressively managed with antibiotic therapy and fluid resuscitation, as well as with other supportive measures such as steroids and pressors. If the patient does not respond to these measures, CT imaging is recommended to assess for injury to adjacent structures or other complications that could be contributing to the sepsis. Fungal urosepsis should be considered in patients who are at risk, such as those who are immunocompromised or diabetic or who have had prolonged ureteral stenting.[142] Additionally, patients who are appropriately managed with pre/perioperative antibiotics may still suffer from postoperative systemic inflammatory response syndrome (SIRS)/sepsis due to endotoxemia, which similarly will require supportive measures such as fluid resuscitation, close monitoring, and possibly pressor support.

FLUID OVERLOAD

Irrigating fluid can be absorbed during PRS. Collecting system perforation and bleeding have been shown to increase the amount of fluid absorbed significantly.[143] Careful intraoperative monitoring of the input and output of irrigating fluid can help detect this problem. Signs of fluid absorption and subsequent fluid overload include unexpected hypertension and hypoxemia. Maintaining the lowest irrigation pressure that permits visibility can minimize fluid absorption. The use of a working sheath can reduce pressure in the pelvicalyceal system and thereby can reduce fluid absorption.[143] Limiting the duration of the procedure and discontinuing the procedure in the setting of significant collecting system perforation also reduce this complication. Normal saline solution should be used as an irrigant whenever possible to limit the development of hyponatremia. The administration of diuretics may be required for managing the hypervolemic patient with signs of fluid overload.

HYPOTHERMIA

Core body temperature has been shown to decrease during PRS. Hypothermia, defined as core body temperature <36°C, may occur. Decrease in core body temperature is multifactorial, and causes include vasodilation secondary to anesthesia, length of the procedure, exposed body surface, low room temperature, and the use of room temperature or cold irrigant. The consequences of hypothermia include impaired platelet function, altered enzymatic drug clearance, and shivering leading to significantly increased oxygen consumption. Increased oxygen consumption combined with decreased oxygen delivery can lead to cardiac ischemia or arrhythmias. Measures such as the use of warmed irrigant, proper patient coverage, use of heat-preserving drapes, and keeping patients as dry as possible can help reduce the risk of hypothermia.[144,145]

POSITIONING-RELATED INJURIES

Proper positioning of patients undergoing PRS is essential. Patients are typically placed in the prone position, and injuries to the brachial plexus and other peripheral nerves, shoulder dislocation, and cutaneous skin trauma can occur. All pressure points should be padded, and patients should be positioned to avoid strain on joints. If neurapraxia is suspected, prompt neurologic evaluation is warranted. Most of these injuries resolve over time with conservative treatment such as physical therapy.

Some groups have advocated that PCNL should be performed with patients in the supine position.[146,147] One concern of performing PRS in the supine position is the potential increased risk of damaging adjacent organs, particularly the colon. Multiple studies and meta-analyses have been performed in recent years to compare supine lithotomy positioning to traditional prone positioning. Results have been inconsistent, but most recent studies show a similar postoperative complication rate, similar hospital stay, and similar operative times; supine PRS may lead to slightly lower stone-free rates.[148,149] One such study did note an improvement in intraoperative anesthesia parameters during supine PRS, including heart rate, blood pressure, and peak airway pressures, although the long-term clinical significance of this is unknown.[150] However, a recent study by Siev and associates demonstrated that peak inspiratory pressures did not increase or have significant change from the supine to prone position in both the nonobese and obese patients.[151] Manohar and colleagues demonstrated that the supine position can be used safely and effectively in obese and high-risk patients for PCNL.[147] US proved to be useful aiding in and obtaining access in these reports.

AIR EMBOLISM

Air embolism has been reported during PRS.[152,153] This complication can occur after air is injected into the collecting system to help delineate the anatomy or as a result of airflow reversal in an ultrasonic lithotripter, although Lipkin and colleagues reported on over 150 cases of air pyelograms without a single case of embolism.[154] Intraoperative signs of air embolism include hypoxemia, bradycardia, fall in end-tidal carbon dioxide, and even cardiopulmonary arrest. Other causes should be excluded, and intraoperative diagnosis can be made with echocardiography. Management includes cessation of the procedure and placing the patient in the left lateral decubitus position with the head and thorax tilted downward. A central venous access line can be placed to attempt to aspirate the air. Patients may require close postoperative monitoring, inotropic support, supportive care, and – in certain cases with concern for cerebral involvement – hyperbaric oxygen therapy.[155]

DEEP VEIN THROMBOSIS AND PULMONARY EMBOLISM

Deep vein thrombosis has been reported to occur in 1% to 3% of patients undergoing PRS.[53,156] Thromboembolic disease prevention stockings and sequential compression devices help to minimize the risk of deep vein thrombosis. Early postoperative ambulation should be encouraged to help decrease the risk as well. If postoperative deep vein thrombosis does occur, treatment is aimed at preventing propagation of the thrombus and embolic events.[157] Treatment usually consists of anticoagulation, although in the immediate postoperative period bleeding is often a concern. In these patients, an inferior vena cava filter may need to be placed. However, in patients with a mature nephrostomy tract, anticoagulation is usually well tolerated.

MORTALITY

Postoperative death is extremely rare in association with PRS. The mortality rate is reported to be 0.2%.[158] Most reported deaths were caused by myocardial infarction or pulmonary embolism, and this complication occurred in high-risk patients. Careful preoperative evaluation and patient preparation are critical to preventing mortality. In patients who are at high risk, intraoperative invasive monitoring and postoperative cardiac monitoring can help prevent mortality by allowing for early diagnosis of any concerning abnormalities.

LOSS OF RENAL FUNCTION

The effects on renal function from PRS are believed to be minimal. Reports of imaging studies before and after PRS have demonstrated small parenchymal scars at the tract site.[159,160] Chatham and colleagues evaluated patients before and after PCNL with technetium-99m mercaptoacetyltriglycine nuclear renography.[161] These investigators demonstrated stable or improved renal function in 84% of patients and deterioration of function in 16%, although other studies did suggest focal decrease in function at the access site.[162] Handa and associates found a significant increase in serum creatinine of 0.14 mg/dL 1 day after PRS, which was also shown to normalize at approximately 72 hours postoperatively.[163,164] Further studies have isolated ipsilateral and contralateral renal response to PRS and have shown a bilateral decrease in creatinine clearance, with the ipsilateral renal unit showing a more severe response; this injury also appeared to resolve within 72 hours.[165]

Studies have demonstrated no significant change in serum creatinine concentration over the course of 1–2 years after PRS in patients with normal and impaired renal function.[166,167] Using nuclear renography, Dawaba and colleagues evaluated renal function in children undergoing PCNL and found a stable selective glomerular filtration rate (GFR) in 52.8% of renal units, an increase in GFR in 41.7% of renal units, and a decrease in GFR in 5.6% of renal units.[168]

Patients with staghorn calculi are unique in their increased risk of renal function deterioration. Teichman and colleagues reported that 25% of patients with staghorn calculi treated with PRS had a decrease in renal function.[169] These investigators cited solitary kidney, recurrent calculi, hypertension, complete staghorn calculus, urinary diversion, and neurogenic bladders as further risk factors for functional deterioration in this group, which has been seen in other series as well.[170,171] These findings support the idea that the functional deterioration in this group of patients is not likely to be procedurally related, but rather the result of their stone disease and comorbidities. Additionally, though, the effect of multiple access tracts on renal function has been recently questioned.[170]

Acute renal loss is very uncommon following PRS. It is usually secondary to uncontrollable hemorrhage. The incidence has been reported to be between 0.1% and 0.3%.[53,172] The long-term risk of renal loss has been estimated to be 1.6% in patients who have had staghorn calculus treated with PRS.[173]

Conclusions

PRS is associated with a variety of complications. These include, but are not limited to, hemorrhage, injury to the collecting system and kidney, injury to adjacent organs, infection or sepsis, and even death. Appropriate patient selection, possibly with assessment of functional status, and preoperative workup can help minimize these complications.[174] Patient counseling preoperatively (both with discussion and handwritten and/or online educational material) will also allow for patients to understand the complexity of the surgery and help in establishing expectations for the postoperative period. Surgical technique plays a large role in preventing complications, and care must be taken during each step of the procedure. An experienced surgeon will be able to minimize the risks of this complex procedure; increased caseloads have been demonstrated to decrease the complication rates of PRS.[175] Prompt recognition of problems is critical when they occur; most complications can be managed conservatively.

Chapter 28 Questions

1. During percutaneous access after using an air retrograde pyelogram for percutaneous nephrolithotomy for large right-sided intrarenal stones, the patient becomes hypoxemic and bradycardic. What is the next step in treatment?
   a. Completion of the lithotripsy and stone removal and transfer to the intensive care unit
   b. Cessation of the procedure and placement of the patient in left lateral decubitus position with head tilted downward
   c. Attempt to withdraw air from the renal collecting system with suctioning of the 5Fr open-ended catheter
   d. Immediate cessation of the procedure, placement of pacer pads, and initiation of defibrillation
   e. Immediate placement of chest pigtail catheter or chest tube

2. The response of a patient's renal function after percutaneous renal surgery includes:
   a. Focal renal function increasing at the site of access
   b. A decrease in overall serum creatinine after percutaneous nephrolithotomy
   c. A permanent increase in overall serum creatinine between 2 and 5 years after percutaneous nephrolithotomy
   d. A decrease in creatinine clearance of bilateral renal units after unilateral percutaneous nephrolithotomy
   e. A smaller functional decline after percutaneous nephrolithotomy in renal units with staghorn calculi

3. If post-percutaneous nephrolithotomy chyluria persists after conservative management with dietary measures and somatostatin, the next step in management should be:
   a. Lymphangiography and embolization of the cisterna chili
   b. Urgent nephrectomy
   c. Retrograde sclerotherapy with silver nitrate or povidone-iodine
   d. Angiography and embolization of the affected kidney
   e. Antegrade drainage with nephrostomy tube placement

4. Regarding positioning for percutaneous nephrolithotomy:
   a. Prone-flexed positioning may provide improved access to the upper pole
   b. Supine positioning increases peak airway pressures during percutaneous nephrolithotomy compared to other methods
   c. Typical prone placement puts patients at high risk for brachial nerve injury
   d. Supine position is a significant risk factor for intraoperative colonic injury
   e. Studies show that supine position is not safe for obese patients

5. Which of the following methods will decrease intraoperative blood loss during percutaneous renal surgery?
   a. Access into a posterior calyx perpendicular to the infundibulum
   b. Use of flexible nephroscopy or additional access tracts for staghorn stones
   c. Frequent manipulation of working sheath during the procedure
   d. Use of a larger working sheath during access
   e. Positioning of the working sheath within the renal parenchyma

6. Two days postoperatively from a percutaneous nephrolithotomy, the patient's fever spikes at 102.5°F and she becomes hypotensive and tachycardic. After workup including CT scan, the nephrostomy tube is found to be passing through the colon via a transperitoneal path. The patient becomes unstable at this point; the next step in management is:
   a. Withdrawal of the nephrostomy tube into the colon and placement of an internalized ureteral stent and Foley catheter
   b. Broad-spectrum antibiotics and observation
   c. Urgent open exploration and repair
   d. Placement of a second nephrostomy tube by interventional radiology via a retroperitoneal approach
   e. Nasogastric suction and parenteral nutrition

7. During the initial access for percutaneous nephrolithotomy, significant bleeding is noted. All of the following are suggested methods for managing such intraoperative hemorrhage except:
   a. Urgent transfusion and continuation of the procedure
   b. Ensuring proper position of the sheath within the collecting system
   c. Reinflation of the dilation balloon to tamponade the injured vessels
   d. Placement and clamping of a large-bore nephrostomy tube
   e. Administration of mannitol to induce renal swelling within the capsule

8. Extraureteral stone fragments most commonly result in:
   a. Fibroepithelial polyp formation
   b. Ureteral stricture formation
   c. Recurrent UTIs
   d. Chronic flank pain
   e. No clinical symptoms

9. What is the reported incidence of upper tract stricture after percutaneous renal surgery?
   a. >10%
   b. 5–10%
   c. 2–5%
   d. 1–2%
   e. <1%

10. While the optimal preoperative antibiotic prophylaxis regimen is undetermined at this time, certain risk

factors for postoperative urosepsis have been demonstrated. All of the following factors are associated with urosepsis except:
a. Positive renal pelvis urine cultures
b. Increasing stone burden
c. History of multidrug-resistant bacteria in the urine
d. Lack of antibiotic administration until nephrostomy tube removal
e. Positive stone culture

Cases Studies

CASE 1

A 47-year-old man is undergoing right percutaneous nephrolithotomy for a 2.5-cm renal pelvis stone. Based on the patient's renal anatomy, it is determined that an upper pole access point would allow for the best approach to the stone. Preoperative imaging previously delineated the expected location of the accessible calyces, and access is achieved in a supracostal manner.

1. Based upon the access site, the patient is at increased risk for all of the following except:
   a. Pleural entry
   b. Hydrothorax
   c. Laceration of intracostal vessels
   d. Hepatic injury
   e. Lymphatic disruption

After access is achieved, the stone is reached and fragmented in the typical fashion. The case proceeds as expected, and at the conclusion of the procedure, a stent and nephrostomy tube are placed for drainage of the collecting system. Prior to waking the patient from anesthesia, chest fluoroscopy is performed, and a very small right-sided hydrothorax is noted. Anesthesia notes normal saturations, peak ventilation pressures, and tidal volumes.

2. The next step for this patient is:
   a. Emergent thoracotomy
   b. Tube thoracostomy for drainage of hydrothorax
   c. Placement of tube through the nephropleural tract for drainage
   d. Extubation and postoperative observation for respiratory compromise
   e. Continued intubation and transfer to intensive care

The decision is made at this time to observe the patient for his small asymptomatic hydrothorax. He does well over the morning of his first postoperative day with stable labs, pain controlled, and adequate ambulation. A few hours later the patient is noted to have increased work of breathing, decreased oxygen saturation, and increased right-sided chest pain with inspiration. Chest imaging shows an enlarging hydrothorax compared to his initial fluoroscopy.

3. The next step in management for this patient is:
   a. Thoracoscopy for formal diagnosis and treatment
   b. Tube thoracostomy for drainage of hydrothorax
   c. Urgent nephrostogram to evaluate for nephropleural fistula
   d. Observation
   e. Instillation of silver nitrate into the nephrostomy tube to sclerose the pleural injury

CASE 2

A 54-year-old man is scheduled to undergo percutaneous nephrolithotomy of a left renal stone. While discussing surgery with his urologist prior to his operative day, he requests information regarding different positioning options for the operation, as he has heard that the procedure can be performed in many different positions.

1. Which of the following has been considered a benefit of supine positioning for percutaneous renal surgery over traditional prone position?
   a. Ease of simultaneous antegrade and retrograde access
   b. Lower risk of postoperative infection
   c. Higher stone-free rates
   d. Significantly lower risk of colonic injury
   e. Shorter hospital stay

The procedure is performed in a supine-lithotomy position. After approximately 85% of the stone is fragmented, an area of perirenal fat is noted on rigid nephroscopy, consistent with a perforation of the collecting system. At this point, the patient's flank is noted to be more distended than prior, although he continues to ventilate well.

2. What is the next step in management for this patient?
   a. Endoscopic evaluation of the point of perforation with flexible retroperitonoscopy using a flexible ureteroscope
   b. Conversion to open nephrectomy
   c. Placement of an additional access point
   d. Prompt termination of the procedure with low-flow irrigation, placement of a nephrostomy tube, and nephrostogram at 1 week to ensure closure of the perforation
   e. Endoscopic cauterization of the perforation

Two months after his initial surgery, after all tubes were removed and complete closure of the perforation was documented on imaging, the patient returns to the emergency room with new-onset fevers, left flank pain, and elevated WBC count. Urographic imaging shows an obstructed upper pole calyx without an obstructing stone concerning for infundibular stenosis.

3. The next step in management for this patient is:
   a. Urgent cystoscopy and stent placement
   b. Tube thoracostomy placement to improve ventilatory status
   c. Nephrostomy tube placement with eventual antegrade or retrograde treatment to open the stenotic area
   d. Upper pole hemi-nephrectomy
   e. Observation

Answers

1. **b.** When there is intraoperative clinical concern for air embolism, the first step in management is to place the patient in a left lateral decubitus position to decrease the risk of air lock within the right heart, which can be a cause of ventricular obstruction and death.
2. **d.** Differential studies have shown that bilateral renal units have a negative response to PRS, with the ipsilateral kidney demonstrating a more severe reaction. This injury appears to resolve by 72 hours.
3. **c.** Small studies have found a good response rate with retrograde instillation of silver nitrate and povidone-iodine for sclerotherapy of the lymphatic fistula, although conservative management should be attempted as above prior to such a procedure.
4. **a.** Patients placed in a prone-flexed position have a caudal displacement of the kidney with decreased need for supracostal access, which enables easier access to the upper pole.
5. **b.** The use of flexible nephroscopy and additional access tracts can decrease intraoperative blood loss compared to inappropriate torqueing of the rigid nephroscope. Calyceal access should occur parallel to the line of its infundibulum to decrease risk of parenchymal injury. Manipulation of the sheath, use of a larger sheath, and improper positioning of the sheath all will increase risk of blood loss.
6. **c.** While inadvertent colonic injury during percutaneous access can often be managed conservatively by withdrawing the nephrostomy tube into the colon, placement of a ureteral stent, and broad-spectrum antibiotics, once a patient shows signs of instability urgent open exploration and repair are required.
7. **a.** When significant bleeding is noted during the access for PRS, the initial response should include an assessment of the operative factors that may be contributing to the hemorrhage. This includes ensuring positioning of the sheath and performing maneuvers to tamponade the bleeding. The hemorrhage should not be ignored with transfusion and continuation of the procedure, as the source of the bleeding will likely continue throughout the surgery and needs to be addressed.
8. **e.** Evans and Stoller performed a retrospective review of cases associated with extraureteral stone fragments and found a minimal rate of complications.
9. **e.** The reported incidence of stricture after percutaneous renal surgery is noted to be extremely low – less than 1%.
10. **d.** Multiple studies have noted that antibiotics given at the time of nephrostomy tube removal result in no significant change in infection risk compared to antibiotics given from surgery until nephrostomy tube removal. Postoperative urosepsis has been linked to positive renal pelvis urine and stone cultures, increasing stone burden, and a history of multidrug-resistant bacteria in the urine.

CASE 1

1. **e.** Patients who undergo supracostal access are at an increased risk of pleural entry, hydrothorax, laceration of intracostal vessels, and hepatic injury. There has not been a documented risk increase for lymphatic disruption.
2. **d.** A small hydrothorax can initially be managed conservatively with oxygen supplementation and observation, as they often resolve spontaneously. If they persist or become symptomatic, additional therapies can be employed.
3. **b.** In patients who have worsening/symptomatic hydrothorax after PRS, drainage of the fluid is beneficial with tube thoracostomy. Persistent thoracic fluid after proper drainage with tube thoracostomy may signify nephropleural fistula, although this is an uncommon complication.

CASE 2

1. **a.** Proponents of supine positioning cite the ease of simultaneous antegrade and retrograde access for treatment of the stone, while none of the other options has been proven to be associated with this surgical position.
2. **d.** When intraoperative collecting system perforation is suspected, as in this case, the amount of fluid allowed to extravasate into the retroperitoneum should be minimized. This is done by terminating the procedure as rapidly as possible with low-flow irrigation. Additionally, a nephrostogram should be performed postoperatively to ensure resolution of the perforation.
3. **c.** Given the presentation of infection and obstruction, the best initial treatment for this patient would be placement of a nephrostomy tube into the obstructed calyx to allow for prompt drainage. Once the infection is fully cleared, infundibulotomy should be performed in either a retrograde or antegrade fashion to allow drainage from the obstructed calyx and prevent similar episodes in the future.

29 Complications of Extracorporeal Shock Wave Lithotripsy

NADYA E. YORK and JAMES E. LINGEMAN

CHAPTER OUTLINE

Hematoma
Steinstrasse
Sepsis
Cardiac Arrhythmias
Vascular Injury
Adjacent Organ Injury
Urinary Fistulas
Hypertension
Renal Insufficiency
Diabetes Risk
Fertility Effects
Potential Long-term Complications
Strategies to Reduce Risk of Complications
Conclusions
Chapter 29 Questions and Answers

KEY POINTS

1. Hypertension, especially poorly controlled, is a risk factor for post–extracorporeal shock wave lithotripsy (ESWL) hematoma.
2. Steinstrasse is often asymptomatic and resolves with observation. Active management depends on the patient's clinical status and the presence of sepsis or renal deterioration.
3. Antibiotics are not recommended for uncomplicated routine cases with sterile preprocedure urine. Sepsis is more common after ESWL of infection stones.
4. Cardiac arrhythmias are associated with ungated ESWL, and they usually spontaneously revert with gating.
5. Pulmonary injuries are seen mostly in children and can be prevented by prophylactic padding of the torso.
6. Although gastric and duodenal erosions are common, gastrointestinal injuries requiring intervention are extremely rare.
7. ESWL as the cause of new-onset hypertension remains controversial. It may be more common in older patients and those who have undergone bilateral procedures.
8. Reducing shock wave frequency to 60 shocks/min, stepwise voltage ramping, and brief treatment pause all serve to reduce risk of renal injury.

Extracorporeal shock wave lithotripsy (ESWL) has revolutionized nephrolithiasis management since being introduced in 1980 by providing effective noninvasive treatment in an ambulatory setting. The energy that causes stone fragmentation can also injure renal tissue and surrounding structures. Fortunately, serious complications are rare. The complications and prevention strategies are reviewed in this chapter.

Hematoma

The delivery of shock wave energy to the kidney results in some degree of acute renal injury, including interstitial bleeding and disruption of small to medium renal arteries and veins.[1,2] While transient gross hematuria is frequently seen post treatment, ESWL may also result in intrarenal bleeding (hematoma), which may extend into the perinephric tissue. Hematoma may be commonly detected on post-treatment imaging, but it is rarely clinically significant.[3–6] Fig. 29.1 shows a computed tomography (CT) image of a perirenal hematoma that developed after ESWL.

The reported incidence of renal hematomas varies between 0.28% and 4.1% in large series.[3–6] The most common risk factor is hypertension, especially when poorly controlled. Knapp et al. reported a 0.66% overall incidence of hematoma after ESWL: a 2.5% incidence for patients with well-controlled hypertension versus 3.8% for patients with poorly regulated hypertension.[7] Other risk factors include older age, obesity, diabetes mellitus, clotting disorders, vascular disease,[4,8,9] oral corticosteroid therapy, arteriosclerosis, impaired renal function, increasing stone density and urinary obstruction at the time of intervention.[10–14]

Clinical signs of hematomas include intense flank or abdominal pain, tachycardia, hypotension, and anemia. Hematomas generally are self-limited, and patients respond to supportive measures such as hydration, analgesics, and transfusion. Intervention is rarely necessary and renal loss

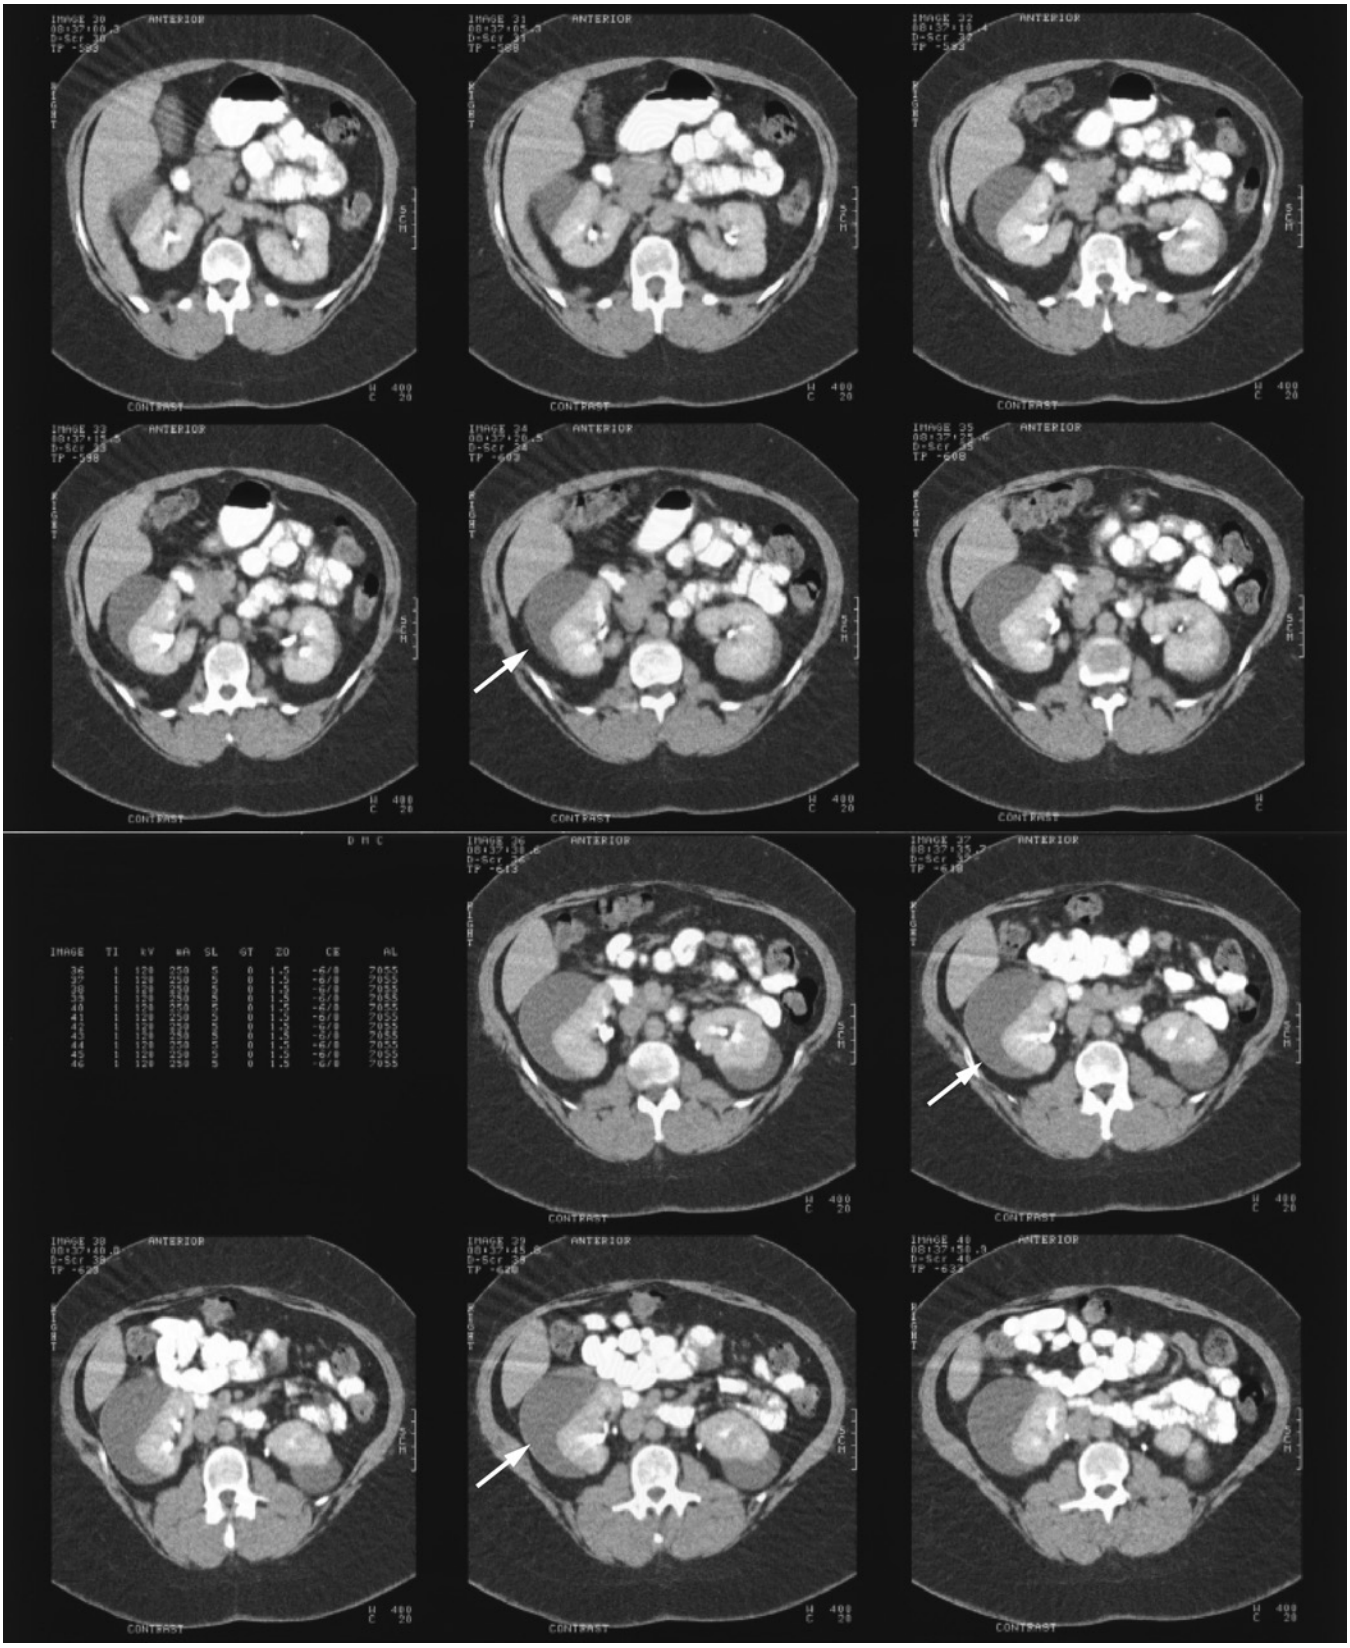

Figure 29.1 A CT scan of a right perirenal hematoma *(arrows)* after ESWL.

or death is exceedingly rare.[3–6,15] Upper tract imaging (CT, magnetic resonance imaging [MRI], or ultrasonography) can be performed to establish the diagnosis when required.

Most hematomas resolve spontaneously over time. In a study of 19 patients with 21 post-ESWL hematomas followed up to 5 years (mean follow-up 19.6 months), 85.7% of the hematomas completely resolved, 9.5% became smaller, and 4.8% did not change size. No patient without preexisting hypertension became hypertensive.[16] However, another study found that 36% of post-ESWL hematomas remained at 18 months after ESWL.[3] Page kidney is a rare cause of hypertension due to renal parenchymal compression from a hematoma.[17–19] Very rarely, incision of Gerota's fascia to decompress a hematoma is an option for large hematomas that significantly impair renal tissue perfusion causing Page kidney. A retrospective review of this practice did not reveal a difference in outcomes with regard to long-term impairment of renal function.[20]

Hematomas can be prevented by using shock wave energy judiciously and ensuring well-controlled blood pressure and absence of coagulation or platelet functional disturbances. Administering a small number of lower energy shock waves (voltage ramping) to the kidney before delivering therapeutic energy doses has been shown to dramatically attenuate hemorrhagic injury in an animal model.[21] It is hypothesized that the initial lower energy shock waves induce vasoconstriction and thus limit the injury.[22] This finding has been confirmed in a large randomized trial published in 2015 where stepwise voltage ramping reduced renal injury, including hematomas.[23]

Another common concern is perioperative anticoagulant management of ESWL patients. Few guidelines on management of thrombotic risk while undergoing ESWL exist, and data are largely retrospective and of poor quality.[24] For example, there is only one human study of aspirin use with ESWL.[25] Potential bleeding risk with ESWL must be balanced with thrombotic risk specific to the patient. In a review by Bourdoumis et al.[26] anticoagulants are stopped 5 days prior to surgery with bridging therapy as required. However, antiplatelet agents, including aspirin, are stopped at least 7 days prior. If the thrombotic risk is judged too high to stop anticoagulants, ureteroscopy is preferred due to higher ESWL complications and lower efficacy in this setting.[27] Patients on anticoagulants warrant perioperative risk stratification and multidisciplinary consult between anesthesia, urology, and cardiology services.

Steinstrasse

Steinstrasse, the accumulation of stone fragments in the ureter after ESWL, usually occurs in patients with larger stones, typically >2 cm. Almost three-quarters of large Steinstrasse occur in the distal portion of the ureter.[16] The reported incidence varies between 2% and 10%.[28–31] An x-ray image of right proximal Steinstrasse is seen in Fig. 29.2. Patients may have symptoms such as flank or abdominal pain, nausea, and emesis, although many are asymptomatic. Weinerth et al. reported that 5 of 19 patients with *large Steinstrasse* (defined as stone fragments occupying greater than one-third of total ureteral length) were asymptomatic.[32] The occurrence of Steinstrasse can be reduced by carefully selecting patients and choosing alternative treatments for patients with stones >2 cm.[31,32]

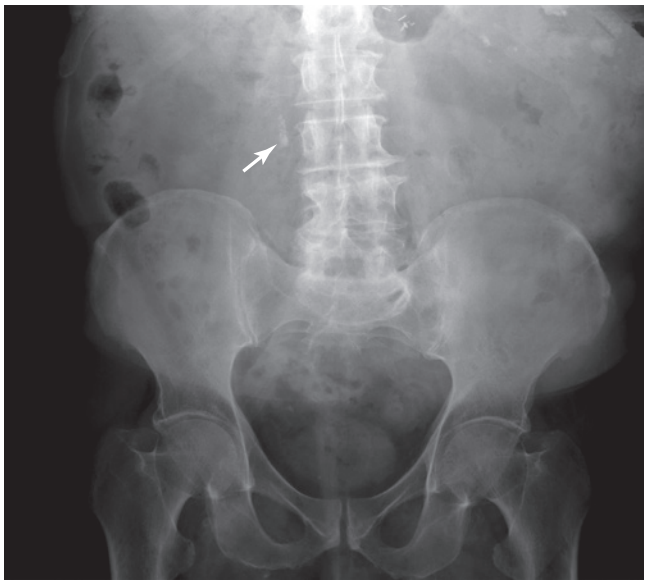

Figure 29.2 An x-ray image of right proximal Steinstrasse (arrow) after ESWL.

Patients with minimal symptoms, adequate renal function, and no signs of sepsis can be managed conservatively as 48% to 63% of Steinstrasse resolve spontaneously.[33,34] However, these patients need to be followed closely to ensure that the Steinstrasse does indeed resolve; otherwise renal function can be affected.

Patients with persistent Steinstrasse, ongoing symptoms, or complications (sepsis, renal impairment) require decompression. Percutaneous nephrostomy (PCN) is an option, with 75% of Steinstrasse passed solely with percutaneous nephrostomy insertion in one study.[35] PCN is especially useful in the setting of profound sepsis as it does not require general anesthesia with attendant hypotension risks. Ureteral stenting is another approach in an unwell patient not suitable for immediate ureteroscopy. Ureteroscopy for Steinstrasse is the definitive treatment with success rates approaching 100%, although it is not often required.[33,34] Repeat ESWL is another approach reported to be 80–90% successful.

The administration of α_1-blockers does not eradicate Steinstrasse. However, patients receiving such agents may have better pain control.[36] Preemptive ureteral stenting may prevent Steinstrasse in some patients with stones <3 cm, but it is ineffective for those with larger stones and is not associated with higher stone-free rates.[28,30] In addition, stented patients often have significant bothersome symptoms.[37] Finally, routine stent placement is not recommended for ureteral stones treated with ESWL.[38] An exception are patients with anatomically or functionally solitary kidneys where stent placement must be strongly considered.[39]

Sepsis

The overall risk of sepsis after ESWL is low at 1%[40,41] except in patients with preexisting treated or untreated urinary

tract infections (UTIs) and especially struvite stones. The risk of sepsis is higher in those with larger stones, especially staghorn calculi.[42] The urine in patients with larger stones more frequently contained endotoxin, which was associated with a higher risk of sepsis.[42,43] Positive preoperative urine culture, symptomatic UTI, indwelling stent, and nephrostomy tube increase the risk of fever post ESWL and warrant preoperative antibiotic therapy.[41] Patients suspected of harboring infection stones should receive broad-spectrum antibiotic therapy because there may be discordance between stone and urine cultures.[44] Despite sterile urine cultures before ESWL, bacteremia developed in 2.6% of those with struvite stones compared to 1.3% of patients with calcium stones.[45] An elevation of the inflammatory mediator C-reactive protein (CRP) has also been identified as a predictor of bacteremia.[45,46] Given the importance of complete clearance in infection and struvite stones, alternative treatment strategy such as PCNL or ureteroscopy should be considered in this setting.[47]

Prophylactic antibiotic administration to patients who have sterile pre-ESWL urine is controversial. A meta-analysis by Pearle and Roehrborn demonstrated significant decrease in the development of post-ESWL UTI in patients who received prophylactic antibiotics.[48] However, another meta-analysis by Lu et al. in 2012 argued against routine antibiotic prophylaxis in this setting.[49] Currently, routine uncomplicated ESWL cases with sterile pretreatment urine do not receive prophylactic antibiotics.

Cardiac Arrhythmias

Cardiac arrhythmias have been reported with both gated (shock delivery synchronized to patient electrocardiogram R-wave) and, more commonly, ungated ESWL. Gating was required with the original lithotriptor, the Dornier HM3, as the water bath allowed the unfocused portion of the shock wave, which expanded spherically from the aperture of the ellipsoid, to pass through the heart resulting in a very high incidence of ventricular arrhythmias. This problem is mostly eliminated with dry head lithotriptors. Zanetti et al. reported cardiac arrhythmia incidence of 8.8% among 269 consecutive patients without a history of cardiac arrhythmia who underwent ungated ESWL.[50] Although 59% of patients who developed arrhythmia converted back to normal sinus rhythm with temporary halting of shocks and remained so after resumption of ungated ESWL, 36% required gating to prevent arrhythmia recurrence and <1% (one patient) required atropine to manage persistent bradycardia. There was no correlation found with the side of treatment with ESWL, the number or strength of shocks, or the anesthetic agents delivered, although another study suggested right-sided renal stone ESWL is more likely to produce arrhythmia.[51]

Greenstein et al. reported asymptomatic premature ventricular contractions in 18.4% of 125 ungated ESWL procedures.[52] No correlations were found with age or gender of patient, presence of heart disease, size or location of stone, presence of ureteral catheter or nephrostomy, mode of anesthesia, and number of shocks delivered. Interestingly, arrhythmia was again seen more often during right-sided procedures.

The immediate postprocedure course of patients undergoing ungated ESWL was studied by Winters and colleagues. Of 82 patients, 21% developed arrhythmias. All but two arrhythmias were benign and all reversed with subsequent gating. No arrhythmias occurred with shock energies lower than 20 kV. No electrocardiogram changes were seen up to 1 hour after the procedures were completed.[53]

Gating and ungating during the same procedure were compared by Ounnoughene and colleagues. Twenty-five patients with no cardiac history underwent ESWL with shocks delivered both gated and ungated. During the gated phase, no arrhythmias developed. During the ungated phase, 7 of the 25 patients developed arrhythmias but all were asymptomatic, and the arrhythmias regressed spontaneously after the procedure was completed.[54]

A comparison of 3288 patients with and without a history of arrhythmia was performed by Cass. In this unique study, ungating was used in patients with known arrhythmias, and gating was used in patients without known arrhythmias. In the group with no known preexisting arrhythmias, one patient developed a malignant arrhythmia during the ungated procedure.[55]

These findings indicate that the development of cardiac arrhythmia is mainly associated with ungated ESWL. The consequences of cardiac arrhythmia appear minimal. Most arrhythmias are benign and resolve with gating, therefore, gating is advocated in the presence of arrhythmia. Of note, gating is not required in the pediatric population as the incidence of arrhythmias is low.[56,57]

Finally, cardiac pacemakers may need to be reprogrammed before ESWL treatment in consultation with cardiology service. The pacemaker should be at least 5 cm from the shock wave blast path.[58]

Vascular Injury

Rarely, bleeding secondary to ESWL can result in hemodynamic instability. This is an indication for embolization or even surgery.[12,59,60] Rupture of abdominal aortic aneurysms (AAAs) has been reported after ESWL.[61,62] However, it is not clear whether the shock wave energy per se promoted rupture. The impact of shock wave energy on atherosclerotic vessels has been assessed in an in vitro study with minimal histologic changes in aortic aneurysmal tissue post ESWL.[63]

There are reports of patients with smaller AAAs (<5.5-cm diameter) undergoing uneventful ESWL.[64] Patients with calcified renal artery aneurysms <2 cm in size and vascular grafts also have undergone successful ESWL.[65,66] One study suggests ensuring a minimal aneurysm to stone distance of 5 cm, with aneurysm not in parallel to the shock wave path.[65] However, given the potentially catastrophic consequences of aneurysm rupture, careful patient consultation is warranted.

Finally, there are reports of patients developing venous thrombosis in the portal vein, renal vein, and iliac veins after ESWL. However, the exact cause of the venous thrombosis could not be determined in these cases.[67–69]

Adjacent Organ Injury

Shock waves may traverse the lung parenchyma and inflict damage. There are reports of pulmonary contusion with ESWL,[70] which typically manifests with hemoptysis or hypoxemia. ESWL has produced blast injury in rat and rabbit lung models.[71,72] Children appear particularly susceptible to this type of injury, as the lung parenchyma is closer to the shock wave path, although it can occur in adults as well.[73] Styrofoam has been applied to the chest area of children, and air vests have been worn by children to prevent such occurrences, although data supporting the use are limited.[74]

Skeletal muscle can be traversed with shock waves during ESWL. Although studies have demonstrated increases in muscle-derived enzymes in the serum and urine of patients subjected to ESWL, we are unaware of any reports of clinically significant muscle damage or rhabdomyolysis after treatment.[75,76] In fact, shock wave energy may have beneficial therapeutic effects in patients suffering from certain musculoskeletal disorders such as plantar fasciitis and calcific tendonitis.[77,78]

A mild degree of hepatic injury is not uncommon after treatment of renal and proximal ureteral stones. Studies report increase in serum bilirubin, aspartate transaminase, and glutamate dehydrogenase (a marker for hepatocellular injury);[79,80] however, significant injuries such as subcapsular hematoma and hepatic fracture are extremely rare.[10,81–83] The signs of subcapsular hematoma and hepatic fracture include hypotension, tachycardia, anemia, abdominal pain, and ileus. Imaging studies (ultrasonography, CT, MRI) should be obtained if hepatic injury is suspected. Patients with subcapsular hematoma are observed closely, whereas an active intervention may be required if hepatic fracture has occurred.

A few cases of injuries to the spleen and pancreas have been reported in patients who received ESWL to treat renal stones, although these complications are rare. The manifestations vary and include abdominal pain, peritonitis, sepsis, and shock. Splenic injury is more common with treatment of the left renal unit, whereas pancreatic injury typically occurs after right-sided procedures. At least two cases of splenic rupture requiring splenectomy after treatment of an 18-mm left upper pole stone[84] and 2-cm left renal pelvis stone[85] have been reported. Infectious sequelae can also arise following splenic injury. Treatment of a left lower pole renal stone resulted in anemia, leukocytosis, and fever with an infected perisplenic hematoma requiring splenectomy and abscess drainage.[86] Although select patients with spleen and pancreas injuries from ESWL can be managed with observation, a death from anemia and sepsis with this wait-and-see approach has been reported.[87]

The pancreas also can be injured when ESWL is used to treat upper urinary tract stones. Pancreatitis has been reported after ESWL of renal calculi,[88] as have histologic changes of pancreatic injury.[89] As expected, the occurrence of pancreatitis is higher with ESWL of pancreatic duct stones, and more severe pancreatic injuries can occur.[90,91] Late presentation of pancreatic pseudocyst requiring open surgical correction 1 year after ESWL has also been reported.[92] Very rarely, hematomas of other organs, even thoracic spinal cord epidural hematoma, can occur.[93]

The stomach, duodenum, small and large bowel may be injured during ESWL. In a literature review, Maker and Layke found 10 reported bowel perforations in 3423 patients (0.34%) who underwent ESWL. There were six small bowel perforations, three colonic perforations, and one dehiscence of a gastrojejunal anastomosis. All 10 patients required open surgical correction.[94] Patients who are treated in the prone position may be at higher risk for this injury. A left ureterocolic fistula in a patient with an impacted stone was also noted in this review; the patient was treated with nephroureterectomy. An additional 12 patients had evidence of less severe injury not requiring surgery including ulcerations of the cecum, colonic hematoma, and hematochezia.[94] The potential for upper gastrointestinal injury with ESWL was assessed by Al Karawi and colleagues who performed esophagogastroduodenoscopy in 40 patients before and after ESWL. New gastric or duodenal erosions were identified in 32 (80%) after ESWL.[95] Although significant gastrointestinal complications are extremely rare, a high index of suspicion is warranted in any patient who develops peritonitis after ESWL. Prompt evaluation and treatment are mandatory.

There are reported cases of skin burns due to overheating of the water-filled acoustic coupling cushion.[96] Finally, ureteral strictures following ESWL for ureteral stones are very infrequent, ranging from 0% to 2% in one meta-analysis.[38]

Urinary Fistulas

There have been scattered reports of patients developing fistulas after ESWL, including pyelocutaneous, pyeloduodenal, ureterocolic, and ureterovaginal. The majority of these fistulas occurred in patients with staghorn stones or undiagnosed xanthogranulomatous pyelonephritis. Nephrectomy was undertaken in most of these cases. The primary renal problem was the most likely inciting factor in these cases.[94,97–102]

Hypertension

The issue of ESWL-induced hypertension remains controversial. This association was first reported in the late 1980s, and numerous conflicting studies have been published in subsequent years. The relevant studies are profiled in Table 29.1.[103–116]

Certain patient factors and treatment approaches have been demonstrated to be associated with the development of hypertension. Janetschek and colleagues reported that age >60 years was a risk factor for the development of new-onset hypertension. They also found that older age correlated with an increase in the renal resistive index measured with Doppler ultrasonography.[109]

In the study with the longest follow-up (19 years), Krambeck and associates reported that hypertension developed more commonly in ESWL-treated patients than in a case-controlled group of patients who had had stones but had not received ESWL. Patients subjected to bilateral ESWL were at higher risk for developing hypertension. However, risk of hypertension did not appear to relate to the number

Table 29.1 Reports of Hypertension and Extracorporeal Shock Wave Lithotripsy

Study	Length of Study (MO)	No. of Shocks Range	Mean	Change in Incidence of Hypertension	Change in Diastolic Blood Pressure
Liedl et al., 1989[103]	40	Not recorded	1043	No change	Not recorded
Williams et al., 1988[104]	21	800–2000	1400	Increased	Increased
Puppo et al., 1989[114]	12	1100–1900	1380	No change	No change
Montgomery et al., 1989[106]	29	110–3300	1429	Increased	No change

Yokoyama et al., 1992[108]	19	1500–3000	Not recorded	Not recorded	Increased
Janetschek et al., 1997[109]	26	2600–3000	2735	Increased (60–80-year age group)	Increased (60–80-year age group)
Jewett et al., 1998[110]	24	Not recorded	4411	No change	No change
Strohmaier et al., 2000[111]	24			Increased	Increased
Elves et al., 2000[112]	26.4	Not recorded	5281	No change	No change
Krambeck et al., 2006a[113]	228	500–4500	1125	Increased	Not recorded
Eassa et al., 2008[115]	43.6	Not recorded	Not recorded	Increased	No change
Sato et al., 2008[116]	204	400–2300	928	No change	Not recorded

of shocks delivered or shock wave intensity.[113] Krambeck and associates also reported that those who received ESWL were more prone to developing diabetes mellitus and that there was a positive correlation to the numbers of shocks delivered and shock wave intensity, whereas the side of the involved renal unit had no influence. A review of 70 pediatric patients by El-Nahas over an average of 5 years' follow-up did not reveal evidence of hypertension or diabetes in this cohort,[117] although there was evidence of reduced renal growth post ESWL in children in another study.[118]

The literature review indicates that the association between ESWL and developing hypertension is not uniformly positive. This is at least partially due to study design and inadequate controls. In addition, hypertension is a multifactorial disease and association does not always equate with causation. Certainly, patients with renal calculi, as a group, are at a higher risk for developing hypertension.[119–123] From a clinical standpoint, the risk of blood pressure effects from ESWL is rarely relevant but might be considered in a patient with poorly controlled hypertension.

Renal Insufficiency

The kidney sustains a degree of acute injury from the received shock wave energy, in part due to cavitation and shear forces exerted.[124] The reduction in renal blood flow that occurs with delivery of shock wave energy to the kidney may produce renal ischemia, which could lead to renal injury.[125] Animal models have demonstrated that this results in the generation of oxygen free radicals, which may further promote injury.[125] Direct shock wave trauma also plays a role in acute renal dysfunction. Koga and colleagues examined canine kidneys after repeated ESWL treatments and positively correlated the degree of tissue hypoxia and rupture of interstitial capillaries with the number of shocks delivered.[126]

While stone formers are at risk of developing renal insufficiency (RI), there is no current evidence to suggest that ESWL promotes it. Krambeck and associates did not find increased rates of RI after long-term follow-up in patients treated with ESWL.[113] The majority of the patients in the aforementioned study received one or two ESWL treatments. The impact of repetitive ESWL on renal function has not been adequately addressed at this time.

There have been a few reports of patients developing renal failure after ESWL, and renal biopsies demonstrated the presence of complement fixation and antiglomerular basement membrane antibodies.[127,128] Westman and colleagues questioned whether ESWL played a role in the development of renal failure because they did not find an increased number of autoantibodies associated with glomerulonephritis in 59 consecutive patients who underwent ESWL.[129]

Although animal models have demonstrated that the smaller or underdeveloped kidney appears to be more susceptible to shock wave injury, a number of longitudinal studies performed on children who received ESWL demonstrated no reduction in renal function or growth over time.[130] One study, by Lifshitz et al., did report attenuated renal growth in children subjected to ESWL.[118] Given limited stone treatment options in children, ESWL is still an acceptable treatment in this group.

Shock wave lithotripsy in patients with preexisting renal insufficiency or a solitary kidney has also been studied. Chandhoke and colleagues found stable renal function after ESWL in patients with solitary kidneys or serum creatinine levels <3 mg/dL. Only patients with serum creatinine levels >4 mg/dL continued to have worsening renal function after ESWL, suggesting continued insult from the primary renal disease.[131]

There is no question that shock wave energy induces renal trauma, with acute histologic evidence of injury at biopsy 1 week post treatment[132] and reduced renal plasma flow immediately post treatment.[133] The renal papilla is

particularly susceptible to shock wave damage, with bleeding initiating inflammatory response and subsequent scarring.[134] Evidence of parenchymal scarring post ESWL was noted in both animal[135] and human studies.[136] Yet it appears that, in the majority of patients, this renal trauma has no significant long-term impact on the renal function.[109,137] Better designed longitudinal studies are needed to assess the impact of repetitive ESWL, especially in patients most susceptible to renal injury.

In the meantime, the judicious use of ESWL should help limit any reduction in renal function. This includes close monitoring for obstructive complications. Some have advocated the administration of free radical scavengers such as allopurinol, nifedipine, verapamil, and mannitol to limit acute renal injury.[138–141] The experience with pharmacologic protection is too limited to advocate its use at this time. Others have shown in animal and human studies that pretreatment with lower energy shock waves may reduce renal injury through vasoconstriction.[21,23]

Diabetes Risk

Theoretical risk of diabetes post ESWL is due to close anatomic position of the pancreas to the treated renal parenchyma, especially on the right side. As detailed above, pancreatic hematomas and histologic changes have been noted in pancreatic tissue post ESWL.[89] In porcine models, single ESWL was not shown to increase risk of diabetes after ESWL, despite specifically targeting renal parenchyma close to the pancreatic tail.[142,143] Similarly, human studies of 9 and 17 years' follow-up were reassuring, with no convincing evidence of elevated diabetes risk.[116,144]

Fertility Effects

Shock wave energy delivered to distal ureteral stones can theoretically injure gonadal tissue. Animal models have been used to determine the acute effects of delivering shock wave energy to the ovary. Recker and colleagues demonstrated minimal subcapsular bleeding, desquamation of superficial cells, and loss of microvilli immediately after shock wave energy was delivered to the rat ovary. However, these were transient and had resolved by 35 days.[145] McCullough and associates demonstrated normal reproductive ability in rats that had shock wave energy delivered to the ovaries. In addition, there were no teratogenic effects noted in the progeny.[146]

Studies of female patients have focused on the subjects' ability to reproduce after ESWL. Two studies evaluated women who underwent ESWL for distal ureteral stones and noted no fertility problems or genetic abnormalities in their children.[147,148] Despite this, the use of ESWL in girls or women of reproductive age harboring distal ureteral stones remains controversial, particularly due to the medicolegal implications of ESWL treatment in this cohort.

Male gonadal function also has been assessed in patients subjected to ESWL. Perisinakis and coworkers compared the radiation dose to gonadal tissue between ESWL of proximal and distal stones and found four times higher radiation exposure to the testes during ESWL for distal stones. They postulated that this would result in a four times higher genetic defect risk in the children of patients, although the overall risk still is thought to be exceedingly rare.[149] Worsening of semen parameters in men who underwent ESWL for distal ureteral stones has been noted. Fortunately, the effects were self-limited, and parameters returned to baseline within 3 months.[150,151] Reports of transient hematospermia in men who have been subjected to ESWL for distal ureteral stones are reflective of the potential temporary perturbation of the male reproductive tract.[152]

Finally, pregnancy remains an absolute contraindication to ESWL treatment, although there is at least one case report of successful treatment of proximal ureteral stone at 25 weeks' gestation.[153] In that particular case the patient was insistent on ESWL treatment despite extensive discussion of the risks.

Potential Long-term Complications

ESWL has been shown to produce acute renal injury, primarily vascular injury with parenchymal hemorrhage and subsequent inflammation, fibrosis, and loss of functional renal tissue.[136,154–156] As discussed above, as yet there is no evidence this trauma would translate into long-term renal dysfunction. There is, however, emerging evidence that repeated ESWL may increase subsequent stone formation risk,[157,158] particularly of calcium phosphate (CaP) composition.[159,160] For example, in porcine models, ESWL causes damage to medullary ascending limbs with a resultant rise in pH. This in turn can increase the risk of CaP stone formation.[161] CaP stones, brushite in particular, are notoriously difficult to treat, making it a concerning development.[162,163] Further studies in this area detailing pathogenesis and clinical implications are awaited.

Strategies to Reduce Risk of Complications

There are a number of methods to reduce complications of ESWL therapy. First, ESWL at 60 shock waves (SW)/min compared to 120 SW/min significantly reduced the size of the acute hemorrhagic lesions in a porcine study.[164] The slower rate at 60 SW/min has also been shown to improve human stone treatment outcomes in a meta-analysis.[165] Unfortunately, slowing the shock wave rate will increase the treatment time. Second, gradual ramping up of voltage (e.g., 100 shocks at low voltage) has also been shown to reduce the risk of hematoma formation in both porcine and human studies.[23,166] This is presumably due to the protective effect of renal vasoconstriction, as confirmed by the rise in the renal resistive index.[21,167,168] The effects of escalating the voltage on stone clearance are conflicting with improvement in one randomized trial but not in the other.[169,170] Third, the protective effect of voltage ramping is amplified by the (~3 min) pause following initial low voltage shocks, and this too should be included in routine treatment protocols.[171,172]

The current standard is treatment at low-to-moderate acoustic pressures with as few shock waves as possible, to minimize acute and lasting tissue injury, and at a slow shock wave rate (60 SW/min or slower), to enhance stone breakage and reduce tissue damage.[172] Next, effective coupling of the treatment head to the patient improves transmission of acoustic energy and reduces the required number of shock waves. For example, coupling defects of only 2% coverage reduced the breakage of model stones by as much as 20–40%.[173] An effective method is to apply the gel directly from the stock jug as a mound to the center of the treatment head, then press the cushion against the patient. The gel can be further spread out by increasing the water inflation pressure of the cushion.[172]

Since degree of renal injury is dose-dependent for pulse amplitude and shock wave number,[172] regular monitoring of stone fragmentation to avoid overtreatment is warranted.[174] Strategies to reduce patient movement and respiratory excursion (e.g., adequate anesthesia) allow for improved shock delivery to the target stone. Controlling blood pressure and avoiding anticoagulant use will reduce hematoma risks. Avoiding distal ureteral obstruction is also renoprotective.[175] Reserving ESWL for stones <2 cm in size will reduce risks of Steinstrasse and potential downstream obstruction.[176] With regard to antibiotic prophylaxis in patients with sterile preoperative urine, a meta-analysis did not show evidence for routine antibiotic administration to reduce risk of UTIs and sepsis in patients without stents, catheters, or infected stones.[49]

Finally, increased risk of long-term adverse effects is associated with multiple lithotripsies. Careful patient selection and consideration of alternative treatment approaches in treatment-resistant cases are recommended.

Conclusions

ESWL is generally a safe and effective treatment for patients with nephrolithiasis. Its noninvasive manner offers several advantages; however, as with any therapy, complications may result. Complications can be limited with proper patient selection, good preparation, and correct technique.

Chapter 29 Questions

1. What is the reported incidence of renal hematoma post extracorporeal shock wave lithotripsy (ESWL)?
   a. <1%
   b. 1–5%
   c. 5–10%
   d. 10–15%
   e. >15%

2. Steinstrasse management options include:
   a. Ureteroscopy
   b. Percutaneous nephrostomy insertion
   c. Conservative management
   d. Ureteral stent insertion
   e. All of the above

3. With regard to injuries to other organs, which of the following is NOT true?
   a. Mild degree of hepatic injury with raised liver enzymes is common
   b. Children are more susceptible to lung injury with ESWL
   c. Pancreatitis is commonly seen following ESWL
   d. Gastric or duodenal erosions are seen in up to 80% of patients after ESWL
   e. Subcapsular hepatic hematoma is typically managed conservatively

4. All of the following are recommended to reduce the risk of ESWL complications EXCEPT:
   a. Reducing shock wave rate
   b. Gradual voltage escalation (power ramping)
   c. Adding a 3-min pause following initial low-voltage shocks
   d. Prophylactic antibiotic administration to all patients presenting for ESWL
   e. Applying gel directly from the stock jug to the center of the treatment head to improve coupling

5. Cardiac arrhythmias associated with ESWL:
   a. Are typically associated with gated ESWL
   b. Resolve with cessation of ESWL
   c. Often require cardioversion
   d. Are more frequent in the pediatric population
   e. Occur in <5% of patients

6. Regarding risks of ESWL, which of the following is NOT true?
   a. Increased risk of hypertension is noted in younger patients
   b. Patients with renal calculi are at a higher risk of developing hypertension than the general population
   c. Worsening of semen parameters is typically transient
   d. Repeat ESWL increases subsequent stone formation risk
   e. ESWL causes acute renal injury with inflammatory response and subsequent scarring

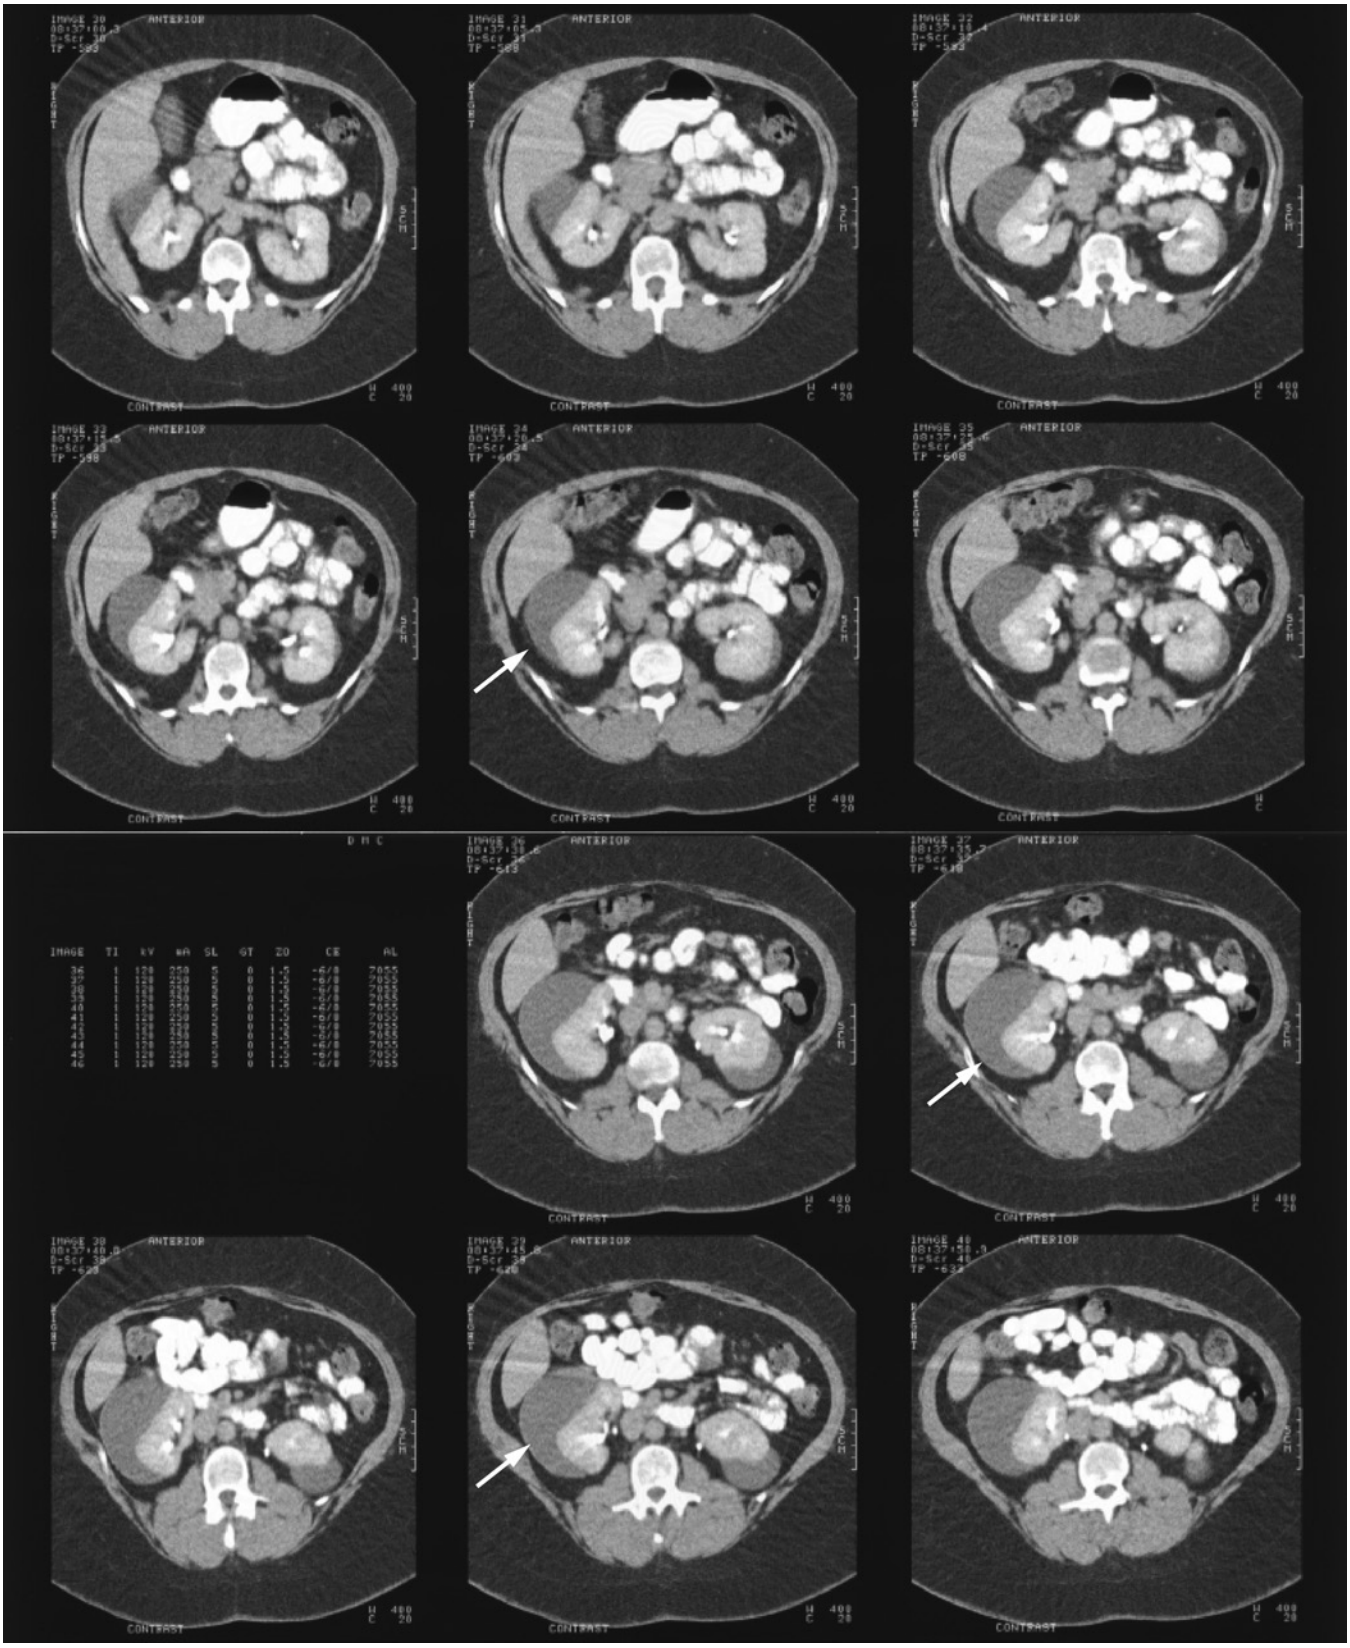
7. Acute effects of ESWL include:
   a. Predominantly cortical injury
   b. Increase in renal plasma flow
   c. Urothelial sloughing
   d. Rupture of interstitial capillaries
   e. B and D

8. Regarding sepsis post ESWL, which of the following is NOT true?
   a. Occurs in <2% of patients
   b. Warrants broad-spectrum antibiotic prophylaxis in struvite stones
   c. Associated with elevated CRP
   d. Higher risk in patients with oxalate-containing stones
   e. Increased in patients with preexisting UTI, indwelling stent, or nephrostomy tube

9. Renal hematomas post ESWL:
   a. Are usually managed conservatively
   b. Do not typically cause hypertension
   c. Can take up to 5 years to resolve completely
   d. Are reduced by medically managing hypertension
   e. All of the above

10. Regarding anticoagulant use with ESWL:
    a. Aspirin should be stopped 3 days prior
    b. The need for anticoagulants is a relative contraindication for ESWL
    c. Aspirin can be safely continued throughout treatment
    d. Few guidelines exist
    e. B and D

Case Studies



CASE 1

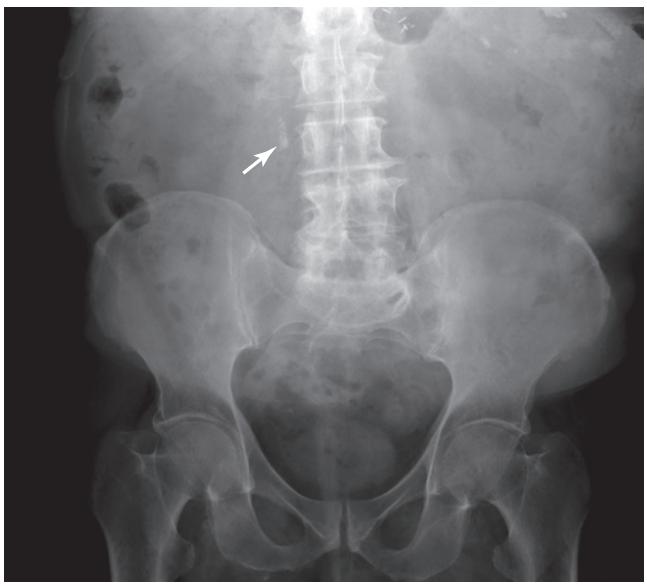
A 34-year-old female patient underwent right ESWL and was discharged home the same day. Routine follow-up imaging was obtained in clinic 6 weeks after the procedure (Case Fig. 29.1). The patient is asymptomatic.

1. What is the management of delayed presentation of large perirenal hematoma?
   a. Percutaneous drainage by interventional radiology
   b. Laparoscopic decortication
   c. Thrombolysis
   d. Observation
   e. Open surgical drainage to ensure complete resolution

2. What is the typical outcome of perirenal hematoma?
   a. Mild but persistent hypertension
   b. Gradual resolution
   c. Abscess formation
   d. Ongoing hematuria
   e. Chronic pain

3. Risk factors for post-ESWL perirenal hematoma include:
   a. Poorly controlled hypertension
   b. Advanced age
   c. Urinary obstruction
   d. Corticosteroid therapy
   e. All of the above

Case Figure 29.1



CASE 2

A 53-year-old male patient presents with pain and fever 38.3°C (100.9°F) 2 days following right ESWL for a 12-mm mid-pole calculus. A KUB x-ray is performed (Case Fig. 29.2). The patient is normotensive.

1. Acute management of this patient includes:
   a. Percutaneous nephrostomy drainage or ureteral stenting
   b. Ureteroscopy and stone fragment treatment/extraction
   c. Urine culture, initiate broad-spectrum antibiotics and observe
   d. Repeat ESWL
   e. Percutaneous nephrolithotomy

2. Once acute symptoms are treated definitive management of this patient might include:
   a. Ureteroscopy and stone fragment retrieval
   b. Repeat ESWL
   c. Observation with serial imaging
   d. Addition of alpha blockers
   e. All of the above

3. Reported incidence of Steinstrasse post ESWL is:
   a. <2%
   b. 2–10%
   c. 10–18%
   d. 18–25%
   e. >25%

Case Figure 29.2

Answers

1. **b.** Studies report low incidence of post-ESWL renal hematoma at 1–5%.[13]
2. **e.** As discussed in the chapter, Steinstrasse can be managed in a number of ways, depending on patient and stone factors.
3. **c.** Pancreatitis is rarely reported post ESWL.[88]
4. **d.** Routine antibiotic administration is not necessary for uncomplicated patients with sterile urine prior to ESWL.[49]
5. **b.** Arrhythmia is precipitated by ESWL shocks in some patients, thereby resolving with cessation of shocks.
6. **a.** Risk of hypertension is higher in older patients.
7. **d.** Tissue effects of ESWL are discussed in this chapter under the "RENAL INSUFFICIENCY" heading.
8. **d.** Struvite stones present the highest risk of sepsis.
9. **e.** Renal hematomas post ESWL are discussed at the beginning of this chapter.
10. **e.** Complexities of managing anticoagulants in ESWL are discussed in this chapter. Aspirin should be stopped 7 days prior to ensure complete reversal of anticoagulant effects.

CASE 1

1. **d.** Since most hematomas resolve over time, observation is an appropriate option in an asymptomatic patient.
2. **b.** Most hematomas resolve spontaneously.
3. **e.** All of these are known risk factors for hematoma formation.

CASE 2

1. **a.** Given concern for sepsis in combination with obstruction (steinstrasse), the first management step is decompression of renal collecting system with either a nephrostomy or a ureteral stent.
2. **e.** All listed options may be appropriate depending on the severity of symptoms, stone size and surgical factors.
3. **b.** The reported incidence of steinstrasse 2–10%[28–31].

Chapter 30 Questions and Answers

KEY POINTS

1. Laparoscopy is associated with excellent outcomes and low complication rates in properly selected patients.
2. Careful patient positioning and knowledge of specific neuromuscular injuries are critical to prevention, recognition, and management of neuromuscular injuries.
3. The laparoscopic surgeon must be facile with laparoscopic access, quickly recognize and manage associated complications, and be equipped to convert to an open approach when necessary.
4. The laparoscopic surgeon should understand the instruments, tools, and electrosurgical technology used. The laparoscopic surgeon should be aware of hazards of direct injury, insulation failure, and capacitive coupling.
5. Always consider the potential for injury to the superior mesenteric artery during left-sided nephrectomy, and the inferior vena cava during dissection of the right gonadal vein, particularly when the anatomy is distorted by tumor, lymph nodes, or prior surgery.
6. Bowel injuries require prompt diagnosis and management.

Introduction

Since the performance of the first laparoscopic nephrectomy in 1991, the expansion of surgical technology has enabled application of laparoscopic techniques to nearly every operation in urology.[1] In fact, laparoscopic approaches have become the standard of care for many of these operations with advocates citing decreased patient pain, shorter hospitalizations, lower intraoperative blood loss, and, in some cases, decreased technical difficulty. When laparoscopy was initially introduced complications were often attributed to novel technical difficulties and surgeon inexperience. However, large contemporary series of urologic laparoscopic surgery report overall intraoperative and postoperative complication rates of 4.7% and of 17.5%, respectively, which are similar to historical series, thus suggesting that not all complications can be circumvented via technologic advancement and experience.[2]

Although laparoscopic techniques are often analogous to open surgery, there are many salient differences in patient selection, instruments, and technique as well as complications unique to laparoscopy. It is incumbent upon the urologic laparoscopist to be aware of these factors in order to prevent complications when possible and to promptly recognize and expertly manage them when they do arise. In this chapter we aim to outline many of the special considerations and unique complications of urologic laparoscopy with a focus on diagnosis and management.

Patient Selection and Anesthetic Considerations

Appropriate selection of patients for surgery is critical to ensure a good outcome and is especially important when determining optimal surgical approach. Historically there were considered to be several absolute contraindications to laparoscopic surgery; however, laparoscopy may now be safely undertaken in almost any patient. Despite the expanding role of laparoscopy and its relative safety, certain patient factors, including uncontrolled bleeding diathesis,

active bowel perforation or obstruction, extensive past surgical history, or a history of diffuse peritonitis, are associated with greater risk of complication and should give the surgeon great pause before pursuing a laparoscopic approach.

Obesity is becoming increasingly more common in the Western world. While obesity was historically considered an absolute contraindication to laparoscopic surgery, contemporary series suggest that while obese patients may be at higher risk of overall complications this risk is not increased by use of a laparoscopic surgical approach.[3,4] Proper positioning of the obese patient can be challenging, but is also critical for prevention of deep vein thrombosis, neuropraxia, and rhabdomyolysis for which obese patients are at higher risk irrespective of surgical approach.[5] Often special operative tables and equipment are necessary, and the surgeon must be aware of weight limitations of commonly used equipment. When placed in the steep reverse Trendelenburg position, obese patients have increased pressure on the diaphragm resulting in decreased respiratory compliance and subsequent difficulty with mechanical ventilation.[6] If the anesthesia team is having difficulty ventilating a patient, it is often necessary to decrease the pneumoperitoneum pressure, although this may increase the technical difficulty of the operation. In contrast to the Trendelenburg position, obese patients tolerate the flank position well, both from a hemodynamic and a respiratory standpoint.[5] Please see Chapter 9 for more information.

Patients with cardiopulmonary disease are at unique risk during laparoscopy using carbon dioxide insufflation. Carbon dioxide is highly soluble and readily diffuses into extra-pulmonary tissues and fluids, which may lead to hypercarbia even many hours postoperatively. Patients with chronic obstructive pulmonary disease (COPD) may be unable to increase their ventilation to respond to hypercarbia and should be closely monitored with serial ABGs postoperatively. COPD is not an absolute contraindication to laparoscopy, but in the setting of severe COPD and/or anticipated long operative time an open surgical approach should be considered.[7] Helium is a physiologically inert and noncombustible gas that does not contribute to hypercarbia and can be used as an alternative insufflant. Although helium is significantly more expensive than carbon dioxide, it can be used to salvage a case complicated by severe hypercarbia that may otherwise be aborted or converted to an open approach.[8]

While surgical indications should be carefully considered in pregnant patients, pregnancy itself is not an absolute contraindication to laparoscopy. Performing laparoscopy on pregnant patients presents several unique considerations with regard to obtaining initial access, port placement, and prolonged pneumoperitoneum. Initial access should be away from the gravid uterus and is generally obtained at Palmer's point located in the left upper quadrant in the subcostal midclavicular line. Port placement is generally more cephalad and should be performed under direct vision in order to minimize the risk of uterine injury. Pneumoperitoneum pressure should be set at 10 mm Hg and should not be increased above 15 mm Hg as venous return is already compromised by a gravid uterus. Prolonged pneumoperitoneum should be avoided as hypercarbia could have harmful effects on the fetus. [9,10]

POSITIONING

Careful attention to appropriate patient positioning is critical to minimize the risks of nerve injury and rhabdomyolysis during and following laparoscopic surgery. In a review of 4000 insurance claims, complications related to nerve injuries accounted for 16% of claims associated with laparoscopic surgery. Of these, ulnar nerve injuries were most frequent (28%) followed by brachial plexus injuries (20%).[11] Mechanisms of nerve injury related to positioning include stretching, compression, and ischemia. Ulnar nerve injuries are often related to external compression of the nerve as it courses behind the medial epicondyle in the antecubital tunnel where it is not shielded by muscle or bone. Injury to the ulnar nerve results in hypoesthesia of the medial half of the fourth finger and the entire fifth finger. Weakness can lead to difficulty with thumb adduction. Claw hand may be seen due to hyperextension of the fourth and fifth digits at the metacarpophalangeal joints, and flexion at the interphalangeal joints.[12] Careful attention to avoid compression injury through adequate padding of the elbow is necessary, especially with the use of gutter armrests. The brachial plexus is at highest risk of stretch injury when the arm is abducted and extended, especially in deep Trendelenburg and with use of shoulder braces.[11] Signs of brachial plexus injuries vary widely but most commonly include sensory deficit to the shoulder area and impairment of upper arm abduction.

A large majority of lower-extremity positioning complications are related to compression of the peroneal (fibular) nerve as it passes laterally to the head of the fibula.[13] Peroneal injuries manifest as paresthesia over the lateral foot and inability to dorsiflex the foot (foot drop). Sciatic nerve injuries are less common and are caused by excessive hip flexion in lithotomy. This injury is exacerbated when the knees are minimally flexed as this increases stretch on the sciatic nerve. Sciatic nerve injuries present as paresthesia over the posterior legs and feet and weakness in foot extension and flexion. To avoid these lower-extremity injuries patients in lithotomy must be carefully positioned to ensure the weight of the leg is supported in the heel, external rotation and hip flexion are not excessive, and the lateral aspect of the leg is appropriately padded (Table 30.1).

Rhabdomyolysis following laparoscopic surgery is a severe and potentially life-threatening complication with a reported incidence ranging from 4.9% following laparoscopic renal surgery to 0.13% in a series of over half a million patients following urologic surgery.[14,15] In the surgical setting, rhabdomyolysis most commonly occurs secondary to prolonged direct pressure on soft tissues resulting in structural changes and necrosis of skeletal muscle. Once the pressure is released, ischemia-reperfusion injury can occur and the intracellular components of lysed cells are released into the systemic circulation. This leads to myoglobinuria, which has a direct toxic effect on renal tubules and can cause devastating acute renal failure, particularly when occurring in the context of extirpative renal surgery. The clinical signs of rhabdomyolysis are myglobinuria, muscle weakness, pain, and acute renal failure. The creatinine kinase (CK) is elevated and is usually between 1000 and 100,000 IU/L.

Gelpi-Hammerschmidt et al. attempted to quantify the risk of postoperative rhabdomyolysis, reporting a 1.8%

Table 30.1 Common Positioning Nerve Injuries

Nerve	Location	Mechanism of Injury	Deficit
Ulnar nerve	Unprotected near medial elbow	External pressure on medial elbow, especially with arm gutters	Paresthesia of 4th and 5th finger, claw hand
Brachial plexus	Axilla	Hyperextension or abduction of arm, deep Trendelenburg, use of shoulder braces	Variable, paresthesias and weakness of upper extremity
Sciatic nerve	Well protected in thigh	Excessive hip flexion especially with extended knees	Paresthesia and weakness posterior leg, foot
Peroneal nerve	Lateral leg	External compression as it passes head of fibula, external hip rotation	Paresthesia over lateral foot and foot drop

Figure 30.1 Major Abdominal Vessels. The location of the major abdominal vessels and of the inferior epigastric vessels in relation to surface landmarks is shown in a photograph of a patient with the superimposed course of vessels. The umbilicus (arrowhead) acts as a superficial landmark for the aortic and vena caval bifurcation. Direct entry at 0 to 30 degrees in the sagittal plane by a needle or trocar creates a high risk of puncturing the aorta, right common iliac artery, or the left common iliac vein. The inferior epigastric vessels take an ascending course medially and eventually travel in the substance of the rectus muscle. A port placed at or just below the umbilicus at the paramedian location (arrows), such as is frequently done during pelvic cases (e.g., laparoscopic prostatectomy), poses a higher risk of causing injury to these vessels. (Copyright S. F. Matin, 2007.)

Box 30.1 Risk Factors for the Development of Rhabdomyolysis

- Robotic surgery (independent risk factor)
- Operative time greater than 5 hours
- Obesity
- Diabetes mellitus
- Male gender
- Poor padding
- Prolonged use of the kidney rest

incidence in patients with any three of the following five risk factors: operative time greater than 5 hours, robotic surgery, obesity, male gender, and Charlson comorbidity index greater than 2.[15] Other identified risk factors include preexisting renal disease, high intraoperative blood loss, and positioning factors such as poor padding of bony prominences, operative table flexion, and use of the kidney rest. A recent review also suggests that robotic surgery presents a greater risk for rhabdomyolysis compared to laparoscopic or open renal surgery likely due to comparatively longer operative times.[16] Rhabdomyolysis is often a devastating complication causing major collateral morbidity as well as increased resource utilization.[15] As such, once a clinical suspicion of rhabdomyolysis is established, aggressive treatment focused on vigorous hydration, urinary alkalization, and renal replacement therapy should not be delayed. While a less common complication of rhabdomyolysis, compartment syndrome is life threatening and requires decompressive fasciotomy for definitive management. In cases involving lithotomy for greater than 5 hours, sequential compression devices may increase the risk of compartment syndrome and should be used with caution[17] (Box 30.1).

ACCESS INJURIES

Obtaining initial peritoneal access is often the most dangerous step in laparoscopy, and multiple initial entry techniques have been described, each with the goal of minimizing morbidity (Fig. 30.1). These techniques can be broadly

Box 30.2 Tips for Safe Veress Placement

- Check the needle and ensure spring-loaded blunt tip is working
- Incise the skin prior to Veress placement
- Once placed, aspirate to observe for blood or succus
- Perform the saline drop test prior to insufflation
- Observe the insufflation pressures and stop and replace Veress if initial pressure reaches 6 mm Hg
- Percuss insufflating abdomen for asymmetric tympani
- If concerned about Veress placement, leave Veress in place, obtain another access, and observe Veress location with laparoscope

classified into "open" methods in which trocars are placed into the peritoneal cavity under direct vision, and "closed" methods in which instruments are passed blindly through the abdominal wall prior to insufflation. Of these, the most commonly used are the "open" Hasson and the "closed" Veress methods. However, other techniques including direct trocar entry, radially expanding trocars, primary insufflation through a hand assist port, and optical trocars may be used. No method of primary laparoscopic entry is absolutely safe, and experts disagree on which method provides the safest, most expedient, and most reliable means of obtaining laparoscopic access. This controversy is compounded by a lack of high-quality clinical data.

The surgeon should be comfortable with multiple methods of laparoscopic access. Because the Veress needle is inserted blindly, it should be used carefully (Box 30.2). The needle should be checked to make sure the spring-loaded blunt center is functioning. Once placed, multiple maneuvers may be employed to confirm intraperitoneal

position of the Veress needle. First, the needle should be aspirated to make sure there is no blood or succus indicative of vascular or visceral injury. Second, as a saline-filled syrine is disconnected from the Veress needle hub, the saline remaining in the needle hub should quickly drop into the abdomen in the so-called "drop test." If the fluid does not freely flow into the abdomen this may indicate that the needle is either not intraperitoneal or is abutting a structure that is limiting flow. During initial insufflation intraperitoneal pressures should not exceed 6 mm Hg, and higher pressures and/or a rapid rise in measured pressure may indicate extraperitoneal position. The abdomen may also be percussed during insufflation; asymmetric tympani could represent pre-peritoneal or colonic insufflation. If any of these steps raises concern for a visceral injury, the Veress needle should be left in place and alternate access should be obtained. Once access is obtained, the original Veress site should be inspected for any signs of injury. Veress needle injuries to bowel and bladder can usually be managed conservatively while trocar injuries invariably require operative repair.

An optical port may be utilized to place the initial trocar using a 0-degree laparoscope under direct vision either with or without initial insufflation. The layers of the abdominal wall (subcutaneous fat, anterior fascia, rectus, posterior rectus sheath, transversalis, and peritoneum) should be visualized during advancement to confirm intraperitoneal position. The tip of the optical trocar is usually radially dilating so rotation is important to traverse the layers of the abdominal wall. If this technique is employed prior to insufflation the initial access site should be located off midline so the layers of the abdominal wall can be visualized. The remaining ports should be placed under direct vision, and any adhesions seen near the desired port location should be taken down prior to trocar insertion.[18]

Open access is considered very safe as the surgeon retains direct visualization; however, it can be more technically challenging and complicated by pneumoperitoneum leakage (Box 30.3).[18] The technique is similar to a mini-laparotomy where a small incision is made near the umbilicus and taken down to fascia. The fascia is incised, the peritoneal cavity opened, and the trocar placed using a blunt obturator. Once in an intraperitoneal position fascial sutures are placed to secure the Hasson trocar and the balloon is inflated to create a seal between the trocar and the peritoneal edges enabling establishment of pneumoperitoneum.[19]

The Cochrane Collaboration released in 2015 a systematic review of all available prospective randomized controlled trials (RCTs) comparing laparoscopic entry techniques. In a review of three RCTs including 795 patients comparing open versus closed primary entry techniques, no differences were found with respect to incidence of visceral or vascular injury.[20–22] In the same series, the risk of failed entry, extraperitoneal insufflation, and omental injury were all less likely with use of open entry techniques, although the authors note that all reviewed studies were of low or very low quality.[20–24] Visualized trocar entry without insufflation ("direct trocar entry") is becoming increasingly popular as initial studies support its superior safety and speed. The Cochrane report included systematic review of five RCTs that reported lower risk of vascular injury with direct trocar entry, but no difference with respect to visceral injury.[20,25–28] See table 30.3 for a summary of randomized controlled trials comparing methods of initial laparoscopic access.

Another area of controversy is the necessity of laparoscopic trocar site closure in order to prevent hernia formation. The absolute incidence of trocar site hernia is unknown, but is estimated to be between 0.65% and 2.80% by large general surgery series and is likely underreported.[29] Although uncommon, such hernias may result in small bowel obstruction or incarceration and as such represent a serious source of morbidity and mortality in laparoscopic surgery. Initial studies of bladed trocars supported the necessity of trocar site fascial closure as hernia rates at 12-mm trocar sites fell from 8.0% to 0.22% with formal closure.[29–32] Since the development of bladeless and radially dilating trocars that permit atraumatic separation of the abdominal wall, the necessity of fascial closure is less clear. A randomized prospective trial comparing bladed to bladeless trocars concluded that routine closure in the absence of risk factors was not necessary.[33] Another study of 747 patients undergoing laparoscopic Roux-en-Y bypass with the use of radially dilating trocars reported no hernias at extraumbilical sites that were not closed; however, there was a 1.2% rate of hernia at the umbilical site of Hasson entry despite formal fascial closure.[34] The authors similarly concluded that routine closure of extraumbilical trocar sites was unnecessary.

It is imperative to maintain a high index of suspicion for trocar site hernias as clinical signs and physical exam findings can be deceiving. This was demonstrated in a recent retrospective review of 1055 patients undergoing either RALP or laparoscopic renal surgery at a single center.[35] The authors describe seven hernias (0.66%), all of which occurred at 12-mm trocar sites where fascia was not closed. Six of the seven patients with hernia presented with signs and symptoms of bowel obstruction, and all required operative intervention. Although diagnosis of hernia was made on cross-sectional imaging, four of the seven patients were noted to have intra-fascial hernias (occurring between the transversalis and internal oblique fascia) at the time of surgery and were without overt evidence of hernia on physical exam.

Currently it is our practice to close all 12-mm port sites and remove all trocars under direct vision to minimize the risk of hernia.

Minor Vascular Injuries

Vascular injury is the most common intraoperative complication of urologic laparoscopy, ranging from 2.6% to 19.8% in large series.[2,36,37] The majority of these injuries occur while obtaining laparoscopic access or during dissection. Types of vascular injury include injury to the abdominal wall vasculature, great vessel injury, or mesenteric artery injury.

The inferior epigastric vessels are the most common site of minor vascular injury, occurring in 2.5% of laparoscopic hernia repairs.[38] Although injury to the vasculature of the abdominal wall is less likely to be life threatening, it may confer considerable morbidity requiring conversion to an open approach, transfusion, and the need for additional procedures or operations. The anatomic location of the inferior epigastric vessels at the lateral aspect of the rectus sheath place them at risk for injury that invariably occurs during placement of secondary cannulas. Significant injury

is most common in the lower abdomen, as the epigastric vessels exist as a plexus in the upper abdomen rather than a discrete vessel vulnerable to laceration.[39]

Injury to the abdominal wall vasculature is most commonly identified at the time of initial port placement, but can also be recognized when ports are removed, or present in a delayed fashion as abdominal wall or rectus sheath hematomas. Techniques to avoid abdominal wall vascular injury include use of the smallest appropriate cannula, transillumination of the body wall to identify and avoid large vessels, an adequate skin incision to avoid use of excessive force, not angling trocars toward the midline, and placement of cannulas under direct laparoscopic vision.[39] Particularly in obese patients use of a "finder" needle with local anesthetic can be useful in planning port placement and avoiding minor vascular injury. This additionally allows infiltration of local anesthetic, which can aid postoperative pain control.

Once an injury to the inferior epigastric vasculature is identified, there are multiple techniques available to obtain hemostasis. Initially, direct pressure can be applied by angling the laparoscopic cannula to tamponade the bleeding vessel. The vessels can be suture ligated either by extending the port site skin incision to gain adequate exposure for direct suturing or by use of a laparoscopic-assisted, transabdominal suture technique with either a Carter-Thommason device or Keith needle. In either case, placement of either interrupted or horizontal mattress sutures or a wide-based figure-of-eight suture is usually necessary to control hemorrhage. As a last ditch maneuver, a Foley catheter can be placed through the abdominal wall fascia, the balloon inflated intraabdominally, and pulled snug against the abdominal wall to provide tamponade for 24–48 hours or until hemostasis is achieved.

Abdominal wall vascular injury can also result in rectus sheath hematoma, which most commonly presents in a delayed fashion with palpable abdominal mass and severe abdominal pain.[40] While all patients are at risk for developing a rectus sheath hematoma, those on anticoagulation are at higher risk. Computed tomography is the imaging study of choice in diagnosis of rectus sheath hematoma.[40] The majority of rectus sheath hematomas are self-limiting, resolving with careful observation and reversal of anticoagulation if applicable; however, hemorrhagic shock occurs in 37.5% of cases with mortality as high as 25% in anticoagulated patients.[41] In severe cases selective angioembolization is preferred to surgical exploration, as the latter will release any tamponade, is less likely to be definitive as localization of the injury may be challenging or impossible, and carries considerable morbidity.

Box 30.3 Tips for Successful Trocar Placement[79,80]

Factors Facilitating Safe Placement of Trocars During Laparoscopic Surgery

- Low table height
- Noting of anatomic landmarks and abdominal scars
- Adequate skin incision size for trocar
- Application of appropriate axial force during trocar insertion
- Use of the Trendelenburg position (for umbilical access)
- Elevation or stabilization of abdominal wall
- Transillumination of abdominal wall vessels
- Avoidance of lateral deviation of needle or trocar
- Avoidance of angling of needle or trocar toward the midline

Major Vascular Injuries

Major vascular injuries are rare during laparoscopy, but are the most common cause of intraoperative death at up to 15%, second only to anesthetic complications.[39,42] While the specific incidence of these injuries is lacking in the urologic literature, it ranges from 0.03% to 0.30% in large series in the general and gynecologic surgical literature.[39] Most vascular injuries occur during initial establishment of pneumoperitoneum with a Veress needle (39.8%), but can also occur with placement of the primary trocar (37.9%) or with secondary trocars (22%).[43] Of interest, a large French series found that while the rate of overall complications decreased with increasing surgeon experience, the rate of vascular injury remained static at 0.02% independent of surgeon experience.[44]

The anatomy of the retroperitoneal vasculature places the distal aorta and common iliac vessels at highest risk of injury during periumbilical laparoscopic access (see Fig. 30.1), as these vessels can be as close as 2 cm from the anterior abdominal wall in thin patients. Arterial injuries are most common, and when venous injuries do occur they are usually in conjunction with arterial injury.[45] A review of vascular injury during gynecologic laparoscopy reported that distal aortic injury was most common (25%), followed closely by injury to the right common iliac artery (21%), with the remainder of arterial injuries being distributed between the bilateral external and internal iliac arteries (29%).[45–47] Injury to the inferior vena cava (IVC) occurred in 11% of patients.[45–47] The IVC is at particular risk during dissection of the gonadal vein during right-sided nephrectomy. As such, it is critical to release the gonadal vein away from the ureter and allow it to return medially in order to avoid avulsing the gonadal vein from the IVC.[48]

Major vascular injuries occurring during the access phase of laparoscopy are most commonly signified by identification of a large retroperitoneal hematoma. Depending on the location and nature of the injury, blood within the peritoneal cavity may be scant or absent.[39] Additional signs of injury include hypotension and hemorrhagic shock, as well as decreased end-tidal carbon dioxide as a result of carbon dioxide embolism. Lastly, if there is significant intraperitoneal bleeding, absorption of visible light by hemoglobin may result in poor laparoscopic visibility serving as another clue as to possible vascular injury.[39]

While the principles of managing significant intraoperative hemorrhage during laparoscopy are the same as during open surgery, the specific techniques differ. If the site of vascular injury is immediately apparent, laparoscopic grasping and dissecting instruments can be used to apply direct pressure and obtain initial control. Care should be taken not to injure adjacent structures or worsen the vascular injury through careless maneuvers or inappropriate use of instruments. Once temporary control is obtained, the anesthesia team can be notified to allow for appropriate resuscitation and to ensure availability of blood products. The insufflation pressure can be increased to 20 mm Hg in order to help tamponade bleeding; however, this maneuver

carries the risk of causing venous gas embolism should there be a significant venous injury. If bleeding is sufficiently controlled and visibility maintained, it is reasonable to continue laparoscopic dissection to further expose the site of injury. Once definitively identified, the source of bleeding can be controlled with electrocautery, surgical clips or staplers, suture ligation, or hemostatic agents. Additional ports, including hand-assist ports, may be placed in order to improve exposure and facilitate passage of instruments.

If bleeding cannot be controlled using laparoscopic methods, or if an injury is identified that will require formal vascular repair, conversion to an open surgical approach may be necessary. It is important that this decision be made quickly because even experienced surgical teams can take a considerable amount of time to convert and significant blood loss can occur in the interim. Open surgical instruments should be at hand during all laparoscopic cases, and it is prudent to plan the open incision site at the beginning of difficult cases where conversion is more likely. If laparoscopic or robotic instruments are being used to provide direct pressure, these instruments should remain in place and pneumoperitoneum maintained during conversion to aid hemostasis and tamponade. The open incision should be planned in order to gain optimal exposure for vascular repair; however, extension of an existing port site is preferable as laparoscopic instruments, or the laparoscope itself, can be used to expose and facilitate division of the abdominal wall.

Superior Mesenteric Artery Injury

A special consideration during laparoscopic renal surgery is the possibility of injury to visceral vasculature, particularly the superior mesenteric (SMA) and celiac axis (CA). Anatomic studies by Brunet et al. demonstrated that the average proximity of the ostia of the left renal and superior mesenteric arteries, and the ostia of the CA and SMA, are 11.3 mm and 3.8 mm, respectively.[49] This close anatomic proximity places these vascular structures at high risk of injury during laparoscopic renal surgery, especially in the setting of large renal or adrenal masses, adenopathy, adherence of the kidney to surrounding tissues, and accessory renal vessels that may distort normal anatomy. Anomalies of the renal vasculature are frequent, with Kaneko et al. noting 21.1% of renal arteries with multiple origins, while aberrations of the aorta and mesenteric vasculature are extremely rare.[50,51] Therefore it is imperative to review preoperative imaging to identify all renal arterial branches and to exercise extreme caution prior to vascular ligation when operative findings do not correlate with preoperative imaging. In difficult laparoscopic dissections, the gonadal vein can be used as a guide to definitively identify the hilar vessels. While difficult hilar dissection and failure to progress are commonly cited reasons to convert from a laparoscopic to open surgical approach, only 7% of reported SMA injuries during left nephrectomy occurred during laparoscopy, suggesting that open surgical exposure does not completely protect from these injuries.[52–55]

Injury to the SMA may be detected intraoperatively by identification of hemorrhage, signs of hemorrhagic shock, worsening metabolic acidosis due to bowel ischemia, and oliguria due to shock and massive fluid shifts to the bowel. Notable clinical signs of bowel ischemia such as serosal color change, loss of palpable arterial pulses, and lack of intestinal peristalsis may occur late or not at all depending on the level at which the SMA was ligated.[56] Postoperatively significant mesenteric arterial injury classically presents with severe epigastric abdominal pain as well as the above listed signs; however, pain may be masked in the postoperative setting. As unrecognized SMA injuries generally result in acute intestinal ischemia and death in most patients, a high index of suspicion for vascular injury is critical especially for left-sided renal surgery, and prompt vascular surgical consultation should be obtained if there is any question of mesenteric vascular injury.

Electrosurgery

Urology has always been on the leading edge of medical technology. Understanding how surgical technology works is critical to operating safely and addressing issues when they arise. Electrosurgery is the single most used piece of surgical technology, but is often poorly understood and is also one of the most common causes of litigation.[57] While often used incorrectly, the term "electrocautery" actually refers to a direct current heating a probe that in turn burns tissue (e.g., portable ocular cautery stick) and is used very rarely in modern surgical technique. Electrosurgery or diathermy refers to the application of a current to the tissue itself and is most commonly used in the operating room.

Monopolar is the most commonly utilized electrosurgical modality. This technology passes an alternating current through a circuit coursing from the generator, to the electrode (pencil or instrument), through the patient, and then back to the generator via the return electrode ("grounding pad"). Central to the utility of monopolar electrosurgery is the concept of current density. The monopolar current density is highest at the point of contact between the electrode and the patient's tissue and rapidly decreases further from the electrode. As the rate of tissue heating is proportional to the square of the current density, only this tissue near the tip of the electrode is heated. Therefore the smaller the surface contact of the electrode to the tissue, the greater the current density and the more quickly that tissue is heated and desiccated. Conversely, the larger the surface contact between the electrode tip and the tissue, the more slowly the tissue is heated and dissected.

Monopolar electrosurgical injuries result from the unintentional application of current to tissue due to unintentional direct contact, direct coupling, poor return electrode application, insulation failure, or capacitive coupling. Unintentional direct contact is self-explanatory and usually occurs when the electrode is activated when the instrument is not in view. Direct coupling occurs when the electrode is in contact with a metal instrument that is in turn contacting tissue. An example of intentional direct coupling is the application of monopolar current to a pair of forceps grasping a bleeding vessel. In this case, the area of tissue contact is small, the current density is high, and the energy applied to the tissue is also high resulting in coagulation of the vessel. Conversely, if the forceps accidentally contacts a surface outside the immediate operative field such as the abdominal wall in addition to the vessel, the current density is low and the energy imparted to intended tissue will also be low (noted as "grounding out"). Lastly, direct coupling can

cause injury if the return electrode is malpositioned such that it contacts a small surface area, thereby creating an area of high current density that may inadvertently injure tissue. Unintentional direct coupling can also occur during laparoscopy through similar mechanisms, such as by inadvertent coupling of current to the laparoscope lens that is also touching bowel. In this case the current will be coupled to the metal sheath of the scope and applied directly to the bowel, potentially resulting in serious injury. Laparoscopic and robotic instruments typically have insulation protecting the nonvisible portion of the instrument; however, it is important to remain vigilant as insulation failure can occur as a result of forceful manipulation or manufacturing defects and result in potentially devastating injury.

Capacitive coupling occurs when a conductor (metal device or tissue) is in parallel with an active electrode but is not in direct contact. This results in the electrode inducing current within the other conductor, the magnitude of which depends on the proximity and level of insulation between the electrode and the conductor. Again, the degree of tissue damage is dependent on the current density applied. An illustration of this concept can be seen with the use of metal robotic trocars. A monopolar current traveling through a robotic arm within a metal trocar will induce a current in the metal trocar. This is normally harmless as the large contact area between the metal trocar and the abdominal wall minimizes current density. The greatest risk of injury occurs when a metal trocar is placed through a plastic outer trocar. In this scenario, the metal trocar is insulated as it passes through the abdominal wall and any area of contact, such as with bowel, will have a very high current density resulting in likely injury. To avoid such injuries it is imperative to ensure that all metal trocars are well "grounded," meaning they have a large area of contact with the skin and are not passed through insulating trocars[13] (Figs. 30.2, 30.3, 30.4).

Bipolar current is another popular form of electrosurgery in which the current is applied to the target tissue

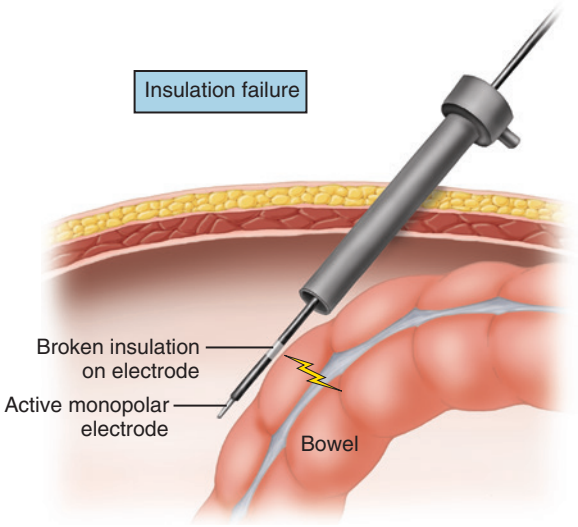

Figure 30.3 Insulation Failure. Except for the working element, monopolar laparoscopic instruments conduct along the entire device. Manufacturing malfunction or forceful use can cause a break in the layer of insulation. If this area comes in contract with tissue, current will be applied to that tissue unintentionally.

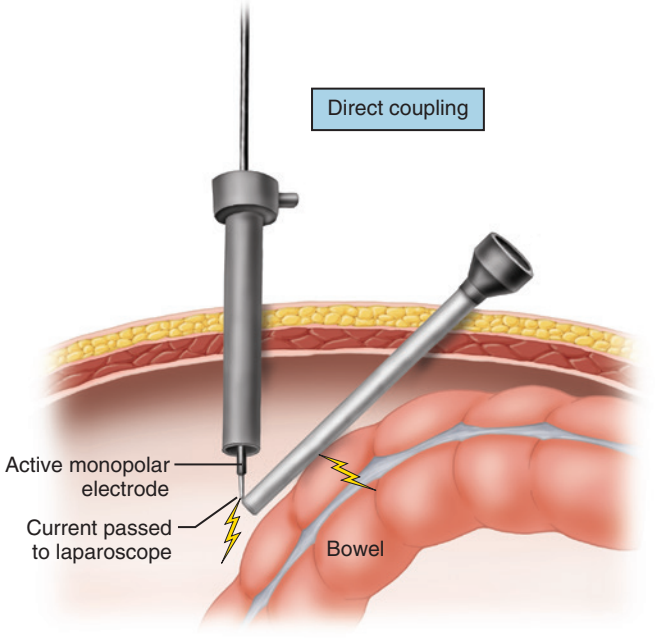

Figure 30.2 Direct Coupling. In the same way that in open surgery a current is applied to a forceps by touching the electrode to the metal instrument, the current can be directed to a metal object such as the laparoscope. This occurs when an active electrode comes in contact or near contact with a metal object, and that metal object touches tissue.

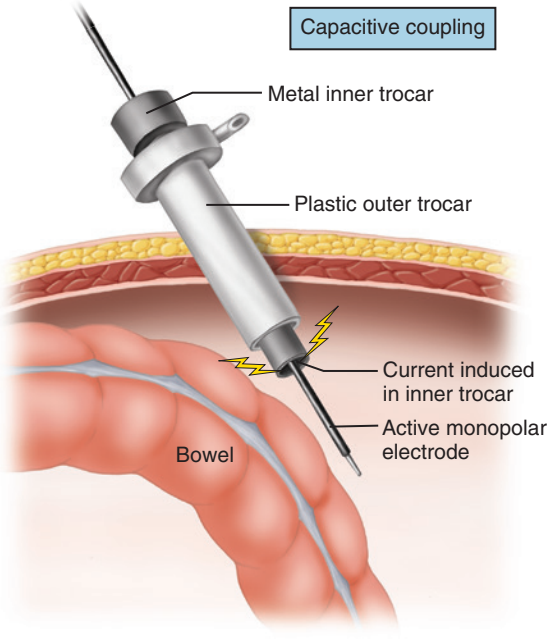

Figure 30.4 Capacitive Coupling. The risk of this effect can best be demonstrated when the current is being passed through a laparoscopic instrument that is within a metal trocar within an outer plastic trocar. Even without direct contact, the current will be induced in the metal trocar and insulated from the return electrode by the plastic electrode. If that metal trocar comes in contact with tissue the current can be applied to that tissue.

Table 30.2 Comparison of Electrosurgical Instruments

Device	Type of Technology	Tissue Temperature	Thermal Spread	Vessel Sealing	Note
Bovie	Monopolar	200–400°C	Variable	Variable	Return electrode
Bipolar	Bipolar	>100°C	2–22 mm	Variable	No return electrode
Harmonic scalpel	Ultrasonic	80°C	1–4 mm	5 mm	Best ability to cut, fastest to use
ENSEAL (Ethicon)	Impedance controlled bipolar + mechanical compression	~100°C	1.1 mm	7 mm	Very large seal strengths of vessels
LigaSure (Covidien)	Impedance controlled bipolar + mechanical compression	~100°C	1.8 mm	7 mm	Minimal charring
PK Trissector (Olympus)	Pulse controlled bipolar	~100°C	6.3 mm	7 mm	Intermittent tissue cooling creates uniform coagulation

positioned between two electrodes in close proximity. The return electrode (grounding pad) is not necessary as the bipolar current does not pass through the patient's entire body. It is a potentially safer form of electrosurgery as there is no potential for capacitive coupling and return electrodes are unnecessary.[58] Traditional bipolar instruments were limited by their inability to divide tissue since the necessary voltages cannot be safely delivered. However, there are now multiple commercially available devices that overcome this limitation through the use of bipolar current with real-time impedance feedback coupled with mechanical compression and/or blade transection. The LigaSure (Covidien), ENSEAL (Ethicon), and PK Trissector (Olympus) are examples of such devices. PK technology is unique in that it uses pulsed bipolar energy, which allows for intermittent cooling of the tissue. These more advanced bipolar devices use impedance detection that senses when adequate current has been applied and mechanical compression. This permits use of a lower voltage thereby minimizing thermal spread and allowing ligation of larger blood vessels (see Table 30.2). These devices are a safe alternative to suture ligation, but the added cost might not be offset by operative time saved.[59] It is critical to maintain tension-free mechanical compression for these devices to work properly.[60]

Ultrasonic technology, such as the "harmonic scalpel," has become very popular in laparoscopic surgery. These instruments do not pass electrical current through tissue and instead use an ultrasonic "blade" that generates mechanical energy and heat to coagulate blood vessels and divide tissue. Vessels up to 5 mm can be sealed but 2–3 mm is considered safer.[60] The vibrating of the blade tip produces pressure changes that vaporize cellular water allowing dissection at a much lower temperature (50–80°C) compared to electrosurgical techniques, thereby minimizing char and thermal spread to surrounding tissues (Table 30.2). Unlike electrosurgical instruments, it is important to remember that the blade of the harmonic scalpel remains hot between uses and injury can occur if the instrument comes in contact with tissue unintentionally. Because of this care must be taken when alternating between hot and cold dissection. The disadvantage of the harmonic scalpel is increased disposable cost and a limited ability to seal vessels larger than 5 mm. The surgeon may also have to alter his or her technique when using this instrument.

The Thunderbeat device (Olympus) combines bipolar and harmonic energy to obtain the cutting benefits of ultrasonic technology with the coagulation benefits of bipolar. While initial studies praise this technology for versatility compared with the other instruments tested with faster dissection speed, similar bursting pressure, and acceptable thermal spread, it is a relatively new device and comparative studies are lacking.[61,62]

The argon beam coagulator is a device that has many applications in open surgery; however, it is not suitable for laparoscopic and robotic surgery. This device works by passing a monopolar current through an ionized argon gas creating a plasma beam. The device expels a significant amount of gas and will not function properly in a pressurized environment such as an insufflated abdomen. There are reports of argon gas emboli associated with its use in laparoscopy. If it is absolutely necessary to use the argon beam coagulator, a port should be vented during its use[63] (see Table 30.2).

Monopolar electrical current poses a risk to patients with implanted electrical devices such as neuromodulators, intrathecal pumps, cardiac pacemakers, or defibrillators. These devices are susceptible to electromagnetic interference depending on the location of the electrodes, the pathway of current, and the power and type of current. As electrosurgical current passes through the patient from electrode to electrode (i.e., from hand-held instrument to grounding pad) the risk of interference is lowest when the device is father away from the path of current. In pelvic surgery, a monopolar current is felt to be safe in patients with implanted cardiac devices if the return is placed on the lower extremity as the current travels through the patient from the pelvis to the lower extremity and away from the device. The surgeon should be aware that the wire that connects the instrument to the generator carries a current and thus emits electromagnetic interference. The cord should be placed in the location opposite the implanted device. That is, if the patient has a cardiac device, the wire should be coming from the patient's feet. If the situation allows, bipolar current or ultrasonic energy is preferable as these modalities do not transmit current through the patient. If this is not possible, the lowest power needed to successfully complete the case should be utilized recognizing that coagulation current generates more interference than cutting

Table 30.3 Summary of Randomized Controlled Trials Comparing Commonly Employed Methods of Initial Laparoscopic Access[81–83]

Vascular Injury

current. Additionally, the implanted device should be evaluated pre- and postoperatively to check for error codes and ensure proper functioning. [64]

Mechanical Failure

The performance of laparoscopic surgery is dependent on the use of devices that are subject to mechanical failure, and the laparoscopic surgeon must be prepared to manage such failures.[65] There is a significant body of literature related to hemorrhagic complications following the use of surgical clips to ligate the renal vasculature during living donor nephrectomy. These studies concluded that nonlocking clips should not be used on the renal hilum as they were more likely to be involved in fatal arterial hemorrhage when compared to vascular staples and locking clips.[65] Given these data, locking clips (e.g., Hemo-o-loc Teleflex Medical) have been a mainstay of hilar control during laparoscopic nephrectomy since their introduction. However, in April of 2005, the manufacturer issued a contraindication for renal artery ligation during donor nephrectomy due to concern for clip failure. Shortly thereafter, in 2008, a multi-institution retrospective study of the locking clip in

1695 laparoscopic nephrectomies, including 486 donor nephrectomies, reported no clip failures on the renal artery and concluded that prior failures were likely related to poor application.[66] This is especially relevant for donor nephrectomy, as the transplant surgeon is attempting to preserve as much length on the renal artery as possible. Techniques to improve safety when using locking clips include applying multiple clips, leaving a 1- to 2-mm vascular cuff, keeping tissue in the center of the clip while avoiding tissue in the locking mechanism, visualization of the locking mechanism around the completely dissected vessel before closure, and use of appropriately sized clips.[67] If used correctly, self-locking clips are felt to be a safe mechanism for securing the renal hilum.

The endoscopic gastrointestinal anastomosis (Endo GIA) stapler is ideal for controlled ligation and division of large vessels such as the renal artery and vein and is widely, safely, and effectively used for this purpose.[67] However, failures do occur, with retrospective reviews reporting the incidence of stapler malfunction at 0.2–1.7%.[68] Most malfunctions are not due to device failure, but rather inappropriate use such as attempting to staple through a titanium clip, locking clip, or over another staple line. These failures may be avoided by adequate dissection and use of a harmonic scalpel or advanced bipolar device in regions where staple use is anticipated (e.g., during hilar dissection). Another cause of failure is adjacent tissue entrapment in the sliding mechanism on the lateral aspect of the stapler. If staple failure does occur the surgeon has to make the decision whether to open or proceed laparoscopically.[69] If a malfunction occurs during firing, the stapler should be left in place and a second stapler or locking clip should be used to obtain proximal control. Having multiple 10/12-mm ports is recommended to allow for more flexibility when using the stapler.

Visceral Injuries

Visceral injuries are rare events during laparoscopy, but can carry a high rate of morbidity and mortality. Of the abdominal viscera the bowel is most commonly injured, with a recent meta-analysis of the gynecologic literature reporting the incidence of bowel injury during abdominal laparoscopy at 0.13%. The small bowel is more likely to be injured followed by the colon. In the same series, bowel injury occurred most commonly during initial laparoscopic access (55%) and during electrosurgical dissection (29%). Less commonly, injury occurred during lysis of adhesions or with bowel graspers.[70] These trends are mirrored in the urologic literature.[71]

The incidence of rectal injuries in laparoscopic robotic surgery is about 0.2%. Historically these were treated with proximal diversion, but primary repair without a diverting colostomy is advocated in most cases. It has been reported that the overall percentage of colostomy applied in cases with rectal injury was only 32%.[72] A recent review noted that while mechanical bowel preparation may reduce the technical difficulty of the operation, it did not have a beneficial impact on the likelihood of injury or need for a diverting colostomy associated with rectal injury during radical prostatectomy.[72]

If recognized intraoperatively bowel injuries can be managed laparoscopically, but the surgeon should always consider conversion to laparotomy if this will enable superior repair.[70] Minor bowel injuries may be repaired primarily, but bowel resection and enteric diversion may be necessary for extensive injuries. When assessing a potential injury the anterior and posterior wall of the bowel should always be inspected to evaluate for through-and-through injury. If there is any question of bowel injury, an intraoperative general surgery consultation is recommended. It is also important to realize that assessing the true degree of electrosurgical injury is challenging in the acute setting as the extent of thermal injury is oftennot immediately apparent. It is possible that the coagulation effects of electrosurgery may temporarily seal off a perforation, making intraoperative recognition more challenging.

Up to 75% of bowel injures during laparoscopy are unrecognized intraoperatively and are diagnosed 4–10 days after surgery.[60] Clinical signs of bowel injury include severe abdominal pain localized to a single trocar site, abdominal distention, diarrhea, and leukopenia followed by acute cardiopulmonary collapse secondary to sepsis. It is notable that these signs, particularly localized abdominal pain and leukopenia, differ from the classic description of perforated viscus and may cause diagnostic confusion and delay.[73] If there is clinical concern for bowel injury, axial imaging with oral contrast should be immediately obtained. Note that free air is not a reliable sign, as it is typical for recent abdominal surgery. With any major abdominal organ injury, it may be advisable to consult a general surgeon to ensure appropriate evaluation and management.

Solid organ visceral injuries, including those to the liver, spleen, or pancreas, may occur during laparoscopic surgery. Injuries to the liver are usually due to retraction during right-sided renal or adrenal procedures. Careful lysis of hepatic adhesions should be performed prior to placing liver retraction.[74] Injuries to the liver and spleen can typically be managed conservatively with application of direct pressure, use of coagulation current, and/or application of hemostatic agents. While data regarding iatrogenic splenic injury during laparoscopy are limited, blunt splenic injury is well studied and many of the principles of management extrapolated. Splenectomy is rarely necessary, and delayed postoperative splenic bleeding can be managed with splenic artery embolization. If splenectomy is necessary it can be achieved laparoscopically if the surgeon is comfortable with the approach.[75] Pancreatic injury may also occur, most commonly following left-sided laparoscopic renal and adrenal surgery. The overall incidence of pancreatic injury in laparoscopic surgery is around 0.2%, but is estimated at 2–8% during left-sided renal and adrenal surgery, particularly in the setting of large renal and adrenal masses that may distort pancreatic and retroperitoneal anatomy and increase the likelihood of injury.[76] If injured, the tail of the pancreas can be safely ligated and transected with the Endo GIA stapler. In this setting, a drain should be left and amylase and lipase levels in the drainage fluid can be followed postoperatively. Unrecognized pancreatic injury can lead to severe morbidity, and a high index of suspicion is necessary in patients with prolonged ileus and abdominal pain. These patients should be evaluated with serum amylase levels as well as axial imaging if clinical concern warrants.

Bladder injuries can likewise occur with dissection or access, and their management is similar to that of traumatic injury. Bladder injury should be considered when gross hematuria suddenly develops or when the Foley drainage bag inflates with gas. Veress needle injuries can be managed conservatively with or without Foley catheter drainage. By definition, if direct injury occurs during transperitoneal laparoscopy the injury is intraperitoneal and primary repair and Foley drainage should be undertaken. If cystorrhaphy is required, it should be performed with an absorbable suture and a drain should be left. If bladder injury is uncertain, methylene blue dyed saline can be injected retrograde through a Foley catheter to identify a bladder perforation. Potential for ureteral injury may be evaluated by monitoring for efflux of dyed urine following intravenous administration of either indigo carmine, methylene blue, or floroscein; or by retrograde pyelography.

Pleural/Diaphragmatic Injury

Pleural and diaphragmatic injury can occur during laparoscopic dissection of the adrenal gland or the upper pole of the kidney with an estimated incidence of 0.6%.[77] Unlike in open surgery, the use of pneumoperitoneum during laparoscopy can increase the likelihood of pneumothorax, even with a small pleural injury. Even if the pleural injury is not directly visualized, the surgeon may detect an injury by noting loss of the normal concavity of the diaphragm as it billows downward.[78] The patient may also develop elevated airway pressures, higher end-tidal carbon dioxide, and decreased oxygen saturation. These injuries may be managed laparoscopically by oversewing the pleurotomy and evacuating the insufflate from the thoracic cavity. This is accomplished by the anesthesiologist expanding the patient's lungs to vital capacity (breath hold at end inspiration) as the sutures are tied down. If the patient becomes unstable intraoperatively, pneumoperitoneum must be immediately vented and needle or tube thoracostomy may also be necessary. Interventional radiology–placed tube thoracostomy is a treatment option for persistent symptomatic pneumothorax postoperatively.[74]

Conclusions

As the role of laparoscopy in urology continues to expand it is essential that the urologist understand the complications unique to these operations and be expert in their management. In this chapter we discussed the importance of appropriate selection of patients for laparoscopic surgery, unique anesthetic risks, and techniques to avoid positioning-related nerve injuries during surgery. Techniques of laparoscopic access were reviewed with emphasis on the truth that no access method is entirely without risk of vascular or visceral injury and the laparoscopic surgeon must be facile with multiple methods in order to perform safe and effective surgery. Key principles of fundamental technologies such as electrosurgery were explained and their applications to novel devices were presented. As technology continues to evolve it is essential urologists remain at the forefront of innovation by safely incorporating these techniques into their practice.

Chapter 30 Questions

1. During a laparoscopic left nephrectomy, which of the following should NOT be used on the hilum?
   a. Hem-o-loc clip
   b. Titanium nonlocking clip
   c. Endo GIA stapler
   d. Suture ligation after conversion to open surgical approach
   e. None of these are safe

2. Three hours into a robotic assisted laparoscopic prostatectomy, the anesthesia assistant informs you the patient's ventilation has become more difficult and that high positive pressure ventilation is required. The patient is currently stable. Airway sounds, end-tidal CO_2, and oxygen saturation levels are normal. What is the most appropriate first step to reduce the elevated ventilation pressures?
   a. Decrease the pneumoperitoneum to 15 mm HG
   b. Place a chest tube
   c. Abort the procedure
   d. Convert to open prostatectomy
   e. Using the robot, incise the diaphragm to release pressure

3. During a left laparoscopic nephrectomy, the diaphragm can be seen billowing and a pleurotomy is seen. What is the next best step in management?
   a. Consult surgery to place a chest tube
   b. Convert to open procedure as pneumoperitoneum will cause a pneumothorax
   c. Nothing; pleurotomies are common and require no intervention or assessment
   d. Close the pleurotomy with an absorbable suture with the breath held at end inspiration
   e. Close the pleurotomy with an absorbable suture with the breath held at end expiration

4. A patient has an implanted pacemaker and is scheduled for a laparoscopic nephrectomy. All of the following are recommended EXCEPT:
   a. Place the grounding pad directly over the pacemaker to decrease current density
   b. Use bipolar or ultrasonic energy if possible
   c. The monopolar instrument's wire should be directed off the field toward the feet
   d. Evaluate the pacemaker before and after surgery
   e. Use as low a wattage of monopolar current as the case allows

5. A 72-year-old obese patient with poorly controlled type 2 diabetes undergoes a 12-hour, robotic-assisted laparoscopic cystoprostatectomy with ileal conduit diversion. On postoperative day 2, the patient becomes oliguric with tea-colored urine without clots. Labs demonstrate creatinine of 3.4 and CK of 96,000 IU/L. What is the next step in evaluation and/or management of this situation?
   a. Consult nephrology
   b. CT abdomen and pelvis without contrast
   c. Order dose of furosemide
   d. Obtain urine electrolytes and calculate fractional excretion of urea
   e. Perform a thorough upper and lower extremity exam

6. According to a recent Cochrane Collaboration review, which of the following methods of primary laparoscopic entry is least likely to result in vascular injury?
   a. Veress
   b. Hassan
   c. Direct trocar entry
   d. Direct entry with visual obturator
   e. Placement of hand assist gel port

7. What is the most commonly injured vascular structure during laparoscopy?
   a. Inferior vena cava
   b. Superior mesenteric artery
   c. Left iliac artery
   d. Right iliac artery
   e. Distal aorta

8. Which methods can be used to obtain hemostasis following inferior vascular artery laceration?
   a. Incision extension and direct suture ligation
   b. Direct pressure applied by using adjacent trocar
   c. Tamponade applied via transabdominally placed Foley catheter
   d. Transabdominal suture ligation using Carter-Thommason device or Keith needle
   e. All of the above

9. Which of the following is NOT a clinical sign of postoperative bowel injury?
   a. Severe abdominal pain localized to a single trocar site
   b. Abdominal distention
   c. Fever
   d. Leukocytosis
   e. Diarrhea

10. Injuries to the peroneal nerve are most likely to result from:
    a. Excessive external rotation of the hip
    b. Prolonged lithotomy position
    c. Excessive knee extension
    d. Inadequate padding of the lateral knee
    e. b and d

Answers

1. **b.** It is not recommended to use a nonlocking clip on the renal hilum. While there is a black box warning for locking clips, studies show that they are safe when used correctly.
2. **a.** The pneumoperitoneum is the likely factor creating high positive pressure ventilation. Reducing the pneumoperitoneum and returning the patient to a supine position will likely improve ventilation pressure. Aborting or converting to open surgery is not indicated at this point. A chest tube is not necessary because there

is no evidence of a pneumothorax. An intentional diaphragmatic injury is not indicated.

3. **d.** A pleurotomy should be addressed. The initial management is to repair the pleurotomy with an absorbable suture once the air is evacuated from the chest with a held deep inspiration. Converting to an open procedure or placement of a chest tube should not be done unless the patient becomes hemodynamically unstable.
4. **a.** Monopolar current is not contraindicated for patients with implanted electronic devices. It is recommended to place the return electrode far away from the device, to use nonmonopolar current if possible, and to use as low a wattage as the case allows. The wire from a monopolar instrument can cause interference and should be directed away from the implanted device. The device should also be evaluated before and after surgery.
5. **e.** This patient has developed rhabdomyolysis, and urgent intervention is required. The patient needs vigorous hydration and urinary alkalinization, but a thorough upper and lower extremity exam should be performed immediately. This patient is at risk of compartment syndrome. If his compartments are firm, compartment pressures should be obtained and orthopedic surgery should be consulted for a possible fasciotomy. A nephrology consult may be necessary but is not the first step. A CT scan is not needed to confirm the diagnosis. Furosemide is not indicated. Fractional excretion of urea will not help confirm the diagnosis of rhabdomyolysis and is inaccurate in patients with urostomy.
6. **c.** In a systematic review of five RCTs comparing direct trocar entry with Veress technique, the Cochrane Collaboration reported a lower incidence of vascular injury with the direct trocar access. There was no reported difference in the incidence of visceral injuries. It should be noted that the included studies were all of either "low" or "very low" quality.
7. **e.** According to a large review of vascular injury during gynecologic lapasroscopy, injury to the distal aorta was most common (25%), followed closely by the right common iliac artery (21%). It is important to remember that injury to any vascular structure is possible and injury is most common while obtaining initial laparoscopic access.
8. **e.** All of the listed techniques are valid means to obtain hemostasis following injury to the inferior epigastric artery. During management of such injuries, it is reasonable to attempt to tamponade initially; however, if bleeding is persistent, suture ligation will be definitive.
9. **d.** It is notable that the signs of bowel injury following laparoscopy differ compared to classically described signs of perforated viscus. These signs include those listed above as well as leukopenia. In situations where occult bowel injury is suspected, axial imaging with oral contrast should be obtained immediately.
10. **e.** The peroneal (fibular) nerve courses laterally to the head of the fibula where it is vulnerable to compression injury in lithotomy position when the lateral aspect of the knee is inadequately padded. These injuries present with parasthesia over the lateral foot and inability to dorsiflex the foot. In order to minimize the risk of such injuries it is imperative to ensure the weight of the leg is concentrated in the heel, external rotation of the hip is minimized, and the region of the peroneal nerve is well padded.

31 Special Considerations in Robot-Assisted Surgery

STEVEN V. KHEYFETS and CHANDRU P. SUNDARAM

CHAPTER OUTLINE

Introduction
Patient Selection and Preparation
Robotic-team Approach
Patient Positioning
Effects of Pneumoperitoneum
Team Communication
Robotic System Failure
Conclusions
Chapter 31 Questions and Answers

KEY POINTS

1. The surgeon should convey all possible risks and benefits associated with a specific robotic procedure during informed consent, as well as clearly conveying the possibility that the operation may involve conversion to the traditional laparoscopic or an open approach.
2. The basic aim of patient positioning is to allow for maximal access to the surgical target organ without compromising patient safety. Compression-associated peripheral neuropathies are associated with compression of pressure joints, use of shoulder braces, longer operative times, and prolonged Trendelenburg positioning.
3. With pneumoperitoneum, intraabdominal pressure rises and, as a result, can have various end-organ implications, including an increase in both the heart rate and systemic vascular resistance secondary to compression of the intraabdominal aorta and carbon dioxide-mediated sympathetic stimulation.
4. The use of intermittent pneumatic compression (IPC) in Robotic and minimally invasive surgery is recommended by the American Urologic Association to assist with VTE prophylaxis.
5. Passage of laparoscopic instruments outside the console surgeon's field of view can potentially result in damage to visceral organs and blood vessels; thus, laparoscopic instruments should be localized in the body under direct vision, and the bedside surgeon should recognize and memorize the spatial path of the instrument to the target surgical area for subsequent insertion.

Introduction

Robot-assisted laparoscopic surgery has radically changed the landscape of minimally invasive surgery during the past 15 years. Its advantages over traditional laparoscopy include a superior magnified, stereoscopic three-dimensional view, 7 degrees of freedom, no fulcrum effect, and improved surgeon ergonomics. This chapter explores the special considerations surgeons must bear in mind while performing robotic surgery.

Patient Selection and Preparation

The preoperative assessment prior to any robotic surgical procedure begins with a thorough patient history and physical examination. All pertinent laboratory workup and radiologic imaging should be thoroughly reviewed with the patient. Medically complex patients with significant cardiac or pulmonary comorbidities should be referred to medical specialists for operative risk stratification and optimization. A satisfactory informed consent should be obtained, informing the patient of the possible risks and benefits associated with the procedure, as well as clearly conveying the possibility that the operation may involve conversion to the traditional laparoscopic or an open approach. A variety of upper and lower urinary tract procedures can be approached robotically, depending on the surgeon's experience. Specific contraindications to general transabdominal urologic robotic surgery are similar to laparoscopic surgery and include extensive previous abdominal/pelvic surgery or radiation, as well as severe medical comorbidities precluding an operation, such as uncorrectable coagulopathy, severe cardiopulmonary disease, or multiorgan failure. Anatomic anomalies, body habitus, and the specific surgical procedure must be considered when selecting the appropriate robotic surgical system. The da Vinci Xi system (Intuitive Surgical Inc., Sunnyvale, CA) is preferable for multi-quadrant procedures.

Robotic-team Approach

An experienced robotic team is critical to the success of an operation. The sophisticated robotic technology requires a coordinated approach for proper setup of the operating room. A surgical checklist should be conducted to ensure that all pertinent equipment is available and functioning before the start of a case. Prior to the patient's entrance into the operating room, all critical parts of the da Vinci surgical system, including the surgeon console, patient-side cart, and instrumentation (its associated remaining uses and proper insulation properties), as well as the audio-visual connections, should be deemed functional. Furthermore, particular procedures demand specific positioning of the robotic patient-side cart, anesthesia equipment, and instrument table in relation to the operating table. In addition, some procedures require specific intraoperative equipment; for example, if a procedure is expected to necessitate intraoperative real-time ultrasound, then the surgical team must ensure proper function of the TilePro (Intuitive Surgical Inc., Sunnyvale, CA); this involves the digital output cable from the ultrasound machine being connected to the digital video interface (DVI) or S-video input of the robotic da Vinci console.[1]

Patient Positioning

The basic aim of patient positioning is to allow for maximal access to the surgical target organ without compromising patient safety. For lower urologic tract surgery, such as robotic-assisted laparoscopic radical prostatectomy (RARP) or robotic-assisted laparoscopic cystectomy (RARC), the patient's arms are secured at the sides and lower extremities are placed in low lithotomy position using Yellofins elite stirrups with Lift-Assist (Allen Medical, Acton, MA) with careful attention paid to avoiding undue hip abduction, flexion, and extension (Fig. 31.1). All pressure points should be carefully padded with care. The patient should then temporarily be placed into a steep Trendelenburg position between 25 and 45 degrees in order to test whether respiratory compliance and effort is tolerated in this position. For robotic transperitoneal renal surgery, our preference is to place the patient in a modified lateral decubitus position (i.e., 45-degree partial flank position) (Figs. 31.2–31.4) and to rotate the table laterally to achieve roughly a 90 degree angle in relation to the floor. In this position, gravity assists with medial mobilization of the large and small bowel. At the beginning of the surgery, in most patients, we rotate the patient to a supine position to establish pneumoperitoneum in the umbilicus. After insertion of the midline trocars, the patient is rotated to a 90-degree lateral position for the rest of the operation. In morbidly obese patients, umbilical and midline trocars are avoided and pneumoperitoneum is obtained laterally. The patient's ipsilateral arm is padded and taped alongside the chest and abdomen so that it does not interfere with the robotic cephalad arm. The patient's

Figure 31.1 Appropriate positioning for robotic prostatectomy.

Figure 31.2 Appropriate positioning for robotic renal surgery in partial flank position.

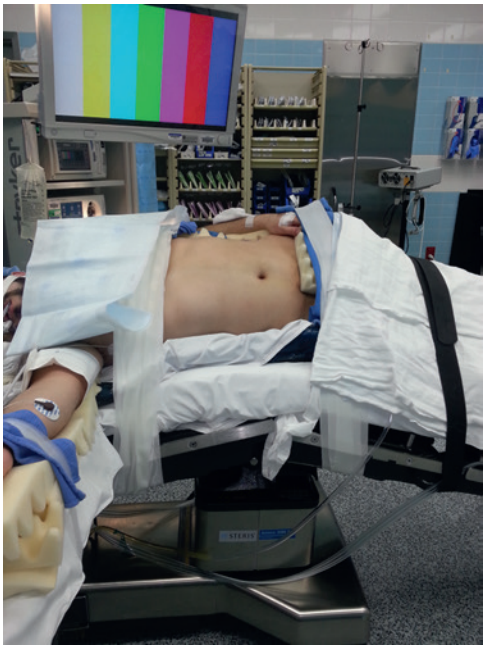

Figure 31.3 Appropriate positioning for robotic renal surgery in partial flank position with ipsilateral arm secured in an adducted position at the hip.

Figure 31.4 Appropriate positioning for robotic renal surgery in full flank position with ipsilateral arm secured in a cephalad position.

bottom leg is flexed while the top leg is extended. Adequate padding is essential and placed at all pressure points. The table is mildly flexed to increase the angle between the costal margin and iliac crest, thereby increasing lower abdominal space to utilize a 4-arm robotic approach. For the robotic retroperitoneal renal approach, similar to traditional open renal surgery, the patient is placed in a full lateral decubitus position, and a sub-axillary roll is used to help prevent brachial plexus injuries. Furthermore, the table is flexed fully to allow for maximum retroperitoneal working space.

Long operative periods in these exaggerated positions predispose the patient to various position-related complications, including ocular manifestations, facial and laryngeal edema, various neuropathies, compartment syndromes, rhabdomyolysis (RM), deep venous thrombosis, and deficiencies in skin integrity.[2]

A recent large, national population-based sample of patients undergoing open and robotic procedures reviewed the rates of eye-related complications. The data revealed that robotic hysterectomy carried a 6.5 times greater risk of experiencing a corneal abrasion than with the open approach; however, there was no statistical difference in corneal abrasion when open prostatectomy patients were compared to robotic prostatectomy patients.[3] Several purported risk factors for corneal abrasions include raised intraocular pressure secondary to prolonged, steep head-down position, corneal exposure and dryness, and mechanical trauma; in this study, African American race served to be a protective factor. Wen et al.[4] conducted an analysis of another large, national inpatient sample of patients who underwent open, laparoscopic, and robotic-assisted prostatectomies and compared the position-related complication rates between them. This study of 175,699 men revealed an overall complication rate of 0.79%, with ocular-related complications (visual disturbances, unilateral eye blindness, and corneal-foreign bodies) being the most common (51% of total complications). The remainder of injuries (49%) were related to nerve lesions, RM, and compartment syndrome. Undergoing a laparoscopic prostatectomy (OR = 2.88) and having multiple comorbidities (OR = 2.34) conferred the greatest statistically significant risks of experiencing a positional injury. In contrast, the robotic approach was not associated with developing a higher rate of position-related complications when compared to the open procedure. Overall ocular complications as well as visually threatening eye complications (i.e., visual loss) proved to be more common in the open group versus the robotic cohort. Development of a positioning complication was found to have a resultant threefold increase in length of stay and fourfold increase in inpatient costs when compared to not incurring a position-related event. The authors conveyed surprise in their analysis of these data, as they initially hypothesized that robotic prostatectomy would carry an increased risk of positioning complications compared to the open approach, resulting from a greater operative length, an association revealed in previous studies.[5–7] Although this study was not able to account for operative times, its large national sample size suggests generalizable results.[4]

Positioning injuries involving the extremities include brachial plexus injuries as well as peripheral neuropathies. In the Trendelenburg position, inadvertent movement of the patient via gravity is possible; this is especially prone to occur in the obese patient population and can result in neuropathies and potential robotic port site abdominal injuries, incisional widening, and increased postoperative port site pain, as the patient shifts downward on the operating table while the robotic trocars remain in a stationary position.[2,8] Thus, various surgical immobilization mechanisms have been used to help prevent the patient from sliding downward. Shoulder braces have been identified in several retrospective reviews as a risk factor for brachial plexus injury via compression or stretch,[4,5,9–11] especially with concomitant abduction of the upper extremities to 90 degrees or greater.[10,11] However, Gainsburg et al. reported no evidence of brachial plexus injury on 575 consecutive RARP patients with the careful application of a horseshoe-shaped shoulder immobilization restraint around the acromio-clavicular joints in patients with a weight greater than 75 kg. Chest straps have also been used to prevent downward shifting of the patient while in steep head-down position; however, this has been shown to further decrease lung compliance and ease of ventilation.[12] Anti-skid foam pads secured to the surgical bed or bean bags are also utilized in some centers with success.[5,13]

Lower extremity peripheral neuropathies can manifest with postoperative pain, weakness, and sensation deficits/alterations and are thought to be caused by protracted flexion, abduction, and external rotation of the hip joints, or by compression of pressure points.[14] Operative lengths greater than 2–4 hours in the lithotomy position have proved to be a risk factor for the development of lower extremity neuropathies.[14–16] Interestingly, a higher BMI is proposed to be a protective factor against compression-related neuropathies.[14,15] The incidence of lower extremity neuropathies appears to be less than 2% in urologic robotic-assisted pelvic surgery; Manny et al.[17] report an incidence of lower extremity neuropathy of 1.7% in patients undergoing RARP or RARC while Koc et al.[14] report an incidence of 1.3% in their series of RARP patients. Furthermore, Warner et al.[15] performed an analysis on a series of 198,461 patients who underwent various surgical procedures in the lithotomy position and reported a 0.028% rate of lower extremity peripheral neuropathy (1 per 3608 patients) most commonly involving a motor neuropathy of the common peroneal nerve (78%). In contrast to the

lithotomy position, a split-leg position appears to pose a higher risk for femoral nerve palsy in performing RARP secondary to hyperextension of the hip joint to assist with docking of the patient-side cart.[14] Although a majority of peripheral neuropathies transiently improve several weeks to months postoperatively, some may persist longer and become permanent.[14–17]

Facial and laryngeal edema are other manifestations of a steep head-down tilt in lower urinary tract robotic surgery.[9] Facial congestion results from a protracted state of steep Trendelenburg position and can be minimized via limiting intravenous fluids during this portion of the procedure; it is important to replete the patient's intravascular volume prior to conclusion of the surgery. Laryngeal and pharyngeal edema is also implicated with lengthy Trendelenburg positioning, and extreme cases of this can result in respiratory distress occurring after a patient is extubated, necessitating reintubation.[8,18] Again, somewhat restrictive fluid management (less than 2000 mL) in the lithotomy position is thought to alleviate laryngeal edema.[9]

Postoperative RM and compartment syndromes of the gluteal muscles and lower extremities (well limb compartment syndrome, WLCS) resulting from robotic surgery are exceedingly rare complications and are associated with prolonged exaggerated flank or lithotomy positions.[19–23] Surgically induced RM is thought to result from prolonged compression of skeletal muscle associated with decreased blood flow, necrosis, possible compartment syndrome, and, ultimately, skeletal muscle breakdown, with subsequent release of myoglobin and creatine phosphokinase (CPK). CPK levels two to three times greater than normal in the proper clinical setting should alert the physician to a possible diagnosis of RM. Patients may experience tenderness at the site of injury, edema, muscle pain, and dark-colored urine, or may alternatively lack symptoms. Acute renal failure may result in 30–40% of patients and is thought to be mediated by reduced glomerular filtration, intratubular heme cast formation with subsequent obstruction, tubular obstruction by precipitated myoglobin, and a direct nephrotoxic effect via ferrihemate. Aggressive fluid hydration is recommended to produce a urine output of 200–300 mL/hour, and alkalanization of urine is recommended to prevent acute renal failure. Compartment syndromes warrant emergent consultation of orthopedic colleagues to perform fasciotomies.[22,24]

Pariser et al.[22] recently reported on a broad population-based sample of 1,016,074 patients undergoing major urological surgeries (prostatectomy, radical nephrectomy, partial nephrectomy, and radical cystectomy) in the largest study to date investigating risk factors for development of RM. This study revealed a 0.1% (870 patients) overall incidence of RM. Patients who underwent radical prostatectomy were least likely to experience postoperative RM; patients who underwent radical/partial nephrectomy and radical cystectomy had odds ratios of 2.66 and 3.69 (p values < 0.001), respectively, of developing RM when compared to radical prostatectomy patients. Independent risk factors for RM included males, younger patients, diabetes mellitus, obesity, preexisting chronic kidney disease, and perioperative bleeding. Minimally invasive surgery was not associated with RM. Operative times were not available for analysis in this national patient sample. Length of stay and total charges were significantly greater for the RM cohort. Furthermore, 66.3% of patients with RM developed acute kidney injury and experienced a 6.4% inpatient mortality rate. In another large, population-based study, Gelpi-Hammerschmidt et al.[25] analyzed the rates of RM following open, laparoscopic, and robotic extirpative renal surgery. The overall incidence rate of RM was exceedingly low at 0.001%; the robotic approach was associated with a greater than twofold higher risk of developing RM compared to laparoscopic surgery. Additional significant risk factors for RM included obesity, male gender, significant medical comorbidities, and operative time greater than 5 hours. Patients who experienced postoperative RM were more likely to suffer from other nonfatal complications as well as endure twice lengthier hospital stays. Deane et al.[26] measured mean pressures exerted on patients' skin during lateral decubitus positioning with different degrees of table flexion, kidney rest position, and operating table surfaces. Male gender (irrespective of BMI), BMI >25, table flexion (half flexion and full flexion compared to flat position), and kidney rest elevation (compared to nonelevation) were associated with higher interface pressures. Supplementary padding of the operating table with egg crate pad did not prove to significantly decrease interface pressures, while the addition of gel padding significantly increased the mean skin interface pressures by 1.61 mm Hg; thus, the authors concluded it is unnecessary to place extra protective material over the normal operating table mattress during renal surgery.

The prevalence of venous thromboembolism (VTE) events following robotic pelvic surgery has been described in the literature. In a recent multicenter analysis of a prospectively maintained LAPPRO (Laparoscopic Prostatectomy Robot Open) database, Tyritzis et al.[27] reported on the occurrence of VTE (i.e., deep venous thrombosis and/or pulmonary embolism) in their cohort of 3544 patients undergoing open radical prostatectomy (ORP) and RARP. Their results reveal an overall incidence of VTE in 18 cases (2.2%) in the ORP cohort and in 16 cases (0.6%) in the RARP group. Importantly, a significant eightfold increased risk of development of VTE was reported when lymph node dissection (LND) was performed. Overall, ORP was associated with a significantly higher (more than threefold) risk of experiencing a VTE when compared to RARP; however, there was no significant difference in VTE events when comparing ORP and RARP with concomitant LND. When LND was taken into account, ORP resulted in a significant more than threefold incidence of postoperative VTE compared to RARP. Independent risk factors for development of VTE included a history of thrombotic incidents, advanced stage disease (pT4), and a Gleason score of at least eight or higher. Liu et al.[28] reported similar overall rates of VTE following ORP (1.79%) and minimally invasive radical prostatectomy (0.82%) in their series of 5319 cases. Abel et al.[29] performed a retrospective single institution review of 549 consecutive patients undergoing RARP and reported an overall postoperative VTE incidence of 1.8%; significant predictors for VTE development included increased operative time, higher BMI, and blood transfusion. Prophylaxis with unfractionated heparin prior to incision was not associated with significantly lower VTE rates or significantly higher bleeding episodes. Secin et al.[30] reported an overall incidence of 0.5% (31 events) of VTE in a multi-institutional study that included 5951 patients undergoing minimally invasive radical prostatectomy (i.e., laparoscopic and RARP). Risk factors for VTE included history of thrombosis, smoking, increased operative time,

reoperation, length of hospitalization, and increased prostatic volume. Prophylactic use of heparin either prior to surgery or postoperatively was not significantly associated with VTE ($p = 0.7$); in fact, centers utilizing heparin prophylaxis had similar rates of VTE when compared to centers not incorporating heparin prophylaxis. Preoperative prophylactic use of heparin was associated with significantly higher intraoperative estimated blood loss ($p < 0.0005$) as well as longer hospitalization ($p < 0.0005$). LND did not represent a significant risk factor for VTE in this series. Other RARP series have reported similarly low (less than 2%) incidence rates of postoperative VTE.[31,32] Saily et al.[33] reported on bleeding and VTE rates with preoperative and inpatient postoperative heparin administration, as well as a 15-day postoperative outpatient course of an oral anticoagulant (dabigatran) in 400 consecutive RARP patients; overall, one patient (0.25%) developed VTE, and nine patients (2.3%) developed significant postoperative bleeding, with eight patients requiring transfusion.

The safety and use of pharmacologic prophylaxis (PP) for prevention of VTE in robotic renal surgery are sparse in the literature. A current National Surgical Quality Improvement Program (NSQIP) database revealed an overall low incidence rate of patients developing VTE after minimally invasive partial nephrectomy (0.23%) and radical nephrectomy (0.42%); in this study, the occurrence of VTE was associated with more than a 12-fold increase in readmission rates ($p = 0.001$).[34] Information regarding VTE prophylaxis was not provided in this national registry review. Recently, a large single institution retrospective review by Kara et al.[35] compared perioperative outcomes of a robotic partial nephrectomy (RPN) cohort of 984 patients, of which 222 patients received PP (subcutaneous heparin or enoxaparin) at any time (preoperatively or postoperatively) and 762 patients who did not receive PP. The incidence rates of postoperative VTE were not significantly different, with 1.8% in the PP group compared to 2.1% in the non-PP group ($p = 0.75$); likewise, the rates of adverse hemorrhagic events were also comparable, occurring with a frequency of 3.1% and 5.6% in the PP and non-PP groups, respectively ($p = 0.13$). A majority (93.3%) of VTE episodes occurred within 1 month and after hospital discharge; thus, the authors concluded that inpatient-only VTE prophylaxis did not help to prevent VTE, and that a lengthier regimen (30 days postsurgery) of outpatient PP should be considered in patients undergoing RPN, as based on prior randomized control trials that evaluated prolonged PP for VTE events in open surgeries.[36,37] At this time, the American Urologic Association recommends the use of intermittent pneumatic compression (IPC) in laparoscopic and robotic surgery as well as identification of high-risk patients who may benefit from VTE prophylaxis.[38]

Effects of Pneumoperitoneum

The various techniques in the establishment of pneumoperitoneum (i.e., Veress needle vs Hasson technique or other modified hybrid methods) and trocar placement and their potential complications (e.g., vascular injury/organ injury), as well as troubleshooting, are discussed extensively elsewhere in this text. Once establishment of peritoneal gas insufflation is successfully obtained, communication with the anesthesiology team becomes crucial when performing robotic surgery, as physiologic alterations are common. With pneumoperitoneum, intraabdominal pressure rises and, as a result, can have various end-organ implications. From a cardiovascular standpoint, both the heart rate and systemic vascular resistance increase secondary to compression of the intraabdominal aorta and carbon dioxide–mediated sympathetic stimulation.[39] Increased intraabdominal pressure places mechanical compression upon the inferior vena cava, causing decreased perfusion to the heart, ultimately resulting in reduction of cardiac output, especially in a hypovolemic hydration state. Of note, the reverse Trendelenburg position causes venous pooling of blood in the lower extremities, further reducing cardiac preload, while the Trendelenburg position serves to increase cardiac preload.[39–41] Pneumoperitoneum causes respiratory changes, including a reduction in functional reserve capacity (FRC), restricted diaphragmatic excursion, and predisposition to atelectasis. Placing the patient in a concomitant Trendelenburg position pushes the diaphragm cephalad, further reduces lung compliance, worsens ventilation–perfusion mismatch, and requires higher airway pressures to maintain a steady tidal volume.[42] An increase in intraabdominal pressure also has downstream consequences on renal perfusion and function. A decrease in renal blood flow as well as in renal function (as measured by urine output, GFR, and effective renal plasma flow) is a transient change expected during induction and duration of pneumoperitoneum.[43] In order to limit adverse hemodynamic and physiologic changes secondary to pneumoperitoneum, our preference is to maintain an insufflation pressure of 12–15 mm Hg or lower during our robotic procedures. In cases of venous bleeding or poor surgical exposure, the insufflation pressure can be transiently increased to 20 mm Hg.

Team Communication

Once pneumoperitoneum, strategic port placement, and patient-side cart docking is achieved, effective team communication between all members of the operating room continues to be critical as the primary surgeon transitions away from the operating table to the console to begin the robotic part of the procedure. The bedside surgeon becomes responsible for assisting the console surgeon with numerous tasks, including laparoscopic instrument passage, laparoscopic tissue retraction and manipulation, suction as well as irrigation of the surgical field, robotic instrument exchange, oversight of potential internal versus external robotic arm clashing, and maintenance of pneumoperitoneum. Passage of laparoscopic instruments outside the console surgeon's field of view can potentially result in damage to visceral organs and blood vessels; thus, laparoscopic instruments should be localized in the body under direct vision, and the bedside assistant should recognize and memorize the spatial path of the instrument to the target surgical area for subsequent insertion. The bedside surgeon should vocalize when passage of a laparoscopic instrument is impeded and withdraw and redirect its course under direct vision to avoid injury to surrounding structures. Similarly, although the patient-side robotic arms are designed to retain positional memory of the instruments inside the body during exchanges, the bedside assistant

should always locate the instrument under direct vision during re-entry, as bowel or other structures can inadvertently shift position into the path of reinsertion. Again, robotic instruments should never be forced against resistance, as significant intracorporeal damage can result; instead, the problem (e.g., inadvertent robotic port withdrawal from the peritoneum) should be identified via communication between the bedside and console surgeon and remedied in a coordinated manner. In the event of an emergent conversion to an open procedure, clear communication should occur between the console surgeon and all the members of the operating team; the bedside surgeon should expeditiously and safely remove all instruments from the body and undock the patient-side cart. Open instrumentation should be available for immediate use, and a plan for open incision should already be prepared.[44,45]

Robotic System Failure

Robotic system failures have been described in the literature. While no standardized method to report system malfunction currently exists, the United States Food and Drug Administration's (FDA) Manufacturer and User Facility Device Experience (MAUDE) database provides a vehicle that allows health-care professionals to voluntarily and anonymously report adverse events related to device failures or malfunctions that impact patient safety.

Friedman and Lendvay[46] performed the most recent analysis of da Vinci robotic instrument malfunction between 2009 and 2010 using the MAUDE database and detected a total of 565 instrument failures. They divided these into five categories of failures in the order of most to least common: wrist/tool-tip, cautery, shaft, cable, and housing failures. Wrist or tool-tip failures were the most frequently reported type of instrument failure accounting for 285 malfunctions; of these, 150 involved a fractured or otherwise broken jaw or tool tip, affecting 108 monopolar curved scissors. In a majority of these events, a tool tip fractured into the patient and was subsequently safely removed. Cautery failure was reported to be the second most common malfunction with 184 incidents; 174 of these events involved electrical failure, a majority (90%) of which included observed arcing or heat-damaged tissue and most commonly (125/174 events) involved monopolar curved scissors. The third most frequent type of instrument failure involved shaft dysfunction (76 events), including protective material fracturing off the shaft or cracked shafts (36 failures), observation of significant scratch marks on the shaft, or inadvertent material removal off the shaft (19 failures), as well as outright circumferential shaft breaks (eight failures). Cable malfunction accounted for the fourth most common type of instrument failure with 29 events; 28 of these incidents involved a frayed or fractured cable at the distal tool-tip side of the instrument. Lastly, the least common type of instrument failure involved seven incidents of housing malfunction, including two events where the instrument was unable to be extracted from the robotic arm, one incident of a defective instrument not registering despite having sufficient lives, one event where the cleaning tube was thrust into the housing, and the last failure involved jaws that failed to open and shut.

Lucas et al.[47] performed an earlier review of the MAUDE database between 2003 and 2009 and found a total of 1869 reported adverse events involving 991 pertaining to the da Vinci S (dVS) and 878 associated with the earlier da Vinci (dV) platform. Similar to Friedman's series, Lucas et al. also identified instrument failure to be the most common type of robotic malfunction, with 995 (74.2%) events occurring between 2007 and 2009 and 379 (72.3%) reported incidents between 2003 and 2006. The older generation dV system was associated with significantly higher rates of instrument fragmentation into the patient (27.8% vs 7.5%) and arcing (32.9% vs 12.7%). Reported failures associated with the robotic console and patient-side cart decreased significantly after 2007. Between 2007 and 2009, 71 (5.3%) console failures were reported, while 49 (9.4%) were identified between 2003 and 2006; similarly, 91 (6.8%) patient-side cart failures were cited between 2007 and 2009, while 57 (10.9%) were reported between 2003 and 2006. Furthermore, the dV platform was associated with significantly higher console and patient-side cart failures compared to the newer dVS system. Reported incidents of camera failures were comparable between the two systems. The rates of conversion to open procedures proved to be significantly lower over time while rates of aborted procedures increased over time. The authors also analyzed the association between system malfunction and patient outcomes. Robotic platform failures leading to patient injury did not change significantly between 2003 and 2008. Although the patient injury rate (24.1%) of 33 injuries resulting from 137 robotic failures was significantly higher in 2009 compared to previous years, it was thought to be artificially inflated secondary to incomplete data collection that year. Patient deaths were significantly increased in the years between 2007 and 2009 (1/16,000) when compared to between 2003 and 2006 (1/70,000). Once again, incomplete data collection in 2009 may have caused a falsely elevated rate; however, the authors also note that a willingness to tackle procedures of higher complexity may have also led to this finding. Andonian et al.[48] reviewed the MAUDE database between 2000 and 2007 and reported 189 adverse events related to robotic malfunction; they estimated an overall device failure rate of 0.38%, provided that about 50,000 robotic procedures had been performed during that time period.

Although the MAUDE database provides an effective tool for reporting device-related adverse events, it also poses significant limitations, as reporting to the database is completely voluntary and thus prone to underreporting of adverse robotic system failures.[47]

Buchs et al.[49] performed a single institution retrospective review of a prospectively maintained database of 526 consecutively performed general surgery procedures. Overall, 18 cases (3.4%) of device failure were identified. Of these, nine cases (50%) were related to robotic instrument malfunction, four cases (22.2%) involved arm failure, three cases (16.7%) were associated with console failure, and two cases (11.1%) were attributed to optic system dysfunction. Two out of 18 cases (11.1%) were nonrecoverable faults, and one case (0.2%) required conversion to traditional laparoscopy. Chen et al.[50] reported a similar overall rate (3.5%) of robotic device failure in their review of 400 urologic cases at a single institution; their study cited robotic arm

failures to be the most frequent (78.6%) cause of device malfunction.

Kaushik et al.[51] conducted an international survey of 176 urologists performing RARP over a 5-year period; rates of robotic mechanical failures and subsequent management were explored. In total, 100 (56.8%) surgeons reported experiencing a nonrecoverable fault. These events were further stratified to time period they occurred during the procedure. Eighty mechanical failures were cited prior to the start of the procedure; as a result, 46 (57.5%) cases were resecheduled, while 15 (18.8%) and 12 (15%) cases were instead performed in open and laparoscopic fashion, respectively. Sixty-three cases of mechanical failure were reported prior to beginning the urethrovesical anastomosis, and a majority of these procedures (26 cases; 41.2%) were converted to open radical prostatectomy, while 20 (31.7%) cases were converted to conventional laparoscopic prostatectomy. Thirty-two mechanical failures were reported prior to completion of the urethrovesical anastomosis and were completed in conventional laparoscopic fashion in a majority of the cases (62.5%); completion of the urethrovesical anastomosis via laparoscopic means was significantly associated with possessing fellowship training. In general, robotic failure was significantly associated with higher volume surgeons, and the rates of system malfunction were not significantly different between fellowship-trained and nonfellowship-trained urologists. Robotic arm malfunction was reported to represent the most frequent (38%) type of robotic failure. Interestingly, only 68.8% of surveyed urologists reported discussing potential robotic system failures as part of their preoperative patient counseling. Limitations to this study involve its survey format and associated inherent recall bias. It represents a retrospective collection of malfunction events; however, it does not further elucidate the incidence of robotic malfunction, since an absolute number of total cases was not recorded.

Kim et al.[52] reported on a multi-departmental, single institution analysis involving 1797 robotic surgeries; the urology (779 cases; 43.4%) and general surgery (855; 47.6%) departments contributed to the majority of performed procedures. A total of 43 (2.4%) robotic failures were identified involving 24 cases (1.3%) related to mechanical or system error and 19 cases (1.1%) linked to instrument failure. Three cases (0.17%) required conversion to open or laparoscopic surgery.

Nayyar and Gupta[53] performed a retrospective single institution analysis of 340 consecutive robotic urologic surgeries and reported 37 (10.9%) robotic failures. A majority of failures were attributed to robotic instrument malfunction (23/37 failures). Overall, 28/37 (76%) incidents were able to be rectified intraoperatively, leading to successful completion of the robotic-assisted cases. Two cases (0.6%) required conversion. No patient injuries were reported as a result of robotic device failure.

Several studies have explored robotic system failure specifically in RARP. Lavery et al.[54] performed a multi-institutional survey of 11 high-volume centers assessing the frequency of critical (nonrecoverable) robotic malfunction during RARP. During the study time period, 8240 total cases were performed, and 34 (0.4%) nonrecoverable faults were reported. Of these 34 critical failures, 24 cases were aborted and rescheduled, eight were converted to the traditional open approach, and two were completed via laparoscopic technique. The optics (34%) and robotic arm (34%) components were the most frequent culprits involved in robotic system failure. Zorn et al.[55] reviewed a total of 725 RARPs performed at a single institution by two urologists. Four cases (0.5%) of robotic system failure were identified, and all incidents occurred prior to patients' arrival into the operating theater. Optical system malfunction (three cases) and power system failure (one case) were responsible for the dysfunction. All four cases were canceled and rescheduled. Borden et al.[56] (2007) found an overall robotic device failure rate of 2.6% (9/350 cases), with three of these cases requiring conversion to open/laparoscopic procedures.

Consequently, the incidence of robotic device failure is variable in the literature, ranging from as low as 0.4% to as high as 10.9%. The variability between studies may be secondary to different degrees of surgeon learning curves, single- versus multi-institution centers, and the specific generation of robotic model studied. The rates of direct patient harm resulting from robotic system failure remain low. As many of robotic system faults can be detected preoperatively, it is critically important to routinely conduct preoperative safety checks prior to the patient's arrival into the operating room to ensure that all robotic parts are fully functional. Intraoperative management of robotic system failure is performed by first identifying the culprit at fault (e.g., robotic instrument malfunction, robotic arm failure, console failure, optical system malfunction) and determining whether the fault is recoverable or nonrecoverable. Recoverable instrument malfunction may simply require replacement of the instrument to remedy the problem. Often robotic arm collisions or unexpected, quick arm movements may cause recoverable fault errors and can be rectified by clutching the robotic arms and resetting them into a more optimal position. Error codes should be noted in order to report to da Vinci technical support. In cases of nonrecoverable faults that do not resolve with a system restart, the da Vinci Surgical Technical Assistance Team can be contacted to attempt resolution. If unsuccessful, the robotic instruments should be withdrawn, and the robotic arms and patient-side cart should be undocked in preparation for laparoscopic or open surgery conversion. Thus, although the incidence of robotic platform malfunction is low, it is critically important to discuss this possibility with patients, as this has resulting consequences on their course of surgery.

Conclusions

With the undeniable technologic advancements in the minimally invasive field, it is critical for surgeons to keep pace with and advantageously incorporate them into their surgical tool boxes. The key to avoiding the complications associated with robotic surgery is to understand the technology and its pitfalls as well as to continue employing effective core surgical techniques and principles.

Chapter 31 Questions

1. Which one of the following factors precludes a patient from undergoing transperitoneal robotic surgery?
   a. Age
   b. BMI
   c. Previous retroperitoneal procedure
   d. Uncorrectable coagulopathy
   e. None of the above

2. The advantages of robotic surgery over laparoscopy does not include which one of the following?
   a. Magnified, stereoscopic three-dimensional view
   b. 7 degrees of instrument freedom
   c. Lack of fulcrum effect
   d. Decreased surgeon ergonomics
   e. Increased surgeon ergonomics

3. Which one of the following is not a potential physiologic effect of pneumoperitoneum?
   a. Tachycardia
   b. Increased functional reserve capacity
   c. Decreased urine output
   d. Decreased cardiac preload
   e. Increased systemic vascular resistance

4. Which of the following is a proposed protective factor against compression-related neuropathies during robotic surgery?
   a. Longer operative time
   b. Prolonged Trendelenburg position
   c. Higher BMI
   d. Compression of pressure points
   e. Use of shoulder braces

5. According to the Manufacturer and User Facility Device Experience (MAUDE) database, which of the following accounts for the most frequent robotic system failure?
   a. Console failure
   b. Nonrecoverable fault
   c. Recoverable fault
   d. Camera failure
   e. Instrument malfunction

6. What is the American Urologic Association's stance on venous thromboembolism (VTE) prophylaxis in minimally invasive surgery?
   a. Provide pharmacologic prophylaxis to each patient undergoing minimally invasive surgery
   b. Use intermittent pneumatic compression (IPC) in laparoscopic and robotic surgery as well as identify high-risk patients who may benefit from VTE prophylaxis
   c. Continue pharmacologic prophylaxis after discharge
   d. Discourage use of pharmacologic prophylaxis for patients undergoing robotic partial nephrectomy
   e. Provide pharmacologic prophylaxis only to patients undergoing robotic lower urinary tract surgery

7. Which of the following statements is appropriate in counseling a patient on robotic surgery?
   a. "Robotic surgery is much safer and more effective than open surgery"
   b. "There is no chance that your surgery will require a conversion to an open surgery"
   c. "The robotic platform never experiences a nonrecoverable system failure"
   d. "There is a small but not unrealistic chance that conversion to an open procedure may be required during the course of your procedure"
   e. All of the above

8. Which of the following is not a risk factor for corneal abrasion during robotic surgery?
   a. Increased intraocular pressure
   b. Mechanical trauma
   c. Prolonged Trendelenburg position
   d. Corneal dryness
   e. African American race

9. Which one of the following is false regarding postoperative rhabdomyolysis?
   a. This condition is managed by conservative fluid resuscitation
   b. Patients may experience localized pain or may alternatively lack symptoms
   c. Alkalanization of urine is recommended to prevent acute renal failure
   d. A high BMI is a proposed risk factor for development of this complication
   e. None of the above

10. When exchanging a robotic instrument, the bedside assistant feels resistance; what would be an appropriate next step?
    a. Continue to forcefully advance the instrument against resistance
    b. Gently advance the instrument against resistance
    c. Vocalize that there is an impedance to advancing the instrument, and localize the robotic port as well as instrument under direct vision intracorporeally
    d. Blame the nursing staff for handing over a faulty instrument
    e. All of the above

Answers

1. **d.** Specific contraindications to general trans-abdominal urologic robotic surgery are similar to laparoscopic surgery and include extensive previous abdominal/pelvic surgery or radiation, as well as severe medical comorbidities precluding an operation, such as uncorrectable coagulopathy, severe cardiopulmonary disease, or multiorgan failure.
2. **d.** The advantages of robotic surgery over traditional laparoscopy include a superior magnified, stereoscopic three-dimensional view, 7 degrees of freedom, no fulcrum effect, and improved surgeon ergonomics.
3. **b.** With pneumoperitoneum, intraabdominal pressure rises and, as a result, can have various end-organ implications, including an increase in both the heart rate and systemic vascular resistance secondary to

compression of the intraabdominal aorta and carbon dioxide–mediated sympathetic stimulation. Increased intraabdominal pressure places mechanical compression upon the inferior vena cava, causing decreased perfusion to the heart, ultimately resulting in reduction of cardiac output, especially in a hypovolemic hydration state. Pneumoperitoneum causes respiratory changes, including a reduction in functional reserve capacity (FRC), restricted diaphragmatic excursion, and predisposition to atelectasis. A decrease in renal blood flow as well as in renal function is a transient change expected during induction and duration of pneumoperitoneum.

4. **c.** Longer operative times, prolonged Trendelenburg positioning, compression of pressure joints, and use of shoulder braces are all risk factors for compression-associated peripheral neuropathies. Interestingly, a higher BMI is proposed to be a protective factor against compression-related neuropathies.
5. **e.** The MAUDE database provides a vehicle that allows health-care professionals to voluntarily and anonymously report adverse events related to device failures or malfunctions that impact patient safety. Instrument failure is reported to be the most common type of robotic malfunction.
6. **b.** At this time, the American Urologic Association recommends the use of IPC in laparoscopic and robotic surgery as well as identification of high-risk patients who may benefit from VTE prophylaxis.[38]
7. **d.** A thorough informed consent should be performed, informing the patient of possible risks and benefits associated with a specific robotic procedure, as well as clearly conveying the possibility that the operation may involve conversion to a traditional laparoscopic or an open approach.
8. **e.** Several purported risk factors for corneal abrasions include raised intraocular pressure secondary to prolonged, steep head-down position, corneal exposure and dryness, and mechanical trauma; in this study, African American race served to be a protective factor.
9. **a.** Surgically induced rhabdomyolysis is thought to result from prolonged compression of skeletal muscle associated with decreased blood flow, necrosis, possible compartment syndrome, and, ultimately, skeletal muscle breakdown, with subsequent release of myoglobin and creatine phosphokinase (CPK). Patients may experience tenderness at the site of injury, edema, muscle pain, and dark-colored urine, or may alternatively lack symptoms. Acute renal failure may result in 30–40% of patients and is thought to be mediated by reduced glomerular filtration, intratubular heme cast formation with subsequent obstruction, tubular obstruction by precipitated myoglobin, and a direct nephrotoxic effect via ferrihemate. Aggressive fluid hydration is recommended to produce a urine output of 200–300 mL/hour, and alkalanization of urine is recommended to prevent acute renal failure. Compartment syndromes warrant emergent consultation of orthopedic colleagues to perform fasciotomies.
10. **c.** Passage of laparoscopic instruments outside the console surgeon's field of view can potentially result in damage to visceral organs and blood vessels; thus, laparoscopic instruments should be localized in the body under direct vision, and the bedside assistant should recognize and memorize the spatial path of the instrument to the target surgical area for subsequent insertion. The bedside surgeon should vocalize when passage of a laparoscopic instrument is impeded and withdraw and redirect its course under direct vision to avoid injury to surrounding structures.

32 Complications of Robotic-Assisted Laparoscopic Radical Prostatectomy

ALON Y. MASS and SAMIR S. TANEJA

CHAPTER OUTLINE

Preoperative Considerations
Complications of Positioning
Complications of Access
- Port Insertion/Insufflation
- Bowel Injury
- Bladder Injury
- Retroperitoneal Vascular Injury
- Epigastric/Abdominal Wall Vascular Injury

Intraoperative Surgical Complications
Bleeding
Visceral Injury: Bladder, Bowel, and Rectum
Ureteral Injury
Nerve Injury

Early Postoperative Complications
Bleeding
Anastomotic Urine Leak
Lymphocele
Urinary Tract and Wound Infection
Thromboembolic Complications
Port Site Hernia

Late Postoperative Consequences
Incontinence
Impotence
Oncologic Outcomes

Chapter 32 Questions and Answers

KEY POINTS

1. Candidates for robotic-assisted laparoscopic radical prostatectomy (RALRP) must have adequate ventilatory reserve and appropriate body habitus to allow maximal Trendelenburg position during the procedure.
2. The risk of nerve and pressure injuries during RALRP can be reduced by avoidance of stirrups, adequate padding, and shoulder support.
3. Unrecognized bowel injury most commonly occurs due to movement of instruments outside the visual field of the camera.
4. Blind trocar insertion risks injury to the aorta, common iliac arteries, mesentery, bowel, and bladder.
5. Bleeding resulting from incision of the dorsal venous complex can generally be managed by completing the transection, slightly increasing insufflation, and directly suturing the stump.
6. Controlled urine leak from the vesicourethral anastomosis can generally be managed conservatively with catheter drainage, but persistent leak should draw concern for a ureteral injury.
7. Ureteral injury can occur during node dissection, adjacent to the seminal vesical pedicle, but generally occurs during bladder neck transection.
8. Rectal injury can be managed by robotic-assisted laparoscopic repair, except in cases of fecal soiling, large injuries, devitalized rectal wall, or previous radiation. In these cases, colostomy diversion should be considered.

The surgical management of prostate cancer has rapidly evolved over the past decade from a procedure most commonly performed open by a subset of urologists skilled in the approach, to a minimally invasive procedure more accessible to a wide range of well-trained urologists. The proportion of prostate cancer operations performed laparoscopically, with or without robotic-assistance, continues to grow globally. The choice of robotic-assistance is, in many cases, a function of accessibility within a given health-care system, but use of the robot often shortens the learning curve and facilitates a minimally invasive approach among surgeons not comfortable with the laparoscopic, nonassisted, approach.

As a result, robotic-assisted laparoscopic radical prostatectomy (RALRP) became the surgical technique of choice in the treatment of localized prostate cancer with 60% of patients in the United States treated with this technique by 2009,[1] and presumably far more by 2016.

Early evidence showed that RALRP was associated with reduced blood loss, decreased transfusion rates, and lower narcotic requirements postoperatively,[2] but concerns remained regarding catastrophic complications in the hands of inexperienced surgeons, high cost, and a failure to demonstrate improvements in functional recovery following surgery. More recent data have also been promising regarding more durable – and arguably more clinically meaningful – outcomes, such as long-term cancer control, functional recovery, and health-related quality of life. Data suggest that these outcomes are at least equivalent to, and possibly superior to, outcomes after traditional open radical prostatectomy (ORP).[3–5]

It is notable that in the hands of most surgeons experienced with the technique of RALRP, the procedure has become routine. A primary attraction of the procedure is that the approach allows adaptation, in most cases, irrespective of anatomic variation, gland size, or previous surgery. These factors add complexity to the operation, and thus surgeon experience remains a critical determinant of success or failure. While most surgeons carry a high level of comfort with the RALRP procedures, a risk of complications remains, and given the number of procedures performed in the United States, review of potential complications, their management, and strategies for prevention are critically important.

Preoperative Considerations

As with any surgical procedure, determining surgical candidacy is an important element of the preoperative evaluation before considering RALRP. There are general contraindications to surgery that may relate to either general comorbidities precluding anesthesia, or cancer-related risk factors that predict a high likelihood of treatment failure. The oncologic indications for surgery are beyond the scope of this chapter, but given the wide variation in selection criteria, the ultimate decision to offer RALRP depends largely upon the treatment biases and strategy of the managing surgeon and institution. In general, candidates for a laparoscopic approach include patients at relatively low risk for adverse cardiopulmonary and anesthetic complications associated with the surgical procedure. In some circumstances, anesthetic considerations related to pulmonary disease and the ability or inability to compensate for the hemodynamic, cardiovascular, and metabolic changes associated with the various physiologic particularities that occur during laparoscopy might serve as relative contraindications. The steep Trendelenburg positioning undertaken during RALRP could further increase respiratory stress, and patients with underlying respiratory disease, morbid obesity, or anatomic abnormalities may not tolerate this surgical approach well.

A prior history of intraabdominal and pelvic surgical procedures, disease processes, or previous radiation therapy may also influence the appropriateness of a laparoscopic robotic-assisted approach. Although no clear guidelines are available, the presence of intraabdominal or pelvic adhesions may certainly make exposure and creation of a working space more difficult, and the decision to proceed laparoscopically is based upon surgeon experience and comfort level.

In general, we have not found previous intraabdominal surgery to be a contraindication to RALRP, but surgical time is clearly extended due to the need for laparoscopic lysis of adhesions to create working space. In these patients, options such as extraperitoneal approach RALRP could also be considered, but such an approach requires experience with the technique, and development of the extraperitoneal space may be limited by incisional adhesions as well. The need for conversion to an open surgical approach is a realistic possibility in these patients, and as such, preoperative arrangement for availability of a surgeon experienced with ORP is advisable. Likewise, in cases of complicated previous intraabdominal surgery or infection (i.e., perforated diverticulitis, trauma, abscess, etc.) one might consider advising ORP rather than attempting RALRP, depending upon the experience level of the surgeon.

Previous pelvic surgeries, including bladder surgery, simple prostatectomy, lower abdominal mesh placement, renal transplant, or vascular grafting, may create challenging extraperitoneal adhesions, limiting the approach to the prostate during RALRP. In our experience, mesh is the most commonly encountered obstacle, and a careful history with review of previous operative reports may aid in surgical planning. When mesh placement is limited to the deep inguinal ring or anterior abdominal wall, cautery along the mesh surface generally allows the bladder to drop easily away. Caution must be exerted not to stray laterally to the mesh, or through the mesh into the anterior abdominal wall, to avoid vascular injury. In this regard, dealing with mesh placed extraperitoneally over the inguinal ring is better dealt with by RALRP than ORP, as mesh is more likely to be encountered and traversed during the open or extraperitoneal approach while attempting to access the space of Retzius. Most troublesome is the scenario in which mesh extends over the iliac brim and vessels. In these cases, we generally do not attempt pelvic node dissection due to risk of vascular injury, and the bladder is released laterally only to the root of the superior pedicle. In general, mesh does not extend beyond the distal iliac vessels in these cases, and adequate bladder mobility can be achieved through simple release from the mesh.

In cases of previous bladder surgery, perivesical adhesions can be more substantial, and bladder injury often occurs during mobilization. Intravesical instillation of dilute methylene blue can allow recognition of small injuries that can easily be repaired. In patients with previous renal transplant or pelvic vascular graft, RALRP may be contraindicated, depending upon the experience level of the operating surgeon. Liberal use of cautery during bladder mobilization should be avoided if RALRP is undertaken, as inadvertent injury of blood vessels or transplant ureter can have dire consequences. We have previously performed RALRP in men with previous renal transplant, and preoperative assessment of anatomy is essential. In these patients, the allograft is generally seated well above the bladder, and the ureter enters the dome of the bladder. Avoidance of this

region is feasible through cautious entry into the retropubic space along the anterior abdominal wall.

Salvage laparoscopic robotic-assisted prostatectomy following radiation therapy may be particularly challenging. In complex cases characterized by anticipated fibrosis, adhesions, and altered anatomic features, the decision to proceed with a laparoscopic approach should be based on risk assessment and the surgeon's experience. In general, we have found salvage prostatectomy to be simpler through a robotic-assisted approach rather than open.

Morbid obesity itself does not pose a contraindication to RALRP, but particular preoperative considerations should be taken. Specifically, the surgeon should be aware that full Trendelenburg positioning might not be possible in these patients, due to difficulty with ventilation in the setting of abdominal insufflation. Further, port placement may need to be displaced somewhat inferiorly, often below the umbilicus, in order to allow for the robotic arms to gain access to the most caudad portions of the pelvis.

As in open radical prostatectomy, patients undergoing laparoscopic robotic-assisted prostatectomy should receive appropriate perioperative antibiotic and deep vein thrombosis prophylaxis. We have utilized both compression stockings and preoperative administration of prophylactic dose subcutaneous heparin as a routine in all men undergoing RALRP.

COMPLICATIONS OF POSITIONING

Complications of positioning are discussed in detail in Chapters 9 and 31. The da Vinci Si system (Intuitive Surgical, Sunnyvale, CA) has typically been employed with the patient in a modified low lithotomy position with steep Trendelenburg decline. The robot is generally positioned between the legs allowing the operating component of the robotic system to come into close proximity to the patient, with the operating arms and camera oriented toward pelvic targets, including the prostate, bladder, seminal vesicles, urethra, and genitourinary diaphragm. Alternatively, a side-docking approach, in which the robot is positioned at an angle lateral to the pelvis, allows adequate exposure and enables versatility of positioning the patient in a supine or lithotomy position. Since adaptation of the Xi system, we have routinely placed the patient supine in steep Trendelenburg position. Such an approach minimizes the risk of lower extremity compartment syndromes and perineal nerve injury related to the stirrups.

Close attention to positioning is important to prevent pressure or traction-associated nerve injuries. Accordingly, all pressure points should be padded adequately, and the surgical team, including the anesthesiologist and nursing staff, should ensure that areas of potential injury are addressed before sterile skin preparation and draping. In the SI positioning, the weight of the patient's legs should be transmitted through the heel and foot, minimal pressure should be present on the lateral aspect of the calves and thighs, the extension of the hip and thigh should be anatomic to minimize the risk of femoral nerve injury, and the lower back should be contoured with lumbar support if necessary. If the arms are positioned by the patient's side, the wrists and elbows should be well padded, and care should be taken to protect the patient's hands and fingers from injury secondary to positioning of the table, robotic equipment, or the assisting surgical team. When the patient's arms are not tucked, a natural anatomic position of the arm and shoulder should be achieved to prevent brachial plexus injury. Adequate shoulder support, without compression of the shoulders, is essential to avoid brachial plexus stretch injury.

Once the patient has been correctly positioned, he should be secured to the surgical table to prevent shifting during the surgical procedure. We generally observe the patient in Trendelenburg position prior to draping to ensure no slipping occurs. This goal can be achieved relatively easily by using padded straps across the patient's chest. Additionally, the use of a high-density padding with a high coefficient of friction, such as the Pink Pad (Xodus Medical, Inc.),[6] helps prevent patient slippage while in steep Trendelenburg and also protects against pressure ulcers and nerve injury. Prior to initiating the procedure, the patient's airway pressure, facial swelling, and body habitus should be carefully observed. Inability to tolerate the position, prior to insufflation, may indicate limited ventilatory reserve, extreme truncal weight impinging upon the diaphragm, or poor venous return from the upper body. In these rare cases, the patient may be a poor candidate for robotic prostatectomy and one could consider aborting the procedure. Additional effects of Trendelenburg procedure can be reviewed in Chapters 9 and 31.

In positioning the operating element of the robotic system, care must be taken to ensure that unintentional contact between the robot and the patient does not occur. The only contact between the robot and the patient occurs through the working ports, and at no time should any other moving or static element of the robot place pressure on the patient's core or extremities. The most common area of potential contact is between the working elements (arms) and the patient's thighs. This contact can be avoided by pivoting the arms of the robot up and away from the patient when the robotic arms are attached to the working ports. Of note, these complications may be less common with use of the da Vinci Xi system due to the fact that the patient is positioned in the supine rather than low lithotomy position, but in that case injury to the feet and lower extremities can occur as the robot is pulled in or out of the field.

One practical concern that may go unrecognized but is potentially serious is the placement of equipment (cables, light source, camera, suction tubing) in the vicinity of the patient's face and the endotracheal tube. Care should be taken when considering placement of these laparoscopic accessories, and if at all avoidable, they should be routed away from the area of the patient's head. In laparoscopic robotic-assisted prostatectomy, however, these accessories are often placed in that area out of necessity. In these cases, a protective foam barrier may be placed over the patient's face after the endotracheal tube has been secured. This measure may prevent facial injuries such as corneal abrasion and may also reduce the risk of unintentional dislodgment of the endotracheal tube during the surgical procedure. Similarly, cords running along the floor should be neatly coiled and protected to avoid inadvertent pulling or disconnection from the robot or endoscopic tower. Such events during the course of surgery can result in loss of vision or failure of the robot.

Critical system failures, although uncommon, may occur, requiring abortion of the robotic-assisted approach and conversion to either a straight laparoscopic procedure or open prostatectomy. A recent survey of 176 urologists who perform RALRP reported that 57% of respondents had ever experienced "irrecoverable intraoperative malfunction" of the da Vinci robotic system either before or during a case. In some cases, system errors prevented initiation of the surgical procedure using a robotic approach (58% of these cases were rescheduled, 19% were performed open, and 15% were performed laparoscopically). Other times, these system errors occurred intraoperatively and required conversion to open or pure laparoscopy. Overall, fellowship trained urologists were statistically more likely to convert to a pure laparoscopic approach versus an open approach.[7] Although information on estimates of system failure is limited, the impact of this system-specific complication on patient and cancer-related health outcomes has not been measured to date.

COMPLICATIONS OF ACCESS

Port Insertion/Insufflation

Complications of laparoscopic access are additionally reviewed in Chapters 30 and 31. Laparoscopic robotic-assisted radical prostatectomy may be performed through either a transperitoneal or an extraperitoneal approach. Although the transperitoneal approach is more commonly used, some surgeons prefer the extraperitoneal approach because the peritoneal contents can be avoided. In this case, the working space is generally smaller, and cranial access to high lymph nodes may be limited. Both approaches have advantages and disadvantages and present different potential challenges in access. Regardless of which approach is used, initial access to the peritoneal or perivesical space is typically achieved through a small periumbilical or infraumbilical skin incision.

The transperitoneal approach uses intraperitoneal access with secondary entry to the retropubic, extravesical space through eventual incision of the parietal peritoneum. Access to the peritoneal cavity may be gained by abdominal insufflation through a Veress needle followed by blind insertion of the initial camera port or use of a Hasson technique for direct cut-down and visualization of the peritoneal incision. While we have generally preferred a Hasson technique of insertion in all cases, this technique is strongly indicated in cases of previous intraabdominal surgery from which bowel adhesions may be present, when direct visualization is preferable. Following standard laparoscopic principles, confirmation of an intraperitoneal position is necessary before insufflation. In obese patients, when using the Hasson technique, the trocar tip can easily be displaced to the preperitoneal space. Abnormally high initial intraabdominal pressures indicate probable malpositioning, and insufflation should not be initiated in this setting. Repositioning, removal, and replacement of the device are options to establish correct placement before insufflating the abdomen. Nonvisualized passage of the Veress needle and the initial trocar following insufflation is associated with potential injury to gastrointestinal and vascular structures. If an injury is suspected after placement of the Veress needle, insufflation should be delayed and the needle should be carefully removed in the trajectory of entry to avoid converting a penetrating injury to a potentially more severe laceration. In these cases, or in cases of previous midline incision, a Hasson technique for trocar insertion can be carried out laterally to visualize the midline adhesion and perform laparoscopic lysis of adhesion, or inspection of suspected injury, prior to placing midline trocars. Once safe access has been established in a different location, the area of initial entry and potential injury should be examined closely. In cases of small penetrating injuries due to needle insertion, usually no additional management is required for bowel or bladder entry.[8] Injuries associated with trocars are generally more severe and often require laparoscopic or open repair. The surgeon must use his or her discretion regarding the need for repair or conversion to an open procedure.

The extraperitoneal approach requires port placement slightly lower than in the transperitoneal approach but in the same configuration. Potential benefits of the approach include reduced anesthetic problems associated with increased intraperitoneal pressures, avoidance of the peritoneal contents and all associated intraoperative and postoperative consequences (ileus), and decreased need to retract the bowels during the surgical procedure. Additionally, the risk of trocar injury to the bowel is reduced, but bladder injury or vascular injury due to the reduced size of working space remains a potential problem. The working space is smaller, and care must be taken in developing the extraperitoneal space before port placement, particularly in the cranial and lateral areas where the robot working ports are placed. A balloon dilator is used to develop the prevesical space bluntly and may result in laceration or avulsion of small pelvic vessels. This is generally not problematic, except in the case of previous pelvic surgery or fibrosis secondary to previous pelvic infection. In these cases, fused tissue planes can result in adherence of the peritoneum to pelvic vessels, resulting in more significant vascular injury on insufflation. In cases of suboptimal development of the prevesical space, the working space can be limited, resulting in a relatively reduced ability to manipulate the working elements and translating to more difficult surgical dissection. Initial port placement to gain proper access to the space is essential because improper placement may result in occult or obvious intraperitoneal entry and bothersome intraperitoneal leak throughout the procedure. In cases of intraperitoneal insufflation, bulging of the peritoneum further restricts the working space. In the event of an intraperitoneal communication, a 5-mm port can be placed into the peritoneal space for decompression. Conversion to an intraperitoneal approach should be done if a large intraperitoneal CO_2 leak occurs.

Subcutaneous emphysema may develop during the course of the procedure, either due to trocar placement or migration to the preperitoneal space, a very prolonged procedure, or a CO_2 leak around the trocar site. Scrotal emphysema is common, and in prolonged cases, emphysema may migrate up the abdominal wall and involve the subcutaneous tissues of the neck and face. This problem is directly related to the extent of CO_2 leakage into the extraperitoneal space, which may be exacerbated by prolonged surgical time, use of high insufflation pressures, and insufflant leak around the fascial opening. Palpable crepitus is the principal clinical sign. When subcutaneous emphysema is

associated with high CO_2 blood levels, delayed extubation may be required to allow the partial pressures of CO_2 and of oxygen to normalize. Maintaining intraperitoneal pressures of ≤15 mm Hg assists in minimizing this complication.

Many devices, including the Kii Balloon Blunt Tip System by Applied Medical, can reduce the chances of troublesome air leak around the trocar throughout the case, given the relatively large fascial opening required during the Hasson approach. This device works by trapping the fascial opening in an airtight manner between an external mobile gel cone and an internal balloon posterior to the peritoneal opening.[9] Alternatively, a pre-placed "purse-string" fascial stitch can be used to tighten the point of fascial entry around the trocar, reducing the tendency of air leak. We have found the latter maneuver to work poorly and have routinely utilized the balloon port, both with the Si and Xi systems.

Although uncommon, the risks of gas embolism and resulting cardiopulmonary collapse are elevated during laparoscopy. Embolism is less common when one uses CO_2 compared with other insufflants, given the dissolvability of CO_2 in blood.[10] In cases of unrecognized intravascular entry, injury, and insufflation, a CO_2 embolus may precipitate rapidly and may result in catastrophic consequences such as acute cardiovascular collapse. This is the most common cause of a gas embolism in the setting of CO_2 insufflant. Classic signs include an abrupt increase in end-tidal CO_2 accompanied by a sudden decline in oxygen saturation and a subsequent decrease in end-tidal CO_2.[10] Such cases should be managed on an emergency basis with immediate cessation of insufflation and repositioning of the patient in the left lateral decubitus position to minimize right ventricular outflow. The patient should then be ventilated with 100% oxygen, and in extreme circumstances, aspiration of the air embolism may be required.

Bowel Injury

Perforation of the small bowel or large intestine is the most common injury associated with initial blind trocar placement and usually relates to bowel adhesions or a downward angulation on trocar insertion. Prompt recognition of the injury is essential, and the decision regarding management is largely based upon surgeon experience and the severity of the injury. In cases of injury to bowel fixed by adhesion, release of the adhesion is essential to properly evaluate and, if needed, repair the injury. Additionally, tethering of the bowel can stretch and expand the diameter of the injury. Repair can be performed laparoscopically, with or without robotic assistance, or through an open converted approach, depending upon the comfort level of the surgeon. If converting to open, completion of the prostatectomy could be considered, with repair of the bowel via the specimen extraction site if intraoperative fecal spillage is not noted. In that case, isolation of the bowel with stay sutures until the time of repair is prudent. General principles of bowel repair are employed. Injury to intraperitoneal structures is less common with an extraperitoneal approach because the peritoneal contents are avoided. Nonetheless, small bowel and large intestine injuries are possible secondary to unintentional peritoneal entry during establishment of access, thermal injuries, or inadvertent traction to fixed bowel segments within the peritoneal cavity. Delayed recognition of a bowel injury can be catastrophic. Patients will often present with peritonitis, sepsis, and intraabdominal abscess within 2–7 days following surgery.

Bladder Injury

Significant bladder injuries may also occur during the establishment of access. Bladder injury by trocar is usually quite evident and is easily managed by direct repair. Suspected needle bladder injuries can be detected with intravesical instillation of dilute methylene blue. Small penetrating injuries associated with narrow-gauge needles can be managed conservatively.[8] Urinary decompression with a Foley catheter reduces the risk of injury and should be routine practice before laparoscopic access is gained.

Retroperitoneal Vascular Injury

Major vascular injuries are rare and have been reported in recent meta-analyses to occur in 0.044% and 0.03% of laparoscopic cases using the Veress needle and Hasson approaches, respectively.[11,12] The aorta and common iliac vessels are the most commonly injured vascular structures, as they lie directly beneath the periumbilical trocar insertion site. Injury to these major structures can result in catastrophic bleeding, but such injuries can usually be salvaged through prompt intervention. Mesenteric vessels may also be injured, resulting in mesenteric hematoma followed by possible vascular compromise and bowel ischemia. Clinical signs of significant bleeding are hypotension followed by compensatory tachycardia. After trocar entry into a major vessel, injury is often readily apparent on removal of the obturator or pull back of the trocar and insertion of the camera. If the trocar has not been withdrawn or manipulated, a blunt obturator should be replaced through the lumen and the trocar should be left in place while preparations are made for open conversion and repair. While usually evident, during some cases of tangential vascular injury, blood may dissect beneath the mesentery and bleeding may not be apparent, even on intraperitoneal inspection. An emergency laparotomy should proceed rapidly with vascular control and repair.

Epigastric/Abdominal Wall Vascular Injury

Trocar insertion commonly can also result in injury to the inferior epigastric artery and veins, or their tributaries. Injury is recognized either at the time of insertion, based upon visual inspection, or at the time of port removal. In general, the risk of injury can be minimized when the vessels are directly visualized and ports are placed >6 cm from the midline,[10] and lateral ports are placed under direct vision. In thin patients, use of the laparoscope light to transilluminate the abdominal wall can aid in selecting an appropriate site for port insertion. Use of a spinal needle to map the trans-abdominal course of the trocar may also help prevent injury to the inferior epigastric vasculature.

Recognized inferior epigastric injuries should be managed promptly either laparoscopically or with a cut-down technique. When laparoscopic ligation or electrocautery is possible, additional skin incisions or port placements may be avoided. In some instances, the location of the injury may prevent adequate control without additional port placement. These cases may be managed effectively with additional port placement and subsequent internal ligation. When access to the site of bleeding is difficult, an externally

placed (on the skin level) hemostatic occluding figure-of-eight stitch can be placed in the quadrant of identified bleeding to provide occlusion and control. Endoscopic suturing devices are very useful in this application because they allow full-thickness transabdominal suturing, and this has been our preferred management of abdominal wall bleeding when recognized intraoperatively. Unrecognized or inadequately managed hemorrhage from the inferior epigastric vessels may progress to a significant rectus sheath hematoma resulting in clinically significant pain, acute blood loss, anemia, and possible hemorrhagic shock.

Intraoperative Surgical Complications

Specific intraoperative complications arising during RALRP, unrelated to port insertion and insufflation, are similar to those occurring during ORP, but their cause and management may be distinct, owing to the surgical technique. Complications of ORP are reviewed in detail in Chapter 42, and there may be great overlap with this chapter as they are by the same author. Complications of pelvic lymphadenectomy are detailed in Chapter 40 and will not be covered in this chapter.

BLEEDING

A major attribute of RALRP as compared to ORP is the relatively small amount of bleeding encountered during the procedure. In general, while bleeding can occur at any point during the procedure, the severity of bleeding is relatively minimal as compared to with ORP, thus improving intraoperative vision, and improving the ability to control small bleeding sites through enhanced vision. The hemorrhagic advantage of RALRP over ORP is underscored by the differential blood loss between the two approaches: A recent prospective study of 2506 patients found an average blood loss of 185 mL versus 683 mL for RALRP and ORP, respectively.[13] Another study which had similarly significant surgical blood loss differences (207 mL vs 852 mL) also showed that the RALRP group had a reduced incidence of perioperative transfusion rates as compared to the ORP group (4.3% vs 30.3%) and that this likely contributed to a shorter hospital stay (1.8 d vs 2.9 d).[14] It is important to remember that this is surgeon-dependent, and the high rate of transfusion reported in the latter study is extremely high for surgeons of experience performing ORP.

Sources of bleeding are the same as those described for the open procedure: the dorsal venous complex and Santorini's complex overlying the anterior and lateral surfaces of the prostate and bladder, the inferior vesicle and proximal prostatic vascular pedicles, the neurovascular bundles coursing posterolateral to the prostate, the apical prostatic vessels, and the bladder neck. One reason for reduced bleeding during RALRP is the pneumatic pressure provided by insufflation of the working space. Under conventional insufflation pressures, small vessels surrounding the prostate, and in many cases even the dorsal venous complex, can be cut without major bleeding. This is an important recognition, as a common cause of delayed bleeding is de-sufflation with ensuing bleeding from uncontrolled small vessels controlled by pneumatic pressure during the procedure. As such, following completion of the procedure, inspection of the field under reduced insufflation pressure of 5–8 mm Hg can be a valuable tool in preventing delayed bleeding.

Division of the dorsal venous complex can be performed early in the procedure or late. If performed prior to bladder neck division and prostate mobilization, the dorsal vein should be controlled directly with a figure-of-eight suture of 2-0 Vicryl or, in some cases, an Endo GIA stapler. Adequate suture ligature of the dorsal vein requires sufficient division of the adjacent endopelvic fascia to allow central bunching of the complex within the suture. In cases of retraction of the dorsal vein following division, direct oversewing of the vein stump is generally feasible. We have generally divided the dorsal vein complex after division of the bladder neck and complete mobilization of the entire gland. In doing so, the complex can be sharply divided without prior suture ligature, allowing maximal anterior surgical margins while avoiding excessive dissection or suture placement in the periurethral space. During division of the uncontrolled dorsal vein, bleeding can be encountered, particularly when only partially transected. Bleeding can be minimized by avoiding stretch or traction on the vein, avoiding excessive suction or reduction of insufflation pressure, and, on occasion when needed, actually transiently increasing insufflation pressure to 20 mm Hg. The latter maneuver is generally safe, but one must be cautious if large open venous sinuses are visible, due to the rare occurrence of air embolus. Following division, we generally oversew the edge of the dorsal vein complex in a running fashion, incorporating only the edges of the vein complex to avoid deep suture placement. The complex is then suspended to the pubic symphysis by incorporating the posterior pubic periosteum into the running closure stitch. In general, dorsal vein complex bleeding should not be excessive in RALRP, regardless of the technique of division utilized.

In general, use of sharp dissection and nonthermal mobilization of the periprostatic layers, desirable for minimizing trauma to the adjacent neural structures, increases the risk of bleeding both in the field and postoperatively. High anterior release of the lateral prostatic fascia requires mobilization of the fascia from the lateral surface of the prostate. As the fascia is often intimately adherent to the periprostatic venous complex, small venotomies are frequently encountered. We have generally utilized an approach of retrograde neurovascular bundle mobilization, adapted from our open technique (Fig. 42.3), by releasing the lateral fascia of the prostate and mobilizing it sharply and bluntly from the posterolateral prostate, to the level of Denonvillier's fascia, thus laterally displacing the nerve bundle (Fig. 32.1). Denonvillier's fascia is then incised, entering the perirectal space (Fig. 32.2), and a cottonoid sponge is packed into the defect to tamponade venous oozing from the mobilized nerve bundle and lateral fascia (Fig. 32.3). After excision of the prostate, bleeding encountered along the neurovascular bundles or lateral prostatic fascia can generally be controlled by reapproximating the overlying fascial layers in a running or interrupted layer of 3-0 Vicryl suture, or by cautious point coagulation with bipolar cautery, as needed.

Division of the bladder neck, particularly the lateral attachments of the bladder to the prostate, when establishing the posterior plane behind the bladder neck can

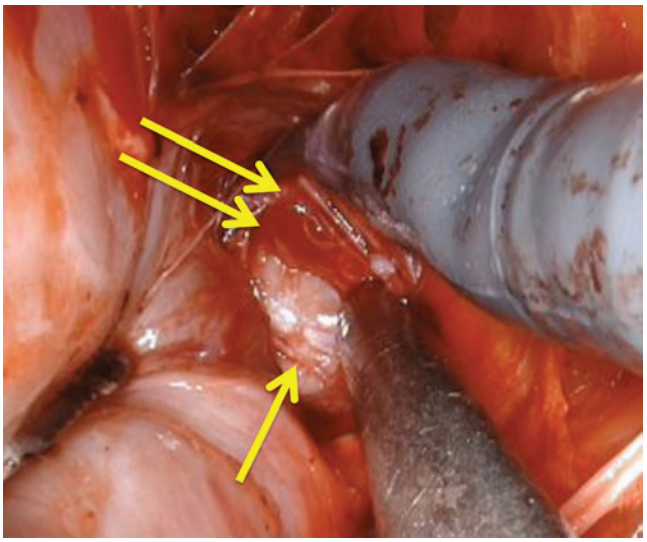

Figure 32.1 Taneja's retrograde technique of neurovascular bundle dissection. Prior to division of the urethra or bladder neck, the endopelvic fascia is incised and the prostate is freed from the sidewall to the level of the perirectal fascia. The lateral fascia is incised and reflected off the posterolateral surface of the prostate. The neurovascular bundle is reflected laterally in an extrafascial fashion (double arrow), exposing Denonvillier's fascia medial to the nerve bundle (single arrow).

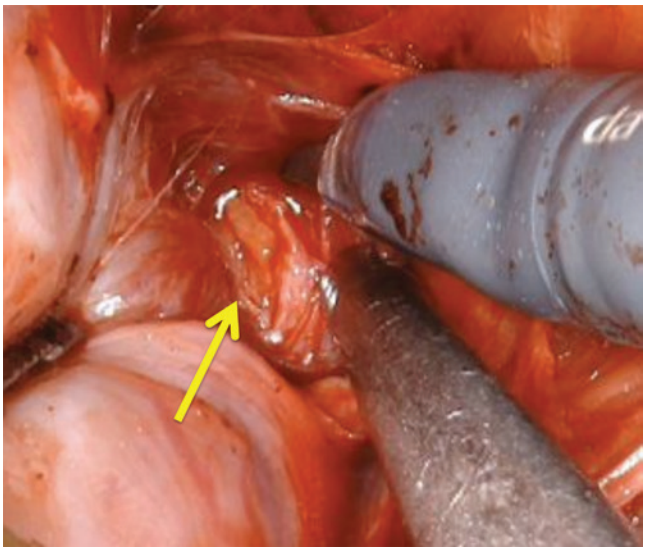

Figure 32.2 Taneja's retrograde technique of neurovascular bundle dissection. Denonvillier's fascia is sharply incised, exposing the perirectal fat in the retroprostatic space (arrow).

result in significant bleeding from the perivesical extension of Santorini's plexus and the arterial branches extending to the bladder neck. Generous use of bipolar cautery or preemptive clip placement can avoid oozing from this location, which may impair vision greatly. Once bleeding from a transected vessel occurs, it often retracts within the partially divided bladder neck. Efforts to control small bleeding points are often fruitless and may be best employed following complete division of the bladder neck and prostate pedicle. Prostatic pedicle bleeding is not unusual, but is generally minimizing by liberal use of clips during

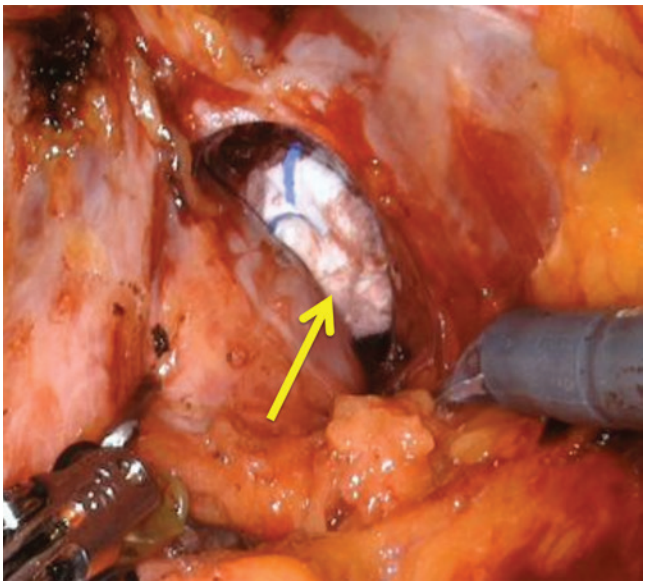

Figure 32.3 Taneja's retrograde technique of neurovascular bundle dissection. A cottonoid sponge is packed into the defect to tamponade any bleeding along the neurovascular bundle, until the prostate is excised.

the division to avoid excessive cautery. Upon division of the pedicle, small venous bleeding often stops as traction on the cut vessel is released. Direct suture ligature of the divided pedicle is preferable to attempts at clipping or cauterizing retracted vessels.

A final point of potential bleeding is the seminal vesical pedicle. Arterial supply of the seminal vesical branches arises from the inferior vesical circulation of the hypogastric artery. As such, retracted vessels can be the cause of intraoperative or delayed postoperative bleeding. Direct control of the pedicle with clips is desirable to avoid transmission of cautery to the neurovascular bundle, but if avulsed and retracted, exposure followed by point coagulation with bipolar cautery can be utilized.

VISCERAL INJURY: BLADDER, BOWEL, AND RECTUM

Visceral injuries during RALRP can include injuries to bowel, bladder, and rectum by a number of variable mechanisms. Early recognition and repair is a critical tenet of management, regardless of the site of injury. Direct injury during dissection or mobilization is often recognized while injuries due to instrumentation out of the visual field, thermal injuries, or traction injuries may go unnoticed and present later at the time of visceral leak or infection.

Bladder injuries commonly arise during mobilization of the bladder. In the transperitoneal approach, division of the urachus and entry into the retropubic space can result in an inadvertent cystotomy. Such injuries are most often encountered in cases of previous pelvic surgery, hernia mesh, or by entry into the incorrect plane, too close to the detrusor muscle. Similar risks of injury to the bladder exist during insufflation of the perivesical space for an extraperitoneal approach prostatectomy. The incidence is <2% during laparoscopic prostatectomy, and this complication

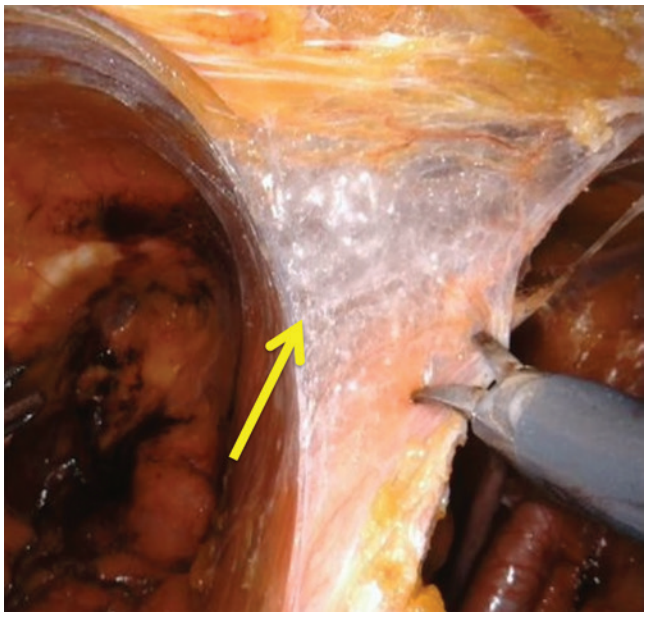

Figure 32.4 In mobilizing the bladder from the anterior abdominal wall, after division of the urachus, an avascular plan is identified between the perivesical fat and the posterior rectus fat, in order to avoid cystotomy and injury to the tributaries of the epigastric vessels. This plane (see arrow) is extended to the level of the pubic symphysis.

can be effectively managed with two-layer closure and bladder decompression.[15] In cases of multiple cystotomies or when the integrity of the anterior bladder has been compromised secondary to misguided surgical dissection, additional repair may be necessary.

Mobilization of the bladder should be carried out in a largely avascular plane, identified upon complete division of the urachus (Fig. 32.4). When traversing this plane to the level of the endopelvic fascia, excessive bleeding may indicate entry into the perivesical space or the posterior rectus fat, adjacent to the epigastric vessels. Early lateral mobilization of the bladder during the pelvic node dissection often defines the appropriate plane, thereby facilitating release of the urachus. In cases of sliding hernia, the bladder wall may extend into the hernia defect. Early recognition of the hernia, followed by reduction of the contents prior to further bladder mobilization, will avoid inadvertent cystotomy.

Bowel injury to the small bowel, colon, or rectum can occur at various points during the surgery. In handling the bowel, blunt retraction, rather than grabbing and pulling, is desirable as the strength for the robotic instruments is often underestimated. Any tether of the bowel due to adhesion or peritoneal attachment can result in a serosal or full thickness injury of the bowel wall. Commonly, injuries may occur when robotic instrumentation is moved while out of the visual field, or by the assistant's instrumentation as it is moved in and out of the visual field. As such, in establishing the pelvic working space, it is critically important to ensure the bowel remains well mobilized and out of the path from assistant port to operative field. Robotic instruments should remain in the field with short, controlled movements, paralleling movement of the camera.

As the sigmoid colon is often adherent to the left pelvic sidewall overlying the pelvic brim, wide release of lateral attachments and medial reflection sufficient to drop the rectosigmoid well below the dome of the bladder are advisable. Small bowel, present in the posterior cul-de-sac of the bladder should be swept out of the pelvis toward the upper abdomen with release of any tethering adhesion. Upon division of the urachus, the bladder serosa layer and urachus can be used to protect the underlying bowel through cranial retraction.

In addition to direct injury, cautery injury is common, and a more difficult to identify, mechanism of injury to the bowel. Arc injuries occur when cautery is transmitted to adjacent structures from a monopolar instrument. Careful inspection of the overlying sheath of the instrument will avoid unexpected transmission of cautery from the shaft, and limit delivery of cautery to the tip of the instrument, where it can be better controlled. When cautery injury does occur, inspection of the tissues will determine the necessity for repair. Blanched tissue with apparent lack of capillary refill is suggestive of devitalized tissue, and one should consider preventive repair, either through imbrication and reinforcement with interrupted seromuscular sutures, or, in the case of severe injury, bowel resection and primary repair. Delayed recognition of thermal injury to the bowel can have catastrophic outcomes, with patients often presenting 3–10 days after surgery with fever, leukocytosis, abscess formation, peritonitis, and/or sepsis.

Rectal injury, which has an incidence of 0.2–1.0% during RALRP, usually occurs during the dissection of the prerectal space or mobilization of the seminal vesicals. It is more common in patients with a history of prior transurethral resection of the prostate, pelvic radiation, or with periprostatic inflammation as in the case of multiple transrectal prostate biopsies or prostatitis.[16] Further, patients with high-grade or locally advanced disease, who require a wider resection of the neurovascular bundles, may be susceptible to rectal injury along the anterior and lateral rectal wall. For this reason, it is advisable to consider mechanical bowel preparation prior to surgery in patients considered to be high risk for rectal injury.

Like other intestinal segments, thermal injury to the rectum can have significant consequences, leading to abscess formation and subsequent rectourethral fistula with or without secondary sepsis. Caution should be exerted to avoid using cautery when mobilizing the seminal vesicals or in elevating the prostate from the anterior rectal wall. Our preference in most cases of low- and intermediate-risk prostate cancer is to traverse between the layers of Denonvillier's fascia when establishing the plane posterior to the prostate. In high-risk patients, excision of both layers of Denonvillier's fascia may be desirable, and in these cases, sharp and blunt dissection under direct vision along the rectal serosa can avoid inadvertent traction injury.

Direct two-layer repair is feasible, by robotic-assisted approach, for most small injuries of the rectum <2 cm in size. In these cases, mucosal closure, followed by an imbricated inversion of the repair with seromuscular sutures, can be utilized. Testing of the air-tight nature of the repair can be performed by instillation of air into the rectum with a piston syringe after filling the pelvis with water. Broad-spectrum antibiotics can be administered for 48 hours, but

in the absence of excessive fecal soiling in the field, prolonged antibiotics are not warranted. Following repair, interposition of tissue between the repair and the vesicourethral anastomosis is desirable. This can be achieved by eversion of the urachus, bladder serosa, or posterior peritoneum through the posterior cul-de-sac and anchoring it to the cut rectourethralis muscle, or using the posterior cul-de-sac peritoneum as a pedicalized flap. Posterior plication or anchoring the detrusor apron to the rectourethralis, can also achieve the goal.

In cases of large or irregular rectal injuries, devitalized rectal wall, previous radiation, or excessive fecal soiling, surgical consultation should be considered along with proximal diversion by loop colostomy at the time of repair. In some cases, rectal resection, with or without primary repair, may be considered. Failure to divert the fecal stream in the setting of complex rectal injury can result in pelvic abscess and sepsis in the event the repair fails to heal.

URETERAL INJURY

Ureteral injury is exceedingly uncommon complication during RALRP, with large series reporting incidences between 0.046% and 0.3%. Authors suggest that ureteral injuries usually occur in the context of difficult anatomic dissection from a history of previous abdominal surgery, prostatitis and pelvic radiation, or during extensive lymphadenectomy. In these patients, it may be useful to preplace ureteral stents for easier ureteral identification and to prevent injury.[17]

Ureteral injury can occur during mobilization of the superior vesical pedicle during pelvic lymph node dissection. It is important to note that the ureter courses medial to the superior pedicle and that injury can be avoided by maintaining node dissection lateral to the pedicle (Fig. 32.5). Inadvertent thermal injury can also occur during seminal vesical dissection. The ureter courses lateral and deep to the tip of the vesical as it enters the trigone. Ureteral injury most commonly occurs, however, at the level of the orifice during bladder neck division. Risk factors include a large median lobe or infiltration of cancer at the bladder neck, requiring wide excision. Similarly, excessive traction following division can tear the posterior bladder neck, bringing the orifices very close to the cut edge.

Ureteral injury management is discussed in detail in Chapters 14 and 43. Extravesical ureteral injury is generally treated by reimplantation of the ureter to the bladder dome. Similarly, transection of the intramural ureter may require reimplant, depending upon the length of ureter retained in the bladder wall. In those cases in which the ureteral orifice or distal intramural ureter is transected, or the cut edge of the bladder neck lies close to the orifice, placement of a double J stent followed by incision of the intramural ureter to mobilize the orifice cranially can provide sufficient distance from the orifice to the cut edge of the bladder neck to allow bladder neck closure or anastomosis.

Failure to recognize ureteral injury at the time of surgery can lead to delayed complications. Urine leak from the injured ureter may manifest as increased drain output in the days following surgery or present at a delayed interval with hydronephrosis, urinoma, infection, or sepsis. In patients with intraperitoneal extravasation of urine, serum creatinine may be elevated. Likewise, inadvertent ligation of the ureteral orifice at the time of vesicourethral anastomosis can result in a transient rise in serum creatinine due to obstruction. As such, any rise in serum creatinine in the early postoperative period should result in consideration of cross-sectional imaging or ultrasound to rule out hydronephrosis and/or urinoma. On rare occasions, ureteral injury may be discovered at a very delayed interval following surgery upon discovery of an atrophic, hydronephrotic kidney.

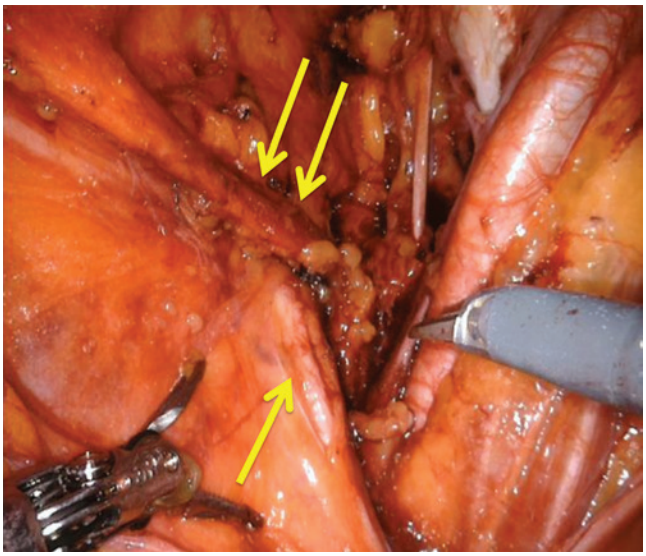

Figure 32.5 In the performance of pelvic lymph node dissection, the ureter (single arrow) courses over the iliac brim and underneath the superior vesical pedicle (double arrow) to enter the retrovesical space. Maintaining dissection lateral to the superior vesical pedicle helps to avoid inadvertent ureteral injury.

NERVE INJURY

Nerve injury may result from patient positioning, inadequate padding, and prolonged surgical duration and occurs in approximately 1.3–1.7% of RALRP cases. Femoral nerve injury is relatively more common during robotic prostatectomy that employs the split-leg bed configuration, while common peroneal nerve injury is associated with RALRP in the dorsal lithotomy position. It is unknown if the incidence of peripheral nerve injury has been decreased in RALRP cases that utilize the da Vinci Xi system, in which the patient is in the supine and Trendelenburg position,[18,19] though side-docking with supine position is generally felt to lower this risk.

The management of nerve injury is discussed in detail in Chapter 9.

Early Postoperative Complications

BLEEDING

Postoperative bleeding following RALRP, while unusual, can be segregated into early postoperative bleeding, occurring

immediately following surgery, or delayed bleeding, which occurs over the first 3–4 days. In general there is overlap between these two scenarios. Profound hypotension, oliguria, or tachycardia in the recovery room, with or without increased sanguinous drain output, should alert the surgeon to the possibility of uncontrolled intraperitoneal bleeding. In these cases, rapid resuscitation is warranted, and early return to the OR should be considered. Most commonly, such bleeding may be from the iliac fossa, due to an uncontrolled vessel within the bed of the lymph node dissection, uncontrolled epigastric bleeding, or unrecognized mesenteric injury. Reoperation, if performed early, could be considered by a robotic-assisted approach, with reinsertion of ports, inspection, clot evacuation, and, when needed, open conversion. In the case of laparoscopic exploration, volume repletion and transfusion is essential as insufflation may reduce venous return, causing hypotension in the hypovolemic state.

More commonly, postoperative bleeding does not result in hemorrhagic shock. A study of 317 RALRP patients reported on five patients who all presented with delayed bleeding in the form of abdominal wall hemorrhage/hematoma that often spread to the lower extremity, all of whom were able to be managed conservatively with blood transfusions. The authors attributed the source of this type of bleeding as being likely from port placement trauma to the inferior epigastric vessels, either from direct laceration of the vessel, or from the extreme tensions caused by the robotic arm movements.[20] Patients with more delayed postoperative bleeding usually demonstrate oliguria, tachycardia, and occasionally hypotension responsive to fluids, over the first 1–3 days postoperatively. Serial hematocrit demonstrates continued decline, even in the face of transfusion. Cross-sectional imaging will usually demonstrate variable amounts of pelvic fluid, as well as subcutaneous and intraperitoneal blood, but is usually not helpful in our experience. Conservative management, with liberal transfusion, fluids, and bed rest, is generally adequate, with bleeding resolving in 3–4 days. Re-exploration in these cases is generally not helpful as a discrete bleeding site within the abdominal wall, or in the pelvis, is usually not identified. In the days that follow, ecchymosis tracking to the scrotum, inguinal crease, and flank may be noted, but should not be alarming as this is dissipation of the previous bleed (Figs. 32.6A–C).

ANASTOMOTIC URINE LEAK

The rate of urethrovesical anastomotic leak (UVAL) varies according to surgical technique and the surgeon's experience, but is generally infrequent. As described in a recent comprehensive evaluation of UVAL in open, laparoscopic, and robotic approaches, the incidence was noted to be highest immediately after surgery (up to 78%) and becomes stable and quite low (8–14%) after about 3 weeks, suggesting no need for continuing the indwelling catheter after that time.[21] In regard specifically to RALRP, one large series showed that the incidence of UVAL based on postoperative cystography at day 7 was 67/442 (13.6%).[22]

Several specific techniques have been proposed to attempt to reduce the incidence of UVAL during RALRP. One study randomized 116 consecutive RALRPs to undergo either single- or double-layer urethrovesical anastomosis. While the single-layer group had statistically higher rates of UVAL at the 1-week cystogram, this did not correlate to long-term urinary leak, bladder neck contractures, or rates of incontinence.[23] A few groups have investigated the role of a barbed plastic "self cinching" suture, the V-Loc,[24] in the completion of the vesicourethral anastomosis. One group found that use of the V-Loc suture led to significantly shorter anastomotic times compared to standard technique (8 min vs 13.5 min).[25] Another group showed no difference in UVAL after the use of this novel suture,[26] and a third group found that the use of the V-Loc led to time reduction, minimal cost savings, and no change in UVAL, bladder neck contracture, or rates of incontinence.[27]

In our experience, clinically significant urethrovesical anastomotic leak is a rare occurrence, largely due to the specific technique utilized in the anastomosis. Given the use of a continuous running suture technique, the likelihood of a gap between sutures or poor coaptation of the mucosa is very low. The ability to accommodate disparities in luminal caliber between the urethra and the bladder neck, without tapering in most cases, adds to the technical advantage over an interrupted suture anastomosis. Suturing is generally carried out from posterior to anterior in a simple continuous technique, with more advance on the bladder neck than the urethra. We utilize two barbed sutures from the 6-o'clock position. Sutures should incorporate a full thickness of urethra and more mucosa than muscle on the bladder neck, in order to create eversion and coaptation.

Figure 32.6 Postoperative bleeding from an abdominal wall vessel can result in significant ecchymosis tracking along the flanks (A and B) and inguinal crease (C). Such bleeding generally is self-remitting and resolves with observation.

Such a technique reduces the risk of leak, but, likewise, greatly reduces the risk of contracture.

If a leak is suspected in the very early postoperative period, it is usually on the basis of increased drain output. Measurement of drainage fluid for creatinine will confirm the presence of a leak. Prolonged catheterization, and drainage, without further intervention, is usually sufficient for management. In cases of very high drain output, and minimal catheter output, slight traction on the catheter could be employed, but the position of the catheter should be confirmed by CT or cystogram to rule out complete disruption. Additionally, high drain output should alert the surgeon to the possibility of ureteral injury. A cystogram can be performed before catheter removal to ensure resolution of the leak, although this is not required in all cases and some authors suggest that after RALRP, as long as the catheter is removed after postoperative day 8, there is little need to perform cystography.[22] In cases characterized by persistent urine leak, a ureteral injury or fistula should be considered as a potential source other than anastomotic leak. In this case cross-sectional urographic phase imaging can be of benefit. In cases of transperitoneal prostatectomy, anastomotic urine leak may contribute to prolonged ileus, which has been reported in approximately 3% of cases.[28] On rare occasions, a urine leak is suspected after catheter removal, on the basis of abdominal distention, ileus, or fever. The presence of intraperitoneal urine can result in an increase in serum creatinine level through reabsorption, but the effect on bowel function is difficult to measure. In approximately 0.4% of cases, urine leak has been seen to extend into the peritoneal cavity resulting in urinary ascites, occasionally requiring CT-guided drainage.[22] While even intraperitoneal leak can resolve with prolonged catherization, drainage of the peritoneal cavity should be considered if ascites is tense, ileus in profound, or secondary infection arises.

LYMPHOCELE

Pelvic lymph node dissection (PLND) during RALRP is thought to lead to increased cancer-specific survival for patients with both node-positive and node-negative disease. The appropriate extent of a lymph node dissection should be directly related to preoperative disease characteristics. Risk of complications such as lymphocele, obturator nerve injury (see above), deep vein thrombosis, and major vascular injury all increase when performing a standard and especially, extended, PLND. Contemporary reviews of PLND during RALRP have assessed that complications attributed to the PLND portion of the procedure range from 0% to 8%. Symptomatic lymphocele is the most common complication after PLND with an incidence of 0–7.9%, but it is thought that minor, subclinical lymphoceles are more common.[29]

The placement of a primary pelvic drain has traditionally been thought to reduce the incidence of symptomatic lymphocele. However, recent studies of patients who underwent robotic PLND show that the incidence of lymphocele does not increase when a pelvic drain is not placed.[30] Many recent studies have also assessed the use of hemostatic agents, ligation devices, and clips in preventing lymphocele creation. One study tested the ability of various energy devices to seal the thoracic duct in pigs and found that bipolar or ultrasonic devices were significantly superior in sealing the large lymphatic channel as compared to monopolar energy devices.[31] Hemostatic agents, although favorable in some studies, have been shown to only add minimal benefits, while adding significant cost. One author suggests that meticulous PLND coupled with the use of bipolar cautery with careful placement of hemostatic clips is sufficient for most experienced surgeons to prevent symptomatic lymphoceles from forming.[32] One novel technique of creating a "peritoneal interposition flap ... by rotating and advancing the peritoneum around the lateral surface of the ipsilateral bladder to the dependent portion of the pelvis and fixing it to the bladder itself" has recently been shown to greatly reduce the incidence of lymphocele formation.[33]

Treatment of lymphocele, discussed in detail in Chapter 40, is dependent on the lymphocele's size and location and whether the lymphocele is infected or symptomatic. Most lymphoceles decrease in size over time, precluding the need for intervention, but those that remain symptomatic usually require more invasive treatment. Percutaneous aspiration often resolves symptomatic lymphoceles without the need for prolonged drainage. In cases of symptomatic reaccumulation, percutaneous drain placement usually alleviates symptoms of pain, serves to drain any infected fluid, and also may decrease the incidence of late DVT. Drains with high output should remain in place until output decreases. However, prolonged high-output lymphoceles may have to be treated with a sclerosing agent such as iodine, alcohol, talc, bleomycin, or tetracycline, and fibrin sealants such as Tisseel. Sclerosis of a large cavity can lead to loculation, so its use should be reserved for high-output, prolonged leaks with a limited, well-drained cavity. In some cases, such as in loculated lymphoceles, another option is to perform a laparoscopic marsupialization of the lymphocele.[32]

URINARY TRACT AND WOUND INFECTION

Although urinary colonization is common following prostatectomy and the associated prolonged catheterization, symptomatic urinary tract infection (UTI) is, in general, not a significant or prevalent problem. According to a recent series of 1000 consecutive RALRP patients, no patients developed a clinically significant urinary tract infection.[34] The risk of perioperative urinary tract infection can be minimized through numerous measures, including the use of appropriate antibiotics preoperatively, early cessation of therapy postoperatively to reduce the risk of selective resistance and *Clostridium difficile* infection, the use of silver-lined antibacterial catheters, and appropriate catheter care during the early postoperative period. Some physicians also prescribe a single or short antibiotic course at the time of catheter removal. In a series of 729 patients who underwent laparoscopic radical prostatectomy, patients who took antibiotics around the time of catheter removal were less likely to develop a UTI (3.1%) as compared to patients who did not take antibiotics (7.3%).[35]

Postoperative wound infection is another uncommon infectious complication of RALRP. In a series of 1000 consecutive RALRP patients, 0.4% developed a wound infection.[34] Contributing factors include suboptimal skin preparation, inadequate sterile surgical technique, prolonged length of operation, suboptimal timing of preoperative antibiotic

administration, incorrect selection of antibiotic coverage, surgical treatment in the setting of active infection or colonization, rectal or bowel injury, and lack of wound irrigation before skin closure.

THROMBOEMBOLIC COMPLICATIONS

The rate of clinically significant venous thromboembolic events (VTEs) has been very low in large RALRP series. For example, in one series of 5951 RALRP patients, the rate of thromboembolic complications was only 0.5%. This found that current smoking, longer operative time, and larger prostate volume were independent risk factors for developing a VTE.[36] Another group found that patients who underwent pelvic lymphadenectomy during RALRP had a significantly higher risk of developing DVT or PE (RR = 7.80 for DVT; RR = 6.29 for PE).[37] Despite the associated risks of pelvic surgery and relative venous stasis secondary to laparoscopic insufflation and increased intracavitary pressure, deep vein thrombosis actually appears to be less common than in the open approach. A study of 94,709 men who underwent either open RP or RALRP found that the comparative odds ratio of developing a VTE was 0.61 (95%, CI 0.45–0.99) for men who underwent RALRP.

There is some controversy regarding the use of periprocedural heparin for the prevention of VTE. The above study of 94,709 men found that patients who received DVT prophylaxis (either mechanical, pharmacologic, or both) were less likely to develop a VTE (OR = 0.67; CI 0.50–0.88).[38] Two studies that compared the use of sequential compression devices (SCDs) alone versus SCDs and heparin found that there was no difference in the rate of VTE between the two groups.[39,40] We have routinely utilized perioperative subcutaneous heparin starting prior to induction, along with SCDs, in our prostatectomy patients, which is discontinued prior to discharge. The management of DVT is discussed in detail in Chapter 4.

PORT SITE HERNIA

Port site hernia is a relatively uncommon complication after laparoscopic surgeries in general, occurring approximately 1% of the time. Most surgeons advocate for port sites >10 mm, located below the arcuate line, to be closed to prevent postoperative small bowel entrapment and herniation during a transperitoneal approach. One study of 498 patients who all underwent RALRP with six port sites (two 12-mm, three 8-mm, and one 5-mm) found that after only closing the 12-mm ports, the incidence of port site hernia was 0.4%.[41]

Bowel herniation from a port site can be prevented by visual inspection of the port entry site and fascia closure before removal of the final camera port. We have pre-placed figure-of-eight closure sutures, at the time of port insertion, to be tied down upon trocar extraction, using an endoscopic stitching device. The Carter-Thomason suturing device is useful for placing simple and figure-of-eight fascial sutures. Many companies have recently come out with newer devices to aid in port site closure. For example, the WECK EFx Endo Fascial Closure System[42] allows for a reproducible closure. One study compared the Carter-Thomason closure device to the WECK EFx system in cadavers. They found that the EFx was superior in terms of time needed to close the defect, safety, and facility, while the Carter-Thomason device was superior in terms of maintaining pneumoperitoneum.[43] A meta-analysis of skin adhesives versus sutures in closure of laparoscopic port site wounds found that skin adhesives were associated with fewer wound infections and less wound dehiscence in addition to higher patient satisfaction.[44]

If bowel does become entrapped in a port site, laparoscopy should be performed with concomitant external manual reduction of the bowel loop. The portion of bowel in question should then be examined, and if it is not viable, bowel resection may be required. When an extraperitoneal approach is used, ports generally do not require fascial closure because intraperitoneal contents are contained within the peritoneum and are therefore not able to herniate through the port sites. The central incision, which is typically extended for retrieval of the specimen, should be closed with care to ensure adequate suture strength and fascial apposition to prevent fascial dehiscence.

Late Postoperative Consequences

Functional complications and oncologic outcomes following laparoscopic robotic-assisted prostatectomy are of particular interest to most surgeons and patients, but they are more difficult to interpret given the variability in reporting methods, the absence of large multicenter datasets, and the poor compliance with long-term follow-up. Nonetheless, emerging data indicate that late postoperative consequences after RALRP such as urinary incontinence and erectile dysfunction are at least equivalent to open RP, if not slightly better. Perhaps intuitively, surgeon-related factors appear to be more important than are patient-related factors. Although complications may or may not vary according to approach (transperitoneal versus extraperitoneal) [45] or other important clinical factors, such as body mass index,[46,47] the experience of the surgeon appears to be a principal determinant of the likelihood of postoperative complications, as RALRP has been consistently shown to have a long learning curve.[48–50]

INCONTINENCE

Most series have reported favorable recovery of urinary continence. Early reports from experienced groups reported 12-month incontinence in 1% of cases[51] whereas others reported return to baseline urinary function in >70% of cases and subjective continence in 90% of cases using more standard assessment methods.[52] More recent series show similar outcomes. One series of 2625 patients reported 78.7% continence rates at 1 year.[53] Another group that recently studied over 4000 patients found that continence rates 1 year after RALRP decreased from 95.1% to 85.6%, 87.8%, and 85.8% in the setting of age ≥70, BMI ≥35, and prostate weight ≥80 g, respectively. Continence at 1 year after salvage RALRP was found to be 51.3%.[54]

When directly compared to the open approach in terms of continence rates at 1 year, the adjusted odds ratio was 1.08 in favor of the RALRP group, although this was not

significant.[53] Another study of one experienced surgeon who performed 1552 consecutive RALRPs or ORPs found that continence scores for RALRP surpassed ORP after the surgeon's 182nd case, suggesting a fairly long learning curve for achieving similar function outcomes.[55]

Many groups have assessed various techniques with the goal of achieving early recovery of urinary continence, including posterior plication, anchoring the detrusor apron of the bladder to the rectourethralis, and dorsal venous complex suspension to the pubic periosteum. One study, for example, describes 252 patients who underwent the total anatomic reconstruction (TAR) technique and showed a continence rate of 98% at 24 weeks post RALRP.[56] Another group compared various reconstruction techniques in a smaller group of patients and concluded that a maximal urethral length preservation (MULP) technique led to statistically significant increases in urinary continence at 1, 3, and 6 months post RALRP.[57]

IMPOTENCE

Recovery of sexual function appears to be more variable and, as reported in open series, more problematic. In one RALRP meta-analysis, 12 and 24 month potency rates ranged from 54% to 90% and from 63% to 94%, respectively. The same study compared potency rates in RALRP versus ORP patients and found an odds ratio of 2.84 favoring RALRP patients for 12-month potency rates.[58] In the aforementioned series of 2625 patients, 70.4% of patients still had some form of erectile dysfunction 12 months following RALRP. This was similar to the ORP group that had a 74.7% erectile dysfunction rate at 12 months.[53]

One group retrospectively studied the potency outcomes of men who underwent RALRP with or without countertraction being placed on the neurovascular bundle. They found a significant increase in potency rates at 6 months when the surgeon used no countertraction, but no differences were observed at 12 months.[59] Another group analyzed erectile function after bilateral nerve-sparing RALRP, which employed an antegrade nerve-sparing approach in 172 patients versus a retrograde approach also in 172 patients. They found that the retrograde approach was associated with increased potency at 3, 6, and 9 months when compared to the antegrade approach, with no change in positive margin rates or continence.[60] As noted earlier, we have routinely employed a technique of retrograde nerve sparing in which little to no traction is placed on the nerve bundle (see Figs. 32.1–32.3).

ONCOLOGIC OUTCOMES

Cancer control following RALRP, as measured by proportion of positive margin, biochemical recurrence, and disease progression, has been shown to be equivalent to, if not better than, ORP. A large contemporary series of 483 consecutive RALRP patients showed biochemical recurrence-free survival, metastasis-free survival, and cancer-specific survival of 73.1%, 97.5%, and 98.8%, respectively at 10 years' follow-up.[61] Another group assessed biochemical recurrence-free survival in 282 RALRP patients and 621 ORP patients across many academic centers and found no difference at 3- or 5-year follow-up periods (HR = 0.98).[62] A third study performed a retrospective analysis of 669 RALRP patients and 357 ORP patients, all of whom had their surgery and pathology analysis performed by the same surgeon and pathologist. Their overall positive margin rates were statistically similar, 18% for RRP and 14% for RALRP. RALRP patients also had lower, although statistically similar, positive margin rates when they analyzed only patients with extraprostatic disease (26.9% vs 35.6%) or men who underwent bilateral nerve-sparing procedures (8% vs 12%).[63] A population-level study used propensity-score matching to compare oncologic outcomes in 13,000 patients using SEER-Medicare data. It found that RALRP patients had statistically lower positive margin rate when compared to the ORP group (13.6% vs 18.3%, HR 0.70; $p < 0.001$), and that RALRP patients had a statistically smaller chance of undergoing additional oncologic-related therapy after surgery (OR = 0.75).[64] In general, given the paucity of randomized comparative data proving superiority of RALRP over ORP, it can be safely assumed that oncologic control is at least equivalent.

Since most positive margins after RALRP have been found at the apical and posterolateral dissection plains, some authors have described techniques that are supposed to decrease positive margin rates at these areas. One author described a technique that employs cranial traction and a 30-degree lens during the apical dissection and found that this decreased the overall positive margin rate by 3%.[65]

Chapter 32 Questions

1. During the course of robotic-assisted laparoscopic radical prostatectomy, brisk bleeding is noted from division of the dorsal vein. The next step is:
   a. Increase suction to improve vision
   b. Increase insufflation pressure
   c. Attempt to staple the dorsal vein stump
   d. Infrapubic cut down to suture dorsal vein
   e. Open conversion

2. The most common site of major vascular injury during blind trocar insertion is:
   a. Superior vesical pedicle
   b. Vena cava
   c. Aorta/common iliac artery
   d. Hypogastric artery
   e. External iliac vein

3. Unrecognized bowel injury during robotic-assisted laparoscopic radical prostatectomy is most likely to occur due to:
   a. Thermal arc
   b. Excessive traction on the bowel during dissection
   c. Lysis of adhesions
   d. Movement of instrumentation outside the visual field
   e. Trocar injury

4. Prolonged postoperative bleeding resulting in significant ecchymosis of the flanks and inguinal crease most often is the result of bleeding arising from the:
   a. Dorsal vein complex
   b. Iliac vein or tributaries
   c. Superior vesical pedicle
   d. Abdominal wall vessels
   e. Bowel mesentery

5. In patients with rectal injury incurred during radical prostatectomy, colostomy need not be performed in all patients with:
   a. Rectal injury >4 cm
   b. Devitalized rectal wall
   c. Previous radiation therapy
   d. Large amounts of fecal soiling
   e. Thermal injury

6. Following an uncomplicated robotic-assisted radical prostatectomy, large-volume drain output is noted. Chemical evaluation of drainage is consistent with urine. The urethral catheter is draining and irrigating well. The next step is:
   a. Observation
   b. Place larger urethral catheter
   c. Place suprapubic catheter
   d. CT urogram
   e. Cystogram

7. Three weeks following robotic-assisted laparoscopic radical prostatectomy, a 62-year-old man presents with left lower extremity swelling, amd pain on ambulation and adduction. Imaging demonstrates a 12-cm, multi-loculated fluid collection in the left iliac fossa, compressing the left iliac vein. Venous duplex demonstrates no evidence of deep venous thrombosis. The next step is:
   a. Bed rest, leg elevation
   b. Percutaneous aspiration
   c. Percutaneous drain placement
   d. Drainage and sclerosis
   e. Laparoscopic marsupialization

8. An absolute contraindication to robotic-assisted laparoscopic radical prostatectomy (RALRP) is:
   a. Previous intraabdominal surgery
   b. Renal transplant
   c. Obesity, with BMI >35
   d. Inability to tolerate Trendelenburg position
   e. Abdominal wall mesh

9. During robotic-assisted laparoscopic radical prostatectomy, the dorsal venous complex is divided. Moderate bleeding is encountered and the insufflation pressure is increased. The patient's oxygen saturation drops, end-tidal CO_2 increases, and blood pressure precipitously drops as well. The next step is:
   a. Undock and reduce Trendelenburg position
   b. Increase insufflation pressure and complete venous repair
   c. Desufflate and increase ventilatory pressure
   d. Desufflate and place in left lateral decubitus position
   e. Convert to an open procedure

10. In positioning a patient in the supine Trendelenburg position for RALRP, support is needed to prevent injury of the:
    a. Cervical spine
    b. Peroneal nerve
    c. Gluteal muscle compartment
    d. Brachial plexus
    e. Calf muscles

Case Study 1

A 70-year-old male undergoes an uncomplicated robotic-assisted laparoscopic radical prostatectomy. Following surgery, his pelvic drain is noted to have an overnight output of 350 mL of serosanguinous fluid. His urethral catheter has an output of 300 mL. The following morning, his drain output persists.

1. The next step is:
   a. To check creatinine level from drain
   b. A cystogram
   c. A pelvic ultrasound
   d. A CT urogram
   e. To irrigate catheter and observe

2. A drain creatinine level is noted to be 35 mg/dL, consistent with urine. The next step is:
   a. Continued catheter drainage
   b. Suprapubic catheter insertion

c. A CT urogram
d. A pelvic ultrasound
e. A cystogram

3. The patient is observed for 3 days without improvement in the volume of his pelvic drainage. A repeat creatinine level from the pelvic drain is 38 mg/dL, consistent with urine.The next step is:
   a. Continued catheter drainage
   b. Suprapubic catheter insertion
   c. A CT urogram
   d. A pelvic ultrasound
   e. A cystogram

Case Study 2

A 63-year-old man undergoes a radical prostatectomy by robotic-assisted laparoscopic approach. The dorsal venous complex is sharply incised, following bladder neck division and prostate mobilization, without suture control prior to incision. Brisk bleeding is encountered, precluding vision.

1. The next step is:
   a. To blindly cut toward the urethra to complete division of the dorsal vein
   b. To insert a second suction device to improve exposure
   c. To increase insufflation pressure
   d. To pack the region and proceed with urethral division
   e. Open conversion

2. After increasing insufflation pressure, sufficient vision is obtained to complete the division of the dorsal vein complex. The prostatectomy is completed after oversewing a number of small bleeding sites in the surgical bed. Following surgery, the patient is noted to be oliguric, requiring several fluid boluses overnight. He is mildly tachycardic with normal blood pressure. His hemoglobin has declined from 13.2 g/dL to 8.9 g/dL overnight. The next step is:
   a. Continued observation
   b. Transfusion, bed rest, serial hemoglobin check
   c. A renal ultrasound
   d. A pelvic CT
   e. Transfusion and re-exploration

3. The most likely source of bleeding is:
   a. Dorsal venous complex
   b. Seminal vesical arteries
   c. Abdominal wall vessels
   d. Neurovascular bundles
   e. Iliac vessel tributaries

Answers

1. **b.** Increasing suction in the face of bleeding will secondarily lower insufflation pressure, thereby increasing bleeding. An increase in insufflation pressure may reduce bleeding enough to visualize the dorsal venous complex, allow completion of division, and allow suture control. Stapling of the dorsal vein complex is ideally performed prior to division. Upon division, it would likely not be feasible to staple the complex. Open conversion of any sort would only be a last resort, if attempts at control of bleeding were unsuccessful.
2. **c.** The aorta and its bifurcation lie directly beneath the umbilical position in most patients and are most likely to be injured during blind port insertion in the typical periumbilical position.
3. **d.** While all the choices reflect potential sources for injury to the bowel, movement of instrumentation, either by the surgeon or the assistant, outside the visual field is most likely to result in an unrecognized injury to the bowel. Careful inspection of the operative field prior to removal of the scope is always wise at the end of each case.
4. **d.** While postoperative bleeding can arise from the iliac vessels or a poorly controlled dorsal vein complex, such bleeding is more likely to result in profound early bleeding, requiring eventual return to OR due to hemodynamic instability. Significant bleeding that does not result in hemodynamic instability, but causes continued decline in hematocrit and abdominal wall ecchymosis, is most likely to arise from the abdominal wall vessels.
5. **e.** While colostomy could be considered in patients with thermal injury to the rectum, it need not be performed as routine, depending upon the size and severity of the injury. Excessive thermal injury may result in devitalized rectal wall, and because this can be difficult to determine, if there is any suspicion based upon the severity of the injury, colostomy might be considered. The remaining choices are all absolute indications for general surgical consultation and colostomy.
6. **a.** In this patient with early postoperative evidence of a urethrovesical anastomotic leak, observation is the most reasonable initial approach. As long as the catheter is draining and well positioned, most controlled leaks will resolve with time. If the leak were to persist or if the patient were to develop further complications such as infection, ileus, or ascites, further evaluation might be warranted.
7. **e.** The patient appears to have a loculated lymphocele that is relatively large and symptomatic. While aspiration or prolonged drainage may alleviate some symptoms, the loculated nature of the collection makes it unlikely that full drainage would be achieved. In this case, marsupialization of the lymphocele would offer the greatest likelihood of durable resolution.
8. **d.** While the remaining choices are relative contraindications to RALRP, the ability to proceed with surgery in these individual scenarios is often dependent upon the surgeon's comfort level and experience. Morbid obesity may lead to an inability to tolerate positioning or access the pelvis upon docking of the robot, but many obese patients can undergo RALRP without a problem. Inability to tolerate Trendelenburg position precludes the ability to successfully proceed with RALRP as the position is largely essential.
9. **d.** The clinical scenario is most consistent with a gas embolus from the insufflation. Increasing insufflation pressures in the face of bleeding may improve vision, but also increases the risk of advancing CO_2 into the venous system. In these cases, immediate desufflation and placement of the patient in the left lateral

decubitus position are desirable. In extreme cases, aspiration of the embolus may be needed, but in general, CO_2 is quickly absorbed.

10. **d.** While injury can occur to any region of the body during positioning, while in the supine position for RALRP, injury to the calf or peroneal nerve is unlikely. The cervical spine should be supported, but undue stretch or twist of the neck is not as great a risk as stretch on the brachial plexus through inadequate or excessive support of the shoulders.

CASE STUDY 1

1. **a.** Increased drain output following robotic-assisted laparoscopic radical prostatectomy can be representative of urine, lymphatic fluid, or peritoneal ascites. Testing for serum creatinine will rule out, or in, a urine leak. While this may not require intervention, it will aide in determining if the drain can be removed.
2. **a.** Most urine leaks in the early postoperative period after robotic-assisted radical prostatectomy can by treated conservatively with catheter drainage. Ultrasound to rule out urinoma and adequate extravesical drainage can be useful if the drain persists beyond the first 7–10 days. Most often, urine leaks will resolve within 1–3 days with adequate drainage. Increasing abdominal distention, fever, or ileus should alert the physician to the possibility of urinary ascites. In some cases, ascites may require additional drainage to reduce related morbidity.
3. **c.** Persistent urinary leakage following radical prostatectomy should caution the managing physician with regard to the possibility of a ureteral injury. While cystogram may demonstrate the extent of urine leak from the bladder, it would not rule out a ureteral injury. CT urogram with delayed sequences is likely to demonstrate any ureteral injury, hydronephrosis, bladder leak, and extravesical urine collections.

CASE STUDY 2

1. **a.** Bleeding from the uncontrolled dorsal venous complex is exacerbated by stretch due to fixation of the complex. This is commonly encountered upon incomplete division of the dorsal venous complex. Increasing suction secondarily lowers insufflation pressure, thereby increasing bleeding. Increasing insufflation can aid with vision, to allow completion of the dorsal vein division. Complete division will likely greatly reduce bleeding in most cases. Caution should be exerted upon increasing insufflation pressure due to the theoretical risk of air embolus. Open conversion would likely only worsen bleeding upon loss of insufflation.
2. **b.** Postoperative bleeding following robotic-assisted laparoscopic prostatectomy, which does not cause hemodynamic instability, generally is self limited and will stop with supportive care, though considerable blood loss can occur prior to cessation. In most cases, pelvic CT will demonstrate blood in the pelvis and subcutaneous tissues, but will not aid in management. If the patient becomes unstable or bleeding persists for more than 1–2 days with supportive care, angiography or re-exploration may be warranted.
3. **c.** Postoperative bleeding following robotic-assisted laparoscopic prostatectomy, which does not cause hemodynamic instability, is most often caused by abdominal wall bleeding from the underlying muscle and branches of the epigastric vasculature.

33 Complications of Robotic Pelvic Floor Reconstruction

NIRIT ROSENBLUM and DOMINIQUE MALACARNE

CHAPTER OUTLINE

Preoperative Considerations
Patient Positioning and Surgical Setup
Intraoperative Complications
Bowel Complications
Hemorrhagic Complications
Urologic Complications
Vaginal Complications
Postoperative Complications
Infectious Complications
Thromboembolic Complications
Bowel Complications
Complications Related to Synthetic Mesh
De Novo Incontinence
Conclusions
Chaper 33 Questions and Answers

KEY POINTS

1. Pre-operative risk stratification for robotic pelvic floor reconstruction should be focused on pulmonary compromise, uterine enlargement or pelvic adhesions, and sacral anomalies such as a horseshoe kidney or sacral bony abnormality in order to minimize operative complications of robotic sacrocolpopexy.
2. Pre-operative assessment of clinical or occult stress urinary incontinence enables the pelvic floor surgeon to properly counsel the patient regarding options for concurrent incontinence procedures at the time of robotic sacrocolpopexy, in order to decrease the risk of post-operative persistent or *de novo* urinary incontinence.
3. Proper patient positioning for robotic pelvic floor surgery includes attention to Trendelenburg and its potential to cause nerve injury, retinal injury and pulmonary compromise. Anti-skid techniques should be employed to avoid inadvertent patient movement after robot docking.
4. Pre-sacral hemorrhage is the most significant and potentially life-threatening complication associated with sacrocolpopexy. Meticulous attention during sacral dissection must be carried out with particular knowledge of aberrant sacral vasculature. The most common site of vascular injury is the left common iliac vein and its appearance can be distorted by the pneumoperitoneum, often mistaken for the anterior longitudinal ligament.
5. Intra-operative pre-sacral hemorrhage is often difficult to control with pressure, topical hemostatic agents or materials and generally requires conversion to open with vascular surgery assistance. It is imperative to maintain local pressure on the site of sacral bleeding while conversion is undertaken, initially utilizing the robotic arm followed by a laparoscopic instrument. Communication with anesthesia and nursing staff is imperative during the conversion process in addition to preparation of blood products.
6. Cystotomy during robotic sacrocolpopexy can be avoided by placement of a vaginal manipulator such as a sponge-stick, EEA sizer or vaginal stent to facilitate dissection in the proper plane between the anterior vaginal wall and bladder. Cystoscopy is imperative at the completion of the robotic pelvic floor procedure to ensure there has been no injury to the bladder or ureters.
7. Bowel dysfunction is a common post-operative complaint following robotic pelvic floor reconstruction. Dyschezia, obstructed defecation and constipation re the most common types. The average time to first bowel movement post-operatively is 3 days and patients should be made aware of this expectation.
8. While rare, post-operative infection of the disc or sacral bone can occur and be both severe and potentially life-threatening. Severe back pain accompanied by fever or signs of sepsis should prompt immediate lumbosacral imaging. When placing sacral sutures, the surgeon must avoid the L5-S1 disc space and the depth of sutures in the anterior longitudinal ligament should not exceed 2–3 mm.

As the life expectancy of the population continues to increase, so does the prevalence of medical conditions associated with advancements of age. Pelvic organ prolapse (POP) is a common condition associated with aging, menopause, and prior pregnancy and delivery. Surgical repair of POP is currently the most common type of inpatient procedure performed in women older than 70 years,[1] and the incidence of procedures for this condition will continue to increase.

The abdominal sacrocolpopexy is regarded as the "gold standard" procedure for correcting symptomatic pelvic organ prolapse.[2] In many patients, minimally invasive routes of sacrocolpopexy and other gynecologic procedures are preferred[3,4] and offer advantages both for the patient and the surgeon. Minimally invasive sacrocolpopexy has been compared with the abdominal approach in various studies and has proven to be as efficacious and safe, with the added benefit of decreased morbidity.[5–7] More recently, two level 1 studies have been published comparing abdominal sacrocolpopexy with a minimally invasive approach. Both trials reveal comparative outcomes between the groups and illustrate that the minimally invasive approach is associated with decreased morbidity, less blood loss, shorter length of stay, dand overall decreased recovery time.[8,9] These data support the use of minimally invasive surgical approaches to sacrocolpopexy and other POP procedures.

With minimally invasive surgery comes a unique set of perioperative considerations, counseling topics, and both intraoperative and postoperative complications. Surgeons should be aware of these unique components of minimally invasive surgery and should understand ways to minimize potential obstacles whenever possible. This chapter aims to highlight the potential perioperative complications unique to robotic female pelvic surgery and to discuss how to safely handle these problems should they arise.

Preoperative Considerations

When determining surgical candidacy for robotic reconstructive pelvic surgery, the surgeon must gather critical information during the office evaluation (Table 33.1). It is imperative to focus the history and physical exam around factors that could increase the risk of complications unique to robotic surgery. When considering a laparoscopic or robotic approach, the medical history should include questions about the patient's exercise tolerance, smoking history, presence of cardiopulmonary or chronic renal conditions, and history of prior pelvic surgeries. The surgeon should have a good understanding of the hemodynamic and metabolic effects of intraabdominal CO_2 insufflation on individuals with these conditions. Potential contraindications to laparoscopic or robotic surgery such as an increase in intracranial pressure or baseline hypovolemic state should be contemplated, especially when the operative time may be prolonged. Patients with pulmonary compromise should be particularly counseled on possible conversion to laparotomy if the degree of physiologic strain, such as impairment of pulmonary functional residual capacity, becomes intolerable to the patient during surgery.[10] It is well documented that patients benefit from smoking cessation prior to surgery, and encouraging patients to stop smoking within 8 weeks of surgery can be beneficial. Studies demonstrate improvements in respiratory function and lower risks of postoperative atelectasis and aspiration pneumonia, known risks associated with the inability to tolerate pneumoperitoneum or steep Trendelenberg positioning.[11] While research indicates that pulmonary complications after laparoscopy may be lower than those associated with laparotomy, surgeons should be aware of the specific risks in patients with cardiopulmonary comorbidities, such as chronic obstructive pulmonary disease. Pulmonary complication risk is also found to correlate with older age and longer

Table 33.1 Preoperative Considerations in Robotic Pelvic Floor Reconstruction

Patient History and Physical Exam	■ Thorough assessment of tolerance of abdominal insufflation/Trendelenberg positioning:
	  ■ Smoking history, exercise tolerance, obesity
	  ■ Cardiopulmonary/renal disease
	  ■ Increased ICP
	  ■ Hypovolemic state
	■ Abdominal survey for scars, hernias, and understanding of prior pelvic surgeries, anatomic variants
	■ Uterine mobility, adnexal mass:
	  ■ Lateral mobility ≥2 cm for uterine vessel access
	■ Gentle preoperative bowel prep only when deemed necessary (surgeon preference):
	  ■ Mg citrate, Miralax

Patient Positioning and Surgical Setup	■ Proper use of corporeal padding
	■ Joint flexion at maximum angle of 30 degrees
	■ Anti-skid materials to decrease risk of nerve injury:
	  ■ Pink pad, egg crate, surgical beanbag
	■ Facial padding, eye taping to reduce facial injury:
	  ■ Direct facial trauma responsible for 20% of corneal abrasions
	■ Be mindful of degree of Trendelenberg positioning absolutely necessary:
	  ■ Less steep degree may decrease morbidity without negative effects on surgical time, visibility (Ghomi et al.):
	■ 30-degree camera for optimal sacral visualization:
	  ■ If distance from umbilicus to pubic symphysis <15 cm, camera port should be supraumbilical
	■ Direct visualization and abdominal survey during trocar insertion:
	  ■ Port site bleeding most commonly from perforation of inferior epigastric artery
	  ■ 55% of bowel perforations occur during intraabdominal access
	■ Use of 8-mm or 5-mm accessory port to decrease hernia risk

operative time.[12] These factors should be taken into consideration when deciding upon the route of pelvic reconstructive surgery.

The physical exam should include assessment of abdominal scars and the presence of any abdominal hernias, particularly if a patient has had multiple prior abdominal surgeries. This will allow for anticipation of potential difficulties with port placement and pelvic adhesive disease when planning a robotic surgical approach. Particular attention should be paid to umbilical hernia as the umbilicus is often utilized as a port site during robotic surgery. Additionally, a bimanual pelvic evaluation to assess uterine mobility and size is necessary. One should attempt to palpate the width of the lower uterine segment (LUS) at its junction with the cervix and assess degree of movement of this segment toward the contralateral pelvic sidewall. In general, lateral mobility of 2 cm or more on each side predicts adequate access to uterine vessels laparoscopically. The presence of obstructing fibroids or pelvic adhesions should also be considered, as these characteristics can limit uterine mobility and preclude successful minimally invasive pelvic surgery. Placing cephalad pressure on the LUS and attempting to elevate the uterus out of the lower pelvis can help with understanding of circumferential space that is present. This technique may be inhibited by patient body habitus. At times, pelvic imaging may be necessary to adequately assess uterine size and other pelvic pathology that may make laparoscopy more difficult.

Obesity itself should not preclude minimally invasive surgery; however, it can make a laparoscopic or robotic approach to pelvic surgery more challenging due to the impact of this condition on both respiratory and gastrointestinal mechanics. Obese patients, particularly with a BMI >40, are prone to poor gas exchange and delayed gastric emptying, increasing the risk of impaired respiratory function and aspiration during and after surgery. Obesity also is commonly associated with increased central adiposity, which can preclude optimal patient positioning, trocar placement, and visualization intraoperatively.[13,14] It is imperative to consider these risk factors when counseling patients on minimally invasive surgery, and extra time should be allotted perioperatively to ensure optimization of patient positioning.

The surgeon should inquire about any known anomalies of pelvic anatomy. Anatomic variances such as a horseshoe kidney, transplant kidney, or any sacral anomalies could make robotic sacrocolpopexy more difficult or contraindicated. Knowledge of these potential structural alterations should prompt adequate imaging to obtain a clearer understanding of any variations or abnormalities in pelvic anatomy. Surgeons can then plan for any required modifications in instrument placement or surgical technique when performing pelvic surgery.

Screening for stress incontinence is pertinent when performing any prolapse procedure, and if present, discussion of a possible concomitant anti-incontinence procedure is needed. The surgeon should take into account the risks and benefits of added operative time with concomitant procedures and the potential complications this could pose. Conversely, even without the presence of stress incontinence, the possibility of de novo stress incontinence following sacrocolpopexy should be discussed. Ideally, patients should be screened for occult stress incontinence with prolapse reduction preoperatively to allow for proper counseling and surgical planning. Management of expectations is critical, and patients should be made aware that midurethral sling placement at the time of minimally invasive sacrocolpopexy may be associated with lower incontinence cure rates, when compared to sling surgery alone.[15]

Traditionally, preoperative mechanical bowel preparation (MBP) has been used as a way to enhance visualization of the surgical field and improve intraoperative bowel handling. In theory, this practice leads to a decreased incidence of bowel injury and lowers minimally invasive operative times. More specifically, bowel preparation can facilitate sacral visualization during robotic sacrocolpopexy. Recently there has been evidence in the literature refuting the necessity of mechanical bowel preparation in minimally invasive surgery in gynecology.[16,17] In a recent systematic review of high quality trials across surgical specialties, there were no or few benefits of MBP or rectal enemas and no negative effects on perioperative outcomes were reported.[18] These data should prompt surgeons to contemplate the risk and benefit of MBP when performing minimally invasive prolapse surgery. In surgical procedures where this practice seems beneficial, preparations using magnesium citrate or Miralax combined with 64 oz of Gatorade appear to be the best tolerated.[17] We routinely recommend a modified mechanical bowel preparation preoperatively to enhance pelvic visualization during robotic surgery, minimize the need for bowel manipulation intraoperatively, and improve postoperative return to bowel function. We utilize a clear liquid diet the day before surgery as well as one bottle of magnesium citrate and two doses of oral bisacodyl.

Patient Positioning and Surgical Setup

Intraoperatively there are many techniques that can be adopted to allow a surgeon to decrease the risk of complications when performing robotic pelvic reconstructive surgery (see Table 33.1). It is critical to maintain constant communication between the anesthesia and surgical teams when choosing the most appropriate operating room setup, as each case may require adaptations to the arrangement of room layout, instrument choice, and other ergonomic considerations. For both laparoscopic and robotic-assisted prolapse repair, proper patient positioning is imperative to sustain optimal surgical exposure and prevent neuromuscular compromise. One obvious concern with these surgical techniques is sliding of the patient on the operating table during steep Trendelenburg positioning. This can result in skin breakdown and neuropathic injuries, as well as incisional extensions and formation of hernias through port sites due to the overstretching caused by incidental changes in patient position. Nerve injury is increased in obese patients, who most commonly suffer from ulnar and sciatic neuropathies.[14] The surgeon should ensure proper corporeal padding of both upper and lower extremities. The knees should be flexed at a maximum angle of 60 degrees when patients are placed in dorsal lithotomy position. Any greater flexion increases the risk for femoral nerve compression. Arms should be tucked at the patient's side, and all pressure points should be adequately protected. Leaving the arms

extended or the use of shoulder blocks can increase the risk of brachial plexus injury, and these practices should be avoided.[19] Recent evidence illustrates that use of anti-skid materials such as egg crates, surgical beanbags, or gel pads minimizes the risk of shifting and therefore decreases the potential for nerve stretch injuries, even in patients with a BMI >30.[20] After the anti-skid material is placed on the operating table, the patient should be placed directly on this material without intervening bedsheets. This direct contact allows for optimal drag coefficient to keep the patient from slipping and is very effective for steep Trendelenburg positioning during pelvic reconstructive surgery.

The risk of facial trauma and corneal abrasions should also be considered, especially when performing robotic surgery. The patient's face can be in close proximity to the robotic camera system and instruments, especially when port sites are placed superior to the umbilicus or when using a 30-degree down scope in steep Trendelenburg position. In these instances the robotic camera system may be only a few centimeters away from the face, and facemasks or adhesive eye shields should be used to protect from facial trauma. Direct trauma is known to be the cause of up to 20% of corneal abrasions, and most are thought to be due to lagopthalmos, or failure of complete eyelid closure.[21] To protect this perioperative complication, the eyes can be taped closed after induction of anesthesia. It is important to consider these potential adverse events and discuss ways to minimize risk with the anesthesia team.

Whether performing laparoscopy or robotic-assisted pelvic surgery, the utilization of Trendelenburg positioning is traditionally noted to be essential to achieve adequate pelvic and sacral exposure. Compared with traditional laparoscopy, robotic surgery has been associated with the use of more pronounced Trendelenburg positioning. Although there is no consensus in the medical literature as to the appropriate amount of Trendelenburg used in pelvic surgery, experts have routinely called for "steep" Trendelenburg positioning, usually categorized as 25 to 45 degrees. While this has long been the routine positioning of patients undergoing robotic pelvic surgery, recent data have suggested that gynecologic surgeries can be effectively performed without use of this steep angle positioning, which is often associated with increased morbidity, especially in the elderly or obese populations. In a recent article by Ghomi et al., 20 women underwent robotic-assisted gynecologic surgery for benign disease. The procedures included total and supracervical hysterectomy as well as sacrocolpopexy. Surgeons were blinded to the degree of Trendelenburg used, but were instructed to choose the degree of positioning that would allow them to obtain adequate exposure of the surgical field. Degree of Trendelenburg was measured at the end of each case and results revealed the mean Trendelenburg position used was 16.4 degrees and no patient was placed further than 24 degrees. There were no incidences of conversion, no perioperative complications, and average BMI was 28.5, while median console time was 87.5 minutes.[22] Though the only study of its kind, these data defy the practice of routine adherence to steep Trendelenburg positioning if not absolutely necessary and surgeons should take care to individualize patient positioning for each case in order to minimize complications associated with a considerable degree of Trendelenburg placement. Extra caution should be taken in any patient with retinal disease or prior retinal surgery, as Trendelenburg positioning has been associated with retinal complications in some reports.

Having a clear understanding of abdominal wall anatomy is crucial for proper port site placement, in order to avoid vessel injury during this portion of the case. Both robotic and laparoscopic ports are generally placed in either a W configuration or in a straight line, a minimum length of 10 cm apart, to allow for adequate space and optimal utilization of all ports and to minimize arm collisions. To optimize visualization of the sacral promontory, the camera port should be placed above the umbilicus if the distance from the umbilicus to the pubic symphysis is less than 15 cm. The use of a 30-degree (up) robotic camera to place the four additional ports is often helpful to adequately evaluate the pelvis for any intrusive adhesions and also to position ports properly and ensure avoidance of epigastric vessels. Port site bleeding is noted to occur at an incidence of about 0.7%,[23] and the origin is most commonly due to perforation of the inferior epigastric artery. If perforation does occur it is best to leave the offending trocar in place to denote the location of the injured vessel. If each end of the transected vessel can be identified, cauterization of both ends using bipolar cautery should be attempted. If this is not successful, the method of tamponade using a Foley catheter can be used. A size 10 or 12Fr Foley catheter should be introduced through the 5-mm trocar and inflated with approximately 10–15 mL of sterile water. The trocar is removed only once the balloon has been inflated, and then traction should be applied to allow the balloon to tamponade the port site.[24] Clamping the catheter on steady traction with use of an umbilical clamp or hemostat is helpful, and this can be left in position postoperatively if necessary, until hemostasis is achieved. If neither of these methods will stop port site bleeding, interrupted 0-Vicryl sutures can be placed into the abdominal wall using a CT or CT-1 needle. One suture should be placed on either side of the trocar site and tied externally. These sutures can be removed after 12–24 hours of observation, and the trocar should be left in place during this time.

The use of an 8-mm accessory port is our preference, as the literature reveals a smaller accessory port results in less postoperative pain and decreased risk of port sight hernias when compared to larger accessory ports. In a survey conducted by the American Association of Gynecologic Laparoscopists, port site hernias were found to occur in port sites 10 mm or larger in 86% of cases, while those 8 mm or smaller were associated with only 3% of port site hernias reported.[25] More recently, Paraiso et al. discussed the notion of lower postoperative pain with use of smaller ports when comparing postoperative pain scores in patients undergoing robotic and laparoscopic prolapse surgery. Those undergoing laparoscopy endured fewer and smaller trocar incision sites, which correlated with lower postoperative pain scores.[26] Given this, we routinely use the smallest size ports necessary when performing minimally invasive pelvic organ prolapse surgery. For robotic sacrocolpopexy, once ports are placed and the robot docked, introduction of robotic instruments should be done under camera visualization in a 3, 2, 1 consecutive order to increase efficiency; it can be difficult to rotate the camera to visualize placement of arms 2 and 3 if arm 1 has already been placed. Lastly, each arm's range of motion should be thoroughly assessed to minimize arm collisions during robotic pelvic surgery.

Many of these technical issues have been overcome with the new da Vinci Xi robot, which has a much smaller and lighter weight camera and slimmer arms allowing more range of motion and less problems with clashing.

Intraoperative Complications

BOWEL COMPLICATIONS

Unique intraoperative complications associated with robotic pelvic floor reconstruction can be avoided with knowledge and prevention as outlined here (Box 33.1). During robotic sacrocolpopexy, it is our preference to begin with the dissection of the sacral promontory, in order to complete the more difficult portion of the surgery first. The 30-degree (down) camera is preferred by some surgeons, allowing for better visualization of the sacral promontory. This portion of the procedure requires adequate retraction of the sigmoid colon toward the left pelvic sidewall, in order to maintain optimal visualization of the sacral promontory. Prior to mobilization, however, the surgeon should thoroughly survey the abdomen and maneuver the small intestine into the upper abdomen if steep Trendelenburg positioning has not already accomplished this. Bowel injury during pelvic surgery, although occurring in only about 0.5% of cases, most commonly occurs in the small bowel at the time of intraabdominal access (55%), and delay in identification of a bowel injury can result in mortality in an average of 3% of cases.[27] For this reason, it is imperative to be mindful of this complication and take extra time to evaluate for any potential injury during abdominal entry. If a puncture injury of the bowel is identified, a step-by-step inspection of the entire bowel is recommended to ensure no additional injuries are present. The most common cause of nonentry-related bowel injury is usually due to thermal defects, and these are more likely to go unnoticed.

Small serosal or muscularis defects should be repaired using 3-0 delayed absorbable sutures in a two layer, imbricating technique.[28] Recently, barbed suture has also been used for repair of bowel and bladder injuries with good results. This has been described with use of a single layer of 3-0 barbed suture for seromuscular injuries, while two layers of 3-0 barbed suture are used for full-thickness defects. Additionally, some surgeons will use one layer of barbed suture for repair, followed by a second layer of continuous or interrupted delayed absorbable suture.[29] During small bowel repair, sutures should be placed perpendicular to the long axis of the intestine to prevent stricture formation. Conversely, large bowel enterotomies should be repaired with care to avoid any tension on the tissue. Given the larger lumen at this level, stricture formation is less likely; however, any suture tension at the level of the rectosigmoid colon could compromise the integrity of the repair. Although some injuries can be repaired laparoscopically, a number of bowel injuries may require laparotomy.[27] It is important to confer with colleagues intraoperatively at the time injuries are identified, as resection and temporary diversion may be required in some cases.

Avoidance of the above complications can be maximized with proper patient positioning in Trendelenburg, proper mobilization techniques, and use of blunt tools for assistance. The small bowel should always be reflected first so that the large bowel can then secure hold of the small bowel out of the pelvis. Use of fan retractors may also prove helpful in laparoscopic procedures. In the obese patient, there may be redundant rectosigmoid colon, requiring cephalad mobilization and/or retraction. Scheib et al. has described use of an accessory stitch placed through the epiploic appendices and subsequent suspension of the colon to the anterior abdominal wall or left upper quadrant to remove the bowel from the operative field. The ENDOLOOP ligature can also be used in a similar fashion and can be drawn out through ports and secured temporarily.[14,30]

Box 33.1 Intraoperative Considerations in Robotic Pelvic Floor Reconstruction

- Port Site Bleeding
  - Attempt to cauterize injured vessel with offending trocar in place
  - Tamponade can be attempted using a 12-Fr Foley catheter through trocar
  - Sutures can be placed at each side of trocar site and tied externally with removal after 24-48 h
- Bowel Injury
  - Use of fan retractors, accessory stitch, ENDOLOOP ligature to retract bowel effectively
  - If injury detected, Vicryl or barbed suture can be used for repair
  - Repair should be performed in two layers with sutures placed on the long axis of intestine to prevent stricture
- Presacral Hemorrhage
  - Middle and lateral sacral vessels should be well delineated
  - Assess for variability of sacral/iliac vessels, particularly on the left side of anterior longitudinal ligament
  - Apply direct pressure with a Ray-Tec or cottonoid as first-line treatment
  - Hemostatic agents (Floseal, Surgicel) and laparoscopic vessel fasteners should be readily available
- Urinary Tract Injury/Vaginotomy
  - Use of EEA sizers or vaginal stents to allow for proper visualization of vesicovaginal junction
  - Dissection of this junction should be bloodless if correct plane has been identified
  - 25-mg ICG in 10 mL sterile H_2O can be injected into ureters prior to RASC for ureteral identification
  - Bladder/vaginal injury should be repaired in a double, imbricating layer using Vicryl or barbed suture
  - Mesh should not be placed directly over vaginotomy site, should one occur

HEMORRHAGIC COMPLICATIONS

Another significant complication of robotic prolapse surgery, namely sacrocolpopexy, is that of presacral hemorrhage. Although rare, this complication can be life threatening and it is imperative to identify the middle and lateral sacral as well as common iliac vessels, the most common sites of hemorrhage in sacrocolpopexy. Although robotic sacrocolpopexy has been associated with lower overall blood loss when compared to both abdominal and laparoscopic approaches, a recent meta-analysis reported a 0.4% incidence of intraoperative vascular complications, namely left iliac venotomy, with both laparoscopic and robotic

approaches to sacrocolpopexy.[31–33] With this in mind, the surgeon should make it a priority to properly identify the sacral promontory as a landmark, which is best identified just below the bifurcation of the common iliac arteries (Fig. 33.1). The assistant surgeon should be utilized to help with tactile feedback during this process. When incising the peritoneum overlying the promontory one should be cognizant of the variability of the vascular pattern of the presacral space. There can be significant variability in the location of both sacral and iliac vessels, particularly on the left side of the anterior longitudinal ligament of the sacrum.[34] Many surgeons prefer to expose the ligament and vessels thoroughly in a layer-by-layer fashion, in order to minimize injury. The left common iliac vein has a highly variable course and can be difficult to identify as it often appears flat and white due to the effects of the pneumoperitoneum and can be easily confused for the anterior longitudinal ligament.

If presacral vascular injury is encountered, it has been well documented that conventional hemostatic measures have often proven to be futile, probably due to the increase in hydrostatic pressure when in lithotomy position, as well as the fixed nature of the venous plexus to the sacral periosteum. When the hemorrhage is identified it is important to communicate effectively with the operative team and immediately apply direct pressure to the area with the nearest blunt robotic instrument. A RAY-TEK or cottonoid sponge can be passed into the field by the side surgeon and this can also be used to apply direct pressure for a minimum of 5 minutes. If the bleeding persists, topical hemostatic agents should be considered. Germanos et al. described three cases of presacral hemorrhage that were successfully managed using a combination of a hemostatic matrix (Floseal; Baxter, Hayward, CA), which should be directly applied over the area of bleeding, followed by application of an absorbable hemostat (Surgicel Fibrillar; Ethicon, Somerville, NJ) that is applied over the top as a pad.[35] Topical hemostatic agent use should be accompanied by temporary pressure applied with gauze to secure the hemostatic matrix. Laparoscopic tacks or clips can also be placed and should be readily available in anticipation of vascular injury. Another method described in the literature utilizes absorbable hemostat material (Surgicel), which is then secured in place using laparoscopic fasteners. These fasteners are then anchored to the sacrum to apply targeted pressure to the bleeding area.[36] These techniques can only be utilized for relatively small sacral vessels. In the case of a common iliac venous injury, formal vascular repair is critical to stop hemorrhage.

When these minimally invasive approaches fail, the surgeon should be prepared to convert to an open procedure. If a robotic approach is underway, the team should have an "emergency undock" protocol in place. The surgical and anesthesia teams should always be in constant communication regarding extent of blood loss and potential need for transfusion protocols to be activated. While preparing for conversion to laparotomy, pressure using a gauze, cottonoid, or blunt instrument must be maintained to prevent further hemorrhage. This can be accomplished with a robotic arm followed by a laparoscopic instrument through an accessory port when the robot is being undocked. Blood products should be ordered and brought to the operating room. Vascular instruments should be prepared and intraoperative vascular surgery consultation requested.

UROLOGIC COMPLICATIONS

Urinary tract injury, although rare, is a conceivable complication of robotic prolapse surgery, and many genitourinary injuries go unrecognized at the time of the procedure. Minimally invasive sacrocolpopexy has been associated with an intraoperative bladder injury rate of 0.4–3.3% and up to 10% in patients with post-hysterectomy vaginal vault prolapse.[32,37] While some of this could be due to the learning curve associated with newer robotic-assisted techniques, it is important to recognize the possibility of bladder injury and to be prepared to identify and attend to this complication, should it occur. Ureteral injury does appear to occur less frequently, and there is a paucity of literature to determine exact ureteral injury rate during laparoscopic prolapse repair specifically. That being said, laparoscopic hysterectomy has been most recently associated with a ureteral injury incidence of 0.02–0.54%, and incidence does not significantly differ between subtotal and total hysterectomy.[38,39]

In order to minimize risk of genitourinary injury, the surgeon should develop a command of the anatomy and knowledge of the most common sites of injury. Additionally, preoperative risk stratification and intraoperative assessment of ureteral and bladder integrity is essential in preparing for and preventing urinary tract complications. It is imperative to address patient-specific risk factors, such as prior pelvic surgical history and anomalous anatomy. History of three or more previous cesarean sections comes with a cystotomy rate of 20% in the setting of laparoscopic hysterectomy.[40] With regard to type of injury, the dome of the bladder is most commonly involved in injury during total hysterectomy, while the most common sites of ureteral injury occur in close proximity to the uterine artery or at the pelvic brim, near the infundibulopelvic ligament. Identification of the vesicovaginal junction is crucial to avoiding bladder injury. The placement of a sponge stick or end-to-end anastomosis (EEA) sizer vaginally can help with mobilization of the vagina and detection of the plane between the vagina and bladder. This dissection should be bloodless, and areolar tissue should be easily identified. If bleeding is encountered, the surgeon should suspect compromise of bladder wall integrity. Bladder insufflation can also prove helpful during this time to ensure proper dissection. If bladder injury occurs, a double layer closure should be performed with 2-0 or 3-0 absorbable sutures after dissection is complete. Bladder repair can also be successfully performed with barbed suture or a combination of the two types.[29] Subsequently a retrograde fill of the bladder should be performed to ensure adequate closure. We recommend indwelling catheter placement for 5–14 days, depending on the size and location of the defect.

Transperitoneal identification of the ureter can usually be performed at the level of the pelvic brim, and the ureter can be coursed from this point. This technique should be routinely performed whenever possible to decrease risk of ureteral injury; however, in patients with aberrant anatomy or those who have had multiple abdominal surgeries, this may be difficult. In these instances, use of prophylactic ureteral catheterization may reduce the risk of injury during

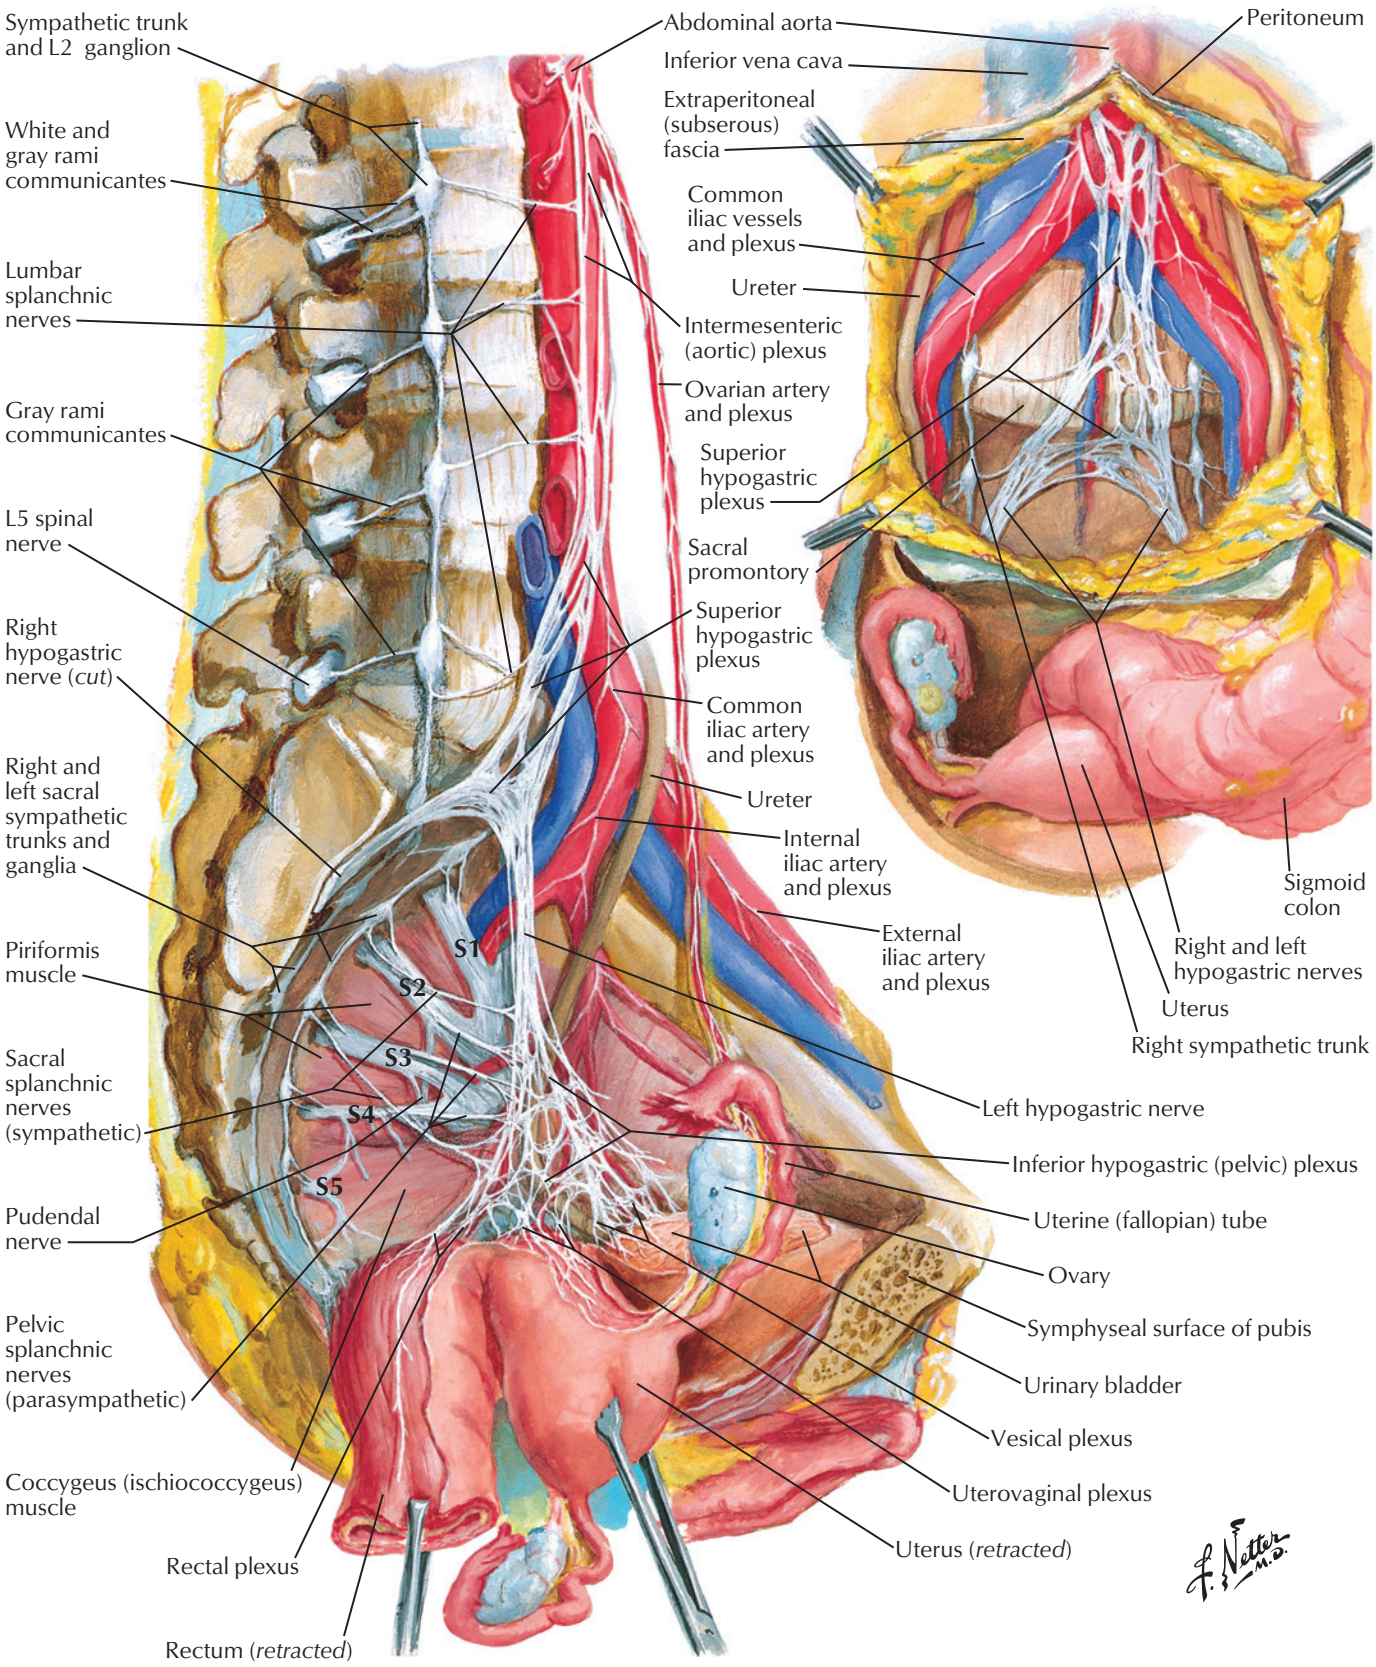

Figure 33.1 Sagittal and coronal depictions of sacral promontory vascular anatomy. (From Netter's Atlas of Human Anatomy. 6th ed. 2014 © Elsevier; Plate 389)

high-risk procedures, although routine use is debated and this practice should not take the place of meticulous surgical technique.[41] Recently, Siddinghi et al.[42] described the use of indocyanine green (ICG) to identify ureters intraoperatively. Prior to the start of surgery, 25 mg of ICG was dissolved in 10 mL of sterile water and injected into each ureter through a 6Fr ureteral catheter. The ICG injection resulted in reversible staining of ureters through protein binding for the entirety of each of 10 gynecologic surgeries. There were no adverse events described at the time of the operation or up to 2 months postoperatively, and cost was approximated at $100 per 25 mg of ICG. This technique can be utilized in anticipation of abnormal anatomy or high-risk prolapse cases when performing robotic-assisted prolapse repair; this technique should be considered as part of one's armamentarium when treating patients with risk factors for urinary tract injury, such as those with diagnoses of endometriosis, multiple abdominal surgeries, ectopic ureter insertion, or duplication of the urinary collecting system. If ureteral injury is identified intraoperatively the ureter should be adequately mobilized and the injured segment excised prior to ureteroureterostomy using 4-0 absorbable sutures. Intracorporeal or cystoscopic placement of a ureteral stent can then be performed. Good success rates of this repair have been described using robotic techniques;[43] however, ureteral repair may require ureteral reimplantation or laparotomy at times.

VAGINAL COMPLICATIONS

Lastly, vaginotomy has been quoted as a fairly common complication of minimally invasive POP repair and has been associated with an incidence from 0.4% up to that of 24% in robotic-assisted sacrocolpopexy with patients who had post-hysterectomy vaginal vault prolapse.[32,33] The presence of this complication has been associated with postoperative vaginal mesh exposure, and for this reason it is of utmost importance to take precautions when performing vaginal dissection.[44] To minimize vaginotomy risk, an EEA sizer or vaginal stent can be placed in the vagina and elevated cephalad either anteriorly or posteriorly by the assistant. This allows the surgeon at the console to delineate vesicovaginal and rectovaginal planes appropriately when performing the vaginal dissection. In cases of post-hysterectomy vaginal vault prolapse it is important to also be mindful of the cuff closure site, as this is usually the area of thinnest peritoneum. Dissection in this area should be only performed after a clear plane has been identified, as vaginotomy is more likely to occur here.[45] It is our preference to leave the peritoneum intact whenever possible, and we routinely forego dissection of the posterior peritoneum from the cervical stump when performing supracervical hysterectomy robotically. We prefer to maintain the peritoneal integrity here to reduce risk of mesh extrusion, as it is felt additional dissection in this area is not significantly helpful. In cases where vaginotomy does occur it is imperative to reinforce this area with a second imbricating layer of suture. Additionally, mesh should not be placed directly over any vaginotomy site. We routinely continue to perform supracervical hysterectomy with sacrocolpopexy rather than total hysterectomy to further minimize mesh exposure or extrusion risk, unless the patient has known cervical pathology or some other medical indication requiring removal of the cervix. Gore-Tex sutures are preferred for anterior and posterior mesh fixation, as their monofilament structure makes vaginal extrusion less likely.

Postoperative Complications

Although overall morbidity remains lower and recovery time is usually shorter in the setting of comparable success rates with an open approach, postoperative complications do occur with robotic sacrocolpopexy.[6,8,9,32,37,46] It is important to recognize those that occur most often, so that one may anticipate these complications and address them in a timely fashion (Box 33.2).

INFECTIOUS COMPLICATIONS

Postoperative surgical site infection (SSI) is found to occur at a rate of approximately 2–4% during minimally invasive hysterectomy and sacrocolpopexy procedures, and this complication is associated independently with intra/postoperative blood transfusion and longer operative time.[37,47] These characteristics are likely representative of longer, more complicated surgeries. Possible reasons for wound infections could include failure to redose antibiotics during longer cases, prolonged tissue and or trocar manipulation, increased risk of violation of sterile technique, and larger potential for thermal or glycemic disregulation. The surgeon should always be mindful of the time

Box 33.2 Postoperative Complications in Robotic Pelvic Floor Reconstruction

- Surgical Site Infection
  - Cephalosporins should be redosed intraoperatively after 4 hours or with >1500 mL blood loss
  - Patients >120 kg should receive a 3-g initial dose instead of standard 2-g dosing when using cefazolin
  - Postoperative antibiotics for wound infection should be targeted at gram-positive bacteria
- Venous thromboembolism (VTE)
  - LMWH should be considered in patients >60 yr, as they are deemed "high risk" with VTE risk 20–40%
- Bowel Complications
  - Dyschezia, obstructed defecation, and outlet constipation are the most common types of postoperative bowel dysfunction, and patients should not expect a bowel movement within the first 3 days after surgery
  - Extensive dissection of rectovaginal septum should be avoided to reduce bowel denervation
- Mesh Complications
  - Mesh should be placed as flat as possible and against sacral promontory to decrease anorectal dysfunction
  - Supracervical hysterectomy is preferred to reduce mesh extrusion rates
  - Use of lightweight type I mesh to reduce risk of graft infection
- De Novo Stress Urinary Incontinence (SUI)
  - Vaginal examination should be performed intraoperatively to assess for anterior/apical overcorrection which could lead to new onset SUI

and discuss potential need for redosing of antibiotics with the anesthesia team. Antimicrobial prophylaxis guidelines should be reviewed. Most often, cephalosporins are used for minimally invasive POP repair. In general, redosing should occur after 4 hours or with >1500 mL blood loss. Additionally, patients over 120 kg should receive 3 g initially instead of the standard 2-g dosing. Operating room assistants should also assist with periodic evaluation of trocar sites or need for repositioning to decrease tissue damage during the case that could lead to SSI postoperatively.[48] If wound infection does occur, antibiotics to cover gram-positive organisms should be initiated, as these organisms are most commonly associated with SSI in those individuals undergoing gynecologic/urogynecologic procedures.[49,50] Any area of erythema around the surgical site should be clearly demarcated. Although the routine use of preoperative antiseptic scrubs has been debated, there is evidence to show that this technique reduces the rate of antibiotic-resistant SSI, and use may be considered in patients with predisposing risk factors to wound infection.[50–52]

THROMBOEMBOLIC COMPLICATIONS

Another postoperative complication to be aware of is that of venous thromboembolism, which is thought to come with a risk of approximately 14% in gynecologic surgery for benign disease.[53] Although there is no consensus on venous thromboembolism (VTE) prophylaxis for patients undergoing pelvic reconstructive surgeries, it should be noted that many of these patients are defined as "high risk" solely on the basis of age >60 years, which comes with a general VTE risk of 20–40%.[54] Both the AUA and ACOG recommend the use of anticoagulation in "high risk" populations undergoing high-risk surgeries such as vaginal wall repairs and sacrocolpopexy.[55,56] Given the average age of the patient undergoing POP repair, strong consideration should be given to these recommendations, and the benefit of heparin intraoperatively should be weighed against individual bleeding risk. That being said, the use of pneumatic compression devices should be employed routinely, independent of other anticoagulation, unless the patient has a contraindication to this. If a VTE is suspected, the patient's pre-test probability should be calculated and diagnostic tests should be performed. Davis[57] provides a concise review of clinical models used for diagnosis and treatment of VTE in gynecologic surgery. These algorithms can be helpful when choosing treatment method and duration for patients.

BOWEL COMPLICATIONS

Bowel complications after minimally invasive sacrocolpopexy can range from very painful constipation to bowel obstruction secondary to adherence of intestines to exposed abdominal mesh. While bowel obstruction rates are rare, ranging from 0.4% to 1.7%,[37] overall rates of bowel dysfunction far surpass this, with an incidence rate of 5–14% in a recent meta-analysis of robotic-assisted sacrocolpopexy. The most common types of dysfunction cited were dyschezia, obstructed defecation, and outlet constipation.[31] Recent studies suggest that having concomitant posterior prolapse repair does not increase bowel dysfunction rates, and these symptoms may be related to surgical technique of sacrocolpopexy.[58] It is imperative to place the mesh as flat as possible against the sacral promontory and to avoid attachment to the levator ani musculature in order to decrease anorectal dysfunction postoperatively. Extensive dissection in the rectovaginal septum should be avoided to reduce the risk of rectal denervation injury. Additionally, management of expectations is important in this area. Patients should understand that average time to first bowel movement (BM) is estimated at 3 days after prolapse surgery, and a recent RCT revealed no difference in average time to BM with a more rigorous bowel regimen. Additionally, bowel movements were comparatively painful in both groups and those with higher incidence of postoperative narcotic intake had higher postoperative pain scores associated with bowel movements.[59] These data are compelling, and clearly more research in this area is indicated. Since there is no consensus in the literature for bowel dysfunction reduction, we use various techniques to attempt to mitigate this postoperative issue. In order to reduce narcotic use, which is a known contributor to constipation, we implement the use of ketorolac every 6 hours as a standing regimen with narcotics only for breakthrough pain. When transitioning to PO regimen, patients are encouraged to use 800 mg of ibuprofen or 1 gm of acetominophen every 8 hours. Additionally, patients are started on twice daily stool softeners and a powder laxative 1–2 times daily postoperatively and encouraged to continue this regimen until BMs are regulated.

Nausea and emesis should always provoke the question of ileus or small bowel obstruction postoperatively. Often this can be managed conservatively with clear liquid diet or nasogastric tube. At times obstruction persists requiring reoperation, and the decision about this intervention should be made on a case-by-case basis. Surgical technique may again contribute to an obstruction of the bowel, and debate exists about whether obstruction is, in most instances, directly related to mesh placement or exposure. In a recent review, surgeons found similar obstruction rates with and without re-peritonealization of sacrocolpopexy mesh.[60] Conversely, one case series demonstrated two cases of delayed obstruction to be directly attributable to the barbed suture used to re-peritonealize the sacrocolpopexy mesh.[61] These are important points to consider. At our institution, we do utilize barbed suture to routinely re-peritonealize sacrocolpopexy mesh; however, we make sure to cinch tissue after each throw of suture to reduce barbed suture exposure, and we routinely cut suture ends flush with peritoneal tissue to decrease the risk of this complication.

COMPLICATIONS RELATED TO SYNTHETIC MESH

Various other mesh complications can also arise, including pelvic pain or dyspareunia, mesh infection, and mesh extrusion. Patients should be extensively counseled on the possibility of these mesh-related complications and the low but present risk of need for reoperation due to mesh complications, which was found to occur at a rate of 2.9% in a recent review article.[62] Mesh extrusion rates associated with minimally invasive sacrocolpopexy hover around 2–3%[33,37] and are shown to be higher with silicone-coated polyester

and polytetraflouroethylene mesh materials.[62] For this reason, use of these mesh types is not recommended. We routinely perform supracervical hysterectomy with minimally invasive sacrocolpopexy to avoid higher rates of mesh extrusion,[62] unless there is a medical indication to remove the cervix at the time of prolapse repair. Although pain and dyspareunia are found to be less with sacrocolpopexy when compared to vaginal prolapse repairs, these issues still do occur. If pain occurs in the absence of mesh extrusion and conservative measures such as analgesics, local hormone therapies, or local antiinflammatory injections fail, reoperation to remove the mesh may be necessary. When evaluating these patients, differential diagnosis should include bowel or bladder mesh erosion, suture erosion, lumbosacral discitis, and osteomyelitis. Possible diagnostic tests should include and not be limited to cystoscopy, colonoscopy, CT scan, and MRI. There are case reports to support the utility of these tools when evaluating postsacrocolpopexy pain.[63]

While extremely rare, back and/or buttock pain accompanied by acute signs of infection could denote pyogenic spondylitis. This class of lumbosacral infections requires immediate attention and can be life threatening. It is imperative to avoid the L5–S1 disc and to localize the sacral promontory and avoid the sacral nerve, which is most commonly found approximately 3 cm from the upper surface of the sacrum and 1.5 cm from the midline.[64] Sutures should be placed at or below the sacral promontory to avoid the disc space, and when this is not possible, surgeons should be mindful of the 1- to 2-mm thickness of the anterior longitudinal ligament and place sutures no deeper than this to avoid the disc itself.[65] This complication may often require reoperation and removal of mesh and suture, followed by a prolonged course of broad-spectrum antibiotics.

DE NOVO INCONTINENCE

Lastly, de novo stress urinary incontinence can occur following sacrocolpopexy in the minimally invasive setting and the need for further intervention with midurethral sling placement in these patients can far exceed 10%.[31] We routinely perform clinical evaluation to assess for occult stress urinary incontinence if the patient does not identify with this symptom profile. Furthermore, we have implemented a "shared decision making" model into our practice, when considering concomitant anti-incontinence procedures in this setting. It is crucial to assess anterior and apical support vaginally at the time of sacrocolpopexy mesh fixation, to ensure that overcorrection of the anterior compartment has not occurred. If there appears to be tension on the tissues of the anterior vaginal wall or splaying of the urethral meatus, adjustment may need to be considered.

Conclusions

Overall, sacrocolpopexy, whether done via a laparoscopic or robotic route, is an extremely safe and effective form of pelvic organ prolapse repair. These modes of surgery are rapidly becoming the new gold standard, as minimally invasive techniques are found to be more appealing to both patient and surgeon. Minimally invasive sacrocolpopexy has comparable profiles of safety and feasibility, parameters that will only continue to improve with enhancement of surgeon efficiency. It is crucial, however, to acknowledge the unique set of complications that may accompany minimally invasive approaches to sacrocolpopexy, so that we may be equipped to avoid surgical pitfalls and optimally prepared to treat complex situations, should they occur. Surgeon understanding of the complications associated with minimally invasive sacrocolpopexy provides for consensus to develop best practices, which can help to decrease the incidence of these complications and increase overall patient satisfaction associated with these procedures.

Chaper 33 Questions

1. Preoperative relative contraindications to minimally invasive/robotic sacrocolpopexy include all of the following, EXCEPT:
   a. Chronic pulmonary disease
   b. Active smoking
   c. Severe gastroesophageal reflux disease with prior aspiration pneumonia
   d. Obesity
   e. Prior pelvic surgery

2. Concurrent incontinence surgery should be recommended preoperatively to patients undergoing robotic sacrocolopopexy except when:
   a. Patient complains of preoperative stress incontinence (SUI)
   b. Reduction of prolapse with a pessary results in occult stress incontinence
   c. Patient denies stress incontinence and accepts potential risk of postoperative SUI
   d. Physical exam preoperatively reveals stress incontinence
   e. All of the above

3. Lack of attention to intraoperative patient positioning for robotic pelvic surgery can result in:
   a. Hernia formation at port site
   b. Femoral nerve compression
   c. Brachial plexus injury
   d. Corneal abrasion or facial trauma
   e. All of the above

4. Intraoperative bowel injury during robotic pelvic surgery occurs most commonly:
   a. During port placement
   b. During positioning of the small bowel into the upper abdomen
   c. During sacral dissection
   d. During retraction of the sigmoid colon
   e. During supracervical hysterectomy

5. Presacral hemorrhage can be a life-threatening complication of robotic sacrocolpopexy and is most often caused by inadvertent injury to the:
   a. Common iliac artery
   b. Left common iliac vein
   c. Middle sacral artery
   d. Inferior vena cava
   e. Hypogastric artery

6. Sacral vascular injury during robotic surgery can be addressed by all of the following EXCEPT:
   a. Elimination of pneumoperitoneum
   b. Conversion to open surgery
   c. Hemostatic agents applied to sacrum
   d. Laparoscopic bony tacks
   e. Surgical repair of vessel

7. Intraoperative urinary tract injury during robotic pelvic reconstruction occurs most commonly:
   a. In the distal ureter near the trigone
   b. In the midureter near the pelvic brim
   c. In the bladder trigone during anterior vaginal wall dissection
   d. At the dome of the bladder in post-hysterectomy sacrocolpopexy
   e. At the bladder neck during supracervical hysterectomy

8. Postoperative surgical site infection (i.e., port site wound infections) is associated with:
   a. Prolonged operative time
   b. Increased operative blood loss
   c. Failure to redose intraoperative antibiotics
   d. Poor glycemic control perioperatively
   e. All of the above

9. The most common bowel complications postoperatively following robotic pelvic organ prolapse surgery include the following EXCEPT:
   a. Constipation
   b. Upper GI bleed
   c. Bowel obstruction
   d. Nausea and vomiting
   e. Ileus

10. Mesh-related complications associated with robotic sacrocolpopexy include the following EXCEPT:
    a. Vaginal mesh extrusion
    b. Bowel obstruction
    c. De novo stress urinary incontinence
    d. Dyspareunia
    e. Bladder mesh erosion

Answers

1. **e.** Intraabdominal CO_2 insufflation and steep Trendelenburg positioning during robotic pelvic reconstructive surgery have acute hemodynamic effects, which must be considered preoperatively when assessing a patient's risk for surgery. Any conditions that compromise pulmonary function, such as chronic pulmonary diseases, active smoking, and a history of prior aspiration pneumonia, may preclude a patient's ability to tolerate the hemodynamic and pulmonary effects of robotic pelvic surgery. Obesity may limit the ability to achieve adequate pneumoperitoneum and may limit proper positioning for robotic pelvic surgery. Prior pelvic or abdominal surgery does not necessarily eliminate the option of minimally invasive surgery and can be accomplished safely with careful port placement and potential lysis of adhesions.
2. **c.** Patient satisfaction following prolapse repair can be greatly improved by addressing stress incontinence at the time of a planned surgery for her prolapse. Initial evaluation prior to surgery should include assessment of baseline SUI, including both history and physical exam. Advanced pelvic organ prolapse can mask urethral incontinence because as the anterior vaginal compartment descends, there is a kinking effect on the urethra that may prevent incontinence. With

restoration of pelvic support and prolapse reduction, occult SUI can develop. Preoperative evaluation for occult SUI in patients who deny incontinence can be accomplished by at-home pessary use, in-office stress testing with prolapse reduction, or formal urodynamic evaluation with prolapse reduction. If a patient is continent preoperatively (with negative stress testing) and is willing to accept the risk of postoperative de novo SUI, she may choose to forego concurrent incontinence surgery at the time of robotic prolapse repair.

3. **e.** Robotic pelvic surgery requires careful attention to intraoperative positioning prior to robot docking. Both the surgical team and anesthesia should be involved in proper positioning. Adequate protection of the eyes and face is needed to avoid trauma from overlying camera or equipment. Careful tucking of arms is done to prevent traction on the brachial plexus. Lithotomy positioning must avoid overflexion of the knees and overextension of the hips, which can result in femoral nerve injury. Finally, inadequate padding beneath the patient can result in sliding with Trendelenburg positioning, leading to excessive traction at the robotic port sites and potential hernia formation.
4. **a.** Bowel injury occurs in approximately 0.5% of pelvic surgeries and most commonly occurs during entry and port placement. The small bowel is injured most commonly, and lack of recognition of this injury can lead to mortality in 3% of patients. Port placement should be performed carefully and meticulously, with attention to abdominal wall vasculature and with careful inspection visually after camera port placement. Robotic ports should always be placed under direct camera visualization, and removal of the inner obturator after entry into the peritoneal cavity can help to minimize bowel injury during port placement. The surgeon should also ensure adequate abdominal insufflation prior to placement of ports. Any enterotomy should necessitate careful inspection of the bowel and adequate tension-free repair. An intraoperative consultation may be required to determine the ideal method of repair.
5. **b.** Sacral vascular anatomy can be highly variable. Robotic dissection of the sacral promontory lacks tactile feedback and the surgeon must rely upon visual indicators and knowledge of anatomy. The assistant surgeon can also assist in identifying the bony structure with tactile laparoscopic feedback. Dissection should begin caudal to the bifurcation of the common iliac artery, which is visible in most patients. The left common iliac vein has a variable course along the promontory and anterior longitudinal ligament. With pneumoperitoneum the left common iliac vein can be easily mistaken for the anterior longitudinal ligament, as it may appear flat and white. The middle sacral vessels can be avoided by suturing lateral or medial to them or by using monopolar or bipolar cautery to cauterize small vessels in preparation for suture placement in the anterior longitudinal ligament.
6. **a.** Vascular injury during robotic pelvic surgery requires immediate attention and effective communication with the operating room team, including both nursing and anesthesia. Blood products and open surgical instruments should be prepared during attempts to control the bleeding robotically. Hemostatic agents, laparoscopic tacks, and direct pressure can be tried initially. Depending on the extent of vascular injury, conversion to open and direct surgical repair of the injured vessel may be necessary. During conversion and undocking, it is very important to maintain tamponade of the bleeding vessel to prevent severe, life-threatening hemorrhage. Elimination of pneumoperitoneum would worsen the acute bleeding and make conversion very challenging.
7. **d.** Minimally invasive sacrocolpopexy is associated with a risk of bladder injury ranging between 0.4% and 3.3% and up to 10% in patients with post-hysterectomy prolapse. Proper patient counseling preoperatively should include a discussion of this risk and the potential need for a postoperative Foley catheter should cystotomy occur. Ureteral injury occurs less commonly; however, ureteral integrity should be assessed during each case. Steps to minimize risk of cystotomy during robotic sacrocolpopexy include clear identification of the vesicovaginal junction during anterior vaginal wall and vaginal cuff dissection. Placement of a spongestick, EEA sizer, or vaginal stent can aid in this dissection, and the plane of dissection should be relatively bloodless. Bladder distention can also aid in avoiding cystotomy.
8. **e.** Several factors contribute to the risk of postoperative surgical site infections (SSI). Overall, the reported risk of SSI with minimally invasive hysterectomy and sacrocolpopexy ranges between 2% and 4%. Both prolonged operating time and increased blood loss have been associated with an increased risk for SSI. Intraoperative antibiotics need to be redosed according to specific intervals in long cases. Diabetes and poor glycemic control can also contribute to these infections. Generally, second- or third-generation cephalosporins are recommended and must be dosed according to patient weight to achieve adequate blood and tissue levels.
9. **b.** Bowel complaints postoperatively are fairly common following robotic sacrocolpopexy and range between 5% and 14% in a recent meta-analysis. The most common postoperative complaints include dyschezia, obstructed defecation, and constipation. Patients should be counseled that the average time to postoperative bowel movement is 3 days. Postoperative nausea and vomiting may indicate an early ileus versus a bowel obstruction. Management will depend upon the clinical scenario and response to conservative measures such as bowel rest and nasogastric decompression.
10. **c.** Complications with abdominally placed sacrocolpopexy mesh are much less frequent than vaginally placed mesh for prolapse repair. It is important to counsel patients regarding the specific complications that can occur with sacrocolpopexy mesh, including mesh extrusion, dyspareunia, erosion of mesh into the bladder, and bowel obstruction. Careful dissection along the vagina and avoidance of both vaginotomy and cystotomy can help to prevent these complications. Re-peritonealization of mesh can help to reduce the risk of bowel obstruction due to adherence between bowel and exposed sacral mesh. De novo stress urinary incontinence is a risk associated with sacrocolpopexy, but not uniquely caused by the mesh.

34 Complications of Laparoscopic/ Robotic Nephrectomy and Partial Nephrectomy

MARC A. BJURLIN and SAMIR S. TANEJA

CHAPTER OUTLINE

Preoperative Considerations
Patient Selection
Operative Planning
Procedural Complications
Complications Related to Patient Positioning
Rhabdomyolysis
Nerve Injuries
Other Complications
Complications Related to Kidney Exposure
Vascular Injury
Bowel Injury
Spleen Injury
Pleural Injury
Pancreatic Injury
Hepatobiliary Injury
Chylous Ascites
Procedure-specific Considerations
Partial Nephrectomy
Bleeding
Urine Leak
Renal Function
Donor Nephrectomy
Simple Nephrectomy
Conclusions
Chapter 34 Questions and Answers

KEY POINTS

1. In selecting patients for laparoscopic renal surgery, obesity should be cautiously evaluated as it may contribute to ventilatory difficulty, positioning injuries including nerve injury and rhabdomyolysis, and prolonged operative times due to technical difficulty with the surgery.
2. In positioning patients for transperitoneal laparoscopic renal procedures, patients should be placed at a semioblique angle of 45–60 degrees, with the table slightly flexed, and weight distributed to the hip rather than the upper gluteal or presacral compartments.
3. Scoliosis, significant spinal curvature, or a large tumor can alter the aortic anatomy or renal orientations, secondarily creating rotation of the renal hilum, superior mesenteric artery, inferior mesenteric artery, and mesentery, thereby risking inadvertent vascular injury.
4. Injuries to the liver and spleen during kidney mobilization can often be managed with hemostatic agents, argon beam coagulation, and pressure, but these injuries increase the likelihood of postoperative hemorrhage. Injuries to the distal pancreas can usually be managed conservatively with drainage.
5. Large tumors encroaching upon the renal hilum, or hilar lymphadenopathy, can limit early access to the renal artery. In these cases, preoperative angioembolization can be beneficial.
6. Consider CT imaging for patients with disproportionate pain and leukopenia because these findings may be early warning signs of an unrecognized visceral injury.
7. Stapler misfire during minimally invasive nephrectomy is a life-threatening complication and often results from application of the stapler over clips.
8. Selection of candidates for laparoscopic partial nephrectomy can be aided by objective scoring scales such as the RENAL nephrometry score, but the ultimate decision is largely dependent upon surgeon experience and comfort level.
9. Urine leak following partial nephrectomy is generally managed by drainage of the leak and any surrounding urinoma. Stent or nephrostomy placement is only warranted in cases of ureteral obstruction or persistent high-volume leak.
10. Delayed bleeding following laparoscopic or robotic partial nephrectomy is most commonly due to pseudoaneurysm or arteriovenous fistula in the operative bed, and early intervention with angiography and selective angioembolization is advisable.

Since the first report of laparoscopic radical nephrectomy in 1991 by Clayman and colleagues,[1] the indications for laparoscopic and robotic renal surgery have expanded tremendously. Although laparoscopic approaches were initially felt to be most appropriate for benign disease, current indications have extended to malignant disease in the performance of radical nephrectomy, partial nephrectomy, and, depending upon the skill of the operator, locally advanced renal cancers with caval thrombus extension. The utilization of laparoscopic approaches in clinical practice has grown with the integration of laparoscopic training in urologic residency programs, a significant postgraduate training effort for surgeons in practice, and the growth of surgical technologies, tissue adhesives, and robotic-assisted surgical techniques.[2,3]

Robot-assisted renal surgery allows magnified stereoscopic visualization and the use of articulated robotic instruments under precise control. The advent of robot assistance has facilitated the technical performance of laparoscopic procedures requiring reconstruction, for which suturing and increased instrument dexterity is needed. The dissemination of robotic surgery for partial nephrectomy in the United States has been rapid and safe, albeit with greater cost.[4] Hospital acquisition of the surgical robot has been shown to be associated with a greater proportion of partial nephrectomy.[5,6]

Given the considerable morbidity and pain of upper abdominal and flank incisions, the ability to perform renal surgery through laparoscopic techniques has resulted in reduced pain and more rapid convalescence. When performed well, low rates of complication can be achieved, thus further ensuring improved clinical outcomes for patients. Nonetheless, laparoscopic techniques for nephrectomy and partial nephrectom, require operator skill and experience, as well as good surgical judgment in candidate selection. A number of techniques exist for prevention of complications during laparoscopic renal surgery. Knowledge of relevant anatomy and anatomic variations, as well as adherence to fundamental techniques, can avoid a number of common complications. Early recognition and management of complications, when arising, are critical in preserving good outcomes for the patient.

Preoperative Considerations

PATIENT SELECTION

In selecting patients for minimally invasive renal surgery, one must carefully consider factors related to the patient, the tumor, and the individual skill and experience of the operating surgeon. A careful medical history and exam are warranted, as with any other surgery, in order to determine suitability for surgery and the ability to tolerate anesthesia. In patients undergoing laparoscopic procedures, adequate ventilatory reserve is needed to allow insufflation and elevation of the diaphragm. In this regard, significant underlying pulmonary disease, obesity, or anatomic deformity may be a relative contraindication to the laparoscopic approach. In particular, obesity must be considered carefully as it can result in complications related to positioning, ventilation, and tumor/kidney exposure. Anticoagulants are generally discontinued for a week before surgery when feasible as continued anticoagulation increases morbidity during robotic partial nephrectomy.[7] At our institution we frequently continue aspirin during the perioperative period as 81 mg of aspirin is not associated with significantly higher overall bleeding complications.[8] A bowel preparation is done the day before surgery, largely to avoid postoperative constipation.

In considering patients for renal tumor surgery, the surgeon must decide on partial versus radical nephrectomy, open versus minimally invasive approach, and robotic-assisted versus pure laparoscopic technique. These decisions are, to some extent, based upon surgeon experience and preference, but several factors should be considered. Tumor size and degree of local tumor advancement must be carefully considered prior to selection for minimally invasive approaches, but in practice, this consideration is also influenced by operator experience. In the case of radical nephrectomy, we have found that tumors up to 15 cm in size can be extirpated by laparoscopic approach, but this depends upon tumor location, encroachment upon the hilum, and degree of contact with surrounding structures and great vessels. Large tumors encroaching upon the hilum may preclude early access to the renal vasculature and risk significant bleeding in mobilization of the tumor. In these cases, preoperative angioembolization may facilitate laparoscopic excision. Tumors with extension to the vena cava have been successfully resected by laparoscopic approach, but such efforts are highly challenging and require considerable experience and facility with laparoscopic techniques. The oncologic indications for partial nephrectomy are reviewed to some extent in Chapter 38. The decision between partial and radical nephrectomy is no different in minimally invasive surgery than open, and it is largely related to tumor size, focality, and location; host renal function; host age and longevity; and surgeon comfort. The absolute indications include solitary kidney, bilateral tumors, and markedly impaired renal function.[9] In selecting patients for minimally invasive partial nephrectomy, the depth and location of the tumor predicts the difficulty of both the excision and the reconstruction. As most of the complications of partial nephrectomy are associated with reconstruction, one must consider the difficulty and make decisions regarding the approach based upon the surgeon's experience.

The decision to utilize robotic assistance in renal surgery is also highly controversial, and operator dependent. Robot-assisted renal surgery has rapidly emerged as an alternative to laparoscopic surgery for the treatment of renal malignancy. Robot-assisted renal surgery has been shown to be a safe and viable alternative to laparoscopic surgery, providing equivalent early oncologic outcomes and comparable morbidity to a traditional laparoscopic approach. Moreover, robot-assisted partial nephrectomy appears to offer the advantages of less intraoperative blood loss and shorter warm ischemia time, the latter of which may help to provide maximal preservation of renal reserve. In addition, operative parameters for robot-assisted partial nephrectomy appear to be less affected by tumor complexity compared to laparoscopic partial nephrectomy.[10,11] While the benefit of robotic assistance over pure laparoscopy is difficult to measure, due to similar convalescence, we believe that

those procedures requiring reconstruction may benefit from robotic assistance, owing to the greater facility and speed of suturing and the added dexterity of a third arm for the surgeon. As such, we would generally advocate pure laparoscopy for simple nephrectomy, cyst decortication, radical nephrectomy, and any purely extirpative procedure. In the case of nephroureterectomy, the robotic device may allow complete excision of the ureter and bladder cuff without need for open bladder closure, and as such, its use could be considered depending upon surgeon preference. Several large studies have demonstrated that robotic partial nephrectomy confers a superior morbidity profile compared to laparoscopic partial nephrectomy in most perioperative outcomes;[12,13] however, not all studies' findings are consistent.[14,15] It generally appears that robotic partial nephrectomy has a lower rate of conversion to open surgery and conversion to radical surgery, shorter warm ischemia time, smaller change of estimated glomerular filtration rate, and shorter length of stay.[12,13] We have felt the greatest benefit of robotic assistance is in the performance of partial nephrectomy, largely due to the ability to reduce ischemic intervals through more rapid reconstruction, but also due to the ability to incise the renal parenchyma along anatomic lines in a more deliberate fashion, selectively clamp secondary and tertiary branches of the renal artery, and, in select cases, perform off-clamp partial nephrectomy. In general, we have performed all minimally invasive partial nephrectomies, at our institution, using robotic assistance in recent years.

OPERATIVE PLANNING

Upon making the decision to proceed with minimally invasive surgery for nephrectomy or partial nephrectomy, the surgeon must evaluate each case individually to determine the best approach and appropriate procedure. Anatomic considerations are most important, and variation in host renal anatomy must be considered when selecting the optimal approach. Patients with significant scoliotic spinal curvature and secondary rotation of the great vessels and renal hilum are at risk for inadvertent bowel, mesenteric, and great vessel injuries, and anatomy must be carefully evaluated with preoperative CT or MRI angiography prior to surgery (Figs. 34.1A–D). Similarly, anomalous renal vasculature must be identified preoperatively to ensure complete hilar control at the time of surgery (see Fig. 38.1). In particular, supernumerary renal arteries and veins are critical in order to ensure adequate ischemia during partial nephrectomy and to avoid bleeding during nephrectomy. The presence of a retroaortic left renal vein is important, in that, when present, placing the hilum on stretch can be challenging due to the vein crossing posteriorly from the lower pole, tethering the kidney.

In addition to considering the host anatomy, tumor size and anatomy should be carefully studied. Large tumors planned for radical nephrectomy should be evaluated for location, presence of accessory vasculature, and contiguous renal vein tumor thrombus. A lower pole tumor encroaching upon the medial hilar plane can present a particular challenge in that the surgeon may have difficulty in mobilizing the tumor prior to hilar control and is limited in the amount of traction that can be applied in elevating the lower pole, thus impairing hilar exposure. Upper pole tumors generally allow early hilar control, but must be carefully evaluated for presence of splenic/pancreatic/liver adherence or invasion. In some cases, concomitant en bloc organ resection may be required, and with careful planning, it can be achieved laparoscopically. Finally, when tumors are large and encroaching upon the hilum or associated with significant hilar adenopathy, early access to the renal artery may be limited. Preoperative angioembolization may be helpful in those cases. Tumor vein thrombus is best assessed on MRI venogram, but should be suspected on the basis of enlarged renal vein caliber on CT. Tumor thrombi limited to the renal vein can often be managed laparoscopically without difficulty, but those extending to the vena cava require advanced techniques. In these cases, robotic assistance can be helpful, but advanced laparoscopic skills and considerable experience is needed. Technical considerations in caval thrombus extraction are discussed in detail in Chapters 10 and 37.

In the case of partial nephrectomy, tumor location and size correlate with the risk of intraoperative and perioperative complications.[16,17] The depth of tumor invasion in the kidney, tumor size, and relationship to intrarenal structures must be considered. This evaluation has been objectified to some extent by the use of descriptive scoring methods, such as the RENAL nephrometry score.[16,17] In the preoperative evaluation, tumor size, location, endophytic nature, and proximity to the collecting system are examined on preoperative abdominal computed tomography (CT) or magnetic resonance imaging and a RENAL nephrometry score is determined, allowing standardized reporting of renal masses.[18] Both RENAL and PADUA nephrometry scores are associated with predicting warm ischemia time, urine leak, and high-grade postoperative complications after robotic-assisted partial nephrectomy.[16,17,19] The decision for open, versus minimally invasive, technique must be made by each surgeon, based on his/her operative comfort level. At our institution, we utilized robotic-assisted laparoscopic surgery for nearly all partial nephrectomy cases, including those with solitary kidney, significant multifocality, or very centrally located tumor.

A final decision is that of transperitoneal or retroperitoneal laparoscopic approach. Both approaches carry advantages and limitations, and both are easily adapted to the robotic-assisted technique. The location of the renal tumor frequently dictates the surgical approach, based upon the relationship to Brodell's line. At our center, we prefer the transperitoneal approach for all anterior and lateral tumors while employing the retroperitoneal approach for those tumors that are 100% posterior to Brodell's line and located in the mid or upper kidney. Posterior lower pole tumors can be approached in either way, as the lower pole is easily rotated from a transperitoneal approach. Often the angle from retroperitoneal port insertion to the tumor is difficult when using pure laparoscopy to address a lower pole posterior tumor, but robotic assistance can help with this.

The transperitoneal approach allows for a larger working space and more commonly encountered anatomic landmarks. This approach does, however, require bowel mobilization, increasing the risk of bowel injury, particularly with prior abdominal surgery and frequently leading to longer

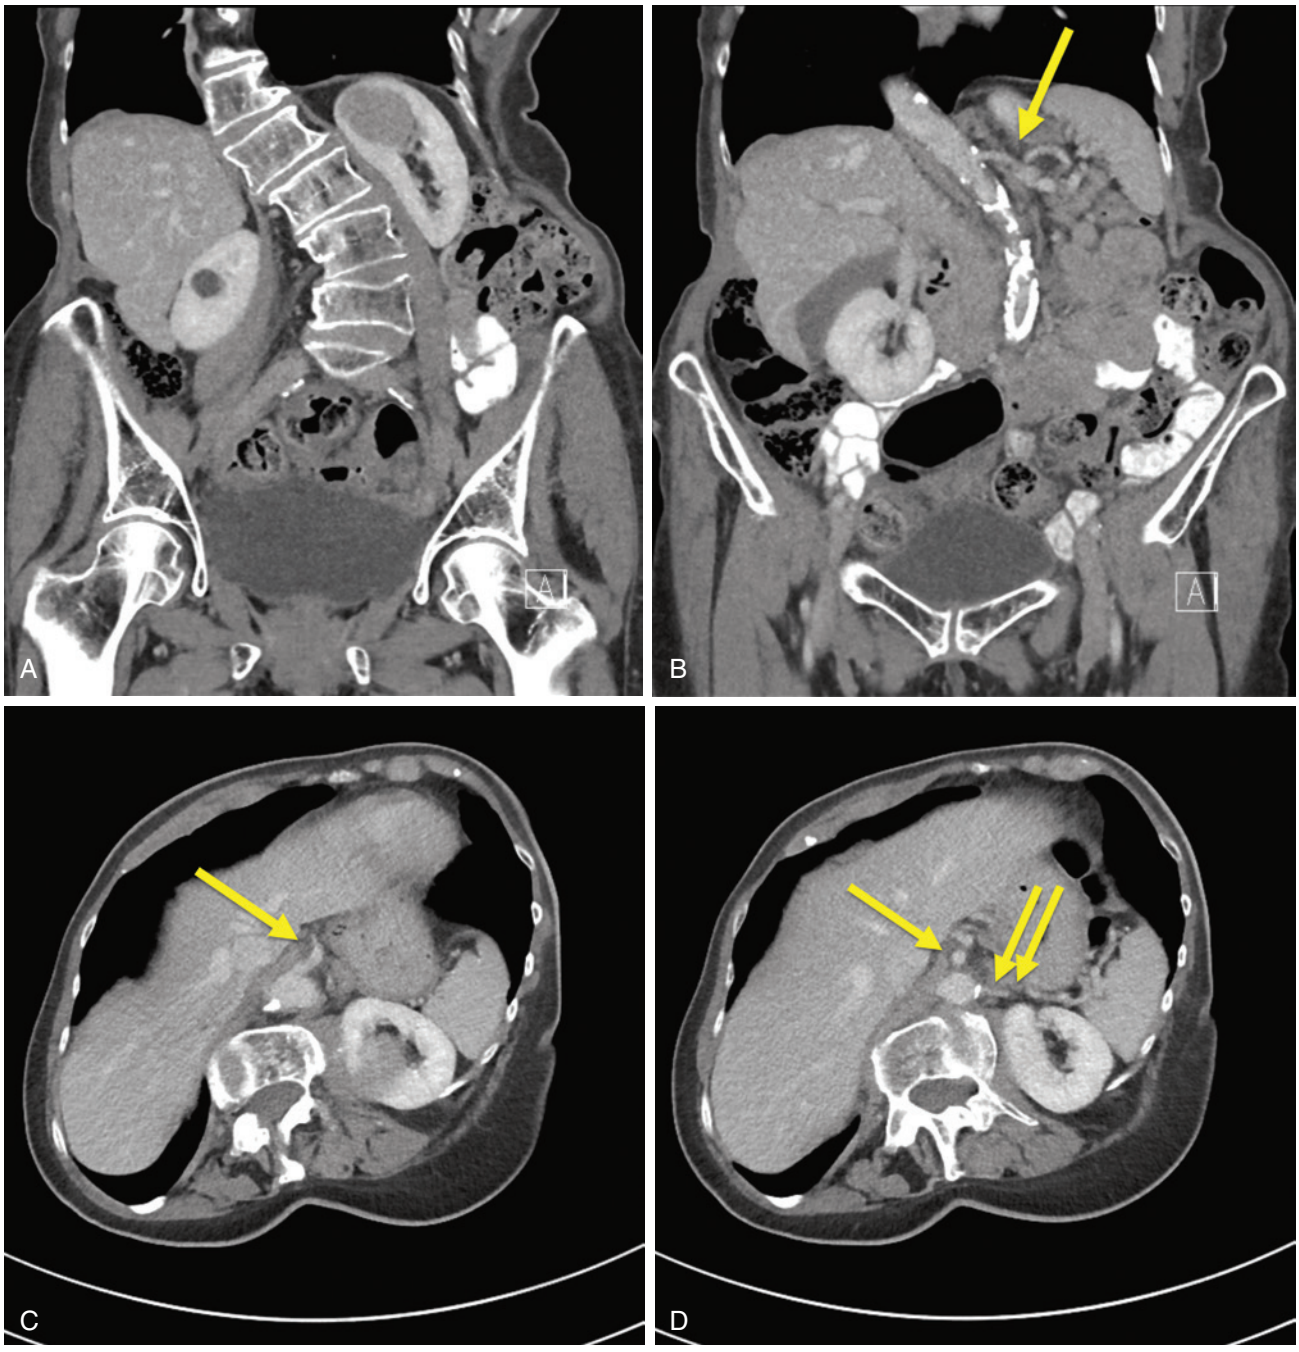

Figure 34.1 A 83-year-old female with severe kyphoscoliotic curvature of the thoracic spine (A) resulting in cranial and medial displacement of the kidney. As a result of the spinal curvature, the aorta is rotated laterally, resulting in a looping renal hilum (single arrow, panel B) with lateral deviation of the celiac trunk (single arrow, panel C) and superior mesenteric artery (single arrow, panel D) and dorsal deviation of the renal artery (double arrow, panel D). In this case, the risk of injury to the mesenteric arteries is high, given the risk of division during renal hilar dissection.

operative times and, ultimately, hospital length of stay.[20,21] The retroperitoneal approach carries a smaller working space, but offers direct access to the posterior surface of the kidney, with lower likelihood of bowel injury and ileus. Previous surgical history may also influence the decision for approach in that intraperitoneal adhesion might be avoided with retroperitoneal access, but in patients with history of previous retroperitoneal surgery, insufflation of the retroperitoneum can result in vascular injuries due to immobility of the vessels and secondary risk of stretch injury.

Procedural Complications

COMPLICATIONS RELATED TO PATIENT POSITIONING

Complications related to positioning are discussed in detail in Chapter 9. Overall, positioning injuries associated with robotic-assisted urologic surgery occur in up to 6.6% of these cases.[22] Positioning complications associated with laparoscopic renal surgery include nerve injuries due to

stretch, most commonly of the brachial plexus, and compartment syndrome with secondary rhabdomyolysis, most commonly of the gluteal compartment. The first reports of minimally invasive renal surgery by a transperitoneal approach described patient positioning in a full flank position with the table flexed. Subsequently, surgeons realized that such extreme positioning was not necessary for exposure, and it increased the risk of neuromuscular injuries.[23] More common now is a modified lateral decubitus position (45 rather than 90 degrees), without table flexion or elevation of the kidney rest. When a retroperitoneal approach is chosen, however, a full lateral decubitus position with the operating room table maximally flexed is often necessary to open up the space between the ribs and the iliac crest (see Fig. 9.5A).

Rhabdomyolysis

Rhabdomyolysis is a rare complication after urologic surgery (0.1%) but is significantly more likely for radical or partial nephrectomy compared to radical prostatectomy.[24] The minimally invasive approach conferred a 1.41 increased OR of rhabdomyolysis. The flank position is associated with higher skin-to-surface interface pressures in men than in women, which has implications for laparoscopic renal surgery and the risk of rhabdomyolysis.[23] Reisiger et al. reported seven cases of rhabdomyolysis after >700 laparoscopic renal procedures (<1%).[25] In a review of six case reports and two case series, 13 patients were reported to have developed rhabdomyolysis in association with laparoscopic nephrectomy.[15] In the setting of a solitary kidney (after laparoscopic nephrectomy), the impact of rhabdomyolysis can be profound; hemodialysis was required in four patients and one developed permanent renal insufficiency.

Prevention of rhabdomyolysis requires careful attention to positioning with avoidance of pressure on the gluteal and presacral compartment. If patients are in the semi-oblique position, they should be placed at a 45- to 60-degree angle to allow pressure to be on the hip rather than the gluteal body or presacral region. This can be particularly challenging in the obese patient. When well positioned, the surgeon should be able to easily pass a hand between the operating table and the upper gluteal region, to the hip.

Patients with gluteal compartment syndrome most commonly complain of unremitting, severe buttock and lower extremity pain upon reperfusion. Most commonly, this complaint is observed in the recovery room, and one should have a very low threshold of suspicion when the complaint is observed. In general, elevation of CPK levels and myoglobinuria lag behind the symptoms. Early intervention with fasciotomy should be considered in order to minimize muscle necrosis. Compartment pressures and cross-sectional imaging are generally noninformative in our experience, and they do not rule out the diagnosis. As swelling in the gluteal muscle increases, lower extremity numbness ensues due to nerve entrapment. In severe cases, the urine may become discolored. Urine myoglobin testing is confirmatory, but early treatment is recommended based on clinical findings. Aggressive intravenous hydration and urine alkalinization can attenuate the impact of rhabdomyolysis on renal function. Risk factors include male gender, muscularity or obesity, and prolonged operative times.[23,25]

Nerve Injuries

Other nerve injuries, including motor or sensory neuropathies, are reported in 1–3% of patients undergoing renal laparoscopy.[26–28] Robotic-assisted surgery is different from laparoscopic surgery in that it often uses more equipment and a steeper Trendelenburg position. Increased injury may be partially due to the robotic arms obscuring the surgeon's view of the patients placing the patient at risk for positioning injuries from slippage or from unrecognized compression from the robotic arms. Neuropraxic injury has occurred in up to 6.9% of robot partial nephrectomies.[22] Brachial plexus injuries can occur if significant pressure is placed on the axilla in the full lateral decubitus position. This complication can be avoided by preventing compression of the axilla with an axillary roll placed under the upper rib cage (but not compressing the axilla) (see Fig. 9.5B). In robotic surgery, we have employed a wedge that supports the upper body, with a carved groove for the lower side arm. This intrinsically protects the brachial plexus. Wrist drop and foot drop can occur when the superior hand or foot are not adequately padded. A rigid arm support attached to the operating room table is more secure than a stack of pillows in terms of supporting the wrist. In recent years, during robotic surgery, we have secured the upper arm to the patient's side in a folded pillow to leave more working space for instrumentation at the upper torso. Foam and pillows are adequate for padding the feet. Careful attention by all members of the operative team to proper fixation of the patient to the operating room table and to padding pressure points before initiating the surgical procedure can help prevent neuromuscular complications.

Neuropathies, usually motor, related to positioning should prompt immediate consultation with a neurologist. Sensory neuropathies are more likely related to the incisions for surgery (even the small ones for laparoscopic ports) or surgical dissection trauma to nerves coursing along the quadratus lumborum and psoas muscles (ilioinguinal, iliohypogastric, and genitofemoral nerves). Incision-related injuries may be unavoidable, but surgical dissection trauma to nerves can be reduced by attention to anatomic features. In most cases, the sensory deficits are transient. Symptomatic improvement while awaiting resolution can be provided by oral gabapentin or amitriptyline.

Other Complications

Testicular or scrotal injuries can result from positioning between the thighs. Scleral edema can develop in the dependent eye. Back or joint pain is not uncommon after a prolonged surgical procedure. Patients with preexisting musculoskeletal pain appear to be more prone to notable postoperative pain in the same locations. Finally, the dependent lung can become atelectatic during a prolonged procedure. In general, many of these complications can be avoided by reducing operative times.

COMPLICATIONS RELATED TO KIDNEY EXPOSURE

Some of the most devastating complications of laparoscopic surgery occur during renal exposure and mobilization. Injury to surrounding vascular structures can be

catastrophic with life-threatening bleeding or organ loss. Delayed recognition of visceral injury can likewise have dire consequences. As such, maintenance of fundamental principles during mobilization is critical, and a keen recognition of anatomy and anatomic variation can avoid unnecessary complications due to injury of surrounding structures.

On the right, exposure requires cranial retraction of the liver and medial rotation of the right colon, duodenum, and, in some patients, the pancreatic head (see Fig. 34.1). Gentle release of such structures through release of fascial attachments and blunt mobilization of the organ can avoid injury. Most often injury results in cases of local adherence of the duodenum or liver due to tumor advancement, peritumoral inflammation, or previous surgery. In such cases, sharp incision is preferable to avoid tearing of adjacent organs during blunt mobilization. On the left, medial reflection of the spleen, left colon, and pancreatic tail is necessary to expose the renal hilum. Wide release of the spleen is advisable in order to facilitate exposure of the upper pole and minimize lateral tethering of the colon. In mobilizing the lateral spleen, injury to the greater curvature of the stomach can occur. Similarly, in injury to the splenic vein or artery can occur if the surgeon wanders medially, out of plane, in mobilizing the medial organs. Maintenance of plane along the ventral surface of Gerota's fascia can avoid such a problem in most cases. In some cases, the splenocolic ligament should be divided to allow more medial exposure of the renal vein and para-aortic space. Excessive traction on the splenic hilum can result in pancreatic tear, adrenal injury, or, if thermal energy is transmitted through the mesocolon, injury to the duodenum at the level of the ligament of Treitz.

While injury to surrounding organs and vessels can occur during any case, most commonly anatomic variation, attributable to body size, habitus, or tumor burden, results in the surgeon becoming "lost" during the dissection and inadvertently crossing to another plane. As an example, rotation of the aorta, occurring in patients with aortic aneurysmal dilatation or spinal curvature, can direct the mesenteric vessels laterally and renal vessels dorsally (see Figs. 34.1A–D), thus resulting in crossing of the mesenteric fold during division of the left renal hilum. Failure to adequately mobilize the upper pole of the hilum can result in misdirection of a vascular stapler across the upper pole of the kidney or the great vessels. Maintenance of perirenal planes in approaching the hilum can avoid inadvertent injury to the vena cava, aorta, or adjacent vascular branches. Previous surgery or the presence of retroperitoneal varices due to portocaval hypertension can likewise create confusion in the operative field.

Vascular Injury

On the left side, the gonadal vein typically drains into the renal vein. This vessel can usually be ligated if necessary with clips or bipolar electrocautery. In multiparous women, this vessel can be quite large and a stapler may be required. Undue traction on surrounding tissue without adequate mobilization can tear the vein. The gonadal artery may also be visualized and controlled with clips or bipolar electrocautery, although this vessel is small and typically is managed effectively even with monopolar electrocautery. The iliac vessels are at risk during dissection of the ureter or distal dissection of the descending colon.

Less common vascular injuries include trauma to the inferior mesenteric artery (most commonly in the setting of a large lower pole mass that displaces the dissection medially), the superior mesenteric artery (most commonly in the setting of a large upper pole mass that displaces the dissection medially), and the inferior mesenteric vein (when inadvertent dissection into the colonic mesentery occurs). Suspected injury to the superior mesenteric artery necessitates vascular surgery consultation because the bowel may be rendered ischemic. Inferior mesenteric artery and vein injuries can be managed by ligating the bleeding vessel. Aortic injuries are rare, usually occurring during dissection of the base of an atherosclerotic renal artery, and they may require conversion to an open surgical or hand-assistance procedure because aortic bleeding is difficult to control with laparoscopic instruments.

Any vascular injury may be increased in likelihood by poor visualization or loss of normal anatomic features. In addition, failure to keep the camera "true" with regard to the viewing angle can cause misidentification of vessels. Conversion to a hand-assisted approach or an open surgical procedure may be warranted to provide the surgeon more direct tactile feedback when other anatomic cues are lost.

On the right side the gonadal vein drains directly into the inferior vena cava. Therefore injury of the gonadal vein on the right side is more problematic than on the left side. To avoid injury, the gonadal vein should be identified inferiorly and dissection should occur lateral to the vein. Traction on the vein can easily create a pseudoaneurysm close to the insertion of the gonadal vein into the vena cava, or it can frankly tear the inferior vena cava. Unlike the adrenal vein on the left, which drains into the renal vein and is usually straightforward to manage, the short right adrenal vein drains directly into the vena cava. Especially during radical nephrectomy for a large tumor, this vessel is at risk for avulsion if it is not identified and ligated purposely. Because of the more fragile nature of venous structures, the inferior vena cava is more prone to injury than is the aorta. Predominantly sharp dissection, or only very gentle blunt dissection, should be used around the inferior vena cava. When the inferior vena cava is torn, pressure can be applied and, depending on the skill level of the surgeon, this vessel can be sutured or the procedure can be converted to an open operation. Conversion to an open procedure is recommended if the inferior vena cava is stapled as a result of misidentification.[29] If a decision is made to convert to an open surgical procedure, pressure should be maintained on the injury and all open instruments should be prepared because the loss of insufflation will uncover venous bleeding that was held in check by the pneumoperitoneum.

A critical issue during retroperitoneoscopic renal mobilization is continuous awareness of anatomic landmarks because this approach may not be intuitive to surgeons early in their experience.[30] Once the anatomic features are learned, however, this approach typically allows immediate access to the renal hilum. When approaching the hilum, however, it is easy to keep following the psoas muscle medially and to be in too posterior a location and thus dissect under the great vessels. If this situation is not recognized, it can lead to injuries of the lumbar vessels that are very

difficult to control.[31,32] To aid in maintaining landmarks, it is advisable to keep the psoas muscle as a horizon at all times. Misorienting the camera can lead to disastrous complications such as stapling across the inferior vena cava after mistaking it for the renal vein.[29] The gonadal vein and the ureter, which are often readily apparent if balloon dissection is performed in the correct plane, are useful landmarks. Once identified, these landmarks can be traced to the renal hilum. During dissection toward the hilum, ureteral, vascular, and even visceral injuries can occur during the retroperitoneal approach. Injuries are managed in a manner similar to that described with other approaches to the kidney, but the limited working space may make laparoscopic management more challenging. In some circumstances, the extraction site for the kidney can be used to manage complications with an open approach if the kidney is removed intact.[32]

Bowel Injury

To gain access to the kidney on the left side, it is necessary to mobilize the descending colon off the entire surface of the kidney. On the right side, the colon is already placed medially, and it is often necessary only to incise the peritoneum overlying the right kidney. Colon injuries related to access and thermal injury can occur in 1.5% of patients.[33] To reduce the risk of thermal injury, incision of the parietal peritoneum should be carried out far lateral to the bowel edge along the line of Toldt, with blunt mobilization of the bowel. If a thermal injury to the colon occurs, the extent of the injury can be underestimated at the time of initial inspection; this injury may become more apparent as the surgical procedure progresses. The duodenum needs to be reflected off the renal hilum on the right side, and injury can occur easily to this fragile structure. Additionally, both small bowel and large bowel are at risk during any medial dissection and during the passage of instruments into the abdomen.

For a clearly minor serosal injury, place one or more Lembert sutures to buttress the site. For full-thickness injury, consultation with a general surgeon should be considered,[34] although the current trend is to manage many of these injuries, even of the colon, with primary closure. Depending on the skill of the surgeon, nonabsorbable suture can be used to close a full-thickness injury in two layers. Alternatively, the procedure can be converted to a hand-assisted approach and the segment of bowel can be resected or repaired through the incision.[35,36] Avoidance of electrocautery near the bowel, minimized traction on the bowel, and careful instrument passage can prevent bowel injuries.

Spleen Injury

Injury to the spleen during laparoscopic left renal surgery has been reported to occur in 1.3% of cases.[33] Small thermal injuries, or tears, can often be managed by hemostatic agents and gentle pressure alone.[37,38] Splenic injuries can be very difficult to control, however, and splenectomy may be required. Moreover, delayed hemorrhage can occur from even small splenic injuries that appeared well-controlled intraoperatively.[39] Patients may present in the early postoperative period at a delayed interval following surgery, with pain, hypotension, oliguria, and/or reduced hematocrit. Bleeding may present as a subcapsular hematoma, or free intraperitoneal hemorrhage resulting in hypovolemic shock. Blood transfusion and supportive care may be adequate care in some such patients,[39] but in others splenic embolization or splenectomy may be required. Patients undergoing splenic embolization or splenectomy should be provided appropriate vaccination postoperatively.

Pleural Injury

During medial rotation of the spleen to expose the upper pole of the left kidney, the diaphragm and pleura can be injured through either cautery or sharp dissection. On the right side, injury can occur when a large liver is being reflected. Small injuries can be managed by placing a suction tip into the pleural cavity, sucking out the pleural air, and closing the diaphragm with either suture or clip. If performed at the end of the procedure, closure of the diaphragm may not be necessary if the suction catheter is removed after evacuation of intraabdominal air and removal of ports. At the conclusion of the procedure, forceful ventilation by the anesthesiologist evacuates the CO_2 from the chest cavity prior to suction removal. If the injury is large or cannot be closed adequately with sutures alone, then placement of a chest tube at the conclusion of the procedure may be warranted. If the surgeon is not comfortable with intracorporeal suturing, conversion to an open procedure may be necessary to close large defects in the pleura.[40,41]

Pancreatic Injury

The tail of the pancreas is reflected medially to expose the left renal hilum. Avoiding overly aggressive retraction or electrocautery in this area can prevent injury. If observed intraoperatively, this usually manifests as a small tear in the posterior surface of the distal pancreas. Such injuries are rarely of sufficient depth to injure the pancreatic duct, but if concern for pancreatic ductal injury exists, general surgical consultation with consideration of distal pancreatectomy is warranted. In general, when pancreatic injury is suspected, drainage is an adequate intervention. The drain can be removed following resumption of a regular diet if the drain output does not increase. Unrecognized, injury to the pancreas typically manifests as abdominal pain, nausea, vomiting, fever, and abnormal laboratory values.[42] Minor injuries typically can be managed conservatively with bowel rest, total parenteral nutrition, and percutaneous drainage of pancreatic fluid collections. In severe cases, consultation with a general surgeon may be necessary. Prolonged but eventual recovery is the expected outcome for this complication.

Hepatobiliary Injury

Thermal burns to the liver typically do not require any intraoperative management, nor do minor tears, but larger tears in the liver capsule or incision into hepatic parenchyma may require coagulation with the argon beam coagulator or placement of hemostatic agents.[39] Occasionally, the gallbladder may be injured during removal of adhesions. If this occurs, consultation with a general surgeon to remove the gallbladder is recommended.[43]

Chylous Ascites

An uncommon complication is lymphatic leakage (with formation of chylous ascites) following left-sided laparoscopic

renal surgery, owing to lymphatic disruption during mobilization and dissection of vascular structures.[44–46] This complication is most often seen when concomitant para-aortic lymph node dissection is performed. The use of bipolar devices may reduce the risk of lymphatic leakage, and large lymphatic channels can be directly cauterized or clipped. Although chylous ascites can often be managed conservatively with total parenteral nutrition or medium-chain triglyceride diets and somatostatin, surgical intervention to ligate the source of lymphatic leakage is sometimes required. Biologic adhesives have been used successfully in this setting.[47]

Procedure-specific Considerations

PARTIAL NEPHRECTOMY

Bleeding

Not unlike open partial nephrectomy, bleeding during or after surgery is the most common procedure-specific complication of partial nephrectomy. Principles for avoidance of intraoperative bleeding do not differ greatly from open partial nephrectomy (outlined in Chapter 38), but some differences in technique are worth consideration. Not unlike open partial nephrectomy, careful evaluation of tumor location, relationship to tumor vasculature, and depth of invasion is critical in planning tumor excision.

During excision of the tumor, we have generally utilized renal ischemia for those tumors with a large surface area or depth extending to or beyond the corticomedullary junction. For tumors confined to the cortex that are relatively small (<3 cm), nonclamped excision is generally feasible, particularly when utilizing robotic assistance. In several instances, intraoperative bleeding may be encountered if attempting off-clamp partial nephrectomy. It is important to fully mobilize the kidney and release the perinephric fat from the renal parenchyma well beyond the tumor, in order to avoid undue traction on the divided kidney. Such traction increases bleeding during the unclamped incision. Cutting "downhill," such that blood in the field drips away from the incision line, is also useful to limit the pooling of blood and the loss of vision. If brisk bleeding is encountered precluding vision, then arterial clamping can be conducted at any time, provided the artery has been exposed and prepared for clamp prior to renal incision. Similarly, we generally administer mannitol prior to renal incision, in the event that clamping is required.

For tumors that are resected while the artery is clamped, pulsatile intraoperative bleeding upon renal incision can indicate failure to recognize a supernumerary renal artery. In these cases, the decision to proceed with the partial nephrectomy should be based upon the surgeon's vision and the ability to ensure a negative margin. In the event that vision is obscured, one can attempt to identify the missed renal artery through use of a laparoscopic Doppler probe to allow directed dissection or, if bleeding is brisk, placement of a laparoscopic pedicle clamp through a separate stab incision. Open conversion is rarely required. In cases of good renal ischemia, the cortex appears soft as it is cut, and only minimal oozing is noted. Upon entry into the renal sinus, large venous channels may bleed, particularly on the right. In these cases, bleeding can generally be controlled by placing the hilum on stretch. If this maneuver is insufficient to tamponade the retrograde bleeding, a venous clamp can be placed.

In some cases, in which the vein and artery are clamped for excision, brisk bleeding may be encountered on renal incision. While this may indicate a missed renal artery, more commonly it may reflect venous hypertension within the kidney, secondary to some degree of arterial inflow. In these cases, removal of the vein clamp may allow the bleeding to stop sufficiently in order to complete the resection and reconstruction.

Renal reconstruction requires suture control of larger central vessels, compression of renal parenchyma, and cautery or compression control of smaller, cortical vessels. In open surgery, direct suture ligature of individual vessels, prior to division, is desirable to avoid retraction. Such a technique is not feasible in the case of laparoscopic or robotic partial nephrectomy. In laparoscopic partial nephrectomy, we have described a technique of single-pass suturing that meets all the basic tenets of reconstruction,[48] and we have subsequently adapted this for use in robotic-assisted procedures. In this technique, a suture is passed into the defect through the renal capsule (Fig. 34.2) and is

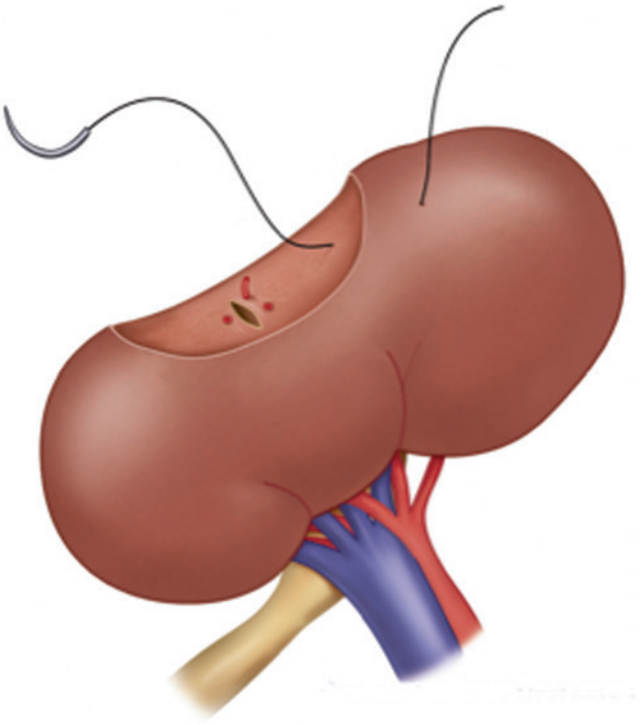

Figure 34.2 The Taneja technique of laparoscopic/robotic renorrhaphy.[48] A 2-0 Vicryl suture on an SH (small half-circle) needle is passed through the outer renal capsule approximately 2 cm from the cut edge of the resection bed into the base of the renal defect. The end of the suture is knotted and preloaded with a 5-mm locking hemoclip (Hem-o-Lok, Pilling Weck Canada LP, Markham, Ontario, Canada) to anchor the suture at the outer capsule. (Courtesy of Division of Urologic Oncology, Department of Urology, New York University Langone Medical Center, New York, 2009.)

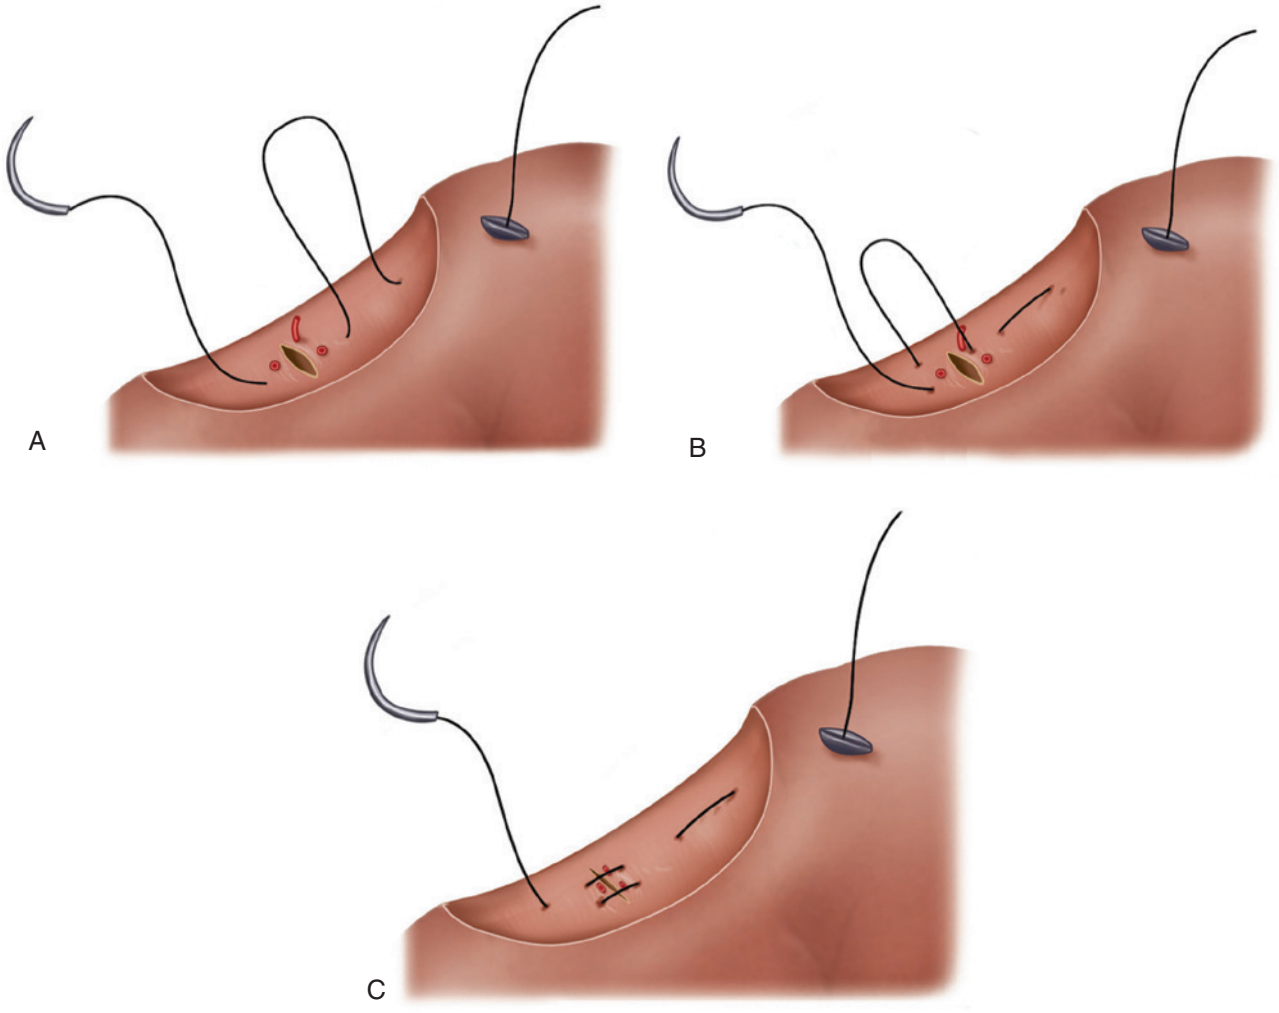

Figure 34.3 The Taneja technique of laparoscopic/robotic renorrhaphy.[48] A–C, The suture is passed in a running fashion along the deepest aspect of the renal defect, with care to incorporate collecting system opening until closure is complete. Adjacent muscular arterial branches or central venotomies are included in the suture to provide central compression, and the renal sinus is imbricated within the closure for compression. In those cases in which the collecting system is not entered, the central, deepest portion of the defect is closed with a similar running suture. (Courtesy of Division of Urologic Oncology, Department of Urology, New York University Langone Medical Center, New York, 2009.)

fixed to the surrounding capsule with a locking clip (Hemo-Lok, Pilling Weck Canada LP, Markham, Ontario, Canada). The suture is passed in a running fashion through the central portion of the defect to incorporate the collecting system and larger cut vascular channels (Fig. 34.3) and then is advanced out of the defect through the contralateral capsular edge. In doing so, the free end of the suture is secured with a clip while cinching down against the capsule (Fig. 34.4). The radial tension of the stitch pulls the central vessels into the defect rather than allowing them to retract, while compressing the surrounding renal capsule. By placing two such sutures in an X configuration, compression is directed to the center of the resection defect (Fig. 34.5). After removal of the clamp, we can add additional sutures in a similar single plane fashion across the center of the defect, as needed, to maximize compression. This is not usually required unless the defect is extremely large. To date, the technique has resulted in one episode of delayed bleeding due to pseudoaneurysm and no arteriovenous fistula (AVF) in over 500 consecutive cases.

Small vessels in the cut parenchyma that continue to ooze despite suture reconstruction can be controlled by cautery or argon beam coagulation. We have preferred use of a wet electrode (Tissue Link, Medtronic, Minneapolis, MN). Reconstruction can be bolstered by the addition of tissue adhesives or hemostatic materials, though we have not found this to be necessary in most cases. The surgeon should be aware of potential allergic reactions related to the use of bovine thrombin especially in patients who have been previously exposed to this product during other surgical procedures (commonly cardiac surgery). An allergic reaction can produce coagulopathy that can be life threatening to the patient. The surgeon must have the patient's complete surgical history before these products are used and, if necessary, must review prior operative reports to determine whether the use of the hemostatic agents could place the patient at risk.[49,50]

On rare occasions, postoperative bleeding following partial nephrectomy can present any time up to 60 days following partial nephrectomy. This is most commonly due

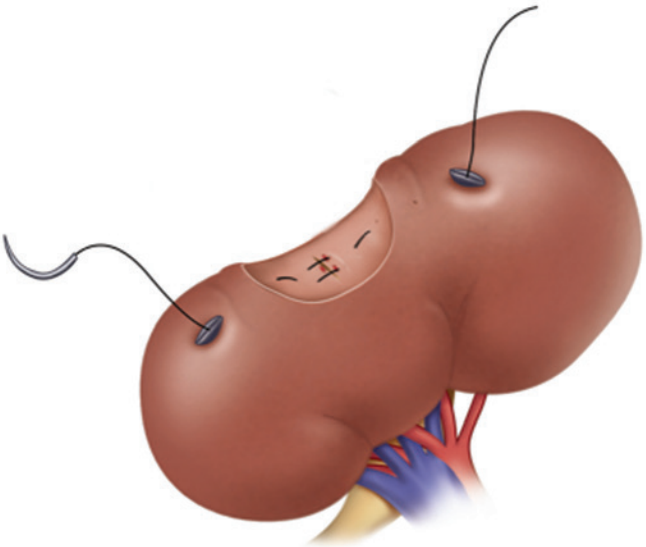

Figure 34.4 The Taneja technique of laparoscopic/robotic renorrhaphy.[48] While the surgeon holds the leading edge of the suture on tension, the needle is passed out of the resection bed through the outer renal capsule opposite the site of entry. A locking hemoclip (Hem-o-lok, Pilling Weck Canada LP, Markham, Ontario, Canada) is used to cinch the suture, compress the defect, and lock the suture in place. Compression of the resection defect is achieved by cinching the suture ends in the direction of the central portion of the defect. (Courtesy of Division of Urologic Oncology, Department of Urology, New York University Langone Medical Center, New York, 2009.)

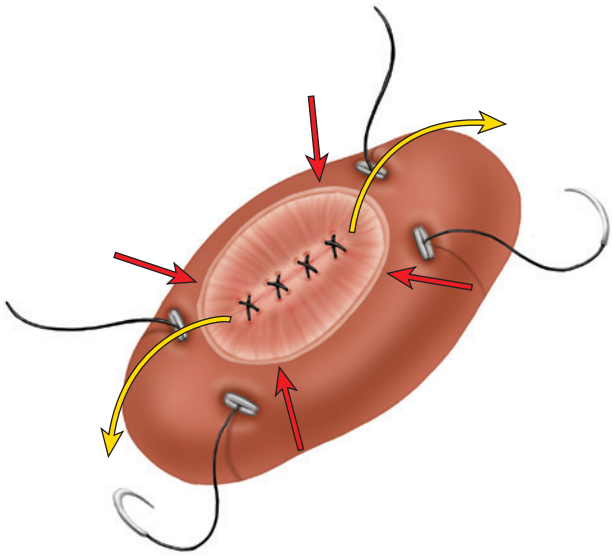

Figure 34.5 The Taneja technique of laparoscopic/robotic renorrhaphy.[48] By placing two such sutures in an X configuration, compression is directed to the center of the resection defect. The radial tension of the stitches pulls the central vessels into the defect (yellow curved arrows) rather than allowing them to retract, while compressing the surrounding renal capsule (red arrows).

to formation of a pseudoaneurysm that breaks into the collecting system or bursts. Similarly, an AVF can do the same, but often presents earlier in the postoperative course. It is our experience that delayed bleeding due to pseudoaneurysm or AVF is far more common with minimally invasive procedures than with open, and this may reflect less precise

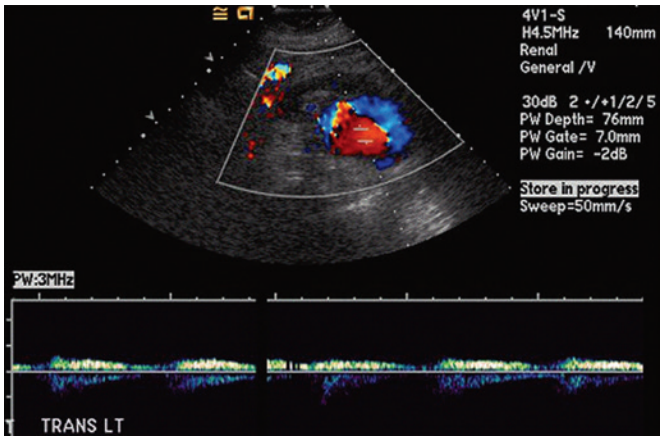

Figure 34.6 Duplex ultrasonography demonstrating the "yin-yang" sign of turbulent mixing of arterial and venous blood following laparoscopic partial nephrectomy. (Courtesy of Michael Stifelman, MD.)

suturing techniques. Generally, patients may present with sudden gross hematuria. Retroperitoneal bleeding, resulting in hemodynamic instability, is possible but far less common. At presentation, the surgeon should have high suspicion for pseudoaneurysm or AVF and proceed to angiography. Although duplex ultrasound (Fig. 34.6) or CT may identify the fistula, angiography can identify the fistula and allow for management through selective embolization in the same setting (Figs. 34.7A–C).[51]

Urine Leak

Urine leak has been reported in 3– 5% of patients undergoing laparoscopic partial nephrectomy.[52–55] Urine leak was noted in 0.78% of patients who underwent robotic-assisted partial nephrectomy in one large multi-institutional study.[56] Management of urine leak is discussed in detail in Chapters 13 and 38, and the management of urine leak following laparoscopic or robotic-assisted partial nephrectomy does not differ greatly from that of an open partial nephrectomy. As laparoscopic procedures are more often performed through a transperitoneal exposure, the risk of urinary ascites and secondary ileus may be greater. Variables associated with urine leak include: tumor size, hilar location, operative time, warm ischemia time, and pelvicalyceal repair.[56]

If the collecting system is entered, the surgeon should leave a closed drain near the tumor resection bed and a Foley catheter in the bladder during the initial postoperative period. If no drainage is noted from the drain, the catheter is removed 1–2 days postoperatively, and the drain is monitored before removal. We routinely check creatinine level from the drain prior to removal.

Most urine leaks following laparoscopic partial nephrectomy present in the very early postoperative period with increased drain output, which on chemical testing is found to be most consistent with urine. Upon demonstration of urine leak, ultrasound or cross-sectional imaging should be performed to rule out undrained urine collections, hydronephrosis, and concern for ureteral injury. In the absence of these findings, the patient is generally sent home with the drain to wait for resolution of the leak. The drain can be left in place for several weeks to allow healing of the fistula, which generally occurs by scarring down the perirenal

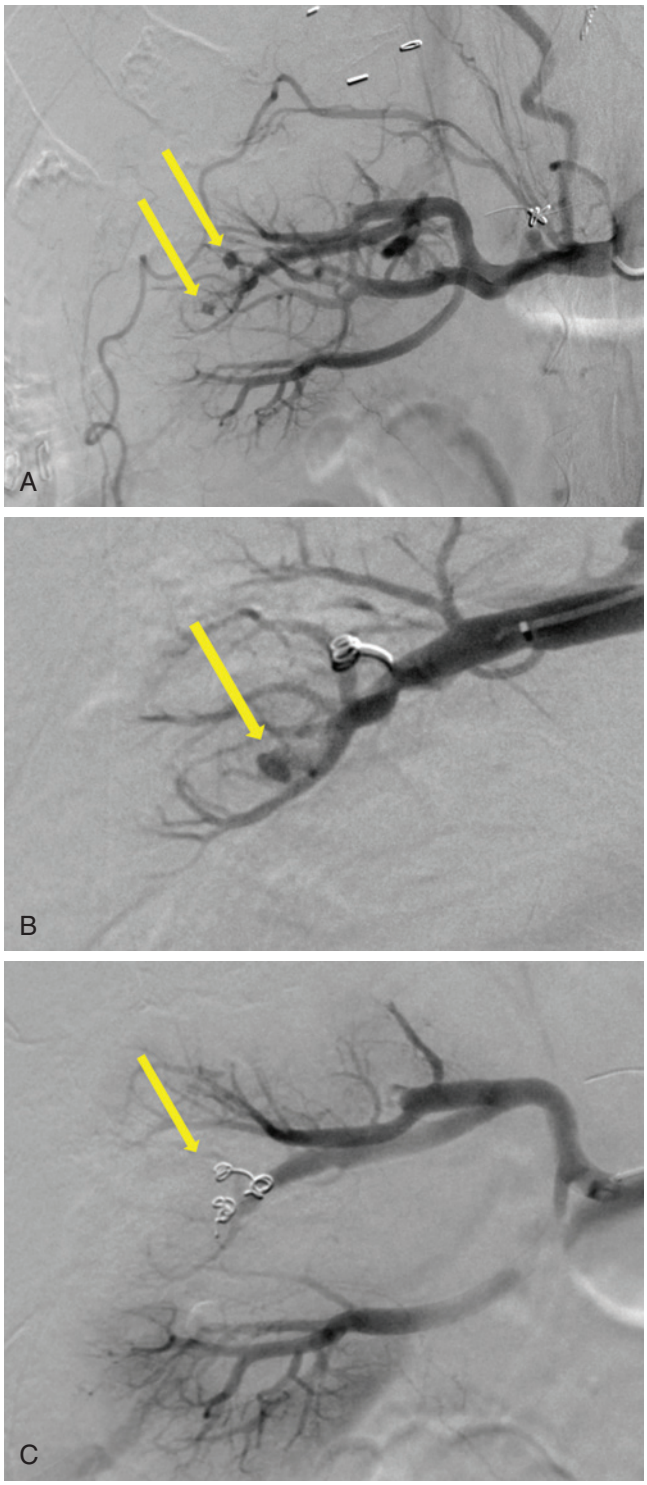

Figure 34.7 Angiography in a 75-year-old man presenting with gross hematuria, 10 days after robotic-assisted laparoscopic partial nephrectomy for three right renal tumors. A midpole branch of the posterior segmental artery demonstrates a 3-mm pseudoaneurysm and an adjacent arteriocalyceal fistula (yellow arrows, panel A). Following selective embolization of that branch, an adjacent arterial branch demonstrates an arteriovenous fistula (yellow arrow, panel B). Following selective embolization of both branches, no further bleeding sites are noted (panel C). (Courtesy of Michael Stifelman, MD.)

space around the drain. As drain outputs decline, the drain can be advanced out slowly to allow the tract to scar down and close the leak. It has not been our general practice to place ureteral stents or nephrostomy, unless there is hydronephrosis due to obstruction present in the operated kidney. On occasion, large lower pole leaks resulting in pooling of urine around the proximal ureter or ureteropelvic junction may warrant stent or nephrostomy drainage due to the risk of periureteral fibrosis and secondary obstruction with perpetuation of the leak. Leaks that persist at high volume (>500 mL/day) may indicate anatomic abnormality or infarction of tissue, and in these cases, placement of stent or percutaneous nephrostomy may be considered. Occasionally, persistent urinomas require percutaneous drainage under ultrasound or CT guidance.[55,57]

Delayed presentation of leak is less common, but since most patients appear well after minimally invasive surgery, the surgeon should be careful to rule out the presence of urinoma in follow-up. We have employed postoperative ultrasound to rule out urinoma in patients recovering from partial nephrectomy, but this is extremely low yield when used empirically. Additionally, it is not unreasonable for uncomplicated urinomas away from the ureter, in the absence of infection or obstruction, to be observed. They will often resolve on their own over time or become small diverticuli off the collecting system.

Renal Function

Prolonged renal ischemia can result in postoperative acute tubular necrosis (ATN) and acute failure of the kidney. These complications are especially problematic if the partial nephrectomy is performed for absolute indications (solitary kidney, poor renal function). Because suturing is required for deeper resections, the likelihood of prolonged ischemia times during minimally invasive partial nephrectomy is greater in the setting of deep tumors. Given the considerable learning curve of sutured bolster application for minimally invasive partial nephrectomy, it is recommended that early in a surgeon's experience the procedure should be limited to small exophytic tumors to allow the surgeon to gain comfort with the steps of the procedure.[58]

Most minimally invasive partial nephrectomies should reasonably be completed with a clamp time of ≤30–45 minutes. Although a warm ischemia time of <60 minutes has been reported to be safe, if a longer ischemia time is anticipated because of the complexity of the procedure, several maneuvers may assist in limiting ischemic injury. We routinely give 12.5 g of mannitol before clamping the renal hilum, followed by an additional 12.5 g when the hilum is unclamped. However, the influence of mannitol on renal function recovery remains controversial.[59] Additional maneuvers to limit global renal ischemia include "zero ischemia" in which tumor-specific clamping of the artery/vein occurs, coupled with carefully calibrated and timed intraoperative reduction of blood pressure,[60] selective/segmental arterial clamping without main renal artery clamping,[61] early arterial unclamping,[62] and off-clamp partial nephrectomy.[63] The benefits of limited arterial clamping appears to be attenuated by 3 months' follow-up.[64,65] In addition, intracorporeal cooling techniques have been introduced to facilitate cold ischemia during robotic partial nephrectomy.[66]

We have generally felt that most of these maneuvers are unnecessary, and we have been able to perform partial nephrectomy by laparoscopic robotic-assisted technique in the majority of patients with deep or complex tumors, solitary kidney, multifocality, and preexisting renal disease. In cases at high risk for postoperative ATN, off-clamp partial nephrectomy is desirable whenever feasible.

Repeat robotic partial nephrectomy poses challenges and complications. Repeat surgery is technically challenging with some studies reporting an association with increased blood loss and postsurgical length of stay as well as increased rates of urine leak.[67] Repeat robotic partial nephrectomy can be safely and effectively performed in patients presenting with local recurrence after primary nephron-sparing surgery for kidney cancer.[68]

Renal malignancies are often diagnosed at an older age, and although the elderly have more comorbidity and often lower eGFR, it appears that elderly patients undergoing robotic partial nephrectomy do not have increased risk of perioperative complications compared to their younger counterparts.[69,70] Hospital readmission within 30 days of surgery after robotic partial nephrectomy occurs at a rate of about 4.5%, associated most commonly with patient comorbidity.[71] Postoperative bleeding is the most common driver of readmissions, occurring in more than 25% of readmitted patients.[71]

Donor Nephrectomy

Laparoscopy is the preferred management for donor nephrectomy and may be responsible in large part for the increase in the number of living related donors for renal transplantation.[72] In several large series, major complications were reported in 4–6% of patients.[73–75] Although these renal units are anatomically normal, the need to remove a functional organ with adequate ureteral and vascular length for anastomosis in the recipient, while maintaining safety for the donor, leaves a small margin for complications in this procedure.

Complications most likely to affect the quality of the graft relate to vascular injury. The left kidney is the most frequently removed from the donor in most institutions. Ligation of the small tributaries of the renal vein without use of clips can reduce the risk of staple misfire due to an entangled clip. In a series of eight stapler malfunctions involving the renal vein during laparoscopic nephrectomy, the most common cause was stapling over a clip.[76] In a reported donor nephrectomy series, six of 738 cases resulted in vascular injury caused by staple misfiring or malfunction and necessitating conversion to an open surgical procedure.[51]

Other vascular injuries reported during laparoscopic donor nephrectomy include laceration of the renal vessels during dissection, clip dislodgment from the renal artery stump, and vascular tears at the junction of the renal vessels and the aorta or inferior vena cava.[77] A significant number of reports of slippage of Hem-o-lok clips (Pilling Weck Canada LP, Markham, Ontario, Canada) off the renal artery during laparoscopic donor nephrectomy caused the U.S. Food and Drug Administration to prohibit the use of these clips to control the renal artery during this procedure.[78] This prohibition is limited to laparoscopic donor nephrectomy, and these clips can still be used at the surgeon's discretion during simple or radical nephrectomy. This decision should be based on the length of remaining arterial stump for secure clip placement.

Several aspects of laparoscopic donor nephrectomy can compromise the function of the graft in the recipient. Ureteral injury can result in inadequate length for ureteroneocystotomy. To ensure adequate distal ureteral blood supply to prevent anastomotic strictures, many urologists preserve the gonadal vein along with the ureter during harvesting.[79] Delayed graft function is likely related to many factors, including prolonged warm ischemia time and vasospasm in the graft. Moreover, delayed graft function is related to overall graft survival.[79] Hand-assistance procedures may minimize warm ischemia time,[80] and these procedures may be safer than bag entrapment as for intact extraction after standard laparoscopy. Several reported cases of renal laceration and hematoma were related to injury from specimen entrapment.[81] "Resting" of the kidney and the use of diuretics and papaverine minimize vasospasm in the kidney and reduce the incidence of delayed graft function.[55] Up to 2% of patients report testicular pain, leg numbness, or other scrotal problems following laparoscopic donor nephrectomy related to gonadal vein ligation (in young patients) and possible injury to the ilioinguinal or genitofemoral nerves.[82]

Simple Nephrectomy

The term *simple nephrectomy* encompasses a large number of benign indications. Laparoscopic nephrectomy has been reported for xanthogranulomatous pyelonephritis, other infectious causes (tuberculosis), polycystic renal disease, and nonfunctioning (chronic hydronephrosis, failed pyeloplasty, reflux nephropathy) or atrophic kidneys. In a meta-analysis of laparoscopic renal complications, simple nephrectomy had the highest incidence of conversion to an open procedure, at 3.7%.[33] The predominant causes of complications associated with this procedure are inflammation distorting normal tissue planes and the lack of working space resulting from enlarged and distorted renal units.

The colon may be at more risk of injury than in other laparoscopic renal surgical procedures because inflammation makes mobilization difficult. A complete mechanical bowel preparation is indicated in this population, in whom the risk of injury approaches 1%.[83–87] A common pitfall during colon mobilization in laparoscopic simple nephrectomy is dissection into the colonic mesentery. A through-and-through dissection can occur easily without recognition. This dissection increases the likelihood of vascular injury, including injury to the mesenteric and contralateral renal vessels.[29] A clue to this incorrect dissection is the finding of vessels directed toward the colon. A large mesenteric opening does not require closure. Small openings may require closure to prevent the possibility of internal hernia.

If colon injury does occur, the extent of the injury should guide management. Treatment can range from reinspection of the area at the conclusion of the procedure for serosal injuries to laparoscopic repair or resection of full-thickness tears. Depending on experience and access to intraoperative consultation, laparoscopic management may be possible, or this injury may require conversion to an open procedure for repair and completion of the operation.

A second potential problem encountered with simple nephrectomy caused by lack of tissue planes is difficulty with renal hilar dissection and management. Inflammatory processes such as xanthogranulomatous pyelonephritis or chronic hydronephrosis resulting from nephrolithiasis may create significant perihilar inflammation or adenopathy that prevents successful isolation of the renal artery and vein. Although we prefer to ligate the renal artery and vein separately, in this circumstance it is often best to place a single clip on the renal artery (to stop blood flow) and then use a vascular laparoscopic stapler to control the hilum distal to the clip. Although not recommended as a routine measure, a stapler can be used to ligate the entire hilum en bloc with little risk of arteriovenous fistula.[88,89]

The real risk in using a stapler to ligate the entire hilum en bloc is not arteriovenous fistula formation, but rather the possibility that the stapler will misfire because too much tissue remains around the hilum for the device to close adequately. Enough dissection needs to be performed to thin the tissue bundle. If that is not possible, consideration of conversion to a hand-assistance procedure or an open operation is warranted, given that failure to control the hilum can be life threatening. If the stapler does fail, the hilum en bloc can often be clamped again for temporary hemostasis. If feasible, a second trocar can be placed adjacent to the one with the stapler and a second stapler can be introduced more proximally on the vessels. The risk here is injury to a great vessel if the surgeon is disoriented.[85]

Because simple nephrectomy is not an oncologic procedure, the tendency exists to dissect close to the kidney. Although the space within Gerota's fascia or a subcapsular plane may provide the best mobilization and dissection of the kidney, this often places the surgeon very close to the renal sinus, where multiple arterial and venous branches may be encountered and vascular control may be more difficult. Identification of the gonadal vein with dissection of this vessel toward the renal hilum typically places the surgeon proximal enough on the renal artery and vein to avoid managing multiple branches.

A common problem encountered intraoperatively is failure to progress. Although this is not a complication, awareness of lack of progression during the case and conversion to hand-assistance procedures or an open operation can prevent the risks associated with prolonged operative time. Failure to progress often results from difficulty with mobilization of the kidney, owing to chronic infection, previous nephrostomy tube, and prior operation on the kidney or ureter, for example.[85–87]

The major risks in patients following laparoscopic simple nephrectomy are infection and abscess formation, especially in patients with xanthogranulomatous pyelonephritis. Before the procedure, obtain a urine culture from the patient and treat any infection appropriately. In such cases, it may be advantageous to leave a drain in place following the procedure. In cases of infection caused by chronic reflux nephropathy, ligate the ureteral stump with a clip. Despite preventive measures, many patients managed by simple nephrectomy have an infectious complication. Medical comorbidities such as diabetes can increase this risk.

Conclusions

Minimally invasive renal surgery when applied to the appropriate candidate and performed with good clinical judgement may allow for low complication rates, ultimately improving clinical outcomes for patients. An adequate technical skillset and an understanding of the relevant anatomy, and anatomic variations, as well as adherence to fundamental techniques, can avoid a number of common complications. Early recognition and management of complications, when arising, is critical in preserving good outcomes for the patient.

Chapter 34 Questions

1. A 45-year-old male undergoes a left robotic-assisted laparoscopic partial nephrectomy for a 3-cm left renal mass. The renal artery and vein are clamped. Upon incision of the renal parenchyma, steady, nonpulsatile bleeding is noted from the tissue, precluding vision of the resection margin. The next maneuver is to:
   a. Attempt to suture bleeding points
   b. Reclamp the renal artery
   c. Unclamp the renal vein
   d. Identify additional renal arteries
   e. Proceed with nephrectomy

2. A 62-year-old woman is scheduled for a left nephrectomy, and she desires a minimally invasive approach. She has had a previous left colectomy and colostomy for perforated diverticulitus, followed by colostomy take down. The most reasonable surgical approach is:
   a. Transperitoneal laparoscopic
   b. Robotic-assisted transperitoneal laparoscopic
   c. Retroperitoneal laparoscopic
   d. Open transperitoneal
   e. Open retroperitoneal

3. A 63-year-old man presents with a 9-cm right renal mass encroaching upon the renal hilum. During surgery the renal artery is effaced by the tumor and local lymphadenopathy, precluding its identification. Significant venous bleeding is noted from the hilar region. The next step is to:
   a. Place a pedicle clamp
   b. Mass divide the pedicle with a stapler
   c. Divide the renal vein to expose the artery
   d. Pack the area, close, and proceed with angioembolization
   e. Identify the right renal artery medial to the vena cava

4. A 56-year-old female develops bright red painless gross hematuria 15 days after a left laparoscopic partial nephrectomy for a lower pole renal mass. The hematuria subsides 10 hours later, and she presents to the office the following day. The next step is:
   a. Urine culture
   b. Cystoscopy
   c. Retrograde pyelogram
   d. Duplex ultrasound
   e. Angiogram, selective angioembolization

5. During mobilization of the left kidney for laparoscopic nephrectomy, an inadvertent 1-cm injury to the posterior capsule of the distal pancreas is noted. There is no evidence of fluid leaking from the injury, and it appears to have a depth of <1 cm. The next step is to:
   a. Abort nephrectomy and leave a drain
   b. Complete nephrectomy and leave a drain
   c. Repair injury with interrupted absorbable suture
   d. Abort nephrectomy and perform distal pancreatectomy
   e. Complete nephrectomy with en bloc distal pancreatectomy

6. A 58-year-old man with a BMI of 33.8 undergoes a left laparoscopic nephrectomy for a 7-cm upper pole renal tumor. He has a previous history of colon cancer, requiring left colectomy. Surgery is prolonged due to adhesions, tumor size, and obesity. In the recovery room, he complains of unremitting pain in his left lower extremity, radiating from the hip to the upper thigh. On exam, the right buttock is tender, but not swollen, and neurologic exam and lower extremity pulses are normal. The most likely diagnosis is:
   a. Lumbar disc herniation
   b. Sciatic nerve compression
   c. Deep vein thrombosis
   d. Gluteal compartment syndrome
   e. Hematoma

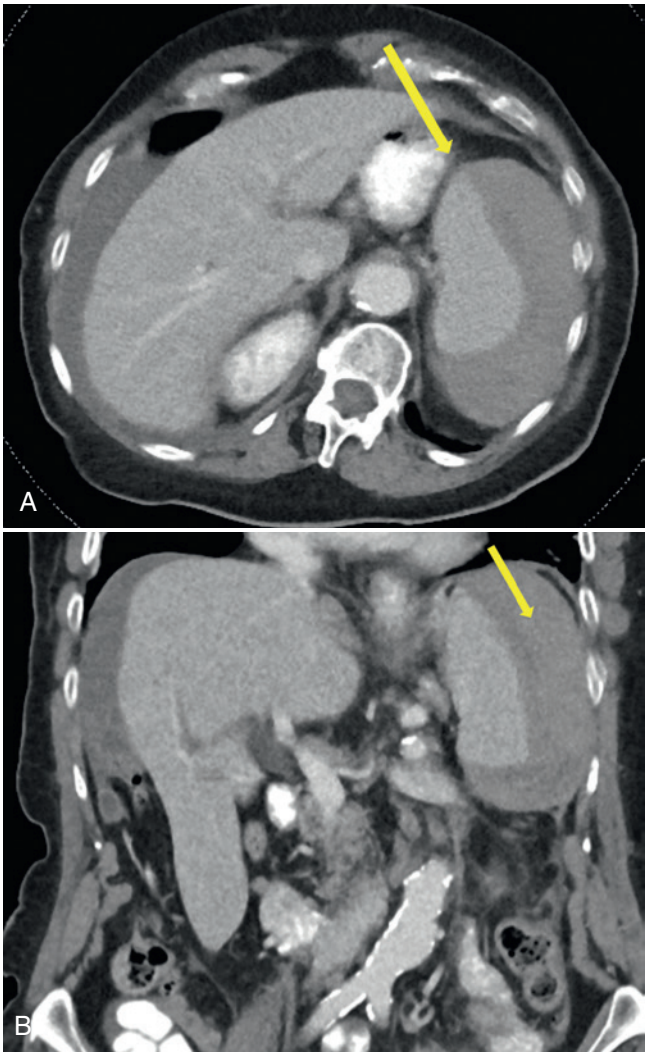
7. The use of locking clips (Hem-o-lok) for control of the renal artery(ies) is prohibited by the Food and Drug Administration during the performance of:
   a. Reoperative renal surgery
   b. Radical nephrectomy
   c. Simple nephrectomy
   d. Donor nephrectomy
   e. Cadaveric nephrectomy

8. A primary advantage of the retroperitoneal laparoscopic approach is:
   a. Large working space
   b. Early identification of the renal artery
   c. Reduced risk of bleeding complications
   d. No risk of bowel injury
   e. Reduced subcutaneous emphysema

9. During laparoscopic transperitoneal simple nephrectomy for xanthogranulomatous pyelonephritis, a good landmark to aid in identifying the renal hilum is the:
   a. Gonadal vein
   b. Adrenal gland
   c. Great vessels
   d. Renal pelvis
   e. Ureter

10. Following an uncomplicated robotic-assisted partial nephrectomy, increased drain output is noted on postoperative day 3. Drainage creatinine is measured at 32 ng/dL. In this patient, one should consider stent placement if:
    a. Cross-sectional imaging confirms a urinoma
    b. Drain outputs exceed 500 mL/day
    c. Imaging demonstrates hydronephrosis
    d. The leak is from the upper pole
    e. Multiple tumors were resected

Case Study 1



A 74-year-old woman underwent an uncomplicated left robotic-assisted partial nephrectomy for an upper pole renal mass. She was discharged home 1 day after surgery, feeling well. On the 14th postoperative day, after coughing, she slowly starts to develop left upper quadrant and flank pain. She denies hematuria. On evaluation, her exam is

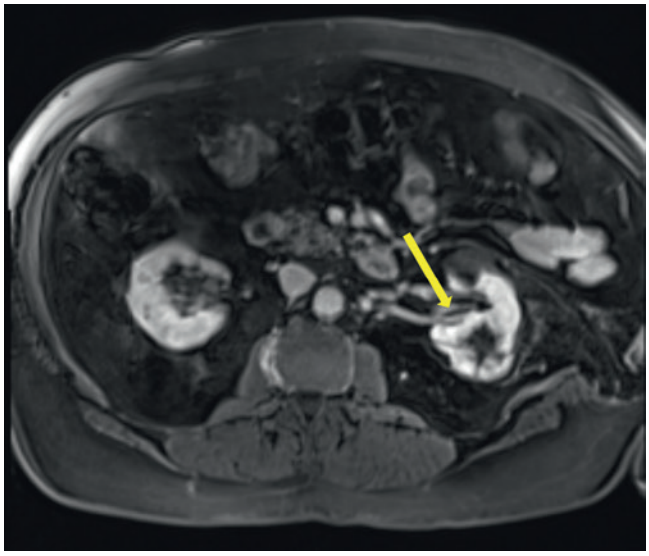
unremarkable, with the exception of mild left upper quadrant/flank tenderness. She has no hematuria. Her hemoglobin is 12.3 g/dL.

1. The next step is:
   a. Observation, antacids, analgesics
   b. Contrast chest CT
   c. Abdominal CT
   d. Renal duplex
   e. Angiography, selective embolization

A CT scan is performed (Case Fig. 34.1) demonstrating a large subcapsular hematoma of the spleen (yellow arrows). Following hydration, the hemoglobin is 8.9 g/dL. Over the next 6 hours, following resuscitation, the hemoglobin declines to 7.8 g/dL.

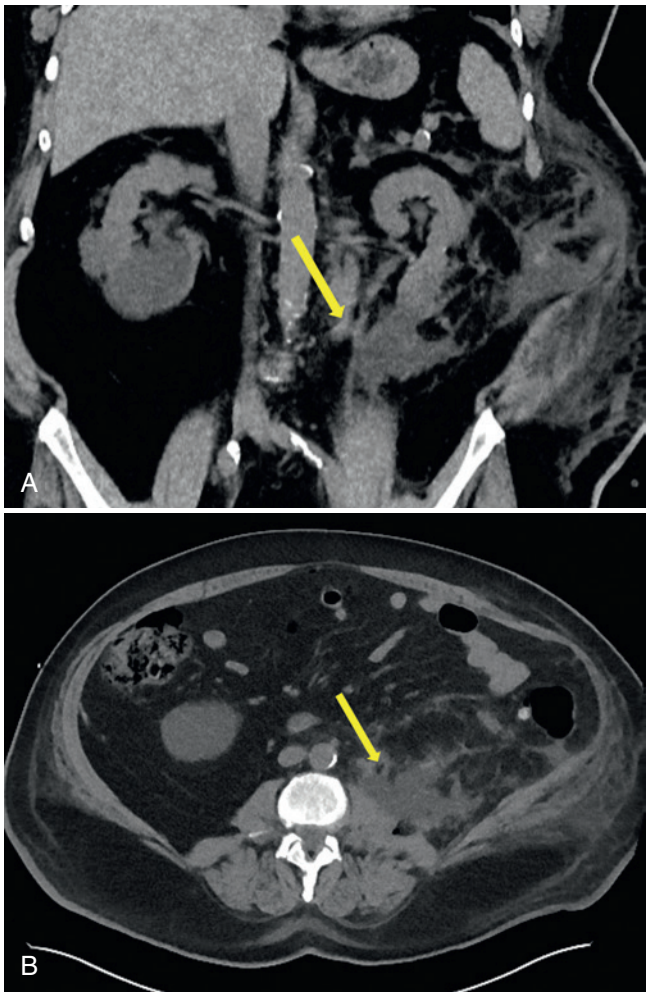
2. If the patient were to undergo a splenectomy, she would require:
   a. Platelet transfusions
   b. Chronic suppressive antibiotics
   c. Pneumococcal vaccine
   d. Immunostimulatory agents
   e. Protective clothing

Case Figure 34.1



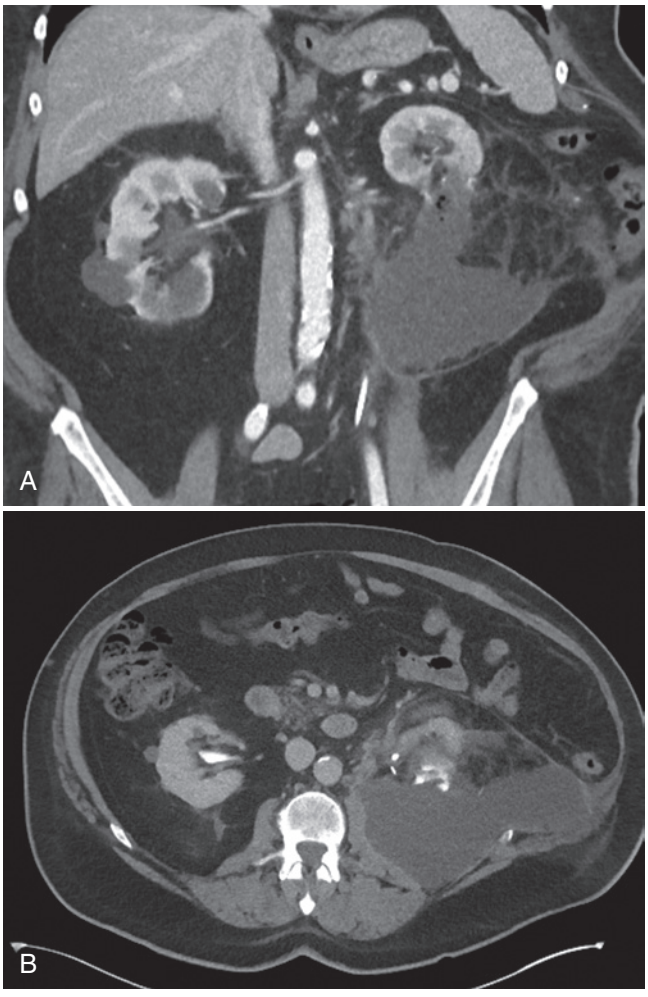
3. If continued bleeding is noted, the optimal treatment would be:
   a. Systemic hemostatic agents, supportive care
   b. Spleen angioembolization
   c. Percutaneous drainage of hematoma
   d. Re-exploration with splenorraphy
   e. Re-exploration with splenectomy

Case Study 2



A 67-year-old male presents with a 4.5-cm left lower pole renal mass (Case Fig. 34.2) and a history of chronic kidney disease. He has undergone a previous open partial nephrectomy through a left flank incision for a renal cell carcinoma located in the midpole, 3 years earlier. A robotic-assisted partial nephrectomy is performed, and, at the time of surgery, severe fibrosis and scarring is identified around the lower pole, renal hilum, and posterior renal plane. With difficulty, the ureter is released from the scar and retracted medially to allow a partial nephrectomy to be performed. The collecting system is visibly entered and repaired. Following surgery, his baseline serum creatinine rises from 1.5 ng/dL to 2.7 ng/dL over 3 days. His drain output is elevated to 150–200 mL per 8-hour shift. Drain creatinine level is 28 ng/dL. He has no fever, and his white blood cell count is within normal limits.

1. The next step is:
   a. Continued observation
   b. Advance the drain
   c. Cross-sectional imaging
   d. Place stent
   e. Place nephrostomy



A CT scan without contrast is performed (Case Fig. 34.3), demonstrating a fluid collection (Case Fig. 34.3A, yellow arrow) surrounding the lower pole and proximal ureter (Case Fig. 34.3B, yellow arrow). There is minimal hydronephrosis. The position of the leak cannot definitively be determined.

Case Figure 34.2

Case Figure 34.3

Case Figure 34.4

2. The next step is:
   a. Continued observation
   b. Retrograde pyelogram and possible stent
   c. Nephrostomy placement
   d. Remove suction from drain
   e. Re-exploration for repair or nephrectomy

A retrograde pyelogram demonstrates patency of the ureter, with considerable extravasation from the lower pole collecting system (Case Fig. 34.3). A stent is placed, along with a urethral catheter, and the patient's drain output subsides greatly over the next 24 hours. He is discharged home with drain outputs of 20 mL per 8-hour shift. He returns 2 weeks later with the catheter removed. His drain is no longer putting out any fluid. He is feeling well. A CT urogram is performed prior to drain removal (Case Fig. 34.4) as shown.

3. The next step is:
   a. Replace urethral catheter
   b. Replace urethral catheter, percutaneous drain placement
   c. Replace urethral catheter, percutaneous nephrostomy placement
   d. Replace urethral catheter, percutaneous drain placement, and sclerosis
   e. Replace urethral catheter, open drainage, and nephrectomy

Answers

1. **c.** Bleeding upon incision of the renal parenchyma, with the hilar vessels clamped generally indicates accessory renal arterial supply that was not identified during hilar exposure. While identification of the additional arterial supply may be warranted, steady bleeding as described may indicate venous hypertension due to arterial inflow, with obstructed venous outflow. In this case, initial release of the venous clamp is a reasonable first maneuver as it will likely reduce bleeding. In the event that bleeding continues, an attempt to identify accessory renal arterial supply, through use of a laparoscopic Doppler probe, or placement of a pedicle clamp is reasonable.
2. **e.** While any of the surgical approaches is feasible, the most difficult, due to previous intraabdominal surgery and infection, is the transperitoneal laparoscopic or open approach. In this case, the use of robotic assistance would not reduce the degree of difficulty, due to adhesions precluding the development of an adequate working space and the presence of pericolic fibrosis. While this patient desires a minimally invasive approach, and laparoscopy by retroperitoneal approach could be considered, it is not the optimal approach as retroperitoneal adhesion is likely present

and would make balloon insufflation of the retroperitoneum risky given the potential for vascular or bowel injury. In this case, an open retroperitoneal approach would be most prudent.

3. **e.** While preoperative angioembolization is helpful in cases of large renal tumors encroaching upon the renal artery, intraoperative identification of the problem precludes such an approach due to ongoing bleeding. In these cases, division of the vein would only increase bleeding significantly, while any attempt at mass ligation of the pedicle would risk vascular injury due to the blind nature of the maneuver. In this case, the ideal approach would be to identify the renal artery away from the affected region of the operative field, in the interaortocaval groove.
4. **e.** The presentation of sudden onset gross hematuria in the patient recovering from partial nephrectomy should prompt a suspicion of pseudoaneurysm or arteriovenous fistula. In this case, the patient has stopped bleeding, but is at risk of bleeding again. In the absence of symptoms, there should be low suspicion for cystitis or renal stone disease. While duplex ultrasound may identify an arteriovenous fistula, the patient is at high risk for re-bleed and potential for significant blood loss. Angiography is the definitive test to rule out a source of bleeding and allow for corrective intervention.
5. **b.** In this case, the location and size of the injury would indicate that there is very little risk of injury to the pancreatic duct. As such, drainage is an adequate management strategy for this injury, and pancreatectomy is not warranted. There is no reason to abort the nephrectomy in this case.
6. **d.** In this patient, his obesity and prolonged surgery put him at risk of gluteal compartment syndrome and secondary rhabdomyolysis as a result of prolonged compression of the right gluteal compartment in the right lateral decubitus position. Prompt evaluation with compartment pressures, urinary myoglobin testing, and measurement of serum CPK is warranted, but may not identify the diagnosis at this early point in his clinical presentation. As such, early consideration of fasciotomy to minimize muscle necrosis is warranted.
7. **d.** A significant number of reports of slippage of Hemo-lok clips off the renal artery during laparoscopic donor nephrectomy caused the U.S. Food and Drug Administration to prohibit the use of these clips to control the renal artery during this procedure. This prohibition is limited to laparoscopic donor nephrectomy, and these clips can still be used at the surgeon's discretion during simple or radical nephrectomy. This decision should be based on the length of remaining arterial stump for secure clip placement.
8. **b.** Retroperitoneal laparoscopic exposure of the kidney allows for early identification of the renal artery, but does not reduce the risk of vascular complications due to the risk of misorientation within a reduced working space and inadvertent injury to the great vessels or renal hilum. While bowel is not present in the field, thermal transmission to the peritoneum risks inadvertent, unrecognized bowel injury. Insufflation of the retroperitoneum, particularly in a thin person, can lead to increased risk of subcutaneous emphysema, pneumomediastinum, and pneumothorax.
9. **a.** Because simple nephrectomy is not an oncologic procedure, the tendency exists to dissect close to the kidney. Although the space within Gerota's fascia or a subcapsular plane may provide the best mobilization and dissection of the kidney, this often places the surgeon very close to the renal sinus, where multiple arterial and venous branches may be encountered and vascular control may be more difficult. Identification of the gonadal vein with dissection of this vessel toward the renal hilum typically places the surgeon proximal enough on the renal artery and vein to avoid managing multiple branches.
10. **c.** In most patients with early urine leak following partial nephrectomy, stent or nephrostomy placement is not needed in the absence of obstruction. Cross-sectional imaging should be performed to rule out urinoma and hydronephrosis. The presence of urinoma should prompt additional extrarenal drainage, and the presence of hydronephrosis should prompt renal drainage. Most early leaks should resolve if well controlled with drain placement, even in the setting of high outputs or complex resections.

CASE STUDY 1

1. **c.** In this patient, the suspicion for renal arteriovenous fistula should be low, given the absence of hematuria and the primary presentation of pain. As such, renal duplex and arteriogram would not be the likely, best first test. While a retroperitoneal hematoma is a feasible cause for left upper quadrant pain and tenderness, the normal hemoglobin does not support this. In this case, a CT scan of the abdomen will aid in determining if a hematoma is present and if a secondary intra-abdominal process is ongoing. As such, in this case, it is the most informative first test.
2. **c.** Patients undergoing splenectomy, either electively or due to incidental injury, are at risk for pneumococcal infections, and it is generally advised they should have a pneumococcal vaccine. Other immunostimulatory, or hematologic, therapy is not needed.
3. **b.** Subcapsular hematoma of the spleen may be a self-remitting process. In this case, continued observation to determine if the bleeding subsides would be a reasonable approach if the patient remains hemodynamically stable. If continued bleeding is noted, or the patient becomes progressively unstable, angioembolization is a reasonable first approach prior to splenectomy with reasonable success rates. If bleeding progresses despite embolization efforts, then splenectomy is likely warranted. Efforts to repair the splenic injury through drainage or re-exploration would likely worsen bleeding and result in splenectomy.

CASE STUDY 2

1. **c.** In patients with a demonstrated early postoperative urine leak following partial nephrectomy, intervention is rarely required, as most leaks will resolve on their own with adequate drainage. While observation is almost

certainly the best course of action, renal imaging to evaluate for hydronephrosis and/or perirenal urinoma should be performed to determine the adequacy of drainage and the necessity for a stent or nephrostomy.

2. **b.** As the patient has a demonstrated urine leak with some hydronephrosis, further evaluation is warranted to ensure the kidney is well drained. In this case, placement of a stent may be warranted if ureteral obstruction is observed on retrograde pyelogram. Additionally, urine pooling around the proximal ureter could result in peri-ureteral fibrosis over time, with secondary obstruction and worsening of the leak. If a urinoma were to persist despite stent placement, then additional extrarenal drainage may be warranted. In this case, the difficulty of the case should also alert the surgeon to the possibility of an unrecognized ureteral injury, given the need for sharp release and traction on the ureter. Stent or nephrostomy would only be warranted if hydronephrosis or suspicion for ureteral injury is noted, or in the event of a large urinoma surrounding the lower pole or proximal ureter.
3. **b.** While nephrostomy drainage may ultimately be required if the persistent leak is not resolved by replacing the urethral catheter, at present, the primary goal should be to drain the extrarenal collection in order to allow the leak to scar in and to avoid periureteral fibrosis. In this case, the patient should have been imaged prior to discharge from the hospital in order to determine no residual urinoma was present upon diminishing drain outputs.

35 Complications of Robotic Upper Urinary Tract Reconstruction

LEE C. ZHAO, KIRANPREET K. KHURANA, and MICHAEL D. STIFELMAN

CHAPTER OUTLINE

Preoperative Considerations
Operative Planning
Intraoperative Complications
Minimally Invasive Pyeloplasty
Minimally Invasive Ureteral Reconstruction
Minimally Invasive Ureterolysis
Minimally Invasive Buccal Mucosa Graft Ureteroplasty
Minimally Invasive Renal Autotransplantation
Postoperative Complications
Minimally Invasive Pyeloplasty
Minimally Invasive Ureterolysis
Minimally Invasive Ureteral Reimplantation
Minimally Invasive Ureteroureterostomy
Minimally Invasive Boari Flap
Minimally Invasive Buccal Mucosa Ureteroplasty
Minimally Invasive Ileal Ureter
Minimally Invasive Ureterocalicostomy
Minimally Invasive Transureteroureterostomy
Conclusions
Chapter 35 Questions and Answers

KEY POINTS

1. All upper tract reconstructive procedures have been performed safely and effectively using minimally invasive techniques, including laparoscopic and robotic surgery.
2. Thorough preoperative planning is critical for upper tract reconstruction, including preoperative imaging geared toward the type of surgery being performed and counseling about the different types of reconstruction that may be required depending on intraoperative findings.
3. Minimizing manipulation of tissue during upper tract reconstruction is critical to reduce risk of ureteral stricture and urinoma formation.
4. Maximal drainage of the urinary tract after upper tract reconstruction (i.e., ureteral stent placement, percutaneous drainage, and bladder drainage) reduces the risk of urine leakage and urinoma formation postoperatively.

The role of minimally invasive techniques in urologic surgery has burgeoned since the late 1990s. As intracorporeal suturing is a challenging aspect of laparoscopic reconstruction, there has been more widespread adoption of robotic techniques. Reconstruction of the upper urinary tract includes but is not limited to the following procedures: pyeloplasty, ureteroureterostomy, retrocaval ureter repair, ureteral reimplantation, psoas hitch or Boari flap, ileal ureter, ureterolysis, and renal autotransplantation. Buccal mucosa ureteroplasty is a new procedure that has been added to the armamentarium. This approach may be used if a ureteroureterostomy is not possible due to the length of the ureteral stricture, limited ureteral mobility due to radiation or fibrosis, or if a concomitant stricture exists in another location of the ureter. Robotic-assisted laparoscopic renal autotransplantation has been described recently, demonstrating the feasibility of using minimally invasive approaches for these cases.[1]

Complications may result from both technical and patient-related factors, although meticulous technique can help to minimize morbidity. Comfort with open surgical techniques is essential for any minimally invasive surgery to ensure competent intervention when conversion to an open procedure is required. This chapter reviews preoperative considerations and the management of complications.

Preoperative Considerations

OPERATIVE PLANNING

Reconstruction of the upper urinary tract relies on a thorough understanding of a patient's anatomy related to both disease and anatomic variation. Planning for pyeloplasty should include computed tomography (CT) or magnetic resonance imaging (MRI) with contrast to assess for crossing vessels and delineate hilar anatomy. Diuretic renal scans are useful to assess relative renal function and extent of obstruction. Additionally, if minimally invasive

ureterolysis is planned, biopsy of retroperitoneal tissue should be considered before ureteral manipulation to exclude malignancy.

Patients may have a mechanical bowel preparation before reconstructive urologic surgery to increase working space and improve exposure. A bowel preparation may also be useful for upper urinary tract reconstruction if harvesting bowel for ureteral interposition is planned.

The decision to use minimally invasive techniques depends primarily on the surgeon's preference and experience. Regarding the use of laparoscopy alone versus robotic assistance, few data suggest superiority of one technique over the other. Selection of transperitoneal versus retroperitoneal approaches for reconstruction depends primarily on the surgeon's preference. Both approaches are safe and effective for upper urinary tract surgery.[2–5] A comparative study evaluated retroperitoneal robotic pyeloplasty and transperitoneal robotic pyeloplasty.[5] Average operative time was similar, and there were no intraoperative complications. There were two recurrences in the retroperitoneal group and none in the transperitoneal group; notably the recurrences occurred in the first 10 cases. Retroperitoneal access may be safer in patients with extensive prior abdominal surgery and obesity, although disadvantages include limited working space and a potentially steeper learning curve.[6]

INTRAOPERATIVE COMPLICATIONS

General principles of perioperative care apply to patients having urologic reconstruction and include the use of bilateral sequential compression boots, prophylactic antibiotics, and generous padding for all pressure points.

Complications related to access and pneumoperitoneum are discussed in Chapter 30. This section describes complications specific to minimally invasive reconstructive procedures and recommendations regarding their management.

MINIMALLY INVASIVE PYELOPLASTY

Laparoscopic pyeloplasty was first described in 1993 and became the standard of care.[7,8] Robotic assistance was first reported by Sung and colleagues in 1999,[9] and numerous series have been published demonstrating the equivalence or superiority of this technique.[10–13]

In a series of 147 patients who underwent laparoscopic transperitoneal pyeloplasty, two cases of bowel injury were reported, including a serosal injury to the small bowel and an inadvertently clipped colonic diverticulum.[14] Both injuries were repaired during the same surgical procedure with no sequelae. No intraoperative complications were reported in a large series of patients who underwent extraperitoneal laparoscopic pyeloplasty.[4] In a multi-institutional series of robotic pyeloplasty among 140 patients, a single minor intraoperative splenic laceration was noted and successfully managed with pressure and topical hemostatic agents.[15] In another series of 131 patients, there was only one conversion to open surgery due to technical difficulties.[16] A multiinstitutional study of 168 patients undergoing robotic pyeloplasty reported no intraoperative complications.[17] Notably 21 (13%) of these cases were secondary repairs.

The reported rate of conversion from laparoscopic to open pyeloplasty is ≈1.6%.[2–4,18] Rassweiler and associates[19] reported a single conversion in their large series of retroperitoneal laparoscopic pyeloplasty based on significant anastomotic tension and the requirement for open dissection and fixation of the kidney during suturing. Mufarrij and associates[15] reported no open conversions in a series of 140 robotic pyeloplasties, whereas another study noted one open conversion out of 131 cases.[16]

The risk of significant bleeding from laparoscopic or robotic pyeloplasty is low. Inadvertent injury to major vessels may be minimized with good operative planning including CT with contrast to identify crossing vessels or anomalous vascular anatomy. However, in our experience, imaging may not be completely reliable; both false-positive and false-negative results of imaging for relevant vessels may occur.

Laparoscopic suturing is the most challenging aspect of laparoscopic pyeloplasty. Technical complications of suturing (e.g., stricture, urinary extravasation) may be minimized by meticulous technique, but patient-related factors (e.g., history of diabetes, secondary repair) may influence the incidence of these complications. Creating a tension-free anastomosis requires careful intraoperative planning and may decrease the risk of complications related to ureteral ischemia and suture line breakdown. Intraoperative techniques for safely creating more length include downward nephropexy and creation of a "handle" in the renal pelvis to decrease the manipulation of healthy tissue. Traction sutures can also be placed in the ureter or pelvis to decrease manipulation of tissue and decrease the risk of ischemia.

Ureteral stent placement across the anastomosis is essential to minimize the risk of urinary leakage. Complications of stent placement include submucosal tunneling and incomplete advancement into the bladder or kidney, depending on the direction of placement. If anterograde placement is performed, the bladder can be filled with 300 mL of methylene blue; refluxed dye confirms correct distal positioning of the stent. Flexible cystoscopy can also be performed to confirm correct placement of the ureteral stent.[20]

MINIMALLY INVASIVE URETERAL RECONSTRUCTION

Laparoscopic and robotic ureteral reconstruction has been performed in all portions of the ureter for diverse indications including trauma, stricture, neoplasm, and anatomic abnormalities.[21–25] Procedures have included ureteroureterostomy, ureteral reimplantation with or without psoas hitch, Boari flap, ileal ureter, ureterolysis, and retrocaval ureter repair. A novel procedure using buccal mucosa graft for ureteral repair has been developed.[26]

Laparoscopic ureteroureterostomy was first reported for treatment of infiltrative endometriosis and has been performed without significant intraoperative complications or need for conversion to an open procedure.[27] Robotic approach has also been used safely and successfully for ureteroureterostomy.[28,29] A unique consideration for ureteroureterostomy relates to the "watershed" blood supply of the midureter and the potentially increased risk of ischemia during manipulation and suturing. Techniques

for reducing the risk of ischemia include minimizing the manipulation of tissues (e.g., using traction sutures), minimizing medial dissection of the ureter and potential disruption of the vascular supply, and ensuring that the ureteral edges appear pink and healthy before anastomosis. A new technique developed by Lee and associates[30] was described to reduce the risk of injury to the ureter during surgery and to assist in localizing the ureteral stricture during repair. The authors used indocyanine green in an antegrade and retrograde fashion into the ureter and visualized it using near-infrared fluorescence during repair. A recent modification is the use of indocyanine green intravenously to evaluate tissue perfusion. Ureteral tissue appears dark if poorly perfused and bright green if well perfused. This technique has since been used by other groups to minimize complications related to poor blood supply.[31–33]

Ureteral stent placement is recommended in all patients having ureteral repair and can be placed preoperatively or intraoperatively in a retrograde fashion or transperitoneally during the surgery. If the ureteral length is insufficient for primary anastomosis, techniques such as psoas hitch or Boari flap can be performed to gain length distally. Buccal mucosa graft ureteroplasty, bowel interposition, or autotransplantation may be necessary if other techniques are unsuccessful. Understanding the patient's anatomy and extent of disease is essential to ensure appropriate operative planning and management of the patient's expectations preoperatively.

Despite limited data, evidence indicates that the intraoperative complication risk of ureteral reconstruction is low. No significant intraoperative complications were noted in series of laparoscopic and robotic ureteral reimplantation (for indications including reflux, distal ureter injury, and low-grade distal ureteral urothelial cell carcinoma),[21,25,34] Boari flap,[35,36] ureteroureterostomy,[37] ureterocalicostomy,[38,39] ileal ureter,[40] and retrocaval ureter repair.[23,41,42] One study of robotic ureteroureterostomy in 12 patients reported a liver and gallbladder laceration during robotic port placement due to adhesions which required a concomitant cholecystectomy.[43] Conversion to open was reported in one out of 16 patients who underwent robotic ureteral surgery. The patient had a prior history of pancreatectomy, and open conversion was needed to complete distal ureteral resection with reimplantation and psoas hitch for cancer.[44]

A study compared open, laparoscopic, and robotic ureteral reimplantation in 130 patients.[45] In the laparoscopic group, there was a 5% rate of intraoperative complications including inadvertent ureterotomies repaired primarily, enterotomy requiring small bowel resection, and injury to appendix requiring appendectomy. There was a 2% rate of conversions to open in the laparoscopic cohort, one for small bowel resection and another for technical difficulty. There were no complications or conversions in the robotic or open cohort. Robotic approach allows for better visualization, easier suturing, and improved hemostasis resulting in minimal complications. An additional two studies compared a total of 35 robotic to 65 open ureteral reimplants and found significantly less blood loss and shorter hospital stay for the robotic group.[46,47] These reports suggest that robotic ureteral reconstruction seems to be at least equivalent to the open approach, but may offer the additional benefits of minimal blood loss and shorter hospital stay.

MINIMALLY INVASIVE URETEROLYSIS

Laparoscopic ureterolysis was first reported by Kavoussi and associates in 1992.[48] Laparoscopic dissection within a fibrotic retroperitoneum can be challenging given diminished tactile feedback. However, low morbidity was reported in several series of laparoscopic ureterolysis.[49,50] Indocyanine green or intraoperative ultrasound can help to identify the ureter if fibrosis obscures retroperitoneal anatomy.[51]

Ureteral injury is one potential complication of laparoscopic ureterolysis. Ureteral injuries should be repaired with either a minimally invasive approach or with an open procedure, based on the extent and location of injury. Omental wrapping or intraperitonealization can be performed to protect the ureteral anastomosis. Rare complications include vascular injury, for example, an iliac vein injury,[35] pneumothorax, and subcutaneous emphysema.[52,53]

Reported conversion rates to open procedures have been 15% in series of laparoscopic ureterolysis.[35,49] Conversion has been required secondary to technical difficulty with periureteral fibrosis, vascular injury, and other emergency indications.

Robotic ureterolysis has been safely performed without intraoperative complication.[51] Improved visualization from robotic technology may facilitate identification of the ureter, and the precision of robotic Pott scissors and greater degrees of freedom may facilitate the dissection and potentially decrease the risk of injury.

MINIMALLY INVASIVE BUCCAL MUCOSA GRAFT URETEROPLASTY

Oral mucosal graft for ureteroplasty was first reported in an animal model in 1984.[54] Ureteral strictures have been treated successfully with buccal mucosa with an open approach.[26,55–57] In a study of five patients, buccal mucosa graft was used for strictures between 3.5 cm and 5 cm. There were no intraoperative complications, and at a mean follow-up of 24 months there was a 100% success rate. Robotic buccal mucosal ureteroplasty was done in four patients in one study, and there were no intraoperative complications. Some of the intraoperative maneuvers to ensure a successful repair were as follows: use of an omental flap or a perirenal flap to provide a vascular bed, simultaneous flexible ureteroscopy to localize the stricture, intravenous injection of indocyanine green to identify well-vascularized ureteral tissue, and flexible ureteroscopy during anastomosis to prevent placement of suture into the back wall of the ureter and to confirm a watertight anastomosis.

MINIMALLY INVASIVE RENAL AUTOTRANSPLANTATION

A technique of completely intracorporeal renal autotransplantation has been recently described in a patient with long ureteral stricture due to ureteral perforation during endoscopic stone treatment.[1] Warm ischemia time for nephrectomy was 2.3 minutes, while cold ischemia time was 95.5 minutes. Total console time for the surgeon was

334 minutes. The patient was discharged home on postoperative day 1 after a transplant Doppler ultrasound showed patent vascular anastomosis and after removal of Foley catheter and drain. The ureteral stent was removed at 6 weeks. A intravenous urogram 2 weeks after stent removal showed no extravasation or obstruction.[1]

Postoperative Complications

Most complications of laparoscopic or robotic surgery are postoperative.[2–4] In addition, intraoperative injuries may not be recognized until the postoperative period. Symptoms that cannot be explained by physical examination or routine studies should prompt further evaluation. CT can lead to diagnosis in most patients with unexplained pain, fever, leukocytosis, or decreasing hematocrit following urologic minimally invasive surgery.[58] See Chapter 30 for a thorough discussion of general postoperative complications of urologic minimally invasive surgery, including trocar site hernia or infection, ileus or bowel injury, bleeding, and medical complications. This section discusses postoperative complications specific to minimally invasive upper urinary tract reconstruction.

MINIMALLY INVASIVE PYELOPLASTY

See Table 35.1 for a summary of postoperative complications from major series of robotic pyeloplasty. These studies did not use standardized definitions of complications and thus may not be directly comparable. Minor and major complications were often grouped together in determining the total complication rate in these studies.

The reported postoperative complication rate for laparoscopic pyeloplasty is 2–22%.[19,59,60] A meta-analysis of laparoscopic pyeloplasty series revealed an 8% postoperative complication rate including hematoma, urinoma, pyelonephritis, bowel serosal injury, transient ileus, thrombophlebitis, and ureteropelvic junction (UPJ) anastomotic stricture.[61] Increasing experience with laparoscopic pyeloplasty within series revealed decreasing rates of postoperative complications.[59] Extraperitoneal laparoscopic pyeloplasty has published complication rates of ≈13%.[2–4]

Postoperative complication rates for robotic pyeloplasty have also been low, ranging from 3% to 11%.[10,15,17,20,62] The complications include urinary tract infection or pyelonephritis, ileus, stent migration or malposition, urine leak, bleeding requiring transfusion, recurrence of obstruction, and complications from operative positioning. Postoperative pyelonephritis may be treated successfully with antibiotics.[16] Stent migration or malposition requires repositioning under general anesthesia. It may be prevented by performing flexible cystoscopy to confirm a curl in the bladder at the time of surgery. Urine leak generally requires diversion of urine with Foley catheter, stent, or nephrostomy tube. If there is a urinoma, percutaneous drain placement into the urinoma in conjunction with diversion of urine may treat the complication. Bleeding may result in the formation of a clot in the renal pelvis requiring stent placement.[17] The renal pelvis should be irrigated before closure to minimize the likelihood of this complication. The failure or recurrence rate is low, but requires repeat pyeloplasty or endopyelotomy.[20] Positioning complications may include gluteal necrosis and rhabdomyolysis.[15] This can be prevented by decreasing operative time and not flexing the table, especially for obese patients, to allow more even distribution of

Table 35.1 Postoperative Complications of Robotic-assisted Laparoscopic Pyeloplasty

Reference	No. Procedures	Postoperative Complication Rate (No. Patients)	Postoperative Complications (No. Patients)
Hopf et al. (2016)[101]	129	13.9% (18)	Clavien I (3), II (5), III (10)
Sivaram et al. (2012)[17]	168	6.6% (11)	Ileus (4), transfusion (3), pyelonephritis (1), urine leak (3)
Mufarrij (2008)[28]	140	7.1% (10) (major) 2.9% (4) (minor)	*Major:* stent migration (7), clot obstruction, gluteal compartment syndrome requiring fasciotomy, pyelonephritis/obstruction *Minor:* febrile UTI, urine leak (2), splenic laceration (intraoperative)
Schwentner et al. (2007)[10]	92	3.3% (3)	Bleeding into renal pelvis/colic with urine extravasation requiring stent exchange and PCN, bleeding into collecting system 2 days postoperatively initially managed conservatively then requiring open pyeloplasty 3 mo later, insufficient closure of resected renal pelvis and excessive urine extravasation requiring transperitoneal exploration and primary closure of renal pelvis
Weise and Winfield (2006)[62]	31	6.5% (2)	Afebrile UTI, urine leak with ileus treated nonoperatively
Palese et al. (2005)[102]	35	11.4% (4)	UTI requiring oral antibiotics, pyelonephritis requiring IV antibiotics (2), gluteal compartment syndrome
Patel (2005)[103]	50	2% (1)	Renal colic after stent removal at 21 days requiring restenting (retrograde pyelogram showed widely patent anastomosis)
Bernie et al. (2005)[104]	7	28.60%	Febrile UTI requiring IV antibiotics, gross hematuria from bleeding at anastomotic site requiring readmission and conservative treatment
Gettman et al. (2002)[11]	9	11% (1)	Urinary leakage requiring open exploration and repair of incompletely closed renal pelvis

IV, intravenous; PCN, percutaneous nephrostomy; UTI, urinary tract infection

weight. Another rarely reported complication is bowel injury, especially in patients with a history of colitis.[16]

In another series of 92 patients undergoing robotic-assisted laparoscopic pyeloplasty, three patients (3%) had early complications requiring reintervention.[10] The first patient required stent exchange and percutaneous nephrostomy tube placement for a clot-related obstruction of the renal pelvis and colic with urine extravasation; the second patient bled into the collecting system 2 days postoperatively and, despite conservative treatment, required open secondary pyeloplasty; and the third patient, who had excessive urine extravasation after inadequate closure of the renal pelvis, required open repair of the renal pelvis. This last patient had prior treatment of UPJ obstruction but the exact treatment was not mentioned. Two other patients in this series had prior pyeloplasty, and nine had prior endopyelotomy or ureteroscopy, none of whom had significant complications. In a series of 31 patients with robotic-assisted laparoscopic pyeloplasty, one patient had nonfebrile urinary tract infection and one had a urine leak with ileus that was treated nonoperatively.[62]

Bleeding or hematoma formation can occur following minimally invasive pyeloplasty. Soulie and colleagues[2] reported that two of 61 patients developed hematoma in the lumbar fossa following laparoscopic pyeloplasty. Rassweiler and associates[19] reported five cases of postoperative hematoma in 143 patients undergoing laparoscopic pyeloplasty. Hematoma can generally be managed conservatively by following serial hematocrit levels and transfusing as necessary. Hemodynamic instability or a precipitous drop in hematocrit may necessitate urgent reoperation. One may need to drain a hematoma percutaneously at a later point based on persistent symptoms or infection.[2–4] CT scan is generally the best modality for diagnosing postoperative hematoma.[58] Delayed bleeding can occur as well; in one series, a patient required hospitalization for retroperitoneal bleeding 1 month after laparoscopic pyeloplasty.[14]

Urinoma is another important complication following minimally invasive pyeloplasty. Urine leakage occurs in ≈2.3% of patients undergoing laparoscopic pyeloplasty,[14,60] and this complication can occur despite meticulous suturing and ureteral stent placement. Urinoma may be indicated by flank or abdominal pain, fever, or elevated liver function tests on the right side.[58] Soulie and colleagues[2] reported that two of 61 patients developed postoperative urinoma. Rassweiler and colleagues[19] reported urinary extravasation in two of 143 patients after laparoscopic pyeloplasty. Secondary pyeloplasty and congenital abnormalities may be risk factors for urinary leakage.[11,12]

In the early postoperative period, leakage can be detected by persistently elevated drain output and can be confirmed by checking fluid creatinine levels. Drains may be required for a prolonged period if leakage persists. Within a urinoma, drains can be repositioned if necessary, including laparoscopically.[14,63] If one suspects urinoma after the acute postoperative period, CT with intravenous contrast is the diagnostic modality of choice. Delayed images may be needed to reveal active urine leak. Urinomas can generally be managed conservatively by leaving stents in place to optimize drainage or by replacing stents for ≥2 weeks and then assessing drainage of the upper urinary tract. Placement of a Foley catheter, or leaving the catheter in place, may also decrease pressure on the upper urinary tracts and maximize healing if leakage is noted. Percutaneous drainage of the urinoma may be required if conservative measures fail.[64] Percutaneous drains may be gradually extracted and serial imaging done to ensure resolution of the collection. Reactive pleural effusions can result from urinary leakage abutting the diaphragm; these effusions may require drainage if symptoms develop or if infection is a consideration. The risk of urinary leakage may be reduced by control of suture tension during collecting system closure.[65] Generally, urinary leakage has no significant sequelae, but periureteral scarring can occur. Repeat laparoscopy to suture an insufficiently closed site is rarely necessary but may be performed.[66]

Stent obstruction can occur after minimally invasive pyeloplasty. Rassweiler and colleagues[19] reported that one of 143 patients developed stent obstruction after laparoscopic pyeloplasty. A second stent can be placed, the stent can be changed, or percutaneous nephrostomy tube placement with or without anterograde stenting may be necessary. Stent migration can also occur requiring repositioning through ureteroscopy or removal, depending on timing relative to surgery.[67] If stent migration below the anastomosis is identified late, stenosis may require reoperation. Proper positioning of the double J stent should be carefully confirmed before leaving the operating room,[67] and erring on the side of longer versus shorter ureteral stents may be helpful. Acute obstruction after stent removal may require repeat stenting or nephrostomy tube placement. If a patient presents with ipsilateral flank pain before stent removal, imaging (e.g., kidneys, ureters, bladder) should be performed to ensure the stent is in the proper position.

Stricture at the UPJ following stent removal causes obstruction 2.5–3.6% of the time.[68] Stenting or nephrostomy tube placement may be required to relieve obstruction in these patients depending on symptoms, the presence of infection, and serum creatinine concentrations.[59,64] Conservative treatment of stricture can be attempted, such as with balloon dilation or endopyelotomy. However, secondary pyeloplasty may ultimately be required, and alternative techniques such as ureterocalicostomy may be necessary depending on the patient's anatomy (e.g., insufficient renal pelvis for anastomosis). Stents are typically removed 4–6 weeks after repair and the anastomosis evaluated at 6–8 weeks by renal scan or intravenous pyelogram. Depending on the timing of restricturing, this process may be considered a treatment failure or a complication. Success rates for both laparoscopic and robotic pyeloplasty are high, and early restricturing is uncommon.[10,69] Mufarrij and colleagues[15] reported that three of 140 patients required treatment of recurrent stricture after robotic pyeloplasty; two patients required endopyelotomy and one required repeat pyeloplasty. These investigators attributed these failures most likely to ischemia or technical factors.

MINIMALLY INVASIVE URETEROLYSIS

Reported postoperative complications of laparoscopic ureterolysis have been mild and have included prolonged ileus, epididymitis, urinary retention, and port site erythema.[35] In a series of five laparoscopic ureterolysis procedures, one patient had a small perioperative ureteral leak that was

managed with prolonged Foley catheter drainage and ureteral stent placement.[51] No postoperative complications occurred after five robotic ureterolysis procedures reported in the same article.[51] A study of 17 robotic ureterolysis cases (21 renal units) reported one case of enterocutaneous fistula due to an unrecognized cautery injury requiring bowel resection.[70]

Postoperative complications of ureterolysis are similar to those listed earlier for pyeloplasty and may include urinary extravasation and ureteral obstruction secondary to recurrent fibrosis or ischemic changes in the ureter. In one study, seven (18%) out of 40 patients undergoing ureterolysis underwent a second surgery for persistent obstruction including endoureterotomy, ureteroureterostomy, ileal ureter, and autotransplantation.[20] Another study showed a similar secondary intervention rate; three of 21 (14%) renal units undergoing robotic ureterolysis required a redo robotic ureterolysis with ureteral reimplantation, robotic ureteroureterostomy, and laser endoureterotomy. Intraperitonealization and omental wrapping can help to decrease the risk of recurrent obstruction, although these procedures may be technically challenging. Efforts should be made to diagnose and treat the underlying cause of fibrosis if possible. Ureteral stent placement may be helpful to minimize the risk of postoperative urinary leak and obstruction.

Unusual complications of ureteral manipulation can occur during ureterolysis. One of our patients developed a midureteral leak after robotic ureterolysis with omental wrapping. Stent placement was performed but the patient had recurrent flank pain and a renal scan demonstrated partial mechanical obstruction. Ureteroscopy revealed a mild midureteral stricture as well as a ureteral diverticulum with a Weck clip within the lumen of the diverticulum that was likely placed during omental wrapping of the ureter in the setting of ureteral perforation and leak. Balloon dilation and stenting were performed and subsequent ureteroscopy revealed sealing of the diverticulum; however, the patient required subsequent laser endoureterotomy and balloon dilation for recurrent stricture.

MINIMALLY INVASIVE URETERAL REIMPLANTATION

Laparoscopic and robotic ureteral reimplantation have been shown to be safe, with a low postoperative complication rate. No postoperative complications were reported in one small series of patients who underwent laparoscopic reimplantation for distal ureteral stricture refractory to endoscopic management.[34] No major postoperative complications were noted in a small series of patients who underwent distal ureterectomy and reimplantation for low-risk ureteral urothelial cell carcinoma.[21] However, minor complications are not unusual after ureteral reconstruction. A study of 16 patients reported a 75% rate of 90-day postoperative complications. Sixty-two percent of those complications were Clavien grade I–II, including urinary tract infection, pneumonia, ileus, prolonged anastomotic healing, femoral nerve lesion with temporary leg weakness and pain, prolonged abdominal pain, and a corneal erosion. Thirteen percent of the complications were Clavien grade IIIb–IVa, including urinary leak and peritonitis and a silent myocardial infarction.[44] Conversion to open approach is an uncommon intraoperative complication during robotic ureteral reimplantation or ureteroureterostomy and was reported in two out of 16 patients (13%) in one study.[71] This series also had a Clavien grade IIIb complication of unrecognized enterotomy requiring additional surgery. Despite the complications, there was a 100% clinical and radiographic success rate at a mean postoperative follow-up of 6.4 months. A more recent study of 31 patients who underwent ureteral reimplantation also reported a 100% radiographic and symptomatic success rate, with a 13% rate of Clavien grade I–III postoperative complications.[20] The robotic approach has also been used successfully in the challenging cases of post–radical cystectomy ureterointestinal stricture[72,73] and will be used more often as experience with intracorporeal urinary diversions increases.

Stricture can occur at the site of anastomosis following minimally invasive reimplantation. A study of 61 pediatric patients who underwent robotic extravesical reimplantation of 93 ureters showed a 10% complication rate including 5% rate of ureteral obstruction, 3% rate of urine leak, and 2% rate of readmission for nausea and vomiting.[74] The diagnosis can be made initially with renal ultrasound and then confirmed by excretory urography. Confirmation of drainage at the time of stent removal can minimize the risk of patients who present again with obstruction. Ureteral stent placement is generally indicated to drain the obstructed system, although percutaneous nephrostomy tube placement may be necessary. Stricture can be managed conservatively with dilation, but it may ultimately require anastomotic revision. Obstruction secondary to edema can occur postoperatively and is generally minimized by stenting for 4–6 weeks postoperatively; however, transient obstruction can also occur after stent removal and may require stent replacement for several weeks.[21]

Urinary leakage can occur following ureteral reimplantation and can be managed as discussed earlier with maximal drainage and consideration of percutaneous drain placement. A cystogram should be performed at the time of stent removal to confirm the absence of leak. Reflux into the ureter through the repair confirms patency of the anastomosis, provided a refluxing anastomosis was performed. If a nonrefluxing anastomosis was performed, diuretic renal scan, CT urogram, or an intravenous pyelogram can be performed to confirm the absence of obstruction at the ureterovesical anastomosis.

MINIMALLY INVASIVE URETEROURETEROSTOMY

The primary postoperative complications of laparoscopic or robotic ureteroureterostomy include anastomotic stricture and urinary leakage. However, published rates of postoperative complications for laparoscopic and robotic ureteroureterostomy have been low.[71,75,76] In a small series of ureteroureterostomy for iatrogenic injury of the pelvic ureter, no postoperative complications were noted ≈13 months after surgery.[77] Midureteral strictures have also been repaired laparoscopically with good results and without complications.[22] In a study of robotic ureteral reconstruction, eight patients underwent robotic ureteroureterostomy. There was a 25% Clavien grade III postoperative

complication rate; however, there was a 100% radiographic and symptomatic success rate.[20]

Obstructed retrocaval ureter has been repaired by laparoscopic and robotic resection of diseased retrocaval ureter and ureteroureterostomy without postoperative complications.[42,78,79] This procedure has been safely performed both transperitoneally and retroperitoneally.[80]

Laparoscopic and robotic ureteral surgery has been reported for upper urinary tract urothelial cell carcinoma and has been shown to be safe. Proximal ureteral segmentectomy and ureteropelvic anastomosis as well as distal ureterectomy with ureteral reimplantation have been performed for low-grade urothelial cell carcinoma without complications.[81,82] Oncologic outcomes at short-term follow-up have been encouraging in these patients. Patients should be carefully selected for any minimally invasive procedure for management of ureteral malignant disease, and principles of open oncologic surgery should be respected.

MINIMALLY INVASIVE BOARI FLAP

Laparoscopic Boari flap has been described for long distal ureteral strictures and has been shown to be safe and effective.[83,84] In a small series of laparoscopic Boari flap, one patient with a history of pelvic radiation developed urine in the peritoneum after Foley catheter removal.[83] The urinoma did not resolve with reinsertion of the catheter, and the patient required exploratory laparoscopy. Another small study of eight patients who underwent robotic ureteral reimplantation with Boari flap reported one case of anastomotic leakage postoperatively that was managed with prolonged catheterization.[85]

The risk of urine leakage can be minimized by leaving a Foley catheter in place for 7–10 days postoperatively and confirming the absence of a leak with cystography. In patients with a history of pelvic radiation, the Foley catheter should be left in place for ≥2 weeks to maximize healing. Ureteral stents should be left in place for 6 weeks to allow for complete healing of the ureter.

A small series of robotic ureteral reconstruction reported one case of robotic ureteral reimplantation with Boari flap that required conversion to open.[71] One of the larger robotic ureteral reconstruction studies evaluated 55 patients in a single institution who underwent robotic ureteroureterostomy, ureteroneocystotomy with psoas hitch and Boari flap. There were no intraoperative complications, median blood loss was 50 mL, and average hospital stay was 1.6 days. At a median follow-up of 181 days, there were three (5.3%) failures and two (3.6%) postoperative complications.[86] One patient needed exploratory laparotomy for bleeding several hours after the surgery, and another had oxygen desaturation due to multiple comorbidities requiring intensive care unit admission.

MINIMALLY INVASIVE BUCCAL MUCOSA URETEROPLASTY

Two cases of robotic buccal mucosa graft ureteroplasty were reported in a larger study of robotic ureteral reconstruction. Postoperative evaluation was with retrograde pyelogram 4–6 weeks after surgery at the time of stent removal and a Lasix renal scan 2–3 months after stent removal. In both patients, there was resolution of obstruction and symptoms at a mean follow-up of 8 months.[20] In a study of five open ureteral repairs with buccal mucosa, there were two early postoperative complications including fever, which responded to antibiotics and antipyretics, and ileus, which was managed conservatively.[55] Ultrasound done every month and intravenous urography done at 3, 9, and 12 months showed that all repairs remained unobstructed.[55] In another study of seven open buccal mucosa graft ureteroplasties, two patients were found to have impaired drainage at a median follow-up of 18 months.[56] To avoid any postoperative complications, in a study of four cases of robotic buccal mucosa graft ureteroplasty, a cystogram was done before removal of Foley catheter at 2 weeks, a retrograde or antegrade pyelogram prior to removal of stent at 6 weeks, an ultrasound after stent removal, and a renal scan at 3 months to assure patency.[33]

MINIMALLY INVASIVE ILEAL URETER

The first report of laparoscopic ileal ureter was reported by Gill and associates after laparoscopic ureterectomy for ureteral urothelial cell carcinoma in a patient with a solitary kidney.[40] No complications were associated with this procedure. Complications can arise from bowel manipulation and suturing including ileus, bowel obstruction, and bowel leak. Management of these complications is discussed in Chapter 11. Five other studies[87–91] of laparoscopic ileal ureter in 13 total patients have been published. Some of the postoperative complications included internal hernia that required exploratory laparotomy,[89] a urine leak requiring an additional percutaneous drain placement, pneumonia, and an enteric anastomotic leak requiring exploratory laparotomy, bowel resection, and reanastomosis.[90] Two case reports of robotic ileal ureter[92,93] have been published with no perioperative complications.

MINIMALLY INVASIVE URETEROCALICOSTOMY

Laparoscopic ureterocalicostomy has been performed without complications.[38] Robotic assistance may significantly facilitate the suturing component of this operation.[39,94,95]

MINIMALLY INVASIVE TRANSURETEROURETEROSTOMY

Laparoscopic transureteroureterostomy was reported in a series of three pediatric patients without significant postoperative complications.[96] Leaving a drain near the anastomosis is recommended to ensure the absence of leakage before the Foley catheter is removed. The literature on open transureteroureterostomy indicates an incidence of urinary leakage of ≈6%.[81]

Obstruction of the common ureter is noted infrequently in series of open transureteroureterostomy and has not been reported for laparoscopic transureteroureterostomy.[81,97–99] Intraoperatively, a stent can be placed either in the recipient ureter or across the anastomosis, although some investigators argue that stenting the recipient ureter is more useful for maintaining ureteral patency during the anastomosis and for preventing placing sutures through the back wall.[96]

Overall, series of open transureteroureterostomy demonstrate a low complication rate[100] and the rare occurrence of obstruction; in skilled hands, laparoscopic or robotic transureteroureterostomy is likely to have a similarly low complication rate.

Conclusions

In competent hands, minimally invasive urologic reconstruction is a safe and effective surrogate for open techniques. The intraoperative and postoperative complications are generally low for minimally invasive ureteral reconstruction surgeries. Inexperience with laparoscopic suturing was the main obstacle to the dissemination of these techniques into the community. As robotic techniques have become more popularized and demand from patients has grown for minimally invasive reconstruction, these techniques have become more prominent in urologic practice.

Unfortunately, reports of experience with minimally invasive surgery for ureteral reconstruction are mostly retrospective case series. Prospective, comparative trials are needed to assess superiority of these techniques to traditional approaches. Longer follow-up is also needed to evaluate whether radiologic and symptomatic success rates are sustained. Furthermore, many reports of complications for urologic reconstruction, and for much of urologic minimally invasive surgery, do not use standardized definitions of complications. Such standardization would help improve our understanding of the epidemiology of operative morbidity and would inform strategies to minimize the risk of these procedures. Modifying classification schemes to reflect urologic procedures specifically could increase the utility of reporting for our field.

Chapter 35 Questions

1. Which statement is true regarding the Clavien–Dindo classification scheme?
   a. It is a classification system to grade complexity of robotic surgery
   b. Postoperative complications can be graded using this scheme from I to V, with V being death of a patient
   c. Ureteral injuries are rated using this classification system
   d. It is used to describe the degree of urine leak
   e. Postoperative complications can be graded using this scheme from I to V, with I being death of a patient

2. The most definitive way to confirm position of the stent intraoperatively during pyeloplasty is:
   a. When placing the stent robotically, one can visualize the stent markings through the repair
   b. Cystoscopy at the time of the stent placement
   c. Abdominal x-ray in the postoperative care unit
   d. Efflux of urine through the side holes of the stent
   e. Visualizing a curl in the renal pelvis

3. Which statement is false regarding indocyanine green?
   a. It is used when doing robot ureteral reconstruction to assess tissue perfusion
   b. It is a fluorescent dye injected intravenously
   c. Ureteral tissue appears bright green when poorly perfused and white when well perfused
   d. It can help identify ureteral fibrosis
   e. It can help identify the length of the ureteral stricture

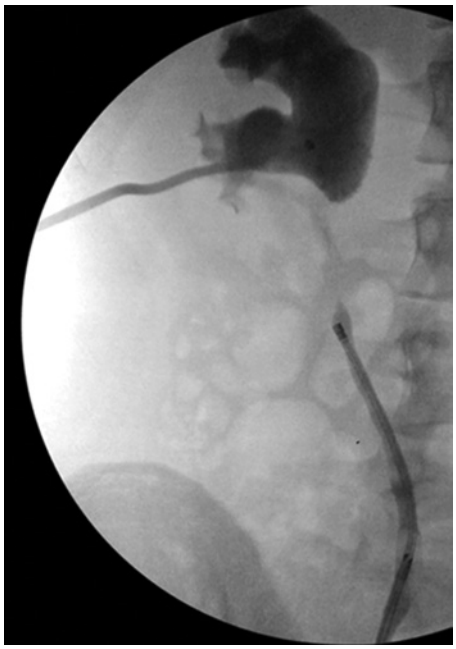
4. Which of the following maneuvers prevents operative positional injuries during laparoscopic or robotic pyeloplasty?
   a. Placing the table on maximum flexion before surgery
   b. Not using additional padding for pressure points
   c. Minimizing the operative time
   d. Keeping the kidney rest to maximum elevation
   e. Not flexing or minimally flexing the table to allow for equal weight distribution

5. Which of the following is a unique complication of ileal ureter that does not occur with ureteroureterostomy or buccal mucosa graft ureteroplasty?
   a. Intestinal anastomotic leak
   b. Pyelonephritis or urinary tract infection
   c. Urinary leak
   d. Bleeding and need for transfusion
   e. Intraoperative bowel injury

6. Which of the following is an advantage of minimally invasive retroperitoneal renal surgery?
   a. Limited working space allows for surgical precision
   b. Retroperitoneal approach is easier to learn than transperitoneal approach
   c. It provides easier access to the ureterovesical junction than does the transperitoneal approach
   d. It is advantageous in those with extensive abdominal surgery
   e. It is proven to have a lower complication rate than does the transperitoneal approach

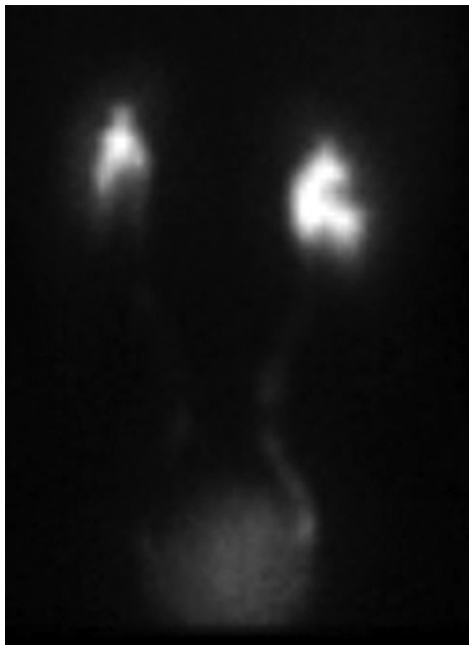
7. Which of the following is false regarding conversion of minimally invasive approach to open approach?
   a. Conversion to open may be done due to uncontrolled bleeding
   b. If there is extensive periureteral fibrosis, conversion to open may be necessary to facilitate dissection
   c. Conversion to open should never be done in a minimally invasive surgery
   d. Failure to progress with minimally invasive approach is an indication to convert to open
   e. Conversion to open is a reasonable option for an emergent situation

8. Which of the following surgical procedures has not been done with a minimally invasive approach?
   a. Ureteroureterostomy
   b. Ureterocalicostomy
   c. Renal autotransplantation
   d. Ileal ureteral substitution
   e. None of the above



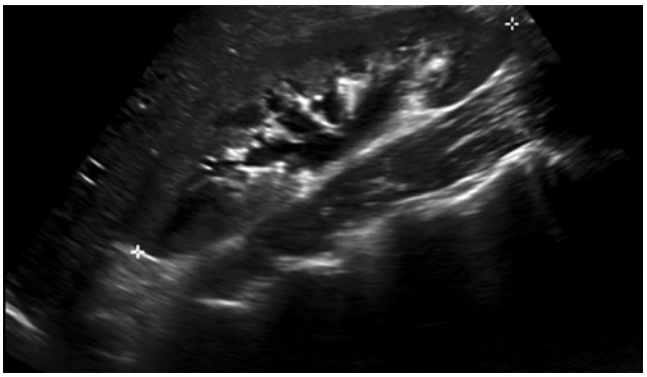
9. The complication rate of minimally invasive pyeloplasty is as follows:
   a. 0–25%
   b. 25–50%
   c. 50–60%
   d. 60–70%
   e. 100%

10. Following ureteral reimplantation surgery, the following exam is done prior to stent removal:
    a. Renal ultrasound to rule out urinoma and hydronephrosis
    b. CT scan to visualize the repair
    c. MR urogram to confirm that repair is healed
    d. Cystogram to confirm reflux (patency of repair) and rule out a leak
    e. Renal scan to rule out obstruction



Case Studies

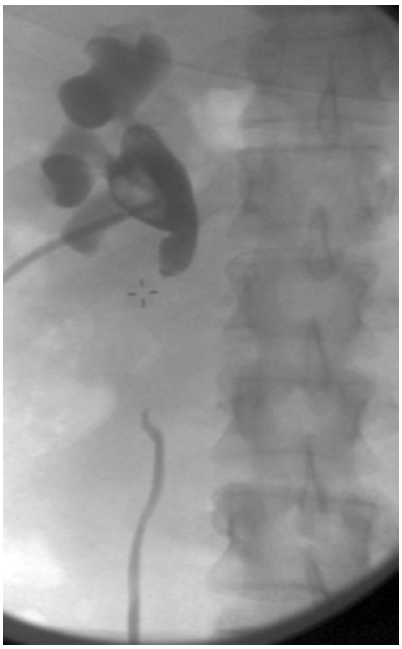
CASE 1



An 18-year-old male with history of ureteropelvic junction (UPJ) obstruction presented for evaluation. He had a history of right robotic pyeloplasty a year prior to presentation, which was complicated by a urine leak. After resolution of the urine leak, the patient developed a proximal ureteral stricture. Endopyelotomy was performed, which was unsuccessful. After a nephrostomy tube was placed, he underwent retrograde pyelogram and antegrade nephrostogram demonstrating a 4-cm proximal ureteral stricture (Case Fig. 35.1). A robotic buccal mucosa graft ureteroplasty was done. The ureteral stricture was opened ventrally in a longitudinal fashion. A

Case Figure 35.1 Antegrade nephrostogram and retrograde pyelogram reveal a 3-cm proximal ureteral stricture.

Case Figure 35.3 Tc-99m mercaptoacetyltriglycine renal scan showed prompt drainage of the collecting system without signs of obstruction.



Case Figure 35.2 Renal ultrasound done 4 months after surgery reveals no hydronephrosis.

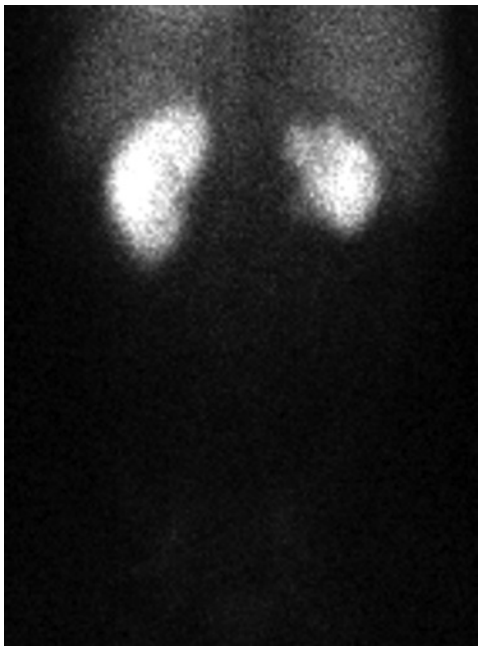
1.5-cm portion of the ureteral mucosa at the level of the stricture was excised leaving the dorsal adventia intact. The mucosal edges were reapproximated dorsally, and the ventral 3-cm defect was patched with a buccal mucosa graft. An omental flap was secured to the graft. Ureteroscopy was done during the suturing. A double J stent was left in place and confirmed to be in the bladder with cystoscopy. A percutaneous drain and Foley catheter were also left. The Foley catheter was removed on postoperative day 2. The percutaneous drain was removed the following day after drain creatinine returned consistent with serum. He was discharged with the nephrostomy tube capped. An antegrade nephrostogram was done 4 weeks later without evidence of extravasation, and the double J stent was removed. Four weeks subsequent to that, another antegrade nephrostogram showed a patent ureter and the nephrostomy tube was removed. At 4 months and 10 months after surgery, renal ultrasound (Case Fig. 35.2) confirmed no hydronpehrosis. A renal scan was done at 4 months and showed no signs of obstruction (Case Fig. 35.3).

1. Which of the following does NOT enable assessment of the length and location of a ureteral stricture?
   a. Renal and bladder ultrasound
   b. Antegrade and retrograde urography
   c. CT urogram
   d. Magnetic resonance (MR) urogram
   e. Intravenous pyelogram

2. Which intraoperative maneuver does NOT help in minimizing postoperative complications?
   a. Ureteroscopy to assure that the ureteral lumen is not closed during suturing and assess if the anastomosis is watertight
   b. Flexible cystoscopy to confirm correct placement of the double J stent
   c. Omental wrapping of the buccal mucosa graft to provide a vascular bed
   d. Not placing a percutaneous drain for patient comfort
   e. Using indocyanine green dye to assess ureteral perfusion

3. Which statement regarding postoperative maneuver to minimize complications after ureteral reconstruction is TRUE?
   a. Checking drain creatinine prior to drain removal is not useful
   b. A urographic study of the repair prior to double J stent removal helps rule out extravasation
   c. Renal ultrasound after stent removal provides no additional information

Case Figure 35.4 Antegrade and retrograde nephrostogram show a proximal ureteral stricture about 3 cm long.



Case Figure 35.5 CT urogram showing a cortical defect in the upper pole of the kidney with contrast extravasating from the collecting system into the perirenal space.

d. The Foley catheter should be removed after stent removal
e. The nephrostomy tube should be removed first

CASE 2

A 29-year-old female presented after a motor vehicle accident and underwent exploratory laparotomy. Five days later she was diagnosed with a complete transection of the right ureter. A nephrostomy tube was placed. She developed a 3-cm ureteral stricture evident on antegrade and retrograde urographic studies (Case Fig. 35.4). She underwent a downward nephropexy and robotic ureterocalicostomy. This was complicated by fevers, and she was found to have an upper pole urine leak (Case Fig. 35.5) seen on CT urogram. A percutaneous drain was placed into the infected urinoma. She remained febrile, and another fluid collection above the kidney was found on repeat CT scan and drained. Imaging also demonstrated that the stent was malpositioned at the anastomosis. An antegrade nephroscopy was performed to reposition the stent. A month after this procedure, a nephrostogram was done demonstrating no leak, and the double J stent was removed. The nephrostomy tube was left capped. A month later a renal ultrasound was done and was normal, and the nephrostomy tube was removed. A renal scan (Case Fig. 35.6) was done 5 months after the original surgery and demonstrated no obstruction.

1. What is NOT an option for proximal ureteral stricture repair?
   a. Ureteral reimplantation with Boari flap
   b. Ureterocalicostomy
   c. Ureteroureterostomy
   d. Buccal mucosa graft ureteroplasty
   e. Ileal ureter

Case Figure 35.6 MAG-3 renal scan showing loss of function in lower pole of kidney at the site of ureterocalicostomy.

2. Which of the following is NOT an appropriate management for urinary leak?
   a. Placement of percutaneous drain into a urinoma
   b. Stent placement to maximize drainage of urine away from the leak
   c. Replace Foley catheter if it has been removed
   d. Immediate open exploration, washout, and repair
   e. Nephrostomy tube placement to maximize drainage of urine away from the leak

3. Which maneuver does NOT help preserve blood supply to the ureter during reconstruction?
   a. Placing holding stitches on the ureter for handling
   b. Ensuring that ureteral edges are pink and healthy prior to anastomosis
   c. Preserving periureteral adventitia to protect blood supply
   d. Widely spatulating the ureter prior to anastomosis
   e. Not using energy sources to cut or spatulate the ureter

Answers

1. **b.** It is a scheme used to grade postoperative complications, not the complexity of robotic surgery (a), ureteral injuries (c), or degree of urine leak (d). Grade V complication is a mortality, not Grade I (e).
2. **b.** Cystoscopy at the time of stent placement is the best way to confirm correct stent position intraoperatively. Visualizing the stent through the repair does not prove that the stent is positioned correctly within the bladder and may result in the stent being in the distal ureter instead of the bladder. Efflux of urine is not an accurate way to assure that the stent is positioned correctly. X-ray in the postoperative care unit can be helpful, but will not be helpful if the stent needs to be adjusted. Visualizing a curl in the renal pelvis will not assess if the stent is properly positioned in the distal ureter or bladder.
3. **c.** Ureteral tissue appears bright green when well perfused, as this indicates that the indocyanine green has made it to the ureter. All the other statements are true.
4. **e.** The table should be minimally flexed or not flexed as positional injuries usually result at points of maximum pressure. Placing the table on maximum flexion distributes weight unevenly and creates pressure points, which increases the chance of injury (a). Padding should be used for pressure points (b). Operative time should be kept as short as possible (c). Kidney rest should be avoided as it increases flexion and the chance for positioning injuries (d).
5. **a.** Ileal ureter has some unique complications including internal hernia and leak from the intestinal anastomosis. The other complications (b, c, d, and e) may occur in any of the ureteral repairs.
6. **d.** The minimally invasive retroperitoneal approach is useful in those with extensive prior abdominal approach and in obese patients. Disadvantages include limited working space and steep learning curve.
7. **c.** a, b, d, and e are true statements. Conversion to open is a reasonable option during uncontrolled bleeding, extensive fibrosis, or failure to progress or any emergent situation.
8. **e.** All the other ones have been described using a minimally invasive approach.
9. **a.** The complication rate of pyeloplasty is 2–22%.
10. **d.** Other imaging techniques do not provide adequate information to confirm potency of repair as well as rule out a urine leak.

CASE 1

1. **a.** Although renal and bladder ultrasound will confirm hydronephrosis, it is a poor study for evaluation of the ureter. Urography with fluoroscopic guidance, CT, or MRI will enable assessment of the length and location of the stricture. Delayed phase images are necessary when using CT or MRI. Intravenous pyelogram can help assess the length and location of the ureteral stricture; however, this test is not commonly used due to advancement in imaging technology.
2. **d.** Percutaneous drain should be placed to allow for maximal drainage in case of a urinary leak. This patient developed a urinoma after the pyeloplasty, which resulted in the ureteral stricture. Checking a drain creatinine prior to removal can help rule out a urine leak.
3. **b.** A retrograde or antegrade urography should be done to rule out extravasation prior to removal of the double J stent. Checking drain creatinine can help rule out urine leak, and if one is present, the drain should be kept until it heals. Renal ultrasound after stent removal is useful to rule out recurrent ureteral obstruction. The Foley catheter is removed first prior to drain or stent removal. The nephrostomy tube is removed last after a urographic study reveals no extravasation at the site of repair.

CASE 2

1. **a.** Ureteral reimplantation with Boari flap is used for distal and midureteral strictures. Stretching the Boari flap up to the proximal ureter could compromise the bladder function. Ureterocalicostomy, ureteroureterostomy, and buccal mucosa graft ureteroplasty are better options for proximal strictures. If the ureteral stricture is long and not amenable to repair, ileal ureter may be used.
2. **d.** Maximizing urinary drainage helps heal the urinary leakage site. Therefore a Foley catheter, a stent, or a nephrostomy tube should be placed along with a drain in the urinoma. Urinary leakage usually resolves with these conservative measures and open repair is unnecessary.
3. **d.** Widely spatulating the ureter ensures a patent anastomosis and prevents stricture formation. The other choices listed assist in maintaining ureteral blood supply.

36 Complications of Robotic Cystectomy

ANGELA B. SMITH, JEFFREY W. NIX, and RAJ S. PRUTHI

CHAPTER OUTLINE

Introduction
Review of Perioperative and Postoperative Complications
Comparisons Between Robotic and Open Radical Cystectomy
Factors Associated With Complications During Robotic Cystectomy
Perioperative Preparation
Patient Selection
Perioperative Pathways
Operative Equipment and Setup
Intraoperative Complications and Management
Ureteral Dissection
Posterior Dissection and Pedicles
Developing Space of Retzius and Prostate Dissection
Lymph Node Dissection
Issues Unique to Female Cystectomy
Urinary Diversion
Postoperative Complications and Management
Venous Thromboembolism
Wound Infection/Fascial Dehiscence
Lymphocele
Ileus
Anastomotic Leak and Enterocutaneous Fistula
Conclusions
Chapter 36 Questions and Answers

KEY POINTS

1. Complications following robotic cystectomy are common, estimated at 44% and 59% at 30 and 90 days, similar to open cystectomy series.
2. Optimizing perioperative care through enhanced recovery after surgery (ERAS) strategies include a number of preoperative, intraoperative, and postoperative maneuvers that can effectively reduce postoperative complications following robotic cystectomy.
3. Operative equipment and set-up for robotic cystectomy using surgical checklists can identify errors with robotic cystectomy and avoid preventable intraoperative complications.
4. Complications during ureteral dissection can be avoided through careful manipulation of the ureter, avoiding tension and crush injury and judicious use of monopolar and bipolar cautery.
5. Posterior dissection can be aided by use of a 30-degree up lens, judicious use of thermal energy, and releasing the anterior bladder attachments as late as possible.
6. By following the psoas muscle deep between the external and internal branches, also known as the Space of Marseille, the external iliac vein can be carefully observed and obturator dissection of the obturator nodes better facilitated.
7. To prevent injury, the obturator nerve must be identified visually prior to clips and ligation during robotic lymph node dissection.
8. Vascular injury during robotic cystectomy can be managed through direct pressure using mini lap sponges, avoiding direct pressure by robotic instruments which may cause further injury, allowing robotic suture possible.
9. Venous thromboembolism risk is similar for robotic and open cystectomy, and should be addressed similarly using the AUA Best Practice Statement for Prevention of DVT by providing extended 4 week prophylaxis when possible.
10. Postoperative complications following robotic cystectomy such as thromboembolism, lymphocele, ileus and anastomotic leak are similar to that of open cystectomy, and may be managed similarly.

Introduction

Bladder cancer is the fourth most common cancer among men and the 12th among women in the United States, with 74,000 new diagnoses each year.[1] While 75% of new diagnoses involve nonmuscle invasive bladder cancer, approximately 25% are diagnosed as muscle invasive, an aggressive malignancy. If left untreated, muscle invasive bladder cancer (MIBC) survival approaches 15% at 2 years.[2] Due to its high mortality rate, MIBC and high-risk nonmuscle invasive bladder cancer warrant aggressive treatment. Treatment options include radical cystectomy or trimodality therapy (with aggressive transurethral resection of bladder tumor, chemotherapy, and radiation). Traditionally, radical cystectomy has become the standard treatment for aggressive bladder cancer, but it can be fraught with a high complication rate and difficult recovery.

Complication rates for open radical cystectomy (ORC) vary from 28% to 64%,[3,4] with higher reported rates among studies using strict standardized reporting.[4] The most common complications include gastrointestinal complications, followed by infectious and wound-related complications. In an attempt to minimize the morbidity of ORC, laparoscopic cystectomy was introduced. Shortly thereafter, the development of robotic surgery refined the more challenging technique of laparoscopic cystectomy, and ultimately opened the door to robotic cystectomy as a feasible alternative to the traditional open approach. Since the first reported robot-assisted radical cystectomy (RARC) series in 2003,[5] robotic cystectomy use has increased along with the addition of robotic intracorporeal urinary diversions. Along with this increase has been accompanying literature comparing complications between robotic and open cystectomy, with widely ranging complications rates, even when utilizing strict reporting criteria.[4,6]

At the University of North Carolina and University of Alabama, dedicated efforts have focused on reducing complications through streamlined perioperative pathways, ensuring appropriate equipment and materials, and perfecting intraoperative techniques. Postoperative enhanced recovery pathways have reduced complications, and these efforts have expanded the ability to treat older patients in need of treatment for aggressive MIBC. By emphasizing these "lessons learned," this chapter focuses on a review of intraoperative and postoperative complications following robotic cystectomy and methods to reduce these rates. More specifically, the review will provide comparisons between complications associated with the traditional open approach and newer robotic approach, predictors of complications, and the importance of the learning curve when transitioning to robotic cystectomy. The chapter will conclude with strategies for avoidance of intraoperative complications, management of common intraoperative and postoperative complications, and advice for both beginning and seasoned robotic cystectomy surgeons.

Review of Perioperative and Postoperative Complications

Data regarding perioperative and postoperative complications following RARC continue to mature. Although a number of these studies include single-center analyses, several additional multi-institutional reports have been reported. Complication rates following RARC vary widely and may reflect differences in operative technique, experience, and postoperative care. Furthermore, some complications may occur at local, nontertiary hospitals and may not be systematically collected or reported. In the past, many studies did not adhere to standardized reporting guidelines, such as the Memorial Sloan Kettering Cancer Center (MSKCC) grading or the modified Clavien-Dindo classification systems.[4,7] However, contemporary studies now routinely report complications using these standardized criteria.

A recent multi-institutional study from the International Robotic Cystectomy Consortium described the complications after RARC using the MSKCC grading system.[8] Of 939 patients who underwent RARC with available complication data and at least 90 days' follow-up, 41% and 48% experienced a complication within 30 and 90 days of surgery, respectively. Approximately 19% of patients experienced a major complication, with gastrointestinal, infections, and genitourinary complications most commonly reported (27%, 23%, and 17%, respectively). On multivariable analysis, the authors found that increasing age, neoadjuvant chemotherapy, and receipt of blood transfusion were independent predictors of major complications.

To summarize the vast array of literature focusing on RARC complications, a recent systematic review identified over 105 articles describing both perioperative and postoperative complications among a variety of single and multi-institutional RARC studies.[6] The overall intraoperative complication rate for RARC was 3%, but 30- and 90-day complication rates were 44% (ranging from 26% to 78%) and 59% (ranging from 15% to 79%), respectively. Among those patients undergoing RARC and extracorporeal conduit diversion, overall 90-day complication rates were 59% (with major complications 15%). For complications following RARC with intracorporeal conduit diversion, 30- and 90-day complication rates were similar at 67% and 59%. Extracorporeal and intracorporeal neobladder complication rates differed somewhat, which may be related to patient selection, surgeon experience, and other factors. Extracorporeal continent diversion complication rates were as high as 77%, whereas overall complication rates for intracorporeal continent diversion were slightly lower at 45.7% for 30 days, and 30% between 30 and 90 days (with no studies exploring overall 90-day complication rates). However, the major complication rate was higher (28%) than that of extracorporeal diversions. Readmission rate overall was 19% for RARC with extracorporeal conduit[6] but as high as 75% in a small single institution study for RARC with intracorporeal neobladder.[9]

COMPARISONS BETWEEN ROBOTIC AND OPEN RADICAL CYSTECTOMY

Given that RARC is a relatively new technique, comparisons of its perioperative outcomes with the ORC gold standard have spurred great interest. Several single institution studies have compared consecutive ORC and RARC series, while attempting to control for selection bias and other factors. Investigators from the University of Michigan compared RARC to ORC complications using a 1:2 matched analysis on age, sex, diversion, and clinical stage.[10] The rate of

30-day minor or major Clavien complications and 30-day readmissions did not differ between operative techniques. These results have been confirmed in two single institution randomized controlled trials.

The first randomized trial comparing ORC and RARC was performed at the University of North Carolina and compared 20 patients undergoing ORC to 21 in the RARC cohort.[11] Although designed as a noninferiority study comparing lymph node yield, several secondary end points were evaluated, including complication rate. No difference in overall complication rates between ORC and RARC were noted (50% vs 33%, respectively; $p = 0.28$). However, RARC had a significantly lower estimated blood loss when compared to ORC (258 mL vs 575 mL; $p < 0.0001$). In a multivariate analysis controlling for age, body mass index (BMI), and pathologic stage there was a trend toward a lower complication rate in the robotic group, but it did not reach statistical significance ($p = 0.0503$).

A recently published randomized controlled trial from Memorial Sloan Kettering compared 90-day grade 2–5 complications between open and robotic cystectomy. Of 118 randomized patients, 60 were randomized to RARC and 58 to ORC, and 90 day complications occurred in 62% and 66% of RARC and ORC patients, respectively.[12] Estimated blood loss was lower in the RARC group by a mean of 159 mL ($p = 0.03$), but operative time favored the ORC group by a mean time of 127 minutes ($p < 0.0001$). The trial was closed early due to futility in its primary outcome (complication rate). Furthermore, no differences were noted for high-grade complications between treatment groups. The types of complications were similar in each arm, with infectious complications most common. The only difference found between techniques was with regard to wound complications, which were more commonly observed in ORC (14%) compared to RARC (3.3%). A multi-institutional randomized trial has completed accrual and will report complications of ORC and RARC by 2017, lending more evidence to any possible benefit of a particular approach.[13]

Among large-scale studies using administrative claims data, a recently published population-based study used data from the Premier database (an all-payer hospital discharge database) to compare complications between 34,000 ORC and 2100 RARC patients.[14] RARC volume increased from 0.6% in 2004 to 12.8% in 2010, with major complication rates (defined as Clavien grade 3 or higher) similar between groups (17% vs 19.8% ORC vs RARC; $p = 0.42$). However, RARC had a 46% decreased odds of minor complications compared to ORC ($p = 0.03$). Readmission rates were similar at 20% versus 18% ($p = 0.35$) when adjusting for pertinent confounders. Based on this and other studies, the overwhelming consensus is that high-grade complications do not differ based on ORC or RARC technique, with minor complications likely lower among RARC due to its lower risk of wound complications.

FACTORS ASSOCIATED WITH COMPLICATIONS DURING ROBOTIC CYSTECTOMY

In a recent systematic review and cumulative analysis, the impact of patient characteristics, aspects of surgery, and diversion type on RARC complications was evaluated.[6] In this analysis, two studies assessed the impact of BMI on RARC complications, with both failing to identify any differences based on this patient characteristic.[15,16] However, a larger multi-institutional study found that higher BMI was predictive of high-grade complications, even when controlling for other pertinent characteristics.[8] Another study evaluating predictors of readmission found that higher BMI predicted 30- and 90-day readmission rates on multivariable analysis.[17] Additional patient characteristics that appeared to predict complications following RARC included older age,[8,18] use of neoadjuvant chemotherapy,[8] and elevated preoperative creatinine.[18] Intraoperative variables predictive of complications included need for blood transfusion,[8] conduit diversion,[8] higher estimated blood loss,[18] and significant intravenous fluids greater than 5 liters.[18]

Given that age is a consistent independent predictor of significant complications following RARC in numerous studies, postoperative complications among octogenarians have also been specifically evaluated. At the University of North Carolina, 119 patients were divided into older and younger age cohorts (61 patients <70 years and 38 patients ≥70 years).[19] No significant differences were found with respect to postoperative outcomes or complication rates between older and younger patients. Another single institution study from Wake Forest University aimed to compare ORC and RARC outcomes among older patients.[20] Among 40 patients, evenly split into ORC and RARC cohorts with comparable preoperative characteristics, major complication rates were lower in the RARC group (10% vs 35%; $p = 0.02$), suggesting that RARC can be safely performed among older, albeit carefully selected patients.

Urinary diversion can also impact RARC complication rates, and to evaluate this relationship, a single institution study from the City of Hope Cancer Center analyzed 209 RARC patients, of whom 68% underwent continent diversion.[21] Within 90 days, 77.5% experienced a complication and 32% a major complication. Multivariable analysis revealed that patients undergoing ileal conduit diversion were less likely to experience complications when compared to Indiana pouch and orthotopic neobladder despite the increased comorbidities noted among conduit diversion patients. Continent diversion patients also were more likely to experience urinary tract infections, similar to open cystectomy series.

Beyond patient characteristics and surgical technique, an important predictive factor for complications following RARC is surgeon experience. The learning curve has been evaluated as a predictor of complications following RARC in a number of single and multi-institutional studies.[6] Conclusions vary based on the reporting institution, with some arguing that complication rates decrease with increasing experience[22–24] and others showing no difference.[25–27] In one single institution study evaluating 60 consecutive cases, 90-day complications decreased from 70% in the first 20 cases to 30% in the last 20 cases.[22] In contrast to these findings, a larger series of 164 patients at Roswell Park Cancer Institute demonstrated stable long-term complication rates, with no differences.[26] Complications following intracorporeal diversion also show mixed results regarding the impact of the learning curve, with some studies demonstrating 30- and 90-day improvements with experience,[23,24] while others showed little change in the first

100 cases reported.[27] Conflicting results are likely related to previous robotic experience, surgeon skill, institutional support, patient selection, and numerous other factors. However, all studies confirm that the learning curve can be overcome with experience. Indeed, centers with higher volume appear to have lower complication rates. In a large study from the IRCC of over 800 patients undergoing extracorporeal or intracorporeal urinary diversion, high-volume centers (defined as those institutions with >100 cases) had lower overall complications following RARC ($p = 0.002$).[28]

Perioperative Preparation

PATIENT SELECTION

Older patients are at risk for complications from cancer treatment, but chronologic age and physiologic age are not equivalent. An expert in cancer treatment in the elderly, Dr. Arti Hurria from the Cancer and Aging Research Group (CARG), defined a tool that predicts treatment toxicity, specifically chemotherapy, in older adults with cancer.[29] This tool included common predictive characteristics such as age, tumor type, treatment complexity, and laboratory values. For example, patients ≥72 years were at increased risk for toxicity, suggesting that the seventh decade of life represents a threshold at which treatment risk increases substantially. Another important risk predictor included anemia, which was independently associated with hospitalization, mortality, and diminished functional status among geriatric cancer patients. Patients with baseline anemia prior to their first cycle of chemotherapy were more likely to have impairments and disability in activities of daily living (ADL) in both self-reported as well as provider-observed functional assessments.[30]

Patients who undergo robotic cystectomy share similar baseline characteristics with the patient population studied by the CARG, but whether this translates to similar findings in the robotic cystectomy population is unknown. The IRCC noted that increasing age, neoadjuvant chemotherapy, and receipt of blood transfusions were associated with increased complications.[8] Although blood transfusion rate is closely linked to intraoperative blood loss (EBL), the IRCC demonstrated that only blood transfusion (not EBL) was associated with postoperative complications. Therefore preoperative anemia, potentially as a marker of global functional status, may be an underlying cause of complications among RARC patients. As part of our perioperative pathway, we carefully assess preoperative anemia in the preoperative setting, and although this does not preclude patients from RARC, these patients are more closely monitored perioperatively.

Beyond laboratory values, additional preoperative characteristics include global geriatric assessment elements such as physical functioning, psychosocial well-being, and social support.[29] A geriatric assessment tool is available online through the Center for Cancer and Aging (mycarg.org) and can be used as an adjunct for preoperative evaluation. At our institutions, we routinely use this tool and have recognized its value in both patient selection as well as risk counseling.

Additional perioperative risk calculators also exist, such as the American College of Surgeons (ACS) surgical risk calculator. The ACS surgical risk calculator was developed from data gathered by over 400 hospitals and 1.4 million surgical procedures identified in the National Surgical Quality Improvement Program database.[31] The calculator allows the user to input specific preoperative characteristics such as age, BMI, and gender to identify a patient's risk for 30-day morbidity and mortality after surgery (riskcalculator.facs.org). Benefits of this risk calculator include ease of use, quick implementation, and graphic output that can be easily shared and understood by the patient, facilitating the real-time informed consent process. With many tools available, providers can utilize these for patient selection and counseling. However, in the absence of rigorous research comparisons, the predictive ability of each calculator as it compares to the others is unknown.

PERIOPERATIVE PATHWAYS

While patient selection is the first step in the perioperative pathway, optimizing perioperative care is vital to reduce complication risk following RARC. Through ERAS (enhanced recovery after surgery) initiatives, high-risk patients are provided with better opportunities for decreased complications. Our practice involves a clinic visit prior to initiation of neoadjuvant chemotherapy in which we assess overall performance status, perform a comprehensive geriatric assessment, and highlight opportunities to improve health prior to cystectomy. Full details of our entire ERAS protocol are detailed in Table 36.1. Another easy-to-follow protocol for perioperative care after radical cystectomy has been published by the ERAS society.[32] Our institutions use these guidelines to establish standard order sets for our cystectomy patients, as they have demonstrated benefit among patients undergoing robotic cystectomy. A comparison of over 200 patients who underwent the standard protocol versus the enhanced recovery protocol was performed at the University of Southern California, demonstrating that patients on the enhanced recovery protocol used less opioids and had shorter length of stay.[33] Several institutions have shown similar findings and incorporate these pathways as a method to optimize postcystectomy care.[34]

OPERATIVE EQUIPMENT AND SETUP

Beyond patient-related perioperative optimization, operative equipment and setup can contribute to maximizing success and minimizing risk during RARC. Useful instruments and equipment are listed in Table 36.2 and described in detail throughout this chapter. Surgical checklists can also provide an additional layer of protection. The development of surgical safety parameters specific to robotic urologic surgery was recently described in a systematic review with rigorous methodology. This review provides an excellent safety checklist that can be used to identify errors within any robotic procedure, including RARC.[35] Several safety items include securing of the patient, equipment and instrument checks, and docking of the robot (Table 36.3).

An additional recommendation that can facilitate success in the operating room is a second time-out to define any new techniques or adaptation in technique. Verbalizing changes in technique can facilitate consensus within the

Table 36.1 Enhanced Recovery After Surgery Strategies

Timing	Enhanced Recovery After Surgery (ERAS) Strategy
Preoperative	Preoperative counseling and education Nutrition consultation Optimization of medical comorbidities Cessation of smoking, alcohol abuse, encouragement of physical activity No bowel preparation Alvimopan initiated
Intraoperative	Compression stockings Low-molecular-weight heparin before anesthesia induction Antibiotic prophylaxis (with redosing if prolonged case) Perioperative fluid management – avoiding overhydration and maintaining hemodynamic control Maintenance of normal body temperature No nasogastric tube (orogastric tube during case, removed at end of case) Ureteral stent placement Intraperitoneal drain placement
Postoperative	Alvimopan continued until return of bowel function Early mobilization Nonnarcotic analgesics Chewing gum as needed Early oral dietary advancement (sips on POD1, unlimited clear liquids on POD2, and regular diet on POD3) Continued enoxaparin prophylaxis for 4 weeks post-surgery Nutrition consultation Early drain removal if warranted Stent removal within 10–14 days with antibiotic prophylaxis

operating room team by placing focus on the patient and can be helpful whether early or late in a surgeon's learning curve. This second time-out can also allow anesthesia an opportunity to provide an update on the patient, nursing to check for shifts in positioning, and the surgeon to assess whether progress is sufficient to warrant proceeding with the robotic approach.

Success with the robotic approach can also be greatly affected by trocar placement.[36,37] To ensure success, the camera port should be placed at least two fingerbreadths above the umbilicus to facilitate cephalad extent of the lymph node dissection as well as intracorporeal bowel work. If considering intracorporeal diversion, the fourth arm should be placed on the patient's left side to facilitate use of the robotic stapler. However, if a laparoscopic stapler will be used (with an assistant), the robotic fourth arm should be placed on the patient's right side to minimize tension on the bowel during staple fire. In an effort to decrease the learning curve between extracorporeal and intracorporeal urinary diversion, an additional 12-mm trocar in the lower midline can facilitate stapling of the bowel segments.[36] Furthermore, the intracorporeal diversion can be better facilitated by undocking and removing 15–20 degrees of steep Trendelenburg for the extirpative portion of the bowel work.

Intraoperative Complications and Management

URETERAL DISSECTION

Initial ureteral identification typically starts with the left side. The surgeon should mobilize the white line of Toldt

Table 36.2 Useful Instruments for Robotic Cystectomy and Lymph Node Dissection

Type	Product Name	Comments
General		
	EA sizer set	Rectal injury
	Mineral oil	Prelubed wire, run inside stent to facilitate easy removal during case
	AirSeal insufflation system	Stable insufflation, allows continuous suction if needed, avoid loss of insufflation on female cases w/open vaginotomy; also easier to remove LN packets as no valve on port
	Mini lap sponges	Utilized in case of vascular injury for pressure if needed
Robotic		
	Robotic clip applier	Assistant having difficulty, allows for better angle; charged per fire not per case, so relatively cheap
	Robotic vessel sealer	Great for pedicle work in pT3 patients, low thermal spread, jaws do not get as hot
	Cadiere forceps	Low grip strength, excellent if attempting intracorporeal diversion
	Double fenestrated grasper	Also low grip strength for use on bowel, large surface area so helpful for retracting redundant sigmoid or large, floppy bladder
	Robotic stapler	Si only has 45-mm nonvascular loads, however Xi has 45-mm and 30-mm loads and has green, blue, and white available
Suture		
	3-0 or 4-0 Prolene; precut 6 in.	Ready to fix vascular injuries if occur
	4-0 or 5-0 chromic; precut 6 in.	For ureteral stent fixation if performing ICUD
	Silk suture (full length) tied to X-Large Hem-o-lok clips	For ureteral tagging, full length allows them to reach all the way out of port so easy to identify w/ mini lap incision for extracorporeal diversion
Female Cases		
	V Care uterine manipulator	Aids mobilization of uterus by assistant, with better definition of colpotomy and maintenance of pneumoperitoneum

Table 36.3 Robotic Cystectomy Safety Checklist

Item	Definition	Failure	System Check
Patient properly secured	Patient in appropriate predetermined position and secured to bed to prevent slippage during Trendelenberg	Patient not secure and slips during prolonged Trendelenburg causing injury/delay. Straps too tight causing injury	Check patient after positioning but before prepping in steep Trendelenburg to confirm no slippage. Anesthesia and surgical team confirm padding not too tight
Faulty equipment check	Equipment needed for case checked ahead of time. TilePro is functional if desired, robot preliminary check occurs	System delays for troubleshooting while patient under anesthesia	Check any equipment needed for case that can be checked ahead of time
Robot docked correctly	Placement of robot is done so that robotic arms are optimized for specific case	Si and Xi systems have different docking characteristics. Failure of team/provider to recognize could lead to injury/delay or increased conversion rate	Team/provider and trainees well versed and review differences in docking between systems
Instruments ready for easy exchange	Instruments needed in urgent and routine situations should be unbundled to improve efficiency	Inability to access instruments quickly may delay procedure and cause patient harm	Operating room setup designed to allow commonly used instruments to be set out for easy exchange
Equipment issues reported	Any issue during the case w/ robotic-specific equipment reported so as to prevent issues arising in next case	Failure to do so could cause delays as instruments at end of life reprocessed and put back in trays for next case also at increased cost	Checklist at end of procedure includes reporting of issues to appropriate personnel and checking "lives" on instruments

(Adapted from Ahmed K, Khan SA, Hayn MH, et al. Analysis of intracorporeal compared with extracorporeal urinary diversion after robot-assisted radical cystectomy: results from the International Robotic Cystectomy Consortium. Eur Urol 2014;65:340-7.)

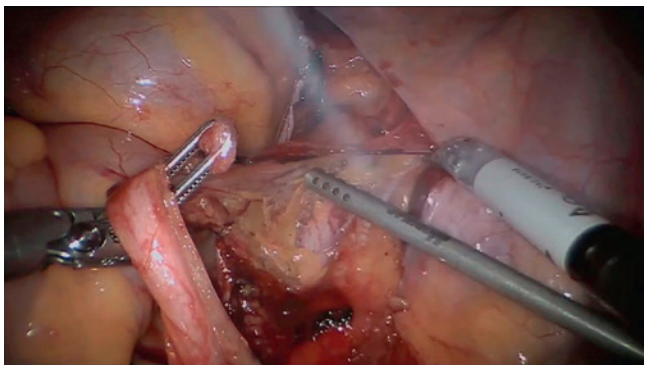

Figure 36.1 Right ureter with preserved adventitia during ureteral dissection of robot-assisted radical cystectomy.

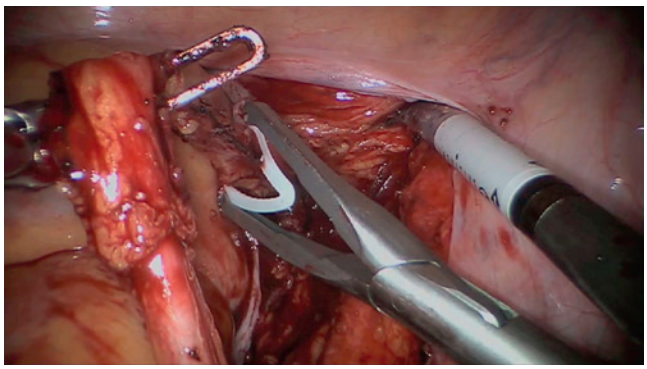

Figure 36.2 Right ureter with clips and stitch identification during distal transection of the ureter near the bladder.

as cephalad as possible to ease visualization of the proximal common iliac artery dissection. We mobilize the ureter cephalad to this point, but no higher, in order to preserve blood supply. Careful handling of the ureter is vital during this dissection, and therefore the ureter should not be grasped directly nor should an inordinate amount of tension be placed either using the fourth arm or by the assistant during dissection. Preserving periureteral fat adjacent to the ureter preserves adventitial blood supply and avoids subsequent ureteral stricture (Fig. 36.1). During the ureteral dissection, identification of the left ureter can be challenging, especially in obese patients. To facilitate dissection in these challenging cases, the medial leaflet of the posterior peritoneum should be skeletonized just lateral to the sigmoid colon and the rectum. This technique often reveals the ureter within the fatty tissue. The double fenestrated grasper (i.e., ProGrasp) can be helpful during this dissection if the fourth arm is on the patient's right side, since its large surface area can retract a redundant sigmoid colon.

During distal dissection of the ureter, the surgeon will begin to encounter the anterior bladder pedicle, which often will demonstrate lateral branches from the superior vesical artery supplying the distal ureter. At this point, clipping the ureter with a large Hem-o-lok with full-length suture attached will aid in later identification of the ureter if attempting extracorporeal diversion (Fig. 36.2). Prior to transection, a distal clip placed on the bladder side of the ureter can guide the surgeon when performing pedicle ligation to prevent inadvertent bladder entry.

As a final point of caution, we advise careful and judicious use of monopolar and bipolar cautery during ureteral dissection. By lowering Bovie settings to 25W/25W for cut and coagulation, inadvertent thermal injury can be avoided. The surgeon must be mindful of both lateral thermal spread as well as jaw temperature profiles of the vessel sealing devices. The degree of lateral thermal spread varies with device type, power setting, and application time. Monopolar cautery has the highest temperature and highest degree of

thermal spread.[38] Estimates for the EndoWrist One vessel sealer are a lateral thermal spread of only 1–2 mm, consistent with the LigaSure.[39]

POSTERIOR DISSECTION AND PEDICLES

Many surgeons elect to perform the lymph node dissection first. However, performing posterior dissection immediately after ureteral mobilization and transection may be preferable for those early in their learning curve. Early posterior dissection tends to be a natural progression for surgeons with experience in the posterior approach to robotic prostatectomy. Once the ureters are dissected distally to the level of the bladder, the incision can be extended horizontally across the posterior peritoneum at the reflection of the peritoneal edge. The dissection plane can then be elaborated posterior to the rectovesical fascia, just superficial to the anterior wall of the rectum, ensuring an adequate margin of tissue posteriorly. To avoid inadvertent rectal injury when moving anteriorly, dissection should be performed as distally as possible. If the 30-degree lens is being used, switching to 30 degrees up will often allow dissection to the prostatic apex. These maneuvers will establish the rectal plane as well as the medial aspect of the vascular pedicle.

A common error that can occur early in the learning curve is early bladder release. Releasing the anterior bladder attachments prior to the posterior dissection can make this step significantly more challenging as tension is paramount to preventing rectal injury. We typically employ the assistant for tension at the peritoneal reflection by pulling posteriorly and slightly cephalad to produce tension on the rectum while the robotic fourth arm pulls up on the posterior bladder wall.

Just as thermal energy is important with ureteral dissection, heat must also be considered carefully during the posterior dissection. Temperature and thermal spread can be minimized by employing the benefits of the EndoWrist One vessel sealer. Studies in porcine models demonstrate burst pressures well above three times systolic blood pressure ranges on vessels up to 7 mm in diameter using this device.[39] The vessel sealer can therefore be used to perform the entire bladder pedicle dissection as well as prostate pedicle if so desired with minimal thermal spread. Alternatively, the vessel sealer can be used to the level of the endopelvic fascia, followed by Hem-o-lok clips for the prostate pedicle with athermal ligation (Fig. 36.3A). Other tools utilized for the vascular pedicles can include clips, the LigaSure device, or staple fire via either the robotic tool or laparoscopic stapler. If using a laparoscopic stapler, it is important to note the length of the shaft. The laparoscopic stapler we typically use has a 440-mm shaft, which facilitates reach into the deep pelvis (Fig. 36.3B). This stapler should be used cautiously when early in the learning curve, as it requires a larger, more accurate dissection plane and careful articulation to prevent positive margin or rectal injury.

If a rectal injury occurs during RARC, it tends to occur during the posterior dissection and pedicle ligation. Although rectal injury is rare, the injury is often recognized intraoperatively and can be repaired robotically in many cases. Rectal repair should initially involve clear delineation of the edges of the defect and an assessment of the mechanism of injury. If thermal injury is suspected, the surgeon must consider debriding the defect back to the healthy bleeding bowel to ensure apposition of edges that are free from injury. The American Association of the Surgery of Trauma (AAST) has a rectal injury grading scale (RIS) used for the management of rectal injury during trauma (Table 36.4). AAST recommendations include primary repair of RIS I to III injuries. The authors recommended a single primary closure using 3-0 monofilament absorbable suture

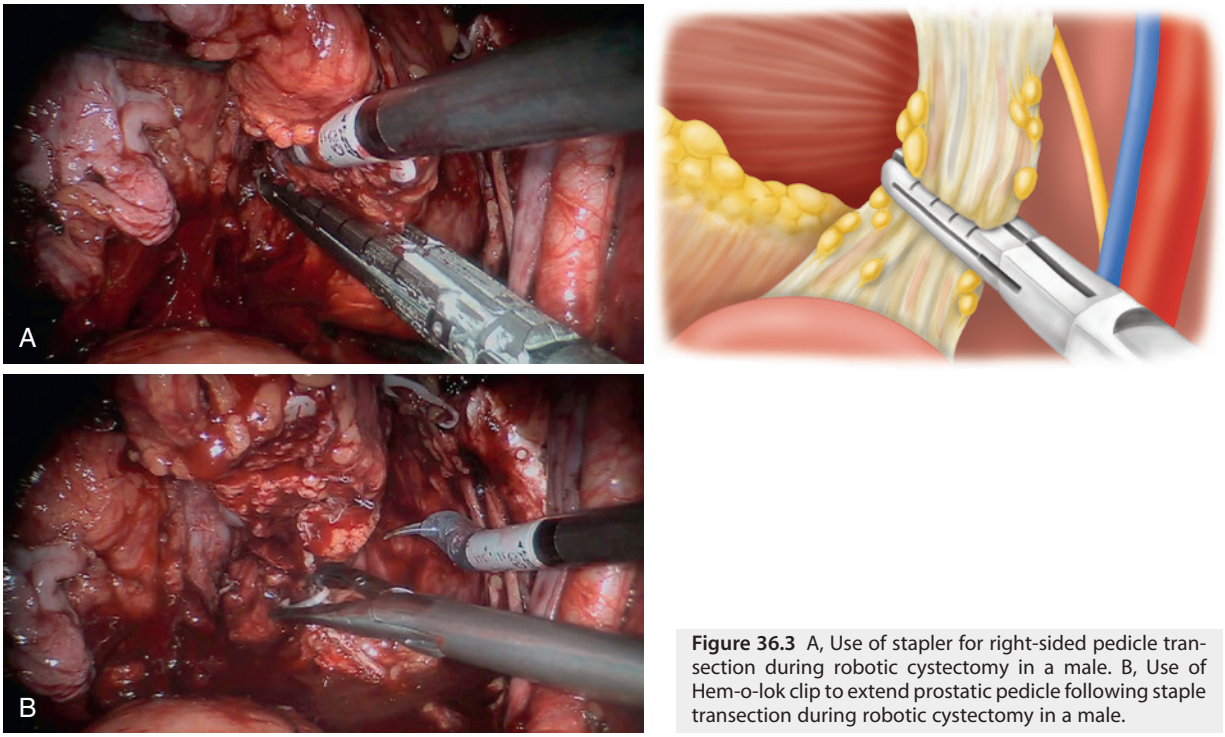

Figure 36.3 A, Use of stapler for right-sided pedicle transection during robotic cystectomy in a male. B, Use of Hem-o-lok clip to extend prostatic pedicle following staple transection during robotic cystectomy in a male.

Table 36.4 American Association of the Surgery of Trauma (AAST) Rectal Injury Grading Scale (RIS)

Grade		Description
I	Hematoma	Contusion or hematoma without devascularization
	Laceration	Partial thickness, no perforation
II	Laceration	<50% circumference
III	Laceration	>50% circumference
IV	Laceration	Full thickness with extension into the perineum
V	Vascular	Devascularized segment

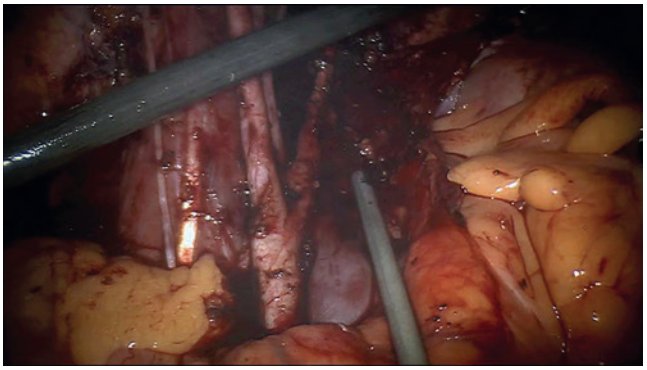

Figure 36.4 Completed robotic extended lymph node dissection.

and did not recommend placement of a drain in the deep pelvis as it is unnecessary and may increase the risk for fistula.[12] Patients in this cohort had not undergone bowel preparation; if contamination is not significant, a primary repair can be performed and diversion is often not required. Similar recommendations have been made within the urologic and gynecologic literature, emphasizing primary two-layered repair with interrupted suture without the need for diverting colostomy.[40,41] Our institutions have used a 3-0 V-Loc simple running suture in these rare instances with excellent result. Following repair, we recommend testing the repair by filling the pelvis with fluid from the suction irrigator and performing an air enema with a catheter or proctoscope.

DEVELOPING SPACE OF RETZIUS AND PROSTATE DISSECTION

When finished with the posterior dissection, the bladder can be released from the anterior abdominal wall. Utilizing the 30-degree up lens can be helpful early in the learning curve to aid visualization of the urachus. The new Xi robot can facilitate a quick switch using the console, but changing the lens angle may not warrant the additional time necessary to switch lenses using older versions of the robot. During this portion of the operation, careful attention to incorporating the perivesical fat is important to avoid a positive margin. On the other hand, if peritoneal mobilization is too wide after release of the medial umbilical ligaments, the inferior epigastric vessels can also be injured. Inferior epigastric vessel injury can be easily prevented with adequate traction by the robotic fourth arm or assistant. If inadvertent injury occurs, simple ligation of the vessel is sufficient with thermal energy.

The remainder of the anterior dissection follows closely the approach used for robotic prostatectomy. One important difference is careful dissection of the urethra to the level of the catheter. If performing neobladder, we advise limiting cautery and maximizing urethral length. Once the catheter is encountered, an extra-large Hem-o-lok clip can be placed across the catheter and cut distally. The cut catheter can then be used for cephalad retraction to mobilize the remainder of the posterior attachments. During the remaining dissection, careful attention to any residual rectal attachments should be noted to avoid thermal injury or rectal perforation.

LYMPH NODE DISSECTION

The Pasadena Consensus Panel (PCP) has laid out recommendations for the extent of lymph node dissection for robotic cystectomy, which involves, at minimum, nodes up to the bifurcation of the common iliac vessels, lateral to the genitofemoral nerve, including nodes of the lateral wall of the bladder to the lateral pelvic sidewall, and extending distally to the femoral canal. All nodes above and below the obturator nerve should also be removed. Common iliac nodes and presacral nodes were not agreed upon as standard but optional and certainly possible via the robotic approach (Fig. 36.4).[37] This portion of the operation involves several different structures that are commonly at risk for injury.

Typically, the dissection begins by focusing on the lateral margin of the dissection. Dissecting down to the psoas fascia and over to the lateral arterial edge helps early identification and preservation of the genitofemoral nerve. If the genitofemoral nerve is inadvertently transected, repair is difficult due to its small size and is not recommended due to its lesser relevance as a sensory nerve only. The anterior surface of the external iliac artery has no branches for the majority of its course, but as dissection proceeds distally, the deep circumflex vein will cross over the anterior surface of the artery, which is at risk for injury. If injury of the circumflex vein occurs, simple ligation is warranted.

Following anterior and lateral dissection, dissection proceeds posterior to the artery. At this point, we will dissect posterior to the artery in order to free the lymphatic tissue from the muscle and the posterior wall of the external iliac vessels. If the psoas muscle is identified and followed posteriorly, the posterolateral lymphatic attachments can be easily removed while maintaining excellent vascular control deep in the recess between the external and internal branches, also known as the space of Marseille (Fig. 36.5). By using this approach, the external iliac vein can be carefully observed and obturator dissection of the lymph node packet is better facilitated.

However, the obturator nerve can be injured from this posterior approach if one is not familiar with this viewpoint, and can also be injured during release of the medial lymphatic tissue. To avoid injury, identification of the obturator nerve prior to ligation is preferred. Additional caution should be exercised when using monopolar cautery near the nerve as it can conduct the current and stimulate the

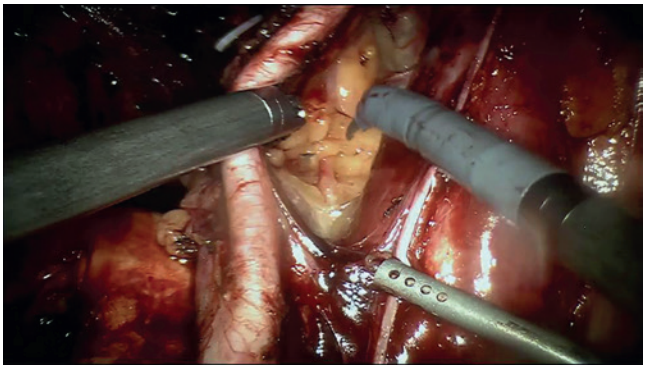

Figure 36.5 Posterolateral lymph node dissection in the space of Marseille.

nerve. If using electrocautery, we advise lowering energy to 25W/25W for cut and coagulation to minimize lateral thermal spread, similarly to what is performed during ureteral dissection. Preferably, the bipolar or vessel sealer better minimizes thermal spread and nerve conduction. If the obturator nerve is injured as a partial transection, repair should be performed immediately in all cases. Simple 5-0 interrupted monofilament sutures should suffice, but some surgeons prefer 4-0 or 6-0 suture. Every attempt should be made to place the suture in the epineurium to reapproximate the nerve ends. In the case of a full-thickness transection in which the ends can be brought together in a tensionless fashion, primary realignment should be performed in a similar fashion to that described above. If the ends cannot be approximated in a tensionless fashion, then a sural nerve graft can be used.[42]

Vascular injury occurs most often during lymph node dissection while performing RARC. A recent review examined major vascular injuries during nonvascular surgery and found that 63% of injuries occurred during cancer surgery, with urologic cases demonstrating the highest frequency at 29.6%.[43] The majority of reported injuries were partial laceration, and the vessel most commonly injured was the iliac vessel. In the majority of cases, primary repair was used, and injury-related complications did not occur.[43] The iliac artery is often easier to repair, but the iliac vein is more commonly at risk due to difficulty in appreciating the vein edges secondary to steep Trendelenburg and pneumoperitoneum. If the surgeon is prepared with robotic instruments and precut Prolene suture, repair can be relatively straightforward.

The initial phase of vascular injury repair requires hemorrhage control. Grip strength of the robotic instruments must be considered, as some tools can cause significant damage to blood vessels if used to grasp them. Mini lap sponges should be on the field in anticipation of this possible complication to apply direct pressure at the site of bleeding without concern for further injury with the robotic instruments. If the surgeon is able to apply direct pressure to the injury to control bleeding, then removing their head from the console will lock the arms in place and hold pressure while the team organizes materials needed for the repair. If blood loss is significant but currently controlled with pressure, communication with anesthesia is essential to ensure that the patient can tolerate additional blood loss before a repair attempt is made. If the injury is isolated with adequate control in a stable patient, robotic repair may be attempted. The method of injury should be determined. If a full-thickness thermal injury occurs to a large artery or vein, involvement of a vascular surgeon should be strongly considered given the requirement for proximal and distal control, debridement, and more complex repair. If the fourth arm has the double fenestrated grasper or a similar instrument with low grip strength, it may be used to directly grasp the vessel while suture is delivered to the robotic surgeon and the instruments are quickly exchanged to needle drivers. If the laceration causes bleeding that impedes vision, a small laparoscopic bulldog clamp can be used to obtain temporary proximal and distal control. Finally, injury to the internal iliac artery can be ligated without serious consequence in the majority of cases. If the repair can be performed with simple suture, then it may be attempted; otherwise, ligation is acceptable.

ISSUES UNIQUE TO FEMALE CYSTECTOMY

If a hysterectomy is to be performed, the VCare uterine manipulator can be an excellent tool to aid in mobilization of the uterus by the assistant during the hysterectomy portion of the procedure. The uterine manipulator also provides the surgeon with better definition of where the colpotomy should be performed. If utilizing the AirSeal inflation system, pneumoperitoneum will be maintained. However, if the inflation system is unavailable, the uterine manipulator can aid in maintaining pneumoperitoneum while the vaginal incision is closed.

The bladder neck and urethral dissection are different in the female patient, and inadvertent entry into the bladder or anterior vaginal wall can occur if the surgeon is not cautious during posterior dissection. If the uterine manipulator is not used, a lubricated sponge-stick can fill the potential space of the vagina and ease identification of its borders during dissection. Once these vaginal borders are identified, the pedicles become apparent and can be ligated in a similar fashion to that of male cystectomy (Figs. 36.6A, B). When elaborating the plane between the bladder and vagina, erring on the side of the vagina is always recommended to avoid inadvertent bladder entry. Any vaginotomy must then be closed carefully, and the remaining urethral stump should also be closed to prevent persistent urethral or vaginal drainage. Rarely, persistent leakage may require a repeat procedure but often will resolve with time. To aid in appropriate healing of the vaginal incision, we recommend estrogen-soaked gauze be put in place immediately after the procedure and removed the following day. In addition, topical estrogen treatments for the first 2 weeks can aid healing.

URINARY DIVERSION

Many of the complications associated with RARC are associated with the urinary diversion. Although many robotic surgeons perform the diversion extracorporeally, the intracorporeal approach (ICUD) is another option. Regardless of robotic approach, diversion type also greatly impacts complication rates, with studies suggesting a higher complication rate among patients undergoing neobladder or Indiana pouch compared to ileal conduit.[21] Regardless of approach, the left ureter should be tunneled prior to undocking the

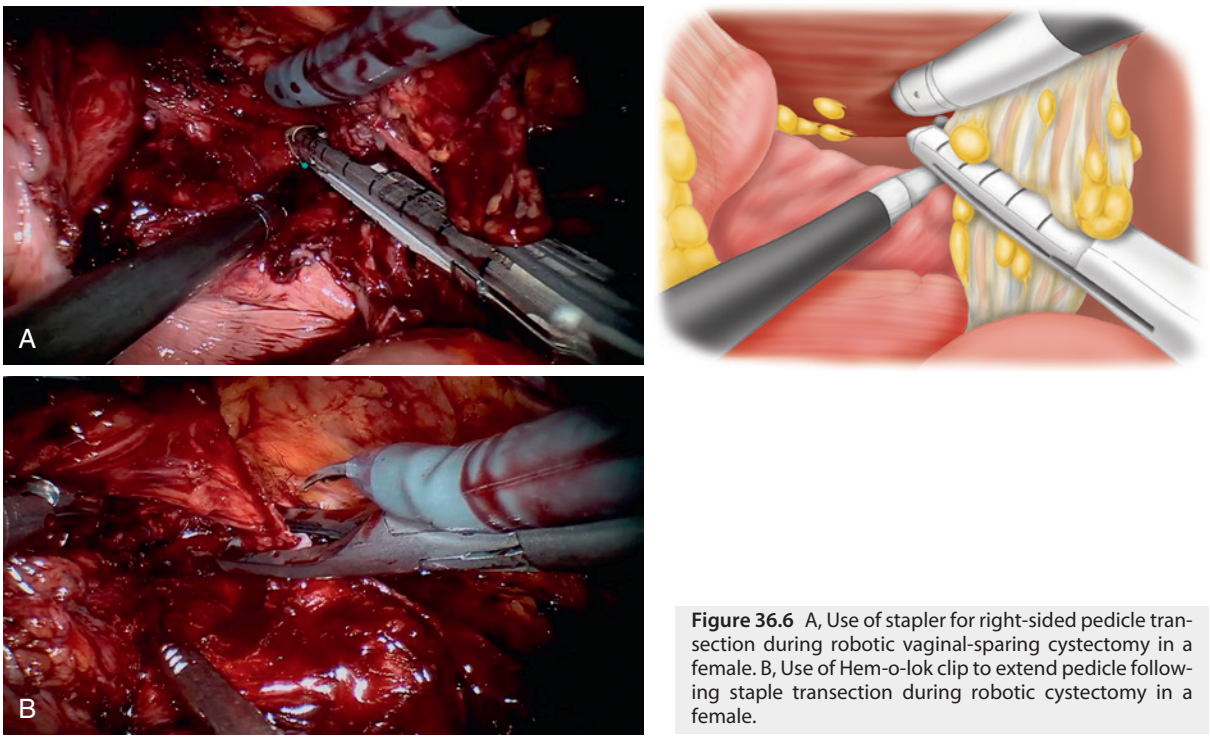

Figure 36.6 A, Use of stapler for right-sided pedicle transection during robotic vaginal-sparing cystectomy in a female. B, Use of Hem-o-lok clip to extend pedicle following staple transection during robotic cystectomy in a female.

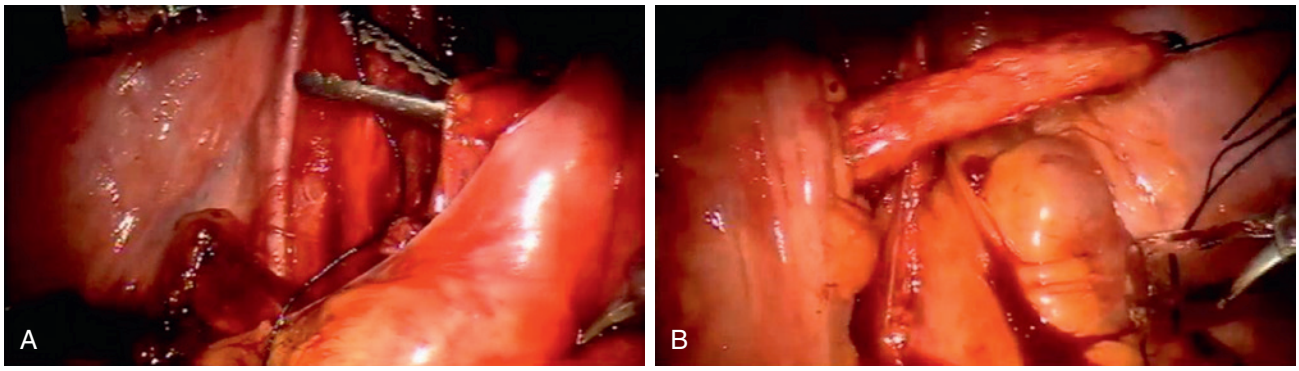

Figure 36.7 A, Grasping the left ureteral suture to tunnel under the sigmoid mesentery. B, The left ureter has been successfully tunneled to the right side, facilitating extracorporeal (or intracorporeal) urinary diversion.

robot as this can be challenging to perform extracorporeally through a small incision. A locking grasper can be placed in the right assistant port (or the undocked right robotic arm) and placed across to the left side. The grasper can then carefully secure the long suture attached to the ureter (Fig. 36.7A) and carefully direct the ureter to the right side (Fig. 36.7B). The extracorporeal diversion can then be performed similarly to an open procedure. For the purposes of this chapter, we will focus the remainder of this section on the robotic intracorporeal urinary diversion.

Intracorporeal ileal conduit is now commonly performed among robotic surgeons. When attempting to transition from extracorporeal to intracorporeal diversion, an additional port near the pubic symphysis can allow easy access and angulation for the stapler when handling the bowel anastomosis as well as performing the Wallace plate for the ureters. By using the long stay sutures on the ureters (as described in the ureteral dissection section), the ureters can be placed on slight tension by bringing these sutures through the additional port and positioning them for easy sewing. Another simple modification is the marionette stitch, which is passed through the abdominal wall on a Keith needle, through the distal end of the bowel segment, and back through the abdominal wall (untied). The marionette stitch allows movement of the conduit, aids in manipulation during the bowel portion, and facilitates positioning of the end of the conduit and the ureters for ureteroenteric anastomosis.[36] When performing the bowel resection, we recommend that the bowel be cut obliquely to remove more of the antimesenteric bowel wall, especially in situations of poor mesenteric circulation.

Intracorporeal neobladder (ICNB) can also be performed, but can be challenging when first embarking on this approach. We recommend reducing Trendelenburg, which can facilitate dropping of the neobladder toward the urethra stump. Confirming adequate mesenteric length to allow neobladder reach to the urethra should be performed prior to bowel resection. Traction loops placed through windows on the mesenteric side of the bowel can also be helpful when determining adequate length and is preferred over traction sutures in the bowel

wall, which can cause damage. The Van Velthoven technique of performing the neourethral anastomosis prior to stapling off the bowel segments can allow easy transition to ICNB for the robotic surgeon. We prefer two V-Lock sutures, with their ends tied, similar to robotic prostatectomy anastomotic suture. The most common intraoperative complication during ICNB is inability to obtain a watertight anastomosis. In order to adequately space sutures, we recommend stay sutures every 5–7 cm before attempting to close the posterior wall. The anterior wall can then be closed in a modified U-pouch configuration leaving a gap at the cephalad-most extent for the afferent ileal chimney. This allows for passage of the stents up the ureters, which are typically connected in a Wallace technique. The remaining hole is closed around the stents, which are brought out through the anterior abdominal wall and placed to an ostomy pouch in the immediate postoperative setting.

We recommend ureteral stents following both diversion types to aid in healing and prevent urine leak. An external stay suture using 5-0 chromic can prevent the stents from inadvertent removal. If considering ICUD, we recommend mastery of the robotic extirpative portion first to minimize operative time and time-related complications.

Postoperative Complications and Management

VENOUS THROMBOEMBOLISM

Inherent to the risks of radical cystectomy for malignancy is postoperative deep venous thrombosis (DVT) and/or pulmonary embolism. Contemporary ORC series approximate thromboembolic risk as 1–4% of all complications.[3,44,45] A retrospective study using data from the National Surgical Quality Improvement Program evaluated 1307 patients undergoing cystectomy from 2005 to 2011. Approximately 6% of patients were diagnosed with venous thromboembolism (VTE), with a mean time to diagnosis of 15 days postoperatively.[46] Among patients diagnosed with VTE, 55% were diagnosed following discharge, and 30-day mortality from VTE was 6% in this series. Specific risk factors associated with VTE included advanced age, longer operative time, and history of sepsis. Another large study using claims data from the Marketscan database extended analysis through 90 days to determine VTE risk following cystectomy. Among 1581 patients undergoing cystectomy, 10% were diagnosed with a VTE within 90 days of cystectomy (3.8% within 30 days after discharge, and 3.3% between 31 and 90 days after discharge). Risk factors associated with VTE risk included orthotopic neobladder urinary diversion, discharge to a skilled nursing facility, and prolonged index hospital stay following cystectomy.[47]

While these studies provide a broad overview of the high risk of venous thromboembolism, coding constraints preclude the ability to determine the impact of surgical approach on VTE risk (and compare RARC to ORC). Additional risk factors that may increase the rate of DVT/thromboembolism following RARC may be related to Trendelenberg, dorsal lithotomy positioning, and prolonged pneumoperitoneum.[48] To determine if RARC does carry an increased risk of VTE, a randomized clinical trial from Memorial Sloan Kettering compared 118 RARC and ORC patients. No differences were noted in thromboembolic complications (8.3% and 8.6%, respectively).[12]

To determine if extracorporeal or intracorporeal diversion impacted hematologic risk, an analysis from the International Robotic Cystectomy Consortium evaluated 935 patients undergoing RARC with pelvic lymph node dissection across 18 international centers between 2003 and 2011. Among 768 patients undergoing extracorporeal and 167 patients undergoing intracorporeal diversion, no differences were noted among preoperative variables such as age, sex, BMI, and preoperative chemotherapy. Additionally, no difference was noted in hematologic complications between extracorporeal (9%) and intracorporeal (10%) conduits.[28] However, hematologic complications included bleeding along with venous thromboembolism risk, with no specific mention made of specific DVT or VTE risk.

Despite no appreciable added VTE risk of RARC over ORC, VTE risk remains high following cystectomy regardless of approach. To better outline the need for VTE prophylaxis, the American Urological Association (AUA) Best Practice Statement for prevention of DVT in patients undergoing urologic surgery emphasizes risk stratification of patients based on both surgery type and patient risk factors (Table 36.5). Given that the majority of patients undergoing RARC are >40 years old with multiple risk factors (e.g., cancer, chemotherapy, smoking), routine DVT prophylaxis is common practice at our institutions. Each patient is provided a dose of low-molecular subcutaneous heparin in the hour before

Table 36.5 Risk Factors for Deep Vein Thrombosis

Surgery
Obesity
Smoking
Varicose veins
Ventral venous catheterization
Trauma
Immobility, paresis
Malignancy
Oncologic therapy (e.g., chemotherapy, radiotherapy, hormonal)
Prior deep vein thrombosis
Increased age
Estrogen-containing oral contraception/hormone replacement therapy
Selective estrogen receptor modulators
Acute medical illness
Heart or respiratory failure
Inflammatory bowel disease
Nephrotic syndrome
Myeloproliferative disorders
Paroxysmal nocturnal hemoglobinuria
Inherited or acquired thrombophilia

(*From Geerts, W.H., Pineo, G.F., Heit, J.A., et al.: Prevention of venous thromboembolism. Chest 2004; 126(3): 338S-400S.)

anesthesia induction, and lower extremity compression devices are activated before the patient is positioned and throughout the hospital course. As has been pointed out in prior studies, at least half of venous thromboembolic events occur in the postdischarge setting. Enoxaparin prophylaxis for 4 weeks after surgical treatment of abdominal or pelvic cancer both is safe and significantly decreases the incidence of thrombosis, as compared with 1-week prophylaxis.[49] Therefore we routinely provide extended enoxaparin prophylaxis to prevent VTE as a complication following RARC for 4 weeks following discharge.

WOUND INFECTION/FASCIAL DEHISCENCE

Wound infection and dehiscence are not uncommon complications following the traditional ORC approach, and while many of these can be managed conservatively, some require reoperation and prolonged hospitalization.[50,51] The incidence of wound infection after ORC is approximately 3–6%, but can be higher in some series, with dehiscence risk much lower at 1–3%.[44,52] A single institution study from Japan evaluated surgical site infections following ORC. Predictors of infection included increased age, thick subcutaneous fat, and absence of a subcutaneous closed-suction drain (in obese patients), which has reduced the risk of subsequent surgical site infection. While this has not been studied in RARC, it could be considered for those patients with larger incisions and extracorporeal diversions.[53]

In comparison to ORC, the incidence of wound infection following RARC appears to be lower, with most robotic series reporting a wound infection rate of 1%. In a randomized clinical trial that compared ORC to RARC, overall infectious complications were not significantly different between RARC (38%) and ORC (29%) ($p = 0.3$). However, wound infection was significantly lower in RARC (3.3%) compared to ORC (14%) ($p = 0.04$).[12]

Risk factors for surgical site infections and dehiscence include a host of factors, including prior smoking history, diabetes, cardiopulmonary disease, and malnutrition.[54–58] Furthermore, elevated blood loss with associated hypovolemia can diminish tissue oxygenation, thereby impacting wound healing by compromising tissue integrity.[59–61] As RARC has been demonstrated to have lower blood loss compared to ORC series, this may contribute to the lower wound infection rates noted in many series. Regardless of approach, we attempt to minimize surgical site infections by using standard preoperative antibiotic prophylaxis (<24 hours) and ensuring a negative urine culture prior to surgery.

LYMPHOCELE

Given that pelvic lymph node dissection is an integral part of RARC for bladder cancer, lymphocele is a potential complication following surgery. In ORC series, the incidence of lymphocele approximated 1–4%, with the majority being self-limited.[62,63] Very few studies have investigated lymphocele as a complication following RARC. In a single institution study evaluating early complications following RARC among 50 patients, only one lymphocele was noted (2%) and treated successfully with percutaneous drainage.[64] In another single institution study investigating complications among RARC with intracorporeal neobladders, the overall lymphocele rate was 5/70 (7%) with 1.4% experiencing no symptoms (and treated conservatively) and the remaining four patients (6%) treated with drainage due to accompanying symptoms.[65] These data suggest that lymphocele rates of RARC are comparable to that of ORC and can likely be treated similarly.

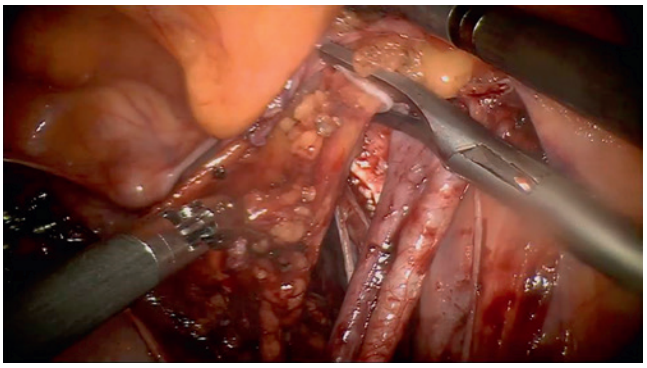

Figure 36.8 Use of Hem-o-lok clip during lymph node dissection to prevent subsequent lymphocele.

Debate between the merits of standard versus extended pelvic lymph node dissection (PLND) is ongoing. While standard PLND is defined by boundaries comprising common iliac bifurcation (cephalad), circumflex iliac vein (distal), genitofemoral nerve (lateral), and hypogastric vessels (posterior, including the obturator fossa), extended PLND also includes nodes to the bifurcation of the aorta as well as the presacral nodes anterior to the sacral promontory.[66] A study of 92 consecutive patients undergoing ORC evenly divided them into standard and extended lymphadenectomy groups, and no differences in 30-day major or minor complications were noted.[67] We encourage meticulous clipping of lymphatic vessels during RARC PLND (either with a titanium clip applier or Hem-o-lok clips as needed) to minimize the subsequent risk of lymphocele formation (Fig. 36.8).

Symptomatic patients may experience ileus, fever, abdominal pain, lower-extremity edema, and gastrointestinal symptoms from mass effect on adjacent organs. Compression of pelvic veins by the lymphocele can also increase the risk of thromboembolic events.[68,69] Diagnosis can be confirmed by radiologic imaging. Ultrasonography might reveal an anechoic cystic structure that may contain thin septations or debris, while computed tomography (CT) often demonstrates a thin-walled hypodense lesion with negative Hounsfield units. A thickened wall with enhancement on CT may indicate an infected lymphocele.

Should lymphocele develop, which has been rare in our experience, most appear to be self-limited. If the patient is experiencing symptoms (either in the form of pain, infected lymphocele, or compression against the vessels), we have found that a simple drain placement will resolve the majority of cases. Should this also fail, additional maneuvers include instillation of sclerosing agents or laparoscopic marsupialization of the lymphocele.[70,71] If the lymphocele is large, fluid obtained by percutaneous aspiration should be evaluated for bacterial culture and analysis of creatinine to exclude urine leak. Success rates with drainage alone approximate 80%, with many only requiring a few days to a week to resolve.[68]

ILEUS

Postoperative ileus, defined as a delay in coordinated movements of the gastrointestinal tract, is a common complication following radical cystectomy, whether performed in an open or robotic manner. The pathophysiologic causes of postoperative ileus are multifactorial and are more common after bowel surgery. Several causes of ileus include inhibitory neural reflexes related to bowel manipulation as well as a large host of neurotransmitters and inflammatory factors that include nitric oxide (an important mediator of initial paralysis) and increased mucosal permeability due to several peptides such as substance P and vasoactive intestinal peptide.[72] Postoperative ileus has been found to be one of the leading causes of prolonged hospital stay following cystectomy.[73]

While historic ORC series approximate prolonged ileus at 15–20%, RARC ileus rates appear to be similar in some series and lower in others. In a single institution study of 104 ORC and 35 RARC patients, ileus rate was similar among RARC and ORC patients (26% vs 30%, respectively).[74] Another single institution study found that ileus rates after RARC were 4/50 (8%).[64] A larger study of 209 consecutive patients undergoing RARC found an overall ileus rate of 22%, with a similar rate between extracorporeal conduit or orthotopic diversion.[21] In a single study investigating complications among RARC with intracorporeal neobladders, the rate of ileus was only 6% (n = 4/70). Among these 4 patients, two were treated conservatively, one was treated with a small intestine enema, and one obstructive ileus was treated with a reoperation.[65]

Regardless of the cystectomy approach, ileus rates have improved with the addition of enhanced recovery protocols in surgery.[3,44] A recent review of enhanced recovery protocols in robotic cystectomy surgery demonstrated that enhanced recovery programs can reduce postoperative ileus and may include preoperative nutritional optimization, the absence of bowel preparation, carbohydrate loading, minimization of narcotic usage, and a structured plan for dietary advancement in the postoperative setting.[75] Additional maneuvers that can reduce ileus among RARC patients include the use of alvimopan. A multicenter randomized controlled trial in which 143 patients were randomized to alvimopan and 137 to placebo demonstrated significantly lower postoperative ileus-related morbidity (8.4% vs 29.1%, respectively; $p < 0.001$).[76]

Intraoperative care can also reduce ileus rates. Epidural anesthesia can reduce the need for opiates, but has additional side effects such as vasodilation, postural hypotension, and reducing mobility. An alternative is the inclusion of rectus sheath catheters, which can directly deliver pain control to the incision.[77]

If prolonged ileus occurs despite preventative measures following RARC, treatment is similar to traditional approaches for ORC. Careful correction of electrolyte imbalances can help restore bowel function, and additional causes should be entertained (including the possibility of intraabdominal abscess or urinoma, which can cause a generalized peritonitis). If ileus continues, we recommend bowel decompression using a nasogastric tube to control nausea and vomiting and to better delineate resolution of ileus. If the nasogastric tube is placed, repletion of output is necessary to maintain fluid status. For those cases not responding to conservative measures, small bowel obstruction must be investigated with further imaging as indicated.

ANASTOMOTIC LEAK AND ENTEROCUTANEOUS FISTULA

Although rare, additional postoperative gastrointestinal complications following radical cystectomy include both anastomotic leak as well as enterocutaneous fistula. Most retrospective studies reveal no differences between ORC and RARC gastrointestinal complications, but no specific comment regarding bowel leak or fistula. In a large cohort of over 800 patients undergoing either RARC with extracorporeal or intracorporeal diversion, gastrointestinal complications occurred in 20% of patients but at a lower rate in the intracorporeal group (10% vs 23%; $p < 0.001$).[28] However, these complications were not stratified by type (e.g., ileus versus anastomotic leak or enterocutaneous fistula). Similarly, a randomized controlled trial from Memorial Sloan Kettering revealed no significant differences in overall GI complications between RARC and ORC (23% vs 29%, respectively), although again no specific details on types of GI complications were recorded. In one single institution study that did specify types of GI complications among 35 RARC and 104 ORC cases, overall GI complications were similar.[74] No cases of enterocutaneous fistula, bowel leak, or rectal injury were reported.

Additional research is needed to determine the risk of anastomotic leak and enterocutaneous fistula following RARC with or without intracorporeal diversion, but likely these rates remain low, given the low rates in the existing literature.

Conclusions

Although RARC is a relatively new procedure, the number of cases are growing and many surgeons are adopting the technique. Complication rates appear to be largely similar to the open approach, with minor variations based on intraoperative challenges, patient positioning, and incisional differences. This chapter reviewed the common complications that occur in the RARC perioperative period as well as methods to avoid these complications. A clear understanding of each complication's presentation, prevention, and treatment can ensure success early in the surgeon's learning curve.

Although complications are common following RARC, many perioperative complications can be avoided through adequate preparation. A thorough understanding of the RARC technique as well as adherence to perioperative pathways, appropriate equipment, and institutional support can successfully minimize complications following RARC.

Chapter 36 Questions

1. During robotic cystectomy, which portion of the case is at most risk for vascular injury?
   a. Lymph node dissection
   b. Urinary diversion
   c. Posterior dissection
   d. Anterior dissection
   e. All of the above (all have equal risk)

2. Which maneuver(s) can assist intracorporeal diversion and avoid complications?
   a. Robotic fourth arm placed on the patient's left side
   b. Removing 15–20 degrees of steep Trendelenberg
   c. Stay sutures every 5–7 cm during neobladder construction
   d. Marionette stitch
   e. All of the above

3. During ureteral dissection, which factor does NOT lead to complications of ureteral stricture?
   a. Hem-o-lok clip of the distal ureter when transecting
   b. Use of monopolar cautery in close proximity to the ureter
   c. Tension of the ureter during dissection
   d. Manipulation of the ureter by grasping with robotic instruments
   e. None of the above

4. During dissection of the ureter or posterior dissection, which instruments/thermal settings cause the most thermal spread?
   a. EndoWrist One vessel sealer
   b. Bipolar device
   c. Monopolar scissors
   d. Ligasure
   e. None of the above cause thermal spread

5. A patient undergoes robotic cystectomy, and during posterior dissection, a rectal laceration is noted. The injury appears to be <50% circumference and did not involve cautery. What is the grade and recommended treatment for this injury?
   a. II / primary repair
   b. III / colostomy
   c. II / colostomy
   d. III / primary repair
   e. I / primary repair

6. After robotic cystectomy with bilateral pelvic lymph node dissection, your patient returns with fever and unilateral lower extremity edema. Imaging demonstrates a large left fluid collection with negative Hounsfield units and a thickened, enhanced wall. What is your next step in treatment?
   a. Chemotherapy for recurrent disease
   b. Drain placement and antibiotics
   c. Observation
   d. Instillation of sclerosing agent into the fluid collection
   e. None of the above

7. Which complications are decreased in robotic cystectomy as compared to traditional open cystectomy?
   a. Deep venous thrombosis
   b. Lymphocele
   c. Wound infection
   d. None of the above
   e. All of the above

8. When performing a female cystectomy with hysterectomy, what tool(s) can be helpful to perform colpotomy?
   a. Lubricated spongestick in the vagina
   b. VCare uterine manipulator
   c. Insufflation of the vagina
   d. All of the above
   e. a or b

9. During a challenging pelvic lymph node dissection, you are using monopolar cautery. Suddenly, profuse bleeding is encountered at the level of the iliac vein. What is your next best step in management?
   a. Using mini lap sponges, apply direct pressure at site of bleeding
   b. Grasp the vein directly with the ProGrasp
   c. Consult vascular surgery
   d. Change instruments to needle drivers
   e. a and c

10. During robotic cystectomy port placement, what considerations can ensure success during the procedure?
    a. Camera port placed at least two fingerbreadths above the umbilicus
    b. Robotic fourth arm placed on the patient's left if considering intracorporeal neobladder and using robotic stapler
    c. Robotic fourth arm placed on the patient's left if considering intracorporeal neobladder and using laparoscopic stapler
    d. a and b
    e. a and c

Case Studies

CASE 1

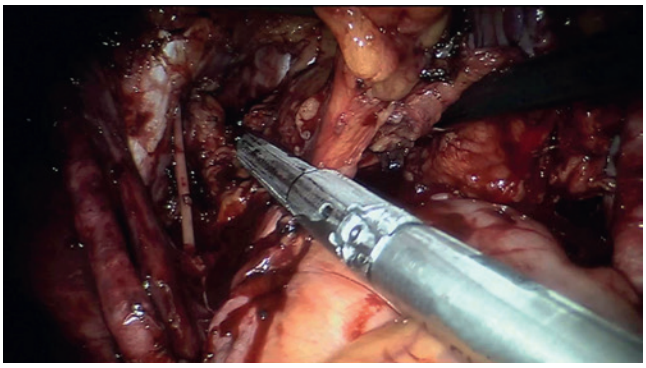
A 69-year-old male presents to your office for evaluation of gross hematuria. Transurethral resection of bladder tumor confirms urothelial carcinoma present in the lamina propria and muscularis propria, and a staging CT chest, abdomen, pelvis is obtained that shows left hydroureteronephrosis (Case Fig. 36.1). No lymphadenopathy is noted.

1. What is the stage based on CT imaging and clinical history?
   a. cT1N0
   b. cT2N0
   c. cT3N0
   d. cT4N0
   e. None of the above

2. Based on the above diagnosis and stage, the patient is offered neoadjuvant chemotherapy and returns to

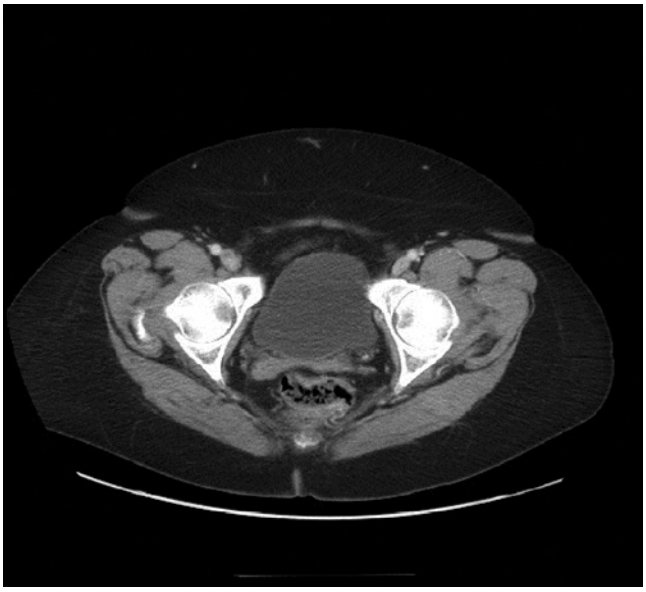
Case Figure 36.1

your clinic for discussion of surgery. Repeat staging CT is obtained that reveals no lymphadenopathy and similar bladder findings as prechemotherapy CT. What options do you offer him?



a. Open radical cystoprostatectomy
b. Robotic radical cystoprostatectomy
c. Partial cystoprostatectomy
d. a or b
e. All of the above

3. The patient opts for robotic radical cystoprostatectomy. During the right pelvic lymph node dissection, the obturator nerve is partially transected. What is the next acceptable step in management of this complication?
   a. Full-thickness interrupted monofilament 5-0 sutures to reapproximate the nerve
   b. Conservative management (no primary repair)
   c. Interrupted monofilament 5-0 sutures to reapproximate the nerve, with sutures in epineurium only
   d. Sural nerve graft
   e. Staple nerve ends together

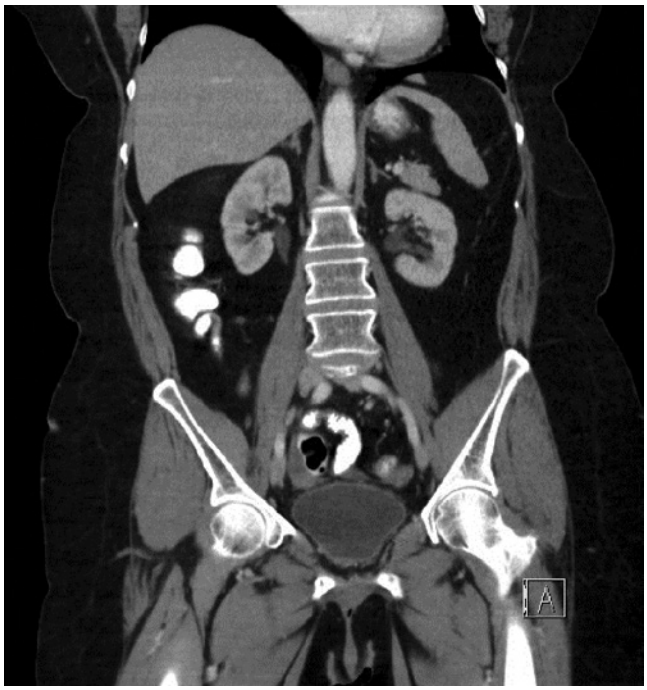


4. Following the lymph node dissection, the posterior dissection proceeds. You experience some difficulty in the right side of this dissection. A stapler is placed to take this pedicle as shown in Case Fig. 36.2. Following the staple load, a small amount of brown fluid is noted, indicating a rectal laceration. You estimate this to be a small tear. What is the next step in management?
   a. Freshen the edges of the rectal laceration
   b. Perform primary closure with a running monofilament suture
   c. Leave a drain at the site of closure
   d. All of the above
   e. a and b

CASE 2

A 60-year-old female presents to you with stage II muscle-invasive bladder cancer. She is interested in robotic

Case Figure 36.2



Case Figure 36.3

cystectomy with intracorporeal neobladder. She is sexually active and wishes to preserve the ability for intercourse following the procedure. She is continent, with no complaints of stress urinary incontinence. Her CT scan is demonstrated in Case Figs. 36.3 and 36.4.

1. What is the best surgical approach based on her disease and preferences?
   a. Robotic cystectomy with vaginal-sparing, intracorporeal neobladder
   b. Robotic cystectomy with non–vaginal sparing, intracorporeal neobladder
   c. Robotic cystectomy with vaginal-sparing, extracorporeal neobladder
   d. Robotic cystectomy with non–vaginal sparing, extracorporeal neobladder
   e. None of the above; the patient is not a candidate for robotic cystectomy

2. As you begin the posterior dissection, the uterus obscures your view, and you have difficulty identifying the location to begin your colpotomy. What is the best next step to assist with this?
   a. Insufflate the vagina
   b. Spongestick placed in the vagina

Case Figure 36.4

c. VCare uterine manipulator
d. All of the above
e. b and c

3. As you proceed with posterior dissection between the vagina and bladder, you find the plane to be somewhat difficult. What options are indicated in this case?
   a. Abort vaginal-sparing procedure and perform anterior vaginectomy
   b. Continue dissection closer to the vaginal wall, and abort if this plane remains challenging
   c. Continue dissection in this plane, as this plane is always challenging
   d. a or b
   e. None of the above

4. You are now ready to begin your intracorporeal neobladder. As you are early in the learning curve, you would like to maximize your chances of success. What maneuvers can be helpful in performing this procedure?
   a. Reduce Trendelenburg positioning by 15–20 degrees
   b. Place a marionette stitch
   c. Perform the Van Velthoven technique of performing the neourethral anastomosis before stapling the bowel segments
   d. Place assistant port on patient's left side to facilitate use of the stapler without undue tension on the mesentery
   e. All of the above

Answers

1. **a.** During the lymph node dissection, the surgeon is removing lymph nodes that are adherent to the external iliac artery and vein, internal iliac artery and vein, and the common iliac artery and vein.

Case Table 36.1 American Association of the Surgery of Trauma (AAST) Rectal Injury Grading Scale (RIS)

Grade		Description
I	Hematoma	Contusion or hematoma without devascularization
	Laceration	Partial thickness, no perforation
II	Laceration	<50% circumference
III	Laceration	>50% circumference
IV	Laceration	Full thickness with extension into the perineum
V	Vascular	Devascularized segment

2. **e.** Placement of the robotic fourth arm on the left side allows the surgeon to more easily manipulate the robotic stapler if desired and manipulate the bowel more easily. Removing 15–20 degrees of steep Trendelenberg will take some of the tension off of the small bowel and allow it to more easily mobilize into the pelvis, which is the most appropriate working space based on the original robotic setup for the case. Stay sutures will allow you to more easily keep the neobladder aligned while sewing it closed in order to get a water tight closure. The marionette stitch can aid in movement of the bowel segment so as to make the ureteral anastomosis easier.
3. **a.** Monopolar cautery will cause more spread with the current used and cause unintentional damage to the surrounding tissue such as the ureter. The anastomosis should be tensionless and handled with care during the dissection. Manipulating the ureter by grasping with robotic instruments is not appropriate in most situations as the grip strength for the robotic instruments is greater than the surgeon realizes, causing crush injury to the ureter.
4. **c.** The monopolar devices in general cause greater thermal spread than bipolar devices.
5. **a.** Please refer to Case Table 36.1. For a grade II laceration, primary repair is the operative step of choice.
6. **b.** Signs of infected lymphocele include fever and imaging consistent with abscess (rim-enhancing fluid collection). While asymptomatic lymphoceles can be managed conservatively, infected lymphoceles require drainage and antibiotics.
7. **c.** Randomized trials comparing open and robotic cystectomy confirm similar complication rates between techniques. However, a recent trial from Memorial Sloan Kettering demonstrated an increase in wound complications (such as wound infection) with open cystectomy (14%) compared to robotic cystectomy (3%).
8. **e.** The VCare uterine manipulator can aid in mobilizing the uterus by better defining the appropriate location where colpotomy should be performed. Similarly, a lubricated spongestick in the vagina can serve the same purpose.
9. **e.** An iliac vein injury secondary to cautery may be more extensive than initially appreciated. Just as in open surgery, your first step should include direct pressure applied at the site of bleeding while simultaneously consulting vascular surgery. Mobilizing this

resource may avoid catastrophic blood loss in this challenging situation. Once you have control (which includes mobilizing blood products as needed), you may wish to attempt repair on your own (changing instruments to needle drivers). However, be cautious in attempting this during challenging lymph node dissections in which the vein is not yet fully exposed. Vascular surgery consults can prove very useful in these situations.

10. **e.** Camera port placement at least two fingerbreadths above the umbilicus facilitates lymph node dissection and intracorporeal bowel work. Furthermore, the robotic fourth arm should be placed on the left if considering intracorporeal neobladder (and using a robotic stapler), which minimizes tension on the bowel during staple fire. If using a laparoscopic stapler, the robotic fourth arm should be placed on the patient's right to allow the assistant to approach the anastomosis from the left.

CASE 1

1. **c.** The patient has apparent invasion of tumor into the perivesical fat near the left ureteral orifice. This finding, combined with left hydroureteronephrosis, suggests clinical T3 disease.
2. **d.** Robotic and open radical cystoprostatectomy are both viable options for this patient. Several research studies confirm that robotic cystectomy can be safely carried out by experienced surgeons with similar oncologic efficacy to that of open surgery. However, for inexperienced robotic surgeons, beginning with less challenging cases would be prudent before considering robotic cystectomy for challenging stage III cases.
3. **c.** Robotic repair of obturator nerve injuries can be successfully performed similarly to open surgery. In fact, use of the robotic instruments can allow for finer control of the anastomosis. Using an interrupted monofilament 5-0 suture can reapproximate the nerve and often avoid postoperative sequelae.
4. **e.** When encountering minimal spillage in a patient without risk factors of wound healing (e.g., prior pelvic radiation), a small rectal laceration can be successfully repaired primarily by freshening the edges of the laceration and performing primary closure with a running monofilament suture. Depending on surrounding and available tissue, a two- to three-layer closure is preferred. Drain placement is needed; however, this should not be placed at the site of closure to avoid undue pressure on the anastomosis, which may prevent wound healing.

CASE 2

1. **a.** Given the patient's interest in preserving sexual function and CT demonstrating no obvious bulky tumor posteriorly, a vaginal-sparing approach is appropriate. The patient is also a candidate for intracorporeal neobladder, and without any obvious contraindications, this procedure should be offered.
2. **e.** In cases in which the uterus obscures view, either a VCare uterine manipulator or (more simply) a vaginal spongestick can provide better visualization when performing the colpotomy.
3. **d.** One must use caution when noting difficulty in the dissection plane between vagina and bladder, as it may indicate tumor in this area. Before aborting a vaginal-sparing approach, dissection may be continued closer to the vagina (to err on the side of vaginotomy rather than cystotomy). However, if dissection remains difficult, the surgeon should perform anterior vaginectomy rather than compromise margin status.
4. **e.** Several maneuvers can ensure intracorporeal neobladder success. These include lessening Trendelenburg by 15–20 degrees to assist with bowel manipulation. Additionally, a marionette stitch can be helpful as can the Van Velthoven technique of performing the neourethral anastomosis before stapling bowel segments. Finally, ensuring that the assistant port is placed on the patient's left side will facilitate use of the stapler without creating mesenteric tension.

Chapter 37 Questions and Answers

KEY POINTS

1. Advantages of anterior incisions, whether midline, subcostal, or chevron, include quick exposure to the renal pedicle and the great vessels.
2. Up to 23% of patients will have a flank sag postoperatively as a result of injury to intercostal nerves that causes laxity of flank muscles at that level.
3. In cases anticipated to have a difficult hilar dissection or anterior approach, in which anatomic access to the artery is more difficult, preoperative renal artery embolization may be helpful.
4. The most common cause of splenic injury is excessive traction on the splenic attachments that rips the splenic capsule.
5. In cases of pancreatic injury, if injury of the duct is noted, distal pancreatectomy is the preferred method of management.
6. If bleeding makes repair of liver injury difficult, total obstruction of hepatic vascular inflow may be obtained by Pringle maneuver.
7. Perioperative strategies to decrease complication rates in elderly patients include minimal operative time, earlier consideration of blood transfusions, and possible gastric tube placement to decrease pneumonia rates.

Surgical removal of the kidney was reported as early as 1861. However, the first planned nephrectomy was probably performed by Gustav Simon in 1869 for a ureterovaginal fistula.[1] Because early nephrectomies were associated with high mortality rates as a result of peritonitis, the flank incision became the preferred approach until the 1950s, when effective antibiotic prophylaxis was developed. In 1969, Robson and colleagues published a seminal article describing their surgical management of renal tumors through the thoracoabdominal approach. Early control of the renal vessels, en bloc excision of kidney and adrenal with Gerota's fascia remaining intact, and extended lymphadenectomy allowed improved survival compared with simple nephrectomy.[2]

The principles outlined by Robson and associates still form the basis for treatment of similar tumors. Since that time, however, advances in imaging techniques have improved detection of smaller lesions and have caused a significant downward stage migration. This change may partially account for improvements in the morbidity and mortality of nephrectomy. Evolving surgical techniques, including laparoscopy and robotic surgery, anesthesia improvements, newer antibiotics, and effective intensive care contribute as well. Contemporary open nephrectomy is likely reserved for larger or more complex lesions thereby, possibly increasing complication risk.

Preoperative Considerations

CARDIOPULMONARY CONSIDERATIONS

Some possible life-threatening cardiopulmonary complications common to all surgical procedures include hypovolemic shock, myocardial infarction, pneumonia, pulmonary embolism, and pulmonary insufficiency. Renal surgery may cause severe stress to the cardiopulmonary system through many etiologies, including patient positioning effects and blood loss. The slow-growing nature of most renal neoplasms allows time for preoperative cardiopulmonary optimization, including the possibility of coronary or carotid artery revascularization. This must be balanced against the anticoagulation typically initiated after these interventions.

Patients undergoing nephrectomy frequently are placed in the flank position for surgical access. This position may severely stress the cardiopulmonary system, especially if the operating table is broken or a kidney rest is extended. First, pressure on the great vessels may decrease preload and increase afterload, thereby decreasing cardiac output. Second, ventilation is limited by the flank position. In addition to limiting the excursion of the dependent diaphragm, increased ventilation–perfusion mismatching may further decrease oxygen exchange and lead to hypoxia. These combined cardiopulmonary effects may make this position intolerable for some patients with limited reserve.

These issues necessitate careful preoperative screening of patients for pulmonary diseases and cardiac status. Cardiology and pulmonology consultation should be obtained if any doubt exists about the patient's condition. Preventive measures instituted preoperatively and invasive monitoring intraoperatively may increase safety for some patients. The potential for blood loss and large hemodynamic shifts should prompt preoperative blood typing. In addition, autologous blood donation should be offered to patients.

UROLOGIC CONSIDERATIONS

Preoperative workup of the urinary tract should include imaging of the operative site, with a specific focus on localized extent of tumor burden, effect on nearby visceral structures, presence or absence of tumor thrombus, and vascular anatomy. Physicians should include assessment of contralateral kidney function in addition to total kidney function. Urinalysis and, if indicated, urine culture and sensitivity should be performed to ensure urinary tract sterility before the planned operation. If urinary tract infection is found, antibiotics with adequate coverage should be given.

PATIENT PREPARATION

General intraoperative preventive measures are very important in avoiding complications common to any surgical procedure. Strict adherence to evidence-based recommendations ensures best possible outcomes. Antibiotic prophylaxis should be initiated ≥30 minutes before incision. Two large-bore intravenous access ports must be in place, and there should be consideration of arterial pressure monitoring and central venous access prior to the procedure. Per the 2008 AUA guidelines on the "Prevention of Deep Vein Thrombosis in Patients Undergoing Urologic Surgery," subcutaneous heparin should be initiated preoperatively to decrease the risk of deep vein thrombosis. Alternatively, compression hose, or preferably sequential compression devices, should be placed on the lower extremities unless contraindications such as open ulcers exist.[3] If this is the case, some evidence suggests that placement of these devices on the arms may still provide some antithrombotic effects. The patient must be positioned carefully with pressure points sufficiently padded. Factors pertaining to specific positions are discussed later.

GENERAL MEDICO-RENAL CONSIDERATIONS

Nephrectomy represents the removal of an important component of the body's mechanism for maintaining blood pressure homeostasis. The incidence of postoperative hypertension is <8%, usually mild, and it frequently resolves.[4] In the long term, hypertension develops in some kidney donors, but it is not significantly different from hypertension in matched population controls or siblings.[5]

Postoperative acute renal insufficiency may be multifactorial, relating to removal of a large percentage of the body's functional nephrons, direct or indirect manipulation of the contralateral kidney that causes arterial spasm, and rhabdomyolysis related to patient positioning. Postoperative acute renal insufficiency is usually transient but may require dialysis in some cases.

In the long-term, radical nephrectomy has been shown to be associated with the development of renal insufficiency, and this should be considered in all patients undergoing nephrectomy, even in the presence of a normal contralateral kidney.[6]

Surgical Approach

Many incisions have been described for nephrectomy. These may be classified into anterior, flank, and posterior approaches. Indications for specific incisions include patient body habitus, size and location of the renal lesion, other concurrently planned operations, indications for lymphadenectomy, and surgeon experience.

SITE VERIFICATION

The Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations) reported

Table 37.1 WHO Surgical Checklist

Before Induction of Anaesthesia	Before Skin Incision	Before Patient Leaves Operating Room
Sign In	**Time Out**	**Sign Out**
Patient has confirmed: ☐ Identity ☐ Site ☐ Procedure ☐ Consent	☐ **Confirm all team members have introduced themselves by name and role**	**Nurse verbally confirms with team:** ☐ The name of the procedure recorded ☐ That instrument, sponge and needle counts are correct (or not applicable ☐ How the specimen is labeled (including patient first name) ☐ Whether there are any equipment problems to be addressed
☐ **Site marked/not applicable**	**Surgeon, anesthesia professional and nurse verbally confirm:** ☐ Patient ☐ Site ☐ Procedure	☐ **Surgeon, anesthesia professional and nurse review the key concerns for recovery and management of this patient**
☐ **Anesthesia safety check completed**	**Anticipated critical events**	
☐ **Pulse oximeter on patient and functioning**	**Surgeon reviews:** ☐ What are the critical or unexpected steps, operative duration, anticipated blood loss?	
Does the patient have a:	**Anesthesia team reviews:** ☐ Are there any patient-specific concerns?	
Known allergy? ☐ No ☐ Yes	**Nursing team reviews:** ☐ Has sterility (including indicator results) been confirmed? ☐ Are there equipment issues or any concerns?	
Difficult airway/aspiration risk? ☐ No ☐ Yes, and equipment/assistance available	**Has antibiotic prophylaxis been given within the last 60 minutes?** ☐ Yes ☐ Not applicable	
Risk of >500 mL blood loss (7 mL/kg in children)? ☐ No ☐ Yes, and adequate intravenous access and fluids planned	**Is essential imaging displayed?** ☐ Yes ☐ Not applicable	

(Adapted from Mahajan RP. The WHO surgical checklist. Best Pract Res Clin Anaesthesiol. 2011;25:161-8.)

statistics on wrong-site surgery and showed that the incidence was increasing, peaking in 2011 at 152 reported events. However, since that time, there has been a continued decrease in reported events; 67 events were reported in 2014.[7] Approximately 10% of cases are reported to be urologic. A review of 7147 sentinel events reported to the AJCC between 2005 and 2010 revealed that 956 events, or 13.4%, were due to wrong-site surgery. In 2011, the World Health Organization published the surgical checklist which helps ensure the reduction of wrong-site surgery (Table 37.1).[8] Rigorous adherence to policies designed to prevent these occurrences is necessary to optimize patient care.

ANTERIOR INCISIONS

A main advantage of anterior incisions, whether midline, subcostal, or chevron (Fig. 37.1), is quick exposure to the renal pedicle and the great vessels. This feature may not be as important for prevention of tumor seeding as was first thought, but ease of exposure and familiarity with anatomy is still advantageous. Other situations that would favor the anterior approach include procedures in trauma patients, patients who cannot tolerate flank approach positioning, planned bilateral nephrectomy in patients with polycystic kidney disease, large or upper pole tumors, bilateral renal neoplasms, left nephrectomy with significant thrombus extension into the vena cava, and other preoperative indications for bilateral dissection. Although rarely indicated because of the accuracy of modern imaging techniques, the anterior approach also allows exploration of the abdomen for metastatic disease. Some investigators advocate extended lymphadenectomy with nephrectomy, and this procedure is easiest through an anterior approach.

The disadvantages of anterior approaches include transection of multiple muscle groups for subcostal or chevron incisions. If the operation is performed transperitoneally, any spillage of tumor or infectious material may have greater consequences than if the material is confined to the retroperitoneum. If the operation is intended to be retroperitoneal, anterior approaches may not be best because entry into the peritoneal cavity may accidentally occur. Transperitoneal operations are associated with formation

of adhesions and possible future small bowel obstruction. This complication was estimated to occur in 2% of patients in some series.[9] Obese patients may not be suitable candidates for anterior approaches because of difficulties associated with excessive extraperitoneal and intraperitoneal fat.

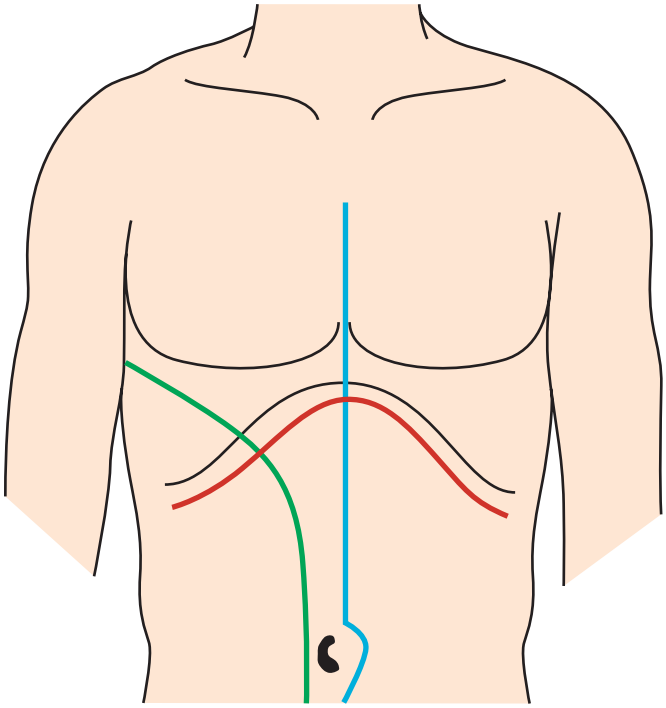

Figure 37.1 Diagram demonstrating anterior incisions. Midline incisions (blue) may be extended superiorly if exposure of the thoracic vena cava is necessary. The subcostal incision (red) may be extended across the midline if a complete chevron incision is necessary. A thoracoabdominal incision (green) offers excellent exposure to the superior renal pole and thoracic vena cava.

FLANK INCISIONS

Flank approaches may be preferable for uncomplicated nephrectomies. This approach allows access to the retroperitoneum while avoiding entry into the peritoneum or chest. Careful attention must be given to positioning and padding of the patient. Taping the hips too tightly to the operating table can result in gluteal necrosis. The incision may be accomplished in the 10th or 11th interspaces, or the 10th, 11th, or 12th ribs may be resected. If an intercostal incision is performed, the incision should be made immediately superior to the rib to avoid damage to the neurovascular bundle that runs immediately below each rib and is between the internal oblique and transversalis muscle layers. Up to 23% of patients have a flank sag postoperatively as a result of injury to intercostal nerves that causes laxity of flank muscles at that level (Fig. 37.2).[10] This condition may be difficult to distinguish from a true hernia, which is a rarer complication requiring surgical treatment to prevent incarceration. Poor nutritional status, diabetes, and other risk factors for poor wound healing predispose to the risk of hernia formation. Computed tomography (CT) imaging aids in establishing the diagnosis of an incisional hernia. Postoperative pain from flank incisions may be significant, especially during deep inspiration. Pain may become a long-term problem as a result of neuritis or entrapment of an intercostal nerve in the sutures or surrounding scar tissue. This complication may be prevented by careful reapproximation of the muscle layers. Fortunately, these issues usually resolve with time. Reassurance may be all that is required, but some patients require local steroid injections for analgesia.

THORACOABDOMINAL INCISIONS

The thoracoabdominal incision is a large incision now usually reserved for large or complicated radical nephrectomies. The extensive incision allows exploration of the

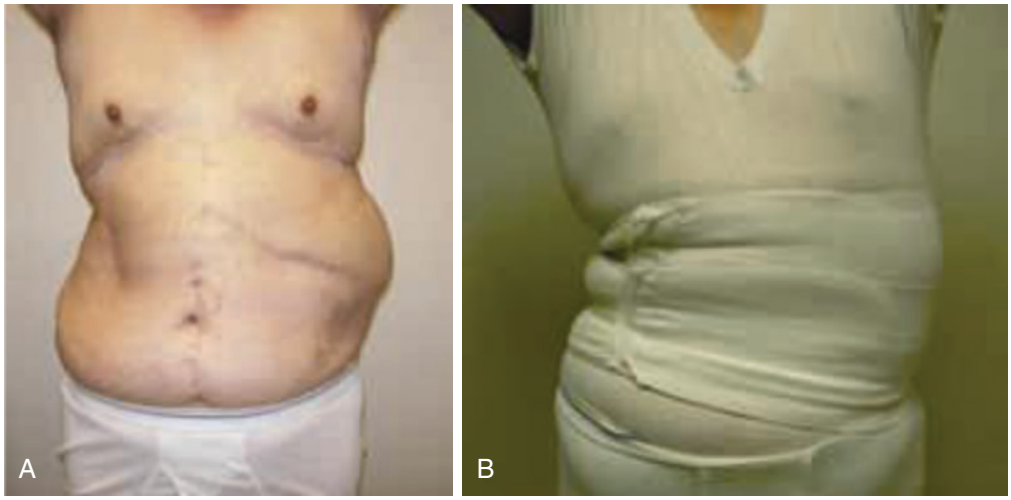

Figure 37.2 A, This patient is a 63-year-old man who underwent left splenectomy through a midline incision secondary to lymphoma and nephrectomy through a flank incision for T3b renal cell carcinoma (RCC). Although the surgical margins were negative, two sequential RCC recurrences of the diaphragm and renal bed were resected through a subcostal incision. Despite subsequent repair of a flank incisional hernia, the patient continues to have flank laxity, in part because of transected intercostal nerves. B, Photograph showing management of flank laxity with an abdominal binder.

peritoneal, retroperitoneal, and thoracic compartments with biopsy or wedge resection of any suspicious lesions. The exposure to the upper pole of the kidney is excellent, and therefore this incision may be used when an extensive upper pole lesion is anticipated. Vena cava thrombi with known extension above the diaphragm or into the right atrium may require entry into the thoracic cavity, and a right thoracoabdominal incision provides good visualization of the thoracic vena cava and right atrium. The disadvantage of this incision is the considerable morbidity associated with it. The size of the incision predisposes it to infection and significant postoperative discomfort. Spillage of tumor or infectious particles may be problematic given that both the peritoneum and the thoracic cavity are affected. Caution must be exercised when the left thoracoabdominal incision is used, to avoid injury to the spleen during incision of the diaphragm. The division of the costal cartilages anteriorly may lead to significant postoperative pain if these cartilages are not fixed securely with nonabsorbable suture. Rare complications include postoperative hemidiaphragmatic paralysis from division of the phrenic nerve and an annoying clicking sensation from nonunion of the costal cartilages.[11]

LUMBODORSAL INCISIONS

A distinct advantage of lumbodorsal incisions is decreased postoperative pain. This incision allows entry into the retroperitoneal space without division of any muscle groups and thereby minimizes the surgical trauma, which is one cause of postoperative discomfort of patients. Wound breakdown is uncommon with lumbodorsal incisions because the only layer to be divided, the lumbodorsal fascia, is very strong. The disadvantages of this incision center on the limited exposure it provides. Because extensive dissection of the vascular pedicle is very difficult, this incision is inadequate for renovascular surgery and radical nephrectomies with large tumors, upper pole disease, or suspected tumor extension or tumor thrombus. Division of the costovertebral ligament of the 12th rib may improve upper pole exposure. However, this maneuver risks damage to the costal neurovascular bundle. Because of the limited exposure provided by lumbodorsal incisions, they are less commonly used than are anterior or flank approaches. At present, laparoscopic surgery has widely replaced the lumbodorsal approach to minimize incision size and postoperative pain.

Intraoperative Complications

HEMORRHAGE

Angiography is not routinely performed before nephrectomy. Thus, prevention of significant intraoperative hemorrhage requires accurate knowledge of renal anatomy and blood supply as well as the variations commonly encountered.

Arterial Anatomy

In the majority of patients, a single renal artery branches laterally off the aorta and enters the renal hilum. On the right, the renal artery usually courses posterior to the vena cava. Multiple renal arteries are not uncommon, seen in >25% of patients in some series.[12] These arteries, if present on the right, generally pass anterior to the vena cava. The renal arteries are end circulation. If the artery or any of its branches is occluded, ischemic infarction of the kidney or the respective segment will occur.

Because the gonadal artery, adrenal artery, and inferior phrenic artery also lie in close proximity to the areas of dissection, these vessels are vulnerable to injury. The inferior phrenic arteries are the first abdominal branches of the aorta and generally have branches coursing inferior to supply a portion of the adrenal circulation. The adrenal arteries branch from the aorta at the level of the celiac trunk anteriorly and course laterally to the adrenals. Additional adrenal arterial branches frequently originate from the renal artery. The gonadal arteries branch laterally off the aorta below the renal arteries. Alternatively, they may occasionally branch off the renal artery. The right gonadal artery most often passes anterior to the vena cava.

Venous Anatomy

Venous drainage of the kidney, in contrast to the arterial circulation, has many collateral vessels. The right renal vein drains directly into the vena cava, usually without major branches. The left renal vein is usually joined by the left gonadal vein, left adrenal, and a lumbar vein before it passes anterior to the aorta to join the vena cava. Both renal veins generally lie anterior to the corresponding renal artery. Multiple renal veins are less common than are multiple arteries but they do occur in approximately 1% of patients, generally on the left. The renal vein may divide, with one limb anterior and one posterior to the aorta. Alternatively, only the posterior branch may remain.[13] The extensive collateral vessels of the renal venous system prevent slowly occurring occlusive processes such as tumor thrombus formation from causing kidney damage, renal failure, or other symptoms. Because of the greater collateral circulation on the left, the left renal vein may be ligated acutely with probable survival of the renal unit. The right lacks such extensive collateral vessels.

Statistics of Hemorrhage

Radical nephrectomy has classically been considered a bloody surgical procedure. Neovascularization and additional collateral circulation to renal tumors can be extensive. In historical series, most patients required transfusions with the average amount reaching 2 L.[2] More modern series report an average blood loss of 300 mL and a transfusion rate of only 15%.[14] Hemorrhage during nephrectomy for neoplastic conditions is more likely compared with benign conditions.[15] Close attention to surgical technique may minimize complications associated with hypotension, anemia, and blood transfusion. Adequate venous access must be ensured preoperatively to allow rapid resuscitation and possible blood transfusion.

Preoperative Embolization

Preoperative embolization is an attractive option when tumor extent makes extensive vascularity probable (Fig. 37.3). Infarction of the entire kidney should theoretically reduce blood loss, although most studies have not found this to be the case.[16,17] Some surgeons believe that embolization

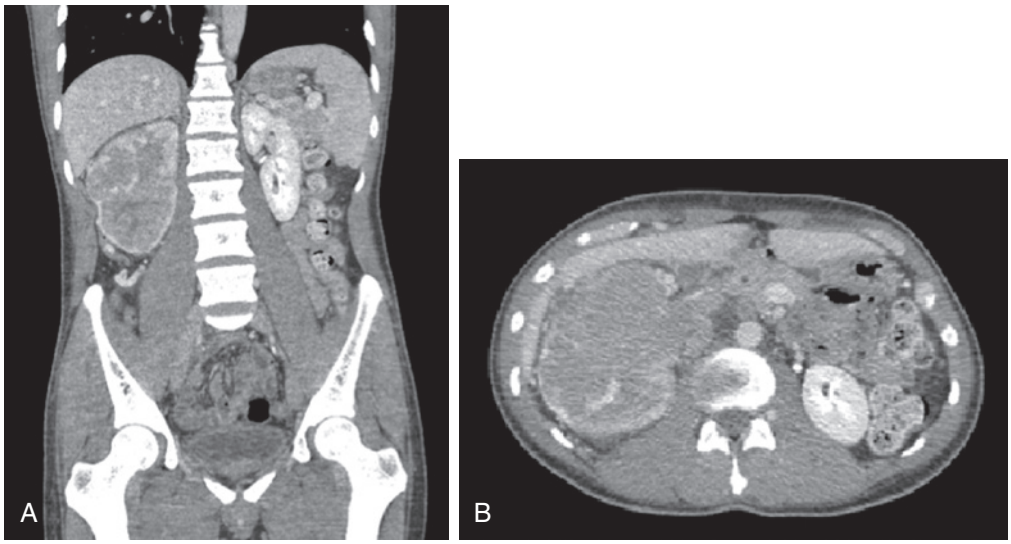

Figure 37.3 This 26-year-old man had a T3a tumor that was managed with preoperative embolization. A, Coronal view and B, Axial view.

may allow easier dissection of the kidney because it forms an edematous plane immediately surrounding the infarcted tissue. Arterial embolization also allows earlier ligation of the renal vein. In cases anticipated to have a difficult hilar dissection or anterior approaches, in which the anatomic access to the artery is more difficult, angioinfarction may be helpful. Examples include patients with large hilar tumors overlying the artery, bulky nodal disease encasing the artery, or bulky venous thrombus. Early ligation of the vein or mobilization of the kidney itself may allow better-visualized division of the renal artery.

In patients with tumor thrombus (discussed later), embolization may cause some regression in the extent of the thrombus.[18] More importantly, in the case of an occluded renal vein, it may allow early division of the collateral venous drainage that encircles the kidney in the perinephric fat. This technique may allow much easier surgical approach and dissection. Although it is not routinely necessary, preoperative embolization may assist in management of large, hypervascular tumors.

Common complications of embolization include the *embolization syndrome* consisting of nausea, vomiting, fever, and flank pain. Nephrectomy should be carried out ≤48 hours after embolization to minimize these symptoms. Another alternative is placement of a thoracic epidural catheter before embolization, a strategy we routinely employ. Embolization contributes to postoperative ileus. Thus, some degree of bowel preparation or a clear liquid diet preoperatively may by useful. More serious complications include acute renal failure, which may be exacerbated by accidental embolization of the contralateral kidney through reflux of the embolizing agent. Accidental embolization of other organs also occasionally occurs and causes serious complications such as heart failure and spinal cord injury. Occasionally, an associated tumor thrombus may embolize and may possibly cause sudden death.[19] The mortality rate for embolization with a variety of techniques has been reported to be ≤3.3% when embolization is used for palliation in inoperable cases.[20] However, the actual complication rate for preoperative embolization is probably lower.

It should be noted, however, that the use of embolization has never been demonstrated to provide benefit in a randomized controlled trial.[17,21] Subramanian and colleagues, in a retrospective review of 255 patients, actually found patients undergoing radical nephrectomy and inferior vena cava (IVC) thrombectomy who received preoperative angioembolization had a greater transfusion rate, longer operative time, more postoperative complications, longer intensive care unit stay, and increased perioperative mortality; no differences were found in intraoperative complications or length of hospitalization.[21] However, as noted, this was a retrospective study and, to date, no prospective study has been completed.

Vessel Dissection

Among the principles of radical nephrectomy, as originally described by Robson and colleagues,[2] are early control and ligation of the renal vasculature to prevent hematogenous tumor spread. Regardless of the incision used, the renal artery should be ligated first to prevent renal congestion. Careful dissection is necessary to confirm the identity of the renal artery. Depending on the approach, the celiac artery, superior mesenteric artery, contralateral renal artery, and lumber vessels may all be mistaken for the renal artery. If an injury occurs to one of these vessels, immediate recognition and primary repair will minimize subsequent complications. Consultation with a vascular surgeon, if available, is suggested. When approaching the renal artery, care should be taken to prevent avulsion of any branches listed earlier. Adrenal arterial branches are particularly prone to such injury. Although they are small, they may bleed profusely.

The renal artery may be clamped but left undivided if the anatomic features dictate it. Once the renal vein is ligated and divided, exposure to the renal artery may be improved. If the renal vein does not decrease in size after ligation of the renal artery, multiple renal arteries may be present.

The renal vein must be handled with care because a lumbar vein may drain posteriorly into it, especially on the left. The thinner walls of the vein make avulsion of these small veins a real possibility. The distal segment may retract

into the paraspinous muscles and render hemostasis difficult. Prevention of this complicating factor begins with recognition. Preoperative imaging may be helpful in some cases.[22] If lumbar veins are visualized, some incisional approaches with more limited visibility should be avoided. If avulsion of these veins occurs, compression of the bleeding site while completing removal of the kidney will improve exposure and thereby facilitate hemostasis. Figure-of-eight sutures in the paraspinous muscle to oversew the bleeding site are usually effective. A bolster of Surgicel (an oxidized cellulose hemostatic agent; Johnson & Johnson Wound Management, Somerville, NJ) placed under the figure-of-eight suture will assist in tamponade of the retracted vein.

Hematoma

Hematoma formation following radical nephrectomy may complicate the patient's postoperative course. In addition to the ability of the retroperitoneum to hold large amounts of fluid, the potential space left behind from bulky tumors allows significant bleeding without causing symptoms. The patient's hematocrit and blood pressure should be carefully followed, and one should realize that healthy individuals may lose up to 25% of their intravascular volume before significant symptoms occur. Even small hematomas may become infected and form abscesses. Verification of a dry surgical bed is an absolute necessity.

Drains are not routinely needed for nephrectomy. When significant intraoperative hypotension has occurred, some vessels may be in spasm, which may cause delayed postoperative bleeding. Placement of a closed drain for 24 to 48 hours postoperatively will permit early identification of bleeding.

INJURY TO NEARBY ORGANS

Spleen

Splenic injury is a well-known complication of intra-abdominal surgery, and left nephrectomy is the third leading cause of iatrogenic splenic injury.[9] Wide ranges of statistics are given (from 2% to 26%), but most modern series report splenic injury in approximately 1–5% of cases.[23,24]

Risk factors for splenic injury include prior abdominal surgical procedures, obesity, increasing age, large left kidney (i.e., polycystic kidney disease), and upper pole lesions.[25] Most case series show very different rates in donor nephrectomy–associated splenectomy and in splenectomy complicating radical left nephrectomy for neoplastic disease. Cooper and colleagues speculated that this discrepancy reflects the different goals of surgery.[25] Donor nephrectomies carry a risk of splenectomy of only 1–2%.[25,26] In addition, retroperitoneal approaches carry a much smaller risk of splenic injury.

Prevention of splenic injury begins with careful planning of the surgical approach and recognition of the importance of adequate exposure to the upper pole of the left kidney.[27] Splenic injuries occur in different ways. The most common cause is excessive traction on the splenic attachments that rips the splenic capsule. In addition, direct injury during dissection of large tumors may lacerate the splenic capsule, and retractors may damage the spleen if excessive force is placed on them or if countertraction is too great. In addition, direct injury during division of the diaphragm is a rare cause of injury from thoracoabdominal incisions.

Avoidance of splenic injury requires an understanding of the splenic attachments. The spleen is attached to all surrounding structures including the diaphragm, colon, stomach, and kidney (the lienophrenic, lienocolic, lienogastric, and lienorenal ligaments, respectively). The most superficial attachment, a lieno-omental band, was described by Lord and Gourevitch.[28] Early division of the inferior lienocolic and lienorenal attachments allows safe retraction of the spleen, although care should be taken to pad all retractors well and to avoid excessive pulling. Some investigators advocate coloepiploic mobilization or separation of the greater omentum off the colon from the midpoint of the transverse colon to the splenic flexure. Mejean and associates retrospectively demonstrated decreased rates of splenic complications ostensibly from increased splenic mobility as a result of early and more complete division of the colic attachments.[29] These investigators further suggested that the subcostal incision is superior to the midline incision for avoiding excessive traction on the splenic ligaments.[23]

Splenic injury is easily recognized by immediate bleeding from this highly vascular organ. Traditional treatment proceeded to immediate splenectomy. Increasing experience with splenorrhaphy from trauma surgery shows that significant numbers of spleens may be salvaged. Superficial lacerations may be treated with argon beam coagulation or hemostatic products such as Avitene (Davon, Cranston, RI) or Surgicel. Packing with laparotomy sponges to promote hemostasis followed by repeat examination is recommended. Deeper lacerations may require bolsters or splenic wrapping with mesh to tamponade the bleeding. Excessive intraoperative bleeding may be controlled by manual compression of the splenic vessels as they course near the tail of the pancreas until splenorrhaphy or splenectomy is completed.

Postoperative management of splenectomy includes vaccination for pneumococcal, *Haemophilus,* and meningococcal infections. Some investigators advocate preoperative vaccine administration to patients who are undergoing left nephrectomy and who have risk factors for splenectomy because the morbidity is minimal compared with the risk of postoperative vaccine administration.[25] Sepsis in splenectomized patients is much more serious than in immunocompetent persons, and the incidence is probably ≥10 times greater. Drains in splenectomized patients, if used, should be removed as quickly as possible to decrease the risk of overwhelming infection.[25]

Pancreas

Pancreatic injuries are rare compared with injuries of other nearby organs. Historical series in open kidney donor nephrectomies gave an incidence of <1%.[26] Pancreatic injuries may occur with right nephrectomy during performance of Kocher's maneuver to mobilize the second portion of the duodenum. However, most injuries occur secondary to the close proximity of the tail of the pancreas to the hilum of the left kidney. Retraction, avulsion of surrounding structures, and direct laceration may all injure the organ. Intraoperative bruising may also cause postoperative pancreatitis or asymptomatic elevation of amylase and lipase concentrations. Risk factors probably include prior operations, inflammation surrounding the kidney, larger lesions, or any other cause of difficult dissection.

Prevention of pancreatic injury includes development of the plane between Gerota's fascia and the visceral peritoneum during dissection of the superomedial pole of the left kidney. Identification, complete mobilization, and careful retraction of the pancreas will help to avoid any avulsion injuries.

Recognition of pancreatic lacerations requires immediate repair. It is important to inspect for injury to the pancreatic duct. If no injury is noted, simple repair of the pancreatic capsule with nonabsorbable suture and an omental bolster is all that is necessary. If the duct is involved, distal resection of the pancreas is probably preferable. General surgical consultation should be obtained if available. The distal pancreas is resected and the duct is closed. The capsule of the pancreas is then closed over the stump. In these cases, placement of a surgical drain is indicated.

Postoperative management of the patient who has undergone significant pancreatic manipulation includes monitoring of amylase and lipase levels, especially as the patient begins to eat. Any patients with significant injury to the pancreas require placement of a nasogastric tube. Parenteral alimentation should be considered early in the postoperative course. If clinical signs or symptoms of pancreatitis do not resolve, a CT scan should be performed. Fluid collections possibly representing a pancreatic leak, if found, require aspiration by interventional radiologic means. The fluid should be sent for measurement of amylase, lipase, pH, Gram stain, and culture. Infected liquid suggests the presence of necrotizing pancreatitis and requires emergency laparotomy for debridement and drainage. If the fluid is not infected, a percutaneous drain should be left and total bowel rest instituted. The addition of octreotide decreases pancreatic output and may be helpful in some cases. The starting dose is 50 μg subcutaneously three times daily, with titration up to 200 μg three times daily based on fistula output.[30]

Duodenum

Duodenal injuries most commonly occur during dissection anteromedial to the right kidney. The second part of the duodenum is most commonly involved. Far more uncommon is injury to the distal duodenum immediately adjacent to the ligament of Treitz. Such injuries occur on reflection of the left mesocolon medial to the inferior mesenteric vein where the mesocolon can be quite thin, or due to thermal injury or direct laceration.

Duodenal injuries are rather rare; in one series only a single injury to the duodenum occurred in 344 right nephrectomies.[23] Risk factors may include prior operations, inflammation surrounding the kidney, larger lesions, or any other cause of difficult dissection and adherence of the duodenum.

Prevention of duodenal injury includes careful dissection and the use of padded retractors. When necessary, Kocher's maneuver mobilizes the duodenum away from the operative field.

Careful inspection of the duodenum for lacerations and hematomas should be performed. Duodenal laceration should be closed with a two-layer technique and possibly reinforced with omentum or jejunum. If a duodenal hematoma is found, it should be opened and drained to prevent transient small bowel obstruction. The duodenum can then be repaired and covered with an omental bolster or jejunal tissue. If more extensive injury occurs, general surgical consultation should be considered. With standard preoperative prophylactic antibiotic coverage only for skin organisms, consideration should be given to adding gram-negative and anaerobic coverage, especially if no bowel preparation was used. Postoperatively, nasogastric suction should be maintained until intestinal peristalsis resumes.

Liver

Liver injury during nephrectomy in general is relatively rare. Many large case series list no liver lacerations. Causes of liver injury generally include forceful retraction during right nephrectomy. Preventive measures include adequate padding of retractors and division of the triangular and coronary ligaments if necessary to achieve adequate mobilization.

On recognition of a liver injury, or during intentional resection of liver extensions of the primary tumor, the liver laceration may be managed with Bovie or argon beam coagulation. For larger defects, Surgicel bolsters with horizontal mattress sutures of 2-0 silk or 1 chromic gut on a blunt-point needle may be more appropriate. If bleeding makes repair difficult, total obstruction of hepatic vascular inflow may be obtained by Pringle maneuver (Fig. 37.4). The hepatic artery and portal vein are isolated at the porta hepatis and are cross-clamped. Studies in liver donors indicated that significant ischemic injury does not take place with intermittent total occlusion from 10 minutes progressing to 30 minutes alternating with 5-minute reperfusion intervals.[31] If the extent of liver injury is judged to present a risk of postoperative bile leakage, drain placement is indicated.

If recognized and treated appropriately, iatrogenic liver injuries typically follow an uncomplicated course

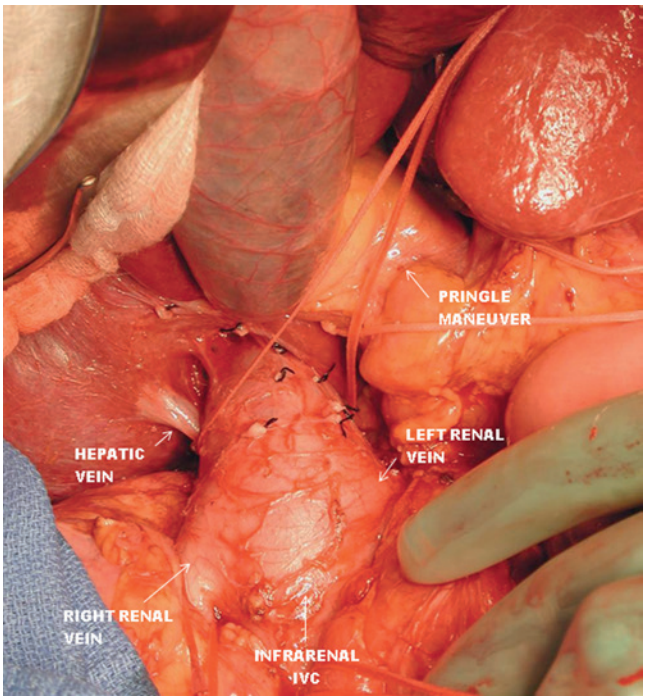

Figure 37.4 Photograph demonstrating technique for isolation of the porta hepatis for possible Pringle maneuver. In addition, umbilical tapes isolate the right renal vein and the inferior vena cava above and below the tumor.

postoperatively. If a significant bile leak develops, percutaneous drainage is indicated. Low-output fistulas typically close with conservative management, whereas high-output fistulas may require intervention with minimally invasive techniques.

Colon and Stomach

Injuries to the stomach, colon, and jejunum or ileum are very rare and are generally thermal injuries from accidental electrocautery arcs. Similar risk factors exist and probably include prior operations, inflammation surrounding the kidney, larger lesions, possibility of tumor extension into surrounding organs, or other causes of difficult dissection. Preventive measures include mechanical bowel preparation if the chance exists of tumor extension complicating resection or necessitating bowel resection. Closure of any hollow viscus is generally accomplished with a double-layer technique with possible omental bolstering. If unanticipated spillage of colonic contents occurs, extensive irrigation with sterile water, drain placement, and postoperative antibiotic prophylaxis for gram-negative and anaerobic organisms should be initiated.

Adrenal Glands

Radical nephrectomy as outlined by Robson and associates included adrenalectomy to maintain the integrity of Gerota's fascia.[2] Improvements in imaging have allowed improved preoperative assessment of tumor volume, extension, and adrenal involvement. In addition, significant stage migration resulting from increasing numbers of incidentally found tumors at early stages mandates reassessment of the practice of routine adrenalectomy. Studies of pathology specimens showed that the incidence of adrenal invasion is directly related to the stage of the primary lesion. Stage T1/2 lesions in general have a <2% chance of adrenal involvement if no adrenal abnormalities are seen on preoperative CT. Upper pole lesions, multifocal lesions, and radiologic stage T3/4 lesions have a much greater incidence (from 7.8% for T3 to 40% for T4).[32–35] In addition, up to one-third of patients with adrenal involvement show evidence of extensive nodal or metastatic disease.[36] However, most experts agree that adrenalectomy is indicated when there is either an abnormal radiographic appearance of the adrenal gland on preoperative imaging or concerning intraoperative findings.[37]

In light of the foregoing data, some surgeons perform adrenal-sparing radical nephrectomies in some patients to spare them from future adrenal insufficiency if metachronous contralateral disease develops that requires adrenal resection. In these patients, the chance for adrenal injury exists during renal mobilization. Usually, a well-defined plane separates the adrenal gland from the kidney. If this plane is not developed sufficiently, traction on the kidney may result in tears of the adrenal capsule, which may bleed profusely. Small injuries may be oversewn or treated with a vessel-sealing device. However, adrenal hemostasis using these methods is marginally successful and adrenalectomy is often the best solution. The vasculature of the adrenal gland, discussed earlier, is at particular risk of injury during nephrectomy, whether adrenalectomy is planned or not.

Diaphragm

Perforation of the diaphragm and parietal pleura with resulting pneumothorax is a possible complication of renal surgery regardless of the approach. The incidence probably rises with increasingly superior flank incision sites. Rates of iatrogenic pneumothorax through sub-12th rib flank incisions are negligible, whereas 11th interspace and 10th interspace incisions have a moderate risk. The overall risk of pneumothorax in modern series varies from 1% to 10%. In general, pneumothoraces requiring chest tube placement occur in approximately 1% of cases.[38–41]

Prevention involves careful attention to the anatomic features during dissection of the diaphragm off the costal attachments. For operations in which Gerota's fascia is opened, such as partial nephrectomy, this tissue can be used to buffer the upper aspect of the flank incision from the retractor. Many surgeons routinely obtain a postoperative chest radiograph to assess for pneumothorax requiring chest tube placement. Several studies examined the necessity for routine chest radiography postoperatively and concluded that it was unnecessary.[42,43] Although the incidence of pneumothorax from the variety of incisions discussed earlier is variable, this complication is usually recognized intraoperatively. The investigators found that only approximately 1% of patients undergoing nephrectomy had pneumothoraces of potential clinical significance that were missed intraoperatively. Many of these pneumothoraces resolved spontaneously with no negative consequences. The investigators concluded that routine chest radiography is unnecessary. Chest radiography should be obtained on the basis of intraoperative pleural injury or postoperative indications such as central line placement, symptoms, or physical examination findings.[42]

If a pleural injury is detected intraoperatively, it should be covered with a sponge to prevent entry of blood from the surgical field into the pleural cavity. At the end of the procedure, a 10 to 12Fr Robinson catheter can be passed through the pleurotomy to aspirate the air. A pursestring suture is placed around it. The distal end of the catheter is placed under water while the anesthetist hyperinflates the lung to 40 mm Hg. Attention should be paid to blood pressure because cardiac preload is decreased with lung hyperinflation. The catheter is then removed and the suture is tied to close the defect. If the pleurotomy is too large to close with this technique, chest tube placement is probably advisable. If no intrathoracic bleeding is noted, a smaller chest tube may be placed, or even a pigtail catheter can be inserted into the second intercostal space. Careful closure of the diaphragm with the sutures on the abdominal side of the repair facilitates pleural healing. Postoperatively, pneumothorax should be monitored with serial upright end-expiratory chest radiographs to verify resolution before the chest tube is removed.

Infection

Currently, infectious complication rates from nephrectomy excluding superficial wound infections are approximately 3–5%.[39] To minimize the risk of spreading infection, the urinary tract's normal sterile state must be verified preoperatively. Positive preoperative urine culture necessitates adequate antibiotic coverage for several days before the surgical procedure. Postoperative infections after any surgical procedure include wound infections, abscesses,

pneumonia, pyelonephritis, cholecystitis, and infections caused by antibiotic treatment such as *Clostridium difficile* colitis. Our discussion focuses on those infections that may be more specifically related to nephrectomy.

PNEUMONIA

Postoperative pneumonia is a common nosocomial infection to which patients undergoing nephrectomy may be especially prone. Radical nephrectomy for neoplastic disease is associated with a greater incidence of pneumonia compared with nephrectomy for benign conditions.[15] Some degree of atelectasis is nearly universal in patients undergoing general anesthesia, especially if the operation is performed with the patient in the flank position. The proximity of the incision site to the diaphragm and the division of accessory muscles of inspiration make deep breathing painful during the postoperative period. This situation perpetuates the stasis of fluid in the atelectatic lung segments, fluid that serves as an ideal culture medium for nosocomial pathogens. Major surgery may also suppress the immune system and thus increase susceptibility to infections.

Prevention of postoperative pneumonia includes preoperative evaluation of respiratory reserve and pulmonary status. Consultation with a pulmonologist is indicated if any doubt exists about the patient's status or if the patient has any history of obstructive, restrictive, or severe infectious pulmonary diseases. These risk factors should be addressed and minimized by adequate treatment preoperatively. Postoperatively, adequate pain control, incentive spirometry, and early ambulation are important for quickly decreasing atelectasis and the risk of pneumonia.

ABSCESS

Abscess formation is a rare complication of urologic surgery (1.7% in one series for renal cell carcinoma).[23] Risk factors are similar to those for wound infection, including preoperative urinary tract infection, entry into gastrointestinal organs, entry into kidney parenchyma or collecting system, and postoperative renal hemorrhage. In addition to avoidance of these risk factors, adequate irrigation, prophylactic antibiotics, and drain placement if indicated minimize the chance of abscess formation. In the presence of risk factors for infection, unexplained postoperative fever should prompt an abdominal CT search for an abscess. If an abscess is found, treatment involves percutaneous drainage by interventional radiologic means and empirical antibiotics. Antibiotic coverage is adjusted if necessary when culture and sensitivity results become available. With increasingly precise interventional radiology techniques, open debridement of abscesses is rarely necessary.

Special Populations

TUMOR THROMBUS

Renal cell carcinoma frequently involves vascular structures. Ten percent to 25% of tumors show thrombus.[44,45] Such vascular extension may manifest as lower extremity edema, varicocele, dilated superficial abdominal veins, proteinuria, pulmonary embolism, right atrial mass, or loss of function in the involved kidney. If a tumor thrombus is found, surgical preparation should include a magnetic resonance imaging (MRI) scan in addition to other preoperative imaging studies, to assess the proximal extent of the tumor thrombus (Fig. 37.5).[46–50] Preoperative MRI accurately measures the extent of tumor thrombus in approximately 98% of cases.[51] If an interval of ≥2 weeks exists between MRI and the surgical procedure, for level II and III thrombus, a follow-up study, such as ultrasound, transesophageal echocardiography, or repeat MRI, should be considered to ensure that significant thrombus propagation has not occurred. Invasive approaches, such as venacavography, are rarely indicated.

Figure 37.5 This 52-year-old man was found to have a tumor thrombus in each of his two right renal veins, each extending into the inferior vena cava separately. This MRI was obtained to confirm the proximal extent of tumor thrombus.

Fortunately, tumor thrombi do not necessarily indicate metastasis, and survival of patients after complete removal is better than in patients with primary tumor invasion into Gerota's fascia. Although some centers are describing minimally invasive techniques for management of lower level tumor thrombi, tumor thrombus remains one of the main indications for open surgical management.[52] In patients with level III or IV tumor thrombus, the importance of adequate preoperative assessment of the cardiopulmonary system should be emphasized in the presence of possible cardiopulmonary bypass.

An uncommon complication of tumor thrombus extension above the hepatic veins is Budd-Chiari syndrome or hepatic venous outflow obstruction. The classic acute presentation of Budd-Chiari syndrome consists of sudden-onset ascites, hepatomegaly, right upper quadrant pain, and elevated liver function test results. This syndrome is rarely seen in renal cell carcinoma–associated tumor thrombus formation, in which a more gradual onset of similar symptoms is typical.[53] Treatment involves an expeditious surgical

procedure to relieve hepatic vein obstruction and thereby spare liver parenchyma if possible. In spite of surgical intervention, severe symptoms usually indicate irreversible liver injury and the onset of hepatic failure. The largest series of patients with renal tumor thrombus–induced Budd-Chiari syndrome showed no survival for >6 weeks in seven patients with severe cases. The outcome of five patients with mild cases was probably similar to that in patients with equivalent renal disease without Budd-Chiari syndrome.[53] Surgeons should carefully consider patient selection for surgery in the presence of Budd-Chiari syndrome in light of probable poor outcomes.

Surgical technique for vena cava thrombectomy has undergone many changes. Because all investigators agree that the proximal level of tumor thrombus dictates the surgical approach, accurate assessment with preoperative imaging is important. At least six systems to categorize thrombi have been proposed.[54,55] Probably the most widely used is the Mayo Foundation (Rochester, MN) classification, which divides thrombi into four groups based on their relationship to the renal vein ostia, hepatic veins, and diaphragm.[56] Various surgical approaches have been advocated for every level.

Basic principles guiding the choice of surgical approach are as follows:

1. Adequate exposure of the primary lesion
2. Adequate exposure to the vena cava
3. Exposure of the contralateral renal vein
4. Ability to mobilize the liver
5. Ability to extend incision if necessary to include the chest
6. Complete control of vena cava above and below the thrombus to avoid pulmonary embolism
7. Avoidance of cardiopulmonary bypass if possible
8. Protection of natural venovenous shunt pathways.

The inferior vena cava above and below the thrombus, both renal veins, and the portal vein should be isolated with umbilical tape and Rummel tourniquets (see Fig. 37.5). Lumbar veins that will be draining into the opened area of the inferior vena cava are best ligated beforehand. The sequence of vascular control of the IVC prior to thrombectomy should be the IVC below thrombus, the contralateral renal vein and lumbar veins, and, finally, the IVC above the thrombus (demonstrated in Video 1). If an unrecognized lumbar vein is bleeding into the open vena cava to a significant extent, it can be occluded either posterior to the vena cava with a sponge stick or within the vena cava with a Kittner device. The Rummel tourniquets can be tightened to occlude the major veins. Alternatively, Satinsky and vascular clamps can be used. Although some vascular surgeons prefer not to use clamps on the vena cava, we have not encountered problems with this method.

Ligation of the short hepatic veins permits increased hepatic mobilization and isolation of an additional 4 cm of infrahepatic vena cava. This technique facilitates infrahepatic vena cava control as well as rotation of the liver to the left side of the inferior vena cava and thus gives excellent exposure to the right adrenal gland and retrohepatic inferior vena cava (Fig. 37.6).

When the tumor thrombus extends into the right atrium, opening the chest cavity is often necessary. This procedure

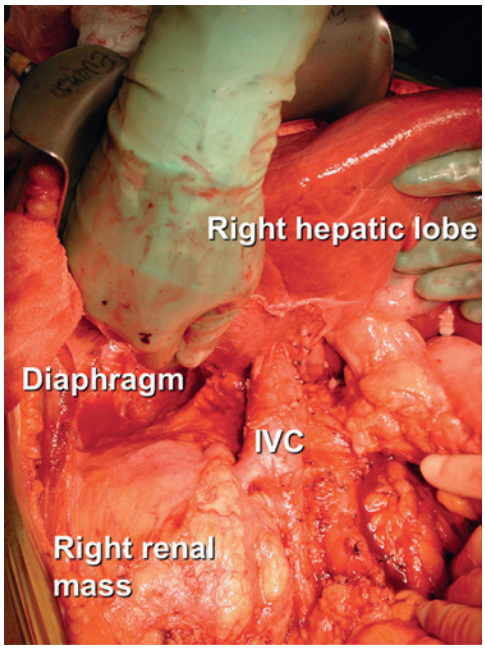

Figure 37.6 Photograph of liver rotated to the left to allow exposure of the retrohepatic vena cava. Note the ligated hepatic veins. IVC, inferior vena cava.

may be accomplished by midline sternotomy, thoracoabdominal incision, or xiphisternal extension of a chevron incision. A second small parasternal incision has also been described to access the thoracic cavity. The extent of tumor thrombus and whether or not it invades significant portions of the vena cava or right atrium dictate the operative time needed for complete excision. This time, in turn, dictates the need for venovenous bypass or hypothermia, cardiac arrest, and exsanguination.[54] Several groups have developed excision techniques for increasingly proximal levels of thrombi without cardiopulmonary bypass through transabdominal approaches.[57] Regardless of the approach, the complication most to be avoided is fragmentation of the thrombus leading to pulmonary embolism.

Verifying complete thrombus removal before reestablishing venous flow is critical. Various methods for removing remnant clot have been described, including manual "milking down" of the thrombus, placement of a Foley catheter past the thrombus followed by inflation and removal, and direct visual techniques employing flexible cystoscopes.[58]

Some complications of nephrectomy with thrombus removal are secondary to inadequate reconstruction of the inferior vena cava. Decreased cardiac preload may cause heart failure in some individuals with limited reserve. Decreased renal drainage of the contralateral kidney may cause acute renal insufficiency requiring dialysis. This condition may be reversible with the development of venous collateral vessels. It is always advisable to perform reconstruction of the inferior vena cava with graft material if inadequate vein remains following resection of adherent tumor thrombus. If the chest cavity is open, defatted pericardium may be used as autologous graft material (Fig. 37.7).

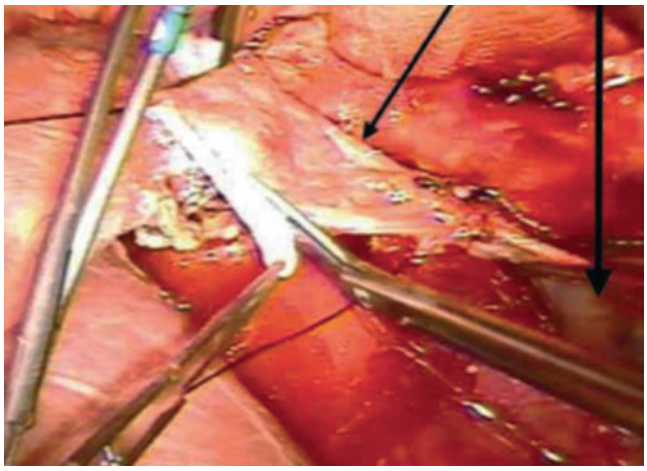

Figure 37.7 Reconstruction of the inferior vena cava with defatted pericardium. The thin arrow indicates the medial border of the graft sewn to the vena cava. The thick arrow indicates the vena cava inferior to graft.

Cardiopulmonary bypass may be associated with small increases in morbidity Most morbidity related to the bypass itself is from two different mechanisms. First, cardiopulmonary bypass results in a systemic inflammatory response through multiple biochemical mechanisms. These mechanisms are generally brought about by contact of the blood with the extracorporeal gaseous interface and biocompatible surfaces of the cardiopulmonary bypass machine. The inflammatory mediators (complement, cytokines) activate leukocytes, vascular endothelial cells, and platelets and generate a systemic response that damages organs.[59] Second, cardiopulmonary bypass generates multiple small emboli from lipoprotein aggregates, gaseous emboli, and other particulate matter. These affect end-organ capillary beds, particularly in the heart, brain, lungs, and kidneys. Healthy individuals with adequate reserve usually have no problems, but patients with significant comorbidities of any of these organs may be significantly affected.[59] Ongoing research is focused on overcoming these difficulties.

Other postoperative complications of cardiopulmonary bypass are usually manageable. Bleeding from heparinization and inadequate reversal with protamine may be extensive. Patients may also experience continuing temperature dysregulation following bypass. In addition to complications of cardiopulmonary bypass, hypothermic circulatory arrest leads to ischemic damage to body structures, some of which may be irreversible. Neural tissue is especially susceptible to such injury, and temporary neurologic dysfunction, stroke, and death may result. These complications are generally rare in radical nephrectomy.[60] Prevention includes shortening operative time to decrease the risk of ischemia. Despite these added risks, hypothermic circulatory arrest may decrease the risk of warm ischemia to the liver and contralateral kidney. Increased visualization and operative time may reduce the risk of tumor thrombus embolization.[60]

A recent large multicenter international analysis reported the use of cardiopulmonary bypass in level III–IV tumor thrombectomy cases did not significantly impact cancer specific survival or overall survival.[61]

CYTOREDUCTIVE NEPHRECTOMY

Two prospective studies from the Southwest Oncology Group and the European Organisation for Research and Treatment of Cancer demonstrated a modest survival advantage for cytoreductive nephrectomy before immunotherapy.[62,63] Morbidity from the renal neoplasm itself, such as pain and hematuria, may require palliative nephrectomy even in patients with extensive metastatic disease. However, in patients with lower performance status, it is advisable to attempt more conservative measures such as improved pain control and renal angioinfarction.

One article compared morbidity and mortality of cytoreductive nephrectomy in patients with tumor thrombus with radical nephrectomy in patients who did not have metastatic disease. Zisman and colleagues[29] found no increase in complications of surgery compared with patients undergoing similar radical nephrectomies without metastatic disease.

LOCALLY RECURRENT DISEASE

Clinical series have reported an incidence of isolated local disease recurrence in the absence of other metastatic disease of <2%.[64–66] Any T stage primary tumor may be affected. It is controversial whether local recurrence represents remnant disease from positive margins, residual lymph node disease, recurrence in residual adrenal gland, or a form of metastasis.[67,68] Positive margin status during open nephrectomy should be rare in the absence of grossly evident disease. Careful dissection with the avoidance of tumor spillage should minimize this possible risk factor. Obviously, patients with positive margin status and patients with gross tumor spillage in the incision require close follow-up because surgical extirpation is the only efficacious treatment available for renal cancer.

In patients with no evidence of metastatic disease in whom resection of local disease recurrence is complete, long-term survival may be achieved at a rate of up to 40%.[64,69] Some investigators have suggested adjuvant immunotherapy in these patients to enhance outcomes.[2] Longer recurrence-free intervals may correlate with improved survival after repeat resection.[36,44]

Complications of repeat resection may be significant. Wide resection of the possible neoplastic recurrence may require en bloc resection of adjacent organs and may thus increase the risk of complications, infection, and perioperative mortality. While older series showed several mortalities,[70,71] more recent series showed a complication rate of 13–45%.[64,68,72,73] Because of the significant complication rate and the small chance of a survival benefit in patients with local recurrence and metastatic disease, these patients should be considered carefully for repeat resection.[74] No efficacy was shown for any adjuvant or adjunctive therapies, including chemotherapy, immunotherapy, external beam radiation therapy, or intraoperative radiation therapy.[68] As systemic therapy for renal neoplasms develops, recommendations regarding proper treatment of metastatic disease will undoubtedly undergo significant change.

DONOR NEPHRECTOMY

The ethical issues surrounding living donor nephrectomy depend in part on the actual morbidity and mortality of the

operation. At this time, most living donor nephrectomies in the United States are performed with minimally invasive techniques. In some other countries, miniaturization of the incision is practiced. Because the operation carries no direct medical benefit to the patient, optimization of outcomes is imperative. Investigators have estimated that the perioperative mortality rate is approximately 0.03% and that rate of major complications of donor nephrectomy is approximately 1–4%.[5,75–77] These rates, much lower than in nephrectomy performed for renal cancer, reflect the elective nature of the procedure, the extensive preoperative workup, and the ability to abandon the operation or resect the contralateral kidney.

Postoperatively, contralateral renal hypertrophy maintains the glomerular filtration rate between two-thirds and three-fourths that of preoperative levels. Long-term sequelae of donor nephrectomy include increased blood pressure, especially systolic, although most patients have blood pressure remaining in the normal range or easily managed mild hypertension. Rates of hypertension in kidney donors mirror national rates, but this finding may reflect selection bias favoring healthy donors. In addition, proteinuria compared with preoperative values develops in 13–22% of patients.[5,78] To our knowledge, no studies have shown any clinically significant effects from these complications of donor nephrectomy.[78–80]

The surgical technique for open donor nephrectomy is similar to that for simple nephrectomy. Different centers use a variety of incisions for the approach. Extraperitoneal approaches may minimize the risk of subsequent adhesions and possible small bowel obstruction requiring reoperation. Rates of small bowel obstruction were ≤2% in older series.[26] However, meticulous dissection of the renal pedicle with sparing of all renal vessels may be easier through an anterior transperitoneal incision, particularly if any aberrant vessels exist. Care must be taken when dissecting the ureter to avoid damaging the collateral vessels from the renal hilum to the proximal ureter. These vessels maintain blood supply in the transplanted organ, and damage to them may cause ureteral necrosis. Complete mobilization of the kidney is performed before the renal vessels are clamped, to minimize warm ischemia time. In the transplanted kidney, application of papaverine may be indicated to avoid possible renal artery spasm.

ELDERLY PATIENTS

Definitions of *elderly* have been changing as the population ages. Case series have moved from 60–65 years as age cutoffs to 70–75 years. Historically, elderly patients were thought to benefit very little from surgical extirpation of neoplasms because the morbidity and mortality associated with surgery were thought to exceed the benefit possible over the remaining life span. These concepts have changed significantly for many neoplasms including renal cancer. Studies have shown no significantly higher rates of morbidity and mortality for nephrectomy in elderly patients.[81] Indeed, most of the increased problems are probably the result of the greater number and incidence of comorbidities commonly associated with increasing age. These comorbidities can usually be managed preoperatively to optimize outcomes.[74,82]

Perioperative strategies to decrease complication rates include minimizing of operative time, earlier consideration of blood transfusions, and possible gastric tube placement to decrease pneumonia rates. Extraperitoneal approaches may decrease ileus and allow an earlier return to a normal diet, a factor that may be more important in elderly patients. Postoperative intensive care for 24–48 hours may allow earlier recognition of possible complications.

TRANSITIONAL CELL CARCINOMA

The current treatment standard for most cases of upper urinary tract transitional cell carcinoma is nephroureterectomy with a cuff of bladder. Low-grade, low-stage lesions may be managed more conservatively.[33] Increasing numbers of nephroureterectomies are performed laparoscopically in some centers. However, open nephroureterectomy still offers unparalleled exposure for difficult cases. It may be performed through many different incisions. Single incisions include midline or a combination of midline and subcostal. Alternatively, two incisions may be used such as a flank or subcostal combined incision with a Gibson or lower midline incision for distal ureteral dissection. In some cases, the distal ureter may be resected endoscopically or laparoscopically. Ideally, en bloc resection of the whole specimen is accomplished, although some institutions divide the ureter to make subsequent resection easier. Surgical dissection of the kidney is identical to that performed in radical nephrectomy. The adrenal gland may be spared in most cases. The cuff of bladder should be resected because this technique decreased the disease recurrence rate in one study.[22]

Complications of nephroureterectomy are similar to those of radical nephrectomy. Other complications associated with cystotomies such as urinoma or fistula formation are rare. In addition, the contralateral ureteral orifice may be damaged by the dissection of bladder cuff. This complication may result in anuria secondary to obstruction of the remaining ureter at the ureteral orifice. Gentle dissection prevents this complication. Management includes retrograde stent placement if possible or nephrostomy if stent placement fails.

Chapter 37 Questions

1. During flank approach for nephrectomy, what step predisposes for flank sag/laxity?
   a. Resection of the 11th rib
   b. Incision in the 10th interspace
   c. Injury to the neurovascular bundle
   d. Too much flexion in the bed during positioning
   e. None of the above

2. Benefits of preoperative embolization include which of the following?
   a. Allows for earlier ligation of the renal vein
   b. Causes regression of tumor thrombus
   c. Easier dissection of the kidney due to formation of edematous plane
   d. All of the above
   e. None of the above, as no studies have demonstrated clear benefit

3. A 68-year-old man with a 15-cm right renal mass and associated level III tumor thrombus undergoes an open radical nephrectomy and tumor thrombectomy via a thoracoabdominal approach. There are no significant complications during the procedure, and while cardiopulmonary bypass is not required, operative time approaches 6 hours. Postoperatively, the patient is observed in the intensive care unit. A few hours postoperatively, the nurse calls noting slightly decreased urine output (~20–30 mL/hr); the patient also complains of left flank pain. On evaluation, he is hemodynamically stable, has some slight bruising of the left flank, and has tea-colored urine. What lab tests can be ordered to assist in diagnosis?
   a. Serum creatinine
   b. Urinalysis and urine microscopy
   c. Serum creatinine kinase levels
   d. Serum amylase and lipase
   e. b and c

4. In the above patient, what is the treatment of choice?
   a. IV hydration with urine output goal ~300 mL/hr
   b. Diuresis with loop diuretic
   c. Acidify the urine
   d. Immediate hemodialysis
   e. None of the above

5. During mobilization of the inferior vena cava in preparation for cavotomy for tumor thrombectomy, lumbar veins must be identified and controlled. If lumbar veins are to be ligated, it is more important to secure which side of the vein?
   a. The inferior vena cava (IVC) side since IVC bleeding will be difficulty to identify and control
   b. The distal aspect since these veins retract into the paraspinous muscle
   c. Both sides ideally, but if one side was preferred, then the inferior vena cava (IVC) side only since IVC bleeding will be difficulty to identify and control
   d. Both sides ideally, but if one side was preferred, then the distal aspect since these veins retract into the paraspinous muscle
   e. None of the above

6. The most common mechanism of splenic injury during open radical nephrectomy is which of the following?
   a. Direct injury during sharp dissection of the left kidney superior pole
   b. Direct injury to the splenic vessels
   c. Traction injury during retraction of the abdominal wall
   d. Direct injury to a previously unrecognized splenule
   e. None of the above

7. Though rare, if pancreatic injury is suspected and identified intraoperatively, which of the following steps should be taken?
   a. General surgery consultation
   b. Evaluation for pancreatic ductal injury
   c. Intraoperative serum amylase/lipase levels
   d. Abort procedure immediately
   e. a and b

8. The best imaging modality to assess for pneumothorax following open radical nephrectomy is:
   a. End-inspiratory lateral chest x-ray
   b. End-expiratory lateral chest x-ray
   c. End-inspiratory upright chest x-ray
   d. End-expiratory upright chest x-ray
   e. CT chest

9. If significant bleeding from the liver is encountered, hemostasis may be achieved through the Pringle maneuver. Which of the following structures is compressed during this maneuver?
   a. Hepatoduodenal ligament
   b. Hepatic artery proper
   c. Portal vein
   d. Common bile duct
   e. All of the above

10. Common symptoms of postembolization syndrome include which of the following?
    a. Nausea/emesis
    b. Flank pain
    c. Fevers/chills
    d. Epigastric pain
    e. a, b, and c

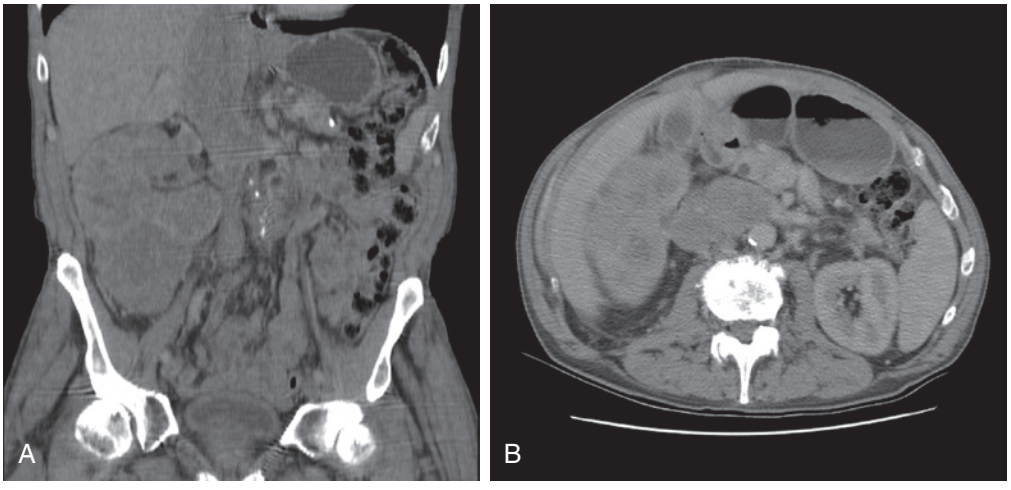
Case Studies

CASE 1

A 60-year-old man presents to your office for evaluation. He has been on hemodialysis for 5 years due to chronic kidney disease (stage V) initially thought to be due to hypertension and diabetes. However, during a recent ER visit for recurrent abdominal pain, he had a noncontrast CT scan completed (Case Fig. 37.1). He continues to have abdominal pain, early satiety, and decreased appetite.

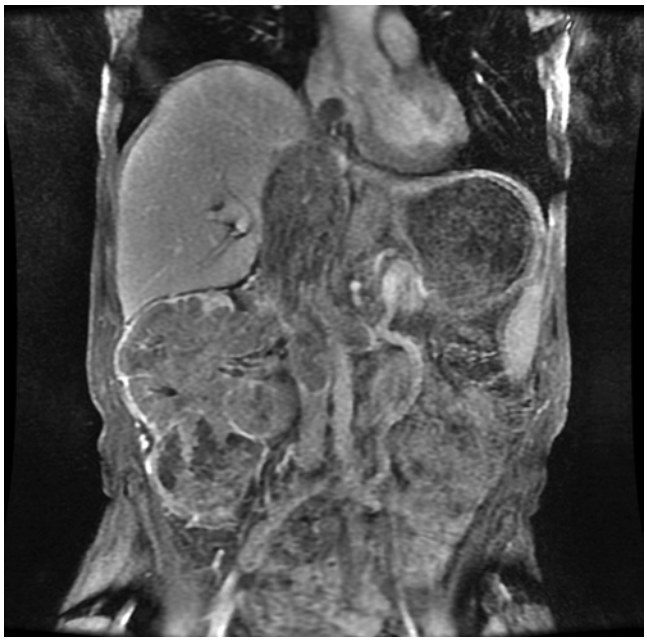
1. What is the diagnosis based on CT imaging and clinical history?
   a. Bilateral renal masses concerning for renal cell carcinoma
   b. Bilateral multicystic dysplastic kidneys
   c. Bilateral ureteropelvic junction obstruction
   d. Adult polycystic kidney disease (APCKD)
   e. Bilateral parapelvic cysts

2. Based on the above diagnosis, you offer to proceed with bilateral nephrectomy for symptom management. What is the best approach?
   a. Thoracoabdominal incision
   b. Bilateral subcostal incisions
   c. Midline abdominal incision
   d. Bilateral lumbodorsal incisions
   e. Chevron incision



Case Figure 37.1

3. During mobilization of the left polycystic kidney, you notice significant bleeding from the left upper quadrant. Closer examination reveals traction injury to the spleen, limited to a superficial laceration. What is the next acceptable step in management of this superficial laceration?
   a. Suture the laceration with a 3-0 absorbable suture
   b. Immediate splenectomy
   c. Argon bean coagulation
   d. Placement of hemostatic product (Avitene, Surgicel) on the site
   e. c, d, and packing, with serial examinations throughout the case



4. Patient does well postoperatively initially. However, he has slow return of bowel function and is managed conservatively for an ileus. On postoperative day six, he begins to develop fevers, subjective chills, worsening nausea, and increasing abdominal distention. CT abdomen/pelvis with contrast (coordinated with hemodialysis) is obtained – a 5-cm × 3-cm abscess of the left renal fossa is identified. What is the next step in management?
   a. Continue conservative management, this will resolve spontaneously
   b. Open exploration and drainage
   c. Consult interventional radiology for drain placement
   d. Blood cultures, broad-spectrum antibiotics
   e. c and d

CASE 2

A 55-year-old man, otherwise healthy, was seen by his primary care physician for a single episode of painless gross hematuria. She orders a tri-phasic CT and refers him to see you. Cystoscopy in the clinic is normal – no masses, stones, or other pathology identified. CT scan is still pending, so you tell the patient you will call him with results once it is completed. One week later, CT scan is completed and images are below (Case Fig. 37.2).

Case Figure 37.2

Case Figure 37.3

1. What is your next step?
   a. Bring patient back for discussion of imaging results
   b. Obtain chest imaging (chest x-ray)
   c. Obtain labwork (complete blood count, serum chemistries, liver function panel, INR/APTT)
   d. All of the above
   e. None of the above, let the primary care physician manage the patient

2. After seeing the above results (chest x-ray without evidence of disease, labwork otherwise normal), you meet with the patient and discuss plans to proceed with nephrectomy and IVC thrombectomy. You schedule him for surgery in 3 weeks. You want to reassess the thrombus prior to surgery–what is the best imaging modality to do so?
   a. Repeat CT abdomen with IV contrast
   b. Color Doppler ultrasound of the IVC
   c. Venacavography with interventional radiology
   d. MRI abdomen with contrast
   e. Transthoracic Echocardiogram

3. The MRI is completed a few days prior to the planned operation. Images are below (Case Fig. 37.3). You pre-admit the patient for angioembolization the day prior to surgery. On the day of surgery, what imaging modality is important to have available if there is concern for extent of the thrombus to the atrium?
   a. Intraoperative Doppler ultrasound
   b. C-arm and fluoroscopy
   c. Cardiac anesthesia and transesophageal echocardiogram (TEE)
   d. Portable CT scanner
   e. MRI scanner

4. You make a chevron incision for optimal exposure to the thrombus and hilum. The right colon is mobilized. In order to best access the suprahepatic IVC, what maneuver can be done?
   a. Pringle maneuver
   b. Hepatic mobilization and flip the right lobe into the left upper quadrant
   c. TEE
   d. Ligation of short hepatic veins to acquire more distance up the IVC
   e. a and c

5. Following removal of the kidney and tumor thrombus, you begin closure of the IVC. At the level of the renal ostium, the IVC appears to be significantly narrowed >50% when reapproximated. What is the next step in management?
   a. Close the IVC as it is–collaterals will develop over time without long-term consequences
   b. Utilize a graft to reconstruct the IVC to prevent narrowing
   c. Place a vascular stent prior to closure of the IVC to prevent thrombosis
   d. Ligate the IVC above and below the narrowed segment
   e. Utilize a portion of the renal vein to reconstruct the IVC

Answers

1. **c.** Up to 23% of patients have a flank sag postoperatively as a result of injury to intercostal nerves that causes laxity of flank muscles at that level.
2. **e.** While surgeons have completed angioembolization prior to nephrectomy based on anecdotal evidence, there have been no studies that have demonstrated clear benefit to pre-operative angioembolization.
3. **e.** This patient is demonstrating classic manifestations of rhabdomyolysis. After a long operation (6 hours) in a compromising position, tea-colored urine, acute kidney injury (decreased urine output), and bruising should all increase threshold for suspicion. Good diagnostic tests include urinalysis and urine microscopy (microscopic hematuria but without red blood cells in urine microscopy) and serum creatinine kinase levels (elevated).
4. **a.** The treatment of choice for patients with rhabdomyolysis is intravenous hydration with urine output goal ~300 mL/hr.
5. **d.** While it is always important to secure both sides of a lumbar vein, if only one side can be secured, then the distal aspect is preferred, as since these veins retract into the paraspinous muscle after ligation, which makes hemostatic control difficult.
6. **c.** The most common cause of splenic injury is excessive traction on the splenic attachments that rips the splenic capsule.
7. **e.** Recognition of pancreatic lacerations requires immediate repair. It is important to inspect for injury to the pancreatic duct, as duct involvement may indicate need for distal resectionof the pancreas. General surgical consultation should be obtained if available, as pancreatic leaks can be significant complications postoperatively. The capsule of the pancreas is then closed over the stump. In these cases, placement of a surgical drain is indicated.

8. **d.** The best instructions to provide for the x-ray technician to evaluate for pneumothorax postoperatively is to obtain am end-expiratory upright chest x-ray.
9. **e.** The Pringle maneuver allows for total obstruction of hepatic vascular inflow. The maneuver involves compression of the all the listed structures as one packet.
10. **e.** A common complication of embolization includes the embolization syndrome, which consists of nausea, vomiting, fever, and flank pain. Nephrectomy should be carried out ≤48 hours after embolization to minimize these symptoms.

CASE 1

1. **d.** The radiographic images are most consistent with adult polycystic kidney disease (APKD). Specifically, the numerous cortical cysts throughout both kidneys make this the most likely diagnosis.
2. **c.** A midline allows easy access to the renal pedicle and major vessels. However, in this specific situation, a bilateral nephrectomy for APKD, a midline approach is also important because it allows extension of the incision in order to access the low abdomen and pelvis in patients with large polycystic kidneys.
3. **e.** Superficial lacerations of the spleen can be managed conservatively. Argon bean coagulation and placement of hemostatic product (Avitene, Surgicel) on the site are recommended. Re-assessment throughout the case can ensure resolution of the bleeding.
4. **e.** As is the case for most postoperative abscesses, the management of choice is drainage (typically with the assistance of Interventional Radiology) as well as systemic therapy with antibiotics if fevers are present. Blood cultures are important to help tailor initial broad-spectrum antibiotic choices.

CASE 2

1. **d.** The CT scan work-up has revealed a large right renal mass with a large tumor thrombus. This patient will need urgent evaluation and be scheduled for surgery. As such, work-up for surgery can be obtained prior to the patient returning (pre-operative labwork), as well as additional staging studies (chest x-ray).
2. **d.** An MRI with contrast is the recommended study of choice for a patient with a tumor thrombus, as it accurately measures the extent of tumor thrombus in approximately 98% of cases. It is important for surgical planning.
3. **c.** Cardiac anesthesia and transesophageal echocardiogram (TEE) should be utilized for patients with Level IV thrombus to monitor thrombus intra-operatively and to provide information regarding the extent of the thrombus.
4. **b.** Access to the suprahepatic IVC can be obtained by mobilizing the liver and flipping the right lobe into the left upper quadrant. Specifically, ligation of the short hepatic veins permits increased hepatic mobilization, which allows rotation of the liver to the left side of the inferior vena cava and thus gives excellent exposure to the right adrenal gland and retrohepatic inferior vena cava.
5. **b.** Inadequate reconstruction of the inferior vena cava may lead to decreased cardiac preload and heart failure, decreased renal drainage of the contralateral kidney and acute renal insufficiency requiring dialysis, or formation of thrombi. It is always advisable to perform reconstruction of the inferior vena cava with graft material if inadequate vein remains following resection of adherent tumor thrombus. If the chest cavity is open, defatted pericardium may be used as autologous graft material.

Chapter 38 Questions and Answers

KEY POINTS

1. Knowledge of renal arterial anatomy is essential for performing partial nephrectomy.
2. Complication rates with both open and laparoscopic partial nephrectomy vary with operator experience, but both can be acceptable with careful attention to detail.
3. The risk of bleeding and urine leak should be balanced against the risk of renal dysfunction from prolonged arterial clamping.
4. Renal incision should be planned by ultrasound study according to arterial anatomy and should be started away from the hilum to minimize the risk of infarct.
5. Identification and direct suture ligature of retracted blood vessels within the line of incision avoid retracted sutures deep in the incision bed.
6. At the time of urine leak, the drain should be positioned to remove any extrarenal urine collections completely. A stent is rarely required unless ureteral obstruction is present.

Since first reports in 1869–1870 by Simon[1] and in 1887 by Czerny,[2] partial nephrectomy has been used to manage many different urologic diseases. The major application of partial nephrectomy since the early 1990s has been as an alternative to radical nephrectomy in the treatment of small renal tumors.[3–22] Several organizations now endorse partial nephrectomy as the standard treatment of small renal masses (cT1a, <4 cm) in those patients whose tumor is amenable to this approach.[23,24] This technique has proven to be oncologically safe for early tumors confined to the kidney. More recent efforts have been made to duplicate open partial nephrectomy techniques in minimally invasive tumor resection and thereby shorten recovery time and reduce postoperative morbidity. The significant downward stage migration of renal tumors resulting from increase in the incidental diagnosis has prompted investigators to expand indications and increase the use of partial nephrectomy.[25–27] Despite this change, the use of the partial nephrectomy remains low nationally, even for small renal tumors, which is likely a reflection of the perception of increased morbidity relative to radical nephrectomy.

Preoperative Considerations

The absolute indications for partial nephrectomy include tumor in a solitary renal moiety, bilateral renal tumors, or preexisting azotemia that would preclude the ability to perform nephrectomy without requiring that the patient undergo dialysis. Despite these indications, in selected patients of this type, nephrectomy followed by dialysis may be indicated for maximal oncologic efficacy. Relative indications include medical illnesses predisposing to renal disease, preexisting medical renal disease, renal stones, recurrent renal infection, mild azotemia, and multifocal tumors associated with a genetic syndrome. *Elective partial nephrectomy* is defined as that in which the patient has none of the foregoing risk factors, normal renal function, and a radiologically normal contralateral renal moiety. Studies have suggested a greater overall reduction in glomerular filtration rate (GFR) in patients undergoing radical nephrectomy as compared with partial nephrectomy (discussed later).[28] Because this finding may correlate with a higher likelihood of morbidity and mortality not related to oncologic factors,

the impetus for consideration of elective partial nephrectomy may be greater in the future.

In considering patients for partial nephrectomy, host factors to be considered include overall health and the ability to tolerate surgery, the presence of comorbidities predisposing to renal disease, bleeding diathesis or a need for anticoagulation, and baseline renal function. Although the need for perioperative anticoagulation does not preclude partial nephrectomy, it certainly does increase the risk of postoperative bleeding, and as such it may be a reason for considering nephrectomy in an otherwise fragile patient. Renal anatomic variants including duplication, anomalous location, and anomalous vasculature are important to be aware of in operative planning, but they do not preclude partial nephrectomy. Previous renal surgery for any indication must be evaluated carefully to ensure that partial nephrectomy will be feasible. Finally, body habitus may influence the operative approach and the decision for surgical intervention.

Retrospective studies demonstrated that patients undergoing partial nephrectomy have better long-term renal function than do patients undergoing radical nephrectomy.[2–31] Investigators have previously demonstrated that the likelihood of having a GFR >45 mL/minute or >60 mL/minute was greater among patients having a partial nephrectomy.[28] The inherent implication of these findings is that individuals undergoing partial nephrectomy may indirectly reduce their risk of nononcologic morbidity and mortality as a result of preserved renal function. A significant positive correlation exists between reduced GFR and cardiovascular mortality or other medical illnesses. Some investigators have suggested that the risk of cardiovascular or nononcologic mortality is greater among patients undergoing radical nephrectomy as compared with partial nephrectomy.[18,19,32] Whether this finding is ultimately related to selection bias remains to be determined in prospective evaluation. Nonetheless, the findings are provocative in suggesting that elective partial nephrectomy should be considered in most patients in whom the procedure is technically feasible, and broadening of the indications may be of value.

Consideration of the tumor is essential in selecting candidates for partial nephrectomy and in planning the surgical procedure. Tumor size and location should be considered within the framework of the surgeon's technical experience and comfort level when deciding whether partial nephrectomy is appropriate. In these tumors, an ample margin can be obtained with limited concern of damaging the remaining renal blood supply. Historically, elective partial nephrectomy was considered appropriate for exophytic tumors <4 cm. In retrospective evaluation of early series, central tumors and larger tumors had worse oncologic outcomes. Admittedly, the majority of patients in those categories may not have had elective indications for partial nephrectomy. As surgeons have become comfortable with the technique, indications for elective partial nephrectomy have been expanded to include central tumors, and those in the T1b (4–7 cm) category. Thus far, no apparent decline in cancer control has been reported among those series.[4]

Operative Planning

Operative planning of partial nephrectomy requires rigorous understanding of arterial anatomy and the relationship of blood supply and collecting system (Fig. 38.1). This knowledge allows planning of the necessity for renal ischemia, the line of resection for margin control, and the likelihood of necessary venous and collecting system repair. Several groups demonstrated the utility of preoperative three-dimensional image reconstruction using computed tomography (CT) or magnetic resonance imaging (MRI).[33] These modalities are extremely useful in identifying multifocality, anomalous vasculature, and venous tumor thrombus in segmental renal veins.

In recent years, the anatomic considerations for planning partial nephrectomy have been objectified through a number of spatial scoring systems that relate the tumor position to intrarenal structures. Most commonly employed is the nephrometry score,[34a] detailed in Chapter 34, which correlates with the risk of complications at time of partial nephrectomy. These scores can be quite useful both for selecting candidates for partial nephrectom, and for determining the optimal approach.

Planning of the incision is important. Partial nephrectomy can be performed through a variety of incisions (Figs. 38.2 A–C, and 38.3A and B) including a traditional flank, subcostal (intraperitoneal), thoracoabdominal, or the more recently described "mini-flank" (subcostal extraperitoneal).[34b] We prefer to perform open partial nephrectomy through an extraperitoneal approach, using a supracostal 11th rib incision. The advantages of such an approach include the ability to tamponade postoperative bleeding and contain urine leaks in the retroperitoneum, to reduce postoperative ileus, and to allow proper exposure for elongation of the renal hilum and "stretch" of the kidney. Disadvantages include increased pain limiting postoperative inspiratory effort, risk of pleural injury, and flank denervation bulge, which often arises from stretch of the intercostal nerve during rib distraction. The subcostal approach is feasible, but we have found it difficult to bring the kidney up to the level of the skin as we can easily do with hilar mobilization through a flank incision. The "mini-flank" incision may represent a compromise between these two approaches, by taking advantage of the benefits of each.

An additional preoperative consideration in contemporary practice is whether to perform the procedure by laparoscopic, robotic-assisted laparoscopic, or open technique. This decision is, in large part, a decision made on the basis of surgeon preference and experience, as it has been shown that the majority of tumors can be safely treated by any of the approaches. A number of considerations, detailed in Chapter 34, may come into play. In general, for most surgeons, open techniques are ideal in cases of centrally located tumors, complex tumor relationship with intrarenal structures, significant multifocality, large tumors, or solitary kidney. For surgeons not facile with minimally invasive techniques, open techniques can obviously be safely employed in any surgical setting. One should consider the morbidity specifically associated with the incision in selecting candidates.

A good benchmark is for the surgeon to determine, within his or her own skill set, an estimated ischemia time for renal reconstruction based on tumor size and position. Although the optimal time for tolerable ischemia is not clearly defined, we use a benchmark of 30 minutes by estimate. If it appears that >30 minutes would clearly be required,

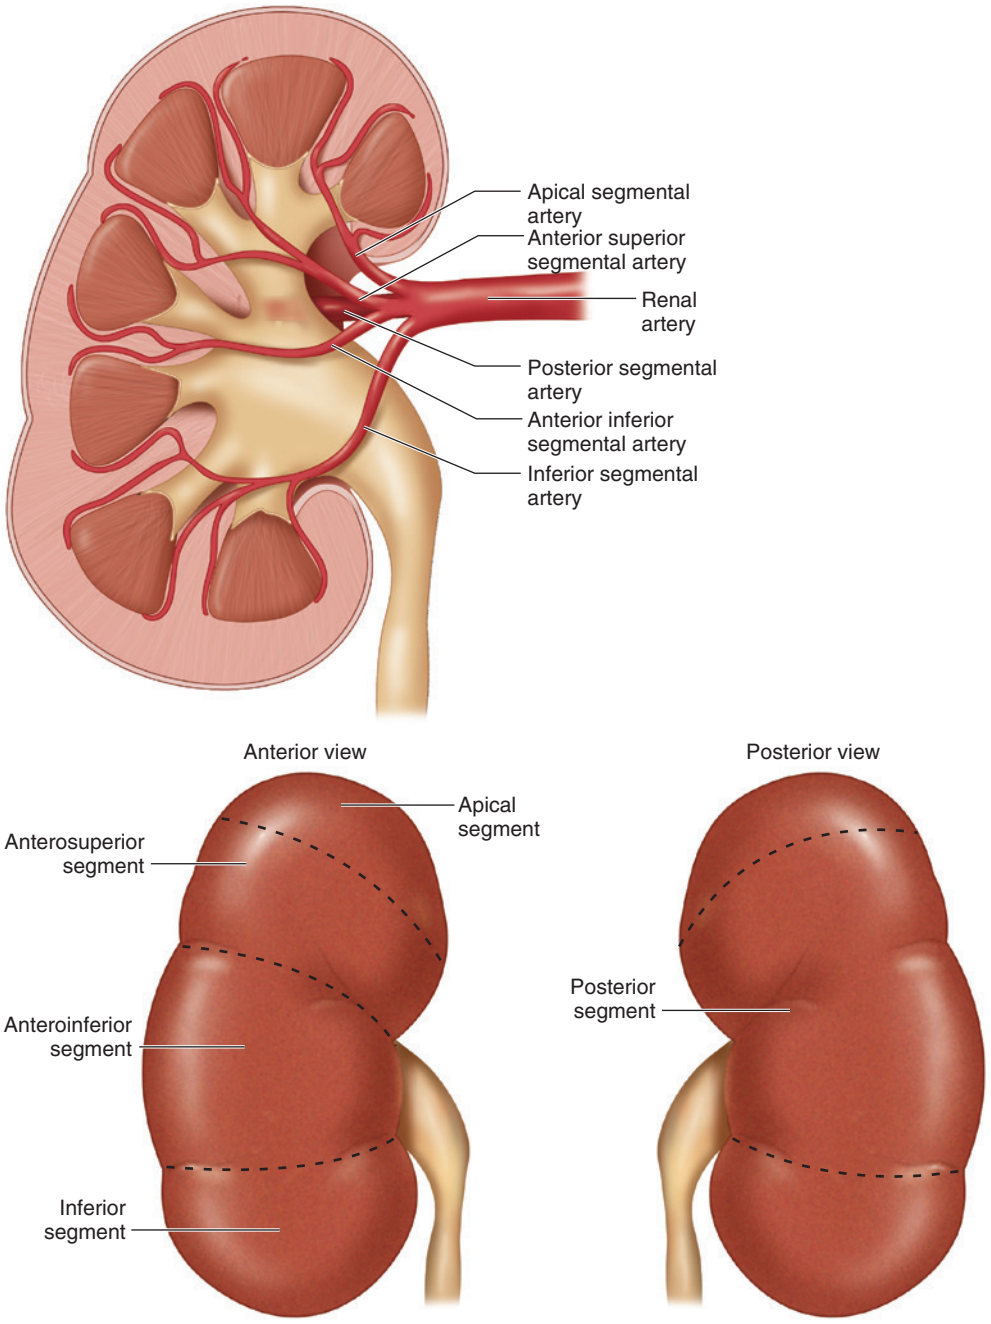

Figure 38.1 The arterial blood supply of the kidney is generally reproducible with five major segmental branches. On occasion, when a tumor is localized to a single arterial segment, selective segmental arterial occlusion may be feasible, thereby reducing the risk of renal ischemia. In resecting, the line of resection should not cross the direction of segmental flow, to avoid peripheral infarct. Similarly, on reconstruction, knowledge of the direction of blood supply relative to the defect is essential.

we would consider open partial nephrectomy. When using a transperitoneal laparoscopic approach, the most difficult tumors for exposure and resection are those located in the medial posterior segment. In these cases, a retroperitoneal laparoscopic approach can be considered if the surgeon is facile with the technique, but an open approach is a reasonable consideration otherwise. Increased morbidity for partial nephrectomy in a solitary kidney has been reported for laparoscopic as compared with open partial nephrectomy even in centers of excellence, a finding suggesting that these procedures are best performed by open partial nephrectomy in most cases.[35]

Given the more rapid general convalescence with laparoscopic partial nephrectomy techniques, in our center we have preferred this technique, in recent years, for most patients and reserve open partial nephrectomy only for those patients with significant multifocality or very centrally located tumor. We have found reoperative surgery, following previous partial nephrectomy, to be easier with a laparoscopic approach.

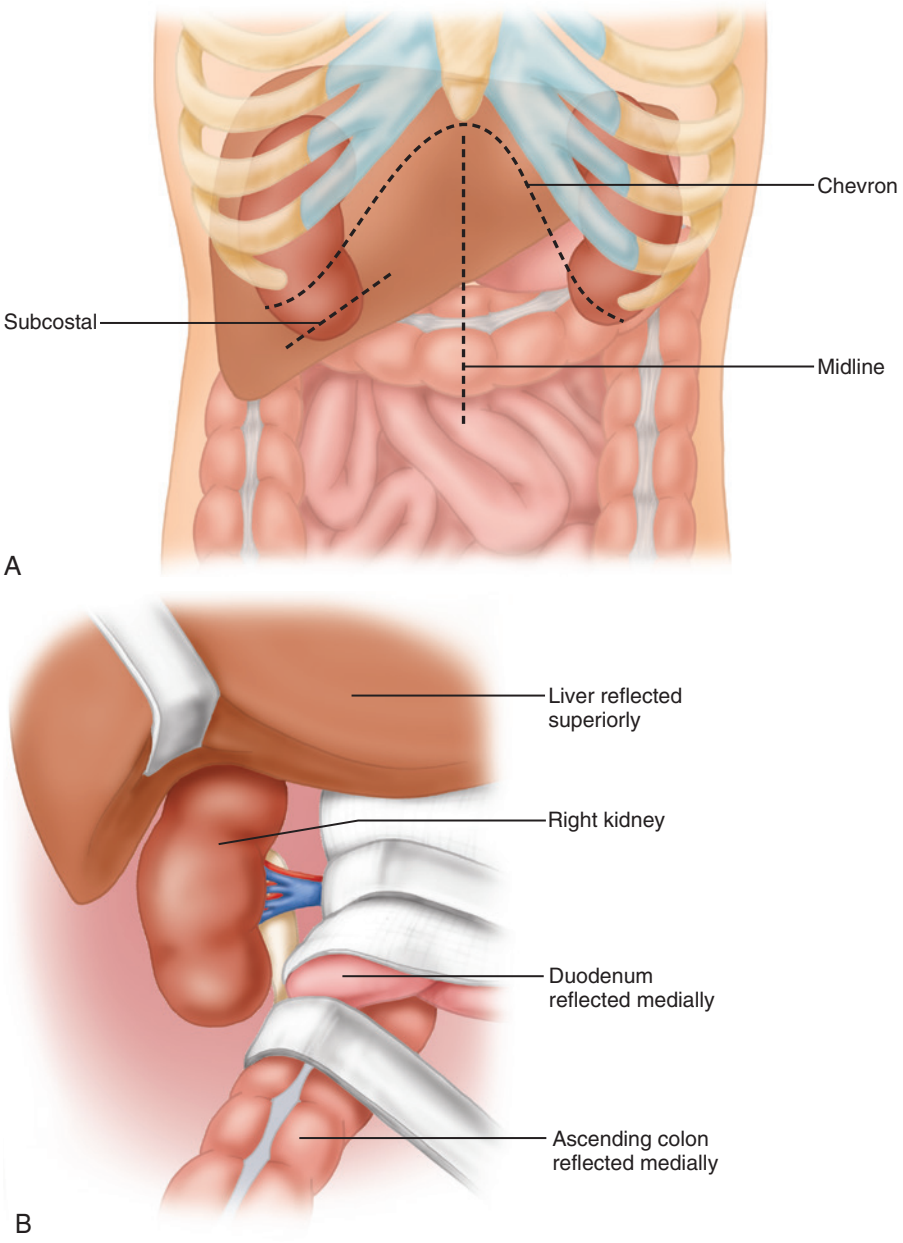

Figure 38.2 A number of options exist for anterior incisional approaches to the kidney (A), including unilateral or bilateral (chevron) subcostal or midline incisions. Transperitoneal, anterior exposure of the right kidney (B) requires reflection of the right colon, duodenum, and triangular ligament of the right hepatic lobe. Medial exposure should be carried out widely to the level of the inferior vena cava.

General Complications

The general complications related to the renal surgery, incision, and medical comorbidity are discussed elsewhere in this book. This chapter focuses attention on complications specifically related to partial nephrectomy. The main technical complications of partial nephrectomy include bleeding, urine leak, renal dysfunction, vascular fistula or malformation, positive margin, renal infarct, and, on rare occasions, renal loss.

The learning curve of partial nephrectomy remains a major challenge for the urologic community, but in more recent series morbidity is improving. In fact, some series comparing morbidity, length of stay, and cost differential associated with partial and radical nephrectomy reported no significant differences and concluded that the nephron-sparing approach can offer the benefit of maximal parenchymal preservation while adding little additional morbidity.[5,8,15,36,37] In a study of 49,983 individuals who underwent open radical nephrectomy (35,712), laparoscopic radical nephrectomy (5327), or open partial nephrectomy (8944) for RCC at 2037 hospitals from the Nationwide Inpatient Sample 2001–2008, only modest differences were observed in the proportion of patients with complications (27.0%, 22.6%, and 24.0%, respectively).[38]

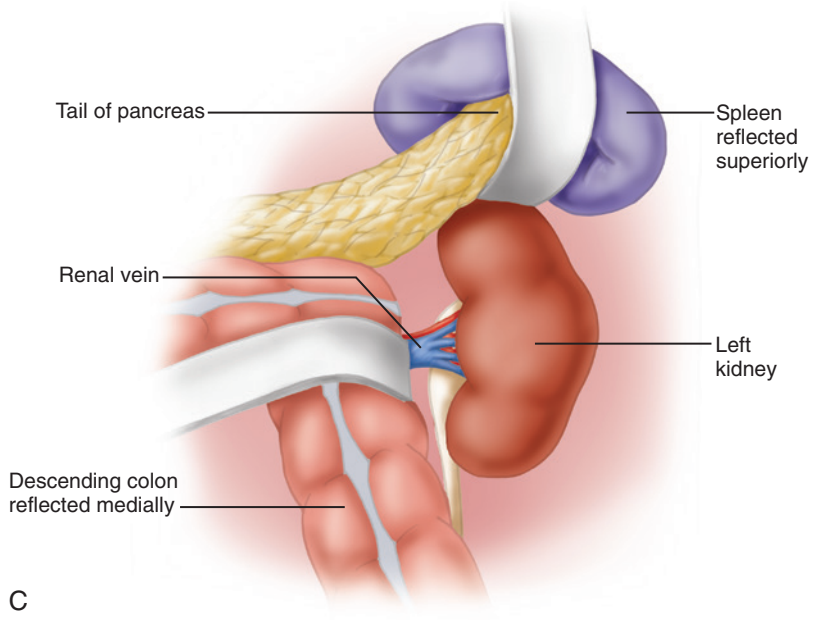

Figure 38.2, cont'd Left renal exposure (C) requires reflection of the left colon, pancreatic tail, and spleen. On occasion, incision of the splenocolic ligament is required. Medial exposure is generally carried out to the para-aortic space, but exposure of the aorta is generally not required, given the length of the left renal hilum. (From O'Malley RL, Godoy G, Taneja SS. Radical nephrectomy for localized renal cell carcinoma. In: Renal Cell Carcinoma. Campbell SC, Rini BI, eds. Shelton, CT; BC Decker; 2009.)

Becker et al. evaluated 2277 patients aged >65 years with T1 renal cell carcinoma who underwent laparoscopic radical nephrectomy, open partial nephrectomy, or laparoscopic partial nephrectomy, using the Surveillance, Epidemiology, and End Results Medicare linked database (1992–2005) and found no difference in the 30-day mortality rates.[37] Observations such as these are clearly based on institutional experience, and training of community urologists to perform partial nephrectomy with low risk of morbidity remains a challenge.

OPEN PARTIAL NEPHRECTOMY: INCIDENCE

Classically, the critical technical challenge of partial nephrectomy has been balancing vascular control to reduce the risk of significant intraoperative hemorrhage against the risk of ischemic injury resulting from prolonged clamping. In most open series, hemorrhage has been the most common intraoperative complication.[39–42] The reported incidences of other significant postoperative complications include those of urinary fistula (0–17.4%), acute renal failure (0–26%), and postoperative bleeding (0–4.5%).[40–45]

In the early experience with open partial nephrectomy, reported complications were high, at ≤30.1% in one series. In that series, hemorrhage was the fourth most common complication, whereas acute renal failure was more common, occurring in 42.3% of patients.[7] In preventing bleeding and renal dysfunction, the surgeon's challenge is to balance efficient reconstruction with as minimal an ischemic injury as possible. Recognizing the deleterious effect of prolonged arterial clamping on renal function, surgeons have adopted a more permissive bleeding strategy and improved reconstructive techniques. With the increased experience of the surgeons, complications of open partial nephrectomy have declined; in a series comparing 1049 consecutive open radical or partial nephrectomies, complications of partial nephrectomy occurred in 9% of patients including urinary fistula (5.5%), acute renal failure (1.3%), perinephric abscess (1.1%), pneumothorax (0.8%), and retroperitoneal hemorrhage (0.8%).[46] Thompson and colleagues,[47] when comparing two groups of patients operated before and after 1995, reported an incidence of hemorrhage of 1.5% and 1.2%, respectively. The incidence of acute renal failure was also much lower (3.8% and 1%, respectively); dialysis was required in only 2% of those operated before 1995 and in 0.6% of those treated thereafter.[47] Urinary fistula or leak has also been a historically frequent complication in some early series (57.6%),[7] whereas in a retrospective review of 1118 partial nephrectomies at one institution, urinary leak was observed in 52 patients for a rate of 4.4%.[48] Clearly, the learning curve of partial nephrectomy has reduced morbidity.

Van Poppel and colleagues[40] prospectively compared the complications of nephron-sparing surgery and radical nephrectomy in a phase III multicenter trial. These investigators found in the nephron-sparing group a rate of severe hemorrhage (defined as blood loss >1 L) of 3.1% and urinary fistula of 4.4%, whereas in the radical nephrectomy group severe hemorrhage was seen in only 1.2%.[40] Reoperation for complications was necessary in 4.4% of the nephron-sparing group and in 2.4% of the radical nephrectomy group.[40] As such, partial nephrectomy has been considered safe and desirable, despite a higher rate of perioperative and early postoperative complications, given the potential benefit of preserving the renal function.[40] We have experienced an extremely low rate of complications

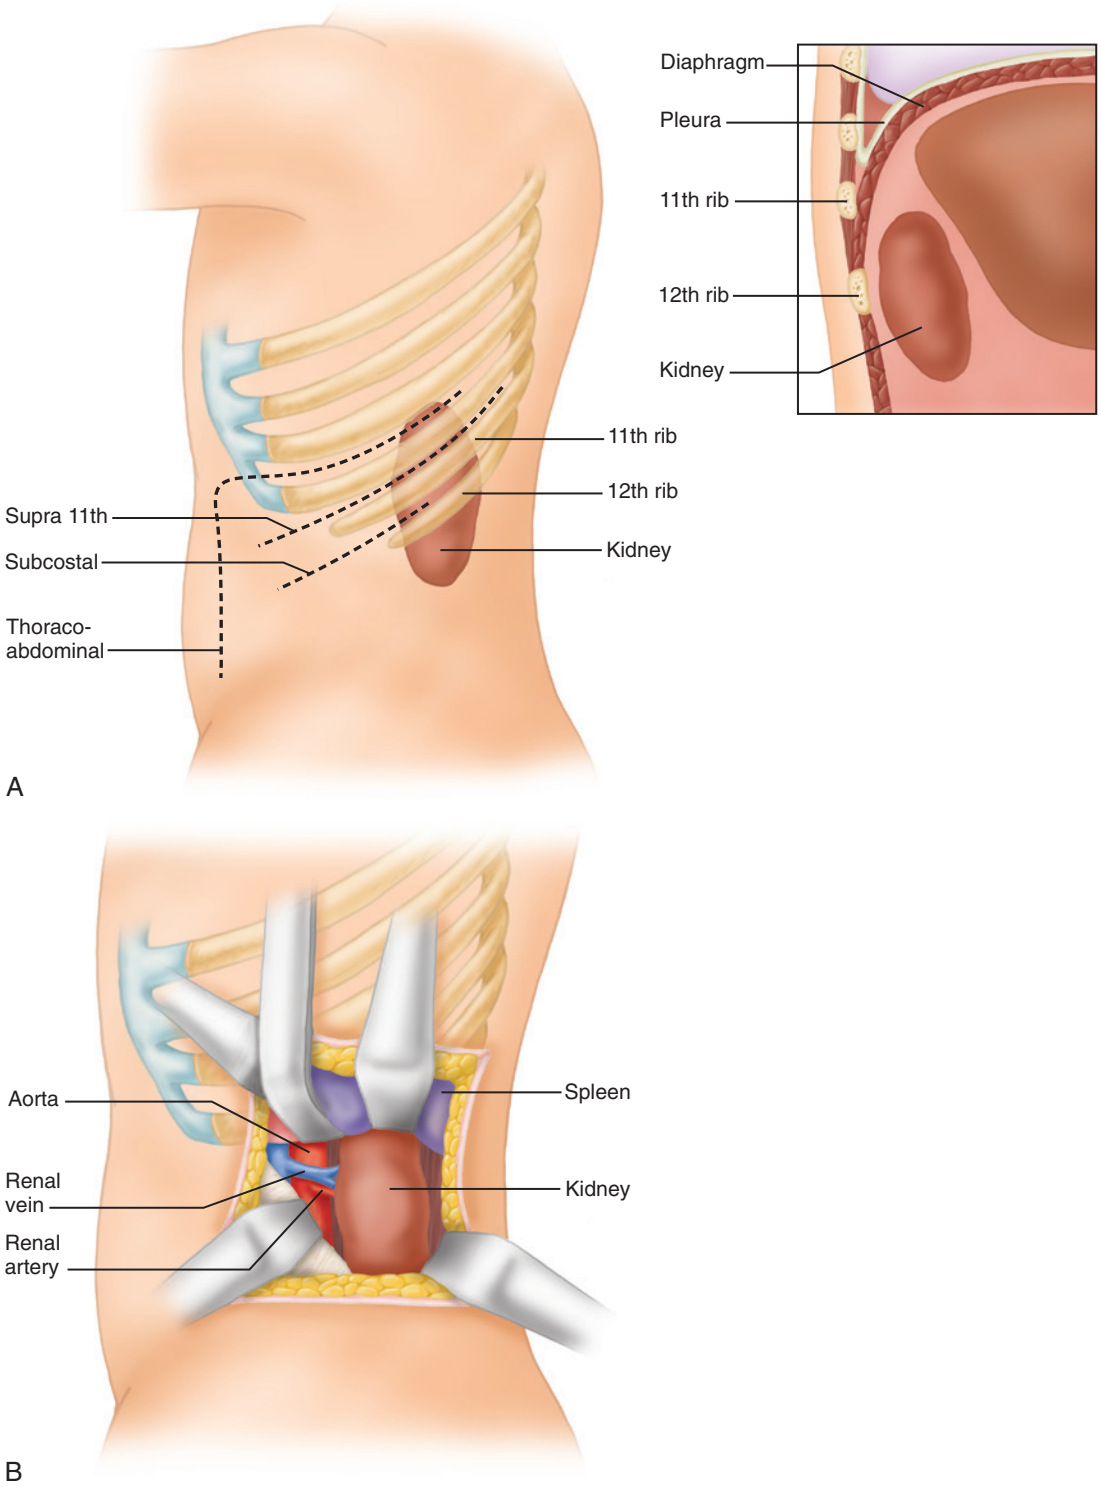

Figure 38.3 Flank incisions can be performed at a number of the intercostal spaces, with or without rib resection (A). In performing a flank incision, the risk of pleural injury increases with decreasing intercostal level, due to the pleural anatomy (inset, A). In a thoracoabdominal approach, the pleura and adjacent peritoneal cavity are intentionally entered. In exposing the kidney through a flank approach (B), intraperitoneal structures such as spleen and liver are not directly observed, but can be harmed by retraction injury. The pancreatic tail and splenic hilum are evident on the left (B), and the duodenum and vena cava are evident on the right. (From O'Malley RL, Godoy G, Taneja SS. Radical nephrectomy for localized renal cell carcinoma. In: Renal Cell Carcinoma. Campbell SC, Rini BI, eds. Shelton, CT; BC Decker; 2009.)

with contemporary partial nephrectomy by adhering to the specific technical concepts outlined later in this chapter. With careful attention to detail, partial nephrectomy can be very safely performed for most patients with early-stage renal tumors.

Specific Complications

POSITIVE MARGIN

Oncologic efficacy in renal cancer relies on a negative tumor margin during partial resection. Although investigators have demonstrated that the thickness of the margin does not appear to be important in predicting recurrence-free survival, a negative margin remains essential.[49] Simple enucleation of the tumor is certainly technically the simplest approach, but in our opinion it increases the likelihood of microscopic residual disease.

Planning the line of renal incision is heavily dependent on the tumor position and the extent of subcortical tumor. Tumors that are predominantly exophytic can be incised in a shallow incision around the circumferential base of the tumor. Tumors that are predominantly endophytic require true resection of a segment of the kidney to ensure an adequate margin. We have found the technique of intraoperative ultrasound most useful for mapping the line of renal incision during both open and laparoscopic partial nephrectomy (Fig. 38.4). The ultrasound probe is passed over the kidney from normal cortex toward the center of the tumor. Radial passes of the ultrasound probe allow mapping of the subcortical extent of the tumor. The line of renal incision is then planned on this basis.

During excision, arterial ischemia is useful in allowing direct visualization of the renal incision as it progresses. This feature is perhaps most important in laparoscopic partial nephrectomy because tactile feedback is less available to assess the surgeon's position in the kidney relative to the tumor. Incision into the tumor, or too close to it, can be redirected by a repeat incision at a greater depth starting 1–2 cm proximal to the leading edge of the incision. We have used visual landmarks in the kidney to guide the adequacy of our renal incision during laparoscopic partial nephrectomy. For example, if a tumor is radiologically positioned within 10 mm of the renal sinus or collecting system (Fig. 38.5A), then visual entry of these structures confirms the adequacy of the margin (see Fig. 38.5B).

Frozen section analysis of shaved margins is widely used to confirm the adequacy of the incision and, although this analysis may reassure the surgeon and patient, it is likely inaccurate in predicting oncologic efficacy. Sampling error and artifactual expansion of the defect during incision render this technique of margin analysis of little value.

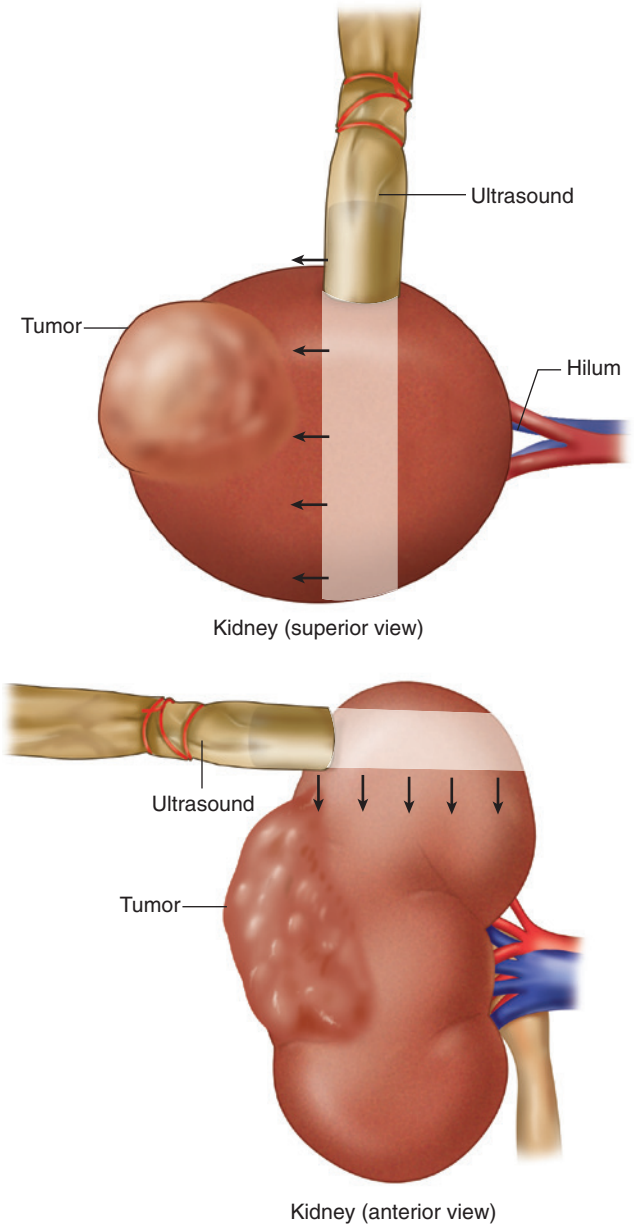

Figure 38.4 In mapping a tumor by ultrasound scan, the probe is passed across the tumor in each direction (arrows point in the direction of the probe movement) to determine the extent of subcortical tumor and to ascertain the optimal line of incision. Tumor can often extend tangential or lateral to the visible exophytic component of the tumor. The probe can be passed across the tumor in radial or perpendicular lines (like the spokes of a wheel) to assess the extent of tumor fully.

BLEEDING

Because partial nephrectomy requires transection of multiple blood vessels during renal incision, it is perhaps intuitive that bleeding is a potential consequence. Bleeding can occur intraoperatively, immediately postoperatively, and at a delayed interval up to several days or weeks after the surgical procedure. Intraoperative bleeding usually occurs from the cut parenchyma, but it can occur from the hilum if the vessels are not carefully dissected during exposure. Preoperative knowledge of the individual renal vascular anatomy is essential in this regard. Bleeding has generally been feared in partial nephrectomy. For large and central tumors, selective embolization or extracorporeal resection of the tumor followed by autotransplantation has been performed, in an attempt to provide clean margins with limited blood loss. In the contemporary era, such techniques are generally not necessary if one adheres to basic tenets of vascular control and renal reconstruction.

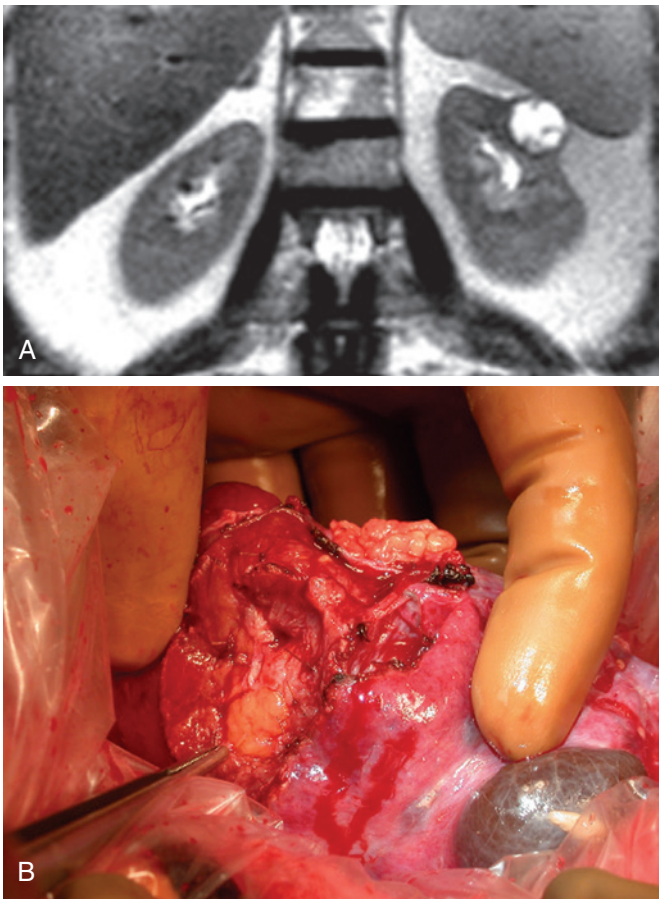

Figure 38.5 On observing the position of a tumor to be within 10 mm of the renal sinus (A), exposure of the sinus during resection (B) is essential to ensure adequacy of the margin.

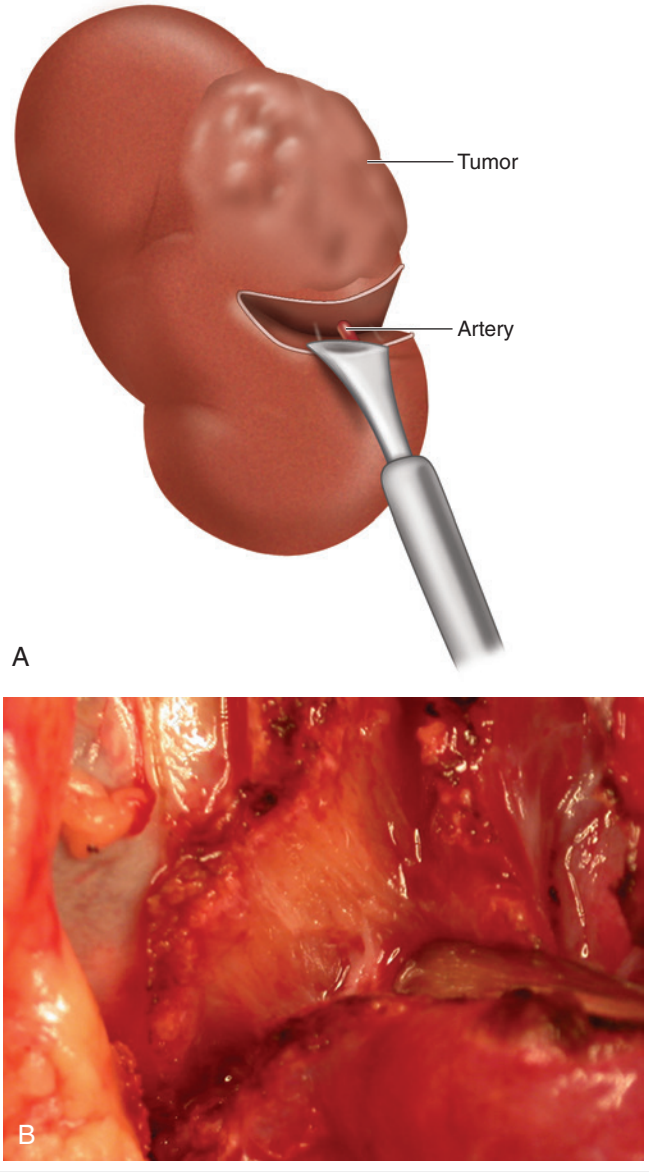

Figure 38.6 Separation of the renal parenchyma with a Freer instrument (A) allows visualization of arterial branches as they enter the specimen (B). On recognition of the vessel, it is directly suture ligated, thereby avoiding placement of deep sutures that may inadvertently injure or ligate a more proximal branch point of the vessel or adjacent vessels. (B, From Nieder A, Taneja SS. The role of partial nephrectomy for renal cell carcinoma in contemporary practice. Urol Clin North Am. 2003;30:536.)

The fundamental tenets of renal reconstruction are as follows:

1. Closure of the collecting system
2. Suture or coagulation control of small transected intraparenchymal vessels
3. Prevention of retraction within cut large central blood vessels
4. Compression of the defect to aid in venous tamponade.

A variety of tools and techniques can be employed for each tenet, but with attention to each, good outcomes can be achieved.

Parenchymal bleeding during resection is usually handled by clamping of the renal artery or vein. In most open partial nephrectomies, arterial clamping is adequate because venous tamponade through hilar stretch and manual compression is easily achieved. Brisk bleeding on renal incision despite clamping can indicate a missed renal artery, and if it is not easily identified, a hilar cross-clamp can be placed during both open and laparoscopic procedures. When performing this maneuver on the left side, the position of the aorta, adrenal, pancreas, and superior mesenteric artery should be known before the clamp is placed. On the right, avoidance of the duodenum and porta hepatis is essential. If brisk bleeding is noted with the venous clamp in place, then venous hypertension resulting from continued arterial inflow should be suspected. Removal of the venous clamp can reduce bleeding in these cases.

Numerous techniques exist for repair of cut renal vessels. Direct suture ligature with 4-0 absorbable sutures is generally preferred. We find it most effective to identify vessels during renal parenchymal incision and suture ligate them before division. The renal parenchyma is separated with a small Freer instrument (Fig. 38.6A), and on identification of the vessel (Fig. 38.6B), a direct suture ligature is placed and the vessel is divided with tenotomy scissors. In this fashion, the line of resection can be controlled and redirected (Fig. 38.7).

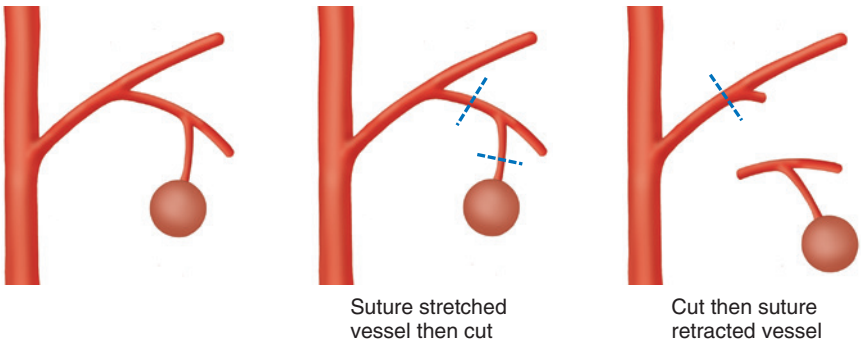

Figure 38.7 By ligating and incising small vessels entering the partial nephrectomy specimen, while they are exposed and stretched from the parent vessel, one can avoid injury to deeper vessels (thereby minimizing radial infarct) and have directional control of the depth and direction of the incision.

If brisk bleeding occurs after removal of the arterial clamp, one should again consider the possibility of venous compression or twisting of the renal pedicle, thus impairing venous outflow. If the vein is not compromised, then suture repair of bleeding should be performed while one manually compresses the defect. Reclamping of the artery should be avoided because of the increased risk of ischemic injury following reperfusion.

In cases of immediate postoperative bleeding, initial management should be conservative with transfusion, bed rest, and serial monitoring of hematocrit. Expanding retroperitoneal hematoma can worsen bleeding through stretch of the renal defect. Therefore if multiple transfusions are required, hemodynamic instability is noted, or the hematocrit is not responsive to transfusion, then one should give early consideration to angiography and selective embolization. In these patients, unlike in renal trauma, attention must be focused on the resection bed in which any visible vessels can be embolized, even if they are not actively bleeding. Intermittent hemorrhage is common, and bleeding may not actually be seen on angiography.

In patients with delayed bleeding (hematuria or flank hematoma) following discharge from the hospital, early angiography should be performed given the high likelihood of arteriovenous fistula or pseudoaneurysm. If the index of suspicion is low, or if the bleeding is minimal and the patient is hemodynamically stable, then one could first perform a duplex ultrasound scan (see Chapter 34, Fig. 34.6) or magnetic resonance angiography (MRA) because these techniques are less invasive. If an abnormality is not noted and bleeding persists, then angiography would be required anyway. Selective angioembolization is extremely effective in the management of these complications.[50] We have on occasion seen delayed hematuria resulting from decompression of an extrarenal hematoma through the collecting system. In these cases, a small, fluid-filled defect (closed urinoma) is noted at the resection bed on an MRI urogram.

INFARCT

In performing partial nephrectomy, preservation of the vascular supply of the retained segments of kidney is essential to avoid renal infarction. Although the functional significance of infarct is not known, certainly infarcted tissue likely decreases the preserved renal reserve over time. Large infarcted segments can result in renin-mediated hypertension, and if a large portion of the repaired collecting system loses blood supply, this situation can promote leakage.

Avoiding infarct again relies on knowledge of renal arterial anatomy. Given the end-arterial nature of renal blood flow, maximizing proximal vascular preservation should be the goal of resection. In approaching polar lesions, straight rather than tangential amputation is desirable, but if the lesion is primarily located within the anterior or posterior segmental vasculature, then a significant amount of parenchyma can be preserved through a tangential cut. Within the anterior and posterior segment, we find that starting the parenchymal incision away from the hilum and cutting toward the center of the kidney will allow identification of arterial branches as they enter the specimen, thereby avoiding radial infarct (Fig. 38.8). We find that starting the incision from the hilum and working outward results in a higher likelihood of injury to main branches and thereby promotes additionally infarcted kidney (Figs. 38.9A–D).

On separation of renal parenchyma along the planned line of incision, individual vessels are identified as they enter the specimen, are suture ligated, and are transected sharply to avoid the necessity for deep suture placement for retracted blood vessels (see Figs. 38.6 and 38.7). This technique is more difficult to recapitulate in laparoscopic surgery, and as such, the likelihood of radial infarct is higher in laparoscopic partial nephrectomy owing to the suturing techniques typically used in the laparoscopic procedure. We have adapted a modified suturing technique (described in Chapter 34) to reduce the likelihood of major infarct or vascular complication.

The general management of infarct is observation. In patients with severe hypertension or persistent leak resulting from infarcted kidney, nephrectomy should be performed.

URINE LEAK

Urine leak rates reported in the urologic literature depend on the operator's definition. This definition has varied widely from leakage for >72 hours to leakage persisting for >3 months postoperatively. We generally define urinary fistula following partial nephrectomy as urine leakage persisting for >4 weeks after the surgical procedure. Nonetheless, any duration of postoperative urine leak must be

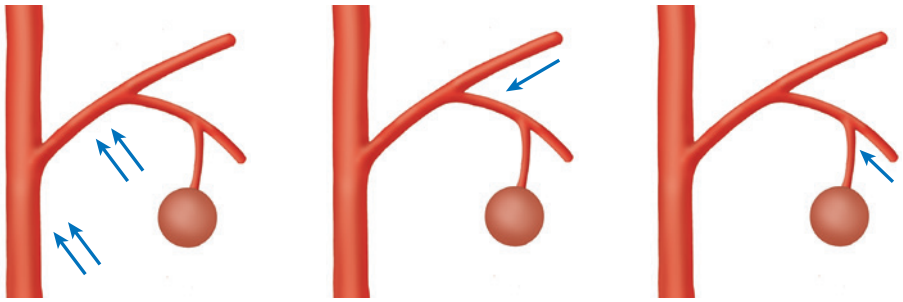

Figure 38.8 Partial nephrectomy incisions carried outward from the hilum (double arrows) often injure larger blood vessels feeding renal parenchyma beyond the planned resection. As a result the risk of radial infarct, or adjacent segmental infarct, is relatively high. Cutting toward the hilum (single arrows) allows incision of only those vessels that are feeding the resected parenchyma as they are encountered, resulting in a lower risk of radial infarct.

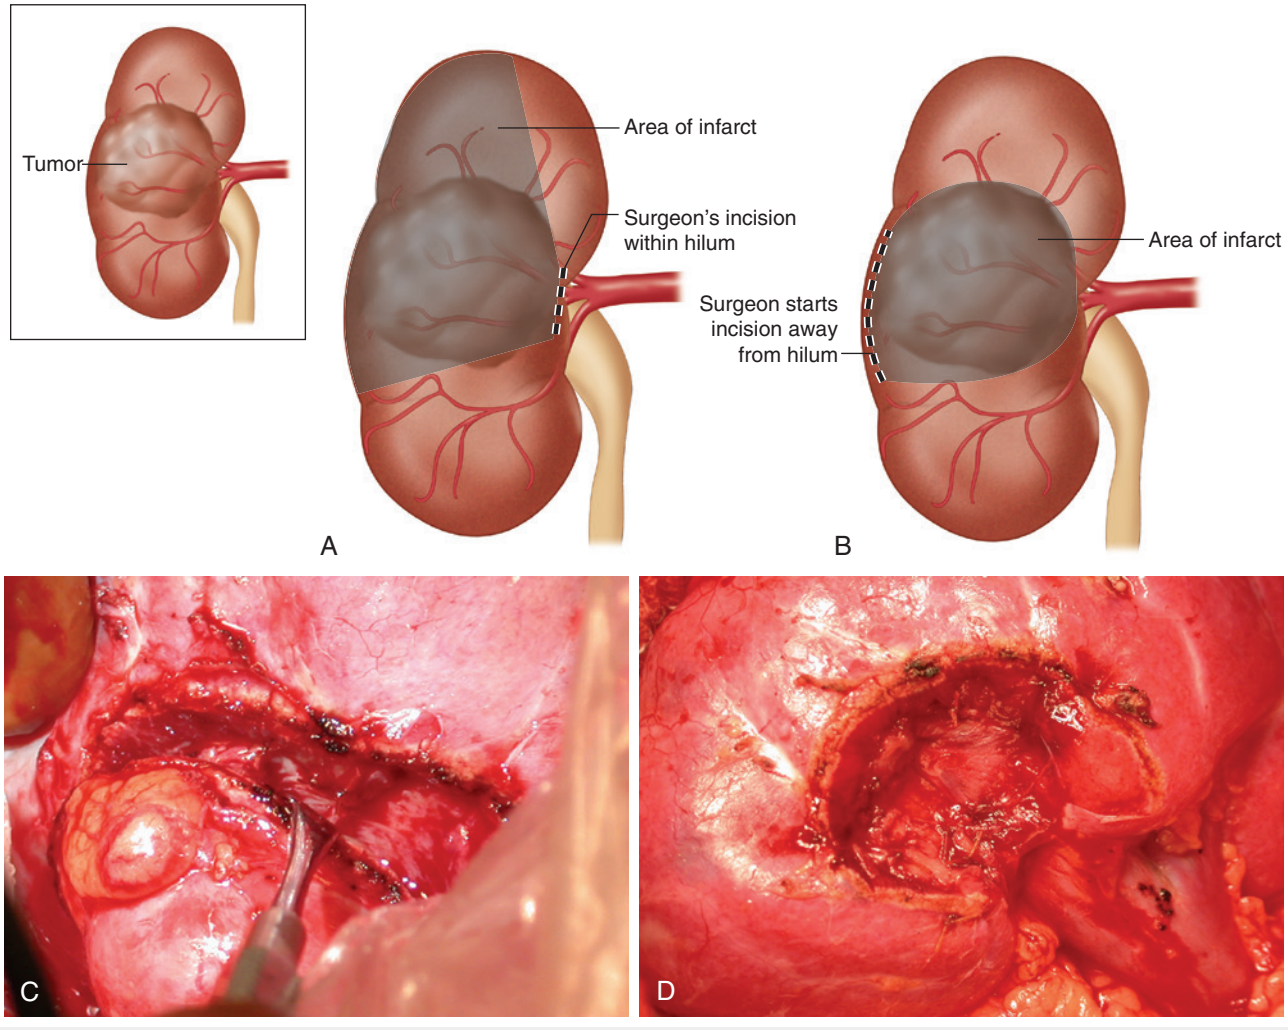

Figure 38.9 The direction of incision can influence the likelihood of injuring arterial branches that feed the residual kidney. As arteries and more proximal branch points are present in the hilar region, we generally prefer to start resection on the side of the tumor opposite the hilum. This is particularly relevant when operating in the anterior or posterior segment. A, If the incision is carried out from the hilum, infarct radial to the defect can often be seen. B–D, When starting the resection away from the hilum, larger central vessels are preserved and the surrounding kidney remains well perfused.

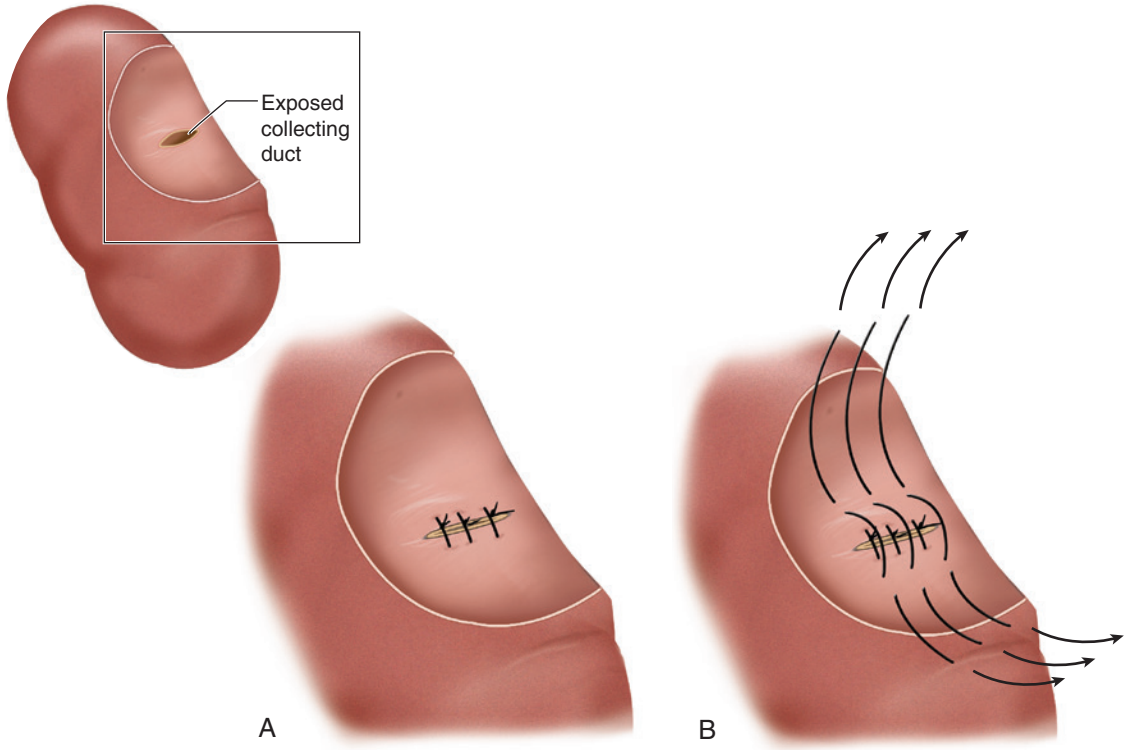

Figure 38.10 Two-layer collecting system closure involves two interrupted layers of absorbable suture. The first layer (A) incorporates the edges of the collecting system, whereas the second layer (B) attempts to imbricate normal renal parenchyma to remove tension from the first line. The use of interrupted rather than running suture reduces the likelihood of tearing the collecting system with the suture.

appropriately managed by the surgeon. Simple principles of drainage, prevention of infection, and avoidance of ureteral obstruction generally allow resolution of the leak. Management of urine leak following partial nephrectomy is additionally discussed in Chapters 13 and 34.

Careful closure of the collecting system generally prevents urine leak. In cases of large resection bed, or in tumors resected from the anterior or posterior segment with tangential renal incision, small calyceal injuries may not be identified, and these are often the site of persistent leak. In general, meticulous closure of the collecting system is performed with a layer of interrupted absorbable 4-0 braided sutures. This stage is followed by a second layer of imbricated sutures that attempt to pull the parenchyma together around the defect and thereby reduce tension on the primary closure (Fig. 38.10).

Two modifications of technique have greatly reduced our leak rate with open partial nephrectomy: (1) retrograde instillation of methylene blue through the renal pelvis and (2) the use of a layer of tissue adhesive over the closure. The use of tissue adhesive is most important in laparoscopic partial nephrectomy because small caliceal injuries are often difficult to identify. We have adopted a standardized technique of infiltrating Gelfoam (Pfizer Inc., New York) with fibrin sealant (Tisseel, Baxter International Inc., Deerfield, Illinois), molding it to the resection defect, and then activating it through infiltration of thrombin. Additional hemostatic materials are packed into the defect, and then the kidney is folded over the materials using horizontal mattress sutures of 3-0 absorbable nonbraided suture anchored to the surrounding renal capsule.

Urine leak presents in one of two ways. Early leaks often become evident in the recovery room and persist, whereas delayed leaks manifest 5–14 days postoperatively and may become symptomatic. It is not clear whether most delayed leaks were simply unrecognized early because of inadequate drainage and lack of symptoms. The old tenet that urine leakage frequently occurs in the first 24–72 hours but then resolves is not entirely true. In fact, most renal reconstruction for elective partial nephrectomy should be watertight. Early leakage generally indicates poor collecting system closure or unrecognized collecting system injury, and in our experience this leakage rarely stops within the first few days.

Early leak is suspected if drainage of >30 to 40 mL per shift is noted >48 hours after the surgical procedure. Large-volume drain outputs within the first 24 hours may lead one to suspect leak, but intervention is not required unless infection is noted, serum creatinine becomes markedly elevated because of reabsorption, or the patient has no urine output (solitary kidney). In these cases, renal obstruction may be suspected and early imaging is advised. Urine leak beyond 48 hours is confirmed by measurement of drainage creatinine level relative to serum. If the drainage is pure urine, creatinine levels will generally be >30 mg/dL. When the drainage creatinine is even moderately higher than that of the serum, then at least part of the draining fluid is urine and a urine leak is likely present. Minimal creatinine elevation may suggest a resolved urine leak with some dilute urine still in the retroperitoneum. After leak confirmation, we generally perform an immediate ultrasound scan or noncontrast CT study for assurance that the drain is

properly positioned, that no undrained urinoma is present, and that the kidney is well drained.

If all these tenets are met, the patient is discharged home with prophylactic antibiotics and a drain in place. Patients are monitored weekly with electrolytes and renal ultrasound studies to rule out worsening urinoma or drain migration. In cases of undrained fluid, the drain is repositioned to sit immediately adjacent to the leak point. This maneuver can be facilitated by contrast CT with delayed cuts. Ideal drain placement is immediately adjacent to the kidney to allow a drain tract to form. In cases of high-output leak, the drain can be converted from suction to gravity, but a follow-up ultrasound scan within a few days is warranted to rule out a secondary fluid collection.

Presentation of delayed leak is usually the result of flank pain, fever, or drainage from an incision. In a patient with fever, evaluation should include a complete blood count with manual differential, blood and urine cultures, and a chest radiograph to identify other potential sources of infection. CT with intravenous contrast should include delayed images to identify urinary extravasation, provided renal function is acceptable for receiving iodinated contrast. Ultrasound can alternatively be used to identify a perirenal fluid collection. Before percutaneous drainage, broad-spectrum antibiotics should be administered. The drain is best positioned immediately adjacent to kidney, but in cases of infection, maximal drainage is paramount to allow defervescence, and this may be best achieved with the patient in the most dependent position.

In the absence of infection, similar evaluation of renal function and imaging to identify fluid collections should be performed. On percutaneous drainage, the fistula output may be quite high initially because of the presence of a large potential space outside the kidney. Maximal kidney drainage is necessary to promote antegrade drainage over time. In general, a ureteral stent is not necessary unless evidence indicates ureteral obstruction, blood clots or debris within the collecting system, or a very large collecting system opening. In our experience, stents often worsen the leak initially, possibly as a result of reflux. It is essential to have a concomitant urethral catheter in place while the leak is perpetuated, particularly in a man with high-pressure voiding. We have generally avoided stent placement unless absolutely necessary because most leaks will close with prolonged drainage.

Resolution of urine leak generally requires scarring in of the potential space around the kidney. This occurs as scar tissue fills in around the drain forming a drain tract. We generally prefer to leave the drain on gravity drainage to promote antegrade urine flow within the collecting system. On converting to gravity drainage, a follow-up ultrasound scan within 36–48 hours will confirm that no urine collection has formed around the kidney or drain tract. If it has, then the drain should be returned to suction. Urine collections prevent the formation of a drain tract and delay leak closure. Over a period of 2–4 weeks, if properly drained, a drain tract should have formed, and on confirmation of the absence of urinoma, the drain can be advanced back 2–3 cm to allow the tract to close between the tip of the drain and the kidney. Every 48–72 hours, the drain can be pulled back another 2–3 cm until it is removed. During this time of drain advancement, one should monitor for urinoma formation and fever, a finding suggesting recurrence of the urinoma within the drain tract. In cases of high drain outputs (>300 mL/24 hours) more prolonged observation (≤12 weeks) may be necessary before attempting drain advancement. Low-output leaks require minimal observation before closure can be achieved. In this regard, closure of a leak is an active process initiated by the surgeon rather than a passive physiologic process.

Urine leak can also result from ureteral injury. Excessive dissection of the renal pelvis, the lower pole of the kidney, and the proximal ureter should be avoided because it can cause devascularization, ischemia, and necrosis with subsequent fistula formation in the dissected segment. On completion of the procedure, fat should be interposed between the lower pole of the kidney and the upper ureter to avoid adherence, scarring, and subsequent stricture of the ureter.

RENAL FUNCTION

Measuring renal functional outcomes after elective partial nephrectomy is most difficult given the compensatory ability of the remaining kidney. Conventional beliefs have been that renal dysfunction following partial nephrectomy is related to the length of renal arterial clamping and the amount of parenchyma resected. In truth, many factors may influence the function of the operated kidney including intraoperative blood pressure variations, fluid resuscitation during the case, and aggressive handling of the kidney. Intraoperative blood loss may result in a higher risk of renal dysfunction because of the possibility of hypotension and reduced tissue oxygenation. When operating on an individual with two kidneys, the risk of postoperative azotemia and the necessity for dialysis depend on the functional reserve of the remaining kidney. Patients with diabetes, hypertension, and known vascular disease are more likely to have transient azotemia postoperatively. Individuals with a solitary kidney are also affected by these factors, but clearly, the risk of azotemia is more strongly affected by renal arterial clamping than in patients with two kidneys and normal renal function.

In patients with bilateral functioning kidneys, the reported rate of acute kidney injury after open surgery has been 4%,[51] whereas chronic kidney disease has been reported to occur in 2–8% of patients.[47,51] Similar patients in laparoscopic series were shown to have negligible rates of renal dysfunction.[52–54] In patients with solitary kidneys, the rates of acute kidney injury after open procedures are more evident, ranging between 13% and 38%, with chronic kidney disease occurring in from 3% to 30% of these patients.[45,55,56] In a series of 103 partial nephrectomies in a solitary kidney, Ghoneim et al. reported that eight patients developed acute kidney failure, but nonmodifiable factors such as age and preoperative eGFR predict long-term postoperative eGFR, rather than modifiable factors such as ischemia time.[57] In laparoscopy series, these data have not been consistently reported. Analyzing an initial cohort of 430 patients who underwent laparoscopic partial nephrectomy at the Cleveland Clinic, Gill and colleagues[58] observed that in 22 cases with solitary kidneys and two of which electively converted to an open procedure, a single patient (4.5%) required temporary dialysis and the chronic kidney disease incidence rate was 13%.

Several maneuvers to reduce renal ischemia have been proposed. The use of an osmotic diuretic, such as mannitol, immediately before and shortly after clamping of the renal artery is thought to reduce the accumulation of free oxygen radicals in the tissues. Similarly, cooling of the kidney during ischemia is believed to reduce the likelihood of tissue injury. During open partial nephrectomy, we have used both these maneuvers. The kidney is placed within an intestinal bag with the opening loosely cinched around the renal pedicle. On ice slush packing, the bag serves to hold the ice to the renal surface. After clamping, a period of 5–10 minutes is necessary to reach the nadir core temperature within the kidney. We generally begin to operate on the kidney during this period to reduce total ischemia time, but other surgeons advocate waiting a full 5 minutes before renal incision.

In general, we do not clamp the renal vein because stretch of the pedicle usually sufficiently reduces venous backflow. Investigators have suggested that retrograde circulation of venous blood may allow low-level tissue oxygenation in the setting of arterial clamping. This possibility has been suggested for laparoscopic partial nephrectomy as well.[59]

An alternative to the use of vascular clamping is manual compression of the renal parenchyma. This technique is quite effective in open partial nephrectomy, particularly for polar lesions. In laparoscopic surgery, the technique can be applied through hand assistance, but this approach is more cumbersome because one-hand suturing is required. Even if the renal vessels are not clamped, they should be fully dissected in case of the need for urgent clamping. Surgery can then be performed by squeezing the renal parenchyma with the hands and using only enough pressure to control the bleeding.

Because of the increased risk of azotemia in the setting of a solitary kidney, we generally avoid arterial clamping in these patients whenever possible.[35] In most cases, this situation requires open surgery, but in the case of small exophytic tumors, a laparoscopic approach with no arterial clamping can be considered.

Postoperatively, attention should be given to avoiding or minimizing nephrotoxic or harmful medications such as angiotensin-converting enzyme inhibitors, nonsteroidal antiinflammatory drugs, and aminoglycosides. Individuals at high risk, including those with solitary kidney, large (>50%) renal resections, prolonged ischemia times, preexisting renal insufficiency, and severe vascular disease, should be prepared mentally for the possibility of temporary or even permanent hemodialysis.

REOPERATION

Urine leak rarely requires reoperation, but in cases of persistent ureteral obstruction perpetuating the leak, recurrent abscess, or severe intraperitoneal leak (laparoscopic), a repeat operation may be necessary. Obstruction may be addressed by temporary stenting maneuvers, or reconstruction if it is clearly the cause of recurrent or persistent leak. In cases of refractory leak, either due to persistent obstruction or renal infarct, nephrectomy is generally performed, particularly if the original procedure was elective in nature. Reoperation for bleeding is required when angiographic techniques fail to control postoperative bleeding. In most cases, reoperation for leak or bleeding results in nephrectomy.

Conclusions

Partial nephrectomy for tumor resection is an increasingly important technique for practicing urologists to master. The long-term benefits may be greater than initially perceived. Careful preoperative imaging, knowledge of renal anatomy, attention to patient- and tumor-related risk factors, and meticulous surgical technique are essential for achieving good surgical outcomes. Complication rates should be acceptably low if following fundamental tenets of surgical technique.

Chapter 38 Questions

1. A 63-year-old woman presents with bright red hematuria and passage of clots 15 days after uncomplicated right partial nephrectomy for a 3.7-cm tumor. What is the best diagnostic study?
   a. Cystoscopy
   b. Retrograde pyelogram
   c. Renal ultrasound
   d. Renal angiography
   e. Computed tomography

2. A 52-year-old woman has a 6-month surveillance MRI after an elective partial nephrectomy (Case Fig. 38.1). What is the most likely sequela of this finding?
   a. Recurrent infection
   b. Renal insufficiency
   c. Recurrence of cancer
   d. Hypertension
   e. Hematuria

3. In preparing the kidney for a right open partial nephrectomy resection of a 3.2-cm upper to midpole tumor through a flank incision, a polar artery is observed coursing into the right upper pole. What is the next step?
   a. Mobilization of the polar artery to aortic insertion
   b. Division of the polar artery
   c. Selective ischemia of the polar artery
   d. Pedicle clamp
   e. Extend to a subcostal transperitoneal incision

4. A 47-year-old man has a 3-cm left renal tumor located in the posterior upper pole. He has a history of inflammatory bowel disease with previous small and large bowel resection, temporary colostomy, and colostomy takedown at age 41. The best surgical approach is:
   a. Subcostal open
   b. Mini-flank open
   c. Flank open
   d. Transperitoneal laparoscopic
   e. Transperitoneal robotic-assisted

Case Figure 38.1

5. A 62-year-old woman has a left renal mass measuring 4.8 cm noted on CT urogram, located over the anterior segment midpole, abutting the hilar structures. In planning her partial nephrectomy renal incision, the most useful evaluation tool would be:
   a. Retrograde pyelography
   b. Ureteroscopy
   c. Duplex ultrasound
   d. Angiography
   e. Intraoperative ultrasound

6. The typical segmental renal arterial blood supply divides the kidney into:
   a. One anterior and one posterior segment
   b. One upper and one lower pole segment
   c. Two polar, two posterior, and one anterior segment
   d. Two polar, one posterior, and one anterior segment
   e. Two polar, one posterior, and two anterior segments

7. In performing a partial nephrectomy for a tumor located 5 mm from the renal sinus, a negative margin can be assured by:
   a. Injection of methylene blue into the renal pelvis
   b. Incision into the renal sinus
   c. Biopsy of the resection bed for frozen section
   d. Not clamping the renal artery
   e. Not clamping the renal vein

8. A 69-year-old man undergoes an open partial nephrectomy through a left flank incision. His postoperative course is notable for increased drainage from the retroperitoneal drain. Assessment of the drain fluid reveals a creatinine of 34 mg/dL. The drain output varies from 100 mL to 250 mL per 8-hour shift and persists for 3 days postoperatively. The next step is:
   a. Continued observation
   b. Renal imaging
   c. Placement of Foley catheter
   d. Placement of left ureteral stent
   e. Surgical revision

9. A 53-year-old man undergoes an elective left open partial nephrectomy for a 4.1-cm upper pole renal mass. He stopped aspirin 9 days before the operation. During surgery, the renal artery is clamped, but the renal vein is not. On renal incision, brisk bleeding occurs. The position of the arterial clamp is confirmed. Hilar palpation and dissection does not reveal additional arteries. The next maneuver is:
   a. Clamp renal vein
   b. Manual compression, proceed with partial nephrectomy
   c. Intraoperative duplex ultrasound, identify additional arteries
   d. Pedicle clamp
   e. Nephrectomy

10. A 55-year-old man undergoes a complex, elective, right partial nephrectomy for a 5.8-cm renal tumor, abutting the lower pole renal sinus. He presents with fever and fluid draining from his incision 11 days after surgery. Evaluation confirms a urine leak, with a 15-cm

urinoma around the lower pole resection bed and proximal ureter. Following drainage, the leak persists, so a ureteral stent and urethral catheter are placed.The leak persists at high volume 6 weeks postoperatively, with stent, drain, and urethral catheter in place. A CT urogram demonstrates an infarcted posterior segment and lower pole, but good perfusion and function of the remaining segments. The next step is:

a. Instill sclerosing agents into the drain
b. Place an additional percutaneous drain
c. Place percutaneous nephrostomy
d. Revision of partial nephrectomy, collecting system repair
e. Right nephrectomy

Answers

1. **d.** In cases of delayed bleeding (hematuria or flank hematoma) after discharge from the hospital, angiography should be performed early because of the high likelihood of an arteriovenous fistula or a pseudoaneurysm. If there is a low index of suspicion or if the bleeding is minimal and the patient is hemodynamically stable, you could first perform a duplex ultrasound or MR angiogram, because these methods are less invasive. If an abnormality is not seen and bleeding persists, angiography would be required anyway. Selective angioembolization is extremely effective in the management of these complications.
2. **d.** The films demonstrate an infarcted anterior segment, likely due to an unrecognized ligation or injury of the anterior segmental arterial branches. In performing partial nephrectomy, injury to deep blood vessels within the kidney may result in infarction of renal tissue beyond the renal defect. Although the functional significance of infarction is not known, infarcted tissue will likely decrease the preserved renal reserve over time. Large infarcted segments can result in renin-mediated hypertension, and if a large portion of the repaired collecting system loses its blood supply, it can promote a leak.
3. **b.** Polar renal arteries typically supply a small portion of the kidney, but they greatly reduce renal mobility. In exposing an upper pole tumor, an upper pole polar artery may greatly impair the ability to expose the resection bed. Division of the artery to improve mobility is advisable.
4. **c.** The presence of dense intraabdominal adhesion is a concern in this patient given his surgical and medical history. In cases of inflammatory bowel disease, injury to the bowel risks fistula and delayed abscess formation. As such, avoidance of the peritoneal cavity is desirable in this case. While a mini-flank incision may be feasible, its anterior location requires blunt colonic mobilization and is less desirable than a posterior, traditional flank exposure given the risks of adherence of the left colon and previous anastomosis. A retroperitoneal laparoscopic or robotic-assisted approach is also reasonable, depending upon the comfort level of the surgeon.
5. **e.** Intraoperative ultrasound is primarily used for mapping of the tumor intraoperatively, rather than the identification of additional tumors, as often thought. In this case, the hilar nature of the tumor creates concern regarding the relationship of the tumor to hilar vasculature, and this requires an assessment of the deep margin of the tumor. While angiography can be helpful in understanding vascular anatomy, it is usually not necessary given the availability of high-quality CT or MRI angiography, as needed. In this case, an angiogram would not likely add greatly to the arterial phase of the CT urogram, and retrograde pyelogram would not add greatly to the urographic phase. Intraoperative ultrasound is the most helpful test in planning the renal incision line.
6. **e.** The typical segmental arterial supply divides the kidney into apical, inferior, anterior apical, anterior inferior, and posterior segments.
7. **b.** For tumors located within 10 mm of the renal sinus, entry into, and identification of, the renal sinus can ensure an adequate resection margin. Biopsy of the resection bed is vulnerable to sampling error. The renal artery should be clamped in order to provide adequate vision to ensure resection in most cases. Not clamping the artery will not increase the likelihood of a negative margin.
8. **b.** In this case, the patient has a leak of moderate volume. It is most likely to resolve with adequate extrarenal drainage, as long as renal obstruction is not present. Renal imaging is important at the point that the leak is demonstrated to be persistent. Renal ultrasound, or cross-sectional imaging, can determine the presence of hydronephrosis, perirenal urinoma, or inadequate drain placement. In the case of hydronephrosis, a ureteral stent would be placed. In the case of perirenal urinoma, an additional percutaneous drain could be considered.
9. **b.** In this case, brisk ongoing bleeding requires some definitive intervention. Clamping the renal vein would likely worsen bleeding, as the described scenario is most suggestive of arterial bleeding due to the missed arterial branch. Intraoperative ultrasound would be unlikely to identify the location of an additional artery, though Doppler may, and would likely waste time, resulting in significant blood loss. While nephrectomy is always an option, the open approach allows the luxury of manual compression of the kidney. In most cases of polar tumors, manual compression would be sufficient to allow completion of the partial nephrectomy, without clamping of the unrecognized arterial supply.
10. **b.** Large volume leaks in the setting of infarcted kidney are unlikely to resolve if collecting system necrosis occurs as a secondary sequela. In this case, the lower pole central location of the tumor makes it likely that the lower pole collecting system, and/or proximal ureter, may have become ischemic with secondary necrosis. In this case, additional drainage is unlikely to resolve the leak, and revision would be extremely difficult, with high likelihood of failure. As such, given the elective nature of the initial partial nephrectomy, a nephrectomy would be the best option.

39 Complications of Adrenal Surgery

MICHAEL DANESHVAR and GENNADY BRATSLAVSKY

CHAPTER OUTLINE

General and Radiographic Workup and Adrenal Incidentaloma
Hyperaldosteronism
Cushing's Syndrome
Pheochromocytoma
Adrenal Carcinoma
Metastasis to Adrenal
Surgical Approaches and Intraoperative Complications
Basic Description of the Different Surgical Approaches
Partial Adrenalectomy
Postoperative Complications and Patient Management
Hyperaldosteronism
Pheochromocytoma
Cushing's Syndrome
Chapter 39 Questions and Answers

KEY POINTS

1. Management of incidental adrenal findings must be done in a stepwise fashion to properly diagnose the lesions.
2. With the advent of improved imaging techniques and laboratory tests, physicians are capable of making correct assessments and design management plans specific for suspected adrenal pathology.
3. Adrenal surgery carries a risk of various complications that can be avoided with proper preoperative preparation and intraoperative management.
4. The evolution of surgical management of adrenal masses has gradually changed from major open operation to minimally invasive laparoscopic and robotic-assisted surgery, offering improved convalescence without the morbidity of an open surgery.
5. For small adrenal masses partial adrenalectomy can offer excellent oncologic and functional outcomes and may be especially beneficial in select patients.

With the widespread use of cross-sectional imaging, the incidence of adrenal mass findings continues to increase with a prevalence of up to 4%.[1] Adrenal tumors are found in as many as 8% of autopsies.[2] While the exact size when the workup must be done is controversial, the NIH consensus and recent recommendation suggests the workup be performed for masses greater than 1 cm.[2,3] The most common scenario requiring an adrenal workup generally begins with the incidental finding of a mass on cross-sectional imaging of the abdomen or chest. In order to standardize the diagnosis and treatment of an adrenal mass, a proper workup must first be conducted (Fig. 39.1). However, there is no standardized protocol that exists and is uniform among physicians and institutions.

The initial goals of workup are based on determining if the lesion is an adenoma or not, and whether the mass is biochemically active. Functioning or biochemically active adrenal masses are those that are hormonally secreting lesions and include pheochromocytomas, aldosteronomas, and cortisol or androgen producing tumors. The nonfunctioning tumors are adrenal masses that are simply enlarged but do not have any increased hormonal activity and most commonly include lipid-poor adenomas or cysts.[4]

This chapter aims educate on the workup and intervention of adrenal masses and how to avoid the pitfalls in diagnosis and complications associated with the management of adrenal tumors.

GENERAL AND RADIOGRAPHIC WORKUP AND ADRENAL INCIDENTALOMA

The general diagnostic approach to adrenal lesions is usually based on three pillars: clinical suspicion, targeted imaging modalities, and hormonal evaluation. While history and clinical examination may provide a basis for suspicion, radiographic and hormonal evaluation should be conducted in order to categorize the lesion as likely benign or not and biochemically active or not. Clinical diagnosis and hormonal testing may require additional imaging prior to definitive treatment planning should the initial imaging be inconclusive. Prior to discussing the biochemical testing for a specific diagnosis, it is imperative to cover the available

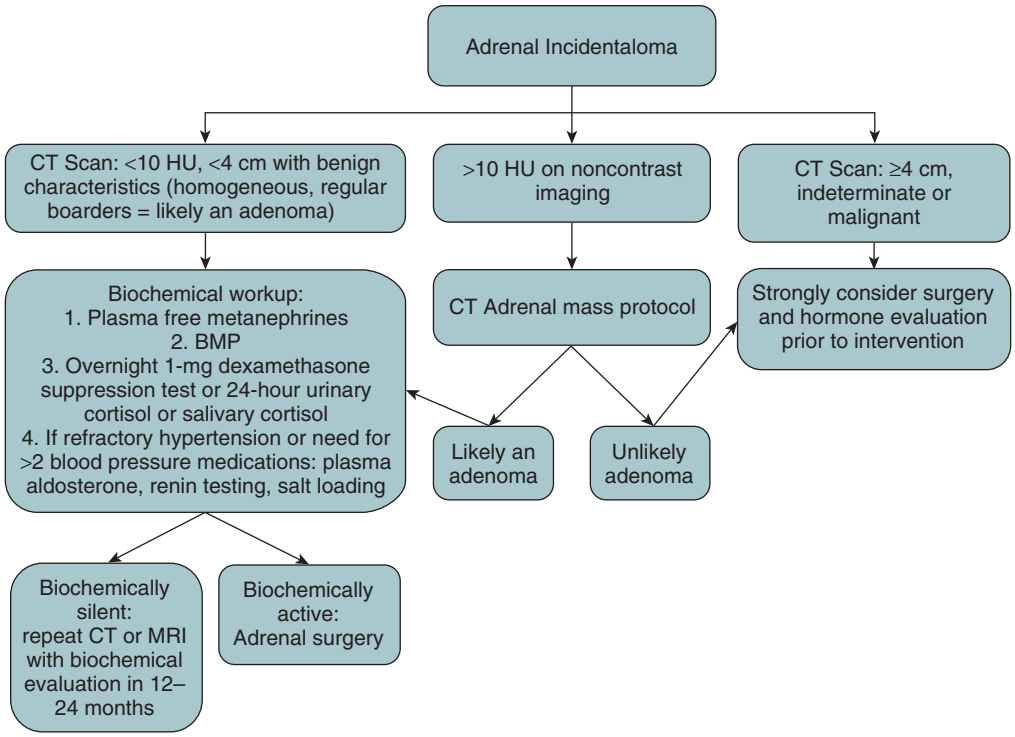

Figure 39.1 Diagnostic evaluation algorithm for a patient with an incidental adrenal finding. BMP, basic metabolic panel; CT, computerized tomography; HU, hounsfield unit.

radiographic imaging and its utility in the assessment of the adrenal lesion.

Radiographic studies play a crucial role not only in detection of adrenal lesions but also in characterizing these lesions as adenoma or suspicious for malignancy. Computerized tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET) scan are usually the three imaging modalities that detect adrenal abnormality.[1] Each of the modalities specifically exploit different physiologic principles necessary in the diagnosis of adrenal masses: identification of intracellular lipid concentration in a mass, percent washout or, and the metabolic activity.[5] First of all, the size itself may be quite informative. If the lesion in question is seen on imaging as larger than 4 cm in diameter, the likelihood of malignancy is increased and intervention may be indicated simply based on the size criteria alone.[4] The rate of growth of the adrenal mass may also be informative, as benign adenomas will grow slower than malignant tumors.[6,7] As with any other tumors, consistency (cystic versus solid), shape, and contour of the tumor may be helpful, with benign lesions appearing smoother and better circumscribed compared to malignant tumors.

Among all modalities, the noncontrasted phase of CT is likely to be the most informative. In the case of attenuation of less than 10 Hounsfield units (HU) the probability of malignancy is minimal and the patient most likely has an adrenal adenoma.[8,9] If, however, attenuation of the adrenal gland on unenhanced imaging is greater than 10 HU, the index of suspicion for malignancy should be higher, and further radiographic workup should be performed. Should the patient have sufficient renal function, enhanced CT with a calculated washout will help differentiate lipid-poor adenomas from potentially more ominous lesions. A vast majority of adrenal adenomas have HU less than 10 while most carcinomas exhibit HU greater than 30 on unenhanced CT.[10,11] Of note, lipid-poor adenomas can also have values higher than 10 HU, indicating that many lesions with HU >10 are still benign.[12] Therefore an adrenal protocol CT (or alternatively MRI) is recommended.

Contrast-enhanced CT, MRI, or PET can help distinguish between benign and malignant lesions. In the case of the adrenal mass protocol CT, a noncontrasted phase is followed by contrasted phase and a 10- to 15-minute delay. In studies evaluating the rate of the enhancement loss at specific time intervals (contrast washout) the adenomatous lesions washed much faster when compared to nonadenomatous or malignant lesions. Some have demonstrated that the washout was observed at as early as 3 minutes.[5] Typically, over 50% of washout of contrast on 10-minute delayed CT is diagnostic of an adenoma.[4] Occasionally, when CT scan is indeterminate it is appropriate to utilize chemical shift MRI to further categorize the lesion.[13] Chemical shift MR imaging detects presence of a lipid within an organ and is regarded as a sensitive method for differentiating adenomas from metastases.[14,15] Typically, MR imaging is more costly and time consuming when compared to the ease of CT and is therefore utilized less often.[4] Lastly, PET scan (using fluorine-18 fluorodeoxyglucose or FDG) can be helpful in selected cases to identify the metabolic activity and exploring the differences of lower activity of benign tumors versus more metabolically active malignant lesions based on glucose utilization and differential FDG uptake.[4]

Additional PET agents are becoming useful in further workup and differentiation of adrenal masses.[16]

Ultimately, the radiographic portion of the adrenal workup will guide the index of suspicion for benign or malignant etiology. Metabolic workup will ultimately provide a more definitive diagnosis. Occasionally, however, the definitive diagnosis is only possible after surgical removal.

HYPERALDOSTERONISM

Aldosterone-producing adenomas (APAs) constitute approximately 2% of incidentally discovered adrenal masses.[12] While often nonspecific, symptoms can range from muscle cramping, weakness, headaches, and polydipsia associated with polyuria. Patients with APA may have hypertension that is refractory to treatment by multiple (usually three) antihypertensive medications. In addition, some, but not all, may exhibit hypokalemia (usually serum potassium <3.5 mEq/L) and hypernatremia.

Identification of an adrenal mass in a hypertensive patient presenting with refractory hypertension or hypertension requiring several types of medication usually leads to further workup for APA. The diagnosis of APA or hyperaldosteronism itself consists of a two-step approach with screening and confirmatory testing.[17] First, the calculated ratio of plasma aldosterone concentration (PAC ng/dL) to plasma renin activity (PRA ng/mL) is performed. To increase the specificity further, PAC to aldosterone renin ratio (ARR) can be obtained.[18,19] Since the levels of renin and aldosterone may be affected by numerous medications, it is important that the screening test is conducted properly. Several types of medications that are mineralocorticoid receptor blockers such as spironolactone and eplerenone must be stopped 4–6 weeks prior to screening.[20] When drawing blood samples for suspicion of APA, the ARR is the most sensitive test. The labs should be drawn in the morning after the patient has been out of bed for over 2 hours and seated for 5–15 minutes.[20]

After the initial plasma levels of aldosterone and renin are obtained, further testing is done by salt loading.[20] This can be performed by measuring 24-hour urinary aldosterone levels after either consuming one teaspoon of salt with the addition of salty foods for a period of 72 hours or by saline suppression testing where isotonic saline is infused at 300–500 mL/h for a total of 4 hours. Extra caution should be exercised in patients with heart failure, severe hypertension, and those who are already taking multiple antihypertensive medications. Failure to suppress 24-hour aldosterone levels to normal levels after the salt loading confirms diagnosis of primary aldosteronism.

Finally, after the diagnosis of primary aldosteronism based on clinical and laboratory tests, the treatment plan is paramount. While cross-sectional imaging (usually with CT) is quite helpful in defining the location of the adrenal nodule, adrenal vein sampling (AVS) is mandatory for lateralizing the disease and distinguishing between unilateral and bilateral processes.[21] This is done to avoid subjecting the patient to erroneous removal of a nonfunctioning adenoma on the wrong side, while the micronodular hyperplasia of the adrenal (not readily seen on cross-sectional imaging) may be producing the aldosterone. The most optimal setting to perform AVS is in the morning and in the fasting state. Failure to lateralize with the use of AVS may lead to improper surgical or medical treatment of APA. One study in particular showed that when CT alone was utilized to establish laterality without AVS, 25% of patients underwent unnecessary or inappropriate adrenalectomy.[21–23]

When the decision to operate has been made, preoperatively patients should be started on a mineralocorticoid receptor antagonist. This approach not only corrects the preoperative hypokalemia but also controls the hypertension. Finally, while working on the diagnosis of primary aldosteronism, we must also be aware that secondary aldosteronism may be seen in patients with renal artery stenosis, malignant hypertension, pregnancy, heart failure, and cirrhosis.

CUSHING'S SYNDROME

Cushing's syndrome is characterized by glucocorticoid excess and exhibits the typical signs and symptoms of hypercortisolism. From a careful history of the patient the following can be elicited: fatigue, sleep disturbances, depression, weight gain, hypertension, and easy bruising. On physical exam patients present with central obesity, facial plethora, thinned skin, acne, striae, hirsuitism, and proximal muscle weakness and wasting. Since the most common cause of glucocorticoid excess is usually from exogenous steroid intake, thorough investigation by the physician should be done to rule out potential iatrogenic sources of cortisol excess.

While clinical diagnosis is an integral part of the Cushing's syndrome diagnosis, biochemical evaluation is paramount and involves screening and confirmatory testing. There are three simple screening tests that can be used for early suspicion of hypercortisolemia. The first of these tests is the late-night salivary cortisol test used for screening Cushing's syndrome. A specimen of saliva is collected at bedtime in patients with a regular sleep pattern and tested in a laboratory. The sensitivity and specificity for diagnosing Cushing's syndrome approaches 90–95% if the nighttime cortisol levels are elevated.[24] Alternatively, the overnight 1-mg dexamethasone suppression test (DST) is used. This test is performed by administering 1 mg of dexamethasone at 11 p.m. and testing for plasma cortisol levels the following morning at 8 a.m. The DST is also used to differentiate between Cushing's syndrome and Cushing's disease (when 8 mg of dexamethasone is used).[25] The third screening tool is the 24-hour urinary free cortisol (UFC) level. Any of the above three tests must be done in a systematic and timely fashion to be accurate and avoid false results or erroneous diagnosis.

Once elevated levels of cortisol are demonstrated in the setting of Cushing's syndrome (and Cushing's disease is appropriately ruled out), proper preoperative planning is crucial. Patients with diabetes and hypertension must be managed appropriately. Because of possible immunosuppression as a result of long-standing elevated levels of cortisol, care must be taken with prophylactic preoperative antibiotics. Due to long-standing suppression of the hypothalamic pituitary axis, imaging may depict a contralateral adrenal gland that is atrophied. In all cases, a stress dose of steroids should be administered preoperatively with a careful taper.[26]

Table 39.1 The Recommended Conditions of Biochemical Testing

Patient preparation	Avoid sympathomimetic agents (including ephedrine, amphetamine, nicotine) Avoid interfering medication (including labetalol, sotalol, acetaminophen, methyldopa, antidepressants) Overnight fast, no caffeinated or decaffeinated beverages
Conditions for blood sampling of metanephrines	Supine condition, after 30 minutes' rest[a] Collection in heparinized tubes on ice Storage of plasma in freezer at –20°C if measured within 3 months
Conditions for urine sampling of metanephrines	Collection in a container without additives or eventually only sodium bisulphate Storage of urine container in a cold place Acidify urine in the laboratory to pH 4 before storing

[a]If a blood sample is taken in the sitting position and the test result is positive: repeat after 30 minutes' supine rest

(Van Berkel A, Lenders JW, Timmers HJ. Diagnosis of endocrine disease: biochemical diagnosis of phaeochromocytoma and paraganglioma. Eur J Endocrinol. 2014;170(3):R109-R119.)

PHEOCHROMOCYTOMA

Patients who present with severe, episodic hypertension, palpitations, tachycardia, anxiety attacks, weight loss, sweating and facial flushing on physical exam should be suspected to have pheochromocytoma. The patient's family history is also important as pheochromocytoma does not only occur sporadically but can be inherited or associated with several genetic syndromes, such as von Hippel-Lindau (VHL) disease, multiple endocrine neoplasia type II (MEN), familial paraganglioma syndrome, neurofibromatosis (NF-1), and succinate dehydrogenase deficiency syndrome of subunits B, C, or D (SDHB, SDHC, or SDHD).

First, biochemical evidence of the disease is confirmed with testing of plasma free metanephrines. In one study, sensitivity and specificity of this test were 96–100% and 87–92%, respectively.[27] While the plasma free metanephrines is the most sensitive test, care must be taken when collecting these samples. There are numerous pitfalls that may affect the results of the testing (Table 39.1). Usually, patients must have an IV inserted and be placed supine in a quiet room for 30 minutes. Any pain or anxiety may significantly affect the results of the test. Additionally, patients should be instructed to avoid any caffeine intake for at least 24 hours and avoid the medications listed in Box 39.1. Perhaps, the most important and common medications to remember are acetaminophen, trycyclic antidepressants and decongestants. Alternatively, (although now used less commonly) 24-hour urine collection for urine metanephrines and vanillylmandelic acid (VMA) testing can be performed. While the test is less sensitive than plasma free metanephrines, it is more specific (VMA specificity 93–97%).[27]

With a high suspicion on clinical exam and confirmation by biochemical workup, the next step in workup of pheochromocytoma is often a combination of anatomic and functional imaging. In the past, contrast enhanced MRI was the preferred method of anatomic imaging in suspected

Box 39.1 Medications That May Cause False-positive Results for Catecholamines and Metanephrines

Tricyclic antidepressants and antipsychotic agents
Levodopa
Drugs containing catecholamines
Ethanol
Withdrawal from clonidine and other drugs
Acetaminophen and phenoxybenzamine (plasma metanephrines)
Labetalol and sotalol

cases of pheochromocytoma for fear of inducing adrenal crisis with the use of iodinated contrast in enhanced CT scanning.[28] Now, however, CT with nonionic iodinated contrast is safe and provides excellent anatomic details. MRI (often bright on T2 sequence) is still a useful imaging modality in patients who have previous allergic responses to contrast mediums, in pregnant women, and in children being scanned.[29,30] Several functioning radiographic studies such as metaiodobenzylguanidine (MIBG) and various types of PET scans are available. Although the detailed review of every imaging modality for pheochromocytoma is beyond the scope of this chapter, care must be taken in those undergoing MIBG scanning by providing patients with super saturated potassium iodide (SSKI) drops to be taken prior to exposing patient to radioactive iodine (thyroid protective measures).

The importance of preoperative preparation for surgical treatment of pheochromocytoma cannot be overstated. It includes patient compliance, preoperative echocardiogram (to evaluate the cardiac function and rule out cardiomyopathy), and evaluation by anesthesiology team. Medical preparation involves the liberal use of α-adrenergic blockade with phenoxybenzamine 10 mg BID with a slow increase in dose over 2–3 weeks prior to surgical intervention. The recommended dose of phenoxybenzamine starts at 10 mg BID and should be titrated up to as high as 400 mg daily until the patient becomes orthostatic or profound side effects become intolerable (such as tachycardia or nasal congestion). In cases of tachycardia, beta-blockers can be added, but should only be added after the adequate alpha blockade. Metyrosine (α-methyltyrosine) 250 TID to increase to 1.5 g in divided doses can also be used as an adjunct to phenoxybenzamine in preparation for surgery. Metyrosine inhibits tyrosine hydroxylase, the rate-limiting enzyme in the catecholamine synthesis cascade. Finally, patients are also encouraged to prepare with adequate fluid and salt intake to volume expand and compensate for the vasoconstrictive effects of pheochromocytomas and intravascular volume depletion.[31]

ADRENAL CARCINOMA

Adrenocortical carcinoma (ACC) is a rare but aggressive tumor with a poor prognosis.[32] Two-thirds of all ACCs are found to be hormonally active, and approximately 25% are found to be >6 cm on diagnostic imaging.[33,34] As discussed

earlier in this chapter, when an incidentaloma is found with an attenuation of greater than 10 HU on noncontrasted CT, the suspicion for ACC should be present. The suspicion is even greater when the mass is large (>6 cm) or has attenuation of >30 HU on noncontrasted CT.[12] Clinically, patients may complain of flank pain, abdominal discomfort, or pressure with no specific symptoms due to the mass compression of adjacent abdominal structures or organs. Hormonally active tumors may present with symptoms such as virilization, hypercortisolism, or feminization. Therefore, similar to other adrenal masses, evaluation of ACC includes the assessment of hormonal activity. Biochemical workup must include thorough hormonal evaluation prior to surgical intervention as stress steroids may need to be administered preoperatively or repleted postoperatively to prevent adrenal insufficiency or addisonian crisis. On imaging studies, several characteristics of tumors may lead to higher suspicion of malignancy such as irregular tumor shape and enhancement with lack of homogeneous patterning of the tumor due to areas of focal necrosis. If there is a high suspicion for ACC, a metastatic workup is also indicated preoperatively. Preoperative planning involves an assembly of an experienced team of radiologists, surgeons, and anesthesiologists, and a great deal of planning from identifying surgical landmarks (as some tumors may invade surrounding structures or organs) to adequate vascular access and adequate amount of blood products available.

METASTASIS TO ADRENAL

One common pitfall in the workup of an adrenal mass is failure to identify metastasis from a primary tumor. Although primary adrenal masses are most common, adrenals are also a common site of metastasis.[35,36] Once metastasis is essentially ruled out, different diagnostic practices will guide a step-by-step workup of an adrenal mass (see Fig. 39.1). Conversely, a suspicion of metastasis should not preclude one from completion of biochemical interrogation of the adrenal mass. For example, one study evaluated patients with a history of primary tumors and suspected adrenal metastasis and found that as many as 24% of those adrenal masses were pheochromocytoma.[37] This further underscores the importance that any adrenal mass should have a biochemical workup.

Most Important Preoperative Considerations and Tips

1. For patients with suspected aldosterone-producing adenoma it is crucial to complete the selective adrenal vein sampling as the presence of a nodule on the adrenal and elevated levels of aldosterone are **NOT** diagnostic of laterality in patients with Conn's disease. We recommend performing selective adrenal vein sampling because the imaging may reveal an adrenal nodule that may be a nonfunctional adenoma, while the functional microadenoma(s) may be present in the radiographically normal contralateral adrenal gland. Therefore selective adrenal vein sampling is paramount in avoiding a wrong-sided surgery.
2. For patients with suspected cortisol-producing adenoma, the appreciation of long-term effects of steroid excess is crucial. Meticulous attention to preoperative blood pressure control and antibiotic administration due to the chronic immunosuppressive effects of steroid administration is essential. The most important prevention of unexpected intraoperative and postoperative complications is the preoperative administration of a stress dose of steroids as the contralateral adrenal gland is often suppressed. Careful taper perioperatively should allow for tight blood pressure control with the avoidance of an addisonian crisis while allowing the contralateral adrenal gland to regain its function and to recover from the suppression due to the steroid excess.
3. For patients with suspected pheochromocytoma the importance of preoperative blockade cannot be over emphasized. Perhaps the most important concept is that the perioperative blockade (most commonly with alpha-blockers, specifically phenoxybenzamine) should be titrated until systolic blood pressure falls below 100 or the patient becomes orthostatic and/or tachycardic. Only at this time should beta-blockade be added. Volume expansion is often done concomitantly with a high sodium diet and large oral fluid intake for the duration of the blockade. Occasionally patients have to be admitted for IV fluid hydration and blood pressure (BP) monitoring. Finally, because of the potential for catecholamine-induced cardiomyopathy, preoperative echocardiogram is recommended to obtain a baseline cardiac function as cardiomyopathy has been demonstrated to occur even in children and young adults. Preoperative knowledge of cardiac function will later help with intraoperative and anesthetic management.
4. Prior to any procedure, a conversation with the anesthesiology team is crucial so as to have appropriate drips, drugs, and expectations for the potential intraoperative complications or blood pressure issues that may arise. Our typical setup (Fig. 39.2) for expected complicated pheochromocytomas includes the following configuration and drips: vasopressin, phenylephrine, norepinephrine, esmolol, nitroprusside, and nitroglycerin. While all of these medications may not be needed, having them readily available, especially for complex patients with poorly controlled hypertension, may be life-saving. Finally, once the pheochromocytoma is removed, the team may have to recognize the earliest signs of blood pressure drop requiring the administration of pressors and boluses of IV fluids. Again, the better the preoperative blockade, the safer the operation.

Figure 39.2 Typical setup for pheochromocytoma surgery with multiple drips.

Surgical Approaches and Intraoperative Complications

Surgical complications for any operative approach or technique are diverse. The most common complications are hemorrhage, adjacent organ injury, infection, postoperative wound healing, and pulmonary problems. Surgical intervention, regardless of method of approach, requires attention to the surrounding anatomy of the adrenal gland and its vasculature. Therefore it is imperative to be well acquainted with adrenal anatomy and surrounding structures prior to surgery.

Adrenal surgical techniques have evolved with the use of laparoscopic and robotic surgery. While no technique completely avoids surgical complications, recent studies have shown that most adverse outcomes are decreased by the use of minimally invasive surgery.[38] These new techniques now serve as adjuncts to the open surgical approach used for the past several decades.[30] This section will describe the different surgical approaches and identify the most common complications faced during adrenal surgery.

BASIC DESCRIPTION OF THE DIFFERENT SURGICAL APPROACHES

Adrenalectomy can be performed in either a transperitoneal or retroperitoneal approach. The underlying pathologic process of the adrenal tumor and surgeon's preference usually dictate the different surgical approaches. Both the transperitoneal and retroperitoneal approaches can be performed via open or minimally invasive approaches. Open transperitoneal approach includes midline, thoracoadbominal, or subcostal incisions. The subcostal anterior approach is an excellent option for large tumors and offers a wide operative field favorable for large unilateral tumors.[39] It can also be used for bilateral tumors with extension by chevron incision to adequately reach both adrenal glands. The thoracoabdominal approach is the most invasive method of gaining access to the adrenals. While the thoracoabdominal approach is used for large tumors or invasive ACC, historically it has caused prolonged ileus due to intraabdominal organ manipulation, increased pain from incision location, and pulmonary morbidity necessitating chest tube placement.[40,41] Additionally, when utilizing the transperitoneal approach, irrespective of open or minimally invasive, the tail of the pancreas may be injured during dissection from the adrenal gland. This warrants placement of a drain for postoperative fluid analysis and diet modification accordingly (from low-fat diet to total parenteral nutrition (TPN) and octreotide).[42] The retroperitoneal approach is achieved via flank and posterior lumbodorsal incisions. Retroperitoneal surgery offers the advantages of less intraabdominal organ manipulation and therefore less postoperative ileus. Retroperitoneal surgery may also be advantageous in the setting of previous abdominal surgery in which adhesions may complicate or limit a transabdominal open or minimally invasive approach.[28] Of importance, when patients are obese, a flank position in both the open and laparoscopic approach will allow the pannus to fall away and thus will make incision or placement of instruments easier.[25]

With the advent of minimally invasive techniques, fewer and fewer adrenal surgeries are performed via the open approach. In a recent meta-analysis that included 600 patients from eight retrospective studies and one randomized control trial, Brandao et al. found a significantly shorter hospital stay and less estimated blood loss with robotic adrenal surgery compared to laparoscopic method.[38] Similar to the study by Brandao et al., recent studies have shown that robotic adrenal surgery is associated with less blood loss, while the surgical time is dependent on surgeon experience in relation to laparoscopic adrenalectomy.[43] Additionally, among the choices of minimally invasive approaches, some argue that a transperitoneal approach affords a larger work space with a more familiar approach to the abdomen and may permit easier removal of large masses when compared with a retroperitoneoscopic approach that offers a smaller working space with a less familiar view of the retroperitoneum as compared with the transabdominal approach.[27,29]

Nevertheless, regardless of the approach, both laparoscopic and robotic adrenal surgical techniques are safe and effective surgical options with improved outcomes of patient satisfaction, shorter postoperative hospitalization, and reduced surgical pain compared to open surgical techniques.[44,45] When comparing the two minimally invasive techniques, robotic adrenal surgery has the advantage of three-dimensional surgeon vision compared to the two-dimensional view of laparoscopic surgery, a stable surgical platform, and improved ergonomics.[46] However, robotic surgery cannot be performed without the advanced surgical training of the operator and the assistance of a robotically trained operating room team. Despite advantages of minimally invasive surgery, open technique is still reserved for large adrenal tumors or tumors with high suspicion of being ACC based on preoperative workup, especially if there is a suspicion of the adjacent organ or structure involvement. Occasionally, conversion from minimally invasive to open approach is necessary to facilitate en bloc resection of the tumor with regional lymphadenectomy and resection of any involved organs. This further underscores the importance of the surgeon's versatility in open skills (as with any minimally invasive operation). Large tumors, for example, that are concerning for ACC may require resection or partial resection of surrounding organs along the inferior vena cava.[47] Therefore, meticulous surgical planning should be conducted prior to making an incision.

PARTIAL ADRENALECTOMY

Partial adrenalectomy can be achieved by any of the above approaches used for total adrenalectomy. Recently, partial adrenalectomy has gained much popularity and attention due to its potential long-term benefits and proven functional outcomes. While initially reserved for patients with bilateral adrenal involvement or in those at risk for bilateral adrenal loss due to various hereditary disorders, new data suggest that partial adrenalectomy may be utilized for small solitary lesions in patients with a normal contralateral adrenal gland.[48] Recent reviews evaluating disease of the adrenal suggest that after the exclusion of those patients at risk for bilateral adrenal pathology due to genetic risks, the life-time risk to a contralateral adrenal is about 1%.[49] While originally performed with an open approach, recent literature

indicates a shift from open to minimally invasive techniques.[48] Robotic and laparoscopic partial adrenalectomy have changed adrenal surgical intraoperative and postoperative outcomes. In fact, the use of robotic surgery in partial adrenalectomy allows the surgeon to utilize the robotic arms in addition to an assistant for adequate exposure when compared to traditional laparoscopy.[50] Exposure and ability of the robot to articulate its wrists in limited space allow for minimal mobilization and manipulation of tumor during removal while likely preserving the delicate blood supply of the remnant adrenal gland.[50] Size of the tumor, timing for intervention, and location of the tumor also play a role in the decision to conduct partial adrenalectomy.[51] Box 39.2 summarizes surgical complications from partial adrenalectomy. Overall, the morbidity of partial adrenalectomy does not supersede that of total adrenalectomy with the overall complication rate about 3%.[48] One notable drawback of partial adrenalectomy is a possibility of development of a new lesion or recurrent disease. In the largest review to date that evaluated the outcomes of partial adrenalectomy, the rate of recurrence was found to be only 3%, with the vast majority of the patients not requiring chronic postoperative steroids.[48] Pedziwiatr et al. suggested that when conducting robotic or laparoscopic adrenalectomy, the risk of complications depends on many variables (not only operator and the surgical team involved), and these complications do not and should not be different for partial adrenalectomy procedures.[52] Interestingly, long-term outcomes for partial adrenalectomy are quite encouraging.[48,51] It is possible that with further acceptance of partial adrenalectomy, this procedure may become a standard of care in the majority of patients with small adrenal masses.

Most Important Intraoperative Considerations and Tips

1. In cases of right adrenal surgery we prefer to proceed with a minimally invasive transperitoneal approach because of the ease of the right adrenal gland access, familiarity of anatomy, and a larger working space. Cephalad retraction of the liver with division of the right lateral triangular ligament while the patient is in the flank position with slight Trendelenburg allows for an immediate approach to the adrenal mass. Of note, no mobilization of colon or kidney or dissection of renal vasculature is required with the first move directed toward the incision of the adventitia over the inferior vena cava (IVC). Because of the lateral decubitus positioning, the normal origin of the posterolateral short right adrenal vein shifts to a more anterolateral location, making its identification, division, and ligation quite simple. One Weck clip on each end should allow for a bloodless operation. In cases of partial adrenalectomy on the right side, the adrenal parenchyma can be clipped using Weck clips allowing for excellent hemostasis and visualization. Should any bleeding be encountered, a suture ligature can be utilized on the caval end or additional clips or even LigaSure can be applied on the side of the adrenal gland.
2. In the cases of left adrenal surgery, we also prefer the transperitoneal, minimally invasive approach. Unlike the surgery on the right side, we perform a mediovisceral rotation with mobilization of the left colon, spleen, and pancreas to allow for the visibility of the left adrenal gland. Identification of the left renal vein allows for easy and early recognition of the left adrenal vein. Unlike in the typical illustrations of the anatomy texts, there are usually more than one adrenal vein originating from the left renal vein. These can be easily ligated and divided to avoid any bleeding complications. Additional blood supply originating from the aorta, phrenics, or running within Gerota's fascia can be easily controlled using Weck clips or even a bipolar instrument. Perhaps one of the most technically important moves during left adrenal surgery is the division of the left lateral attachments of the spleen to allow the spleen to flip toward the right part of the abdomen, frequently allowing visualization of the stomach. With the patient in the lateral position, the spleen, pancreas, and the left viscera are kept self-retracted by their own weight. Hugging Gerota's fascia during the mediovisceral rotation assures avoidance of injury to the colon, pancreas, spleen, or splenic vessels.

Postoperative Complications and Patient Management

General postoperative surgical management guidelines apply to postadrenalectomy and partial adrenalectomy patients regardless of the approach. These recommendations include early ambulation, subcutaneous heparin, and sequential compression devicess for deep vein thrombosis prophylaxis, the use of an incentive spirometer, and adequate pain control. Postoperative vitals and labs including blood counts and electrolytes should be carefully monitored. Most recommend ICU or close level monitoring after adrenal surgery for functional masses to allow for immediate recognition of the addisonian crisis and the opportunity for rapid intervention if needed.[53] While usual surgical complications, such as bleeding, infection, damage to adjacent structures and organs, or pneumothorax can be seen with all types of adrenal tumors, a specific recognition of disease-specific complications is paramount (Boxes 39.3, 39.4).

HYPERALDOSTERONISM

Postoperative management for patients with APA entails monitoring electrolytes and achieving normokalemia with potassium chloride supplements and blood pressure

Box 39.3 Complications of Complete Adrenalectomy

Lack of endogenous steroid production
Steroid dependence, with dosing adjustment issues
  Mood changes, diarrhea, abdominal distention, nausea, dyspepsia, increased appetite, peptic ulcers, adrenal suppression, candidiasis, hirsutism, increased intraocular pressure, immunosuppression, hypertension, edema, hypokalemia
Increased fatigue
Decreased resistance to stress and infection
Increased risk of osteoporosis
Uncontrolled weight gain

(Modified from Kaye DR, Storey BB, Pacak K, Pinto PA, Linehan WM, Bratslavsky G. Partial adrenalectomy: underused first line therapy for small adrenal tumors. J Urol. 2010;184(1):18-25.)

Box 39.4 Postoperative Complications of Adrenal Surgery

Primary Aldosteronism

Hypokalemia: secondary to continued potassium loss immediately postoperatively
Hyperkalemia: secondary to failure of contralateral adrenal gland to secrete aldosterone

Cushing's Syndrome

Inadequate steroid replacement leading to hypocortisolism
Fracture secondary to osteoporosis
Hyperglycemia
Poor wound healing
Increased risk of infection

Pheochromocytoma

Hypotension secondary to α-adrenergic blockade after tumor removal

Generic Complications

Hemorrhage
  Inferior vena cava
  Adrenal arteries
Pneumothorax
Pancreatitis
Pneumonia
Hiccups

(From Vaughan ED Jr. Complications of adrenal surgery In: Taneja SS, RM Ehrlich RM, Smith RB, eds. Complications of Urologic Surgery. 3rd ed. Philadelphia; WB Saunders; 2000:362-9.)

monitoring for risk of hypotension. Antihypertensive medications can be weaned based on blood pressure monitoring, and mineralocorticoid receptor antagonists can be stopped. One rare complication to be aware of is the postoperative paradoxical effect of salt wasting and hyperkalemia as a result of the contralateral adrenal efforts to compensate for the hyperfunctioning gland.[54]

PHEOCHROMOCYTOMA

Patients who undergo adrenalectomy or partial adrenalectomy for pheochromocytoma should receive postoperative monitoring in the surgical intensive care unit for blood pressure control and occasionally hypoglycemia. Side effects of the surgery will largely depend on the quality of preoperative blockade and occur due to the rapid withdrawal of excess catecholamines.[55] Volume status is carefully monitored and IV fluids are slowly decreased postoperatively to allow for intravascular volume to be adequately equilibrated. The preoperative blockade is stopped immediately after the surgery.

CUSHING'S SYNDROME

Negative feedback from a hyperfunctioning adrenal gland with overproduction of cortisol inhibits the production of adrenocorticotropic hormone (ACTH) by means of inhibition of the hypothalamic pituitary axis (HPA). This in turn may cause the contralateral adrenal gland to atrophy. Therefore glucocorticoid must not only be administered preoperatively but be adequately replaced postoperatively to compensate for the lack of contralateral adrenal gland production. Initially, it is recommended to administer high stress doses of the steroid medications with tapering thereafter. The process of adequate replacement must continue until the HPA axis and contralateral adrenal gland are functioning in synchrony, which sometimes may take up to several months.[20] The cosyntropin test can measure the response of the adrenal gland to ACTH stimulation and be a good indicator for the ability to taper the steroids off.[56] In the case of bilateral adrenalectomy for Cushing's disease, patients may require lifelong corticosteroid replacement. In the postoperative period these patients should be monitored closely due to their propensity of wound healing complications and risk of infections. Side effects similar to Cushing's disease may be seen with long-term steroid replacement and include osteoporosis resulting in pathologic fractures, as well as obesity, growth retardation in children, diabetes, and ophthalmologic problems.[57,58]

Most Important Postoperative Considerations and Tips

1. Strongly consider ICU or step-down after any adrenal surgery because of the potential for postoperative hypotension and the need for frequent monitoring of vital signs.
2. In case the patient exhibits signs of hypotension, in addition to IV boluses of fluid and routine postoperative labs, the administration of steroid bolus (100 mg hydrocortisone) should be performed. The importance of communication with house staff or physicians caring for the patient in the perioperative period cannot be overemphasized.
3. In cases of long-standing hypercorticosolemia in patients undergoing a rapid steroid taper or any patient undergoing surgery for any pathology on a solitary adrenal gland a cortisol stimulation test should be strongly considered to evaluate for an adrenal response to adrenocorticotropic hormone (ACTH) stimulation.
4. When discharging patients that underwent surgery after prolonged hypercorticosolemia or in the case of a solitary adrenal gland a prescription for hydrocortisone 20 mg should be given with patients being instructed to carry this medication with them at all times and immediately take 20–60 mg orally should they feel weakness or any suspicion of low blood pressure or symptoms consistent with addisonian crisis at the time of any illnesses, trauma, or potentially other surgeries. These patients need to communicate

their potential risk for the addisonian crisis with every health-care provider they encounter in the future and remain vigilant about their condition even in the case of relatively minor stress such as a simple cold or infection.

Key Points of Adrenal Surgery: Prevention of Complications

1. Know what you are dealing with (complete the metabolic workup).
2. Do not forget to get a washout evaluation in tumors with greater than 10 HU on noncontrasted computerized tomography.
3. Suspect metastasis in every adrenal tumor in a patient with a history of other cancer, but do not forget that primary adrenal tumors can still form in cancer patients (complete the metabolic evaluation).
4. Do not forget to block patients for pheochromocytoma (start with alpha blockade first).
5. Obtain adequate IV access for all adrenal surgeries.
6. Do not forget to give stress dose steroids for those with cortisol-secreting tumors, and taper off carefully postoperatively.
7. Watch for a short right adrenal vein originating posterolaterally from the inferior vena cava during right-sided adrenal surgery.
8. Strongly consider ICU postoperatively and recognize adrenal crisis in postoperative patients who become hypotensive and do not respond to IV fluid resuscitation (use stress dose steroids).
9. Consider adrenal preservation even in those with a normal contralateral adrenal gland (partial adrenalectomy).

Chapter 39 Questions

Case Study 1

A 28-year-old female with a history of high blood pressure presents to the clinic with palpitations, anxiety, headachec and facial flushing. Her recorded blood pressures are generally around 160/90. Routine blood tests are normal.

1. What is the best initial screening test to evaluate this patient's condition?
   a. Adrenal venous sampling
   b. 24-hour urine catecholamines
   c. Dexamethasone suppression test (DST)
   d. Clonidine suppression test
   e. Plasma free metanephrines

2. What is the test with the highest specificity for this patient's condition if the above test is positive?
   a. Plasma free metanephrines
   b. 24-hour urinary catecholamines
   c. MIBG scan
   d. MRI abdomen and pelvis
   e. Adrenal venous sampling

3. Which of the following will not significantly affect plasma levels of metanephrines during the screening of pheochromocytoma?
   a. Tylenol
   b. Motrin
   c. Caffeine
   d. Tricyclic antidepressants
   e. None of the above

4. The above confirmatory test is positive, and the patient has been scheduled for surgery. Which medication(s) below should be started preoperatively?
   a. Alpha-blockers
   b. Beta-blockers
   c. Metyrosine
   d. Beta-blockers followed by alpha blockade
   e. Beta-blockers with metyrosine

5. After the mass is removed, the patient's blood pressure drops to 80/40 intraoperatively. What is the best initial step in management?
   a. Aggressive hydration
   b. Alpha agonist
   c. Beta agonist
   d. Alpha and beta agonists
   e. Vasopressor support

Case Study 2

A 43-year-old male with a history of depression presents with increased upper body obesity, rounded face, and increased fat around the neck. He is concerned because he recently noticed these changes when looking at an old picture of himself in a photo album.

1. Which of the following tests is NOT indicated for initial screening of his disease?
   a. 1-mg dexamethasone suppression test
   b. 8-mg dexamethasone suppression test
   c. 24-hour urinary free cortisol level
   d. Late-night salivary cortisol
   e. a and c

2. The patient is eventually diagnosed with a cortisol producing adenoma that measures 2.3 cm, and he is taken to the operating room for a left robotic-assisted partial adrenalectomy. During the surgery, the anesthesia team reports challenges with ventilating the patient and you notice bellowing of the left diaphragm with limited visualization of the operating field. Your next step in management is:
   a. Changing the ventilator settings to pressure control mode
   b. Identify diaphragmatic injury, evacuate the air from the chest using laparoscopic suctioning, and repair the diaphragm
   c. Convert robotic procedure to open immediately
   d. Reposition the patient, place a chest tube, and complete the procedure in a minimally invasive fashion
   e. Have surgical team place a chest tube without repositioning the patient

3. Two weeks postoperatively the patient presents to the emergency room with nausea, abdominal pain, and fever. CT scan from the emergency room reveals a fluid collection that after drainage by interventional radiology appears milky and high in amylase. What is the next step in management?
   a. Instillation of a sclerosing agent into the drainage tract
   b. Bowel rest, TPN, and continue drainage
   c. Emergent exploration of suspected pancreatic injury
   d. Upper endoscopy and endoscopic retrograde cholangiopancreatography (ERCP)
   e. Medical admission for IV antibiotics

4. Ten years postoperatively the patient is found to have a 4.8-cm right adrenal mass that does not fit the characteristics of an adenoma on CT adrenal mass protocol and is also biochemically inactive. Luckily, there is an excellent left adrenal remnant that appears normal and you choose to proceed with a right adrenalectomy. As you dissect along the IVC, you expect to find:
   a. Short right adrenal vein posterolaterally
   b. Short right adrenal vein anterolaterally
   c. Long right adrenal vein posterolaterally
   d. Long right adrenal vein anterolaterally
   e. None of the above

Case Study 3

A 55-year-old man presents with a 2.3-cm incidental finding of adrenal mass on noncontrast enhanced CT of the abdomen and pelvis. The patient is normotensive and asymptomatic. The mass measures 5 Hounsfield units on noncontrasted imaging.

1. What is the next step in management?
   a. CT adrenal mass protocol
   b. Metabolic workup
   c. MRI abdomen/pelvis with contrast
   d. No further workup is necessary
   e. a and b

Case Study 4

A 63-year-old female presents with a 4.3-cm adrenal mass. She is asymptomatic. Biochemical workup is negative. CT adrenal mass protocol is done and shows an absolute washout of 20%.

1. What is the next best step in management of this patient's findings?
   a. T2-weighted MRI of the abdomen
   b. Metaiodobenzylguanidine scan
   c. Adrenalectomy
   d. Repeat biochemical workup
   e. Observation with repeat imaging in 6–12 months

Case Study 5

A 75-year-old male with a history of kidney cancer 2 years previously is found to have a 2.1-cm adrenal mass on surveillance CT scan.

1. The next step in management is:
   a. Adrenal mass biopsy
   b. Adrenal mass resection
   c. Metabolic workup
   d. Begin systemic therapy for kidney cancer
   e. Observation with repeat imaging in 6–12 months

2. After making the diagnosis of Conn's tumor, prior to taking a patient to the operating room, one must:
   a. Operate only on the site with the visible tumor
   b. Start the patient on alpha-blocker therapy preoperatively
   c. Salt load testing
   d. Perform adrenal vein sampling to lateralize the origin of the increased aldosterone secretion
   e. a and c

Answers

CASE STUDY 1

1. **e.** Plasma free metanephrines are the most sensitive initial screening test for pheochromocytoma.
2. **b.** The highest specificity or pheochromocytoma is 24-hour urine catecholamines.
3. **b.** NSAIDs will not significantly affect plasma levels of metanephrines.
4. **a.** Prior to surgery, first start alpha blockade followed by beta blockade.
5. **a.** Initial management for a drop in blood pressure that can occur after removal of a pheochromocytoma is aggressive fluid resuscitation.

CASE STUDY 2

1. **b.** Given the clinical history, initial testing can be with a 1-mg dexamethasone suppression test, a 24-hour urinary free cortisol level, or a late night salivary cortisol test.
2. **b.** Laparoscopic repair of the diaphragm after evacuating the air from the chest cavity is achievable with suction and closure of the defect.
3. **b.** The treatment strategy for a pancreatic leak includes bowel rest, TPN, and continued drainage of the collection.
4. **a.** The correct anatomy off of the IVC is a short posterolateral right adrenal vein.

CASE STUDY 3

1. **b.** Due to the HU being <10, further imaging is not indicated. But a metabolic workup should be completed.

CASE STUDY 4

1. **c.** Given the size >4cm, strong consideration should be given for removal of the mass which has risk for an adrenal carcinoma.

CASE STUDY 5

1. **c.** Metabolic evaluation is always recommended for adrenal masses.
2. **d.** It is important to determine laterality of these tumors prior to surgical intervention.

Vascular Injury
Complications of Inguinal Lymph Node Dissection
Cutaneous Complications
Lymphatic Complications
Deep Vein Thrombosis
Chapter 40 Questions and Answers

KEY POINTS

1. Lymphadenectomy is a critical component of surgery for many urologic malignancies, providing both therapeutic and diagnostic benefit.
2. A comprehensive knowledge of retroperitoneal and pelvic anatomy is paramount in avoiding serious complications as a result of lymphadenectomy.
3. By providing improved visualization and operator dexterity, minimally invasive surgery may aid in decreasing complication rates in certain clinical scenarios.

Lymphadenectomy is a procedure in which the lymph nodes draining an organ or tumor are surgically removed. This is a critical step in the management of urologic malignancies and has two primary goals. First, it provides diagnostic information that can be used to appropriately stage patients, guiding subsequent treatment. Second, it provides the therapeutic benefit of removing cancerous tissue that is potentially harbored within these lymph nodes.

Much of the morbidity of lymphadenectomy is related to the extent of anatomic dissection required to remove an adequate number of nodes. A significant amount of research is being directed at the development of tests or imaging techniques that can reliably identify cancerous lymph nodes prior to surgery, so only affected nodes may be targeted. Although many important strides have been made, the negative predictive value of current techniques is not yet sufficient to displace the current practice of surgical lymph node removal.

This chapter will focus on anatomic considerations and surgical techniques to avoid the often debilitating complications of lymphadenectomy. We will discuss the incidence of common complications and their management when they occur. We make an effort to comment on the integration of minimally invasive surgery as it applies to the morbidity of lymphadenectomy.

Retroperitoneal Lymph Node Dissection

Retroperitoneal lymph node dissection (RPLND) has played an integral part in the management of testicular cancer since Hinman published the first report of a curative dissection in 1914. Over the past century, the technique has evolved and has been substantially refined. Despite advances in imaging and systemic treatment options, RPLND continues to be utilized in the management of patients with both localized and metastatic germ cell tumors.

Historically, some patients have likely been deterred from choosing RPLND as a primary treatment option despite its excellent success rate of nearly 100% and 95% in stage I and II nonseminomatous germ cell tumors (NSGCT), respectively.[1,2] This is likely due to a combination of factors. First, RPLND is a major abdominal operation with significant associated morbidity and typical hospital course of 7 days or longer.

Second, it is an infrequently performed operation by urologists outside of major academic or cancer centers. However, with the development of the less morbid robotic RPLND in recent years, this procedure will likely see increased use as long as oncologic outcomes prove to be noninferior.

While RPLND for NSGCT will be the basis of our discussion in this chapter, it is employed in a number of clinical scenarios beyond testicular cancer. It is commonly performed at the time of nephrectomy for renal cell carcinoma and has been shown to have benefit in patients undergoing nephroureterectomy for upper tract urothelial carcinoma. The extent of dissection in these last two clinical scenarios is not well defined.[3,4]

COMPLICATIONS OF RETROPERITONEAL LYMPH NODE DISSECTION

It should be noted that complications of RPLND vary based upon the setting in which it is performed. RPLND performed after chemotherapy can be significantly more challenging due to the intense desmoplastic reaction typically present in the retroperitoneum. Not surprisingly, complication rates in these patients are significantly higher than after primary RPLND.[5] Minimally invasive pcRPLND can be even more challenging still. The conversion rate in one early study was as high as 78%, but as experience with this technique has grown, open conversion has become much less common.[6–9] In one case series published in 2013 from an experienced group, only one out of 100 patients was converted to open surgery.[10]

Failure of Ejaculation

Given the young age group in which RPLND is typically performed, preservation of fertility is an important consideration. The process of emission during male orgasm is a complex reflex coordinated by the sympathetic nervous system; the nerves involved in this reflex are at risk during surgical dissection. Thankfully, damage to the sympathetic innervation on only one side will typically not result in loss of antegrade ejaculation.[11] This physiologic principle is the basis for the evolution of the RPLND technique over the last few decades.

Knowledge of the neural anatomy of the retroperitoneum is critical in order to prevent injury. The sympathetic chains run parallel to the great vessels in the space between the psoas muscle and spinal column. The right sympathetic chain is posterior to the inferior vena cava (IVC), while the left sympathetic chain is posterolateral to the aorta. At the level of L1 and L2, the sympathetic chain gives off postganglionic sympathetic nerve fibers, also known as lumbar splanchnic nerves, which form the intermesenteric plexus over the anterior surface of the aorta (Fig. 40.1). The aortic plexus is composed of four bilaterally symmetric ganglia: the right and left spermatic ganglia, the inferior mesenteric ganglion on the left, and the prehypogastric ganglion on the right (Fig. 40.2).[12] The sympathetic nerves from the aortic plexus continue into the hypogastric plexus, typically located between the two common iliac arteries, to eventually innervate the pelvic viscera.

Damage to any of these neuronal structures during the surgical dissection may result in failure of antegrade ejaculation postoperatively. To prevent injury, great care must be taken when controlling the lumbar vessels, which are intimately involved with the sympathetic chain. Also, postganglionic sympathetic nerve fibers on the left side must be isolated with a vessel loop prior to performing "split and roll" over the aorta. This is in contrast to the IVC, where significant nerve tissue is not encountered on the anterior surface.

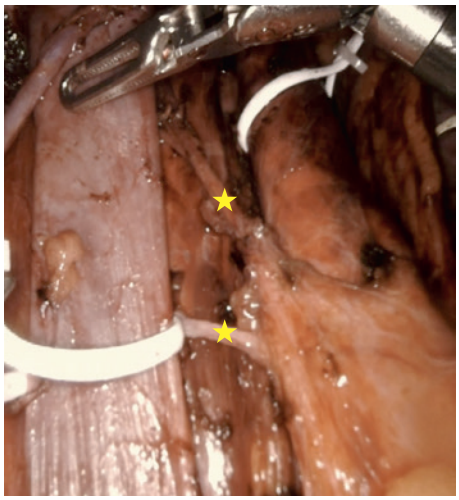

Figure 40.1 Inferior vena cava and aorta are skeletonized and encircled with vessel loops during robotic RPLND. Post-ganglionic sympathetic nerve fibers running over the aorta are spared.

While failure of antegrade ejaculation was a consistent outcome during early, wide boundary bilateral RPLND, more recent series report preservation in 85–100% of patients, and 91% in the largest series of robotic RPLND to date.[9,13–15] This is partly from adoption of nerve sparing techniques, in which the sympathetic chain, post-ganglionic fibers, and hypogastric plexus are identified and meticulously dissected. It is also a result of instituting modified templates for RPLND, which aim to resect all potential disease and landing zones on the ipsilateral side, while limiting dissection of the contralateral side, especially below the inferior mesenteric artery. The particular template used should never compromise cancer control to preserve antegrade ejaculation.

Patients should be asked about their plans for having children and should be offered sperm banking prior to surgery. If there is failure of antegrade ejaculation postoperatively, administration of pseudoephedrine may be useful in select patients with true retrograde ejaculation (as compared with failure of emission).[16] In those with failure of emission, electroejaculation has been shown to successfully produce motile sperm in 87% of men.[17] If no viable sperm can be obtained in this fashion, testicular sperm extraction is typically the last resort.

Lymphocele

As in the rest of the body, retroperitoneal lymphatics run in close association with the vasculature. The lymph from the common iliac nodes passes to the right and left lumbar lymph nodes, which lie on either side of the IVC and aorta. The lymph from the descending colon, kidneys, ureters, and testes also drain into these nodes. The efferent vessels from these nodes then form the lumbar lymphatic trunks, which then join with the intestinal lymphatic trunks to

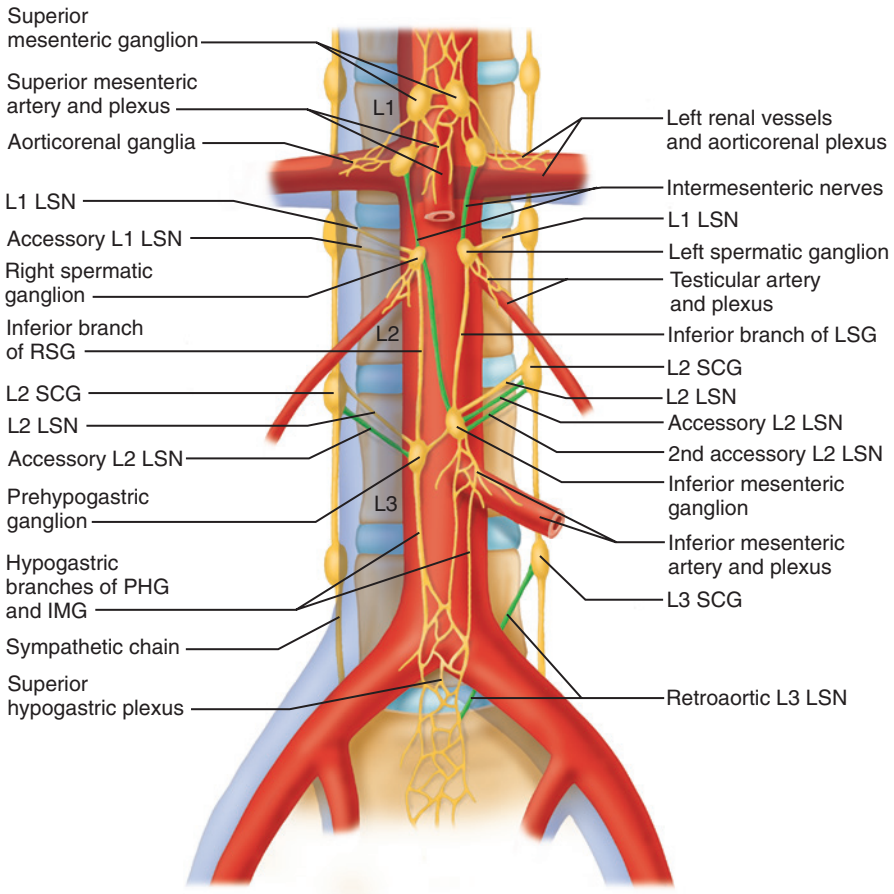

Figure 40.2 Sympathetic ganglia of the aortic plexus. IMG, inferior mesenteric ganglion; LSG, left spermatic ganglion; LSN, lumbar splanchnic nerve; PHG, prehypogastric ganglion; RSG, right spermatic ganglion; SCG, sympathetic chain ganglion. (From Beveridge TS, et al. Anatomy of the nerves and ganglia of the aortic plexus in males. J. Anat. 2015; 226(1):93-103.)

form the proximal thoracic duct. The beginning of the thoracic duct will variably form a saccular dilatation known as the cisterna chyli, found anterior to bodies of the L2 or L1 vertebra between the right crus of the diaphragm and the aorta. The size and shape of this structure varies considerably between patients, if present at all. Often, there will only be a plexus of lymphatic trunks coalescing into the thoracic duct.

Controlling the retroperitoneal lymphatic vessels at the time of dissection is the most important technique to prevent lymphatic complications, including lymphoceles, which are described below, and chylous ascites, which is described in the following section. In addition to the lymphatic channels mentioned above, special attention should be paid to ligating the numerous lymphatic channels when reflecting the duodenum and pancreas off the left renal vein underneath. The same is true when mobilizing the tail of the pancreas near the ligament of Treitz.

A lymphocele is a collection of lymphatic fluid that accumulates in the retroperitoneum after damage to any of the lymphatic vessels during RPLND. Small lymphoceles are common after RPLND, are typically asymptomatic, and require no treatment. However, lymphoceles can become clinically significant if they are large, causing abdominal fullness and discomfort, if they compress other structures in the retroperitoneum such as the ureter or the inferior vena cava, or if they become infected.

If there is a clinical suspicion for postoperative lymphocele, a CT with contrast, or other cross-sectional imaging, should be obtained. Typically, a lymphocele will be identified as a thin-walled cystic structure in the retroperitoneum with simple fluid within. If there is significant loculation, enhancement of the wall, or air within the structure, there should be a high concern for abscess or infected lymphocele, especially in the presence of fevers. These should be treated with percutaneous drainage and antibiotics. The management of noninfected lymphoceles will be discussed in the pelvic lymphadenectomy section later in this chapter.

Chylous Ascites

Intraoperative injury to the larger lymphatic structures within the retroperitoneum, namely the major lymphatic trunks or cisterna chyli, can result in continuous lymphatic leakage that outpaces reabsorption. This fluid will accumulate within the abdomen and cause increasing abdominal distention and patient discomfort. This is known as chylous ascites. In some cases, this can also lead to dyspnea from increased intraabdominal pressure on the diaphragm or from lymphatic leakage into the thorax itself. The latter is usually a result of injury to the thoracic duct during retrocural dissection.[18]

Chylous ascites can occur following RPLND for any indication, including renal cell carcinoma (Fig. 40.3). In GCTs, it is a fairly rare complication but rates vary based on the

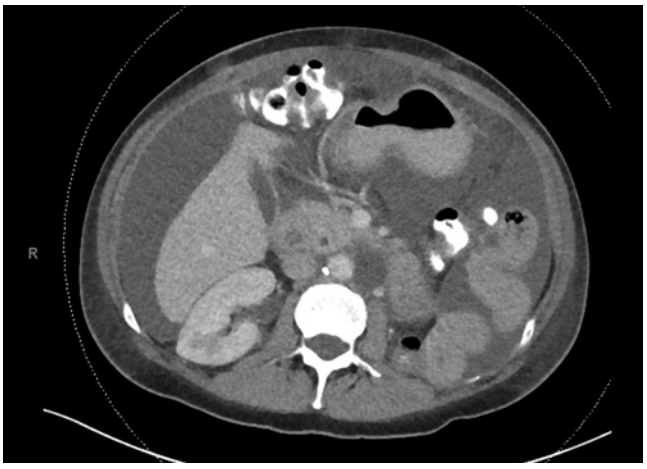

Figure 40.3 Chylous ascites 2 weeks after left nephrectomy and retroperitoneal lymph node dissection for advanced renal cell carcinoma.

setting of RPLND. In primary RPLND, the rate is approximately 2%, compared with 2–7% in pcRPLND.[5,19,20] In laparoscopic RPLND rates of chlyous ascites range from 1% to 7%.[10,21,22] Patients that require resection of the IVC during pcRPLND are at increased risk for chylous ascites, presumably from increased peripheral venous pressure that is transmitted to the lymphatic system. In a series of 603 patients undergoing pcRPLND, half of all patients with chylous ascites had resection of the IVC at the time of surgery.[5]

If chylous ascites is suspected after RPLND, the patient should be percutaneously drained and the fluid sent for analysis. High lymphocyte, protein, and triglyceride levels confirm the diagnosis. Since the majority of chyle is made up of chlyomicrons converted from dietary fat, the first step in management of these patients is to modify their diet to one high in protein and low in fat. The dietary fat should be primarily composed of medium chain triglycerides, which are transported directly to the portal circulation. This type of diet limits the flow of chyle into the lymphatics, promoting spontaneous closure of the injured vessels. Although time to resolution is variable, it typically takes a number of weeks or longer to completely resolve with conservative measures. This may result in repeated paracentesis while awaiting resolution of the ascites. The decision to leave an indwelling drain is controversial. Proponents of indwelling drains cite the ability to track the output and prevent repeated paracentesis, while opponents worry about the increased rate of infection and peritonitis.

If the chylous ascites does not resolve with a fat restricted diet, the second-line option is complete bowel rest with total parenteral nutrition. Evans et al. reported resolution of chylous ascites in 77% of patients with parenteral nutrition and paracentesis with or without abdominal drain placement.[20] A number of studies also support the use of octreotide, a somatostatin analog, as another method to attenuate the flow of intestinal lymph. This should be started at a dose of 100 µg subcutaneously three times a day, but can be titrated up to 12 mg via continuous infusion.[23] Octreotide has proven to be useful both on its own and in conjunction with total parenteral nutrition and medium-chain triglyceride diet.[24–27]

Figure 40.4 Lymphangiography with poppy seed oil in a man with refractory chylous ascites following retroperitoneal lymph node dissection (RPLND) for nonseminomatous germ cell tumor.

If these conservative measures do not resolve the ascites, more aggressive approaches may be necessary. Bipedal lymphangiography along with injection of iodinated poppy seed oil has been shown to resolve chylous leaks, especially those classified as minor (seen only on CT after lymphangiography, not on radiography) (Fig. 40.4).[28,29] The amount of leakage per day with a drain in place is predictive of resolution with lymphangiography. In patients with leakage less than 200 mL/day after conservative measures, lymphangiography was successful in 97% of patients in one study.[30] If lymphangiography itself does not resolve the leak, it can still be a useful adjunct prior to surgery to ligate the leaking vessels.[31] Other approaches to refractory chylous ascites described in the literature include local radiation, sclerotherapy, and peritovenous shunting. However, the latter method is associated with significant morbidity and should be reserved for cases in which conservative measures fail.[20,32–35]

Vascular Complications

The most feared and potentially catastrophic complication of RPLND is vascular injury. Specific management of vascular injury is discussed in detail in Chapter 10, but here we discuss injuries specific to RPLND. While rare in the primary setting for germ cell tumors, injury to major vessels is a significant risk in patients undergoing pcRPLND or in patients undergoing nephrectomy with significant retroperitoneal adenopathy.

In the pcRPLND setting, the factors responsible for this increased risk are twofold. First, there is a dense

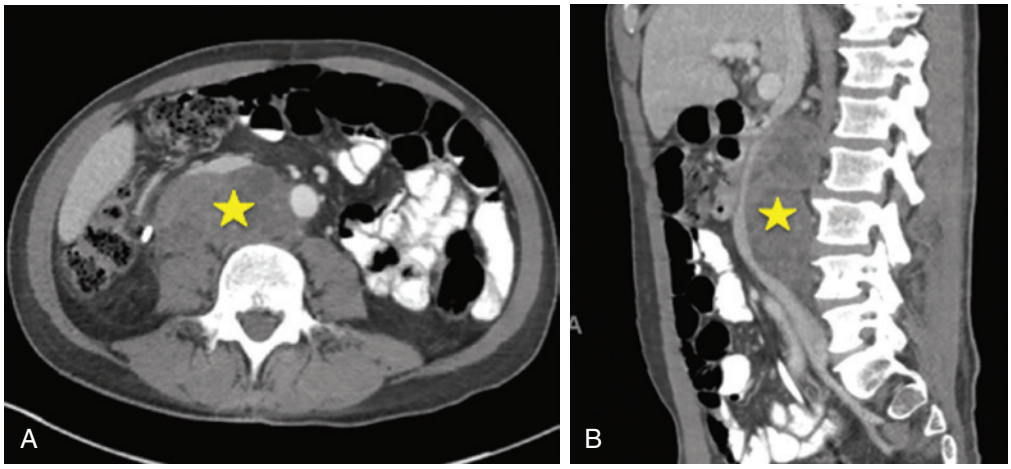

Figure 40.5 Large mass posterior to inferior vena cava (IVC) (star) in axial (A) and sagittal (B) views. The mass both compresses the vein and displaces it anteriorly.

inflammatory reaction within the retroperitoneum after chemotherapy in these men, which makes dissection along anatomic fascial planes much more difficult. Also, pcRPLND is more likely to be performed in men with larger, advanced tumors, some of which can invade adjacent organs or vascular structures. In a nationwide study of patients undergoing RPLND between 2007 and 2012, the rate of adjunctive procedures, such as nephrectomy or vascular reconstruction, was 19% in the post chemotherapy setting, compared to 1% during primary RPLND.[36]

When the need for pcRPLND arises, a thorough evaluation of the patient and all preoperative imaging is paramount. Clues to vascular invasion present on physical exam include lower extremity edema and well-developed abdominal collateral circulation. A large bulky tumor that abuts major vascular structures on CT scan, especially on the right side, suggests that vascular reconstruction may be necessary (Fig. 40.5). While not standard of care, MRI may be useful to further delineate vascular anatomy and the likelihood that the retroperitoneal mass invades adjacent structures.[37]

In all cases, the surgeon performing pcRPLND must be keenly aware of variations in vascular anatomy and must be comfortable with vascular control techniques. Given the complexity of the operation, pcRPLND should be performed in referral centers by experienced surgeons whenever possible. It is also prudent to have a vascular surgeon available to assist with major reconstruction if it becomes necessary.

Venous Complications

Venous hemorrhage can be a significant problem in pcRPLND, especially when dealing with bulky right-sided masses that are encroaching on the IVC and its tributaries. Although injury to vessels should be carefully avoided, transection of most major veins, including the IVC, can usually be overcome without reconstruction, thanks to the rich supply of collaterals in the abdomen and pelvis. The exceptions to this rule are the superior mesenteric, portal, and right renal veins. Damage to these vessels almost invariably requires reconstruction.[38]

One of the most common areas of difficulty is the ligation of the fragile lumbar veins draining into the IVC. While classically described as entering the IVC at each lumbar level, there can be significant variation in the number and location of lumbar veins. In one study from Indiana University, the lumbar venous anatomy was examined in 102 consecutive RPLNDs.[39] The authors noted that the number of infrarenal lumbar veins may vary from 0–4 on the right and 1–4 on the left. Also, a significant number of patients had two or more lumbar veins that combined into a common trunk before draining into the IVC, and 43% of patients had a lumbar vein that entered the left renal vein.

The lumbar veins can easily be avulsed by excessive traction or sheared by excessive force during ligation. To maximize exposure, the IVC should gently be retracted while the lumbar vessels are controlled by suture ligature or hemoclips. If a lumbar vessel is avulsed, it will often retract into the posterior wall musculature or vertebral foramen, resulting in bleeding that may be difficult to control. In these cases, the surgeon may use a sponge stick to compress the psoas muscle against the vertebral body at that level, thereby compressing the lumbar vein and ascending lumbar vein that runs under it. If the bleeding vessel cannot be controlled directly, the psoas muscle may be sutured to the paraspinal ligament underneath. This will usually control the bleeding and preclude the need for retro-psoas exploration.

Unlike the right renal vein, the left renal vein has a longer course and generally has multiple tributaries. Dissection of a large para-aortic mass can obscure the points of drainage of the gonadal, adrenal, or lumbar veins, resulting in injury to the left renal vein. Small lacerations can be repaired with nonabsorbable suture, usually 5-0. If the vessel is transected, avulsed, or there is a large laceration, the need for reconstruction is not clearly indicated.

Much of the data regarding left renal vein ligation come from the vascular surgery literature. Mehta et al.[40] found that postoperative renal functional outcomes were similar between 48 patients undergoing abdominal aortic aneurysm (AAA) repair and left renal vein ligation without reconstruction, and 213 patients with intact renal veins. Stability of renal function after ligation of the left renal vein has been confirmed to at least 1 year after surgery.[41] However, other authors argue that reconstruction of the left renal vein should be attempted, if possible, in order to better preserve preoperative renal function.[42]

Although the above studies are useful to understand the general morbidity of left renal vein ligation, the hemodynamics and drainage of the left kidney in the context of retroperitoneal malignancy are different. In cases where the retroperitoneal mass chronically occludes the left renal vein, collaterals are often well developed, and ligation is likely to be well tolerated. That being said, patients with poor preoperative renal function and those with a solitary left kidney would probably benefit from repair. Similarly, if collateral vessels draining the left kidney are sacrificed during the course of dissection, the renal vein should be repaired. Of note, ligation of the right renal vein without reconstruction will almost invariably lead to loss of the right kidney.

In both renal cell carcinoma (RCC) and GCTs, a small, but not insignificant portion of cases may involve a mass that encases the IVC, invades the wall, or has tumor thrombus extending into its lumen. Also, in the setting of pcRPLND, the severe desmoplastic reaction after chemotherapy may make dissection of the mass from the wall of the IVC impossible. In all of these cases, en bloc removal of a portion of the IVC may be necessary. In a large study of 955 patients undergoing pcRPLND, Beck and Lalka reported 6.8% required infrarenal IVC resection, with almost one-third of those resected harboring tumor within the cava.[43]

Thanks to abundant collateral venous flow, the infrarenal IVC may be sacrificed in order to gain a complete resection and improve survival. However, patients undergoing caval resection can have significant acute and chronic disability. The decreased venous return causes a rise in peripheral venous pressure, leading to increased secretion of lymphatic fluid and risk of postoperative chylous ascites. The increased peripheral venous pressure is also responsible for edema and chronic ulceration of the lower extremities, which can be extremely difficult to treat. Lastly, venous thromboembolism may occur as a result of increased pressures and turbulent flow.

The morbidity of IVC resection is closely related to the chronicity and extent of IVC occlusion. In the case of acute occlusion, where collateral vessels have not had a chance to form, most patients will suffer significant disability. Donaldson et al. discussed long-term outcomes of patients undergoing acute IVC ligation to prevent pulmonary embolism and noted that 61% of their cohort had some degree of leg swelling postoperatively. Stasis ulcers or edema poorly responsive to compression stockings was found in 30% of the same group.[44]

In contrast, there appears to be only minor changes in venous hemodynamics after resection of an occluded IVC.[45] Many authors have demonstrated that transection of the IVC in patients with tumor involvement does not result in significant long-term morbidity in most patients. Spitz et al. reported lower extremity symptoms in four of 11 patients 6 months after IVC resection during RPLND, but these were generally mild.[46] In the study by Beck and Lalka mentioned earlier, of the 20 patients for whom disability scores could be calculated, only two had moderate disability, and one had severe disability at long-term follow-up.[43] In their cohort, Blute et al. reported that no patients had disability that precluded them from working and 70% of patients did not need compression stockings for daily activity of up to 8 hours. Furthermore, their study suggests that venous collateralization continues to occur after IVC resection, as many patients had postoperative improvement of their preoperative disability scores.[47] This has been confirmed in other reports.[48]

Given the available evidence, IVC reconstruction is not necessary in patients with chronic complete, or near complete, occlusion. Preoperative imaging with MR angiography can help to define the extent of tumor involvement and the degree of IVC occlusion, as well as the degree of collateral vessel compensation.[49] If the IVC will not be reconstructed, it is critical to spare these collateral vessels during the dissection, as they are responsible for collateral drainage into the azygous and hemi-azygous system when the IVC is ligated.

In cases where the IVC is only partially occluded, a number of options are available. If feasible, a portion of the IVC can be resected and repaired primarily. The accepted belief is that the IVC may be narrowed by up to 50% of its original diameter without resulting in significant consequence. Alternatively, a patch graft may be used for larger repairs. These types of scenarios have been managed successfully via a minimally invasive approach, with low overall morbidity.[50]

If the IVC must be transected completely and reconstruction is indicated, a biologic or synthetic graft can be used. Reconstruction with a polytetrafluoroethylene (PTFE) graft is most common and has been shown to prevent lower extremity complications in nearly all patients.[51,52] However, patients undergoing grafting have a higher rate of postoperative venous thromboembolic (VTE) events and the graft itself can thrombose.[53] Also, grafting adds significant operative time to an already lengthy procedure. A further consideration is that patients undergoing IVC resection have advanced disease, and many of them may require chemotherapy postoperatively, rendering them immunocompromised. This results in at least a theoretical increased risk of graft infection.

Venous Anomalies

Surgeons performing RPLND should be aware of possible variations in retroperitoneal venous anatomy. These variations can further complicate an already difficult dissection, especially if not anticipated or detected on preoperative imaging. The most common anatomic abnormalities are a double vena cava, a left-sided IVC, a circumaortic left renal vein (circumaortic renal collar), or a retroaortic left renal vein. Complete situs inversus is also possible, but very rare.

A double vena cava occurs in as many as 2–3% of all people, based on cadaveric studies. The left-sided trunk typically joins with the left renal vein and crosses the midline, either posterior or anterior to the aorta, to drain into the right-sided trunk, which then ascends into the thorax normally. Typically, the right-sided trunk is dominant, but this is variable.[54–56]

Transposition of the vena cava or left-sided cava is a rare anomaly, occurring in approximately 0.5% of patients. If present, the vena cava will ascend on the left side until the level of the renal vessels, where it will typically cross the midline anterior to the aorta and caudal to the superior mesenteric artery. It then normally ascends into the thorax. The transposed vena cava may also cross posterior to the aorta, but this is less common.[56]

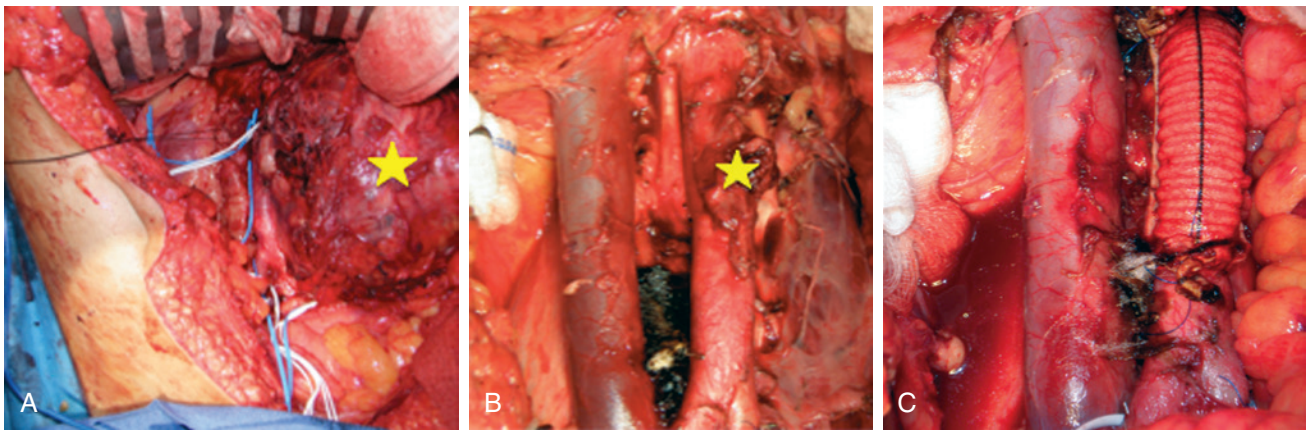

Figure 40.6 A, Large para-aortic mass in a patient with metastatic testicular cancer (star). B, Mass (star) unable to be completely resected from the adventitial wall of the aorta. C, Affected aorta resected and replaced with polytetrafluoroethylene graft.

Anomalous drainage of the kidneys can also be problematic if not recognized. In up to 8% of the population, both an anterior and posterior branch of the left renal vein is present, encircling the aorta. This is also commonly referred to as a circumaortic collar. A somewhat less common variation is a retroaortic left renal vein, which occurs in approximately 3% of the population.[57] Recognition of a retroaortic left renal vein is especially important because it may be mistaken for a lumbar vein and inadvertently ligated. Of note, more than one right renal vein can also be present.

Arterial Complications

The best approach to preventing arterial injury is to have a sound understanding of vascular anatomy. Unlike the venous system, transected major arteries should be repaired in the vast majority of circumstances. The only exception to this rule is the inferior mesenteric artery, which may be divided for better exposure to aortic dissection. Unless the patient has significant atherosclerotic vascular disease, the left colon will receive collateral blood supply through the marginal artery and the arch of Riolan.

During exposure of the retroperitoneum for RPLND, the duodenum and pancreas are reflected cephelad along with the small bowel, cecum, and right colon. Before placing a self-retaining retractor, great care should be taken to ensure the superior mesenteric artery (SMA) is not compressed or injured. A similarly cautious approach must be taken to dissection of a suprahilar mass, where the SMA is again at risk. Failure to promptly recognize an SMA injury leads to ischemic bowel and a generally catastrophic outcome.

Multiple renal arteries occur fairly consistently in about one-quarter to one-third of all patients.[37,39] An accessory or polar renal artery can originate at the level of the renal hilum or at a variable distance caudal to the main renal artery. Accessory right renal arteries that arise caudal to the renal hilum can pass anterior to the vena cava and are at higher risk for injury, especially if not detected on preoperative imaging. Repairing these smaller vessels is very difficult, so they are best avoided.

Injury to the main renal artery is typically more common on the left because the lymphatic drainage on that side is just inferior to the hilum. Intense desmoplastic reaction after chemotherapy or dissection of a large left-sided mass may ultimately result in nephrectomy. In recent reports, 10–14% of patients undergoing pcRPLND will require adjuvant nephrectomy, predominantly on the left.[36,58] The right renal artery is primarily at risk during dissection of bulky interaortocaval masses.

Although injury to the aorta is rare, resection and replacement may be necessary. In the largest series to date, aortic substitution was required in just 1% of 1250 pcRPLND operations.[59] However, a smaller, more recent series cites a much higher rate of 9%, likely as a result of patient selection.[58] The need for repair arises when a subadventitial plane is created in the course of removing a densely adherent mass. Removal of the adventitia along with the mass substantially weakens the aortic wall and may result in postoperative aortic aneurysm or rupture. In cases where large segments of the adventitia are peeled away in the course of dissection, it is generally a good idea to perform aortic substitution with a synthetic graft (Fig. 40.6).[60]

Gastrointestinal Complications

Gastrointestinal complications are fairly rare and can usually be avoided by careful handling of the bowel and placement of retractor blades. Sometimes, mobilization of the duodenum can result in postoperative pancreatitis. This manifests as nausea and vomiting in the setting of elevated amylase and lipase levels. It will resolve with conservative dietary management in the vast majority of cases.

Similarly, excessive manipulation of the bowel or small serosal abrasions may result in postoperative ileus. This happens in approximately 2% of patients undergoing pcRPLND and is more likely to occur as the extent of dissection increases.[5] Conservative management with nasogastric suction and bowel rest is typically effective in resolving this issue.

The bowel can also be directly injured, especially when dissecting the duodenum away from a densely adherent retroperitoneal mass during pcRPLND. If an enterotomy is created, it should be closed in two layers. Furthermore, omental interposition between the injured bowel and the great vessels is prudent in order to prevent formation of an abscess or aorticoduodenal fistula.[60] At the end of the

RPLND, it is important to inspect the bowel so that any injury can be primarily repaired. Lastly, the posterior layer of peritoneum should be loosely reapproximated to avoid bowel adhering to the anterior surface of the retroperitoneal vessels.

Complications of Pelvic Lymph Node Dissection

The removal of pelvic lymph nodes as part of the treatment of muscle invasive bladder cancer, higher risk prostate cancer, or advanced stage penile cancer is a cornerstone in the management of these malignancies. While clearly adding diagnostic and therapeutic value, pelvic lymph node dissection (PLND) also adds substantial morbidity. This morbidity comes in the form of additional operative time, as well as complications specific to lymphadenectomy, such as lymphocele, deep vein thrombosis (DVT)/pulmonary embolism (PE), injury to nerves, or, rarely, injury to major vessels within the pelvis.

In the form that it exists today, PLND is a fairly blunt, non-discriminatory tool, in that the lymph nodes are removed without knowing which, if any, actually harbor cancer. In the current age of imaging, many have attempted to refine the technique by identifying suspicious nodes preoperatively. Unfortunately, both CT and MRI have low sensitivity for detecting lymph node metastases and cannot be used to reliably select patients for PLND.[61,62] Newer imaging modalities such as 11C-choline and 18F-fluoromethylcholine PET/CT showed initial promise, but recent studies do not find that either adds diagnostic efficacy over conventional imaging in prostate or bladder cancer.[63–65]

Therefore, PLND remains the gold standard for identifying and removing lymph node metastasis. In the following section, we describe the complications that are specific to PLND. Complications of surgery for penile cancer will be discussed in a later part of this chapter. Prior to examining each complication, we will first touch on the lack of standardization of PLND in the treatment of prostate cancer, and less so bladder cancer, as this is a significant confounder in interpreting the rates of complications associated with each.

CONSIDERATIONS IN RADICAL PROSTATECTOMY

The decision to perform PLND during radical prostatectomy is an area of significant variability between surgeons and centers. Much of the inconsistency stems from the lack of standardization in guideline statements made by the American Urological Association (AUA), the European Association of Urology (EAU), and the National Comprehensive Cancer Network (NCCN). Although both the EAU and NCCN agree that patients treated for high-risk prostate cancer should undergo PLND, there is inconsistency regarding when it should be performed in intermediate-risk patients. The AUA is more vague, stating only that pelvic lymphadenectomy "is generally reserved for patients with higher risk of nodal involvement."[66,67] The extent of dissection is also not standardized among the three guideline committees. Only the NCCN and the EAU guidelines make recommendations, saying that an extended template should be used if PLND will be performed.[67,68]

The nomenclature regarding the extent of PLND in prostate cancer is also an area of significant variability and confusion among publications. The definition of a limited PLND varies from removal of nodes only between the external iliac vein and obturator nerve, to broader dissections, which also include the nodes below the obturator nerve and around the internal iliac vessels. However, some authors call this a standard, or even an extended, PLND. The most common definition of an extended PLND usually entails the removal of all nodal tissue from around the obturator fossa, as well as the external, internal, and common iliac vessels to the level of the crossing ureter. An extended dissection will also variably include the presacral nodes, which some authors call a super-extended PLND.

Many surgeons believe that the risk of complications increases with the greater extent of PLND. The literature examining this question is conflicting and difficult to interpret because of the inconsistency in terminology used to describe the extent of dissection. Nevertheless, a number of studies report higher complication rates with extended PLND, with much of the increase being driven by the rate of postoperative lymphocele.[69–71] On the other hand, at least one study by Heidenreich et al., showed the complication rate was equivalent between extended and standard PLND in 203 patients.[72] Another study reported that the rate of lymphoceles requiring intervention was actually higher in the standard PLND group.[73]

The oncologic importance of performing PLND is beyond the scope of this chapter. However, despite the potentially increased morbidity with an extended PLND, mapping studies of the lymphatic drainage of the prostate have essentially proven that limited dissections do not adequately control potential prostate cancer landing zones.[74,75] One study cites that up to 63% of positive lymph nodes fall outside the area of standard PLND in patients with node-positive prostate cancer.[74] As a result, the literature has shifted in favor of extended PLND in recent years.

CONSIDERATIONS IN RADICAL CYSTECTOMY

Lymphadenectomy during radical cystectomy for muscle invasive bladder cancer is almost universally accepted as the standard of care. Although primarily comprised of retrospective studies, a recent systematic review of almost 20,000 patients concluded that PLND improves oncologic outcomes over no PLND. Although the proper nomenclature is up for debate, many consider an extended PLND the dissection of all pelvic nodes up to the bifurcation of the aorta. This dissection has been demonstrated in studies to provide an oncologic advantage. A super-extended PLND, which includes dissection of para-aortic and paracaval nodes up to the inferior mesenteric artery, however, has not been convincingly shown to provide further advantage over extended PLND.[76]

Unfortunately, just as in radical prostatectomy, there is substantial heterogeneity in the extent of PLND performed between centers as well as the anatomic boundaries of each type. Furthermore, there are very limited data describing the rates of complications based on extent of PLND during radical cystectomy. For our purposes, the complications of

PLND during radical cystectomy are not significantly different from those encountered during radical prostatectomy. Therefore the following sections apply to both clinical scenarios.

NERVE INJURY

The obturator, genitofemoral, and femoral nerves travel through the pelvis and are at risk for injury during PLND. The obturator and genitofemoral nerves are closely associated with the pelvic lymph nodes, predisposing them to direct injury. In contrast, the femoral nerve is more likely to be damaged as a result of positioning or exposure during the operation. Harming any of these nerves can produce debilitating symptoms that can result in significant patient distress. In certain cases, severe injuries may result in lifelong disability. We will discuss the etiology and prevention of each type of injury in the following sections. Principles of management are similar regardless of injury and will be discussed together at the end.

Obturator

The obturator nerve arises from the anterior rami of the L2–L4 spinal nerves in the lumbar plexus, travels through the fibers of the psoas major, and pierces the medial border of the psoas muscle at the pelvic brim. It then runs along the lateral pelvic sidewall deep to the external iliac vessels, lateral to the internal iliac vessels and ureter, and superficial to the obturator vessels. It eventually leaves the pelvis through the obturator canal with the obturator vessels to provide motor innervation for the medial thigh muscles, which adduct the leg. It also provides sensory innervation to the skin of the medial thigh. Of note, the obturator nerve does not innervate any structures within the pelvis, so there are no branches that are at risk during PLND.

The obturator nerve itself can be injured during the removal of the fibro-fatty lymph node containing tissue surrounding the nerve. Damage can occur in a number of ways, including partial or complete transection, crush injury from direct application of instruments or clips, excessive traction, or the use of electrocautery in proximity to the nerve. The severity of clinical symptoms will depend on the type and extent of injury.

The most common presentation of obturator neuropathy involves altered sensation on the medial thigh, ranging from sensory loss to paresthesias and pain. These symptoms can extend from the groin down to the medial knee. They may be exacerbated by maneuvers that stretch the nerve, which include extension and abduction of the leg. Weakness of adduction and internal rotation of the thigh can be present to varying degrees. Severe weakness can manifest as a gait abnormality characterized by an abnormally abducted and externally rotated ipsilateral hip.[77] If the diagnosis is in doubt, electromyography can be helpful.[78]

The most effective method of preventing obturator nerve injury is to understand the anatomic course of the nerve and its relationship to other structures in the pelvis. Great care should be taken when dissecting and placing clips within the obturator fossa. Small collateral vessels should be controlled before proceeding with the dissection. Lastly, division of the proximal and distal node packet should only be performed after the course of the entire nerve is visualized.

The reported incidence of obturator nerve injury is less than 1% in most studies.[79,80] However, mild symptoms that do not produce significant disability are likely not reported by patients, so the true incidence is almost certainly higher. Although rare, this injury is more likely to occur in patients with prior chemotherapy or pelvic radiation, or tumor involvement of the obturator nodes. The inflammatory reaction associated with these conditions makes dissection of the nerve away from the node packet more difficult.

Severe injuries such as partial or complete transection, recognized intraoperatively, should be primarily repaired with microsurgical techniques at the time of surgery.[81,82] If an end-to-end tension-free primary anastomosis is not possible because of retraction of the transected ends, autologous sural nerve can also be used with good success.[83,84] As long as the nerve is promptly repaired, motor and sensory function is typically restored by 1 year after surgery.

Little is known about the management of patients that have persistent severe weakness and/or pain despite physical therapy. There is some evidence that surgical exploration may identify an unrecognized major injury to the nerve. Repair of the nerve, even months after the initial injury, has resulted in improved adductor muscle strength.[85]

Genitofemoral

The genitofemoral nerve arises from the L1 and L2 spinal nerve roots in the lumbar plexus and pierces the fibers of the psoas muscle. It then runs along the anterior surface of the psoas, where it splits into its genital and femoral branches. The femoral branch travels underneath the inguinal ligament and provides sensory innervation to the upper medial thigh. The genital branch travels into the inguinal canal and supplies sensory innervation to the skin of the anterior scrotum in men and the mons pubis and labia majora in women. It also supplies the motor fibers innervating the cremaster muscle in men.

Damage to the genitofemoral nerve during pelvic lymphadenectomy is most likely to occur where the nerve travels just lateral to the common and external iliac vessels. The key to preventing injury is to start the nodal dissection proximally and to mobilize the iliac vessels medially in order to visualize the nerve. It may be intimately involved with the nodal tissue surrounding the vessels, so a careful split and roll technique should be used.

Femoral

The femoral nerve arises from the anterior rami of the L2–L4 spinal nerves in the lumbar plexus, travels through the fibers of the psoas major, and emerges at its lateral border. It then travels in the groove between the psoas and iliacus muscles until it passes underneath the inguinal ligament to innervate the muscles responsible for hip flexion and extension at the knee. It also supplies cutaneous branches that innervate the anterior and medial lower extremity.

Most commonly, femoral neuropathy results from inappropriate use of a self-retaining retractor in the pelvis, especially when exposing the lateral pelvis for lymphadenectomy. The nerve can be damaged by excessive traction, compression against the pelvic sidewall by the psoas muscle, or by direct compression of the nerve by the blades of the retractor. Femoral neuropathy can also occur with prolonged or exaggerated lithotomy position, which can exert pressure

on the nerve as it passes underneath the inguinal ligament. Lastly, there is some evidence that arterial ischemia to the intrapelvic portion of the nerve can result in neuropathy. This seems to be more common on the left side, where there is less collateral blood supply from the deep circumflex iliac artery.[86]

The role of self-retaining retractors is best highlighted by comparative studies in the gynecologic literature.[87,88] For example, Goldman et al.[88] performed abdominal hysterectomies on over 6000 women and noted the rate of femoral neuropathy fell from 7.5% to 0.7% when a self-retaining retractor was not used. There are also many case studies in the urologic literature that document femoral nerve injury after open radical prostatectomy or cystectomy, implicating self-retaining retractors as the cause.[89–92]

The best method for preventing femoral nerve injuries in open lymphadenectomy is careful, methodical placement of self-retaining retractors. When placed properly, the retractor should only retract the rectus musculature without putting pressure on the psoas muscle. The shortest possible blades should be used, and folded lap sponges should be placed between the blades and the musculature to act as a cushion. The surgeon should check for proper positioning during placement and periodically during the operation.

When using the robotic approach, the risk of femoral neuropathy stems primarily from patient positioning in dorsal lithotomy, or on a split-leg table with extension at the hip to facilitate docking.[93] While this injury can occur during radical prostatectomy without lymphadenectomy, PLND increases operative time. Prolonged positioning in dorsal lithotomy, especially with legs hyperabducted, externally rotated, and flexed at the hip, is a well-established risk factor for lower extremity neuropathies postoperatively.[94] Fortunately, with the newer robotic platforms, the patient is able to remain supine while the robot docks alongside the patient, instead of at the feet. This should minimize the risk of femoral neuropathy in these patients.

Most commonly, femoral neuropathy manifests as difficulty with ambulation in the immediate postoperative period, along with altered sensation over the anteromedial thigh. The most reliable clinical signs are weakness of the quadriceps muscle and an absent or diminished patellar reflex.[95] Patients complaining of significant pain that also have a bleeding diathesis or are on anticoagulation therapy should potentially undergo cross-sectional imaging to rule out a perineural hematoma.[96]

MANAGEMENT OF PELVIC NERVE INJURIES

Regardless of the nerve that is injured, there are a few basic principles of management that should be followed. A neurologist and rehabilitation specialist should be involved early in the care of patients with neurologic symptoms postoperatively. This is important for the purposes of making the correct diagnosis and initiating prompt physical therapy, if necessary. It is also important from the standpoint of properly documenting baseline signs and symptoms, enabling an accurate assessment of the patient's comparative clinical course during treatment.

Management typically involves a multimodal, multispecialty approach. The mainstay of treatment for motor dysfunction is physical therapy, which should begin as soon as possible in the postoperative period. Patients with sensory dysfunction such as pain or paresthesias are typically managed in a stepwise approach, beginning with NSAIDS. Alternative oral medications are essentially those used with all forms of neuropathic pain and include opioids, tricyclic antidepressants, selective serotonin/norepinephrine reuptake inhibitors, and antiepileptics. Topical lidocaine patches have also been used. More invasive options typically involve nerve blocks with an anesthetic solution.[97]

The time course for resolution of symptoms is highly variable and depends on the severity of injury. Minor paresthesias can resolve in days to weeks. Alternatively, pronounced motor weakness can persist for months, years, or, in some cases, indefinitely. Although recovery is dependent on a variety of clinical factors, EMG can be a useful prognostic tool. If EMG suggests anatomic denervation, some form of disability is likely to persist.[98]

LYMPHOCELE

The formation of a pelvic lymphocele is a common complication after pelvic lymph node dissection (Fig. 40.7). A lymphocele is a collection of lymphatic fluid surrounded by a fibrous wall without an epithelial lining. Unlike blood vessels, lymphatic vessels do not contain smooth muscle within their walls and therefore cannot constrict in response to injury or transection. The continued flow of lymph from injured afferent lymphatic channels into a confined space is the mechanism believed to be responsible for lymphocele formation.

While lymphoceles are common after pelvic surgery, only a small percentage become clinically apparent. In studies where patients underwent imaging shortly after surgery, the rate of all lymphocele formation after a laparoscopic approach varies from 30% to 53%[99–102] compared to 15% to 61%[101,103] after open surgery. The large variation in asymptomatic lymphoceles is likely a result of differing patient characteristics and methods of detection. Studies that employed ultrasound typically detect fewer lymphoceles because of the lower sensitivity of ultrasound when

Figure 40.7 Large pelvic lymphocele anterior to bladder after radical prostatectomy and pelvic lymph node dissection. Patient presented with abdominal fullness and urinary frequency.

compared to CT. Symptomatic lymphoceles are much less common. The exact rates vary between studies, but appear to be fairly equivalent between laparoscopic and open lymphadenectomy (0–8%[100,104–106] vs 3–10%[72,101,104,107]).

There are a number of clinical and surgical factors that have been associated with increased risk of lymphocele formation. It was previously believed that minimally invasive surgery, done through the peritoneum, would prevent lymphatic fluid from accumulating in a closed space and be protective against the formation of lymphocele. A few retrospective series support this notion,[108,109] including one large population-based study of Medicare patients where the rate of lymphocele formation was 1.3% versus 2.2% in favor of the minimally invasive group.[110] Unfortunately, the retrospective data are difficult to interpret because of the wide variation in patient selection and extent of PLND. There are currently no randomized trials comparing the two approaches, so no clear answer exists.

One might expect that an extended PLND, which requires a wider anatomic dissection and removal of a larger number of nodes, would carry a higher risk of developing lymphocele postoperatively. Again, the data are mixed. Musch et al. cite a threefold increased risk of lymphocele in patients undergoing extended PLND in their retrospective cohort of 1380 patients.[79] However, other retrospective studies show no significant difference.[73,111]

Administration of perioperative heparin has been investigated as a possible risk factor for lymphocele formation, with mixed results. A number of earlier studies have reported increased lymphocele formation in those receiving heparin prophylaxis.[112–114] More contemporary studies, however, suggest that the risk is equivalent to those not receiving heparin.[115,116] The consensus among most urologists is to continue to administer heparin as the morbidity of DVT and PE outweigh the small potential increased risk of lymphocele formation, especially after radical cystectomy.

Lastly, the placement of a pelvic drain at the conclusion of surgery was thought to be protective against developing a lymphocele by providing a means for the leaking lymphatic fluid to escape. Danuser et al.[108] demonstrated that the risk of lymphocele was significantly reduced if a drain was left until postoperative day 7. However, most surgeons remove the drain in the first few postoperative days to minimize patient discomfort and other complications. Furthermore, other studies showed no increased risk of lymphocele in patients who had no pelvic drain placed.[117,118]

Most symptomatic lymphoceles begin as a vague sensation of abdominal fullness. As they increase in size, they can cause a variety of clinical symptoms as they encroach on anatomic structures within the pelvis. Gastrointestinal symptoms can range from constipation from pressure on the colon to frank ileus, resulting in nausea and vomiting. Urinary symptoms can include urinary frequency from compression of the bladder or, less commonly, hydronephrosis and flank pain from compression of the ureter. Impingement on nerves within the pelvis can result in pain or lower extremity weakness in the distribution of a specific nerve. Lastly, lymphoceles can impair venous return from the genitalia and lower extremities resulting in edema and, sometimes, DVT. Fever associated with lymphocele is typically a sign of superinfection and will necessitate drainage.

Given the variability in presenting symptoms, a heightened level of suspicion must be maintained after prostatectomy or cystectomy to make this diagnosis. Typically, lymphoceles will not be apparent on physical examination until they become very large, at which point one may appreciate a lower abdominal mass. Ultrasound imaging is easy to perform, spares the patient ionizing radiation, and can easily detect large lymphoceles, which are anechoic. However, it is also heavily operator dependent and not as sensitive as abdominal/pelvic CT, which is the gold standard test for diagnosis.

Many lymphoceles will resolve with time and can be managed expectantly, especially when symptoms are mild. The caveat to this is a lymphocele that appears to compress pelvic veins, as this can lead to deep venous thrombosis and further morbidity. For those that require intervention, a number of options are available. Most pelvic lymphoceles are readily accessible to percutaneous drainage and drain placement by an interventional radiologist, typically resulting in rapid resolution of the patient's symptoms. Cell count of the aspirated fluid will show a predominance of lymphocytes and the creatinine will be consistent with serum (in contrast to elevated fluid creatinine in the case of urinoma). Once in place, drain output should be recorded and the drain should not be removed until the output is low. Reported rates of resolution with percutaneous drainage are in the order of 50–97%, and the drain is kept in place for an average of about 3 weeks.[119–121]

If drain output remains high, indicating a persistent lymph leak, a sclerosing agent such as ethanol,[122] povidone-iodine,[120,123] doxycycline,[124] fibrin sealant,[125] etc., may be injected into the lymphocele. The addition of a sclerotic agent does successfully treat most patients that do not respond to simple drainage alone, especially after additional rounds of sclerosis. Importantly, the overall success rate for multiloculated lymphoceles is much lower and may require a different approach.[121]

Laparoscopic marsupialization is an effective alternative to percutaneous drainage.[126–128] Marsupialization involves incising the roof of the lymphocele to create a window into the peritoneum. This can be employed either as primary therapy (especially in cases of multiloculated lymphocele) or after failure of percutaneous drainage and sclerosis. Success rates were as high as 97% in one large study,[128] in which half of patients were refractory cases. This approach is generally safe, but injury to the ureter, bladder, or pelvic vascular can occur.

A number of surgical techniques have been investigated that may help to prevent postoperative lymphocele. A few of these methods include the use of FloSeal in the area of PLND,[129] peritoneal fenestration during extraperitoneal PLND,[109] the use of a TachoSil surgical patch near the femoral canal and in the obturator fossa,[130] as well as a rotational flap of bladder peritoneum brought down into the deep pelvis.[131] While many of these studies show an advantage in the experimental arm, they have been small, single institution series that have not been well validated. At this time, it is controversial whether the utilization of these techniques, which are often costly and increase operative time, justifies the small potential decrease in symptomatic lymphoceles.

Regardless of whether any specific technique or material is used to prevent lymphocele formation, it is important to

maintain sound surgical principles during PLND. As the lymph node packet is dissected, careful attention should be paid to avoiding excessive traction, which may tear small lymphatic vessels. Transected lymphatics, especially larger ones at the proximal and distal ends of the packet, should be meticulously controlled with surgical clips. This can potentially be better accomplished in minimally invasive procedures, where visualization of the complete extent of the delicate lymphatics is excellent.

THROMBOEMBOLIC EVENTS

Deep vein thromboembolism and PE are rare but potentially lethal complications of radical prostatectomy and cystectomy. It is worth mentioning that the performance of pelvic lymphadenectomy during radical prostatectomy significantly increases the risk of DVT and PE.[132,133] In one study, the risk of DVT increased eightfold and the risk of PE increased sixfold, compared to prostatectomy without PLND. Furthermore, the risk of rehospitalization for PE is many-fold higher in patients receiving lymphadenectomy, although the absolute risk of rehospitalization for PE remains low at around 1.3%. There is no difference in DVT or PE between patients receiving open versus robotic prostatectomy and PLND.[134]

The increased incidence of thromboembolic events should not deter surgeons from performing PLND in men with prostate cancer at increased risk for nodal metastasis. However, it is important to remain vigilant; any patient with oxygen desaturation or respiratory complaints after surgery must be evaluated thoroughly and promptly. The American Society of Clinical Oncology currently recommends pharmacologic prophylaxis for all patients with cancer undergoing major abdominal or pelvic surgery starting before the operation and continuing for at least 7–10 days.[135]

It is important to keep in mind that the majority of thromboembolic events occur after discharge from the hospital.[132,136] As a result, some centers routinely use extended thromboprophylaxis for 1 month in patients undergoing cystectomy. After radical prostatectomy and PLND, extended thromboprophylaxis is not routinely used, but may be warranted in some men with additional risk factors.

VASCULAR INJURY

The pelvic lymph nodes are found in close association with the major vascular structures of the pelvis. Vascular injury can certainly occur, but is rare. In general, there is no substitute for careful dissection and retraction of vascular structures away from the area of dissection. If PLND cannot be performed safely because of dense inflammation, significant adenopathy, or altered tissue planes, consider aborting the procedure, especially in cases with questionable benefit such as low-risk prostate cancer. If benefit is considerable and a PLND must be performed, it is wise to involve a vascular surgeon, in case a complicated reconstruction becomes necessary.

Inadvertent transmission of electrocautery current resulting in vascular injury has been reported during robotic pelvic lymphadenectomy. This is thought to occur secondary to failure of the insulating sheath, known as the tip cover accessory (TCA), of the monopolar scissors.[137] Malfunction of the TCA results in arcing current that can damage surrounding structures. This has been shown to occur almost exclusively with first-generation TCAs and is more likely to occur with increased wrist angulation. The second-generation TCA released in 2012 has not been associated with this problem to date.[138]

Complications of Inguinal Lymph Node Dissection

Penile cancer spreads in a predictable, stepwise fashion along the route of lymphatic drainage of the penis. Metastatic cells travel to the superficial, followed by the deep inguinal nodes, before eventually extending into the ipsilateral pelvic nodes. The surgical removal of these nodes is an indispensable part of the management of invasive penile carcinoma. The presence or absence of cancer within the local nodes provides valuable prognostic information.[139–141] Of equal importance, inguinal lymph node dissection (ILND) is associated with a survival advantage, even when the nodes are clinically not involved, and can cure a significant portion of men.[142–144]

Over the last few decades, the indications for ILND have evolved. Prior to the mid-1980s, ILND was mostly performed for clinically palpable disease using the "standard template." The borders of this dissection are a line joining the anterior superior iliac spine (ASIS) and pubic tubercle superiorly, a vertical line 20 cm caudal to the ASIS laterally, a line 15 cm caudal to the pubic tubercle medially, and a horizontal line joining the two vertical margins inferiorly. Nodal tissue deep to the fascia lata in the area of the femoral vessels is also removed, so that the dissection is essentially in continuity with the pelvic lymph nodes. The saphenous vein is typically ligated at its insertion into the femoral vein, and the sartorius muscle is transposed to cover the exposed femoral vessels.

Dissection of clinically negative groins beginning in the mid-1980s mandated a less morbid technique than the standard ILND used at the time, since up to 80% of patients were being overtreated.[141] In 1988, Catalona described the "modified template" ILND for patients with clinically negative groins,[145] which significantly decreased complications and is still used today. Compared to the standard template dissection, the template proposed by Catalona included a narrower field, bordered by the lateral edge of the femoral artery laterally, the external oblique muscle above the spermatic cord superiorly, the adductor longus muscle medially, and the fascia lata just distal to the fossa ovalis inferiorly. The saphenous vein is preserved, the sartorius muscle does not need to be transposed, and a smaller skin incision can be used, making this a significantly less morbid procedure.

In a similar, concurrent effort to detect clinically occult metastasis with minimal added morbidity, dynamic sentinel node biopsy was developed.[146] This approach relies on the belief that lymphatic spread of cancer cells occurs in a stepwise manner, first migrating to the sentinel lymph node or nodes before continuing on to more distant nodes. A formal inguinal lymphadenectomy is performed only if intraoperative frozen section of the sentinel node is positive. Although this technique initially had unacceptably high false-negative rates, it has been refined over the years. In

Figure 40.8 Penile squamous cell carcinoma with large necrotic inguinal mass at presentation.

modern series, the false-negative rate is as low as 5–7%, albeit in a few high-volume specialized centers.[147,148]

Currently, there are three distinct indications for performing ILND. The first is performed in patients with clinically negative nodes and is termed *prophylactic ILND*. Many urologists prefer to use the modified template in this setting, while certain specialized centers will perform dynamic sentinel node biopsy. The second indication is for patients with clinically apparent nodes. In these cases, a standard template for the ipsilateral or bilateral groins is typically used. The last indication is in the setting of bulky, fixed disease, frequently after the administration of neoadjuvant therapy. This is considered to be a palliative dissection and may include large segments of involved inguinal skin, spermatic cord, inguinal ligament, testicle, or other local tissues. Local flaps for coverage are often needed in this last scenario (Fig. 40.8).

The morbidity of ILND largely depends on the indication and extent of dissection.[149,150] Multiple large studies demonstrate that complications after standard template dissections are common. Overall incidence of complications in most studies varies from 41% to 82%, although one recent series of 340 procedures reports a 10% complication rate.[149,151–154] In contrast, a much lower rate of 7–33%[149,152] can be expected with modified dissections. In recent years, minimally invasive approaches have been incorporated in an attempt to reduce morbidity from ILND.[155] Tobias-Machado et al. performed ILND in 10 patients, comparing a minimally invasive approach in one groin with an open approach in the contralateral groin. They found the overall complication rate to be 20% versus 70%, and cutaneous complications occurred at a rate of 0% versus 50%, respectively.[156] The experience with robotic ILND is still immature, but initial studies are promising.[157,158]

CUTANEOUS COMPLICATIONS

A large proportion of early complications after ILND are cutaneous, manifesting as skin infection or skin necrosis,

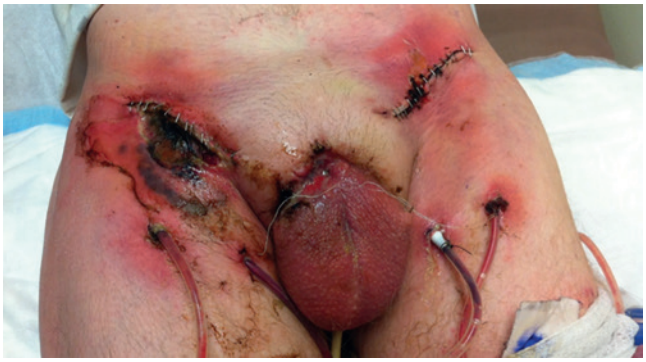

Figure 40.9 Extensive cellulitis and wound necrosis bilaterally after penectomy and inguinal lymph node dissection for penile cancer.

with or without wound dehiscence (Fig. 40.9). Both are a result of the devascularization that occurs in the process of developing skin flaps. During the dissection, the branches of the common femoral artery supplying the overlying skin are often ligated, so viability depends on the small anastomotic vessels running in the Camper's fascia. Furthermore, there is impaired lymphatic drainage, as well as seromas and hematomas that often form in the dead space created by the raised skin flaps, all of which contribute to the development of infection.

Certain surgical tenets should be followed in order to minimize the risk of cutaneous complications. Preoperative parenteral broad-spectrum antibiotics should be administered, and the surgical field should be thoroughly washed and prepped. Care should be taken to limit the mobilization of skin flaps to the boundaries required for dissection, regardless of the template used. Fine skin hooks are used when raising the flaps and the maximum thickness of superficial fascia should be preserved, while ensuring that no nodal tissue is left behind. At the end of the case, the skin flaps should be anchored to the underlying fascia to decrease dead space and to decrease tension on the skin edges. Meticulous hemostasis should be maintained to prevent hematoma formation. Lastly, it is important to debride any necrotic tissue at the skin edge prior to closure.

Management of wound infection without dehiscence is adequately treated with oral or parenteral antibiotics in most cases. Skin edge necrosis and minor flap necrosis can usually be managed with local wound care and bedside debridement. There is some evidence that negative pressure wound therapy may speed time to closure in this setting.[159] Larger defects may need debridement in the operating room and coverage with a split-thickness skin graft once the tissue begins to granulate. Primary reconstruction at the time of ILND with a tensor fascia lata pedicled flap, anterolateral thigh flap, or vertical rectus flap may be indicated in patients with large defects who are at high risk for necrosis postoperatively.[160]

One of the major advantages of minimally invasive ILND is that cutaneous complications are largely avoided. The ability to forgo a large incision near the inguinal crease for laparoscopic incisions on the abdomen or distal thigh seems to significantly decrease rates of infection. A large review of 249 minimally invasive groin dissections for vulvar cancer reported wound infection in 1.2% of cases.[155] Many smaller reports in the urologic literature report no skin

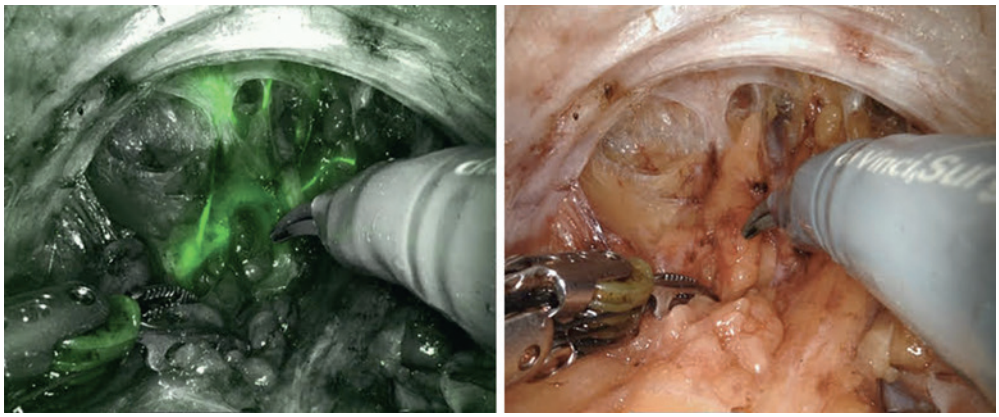

Figure 40.10 Injection of indocyanine green at the base of the penis to improve visualization of lymphatic tissue during robotic inguinal lymph node dissection.

complications with this technique.[156,161] In our initial experience, there have been no cutaneous complications in seven robotic groin dissections.

LYMPHATIC COMPLICATIONS

Disruption of lymphatic channels during ILND can result in lymphocele formation in a small percentage of patients. In an effort to prevent lymphoceles and seromas, most urologists leave a suction drain or drains at the end of the procedure, although there are no randomized trials to support this practice.[162] Drains are typically removed when output is less than 30–50 mL/day. If a lymphocele forms after removal of the drain, it should be drained only if infected or symptomatic. For persistent or recurrent lymphoceles, identification of open lymphatic channels with an injected blue dye and subsequent ligation has been successful in many cases.[163] For a detailed discussion on the management of lymphoceles, please see the earlier section on pelvic lymphadenectomy. Of note, applying fibrin sealant to the area of dissection does not appear to decrease the incidence of fluid collections in the setting of ILND.[164]

The most significant long-term complication of ILND is the development of chronic lymphedema, occurring in 4–22% of patients in contemporary series.[149,152,154,165,166] It clinically manifests as swelling of the affected limb, usually with increased turgor, hyperkeratosis, and papillomatosis. It can lead to significant disability, with many patients experiencing pain, heaviness, impaired function, and recurrent infections. Symptoms may be severe, impairing mobility and preventing patients from working.

There has been significant interest in risk factors and techniques to minimize the development of lymphedema. Larger extent of inguinal dissection, dissection of pelvic nodes, adjuvant radiation therapy, and increased BMI are risk factors.[151,167] Sparing the saphenous vein has been shown to decrease short- and long-term incidence of lymphedema.[168,169] Most urologists recommend leg elevation and lower extremity compression stockings as a method of prevention in the immediate postoperative period. However, a recent randomized controlled trial by Stuiver et al. did not show any benefit.[170] During robotic ILND at our center, we inject indocyanine green (ICG) at the base of the penis and blue dye in the first interweb of the ipsilateral foot to visualize the draining lymphatic vessels of the tumor and ipsilateral lower extremity, respectively. Careful ligation of lymphatics draining the tumor may prevent lymphocele formation, and avoidance of lymphatics draining the foot can potentially reduce incidence of lymphedema of that extremity (Fig. 40.10).

Treating chronic lymphedema is difficult, but advances in microsurgical therapies show promise in refractory cases. Treatment should begin with lower extremity compression devices and lymphatic massage, which are the cornerstones of conservative management.[171] Since muscle contraction is normally responsible for assisting the flow of lymph, regular exercise may be helpful.[172] Also, weight loss for obese patients may decrease the hydrostatic pressure opposing the flow of lymph.[173] For patients that have significant disability despite conservative measures, lymphaticovenous anastomosis and vascularized lymph node transfer are available options.[174] When applied to properly selected patients, these procedures can reduce the need for compression stocking use and the incidence of cellulitis.[175]

DEEP VEIN THROMBOSIS

Inguinal lymph node dissection is associated with rates of DVT as high as 6–12% in standard template dissections.[152,176,177] Intermittent pneumatic compression devices should be routinely applied prior to surgery to help mitigate this risk. Early ambulation is advisable for patients not undergoing simultaneous flap reconstruction. Heparin administration perioperatively is more controversial, due to concern for postoperative seroma, hematoma, or lymphocele formation. Anticoagulation practices are center specific and no high-quality studies exist supporting or refuting heparin use in this clinical scenario. In our tertiary care center, we do routinely administer subcutaneous heparin prior to ILND.

Chapter 40 Questions

1. When performing a "nerve-sparing" retroperitoneal lymph node dissection, which statement is TRUE regarding the dissection of the sympathetic nerves in the retroperitoneum?
   a. The right sympathetic chain travels posterior to the IVC while the left travels posterolateral to the aorta
   b. The sympathetic nerves within the aortic plexus consist of pre-ganglionic nerve fibers
   c. The sympathetic splanchnic nerves innervating the pelvic viscera most commonly originate from L3 and L4
   d. Splanchnic nerves overlying the IVC must be isolated prior to performing the split and roll technique to remove nodal tissue
   e. Damage to the sympathetic splanchnic nerves may result in difficulty achieving adequate erections postoperatively

2. All of the following are accepted methods for the management of chylous ascites after retroperitoneal lymph node dissection EXCEPT:
   a. Medium chain triglyceride diet
   b. Complete bowel rest and total parenteral nutrition
   c. Octreotide
   d. Peritoneovenous shunting
   e. Bipedal lymphangiography and injection of iodinated poppy seed oil

3. Which of the following is/are TRUE regarding the vascular anatomy of the retroperitoneum during retroperitoneal lymph node dissection?
   a. A retroaortic renal vein is important to identify because it may be mistaken for a lumbar vein
   b. Approximately one in ten patients may possess multiple renal arteries
   c. The inferior mesenteric artery may be safely transected in the majority of patients for better exposure to the aortic dissection
   d. a and c
   e. All of the above

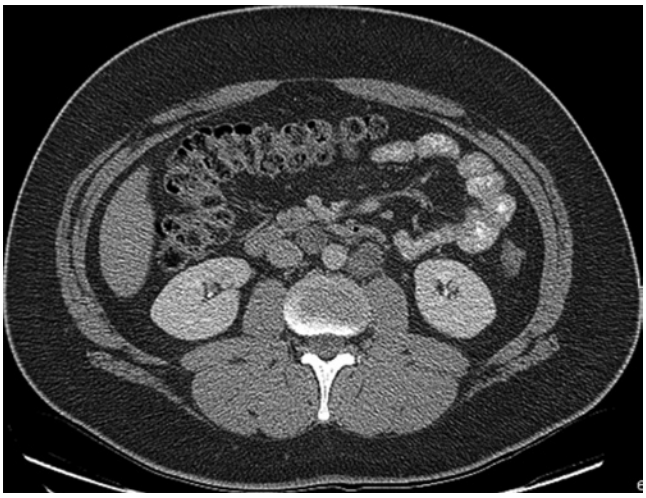
4. A 72-year-old woman has weakness of right leg flexion after an open cystectomy and ileal conduit creation. Which statement is TRUE regarding the nerve injured in this patient?
   a. The cutaneous branches of this nerve innervate the posterior and lateral aspects of the right lower extremity
   b. The nerve emerges to travel at the medial aspect of the psoas muscle after it pierces through its fibers
   c. Injury to this nerve is most likely to occur as a result of using a self-retaining retractor in the pelvis
   d. The length of the operation does not affect the incidence of injury to this nerve
   e. Injury to this nerve can result from prolonged lateral pressure at the knee while in dorsal lithotomy

5. The right obturator nerve is transected during dissection of the pelvic lymph nodes in a 58-year-old man undergoing robotic prostatectomy. All of the following are appropriate next steps EXCEPT:
   a. Primary end-to-end anastomosis of the nerve using microsurgical technique
   b. Creation of a sural nerve interposition graft to bring the two cut ends together if a primary tension-free anastomosis is not possible
   c. Delayed repair of the nerve 3 months after completion of the robotic prostatectomy
   d. Early postoperative consultation with a neurologist and rehabilitation specialist
   e. Early postoperative initiation of physical therapy

6. Which of the following symptoms may be present in a patient presenting with a pelvic lymphocele after radical prostatectomy?
   a. Urinary frequency
   b. Flank pain
   c. Lower extremity weakness
   d. Lower extremity edema
   e. All of the above

7. A 62-year-old man presents to the emergency department with vague abdominal fullness and low-grade fever 3 weeks after radical prostatectomy. CT scan reveals a left-sided lymphocele compressing the left common iliac vein. Which of the following are appropriate management options for this patient?
   a. Observation
   b. Percutaneous drain placement by interventional radiology
   c. Laparoscopic marsupialization in the operating room
   d. b and c
   e. All of the above

8. What is the approximate incidence of hospitalization for pulmonary embolism after pelvic lymphadenectomy?
   a. 0.1%
   b. 0.5%
   c. 1%
   d. 5%
   e. 10%



9. Which of the following is NOT an important surgical principle to prevent cutaneous complications when performing inguinal lymph node dissection?
   a. Administration of parenteral preoperative antibiotics
   b. Ten-minute scrub of the operative field with a chlorhexidine solution
   c. Preservation of the maximum thickness of superficial fascia while still removing all nodal tissue
   d. Anchoring skin flaps to the underlying fascia to decrease dead space
   e. Debridement of necrotic skin edges prior to closure

10. Which of the following is NOT TRUE of lower extremity lymphedema that develops after inguinal lymph node dissection?
    a. It resolves completely within 1 month after surgery in most patients

b. It can lead to significant disability and time missed from work
c. It can result in pain, heaviness, or recurrent infections in that limb
d. The cornerstones of management are compression stockings and lymphatic massage
e. Vascularized lymph node transfer is a treatment option in refractory cases

Case Study 1

A 26-year-old man presents to the office with 6 months of testicular pain and is found to have a 3-cm right testicular tumor. A staging CT of his abdomen and pelvis reveals a 8-cm paracaval mass. A chest CT is negative. He undergoes a right radical orchiectomy, and pathologic examination reveals a nonseminomatous germ cell tumor with primary embryonal component. His postorchiectomy alpha fetoprotein (AFP) and lactate dehydrogenase (LDH) remain elevated. He is referred to an oncologist and receives four cycles of etoposide + cisplatin. After chemotherapy his markers normalize, but a follow-up CT scan demonstrates enlarged residual interaortocaval and aortic nodes (Case Figs. 40.1 and 40.2). The patient is scheduled for retroperitoneal lymph node dissection.

Case Figure 40.1

Case Figure 40.2

1. Upon entering the retroperitoneum there is a dense desmoplastic reaction and it is difficult to isolate the lumbar veins. Which of the following is/are true regarding the anatomy of the lumbar veins?
   a. There are always three or four paired infrarenal lumbar veins
   b. Two or more lumbar veins may combine into a common trunk before draining into the inferior vena cava (IVC)
   c. A lumbar vein can occasionally drain into the left renal vein rather than the IVC
   d. b and c
   e. All of the above

2. During dissection of the adherent nodes, the left renal vein is inadvertently lacerated. After obtaining control of the vessel, examination reveals that the vein is half transected about 2 cm distal to its insertion into the IVC. The patient is known to have two functioning kidneys. Which of the following is the most appropriate next step?
   a. Immediately repair the vein with a 4-0 nonabsorbable monofilament suture
   b. Place an interposition Dacron graft
   c. Ligate the vein with surgical clips, leaving the left kidney in place to drain via collateral venous circulation
   d. Left nephrectomy
   e. None of the above

3. In some cases of post chemotherapy retroperitoneal lymph node dissection, it is impossible to dissect the nodal mass off of the IVC. In these cases, which of the following statements is NOT true?
   a. The IVC can be narrowed to up to one-third of its normal diameter during primary repair without grafting
   b. In the setting of chronic IVC occlusion by tumor, the IVC can usually be ligated without significant patient morbidity
   c. If the IVC is ligated, it is critical to spare collateral venous circulation in the area

d. In the setting of acute IVC ligation without prior occlusion, many patients will experience symptomatic lower extremity edema and/or stasis ulcers
e. If the IVC is to be reconstructed, a polytetrafluoroethylene graft is preferred

Case Study 2

A 59-year-old man with a history of hypertension, hyperlipidemia, and Gleason 4+4=8 prostate cancer undergoes an uncomplicated radical prostatectomy and pelvic lymph node dissection. His catheter is removed on postoperative day 7. Two weeks after surgery the patient develops severe urinary frequency and unilateral right leg swelling. In the emergency department, the patient's vital signs are normal. His white blood cell count and creatinine are both within normal limits. A urinalysis is sent, which is not consistent with a urinary infection. A noncontrast CT scan of the abdomen and pelvis reveals a large pelvic fluid collection (Case Fig. 40.3).

1. A drain is placed into the fluid collection, and the fluid is sent for analysis. Which of the following laboratory values would one expect to confirm the diagnosis of lymphocele?
   a. High fluid lipase
   b. High fluid lymphocyte count
   c. Fluid creatinine more than twice that of serum
   d. b and c
   e. All of the above

Case Figure 40.3

2. Seven days after placement of the drain, the output continues to be over 150 mL/day. Which of the following has been successfully used as a sclerosing agent?
   a. Ethanol
   b. Povidone-iodine
   c. Doxycycline
   d. Fibrin sealant
   e. All of the above

3. Which of the following is NOT a previously attempted technique to reduce the incidence of lymphoceles after lymphadenectomy?
   a. FloSeal placed in the area of lymphadenectomy
   b. Peritoneal fenestration during extraperitoneal lymphadenectomy
   c. Rotational flap of bladder peritoneum brought down into the deep pelvis
   d. Heparin injected into the arm instead of the leg immediately before surgery
   e. Intraoperative lymphangiography to detect lymph leaks at time of lymphadenectomy

Answers

1. **a.** The sympathetic nerves within the aortic plexus consist of post-ganglionic fibers. The sympathetic nerves supplying pelvic nerves most commonly originate from L1 and L2. In contrast to the aorta, there is usually no significant nerve tissue overlying the inferior vena cava. Damage to sympathetic nerves results in failure of emission, not erection.
2. **d.** Peritoneovenous shunting is an invasive measure for refractory chylous ascites that is associated with significant morbidity. It would only be indicated if all other measures listed here were to fail.
3. **d.** Approximately one quarter to one third of patients possess multiple renal arteries.
4. **c.** The nerve in question is the femoral nerve, which is responsible for leg flexion at the thigh and extension at the knee. It also gives off cutaneous branches that innervate the anterior and medial lower extremity. It is most often injured by inappropriate placement of a self-retraining retractor during open cystectomy.
5. **c.** Transection of the obturator nerve during prostatectomy can be highly morbid for the patient. Immediate repair is indicated as well as early consultation with a neurologist and rehabilitation specialist.
6. **e.** Large postoperative lymphoceles can compress the bladder or ureter as well as pelvic nerves or veins. This can potentially result in any one or combination of the symptoms listed.
7. **d.** This man likely has an infected lymphocele as he is presenting with low-grade fever. Observation is not appropriate for infected lymphoceles.
8. **c.** The incidence of symptomatic PE is approximately 1% after pelvic lymphadenectomy.
9. **b.** There is no published evidence that increasing the preoperative scrub time decreases the incidence of complications after inguinal lymph node dissection.

10. **a.** Lower extremity lymphedema is a morbid complication of inguinal lymph node dissection and is notoriously difficult to treat. It may require many months of intensive therapy, and may never completely resolve.

CASE STUDY 1

1. **a.** The number of infrarenal lumbar veins is highly variable between patients, varying from 0–4.
2. **a.** In general, partial lacerations to the left renal vein should be repaired if feasible, even in patients with two functioning kidneys, in order to preserve renal function. If the left renal vein is completely transected or avulsed, the kidney may still remain viable if significant collateral circulation has developed from a chronically occlusive mass.
3. **a.** It has been well demonstrated that the IVC can be narrowed to one half of its normal diameter during repair without significant adverse consequences.

CASE STUDY 2

1. **b.** This patient has a postoperative lymphocele. A high fluid lymphocyte count is diagnostic of a lymphocele. Fluid creatinine more than twice that of serum is indicative of a urinoma.
2. **e.** Many substances have been trialed as sclerosing agents for postoperative lymphoceles, including all of those listed.
3. **e.** Lymhpangiography has been utilized postoperatively to detect the area of leak in chylous ascites. It has not been described at the time of initial surgery.

Neurologic Complications
Delirium
Nerve Injury
Intraoperative Complications
Reoperation
Readmission
Mortality
Special Populations
Elderly
Following Radiation Therapy
Robotic Radical Cystectomy
Conclusions
Chapter 41 Questions and Answers

KEY POINTS

1. Radical cystectomy is associated with a high rate of complications.
2. Contemporary reporting criteria group complications by organ system and define them according to severity.
3. There are several risk factors for complications, including comorbidity and age.
4. Several techniques, including enhanced recovery pathways, restricted fluid protocols, laparoscopic approaches and referral to high-volume centers, may help minimize complications.

Introduction

Radical cystectomy (RC) with urinary diversion has been the treatment of choice for high-risk bladder cancer for over 50 years.[1] The initial experience with RC was associated with a 14% mortality rate, and over 50% of patients experienced early complications.[2] With advances in anesthesia, staging, patient selection, and surgical technique, there has been an improvement in many surgical outcomes. However, RC continues to be associated with substantial short- and long-term morbidity.

Radical cystectomy patients are generally elderly and have multiple medical comorbidities.[3–6] Surgery can take from 4 to 7 hours followed by a hospital stay of 6–17 days.[7–12] As a result of both the complexity of surgery and patient-related factors, 29–68% of patients experience an early postoperative complication and 1–10% suffer a postoperative mortality.[3–23]

There are many explanations for the wide ranges of complications reported after RC. However, the most important is the method by which complications are identified, classified, and described. In 2002 Martin et al. proposed several criteria that can be used to assess the quality of reporting for surgical complications (Box 41.1).[24] This includes the requirement to define the type and severity of complications, which can be accomplished using a method such as the Clavien-Dindo classification system (see Table 8.2).[25] These criteria are intended to standardize complication reporting

and allow for a more accurate comparison of outcomes across institutions. When several studies that reported RC complications were evaluated based on these criteria, the quality of complication reporting was very low.[26]

By using standard reporting criteria and extending the postoperative period to 90 days, significantly more early complications are observed after RC.[5] Furthermore, although population-level studies that report postoperative morbidity are useful for their large numbers and generalizability, they have limited sensitivity to detect, grade, and categorize the vast array of complications that can occur following RC, resulting in lower complication rates.[8,17,18] Reporting of outcomes is discussed in detail in Chapter 8. Herein, we describe the prevalence of the more common and serious early postoperative complications among contemporary RC cohorts and discuss methods for diagnosis, treatment, and prevention.

Box 41.1 Criteria for Quality Reporting of Surgical Complications[24]

- Method of accruing data defined
- Duration of follow-up indicated
- Outpatient information included
- Definitions of complications provided
- Mortality rate and causes of death listed
- Morbidity rate and total complications indicated
- Procedure-specific complications included
- Severity grade utilized
- Length-of-stay data
- Risk factors included in the analysis

Prevalence and Risk Factors

Using modern reporting methods 49–68% of patients experience at least one complication within 90 days of surgery (Table 41.1). Extending the time frame within which complications are measured is critical, as nearly 20% of patients will have complications after 30 days, some of which are severe.[5] Close outpatient follow-up is important as over half of complications occur following hospital discharge, either in the outpatient setting or during subsequent hospital readmissions.[5] The majority of complications after RC are minor (Clavien grade I–II), however from 13% to 22% of patients experience a major complication (Clavien grade III–V) (see Table 41.1). Patients who experience a complication tend to have longer hospital length of stay (LOS) and higher costs.[4,5,7,11]

The most commonly reported risk factor for a postoperative complication is patient comorbidity.[3,5,11,12,17,18] In a

Table 41.1 Summary of 90-Day Radical Cystectomy Complications Based on Institutional Cohorts Using Contemporary Reporting Methods

Complication Years	Shabsigh[5] 1995–2005	Takada[12] 1997–2010	Schiavina[11] 1995–2009	Novara[7] 2002–2006	Hautmann[3] 1986–2008
Number	1142	928	404	358	1013[c]

Mortality	3%	2%	5%	3%	2%

IR, interventional radiology; OR, operating room
[a]Minor complications considered Clavien grades I and II. Major complications considered Clavien grades III–V
[b]Includes return to the operating room and interventional radiology procedures
[c]Includes patients with orthotopic neobladders only

large retrospective study, patients with an American Society of Anesthesiologists (ASA) score of three or four had a 50% increased risk of complications (OR 1.5; 95% CI 1.04, 1.82; p = 0.02) on multivariate analysis.[5] A similar finding was reported by a large Japanese series.[12] Increasing age is also associated with the risk of any complication and severe complications.[3,12,17,18] One series noted a 40% increase in complications among patients over the age of 70.[12] Additional risk factors for complications include longer operating room time,[12] continent diversion,[5] female gender,[5] higher tumor stage,[3] more intraoperative blood loss,[5] and a greater body mass index (BMI).[19] Higher surgeon and hospital volume are associated with lower morbidity and mortality following RC.[4,17,27,28] Use of neoadjuvant chemotherapy does not appear to increase perioperative complications.[29,30]

Several preoperative interventions have been proposed to lessen the morbidity of major surgery, including smoking and alcohol cessation,[31,32] nutritional support,[33] shortened duration of fasting,[34] carbohydrate loading,[35] and exercise programs.[36] Future studies are required to better understand the impact of preoperative interventions, or "prehabilitation," on postoperative outcomes for RC patients.

Complications by Organ System

Postoperative complications can be broadly grouped into 11 different organ systems (see Table 41.1). The most common categories of complications are gastrointestinal, infectious, wound, and genitourinary.

GASTROINTESTINAL COMPLICATIONS

Gastrointestinal complications are among the most common postoperative complications, occurring in 15–29% of patients (see Table 41.1); they additionally are covered broadly in Chapter 11. The majority of gastrointestinal complications are attributed to ileus; however, small bowel obstruction, anastomotic bowel leak, gastrointestinal bleeding, and *Clostridium difficile* colitis (CDC) can also occur. Gastrointestinal complications in this setting are largely due to the urinary diversion, but can be partially attributed to the handling and mobilization of bowel during the cystectomy.

Ileus

Depending on the definition used, 7–23% of RC patients experience postoperative ileus.[3,5,11,12] Ileus is a functional small bowel obstruction due to impairment of peristalsis and is commonly defined by the absence of bowel function by postoperative day 5, nasogastric tube placement, or conversion to NPO status due to nausea, vomiting, or abdominal distention.[3,5] Ileus is the most common cause of prolonged LOS following RC.[37] Risk factors for ileus after RC include higher BMI, increasing age, longer operating time, and use of general anesthesia.[38] Ileus usually presents with abdominal distention in the absence of bowel function, but may progress to abdominal pain, nausea, and emesis.

Ileus is thought to occur due to an insult to small bowel innervation from irritation, inflammation, manipulation, or medication effects, and there are several proposed inciting factors.[39] Abdominal surgery, with manipulation of the bowel, is the most common cause of ileus. Several medications have also been implicated, particularly opioids and anticholinergics, as have metabolic abnormalities, including hypokalemia, hypocalcemia, hypomagnesemia, and hyponatremia.

The primary treatment of ileus is supportive, with intravenous hydration, correction of electrolyte abnormalities, and avoidance of offending medications. Nasogastric decompression is often indicated for patients with emesis or significant abdominal distention. Although widely recommended, there is no evidence that early and aggressive ambulation treats or prevents ileus. There are, however, several treatments that have been studied for the treatment or prevention of postoperative ileus.

Prokinetic agents are widely used to prevent and treat ileus, but there are relatively little data to support their effectiveness.[40] Most studies on prokinetic agents have been conducted following colorectal surgery, although their findings are likely generalizable to RC patients. Metoclopramide achieves prokinetic effects through its action on cholinergic and dopamine receptors in the upper gastrointestinal tract. In a small study of RC patients, metoclopramide was associated with less nausea and vomiting (3% vs 12%, p = 0.01) but no difference in return of bowel function, rate of ileus, or time to discharge.[41] Another study found that when combined with early nasogastric tube removal, metoclopramide is associated with a faster return of bowel function after RC.[42] Erythromycin is a macrolide antibiotic that has been used as a prokinetic given its effects on motilin receptors in the gastrointestinal tract. One small study randomized 22 RC patients to receive low-dose intravenous erythromycin or placebo starting on postoperative day 1 and found no difference in recovery of bowel function.[43] These results are in agreement with other randomized studies from the general surgery literature suggesting erythromycin has limited benefit to treat or prevent postoperative ileus.[40]

Alvimopan is a peripheral opioid μ-receptor antagonist that blocks the effect of opioids on the gastrointestinal tract. It is approved by the U.S. Food and Drug Administration (FDA) to accelerate gastrointestinal recovery following a bowel resection and primary anastomosis. A recent multicenter randomized study examined the use of alvimopan in RC patients to accelerate the return of gastrointestinal function and decrease LOS.[44] A total of 280 patients were randomized to receive alvimopan or placebo between 30 minutes and 5 hours before surgery and continued until the day of discharge or postoperative day 7. Patients receiving alvimopan recovered their gastrointestinal function 1 day earlier (day 5.5 vs 6.8, p < 0.0001), had a shorter LOS (7.4 vs 10 days, p < 0.01), and less postoperative ileus-related morbidity including use of nasogastric decompression and prolonged LOS. Alvimopan has a favorable safety profile and may be associated with lower hospital costs after RC.[45]

Methylnaltrexone is another opioid μ-receptor antagonist that is FDA approved to treat opioid-induced chronic constipation. Although methylnaltrexone has not been studied in RC patients, there have been two randomized controlled trials examining its use in treating postoperative ileus after colorectal surgery.[46] Each was a multi-institution trial that randomized patients to 12 or 24 mg of intravenous methylnaltrexone or placebo following segmental colectomy. With over 1000 patients randomized, neither study

demonstrated faster return of bowel function or time to hospital discharge in patients receiving methylnaltrexone. Ghrelin agonists,[47] cholinergic agents,[48] and even acupuncture[49] have been studied for reducing postoperative ileus; however, none have demonstrated success.

Because ileus is thought to occur from an imbalance of the sympathetic and parasympathetic innervation to the small bowel, the cholinesterase inhibitor neostigmine has shown benefit in treating postoperative ileus.[40] Some centers have routinely administered neostigmine after RC, although this medication has not specifically been studied in RC patients.[50] Due to the inhibitory effect of opioids on gastrointestinal motility, limiting the use of opioids for postoperative pain control has also been tested as a means of reducing postoperative ileus. Intravenous acetaminophen, epidural anesthesia, and nonsteroidal antiinflammatories, such as ketorolac, are all effective means of limiting opioid exposure and may help reduce ileus.[51–54]

Fluid overload may cause bowel wall edema and inhibit bowel function, and fluid restriction can result in faster recovery of bowel function.[55] Recently, 166 RC patients were randomized to receive usual versus restricted intraoperative hydration.[56] Patients in the restricted fluid cohort received significantly less intraoperative fluid (1.7 L vs 4.3 L, $p < 0.0001$) and had an 84% relative reduction in gastrointestinal complications (6% vs 37%, $p < 0.0001$), primarily due to a reduction of ileus (0% vs 10%) and constipation (2% vs 22%).

Based on observations that chewing has a stimulatory effect on bowel motility, gum chewing has been studied as a treatment of postoperative ileus. Kouba et al. compared 51 RC patients who were instructed to chew gum starting on postoperative day 1 to 51 historic RC patients who did not chew gum.[57] Patients who chewed gum had slightly faster time to flatus (2.4 vs 2.9 days, $p < 0.001$) and to first bowel movement (3.2 vs 3.9 days, $p < 0.001$). Coffee also has stimulatory effects on the gastrointestinal tract, and another study randomized 80 patients to drink coffee or water after colectomy.[58] Patients who drank coffee had a shorter time to first bowel movement (60 vs 74 hours, $p = 0.006$), but there was no difference in LOS or postoperative complications.

Routine gastric or nasogastric decompression was often used following RC in an effort to decrease gastrointestinal complications. A large retrospective study compared 221 RC patients that had a prophylactic postoperative nasogastric tube to 199 RC patients who did not.[59] There was no difference in time to first bowel movement or gastrointestinal complications, although patients with nasogastric tubes tended to have longer LOS. Nearly 20% of the patients without a prophylactic nasogastric tube eventually required one, and 15% of patients who had their prophylactic nasogastric tube removed needed reinsertion. These observations are supported by a large meta-analysis and Cochrane review, each of which failed to demonstrate the benefit of routine prophylactic nasogastric decompression following elective laparotomy, and instead found an increased risk of pulmonary complications.[60,61]

In another effort to avoid gastrointestinal complications, RC patients are often kept without food or liquid as bowel function recovers. Given the catabolic effects of major surgery, some centers have used parenteral nutritional support prior to the return of bowel function. Roth et al. randomized 157 RC patients to postoperative parenteral nutrition for 5 days, beginning on postoperative day 1, or usual care with early enteral feeding.[62] Patients receiving parenteral nutrition had more complications (69% vs 49%, $p = 0.013$), including a higher rate of infectious complications (32% vs 11%, $p = 0.001$), but no difference in recovery of gastrointestinal function. Current guidelines from the European Society for Clinical Nutrition and Metabolism state that parenteral nutrition is beneficial in undernourished patients when enteral nutrition is not feasible or not tolerated, or in patients who have impaired gastrointestinal function and an inability to tolerate enteral feeds for at least 7 days.[63]

Recent evidence supports the safety of early enteral feeding following gastrointestinal surgery.[64] A retrospective study of RC patients found that early enteral feeding was associated with fewer postoperative complications and a shorter LOS when compared to parenteral nutrition and nothing by mouth.[65] A Cochrane review found that patients that had colorectal surgery who were fed within 24 hours did not have a higher risk of postoperative complications, including bowel leak, wound infection, and LOS, when compared to patients who were kept with no oral intake until the return of bowel function.[66] Therefore a strategy of early enteral feeding can provide needed nutrition and does not appear to be associated with a higher rate of complications.

Mechanical bowel preparations are often used prior to RC, with the intent of facilitating surgery by decreasing fecal load and reducing gastrointestinal and infection complications. Based on several meta-analyses in the colorectal literature, the use of mechanical bowel preparations has come into question as there is no evidence they reduce anastomotic leaks, wound infections, or gastrointestinal morbidity.[67,68] A retrospective study compared gastrointestinal and infectious complications between 105 RC patients who had a mechanical bowel preparation to 75 who did not.[69] There was no difference in postoperative *C. difficile* infection, wound infection, or severe abdominal or gastrointestinal complications. Another retrospective series compared 37 RC patients who had a mechanical bowel preparation to 33 who did not.[70] There were no differences in time to flatus, time to first bowel movement, LOS, or severe complications between the two groups. While a mechanical bowel preparation may be helpful when using a colonic segment for urinary diversion, it can safely be omitted for a diversion using ileum.

Some have hypothesized that gastrointestinal morbidity following RC may be due to the interaction between the bowel and deperitonealized pelvis, leading to bowel inflammation and adhesion formation. Roth et al. randomized 200 patients having RC and extended pelvic lymph node dissection (PLND) to readaptation of the peritoneum over the dorsolateral pelvic walls versus no readaptation.[71] Readaptation of the peritoneum was associated with faster return of bowel function, fewer complications, and less postoperative pain, but there was no difference in LOS. A follow-up study suggested better long-term bowel function in patients who had peritoneal readaptation.[72] The authors propose this as a safe, effective, and easy way to decrease postoperative gastrointestinal morbidity.

Standardized pathways and enhanced recovery protocols after RC have been employed for over 10 years in an effort

to reduce complications, accelerate the return of bowel function, and reduce LOS using evidence-based medicine.[37] The meaningful gains in postoperative recovery realized from these protocols are achieved by combining the modest benefits of multiple interventions.[73] In 2010 Pruthi et al. described their experience with a "fast track" program for RC that employed several evidence-based strategies, including immediate removal of nasogastric tubes, use of metoclopramide, minimization of narcotic analgesia, early enteral feeding, and use of chewing gum.[41] Although this was not a comparative study, 80% of fast track patients were discharged by postoperative day 5 and the average time to return of bowel function was 2.2 days. A German group randomized RC patients 2:1 to an enhanced recovery pathway (N = 62) and usual care (N = 39).[74] The enhanced recovery pathway included a limited bowel preparation, preoperative nutritional support, early enteral feeding, immediate nasogastric tube removal, early mobilization, and use of prokinetic agents. The enhanced recovery group had better quality of life, fewer inpatient complications, and decreased analgesic demand, but there were no differences in ileus or LOS. Finally, the University of Southern California group described their experience using an extended recovery protocol in 110 RC patients.[75] The extended recovery protocol included pre-, intra-, and postoperative interventions, such as patient education, absence of a bowel preparation, use of alvimopan and prokinetic agents, minimization of intravenous fluid and narcotic analgesia, no prophylactic nasogastric tube use, and early enteral feeding. Patients treated with this protocol had a median time to flatus and LOS of 2 and 4 days, respectively. Still, the 30-day complication rate was 65%, and 21% of patients were readmitted, generally due to dehydration or infection. When combined with surgical expertise, extended recovery programs may lessen gastrointestinal morbidity and reduce LOS; however, they do not appear to reduce overall complications or readmissions.

Small Bowel Obstruction

Ileus is the most common gastrointestinal complication, although approximately 7% of RC patients experience a small bowel obstruction.[5] Because both complications can present similarly, abdominal computed tomography (CT) with oral contrast is often helpful in diagnosing a bowel obstruction, with the characteristic finding of dilated bowel up to a transition point with distal compression. Most small bowel obstructions are the result of internal adhesions or bowel edema. Initial treatment for a small bowel obstruction includes supportive care with intravenous hydration and electrolyte replacement, nasogastric decompression, and bowel rest. While this may be effective at resolving the obstruction, it is critical to monitor for signs of bowel ischemia or perforation through vital signs, serial exams, and periodic blood work, with particular attention being paid to the white blood cell count. If the obstruction does not resolve with conservative measures, abdominal exploration may be required.

Clostridium difficile Colitis

CDC is caused by the gram-positive spore-forming bacterium *C. difficile*. CDC has historically been a rare complication following RC that occurred in fewer than 3% of patients.[5,12,76,77] However, a recent study observed an 8.8% prevalence of CDC within 90 days of RC, with an increase over time.[78] This condition is associated with prolonged LOS, patient morbidity, and increased costs and causes up to 10% of RC readmissions.[77,78]

The diagnosis of CDC is made in the presence of symptoms of colitis, such as diarrhea, abdominal pain, and leukocytosis, and a positive fecal *C. difficile* toxin or culture. Rarely, patients will develop severe manifestations of CDC such as pseudomembranous colitis or toxic megacolon.

The primary risk factor for CDC is exposure to antibiotics that are thought to disrupt normal bowel flora, particularly fluoroquinolones, clindamycin, and broad-spectrum penicillin and cephalosporins.[79] The duration of antibiotic exposure is also an important risk factor. A recent study found that RC patients were on average treated with 10 days of perioperative antibiotics, and use of an extended duration of antibiotics was associated with a 60% higher risk of CDC.[76] Another study found that patients who were treated with perioperative antibiotics for at least 7 days had double the odds of CDC.[78] Other risk factors for CDC include older patient age, immunosuppression, chronic antacid therapy, and longer LOS.[80]

The two most important methods to avoid *C. difficile* transmission are minimization of unnecessary antibiotics and meticulous hand hygiene with removal of bacterial spores using soap and water. Current guidelines recommend treating CDC according to disease severity.[80] Consideration should be made to discontinuing offending antibiotics and consulting with an infectious disease specialist. Patients with mild-to-moderate infection should be treated with oral metronidazole 500 mg three times daily for 10–14 days, whereas those with a severe infection should be treated with oral vancomycin 125 mg four times daily for 10–14 days. Complicated cases may require higher doses of oral vancomycin, intravenous metronidazole, vancomycin enemas, or other antibiotics. Patients who develop a severe infection or toxic megacolon may require a colectomy.

Anastomotic Leak

A bowel anastomotic leak occurs in less than 2% of RC patients.[5,7,8,12] The severity of a bowel leak is variable, but has a risk of causing significant morbidity and mortality.[3,81] There are several risk factors for an anastomotic leak including active smoking, obesity, and immunosuppression.[82] Meticulous surgical technique with creation of a tension-free and well-vascularized anastomosis is necessary to avoid leaks. An anastomotic leak is often diagnosed clinically with signs of systemic infection or peritonitis on physical examination. A radiologic diagnosis can be made by visualizing leakage of oral contrast on a CT scan. Some leaks may be managed conservatively with bowel rest and antibiotics; however, many patients require exploration. A general surgery consult is often warranted.

Acute Colonic Pseudo-obstruction

Finally, acute colonic pseudo-obstruction (Ogilvie's syndrome) is a functional obstruction of the colon due to bowel paralysis, likely due to an imbalance of autonomic innervation.[83] It is a rare complication after RC, and the exact causes are unknown. On imaging, many patients with acute colonic pseudo-obstruction have large bowel dilation to a transition point in the descending colon. Most cases improve with conservative measures, including nasogastric

and rectal decompression, correction of electrolyte imbalances, and avoidance of constipating medications, although there is a small risk of colonic perforation. Patients who fail 2–3 days of conservative treatment as well as those with significant cecal dilation (>12 cm) or long-standing obstruction (>3 days) may require more aggressive treatments. Because acute colonic pseudo-obstruction is likely due to a deficit of parasympathetic innervation, low-dose (2 mg) neostigmine is an effective treatment.[84] Neostigmine causes systemic manifestations of excess cholinergic supply, such as salivation, sweating, bronchospasm, and bradycardia, necessitating cardiac monitoring. For those who fail neostigmine or for whom it is contraindicated, endoscopic decompression may be indicated.[83,85] Patients with colonic ischemia or perforation require colectomy.

INFECTIOUS COMPLICATIONS

Infections are also very common following RC and occur in up to 30% of patients (see Table 41.1). The prevention and management of infections are reported in detail in Chapter 7. The majority of infections occur within the urinary tract, although RC patients are also at risk for intraabdominal infections and abscesses, often from enteric organisms. Symptoms of infection range from a low-grade fever or mild leukocytosis to severe sepsis. Surgeons must be vigilant in monitoring for infectious symptoms and have a low threshold for initiating a complete infectious workup, including blood and urine cultures, chest imaging, and, when indicated, abdominal imaging. Initial treatment includes fluid administration and broad-spectrum antibiotics, which should ultimately be narrowed to culture data. Early source control is critical, including drainage of intraabdominal collections or relief of urinary obstruction.

Although there have been no randomized trials to examine the effectiveness of prophylactic antibiotics to prevent infections in RC patients, both the American Urological Association and European Association of Urology recommend administration of prophylactic antibiotics within 1 hour of incision and not continued for longer than 24 hours postoperatively.[86,87] First-line antimicrobial prophylaxis includes either a second- (i.e., cefazolin, cefoxitin, cefuroxime) or third- (i.e., ceftriaxone, ceftazidime, cefotaxime) generation cephalosporin, or aztreonam plus metronidazole or clindamycin.[86] The choice of antibiotics may also be guided by previous culture data and the local antibiogram.

GENITOURINARY COMPLICATIONS

Genitourinary complications occur in 8–15% of patients and are typically related to the urinary diversion.[5,11,12] Urinary complications related to urinary diversion are covered in more detail in Chapters 13, 45, 46, and 47. The majority of early diversion-related complications are ureteral obstruction and urinary leak.

Ureteral Obstruction

Early ureteral obstruction occurs in 4–10% of RC patients and can cause flank pain, infection, and renal insufficiency.[5,12] Such symptoms should prompt upper tract imaging. The obstruction is most often at the site of the ureterointestinal anastomosis and can generally be prevented by meticulous surgical technique. Treatment requires relief of the obstruction, usually with a percutaneous nephrostomy tube. While not used by all surgeons, ureteral stents placed at the time of the ureterointestinal anastomosis may facilitate healing, avoid anastomotic leaks, and hasten recovery, although there is no evidence they reduce strictures or early obstruction.[88,89]

Urine Leak

A urine leak occurs in up to 4% of RC patients and may originate from the ureteral anastomosis, the proximal end of an ileal conduit, the sutured wall of an orthotopic neobladder or continent cutaneous diversion, or the urethroneovesical anastomosis of an orthotopic neobladder.[5,12] Early leaks may be detected through high intraperitoneal drain output with elevated fluid creatinine that is consistent with urine. Undrained leakage of urine into the peritoneal cavity can result in chemical peritonitis, ileus, and abdominal distention. Often the serum creatinine will be elevated as intraperitoneal urine is absorbed. Treatment of a urine leak requires urinary tract drainage and decompression, using percutaneous drains, nephrostomy tubes, or Foley catheters. Many leaks will resolve with conservative management alone.

There are many uncommon diversion-related early complications such as stomal necrosis, stomal retraction, and neobladder perforation. In general, complications such as these are managed nonoperatively with catheter or nephrostomy drainage, with a potential for a delayed repair.

WOUND COMPLICATIONS

Wound complications occur in up to 21% of patients, the majority of which are infections.[5,12] Complications related to the wound are covered in more detail in Chapter 9.

Wound Infection

Radical cystectomy and urinary diversion with controlled entry into the gastrointestinal tract is considered a clean-contaminated procedure with an estimated 4–10% wound infection risk.[87] With spillage of gastrointestinal contents, the procedure becomes contaminated and the risk increases to 10–15%. Overall, 9–19% of RC patients experience a postoperative wound infection.[5,12] Symptoms of a wound infection are pain, redness, fevers, leukocytosis, and purulent drainage, although early infections can be asymptomatic. Risk factors for wound infection include patient comorbidity, longer procedure duration, open surgery, wound classification, malignancy, malnutrition, diabetes, smoking, blood transfusion, and obesity.[90–93]

Methods to reduce wound infections include perioperative antibiotic prophylaxis, skin sterilization, and abdominal closure techniques, such as incisional lavage, tissue approximation to eliminate dead space, and subcutaneous drains to minimize fluid accumulation.[94] Skin preparations used for preoperative skin sterilization are based either on iodine or chlorhexidine. A recent randomized trial observed a 40% reduction in surgical site infections after clean-contaminated surgery in patients who had a chlorhexidine-alcohol skin preparation, compared to patients with a povidone-iodine skin preparation.[91] Prevention of intraoperative hypothermia and postoperative

hyperglycemia, both risk factors for wound infections, may also reduce surgical site infections.[95,96] It is unclear if hair removal is associated with a decreased risk of surgical site infections; however, electronic clippers should be used if hair removal is performed.[97] Mechanical bowel preparation is not associated with a reduction in wound infections.[67,70]

Several groups have implemented perioperative care bundles to successfully reduce surgical site infections.[98] These bundles include several evidence-based practices such as antibiotic prophylaxis, glycemic control, normothermia, and appropriate hair removal, as well as items implemented during abdominal closure, including a change in gloves and gowns, wound lavage, and using a clean set of instruments.[98]

The immediate treatment of a wound infection is to open, clean, and pack the wound and administer antibiotics. While many patients develop infections from gram-positive organisms, gram-negative infections can also occur, necessitating wound culture and initial use of broad-spectrum antibiotics. Wound packing will be successful in treating the majority of infections, but requires prolonged local wound care and healing by secondary intention.

Skin Separation and Fascial Dehiscence

Other wound complications include seromas, skin separation, and fascial dehiscence. Skin separation is treated with local wound care, including packing or a negative pressure dressing. In the absence of necrotic tissue and infection, healing by secondary intention will occur over the course of several weeks, depending on the size of the wound.

Fascial dehiscence is rare in many series (<1%), although a recent study observed a 3.2% prevalence following RC.[5,7,12,99] In this study, the dehiscence occurred at a median of 11 days postoperatively and all patients who had a dehiscence also had a wound infection.[99] Predictors of dehiscence included obesity, chronic obstructive pulmonary disease (COPD), and wound infection. Fascial dehiscence often requires reoperation and abdominal wall closure given the risk of evisceration. While patient factors may impact the development of fascial dehiscence, it is strongly related to technical factors during fascial closure.

There are several ways to close the abdominal fascia, including use of running or interrupted sutures and choice of permanent, braided absorbable and monofilament absorbable sutures. The fascia must be closed in a tension-free manner with approximation of healthy tissue. A recent trial randomized patients to midline abdominal closure with interrupted braided absorbable suture or a continuous absorbable monofilament suture with a suture:wound length ratio of 4 : 1.[100] There was no difference in incisional hernia rates at 1 year or wound complications, including fascial dehiscence. However, a meta-analysis observed lower rates of hernias with closure using a continuous slowly absorbable suture as compared to an interrupted technique.[101] Specifically regarding the technique of midline closure using a continuous monofilament absorbable suture, a recent randomized trial demonstrated that smaller fascial bites (5 mm every 5 mm) were associated with a significantly lower risk of incisional hernia at 1 year (13% vs 21%; OR 0.52; 95% CI 0.31–0.87; p = 0.0131) than larger tissue bites (1 cm every 1 cm); however, there was no difference in fascial dehiscence or wound complications.[102] In our opinion, high-risk patients especially may benefit from prophylactic external retention sutures for 4–6 weeks.

BLEEDING COMPLICATIONS

Intraoperative blood loss during RC ranges from 600 mL to 1300 mL and 29–82% require a transfusion of blood products.[7–12,19] Risk factors for blood transfusion include female gender,[16] higher BMI,[103,104] lower preoperative hemoglobin,[105] and higher tumor stage.[105] Blood transfusions carry risks of transfusion reactions and transmission of infectious diseases. Patients who receive transfusions after RC may also have an increased risk of postoperative complications,[106] disease recurrence, and mortality.[105,107] The majority of bleeding during RC occurs along the lateral pedicles or dorsal venous complex. In women, the paravaginal tissues are highly vascular and can also be a source of bleeding. Early vascular control is critical to avoid excess bleeding.

There are several methods to control the vascular pedicle, including clips and ties, staplers, and energy devices. A randomized trial demonstrated less blood loss and fewer blood transfusions during RC when a stapler was used to ligate the vascular pedicles compared to conventional techniques.[108] More recently, the same group randomized RC patients to tissue ligation by stapler or the LigaSure, an electrothermal bipolar tissue ligation device.[109] There were no differences in blood loss, operative time, or transfusion requirements between the two groups; however, the device-associated cost was lower with the LigaSure group.

There are a variety of topical hemostatic agents that can be helpful adjuncts to control venous bleeding.[110] The use of topical hemostatic products is common during RC.[111]

Strategies to reduce intraoperative volume administration have shown promise in reducing intraoperative blood loss. In an effort to reduce perioperative blood transfusions, the Bern group randomized 166 RC patients to restricted intraoperative hydration versus usual care.[112] The restricted hydration group had significantly less intraoperative blood loss (800 mL vs 1200 mL, p < 0.0001) and required fewer blood transfusions (33% vs 60%, p = 0.0006). This effect may have occurred through a reduction in pelvic venous pressure.[113] Intraoperative cell salvage collects and reinfuses the patient's own red blood cells during surgery and has successfully been used during RC.[114]

For significant pelvic bleeding that is difficult to control or in a patient with coagulopathy, the pelvis can be packed while the patient is resuscitated and stabilized. In some instances, the pelvis can be packed and the abdomen temporarily closed with return to the operating room at a later time. In these rare circumstances, the urine can be diverted with externalized ureteral catheters.

Ultimately, prevention of bleeding requires a knowledge of vascular anatomy, along with variations in anatomy, and experience in properly achieving exposure during vascular control, regardless of pelvic anatomy. Most often, bleeding occurs when the anatomy of the pelvis is distorted due to anatomic variation, tumor size and extent, previous surgery, or radiation. In these cases, patience of the surgeon and adherence to anatomic principles are critical in avoiding uncontrolled bleeding upon division of the bladder pedicles, mobilization of the pelvic floor, or division of the dorsal vein.

THROMBOEMBOLIC COMPLICATIONS

Venous thromboembolism (VTE) occurs in 1–8% of RC patients within 90 days of surgery.[5,7,11,12] The majority of VTE events are deep venous thrombosis (DVT), although pulmonary emboli (PE) occur in up to 3% of patients and represent a significant cause of postoperative mortality.[5,81,115] There are several risk factors for VTE including older age, higher BMI, personal or family history of VTE, malignancy, smoking, increased comorbidity, and immobility.[116–118] Patients having a long open abdominal or pelvic operation have a particularly high risk of VTE.

The use of prophylactic low-dose unfractionated heparin (LDUH) and low-molecular-weight heparin (LMWH) is associated with a reduced risk of VTEs, including fatal PE and death, but an increase in nonfatal bleeding.[117] LDUH and LMWH are equally effective at VTE prophylaxis. Mechanical VTE prophylaxis, with sequential compression devices or elastic stockings, has also been shown to reduce DVTs, but there is no evidence it reduces the risk of fatal PE or death.[117] When compared to pharmacologic prophylaxis alone, mechanical prophylaxis is associated with an 80% increased risk of DVT, but a 60% decreased risk of bleeding.[117] The combination of pharmacologic and mechanical prophylaxis may further reduce VTE risk compared to pharmacologic prophylaxis alone.

Current guidelines from the American College of Chest Physicians and the American Urological Association recommend individualized assessment of VTE risk for surgical patients (Table 41.2).[117,118] RC patients are generally elderly, have a malignancy, require a prolonged open abdominal operation, and have restricted mobility during their recovery, putting them in the highest risk category for VTE.[117] These patients should be treated with prophylactic LMWH or LDUH beginning at the time of surgery and continuing throughout their hospital stay, unless the risk of bleeding is excessive. Concurrent use of mechanical prophylaxis and early ambulation is also recommended.

A recent study described the prevalence and timing of VTE in over 1300 RC patients.[119] The rate of VTE within 30 days of surgery was 6% and over 50% of VTEs occurred after hospital discharge. A similarly high rate of post-discharge VTE was reported using a large institutional cohort.[120] An increased risk of DVT for up to 12 weeks has led some to recommend long-term use of chemoprophylaxis.[117] Following abdominal or pelvic cancer surgery, use of prophylactic LMWH for 4-weeks is associated with at least a 50% reduction in DVTs compared to a 1-week course.[117,121] The American College of Chest Physicians currently recommends an extended duration of prophylaxis with LMWH for high-risk patients.[117] Preventive strategies for VTE are additionally discussed in detail in Chapter 4.

Table 41.2 Preoperative Venous Thromboembolism Risk Stratification and Treatment Recommendations for Patients Having Gastrointestinal, Urologic, Vascular, Breast, and Thyroid Procedures

Risk Category	Risk Score[a]	VTE Risk in Absence of Prophylaxis	Recommended Prophylaxis
Very low	0	<0.5%	Early ambulation only
Low	1–2	1.5%	Mechanical prophylaxis, preferably with sequential compression devices
Moderate	3–4	3.0%	■ Pharmacologic[b] OR mechanical prophylaxis, preferably with sequential compression devices OR ■ Mechanical prophylaxis if bleeding risk is high, preferably with sequential compression devices
High	≥5	6.0%	■ Pharmacologic[b] AND mechanical prophylaxis OR ■ Mechanical prophylaxis if bleeding risk is high, preferably with sequential compression devices[c]
High-risk cancer surgery			■ Pharmacologic[b] AND mechanical prophylaxis AND extended duration LMWH post-discharge OR ■ Mechanical prophylaxis if bleeding risk is high, preferably with sequential compression devices[c]

[a]Caprini risk score:
1 point: age 41–60, minor surgery, BMI >25, swollen legs, varicose veins, pregnancy or postpartum (<1 mo), history of unexplained or recurrent spontaneous abortion, oral contraceptives or hormone replacement, sepsis (<1 mo), severe lung disease including pneumonia (<1 mo), abnormal pulmonary function, acute myocardial infarction, congestive heart failure (<1 mo), inflammatory bowel disease, medical patient at bed rest
2 points: age 61–74, arthroscopic surgery, major open surgery (>45 min), laparoscopic surgery (>45 min), malignancy, confined to bed >72 hrs, immobilizing cast (<1 mo), central venous access
3 points: age ≥75, history of VTE, family history of VTE, factor V Leiden, prothrombin 20210A, lupus anticoagulant, anticardiolipin antibodies, elevated serum homocysteine, heparin-induced thrombocytopenia, other congenital or acquired thrombophilia
5 points: stroke (<1 mo), elective arthroplasty, hip, pelvis, or leg fracture (<1 mo), acute spinal cord injury (<1 mo)
[b]LDUH and LMWH both acceptable for pharmacologic prophylaxis
[c]LMWH or LDUH can be added once bleeding risk diminishes
(Adapted from Gould MK, Garcia DA, Wren SM, et al. Prevention of VTE in nonorthopedic surgical patients: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. Chest. 2012;141:e227S-77S.)

CARDIAC COMPLICATIONS

Radical cystectomy is considered to have an elevated risk of postoperative major cardiac events,[122] and upward of 11% of RC patients experience a postoperative cardiac complication.[123] Cardiac complications can be associated with significant morbidity and mortality.[81,124] Preoperative cardiac assessment and perioperative cardiac management are reviewed in detail in Chapter 3. Risk factors for perioperative cardiac complications include high-risk coronary artery disease, stroke within 3 months of surgery, coronary artery stent placement within 6 months of surgery, renal insufficiency, diabetes, congestive heart failure, atrial fibrillation, peripheral vascular disease, hypertension, severe aortic stenosis, male sex, and age over 75.[124] The

most common cardiac complication is an arrhythmia, of which atrial fibrillation is most frequent.[123] Patients with a known cardiovascular disease, or risk factors for cardiovascular disease, are at high risk for a postoperative cardiac complication and should have a full preoperative cardiac risk assessment.[123,124]

Patients with a history of coronary disease, and particularly those with coronary stents, should be maintained on low-dose aspirin unless the bleeding risk is unacceptably high.[122] The decision to continue perioperative antiplatelet therapy for patients with cardio- or cerebrovascular disease should be made in conjunction with the treating internist, anesthesiologist, and urologist.[122,125] Patients who are taking beta-blockers and statins before surgery should continue these medications perioperatively.[122] Other factors that may reduce the risk of cardiac events include pain control, avoidance of hypotension, and restricted use of intravenous fluids.[56]

Although anemia may further impair myocardial oxygen delivery to patients with cardiovascular disease, there is no apparent benefit to a liberal transfusion threshold for high-risk patients having noncardiac surgery.[126] Further, blood transfusions are associated with an increased risk of infectious complications and adverse survival outcomes after RC, supporting more conservative transfusion thresholds.[107,127] Current recommendations call for a restrictive transfusion strategy in asymptomatic patients with a history of cardiovascular disease and consideration of transfusion for a hemoglobin <8 g/dL.[122]

PULMONARY COMPLICATIONS

Pulmonary complications occur in up to 9% of patients following RC.[5] The most common complications are pneumonia and respiratory distress, but others include respiratory failure requiring prolonged intubation or reintubation, pleural effusion, and pneumothorax.[5,11,12] There are several risk factors for pulmonary complications after abdominal surgery including increased patient comorbidity, dependent functional status, COPD, obstructive sleep apnea (OSA), smoking, low albumin, and advanced age.[128] Additional procedural-related risk factors include prolonged operating time, general anesthesia, and prolonged LOS.

Patients with known or suspected pulmonary disease may require preoperative pulmonary evaluation and optimization of pulmonary function. Pulmonary function testing can identify patients who are at increased risk for postoperative pulmonary complications and help guide intra- and postoperative management.[128] Preoperative pulmonary optimization includes smoking cessation and alcohol abstinence, as well as treatment of underlying airway obstruction and respiratory infection.[129] Preoperative pulmonary assessment and perioperative management of specific pulmonary complications are reviewed in detail in Chapter 2.

NEUROLOGIC COMPLICATIONS

Neurologic complications occur in less than 5% of RC patients. Peripheral neuropathy and delirium are the most common neurologic complications; however, stroke and seizure have also been reported.[5,7,11]

Delirium

Delirium is significantly more common among elderly hospitalized patients. Risk factors for postoperative delirium include preexisting cognitive or psychiatric disorder, increased patient comorbidity, poor functional status, older age, and polypharmacy, particularly with psychotropic medications and anticholinergics.[130] In a prospective study of 49 elderly patients having RC, nearly 30% experienced postoperative delirium, lasting an average of about 2 days and typically occurring early in the postoperative course.[131] Increased age was associated with an increased risk of delirium, and patients who experienced delirium had higher odds of being readmitted. Most patients developed an acute change in mental status with inattention and disorganized thinking. Patients at risk for delirium should have regular mental status assessments and should not be given benzodiazepines or anticholinergics.

Nerve Injury

Pelvic nerve injury can occur during RC or PLND, as several nerves that provide motor and sensory innervation to the lower extremities are intimately involved with the pelvic vasculature and lymphatic basin. The obturator nerve (L2–L4) traverses the obturator fossa beneath the external iliac vein. The obturator nerve provides motor innervation to the inner thigh and allows for hip adduction. The obturator nerve and vessels are skeletonized during removal of the obturator lymph node packet, and injury can occur secondary to cautery, excess traction, or accidental laceration. The deficit from an obturator nerve injury is inability to adduct the hip and a small area of anesthesia on the medial aspect of the thigh. Problems with hip adduction can cause difficulty walking and driving. Treatment primarily includes postoperative physical therapy, although some have attempted immediate primary reanastomosis or placement of a nerve graft with promising results.[132,133]

The genitofemoral nerve (L1–L2) courses over the psoas and functions as the lateral border of a PLND. This nerve provides sensation to a small area of skin overlying the femoral triangle as well as the scrotum in men and labia and mons pubis in women. It is a relatively thin nerve that can easily be injured or removed with the external iliac lymph node packet if not carefully identified. If injured due to excess traction, sensation may return over the course of several months.[134]

Finally, the femoral nerve (L2–L4) provides motor function to the quadriceps and much of the sensation to the anterior thigh and medial lower leg. It runs lateral to the psoas muscle and beneath the inguinal ligament. Although not typically visualized during RC, the femoral nerve can be compressed due to lateral traction on the psoas by self-retaining retractors or stretched during lithotomy positioning.[135] A femoral nerve injury can result in weakness of hip flexion, lower leg extension, and variable sensory deficits. Injury is best avoided through careful placement of self-retaining retractors and avoidance of exaggerated hip flexion, abduction, and external rotation in lithotomy. Depending on the mechanism of injury, use of early physical therapy to prevent muscle atrophy is often effective, with return of nerve function in many patients.[135]

Nerve injuries can be prevented by careful exposure, knowledge of anatomic landmarks, and control of hemostasis. Stretch injuries can recover over the course of several months. Nerve injuries that have associated motor deficits are best treated with early physical therapy.

INTRAOPERATIVE COMPLICATIONS

At high-volume centers, less than 1% of patients experience an intraoperative complication.[5] Intraoperative complications that can occur during RC include injury to the bowel or rectum, and major blood vessels or nerves. Using a large population-based dataset, approximately 3% of RC cases were complicated by an accidental puncture or laceration to an adjacent organ, and this was associated with higher inpatient mortality, LOS, and cost.[77] Rectal injuries are uncommon during RC, but are more likely in patients with prior pelvic radiation.[136] Small rectal injuries with minimal fecal contamination can be closed in several layers and covered with omental or peritoneal tissue flaps. Tissue interposition is particularly important to prevent fistulization for patients having an orthotopic neobladder. Some rectal injuries are better managed with primary closure and fecal diversion in consultation with a general surgeon. Retained foreign objects following RC are rare, occurring in less than 0.1% of cases.[137] Any urologist who performs RC must be aware of these potential intraoperative complications, understand how to manage them, and know when consultation with other surgical specialists is required.

Reoperation

Secondary interventions are not uncommon, as between 2% and 14% of patients require a reoperation or interventional procedure in the early postoperative period.[5,7,8,12,19] In a multi-institutional report from Sweden, 13% of patients required reoperation following RC.[8] There were 12 indications for reoperation, the most common of which were wound dehiscence (5%), wound infection (2%), and ileus (2%). An Italian series reported a 7% reintervention rate, with wound dehiscence and bowel obstruction the two most common indications for a return to the operating room.[7] A retrospective report from Greece reported a 9% rate of abdominal exploration within 30 days of RC.[138] Among 14 (3%) patients who were explored for bowel obstruction or ileus, approximately half had bowel adhesions and half had a problem with the bowel anastomosis. Only one patient (0.2%) was found to have an internal hernia.

Up to 11% of patients require an interventional radiology procedure after RC, nearly half of which occur following hospital discharge.[5] Most interventional radiology procedures are for drainage of intraabdominal abscesses or lymphoceles, or percutaneous nephrostomy placement for urinary leak or obstruction.

Readmission

Nearly one-third of patients will present to the emergency room and 19–27% require readmission within 90 days of RC.[5,7,22] Most readmissions occur within the first several weeks, although up to 11% of patients are readmitted between 31 and 90 days postoperatively.[15,139] Median LOS for readmitted patients is approximately 3–7 days.[15,139] The most common causes of readmission are ileus, pyelonephritis, urinary tract infection, urinary obstruction, and failure to thrive.[15,22,139] Risk factors for readmission include a higher number of medical comorbidities, postoperative complications, female gender, and discharge to a nursing facility.[15,22,139] Understanding which patients are at risk for readmission may impact the timing and disposition of initial hospital discharge. High-risk patients may require closer outpatient monitoring in the early postoperative period, home nursing visits, or a temporary stay in a rehabilitation hospital.

Complex operations such as RC are becoming more centralized to high-volume centers, thus patients will be increasingly likely to present to local hospitals for management of postoperative complications. Patients admitted to a different hospital than where their surgery was performed are at increased risk for postoperative mortality, in part due to care fragmentation.[140–143] Surgeons who perform RC at tertiary referral centers must work to communicate with patients while at home, identify complications early, and make every effort to admit patients to the index hospital when admission is indicated. Furthermore, it is important for surgeons to understand what resources are available to patients locally and establish a network of trusted providers who can treat or admit patients who are unable to travel to the index hospital.

Mortality

The risk of inpatient mortality after RC may be as high as 2%; however, this increases to at least 9% within 90 days of surgery.[17,21] The majority of deaths occur after hospital discharge.[5] Most deaths are attributed to cardiovascular complications, including myocardial infarction and arrhythmia, or sepsis and multiorgan system failure.[3,7,11,12,81] Most RC patients who die of sepsis have a urinary source or bowel leak.[3,7]

Several models have been created to predict the risk of postoperative mortality.[20,21,144] Using a population-level dataset, 1.1% and 3.9% of RC patients died within 30 and 90 days, respectively.[20] Older age, more advanced tumor stage, and nonurothelial histology predicted an increased risk of 90-day mortality. Patients at highest risk had an estimated 25% risk of mortality. In another population-level study of elderly RC patients, 90-day mortality was over 10% and the risk increased with older age, multiple comorbidities, more advanced stage, lower socioeconomic status, and unmarried status.[23] Patients over 80 with advanced disease and several comorbidities had an estimated 90-day mortality risk of nearly 25%.

Similar efforts have been made using institutional datasets. In one series of over 1000 RC patients treated at a high-volume center, 90-day mortality was 2.8%.[144] Older age, particularly over 70, and a Charlson comorbidity index over two were independently associated with mortality. The highest-risk group had an approximately 6% risk of death in 90 days. Using a multi-institutional cohort of RC patients, a nomogram was created to estimate 90-day mortality.[21] Nine percent of patients died within 90 days, and older age, higher ASA score, lower hospital volume, and metastatic

disease were all associated with a higher risk of 90-day mortality.

Patients who have signs of preoperative malnourishment are also at increased risk for postoperative mortality. Among 538 RC patients, nearly 20% had evidence of a preoperative nutritional deficiency, defined by low albumin, low BMI, and at least a 5% unintentional weight loss.[145] Patients with a nutritional deficiency had a nearly threefold increased risk of 90-day mortality on multivariate analysis (17% vs 5%), although low albumin alone may be the most important predictor.

An inverse relationship between hospital volume and postoperative mortality for RC has been well described.[27] The exact reason for this association is unclear, but may be related to underlying structural or process-related institutional factors.[146,147] High-volume centers may also be more prepared to manage potentially life-threatening postoperative complications.[14]

SPECIAL POPULATIONS

Elderly

Approximately 25% of RC patients are over the age of 75.[5,8] Previous studies have identified older age as an independent risk factor for postoperative complications[3,5,8,12,17,18] and mortality.[148] As a result, RC may be underutilized in elderly patients.[149] However, several institutional studies have specifically examined postoperative outcomes in elderly patients and suggested that elderly patients can do well after RC.

In a large retrospective cohort study, approximately 35% of RC patients were older than 70 and 5% were older than 80.[150] There was no significant difference in perioperative mortality according to age; however, older patients had higher rates of complications within 90 days and a slightly longer LOS. There was no adjustment for comorbidity status, but the authors suggested that properly selected elderly patients are good candidates for RC. A large German RC series described differences in complication rates between patients over and under age 70.[151] Patients over the age of 70 were more likely to have comorbid conditions, but were also at higher risk for postoperative complications after adjusting for comorbidity status.

A recent series described postoperative complications between RC patients younger (N = 1025) and older (N = 117) than 80 years.[152] Older patients had more comorbidities and were less likely to have continent diversions and PLND. Although older patients were more likely to require intensive care unit admission, had a slightly longer LOS, and higher 90-day mortality rate (2.7% vs 6.8%), they had similar risks of minor (55% vs 51%) and major (17% vs 13%) complications compared to younger patients. Elderly patients were, however, more likely to experience neurologic and cardiac complications.[152] After adjusting for preoperative characteristics, there was no increased risk of complications with age over 65.

While elderly patients may have similar risks of complications when treated at high-volume centers, they often require a unique preoperative evaluation. In addition to a thorough history and physical, with particular attention to cardiac and pulmonary risk factors, a preoperative geriatric risk assessment includes evaluation of cognitive function, alcohol and substance use, functional status, nutritional assessment, and frailty.[130,153] Frailty, defined by the presence of shrinking and weight loss, poor endurance or exhaustion, weakness, slow walking speed, and low physical activity level, is more common in elderly patients.[153] Frail patients are at particular risk for postoperative complications.[154] Older patients are also more likely to be dependent and sarcopenic, which are each associated with higher risks of morbidity and mortality.[153,155,156] Preoperative consultation with a geriatrician may help identify high-risk patients and assist with postoperative management.

Following Radiation Therapy

Radiation therapy for pelvic malignancies, including bladder, prostate, colorectal, and gynecologic, can cause significant tissue changes in and around the targeted area, such as obliteration of anatomic planes and a desmoplastic reaction. Radiation can also alter tissue vascularity and impair normal healing. Because of these effects, RC patients with a history of pelvic radiation were historically observed to have very high perioperative morbidity.[157]

Following radiation, RC generally takes longer and may be associated with more postoperative complications, including reoperation and readmission.[158] A series of 148 patients had RC following high dose pelvic radiation therapy, and nearly 80% of patients experienced a complication within the first 90 days, including a 32% high-grade complication and a 6% mortality rate.[159] Although this study was noncomparative, the authors suggested the complication rate in this population was higher than in other contemporary RC series. However, a large retrospective study compared 426 RC patients without to 420 patients with prior pelvic radiation and found no significant differences between postoperative mortality or complications.[157]

Up to 30% of patients with bladder cancer who elect bladder-sparing treatments that include external beam radiation therapy will require a salvage RC.[160] Among 91 patients who failed bladder-sparing multimodal therapy and required salvage RC, 69% experienced a complication within 90 days, including 16% who experienced a major complication.[160] The risk of postoperative complications appeared to decrease for patients treated in more recent years. However, few patients had PLND and nearly all had an incontinent diversion, suggesting PLND and continent diversion are more difficult after radiation.

Although the literature does not clearly describe a higher risk of complications after pelvic radiation, it is reasonable to assume RC can be more difficult in patients with a history of radiation therapy and that more complications may occur.

Robotic Radical Cystectomy

There is an increasing use of laparoscopic techniques for radical cystectomy, and robotic-assisted radical cystectomy (RARC) now constitutes approximately 13% of all RCs performed in the United States.[161] Specific outcomes and complications of RARC are covered in Chapter 36. It was hoped that RARC would lessen the morbidity and hasten the recovery of RC compared to open techniques. There have been several retrospective and prospective institutional reports on RARC and four randomized controlled trials that have examined the surgical outcomes and complications of RARC in comparison to open RC (ORC).[162–166]

The first trial that randomized patients to ORC or RARC included 41 patients and found that RARC patients had longer operative times, but less blood loss and an earlier time to return of bowel function.[165] There was no difference in LOS between the two groups, but possibly fewer complications after RARC. In a multi-institutional study that randomized 40 patients to ORC and RARC, there were no significant differences in early complications.[166] The RARC group had less blood loss, although there was no difference in transfusion rates. However, RARC patients had slightly faster return of bowel function and fewer patients had a LOS of over 5 days. A recent trial randomized 118 patients to ORC or RARC and observed that RARC patients did not have a lower rate of complications or LOS, but did have less intraoperative blood loss, longer operative times, and greater costs.[163] The last randomized trial included 59 patients who were randomized to ORC, RARC and laparoscopic RC, each performed by a different surgeon.[164] Open RC patients had more low-grade complications at 30 days, but there was no difference in 90-day complication rates. As previously observed, RARC patients had longer operative time, less blood loss, and faster return to solid food; however, LOS was longer and there was no difference in time to flatus.

Taken together, the randomized trials to date generally agree that RARC is associated with less blood loss and longer operative times, but there is no clear advantage in terms of postoperative complications. Some institutional reports suggest RARC may be associated with superior outcomes; however, this may in part be due to patient selection and surgeon experience.[162,167] Although the value of RARC continues to be debated, it is possible that with ongoing experience and refinement of surgical technique, RARC may fulfill the promise of lessening the morbidity of RC.

Conclusions

Despite over half a century of experience with RC, it continues to carry significant postoperative morbidity. The majority of RC patients experience an early postoperative complication, but most complications are minor. There are several methods that can help minimize postoperative complications, including enhanced recovery pathways, restricted fluid protocols, laparoscopic approaches, and referral to high-volume centers. Surgeons who perform RC should be aware of the breadth of postoperative complications that can occur, and be prepared to diagnose and treat complications promptly.

Chapter 41 Questions

1. A 63-year-old man experiences fevers 12 days after radical cystectomy and is found to have a 4-cm pelvic abscess. A percutaneous drain is placed by interventional radiology under local anesthesia. This is a Clavien-Dindo grade ___ complication.
   a. II
   b. IIIa
   c. IIIb
   d. IV
   e. V

2. All of the following treatments are associated with a faster return of bowel function after radical cystectomy EXCEPT:
   a. Alvimopan
   b. Restricted fluid protocols
   c. Gum chewing
   d. Routine nasogastric decompression
   e. Enhanced recovery protocols

3. A lower rate of surgical site infections has been associated with:
   a. Mechanical bowel preparation
   b. Hair removal
   c. Chlorhexidine-alcohol skin preparation
   d. Intraoperative hypothermia
   e. Fascial closure with interrupted sutures

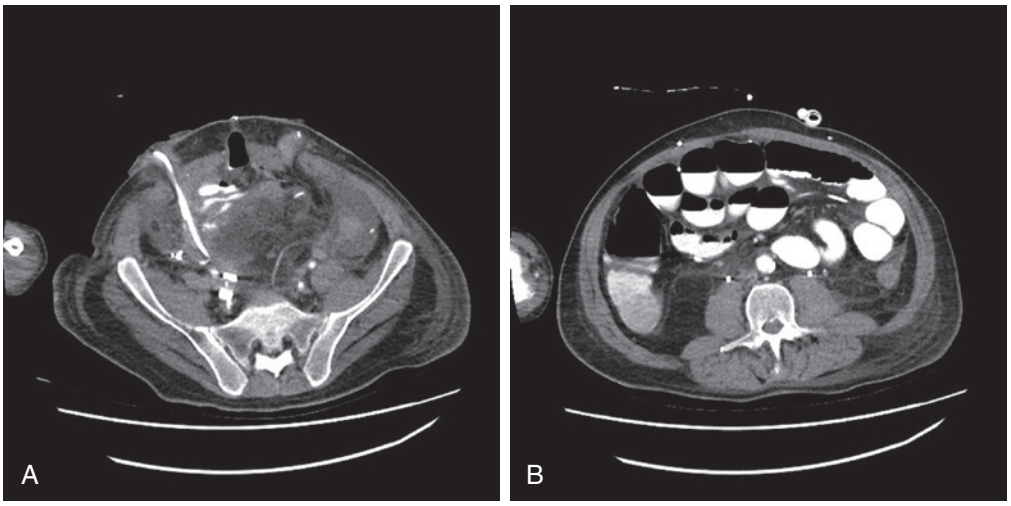
4. During open radical cystectomy, bleeding is encountered along the right vascular pedicle that you are unable to control. The patient is experiencing major blood loss, hypotension, hypothermia, and coagulopathy despite aggressive resuscitation and transfusion of blood products. The next best step is:
   a. Use a stapler to control the pedicle
   b. Pack the pelvis
   c. Apply topical hemostatic agents
   d. Cell salvage
   e. Hypogastric artery embolization

5. Radical cystectomy is considered a high-risk operation for venous thromboembolism. The recommended prophylaxis for a patient who does not have an unacceptable bleeding risk is:
   a. Early ambulation only
   b. Therapeutic unfractionated heparin
   c. Prophylactic low-molecular-weight heparin AND mechanical prophylaxis
   d. Inferior vena cava filter
   e. Mechanical prophylaxis only

6. Inability to adduct the leg is associated with a(n) ____ nerve injury.
   a. Genitofemoral
   b. Femoral
   c. Obturator
   d. Ilioinguinal
   e. Sciatic

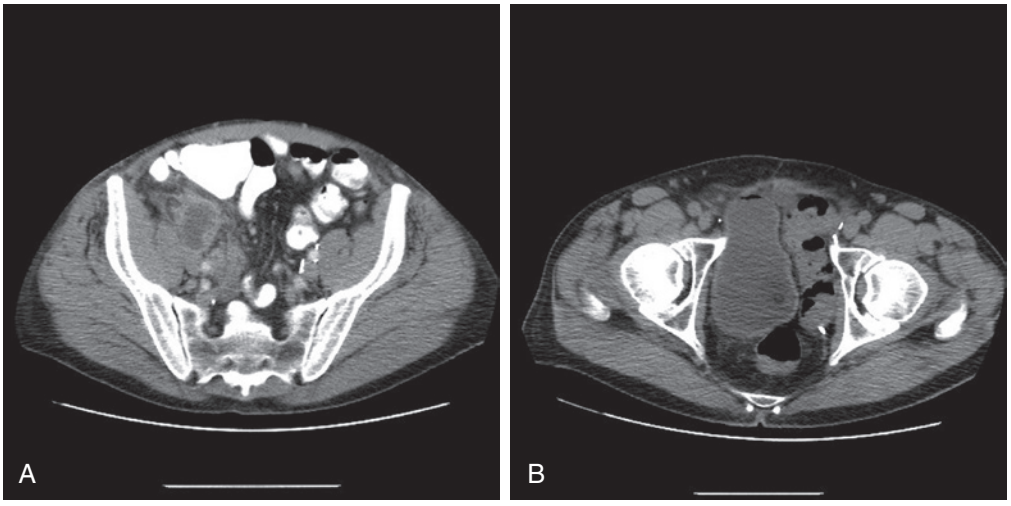
7. Risk factors for postoperative mortality include all of the following EXCEPT:
   a. Older age
   b. Increased patient comorbidity
   c. Low hospital volume
   d. Nutritional deficiency
   e. Neoadjuvant chemotherapy

8. Robotic-assisted laparoscopic radical cystectomy is associated with:
   a. Less intraoperative blood loss
   b. Shorter operative time
   c. More complications
   d. Better outcomes
   e. Lower costs



9. A 76-year-old woman presents with left flank pain and fevers 25 days after a radical cystectomy and ileal conduit. CT scan demonstrates left hydroureteronephrosis and a delayed left nephrogram. The next best step is:
   a. Abdominal exploration
   b. Left percutaneous nephrostomy tube
   c. Observation
   d. Placement of a catheter to drain the ileal conduit
   e. Looposcopy and retrograde left ureteral stent

Case Study 1



A 56-year-old male with invasive bladder cancer had a radical cystectomy and ileal conduit 5 days previously. His medical history is significant for a prior left proctocolectomy with permenant colostomy, active one pack-per-day smoker, and emphysema. His hospital course was uneventful until postoperative day 5 when he developed nausea and vomiting. He also noted some fluid drainage from his midline incision. On exam, he was distended and there was a large amount of clear fluid draining from the midline incision, but the skin was approximated. CT scan demonstrated fascial dehiscence and a small bowel obstruction with the transition point in a knuckle of bowel above the fascia (Case Fig. 41-1).

1. The next step in the management of this patient is:
   a. Placement of nasogastric tube
   b. Open and pack wound
   c. Exploratory laparotomy
   d. Use of an abdominal binder
   e. Fluid culture

2. Given the association between fascial dehiscence and wound infection, how should the wound be managed following a repeat fascial closure?
   a. Primary closure with subcutaneous drains
   b. Negative pressure dressing
   c. Pack wound and perform regular dressing changes
   d. a or b only
   e. b or c only

Case Figure 41.1

Case Figure 41.2

3. You are performing a radical cystectomy on an elderly obese female with severe COPD whom you suspect is at increased risk for fascial dehiscence. A consideration during primary abdominal closure should include use of:
   a. Multiple interrupted absorbable sutures for fascial closure
   b. External retention sutures
   c. Internal retention sutures
   d. Large fascial bites
   e. Skin stapler

Case Study 2

A 64-year-old male with invasive bladder cancer was treated with neoadjuvant cisplatin-based chemotherapy followed by radical cystectomy, bilateral pelvic lymphadenectomy, and an orthotopic ileal neobladder. His hospital course was uneventful and he was discharged home on postoperative day 6. He returned to the hospital on postoperative day 18 with fevers to 102°F and shaking chills. On exam, his abdomen was soft and he had no costovertebral tenderness. His catheter was difficult to irrigate and did not drain well. Labs were significant for a leukocytosis to 17 and increase in his creatinine from 1.2 (baseline) to 1.7. CT scan demonstrated a distended neobladder and a 4-cm rim-enhancing fluid collection along the right pelvic sidewall (Case Fig. 41-2).

1. Initial choice of antibiotics should include coverage for which of the following organisms?
   a. *Escherichia coli*
   b. *Klebsiella pneumonia*
   c. *Enterococcus*
   d. *Pseudomonas*
   e. All of the above

2. Following prompt administration of intravenous fluids and antibiotics, the next step for managing this patient is:

a. Observation with antibiotics
b. Drainage of pelvic abscess by interventional radiology
c. Exploratory laparotomy with abdominal washout
d. Foley catheter replacement and bladder irrigation
e. b and d only

3. CT cystogram demonstrated a small leak from the afferent limb of the neobladder with reflux into both ureters. The most appropriate management is:
a. Bilateral percutaneous nephrostomy tubes
b. Prolonged indwelling Foley catheter
c. Exploratory laparotomy with repair of leak
d. Conversion to an ileal conduit
e. Intravenous antibiotics

Answers

1. **b**. The complication required intervention without anesthesia (Case Table 41.1).
2. **d**. Routine nasogastric decompression, while broadly used historically, has not been shown to enhance return of bowel function. The remaining choices, while not conclusively proven to causally improve bowel function, have been associated with more rapid recovery of bowel function in comparative studies.
3. **c**. Skin preparation with an alcohol-based preparation solution has been shown to lower wound infection rates. The routine removal of hair is not clearly shown to reduce infection, but if performed should avoid nicks and cuts in the skin, which might promote infection. Hypothermia increases the risk of infection, and neither mechanical bowel preparation nor technique of fascial closure has been associated with infectious risk.
4. **b.** Given the instability of the patient, packing to reduce bleeding is the best choice. A return to the operating room, following stabilization of the patient, might allow more effective control of bleeding if arterial in nature. In general, uncontrolled bleeding from the deep pelvis is a combination of arterial and venous bleeding, and usually embolization or ligation of the hypogastric artery is ineffective.
5. **c.** Cystectomy and urinary diversion would be considered to be high risk according to the American College of Chest Physicians Evidence-Based Clinical Practice Guidelines, 9th edition. As such, prophylaxis should include both prophylactic low-molecular-weight heparin AND mechanical methods.
6. **c.** The obturator nerve, commonly injured during either lymph node dissection or bladder pedicle division, supplies the adductor muscles of the leg. As such, injury results in inability to adduct the leg.
7. **d.** Age, comorbidity, poor nutritional condition, and surgeon/center inexperience are all associated with increased risk of perioperative mortality.
8. **a.** The only proven benefit of robotic-assisted radical cystectomy, as compared to open cystectomy, is a reduction in intraoperative blood loss. Operative time, while surgeon-specific, is generally longer than open. Cost is generally higher as well.

Case Table 41.1 Preoperative Venous Thromboembolism Risk Stratification and Treatment Recommendations for Patients Having Gastrointestinal, Urologic, Vascular, Breast, and Thyroid Procedures

Risk Category	Risk Score[a]	VTE Risk in Absence of Prophylaxis	Recommended Prophylaxis
Very low	0	<0.5%	Early ambulation only
Low	1–2	1.5%	Mechanical prophylaxis, preferably with sequential compression devices
Moderate	3–4	3.0%	■ Pharmacologic[b] OR mechanical prophylaxis, preferably with sequential compression devices OR ■ Mechanical prophylaxis if bleeding risk is high, preferably with sequential compression devices
High	≥5	6.0%	■ Pharmacologic[b] AND mechanical prophylaxis OR ■ Mechanical prophylaxis if bleeding risk is high, preferably with sequential compression devices[c]
High-risk cancer surgery			■ Pharmacologic[b] AND mechanical prophylaxis AND extended duration LMWH post-discharge OR ■ Mechanical prophylaxis if bleeding risk is high, preferably with sequential compression devices[c]

[a]Caprini risk score:
1 point: age 41–60, minor surgery, BMI >25, swollen legs, varicose veins, pregnancy or postpartum (<1 mo), history of unexplained or recurrent spontaneous abortion, oral contraceptives or hormone replacement, sepsis (<1 mo), severe lung disease including pneumonia (<1 mo), abnormal pulmonary function, acute myocardial infarction, congestive heart failure (<1 mo), inflammatory bowel disease, medical patient at bed rest
2 points: age 61–74, arthroscopic surgery, major open surgery (>45 min), laparoscopic surgery (>45 min), malignancy, confined to bed >72 hrs, immobilizing cast (<1 mo), central venous access
3 points: age ≥75, history of VTE, family history of VTE, factor V Leiden, prothrombin 20210A, lupus anticoagulant, anticardiolipin antibodies, elevated serum homocysteine, heparin-induced thrombocytopenia, other congenital or acquired thrombophilia
5 points: stroke (<1 mo), elective arthroplasty, hip, pelvis, or leg fracture (<1 mo), acute spinal cord injury (<1 mo)
[b]LDUH and LMWH both acceptable for pharmacologic prophylaxis
[c]LMWH or LDUH can be added once bleeding risk diminishes
(Adapted from Gould MK, Garcia DA, Wren SM, et al. Prevention of VTE in nonorthopedic surgical patients: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. Chest. 2012;141:e227S-77S.)

9. **b.** Patients with concern for obstructive pyelonephritis require emergent upper tract drainage. This is best accomplished in an antegrade fashion after urinary diversion.

CASE STUDY 1

1. **c.** Fascial dehiscence is a surgical emergency that requires urgent exploration and abdominal closure.

2. **e.** Patients with fascial dehiscence commonly have wound infections in which case primary skin closure should be avoided.
3. **b.** Patients at increased risk of dehiscence can be managed with external retention sutures, which should remain in place for 6 weeks.

CASE STUDY 2

1. **e.** Patients with abdominal infections after cystectomy should be treated with broad-spectrum antibiotics to cover both enteric and urinary pathogens.
2. **e.** Urgent source control is critical for patients with sepsis. In this case, both the abscess and obstructed bladder need to be drained. His bladder is likely obstructed by mucous, thus some gentle irrigation is required to ensure maximal drainage of the neobladder.
3. **b.** A small leak in a neobladder may heal with bladder decompression alone. Aggressive surgery would not yet be indicated in a patient with an active infection and without an attempt at conservative management.

42 Complications of Radical Retropubic Prostatectomy

JAMES S. WYSOCK, SAMIR S. TANEJA, and HERBERT LEPOR

CHAPTER OUTLINE

Preoperative Considerations
Intraoperative Complications
Bleeding
Rectal Injury
Ureteral Injury
Nerve Injury
Early Postoperative Complications
Urinary Leak
Urinary Tract and Wound Infection
Pulmonary Embolus and Deep Vein Thrombosis
Loss of Catheter
Delayed Postoperative Complications
Impotence
Incontinence
Bladder Neck Contracture/Anastomotic Stricture
Minor Complications
Salvage Prostatectomy
Chapter 42 Questions and Answers

KEY POINTS

1. When performing open radical prostatectomy, the rate of bleeding varies with operator experience and technique. The use of preoperative erythropoietin or autologous blood donation can lower the likelihood of allogeneic transfusion greatly.
2. Control of the dorsal venous complex prior to division can greatly reduce blood loss during radical prostatectomy. Accurate and complete bunching of the dorsal vein hood over the base of the prostate is helped by wide incision of the endopelvic fascia back to the bladder neck.
3. Early release of the lateral prostatic fascia on the anterolateral surface of the gland facilitates release of the neurovascular bundles prior to urethral division, thereby reducing traction on the neurovascular structures.
4. In performing the urethral anastomosis, tension-free mucosal apposition is essential in avoiding bladder neck contracture.
5. Pelvic hematoma due to postoperative bleeding causes distraction of the urethral anastomosis, potentially causing urinary extravasation and eventual bladder neck contracture. In such cases prolonged catheterization is warranted.
6. Rectal injury at the time of radical prostatectomy does not require diverting colostomy in the majority of cases. Bowel preparation, antibiotics, methodical closure of the rectum, and interposition of either omental or peritoneal closure of the rectum, and interposition of either omental or peritoneal flap can all help in avoiding the need for colostomy.
7. Long-term satisfaction with postoperative urinary and sexual function outcomes relies upon careful discussion with patients to assess risk factors and set expectations.
8. Bleeding complications strongly influence urinary function outcomes, and thus every effort should be made to minimize rates of these complications.

The description of the anatomic nerve-sparing radical retropubic prostatectomy (RRP) by Walsh[2] in 1983 revolutionized the technique. Consequently, the comfort level of urologists performing the procedure has risen to meet the increased need for radical prostatectomy in the current era of prostate-specific antigen testing. Despite numerous options for treatment of localized disease, radical prostatectomy remains the urologic gold standard of treatment.

The complication rate for radical prostatectomy appears to have declined with technical modifications to the operation and increasing experience of urologic surgeons.[3,4] Surgical morbidity following radical prostatectomy is influenced by many factors including the experience of the surgeon, the age and medical comorbidities of the patient, the size of the prostate, the anatomy of the pelvis, the volume of prostate cancer, and the use of preoperative hormonal ablation

or radiation. Intraoperative complications include bleeding, rectal injury, nerve injury, and, in rare circumstances, ureteral injury. Early postoperative complications include urinary leak, infection, deep vein thrombosis or pulmonary embolus, and loss of the urethral catheter. Delayed postoperative complications generally present the greatest problem to the patient. These include incontinence, impotence, voiding dysfunction, and bladder neck contracture.

Preoperative Considerations

Men presenting with prostate cancer range in age, disease aggressiveness, and goals of treatment. Today, the treatment options for localized disease include active surveillance, radical prostatectomy, radiation therapy, and focal or whole gland ablation. Selection of a treatment modality for localized prostate cancer is multifactorial and requires extensive counseling. Realistic preoperative expectations on the part of the patient are a critical determinant of postoperative satisfaction.[5] The process of preoperative education mandates a comprehensive review of all reasonable therapeutic options and their potential complications and relative outcomes.

In general, candidates for radical prostatectomy should be in good health. In contemporary prostatectomy series, the risk of myocardial infarction, pneumonia, cerebrovascular accident, and death from these causes is exceedingly low,[4,6–9] likely because of proper patient selection, surgeon experience, and improved anesthesia techniques.[7–9] Selection of healthy surgical candidates is important not only from the standpoint of avoiding anesthesia-related morbidity but also because the relative advantage of surgical resection over radiation-based therapies lies in the duration of therapeutic response.[10]

The preoperative assessment varies according to comorbidities. Men with significant hypertension, coronary artery disease, and diabetes should undergo medical clearance to ensure these disease states are optimally managed. If there is an individual or significant family history for deep venous thrombosis or pulmonary embolus hematologic consultation is recommended in order to identify genetic predispositions to these untoward events. A plan for preoperative and postoperative anticoagulation management should be defined in consultation with the cardiologist or neurologist for men with coronary stents, valvular replacement, atrial fibrillation, or prior cerebral vascular accidents.

A cardiology consultation may be advisable for men with no history of significant atherosclerotic cardiovascular disease and preoperative erectile dysfunction or significant family history of atherosclerotic cardiovascular disease in order to identify occult disease. Erectile dysfunction may represent the first sign of significant atherosclerotic cardiovascular disease.[11]

Sleep apnea is a condition that is often undiagnosed and associated with obesity. The presence of sleep apnea may influence decisions regarding postoperative pain management. Therefore men with obesity should be queried about symptoms suggestive of sleep apnea.

Individuals with expected longevity >15 years are ideal for the procedure since they are likely to achieve the benefits of both survival and prevention of metastasis even if they present with lower risk disease. In assessing a patient's longevity, the urologist must carefully weigh the aggressiveness of the disease against the patient's health. Higher-grade cancers, which are more likely to result in disease-related morbidity in the short term, may require aggressive therapy in patients with relatively short longevity, whereas radiation-based therapies or watchful waiting may be more important in individuals with moderately differentiated disease and relatively poor health.

In this regard, Albertsen and colleagues[12] described the risk of cancer-related death in 15 years of diagnosis for individuals with various grades of prostate cancer. The estimated risk of death in men managed without curative intervention was 4–7% in patients with Gleason score 2 to 4, 6–11% in patients with Gleason score 5, 18–30% in patients with Gleason score 6, 42–70% in patients with Gleason score 7, and 60–87% in patients with Gleason score 8 to 10. Clearly, individuals with higher-grade disease have worse outcomes with radical prostatectomy than do patients with low-grade disease, but prediction of outcome must be balanced against disease-related risk of death.

In selecting candidates for radical prostatectomy, the presence of voiding dysfunction and prostate size should be carefully elucidated. Individuals with significant preoperative obstructive voiding symptoms may actually experience relief of such symptoms following radical prostatectomy and a reduced risk of subsequent acute urinary retention.[13,14] Preoperative prostate volume was inversely related to positive surgical margins and directly related to blood loss and transfusion rates.[15] Conversely, such individuals, particularly those with large prostates, may experience a worsening of voiding symptoms or progression to urinary retention following radiation-based treatments. The improvement in quality of life resulting from the relief in voiding symptoms following radical prostatectomy may actually outweigh the detriment caused by mild degrees of stress incontinence in the view of the patient[5,16,17] Lepor et al. ascertained the long-term impact of radical prostatectomy on lower urinary tract symptoms.[5,17] At 10 years following surgery, the overwhelming majority of men with preoperative moderate/severe lower urinary tract symptoms (LUTS) experience durable resolution of their symptoms whereas those with mild preoperative LUTS do not develop worsened LUTS.

Radical prostatectomy is the only treatment that has been compared to watchful waiting. The Scandinavian Prostate Cancer Group Study Number 4 demonstrated an absolute risk reduction of approximately 6% for dying of prostate cancer for men undergoing radical prostatectomy versus watchful waiting at 12–15 years of follow-up. Radical prostatectomy conferred a similar risk reduction of developing distant metastases at 12 years as well. This reduction was greatest for men who were less than 65 years of age at the time of diagnosis.[18]

A careful assessment of the patient's daily activities and profession may aid in determining the potential impact of stress urinary incontinence on the individual surgical candidate. Although rates of significant incontinence have drastically improved, the patient should be made well aware of the nature and potential impact of stress urinary incontinence. Similarly, the risk of impotence despite nerve-sparing procedures should be carefully delineated. The preoperative factors influencing preservation of potency include age,

baseline sexual function, history of diabetes, preoperative use of phosphodiesterase inhibitors and the extent of nerve sparing.[19] Although pharmacologic advancements in the field of erectile dysfunction have lessened the impact of postoperative impotence following radical prostatectomy, the presence of a regular sexual partner, the stability of current relationships, and cultural attitudes regarding erectile dysfunction should be carefully evaluated before the surgical procedure.

The overall impact of complications of radical prostatectomy on quality of life is a topic of intense study in many centers. Future focus will lie in preoperative identification of poor candidates for surgery on the basis of potential impact of surgical complications on quality of life.

Intraoperative Complications

BLEEDING

Bleeding during RRP is most commonly encountered during division of the dorsal venous complex of the penis. Before the description of the anatomic approach to radical prostatectomy by Walsh, severe hemorrhage was often encountered during uncontrolled division of the venous complex. On occasion, such bleeding was severe enough to require cutdown onto the prepubic penile shaft and identification of the retracted, uncontrolled venous complex beneath Buck's fascia for ligation.

Despite the advances in surgical technique, the potential for significant bleeding during division of the dorsal venous complex and the remainder of the procedure still exists. The mean intraoperative blood loss reported in large series of radical prostatectomy has varied tremendously and ranges from 579 mL to >2 L and is likely influenced by operative technique, the presence or absence of nerve sparing, time, and the experience of the surgeon.[7,20,21] Several surgeons have suggested various means of perioperative blood management to minimize the need for transfusion. Rates of allogeneic transfusion in contemporary series have varied from 2.4% to 21% independent of autologous blood donation.[21–26] Reoperation for bleeding is extremely rare, with a reported incidence as low as 0.3%[26] and 0.6%[9] in two large series.

The use of autologous blood donation was previously shown to reduce the risk for allogeneic transfusion. Several investigators challenged the need for blood donation.[24,27,28] Koch and Smith[24] reported an overall transfusion rate resulting from intraoperative bleeding of 2.4% in 124 patients undergoing radical prostatectomy without preoperative autologous blood donation. Because it is unlikely that most surgeons will be fortunate enough to experience such a minimal likelihood of intraoperative and postoperative bleeding, it is advisable that some form of preventive management be instituted in patients undergoing radical prostatectomy.

One of the limitations of autologous blood donation is all men are destined to have significant preoperative and postoperative anemia. It has been estimated that the endogenous response to autologous donation produces about one unit of red blood cells.[29] Because of potential risks associated with transfusing autologous blood, the indications for transfusing autologous and allogeneic blood are similar. Therefore the only men who benefit from autologous blood are those who have significant bleeding and require replacement of all three stored units. Therefore the impact of autologous blood donation is a modest reduction in allogeneic blood transfusion at the expense of significant postoperative anemia.

Sultan et al. have reported that return to work and physical activities are dependent on discharge hemoglobin and timing for removal of the urinary catheter.[30] Therefore a blood management strategy should consider both the potential advantages of decreasing allogeneic transfusion rates and minimizing postoperative anemia.

Chun and associates proposed the use of preoperative erythropoietin injections instead of autologous donation.[29] Patients were given one to two injections of erythropoietin, provided their preoperative hematocrit was <48%.[29] On average, an increase in the hematocrit of 3% was noted when 600 U/kg was administered 7–14 days preoperatively. Using this method, the investigators demonstrated an identical risk of allogeneic transfusion in individuals donating autologous blood. Based on safety, efficacy, and dose ranging studies, we currently recommend administering epoetin alfa 300 IU/kg 7 and 14 days preoperatively in men with a baseline hematocrit <48%.[31,32] The postoperative hemoglobin of the group receiving erythrocyte-stimulating proteins was significantly greater than in the autologous blood donation group. The short- and long-term cardiovascular and oncologic safety of erythrocyte-stimulating proteins has been demonstrated.[33,34]

Although dorsal venous complex bleeding can occur regardless of the chosen technique of control, several anatomic points can be helpful for avoiding profuse hemorrhage. The dorsal venous complex courses beneath the pubis symphysis as a bundle of veins over the membranous urethra before it fans over the anterior surface of the prostate and bladder neck. On uncontrolled division, variable amounts of bleeding can occur. Initial descriptions of the anatomic retropubic prostatectomy included isolation of the dorsal venous complex with passage of a right-angle clamp between the membranous urethra and the complex, followed by sharp division with a knife blade. We have, in recent years, chosen to ligate the complex proximally and distally before division.

The dorsal venous complex is covered by an overlying reflection of the endopelvic fascia. To control all the veins fanning over the prostate within the complex effectively, the endopelvic fascia must be fully incised along the lateral sulcus of the anterior prostate. Removing the periprostatic adipose tissue overlying the anterior surface of the prostate allows visualization of the structures required to control the dorsal venous complex. This incision is made in the groove between the prostate and levator musculature during gentle retraction of the prostate contralaterally (Fig. 42.1A). The incision must be carried to the apex of the prostate and bladder neck to allow effective mobility of the proximally located veins. Small perforating vessels may be controlled with surgical clips.

A decussation of the endopelvic fascia, termed the *puboprostatic ligament,* lies at either lateral edge of the venous complex fusing its anterior surface to the posterior surface of the pubic bone. We do not routinely divide the puboprostatic ligaments unless they fan laterally and limit placement of the distal suture ligature controlling the dorsal venous

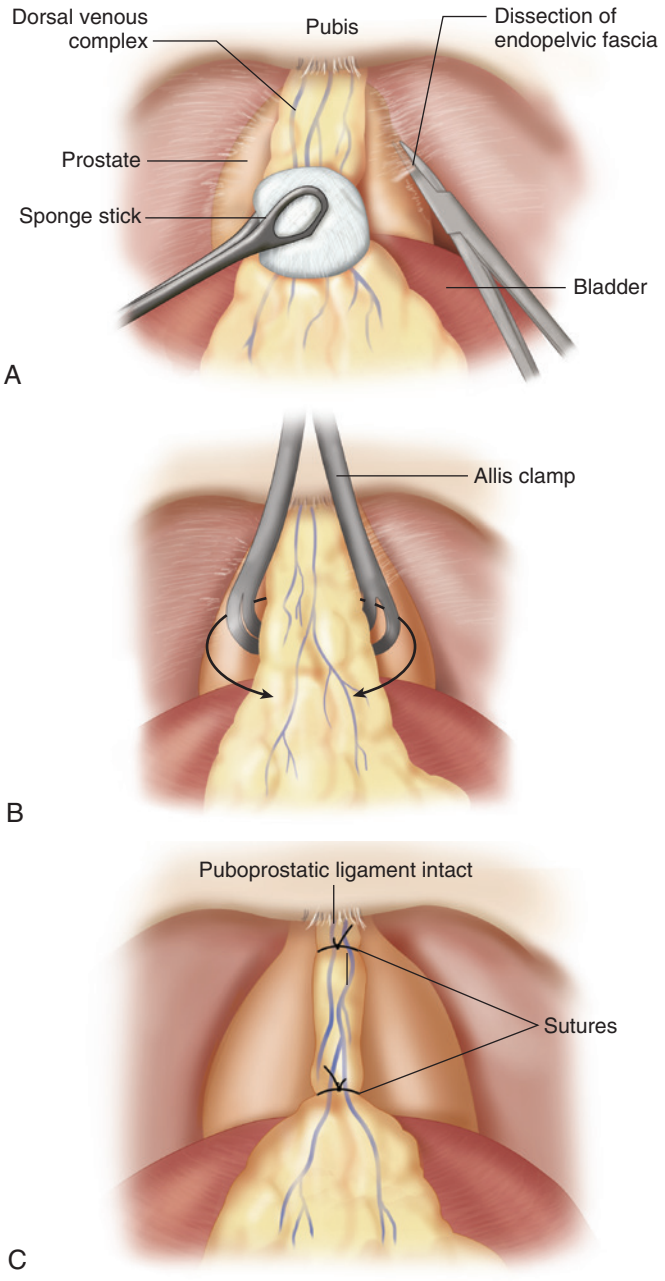

Figure 42.1 The technique of dorsal venous complex control. A, The endopelvic fascia is sharply incised on either side of the prostate. The incision extends from the base of the prostate to the puboprostatic ligament. B, An Allis clamp is used to bunch the dorsal venous complex centrally. The initial bunching is done over the midprostate, proximal to the prostatic apex. Bunching is performed by inserting the jaw of the clamp into the endopelvic fascial incision on each side and thereby incorporating all veins as they fan over the prostate. C, Proximal and distal bunching sutures are in place in the dorsal venous complex. The surface of the anterior prostate reveals no excluded veins coursing over the gland. The first suture is placed proximally at the level of the bunching clamp. A second suture is then placed distal to the puboprostatic ligaments, around the dorsal venous complex, as far caudad as possible without division of the puboprostatic sutures. (From Tareen B, Godoy G, Taneja SS, Complications of Radical Retropubic Prostatectomy, in Complications of Urologic Surgery: Prevention and Management, 4th Edition, Taneja SS (ed), Saunders Elsevier, Philadephia, PA, 2010.)

complex. Incising the puboprostatic ligament may facilitate dropping the venous complex away from the pubis. This is particularly useful when operating on large glands that compress the dorsal venous complex or glands with a large anterior or retropubic component and when the puboprostatic ligaments extend onto the anterior surface of the prostate gland. In these situations, we divide only that portion of the puboprostatic ligament needed for exposure. Preservation of the puboprostatic ligament will hold the vein stump fixed, to some extent, and prevents retraction and uncontrolled bleeding.

Once the endopelvic fascia has been incised on either side of the gland and the superficial dorsal vein has been defined and fulgurated, the deep venous complex is bunched centrally for control (see Fig. 42.1B). One approach is to use an angled or straight long Allis clamp inserted with one jaw in each facial incision. The venous complex is then bunched centrally at the level of the midprostate, with care taken to include all veins but avoiding prostatic capsular injury. Difficulty with bunching may be corrected with further proximal incision of the endopelvic fascia. Once the clamp is in place, the venous complex is controlled with a suture ligature of 2-0 polyglactin 910 (Vicryl) on a wide curved needle, at the level of the clamp placement. The clamp is removed during ligation of the proximal vein. Next, a suture ligature is placed around the distal venous complex as far caudal as possible (see Fig. 42.1C). This is achieved by placing the Allis clamp more apically and gently depressing the visible prostatic apex, thus exposing the distal vein as it courses over the membranous urethra. Double passage of each suture ligature will fix it in place and prevent it from slipping off on division of the vein. Alternatively, securing the proximal suture ligature at the midgland can serve the same function as the Alis clamp.

Sharp incision of the dorsal venous complex is then initiated between the proximal and distal sutures (Fig. 42.2). A plane of dissection is developed sharply within the dorsal complex, with great care taken not to injure the anterior prostatic capsule. A sponge stick is used by the assistant to retract the prostate cranially and gently roll it away from the pubis as the venous tissue is divided. The surgeon should always err on the side of cutting out the distal suture rather than injuring the anterior prostate. If the distal suture is cut out, complete division of the dorsal venous complex should be completed, and then the dorsal venous complex stump can be directly suture ligated. Incision of the dorsal venous complex is sequentially carried out until the anterior urethra is exposed. An effort should be made to preserve the anterior thickness of the urethra maximally.

An alternative approach and advantage of the open approach is the ability to palpate the prostatourethral junction between the thumb and forefinger. A McDougal clamp is then passed at this precise location in order to guide division of the dorsal venous complex so that the entire complex is divided while maximally preserving the rhabdosphincter.

Bleeding can occur throughout the procedure. This bleeding often originates from the bed of the neurovascular bundle if nerve sparing is performed, from the seminal vesicular arteries, or from the bladder neck. The surgeon must balance securing hemostasis while minimizing trauma to the neurovascular bundles. Using a lap pad to pack the pelvis is an effective technique to minimize pelvic bleeding during the

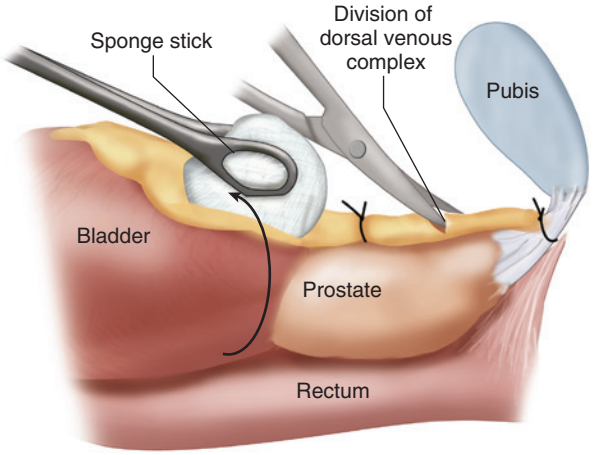

Figure 42.2 Division of the dorsal venous complex begins by incising the centrally bunched tissue between the proximally and distally placed sutures. A sponge stick is used to rotate the gland dorsally and cranially away from the pubic symphysis as the dorsal complex is divided. In doing so the dorsal complex is rotated into the field as it is sequentially divided. Antegrade dissection is carried out within the dorsal venous complex until the membranous urethra is rotated into the field of view. Caution must be exerted to avoid anterior prostate injury. (From Tareen B, Godoy G, Taneja SS, Complications of Radical Retropubic Prostatectomy, in Complications of Urologic Surgery: Prevention and Management, 4th Edition, Taneja SS (ed), Saunders Elsevier, Philadephia, PA, 2010.)

dissection and minimizes blood loss through venous compression. The prostatic pedicles are usually directly ligated before division and for this reason should not be a major source of bleeding. Bleeding from the neurovascular bundles can occasionally be controlled by clipping prostate perforating branches before division, but this is often a fruitless endeavor. In a nonnerve-sparing procedure, early ligation of the neurovascular bundle can save a great deal of trouble when one tries to suture ligate the stump once it is retracted. When steady bleeding is encountered, it is usually best to move ahead with the procedure because operative time likely predicts the cumulative blood loss. Fulguration or clipping of the neurovascular bundles may inadvertently injure the nerve and therefore should be avoided.

Some investigators have advocated an antegrade approach to radical prostatectomy to avoid early bleeding, but in general, if the procedure is to be performed in a timely fashion with early control of the dorsal venous complex, this should not be necessary.[35]

In a personal experience of almost 5000 cases, intraoperative control of bleeding was not achievable in a single case and the patient was closed after tightly packing the pelvis with multiple lap pads. The lap pads were removed the following day with preservation of anastomotic integrity.

Significant and life-threatening hemorrhage typically occurs within a few hours after completion of the case. The surgeon is confronted with the decision to return immediately to the operating room or attempt conservative management with the hope bleeding will spontaneously subside. Significant blood in the pelvis is associated with prolonged hospitalization and catheter drainage with increased likelihood of strictures. In cases with significant hemodynamic instability due to bleeding, we recommend immediate return to the operating room to control bleeding, evacuate the pelvic hematoma, and re-do the anastomosis if necessary.[36] This approach results in an expedited recovery and limits postoperative strictures and incontinence.

RECTAL INJURY

Injury of the rectum occurs in <1–3.6% of patients undergoing radical prostatectomy.[4,6,9,37,38] Risk factors for rectal injury include small prostates, previous radiation, and periprostatic inflammation resulting from previous transurethral resection or excessive bleeding at the time of biopsy. Salvage prostatectomy carries the highest rates of intraoperative rectal injury, with reports ranging from 6% to 15%.[39,40] Immediate repair of the injury results in excellent outcome without long-term sequelae in the majority of patients.

Following division of the posterior urethra, the surgeon encounters the rectourethralis muscle along with underlying Denonvilliers' fascia. It is desirable to divide this layer in a single incision and thus enter the pararectal space and allow an adequate posterior margin of resection. If the surgeon is too timid in division, aggressive retraction of the prostatic apex can result in shearing of Denonvilliers' fascia from the posterior apex and splitting of the gland. If the surgeon is too aggressive in achieving this plane, sharp injury of the rectum can occur. In general, rectal injury results from an overzealous attempt to develop the posterior plane bluntly with the tip of the finger. If the rectourethralis is not completely divided, or if the plane does not develop easily with blunt dissection, the attached rectal wall can be torn. Sharp dissection is preferable if the apex of the gland does not lift away from the rectum easily. It is also advisable to first incise the visceral layer of the endopelvic fascia and develop the plane between the prostate and rectum beginning laterally. An obscured operative field from excessive bleeding hinders the ability to see the tissue planes clearly. Therefore adequate hemostasis is preferable at the time of the apical dissection.

When rectal injury does occur, it is generally acceptable to repair the defect primarily in the absence of gross fecal soiling.[37,41,42] Patients should have been given a preoperative enema specifically for this reason. Débridement of devitalized tissue at the site of laceration should be followed by a two-layer closure of mucosal and muscular layers of the rectal wall. A small opening can be made in the peritoneum to pull down and interpose an omental flap between the rectal repair and the vesicourethral anastomosis. Although this maneuver is not routinely necessary, it can provide an extra safety measure if the surgeon is concerned about the viability of the rectal closure. A pedicalized flap of peritoneum or pararectal fat can serve a similar purpose. In the event of a large injury, a significantly devitalized or devascularized rectal wall, or the presence of gross soiling, serious consideration should be given to a temporary diverting colostomy along with simultaneous rectal wall repair. This procedure is certainly advisable in the setting of a previously irradiated pelvis.

The risk of rectourethral fistula following repair of rectal injury is lowered.[42] Use of prolonged bowel rest, anal dilation at the time of the surgical procedure, and the administration of broad-spectrum antibiotics have all been suggested as potential aids in lowering fistula rates.

Perhaps the greatest risk of fistula formation and risk of morbidity stem from unrecognized rectal injury.[37] If a rectourinary fistula does develop and the patient is otherwise well, an initial attempt at conservative management can be attempted using bladder drainage and a low-residue diet. Complicated cases or patients with a history of radiation will likely require use of a temporary diverting colostomy.[43]

URETERAL INJURY

Ureteral injury during radical prostatectomy is rare, occurring in 0.05–1.6% of cases.[6,9,44,45] When it does occur, it is usually during the bladder neck division, although with many surgeons advocating extended lymphadenectomy, the ureter may be injured above the iliac bifurcation during node dissection. In the setting of a large median lobe, care must be exercised to avoid the ureteral orifices by directly visualizing them. We prefer to use a partial bladder neck–sparing approach, and when doing so, caution must be exerted to avoid straying into the trigonal musculature.

The administration of intravenous indigo carmine on division of the bladder neck should be routinely performed to visualize ureteral efflux on both sides. This is particularly true for the surgeon inexperienced in prostatectomy, but is a good general habit for all surgeons. Occasionally, in a patient who has undergone aggressive transurethral resection of the prostate, the ureteral orifices can be cut during division of the bladder neck. Our simple solution is to perform a ureterotomy for a length of approximately 1 cm, insert an indwelling stent, and then taper the bladder neck posteriorly to relocate the orifices proximally.

On rare occasions, injury to the ureter can occur during posterior dissection of the seminal vesicles. The ureters generally enter the posterior bladder wall anterolateral to the tips of the seminal vesicles and cross toward the midline above the trigone. For this reason, blind placement of sutures should be avoided in the seminal vesical bed. If one suspects an injury, passage of a 3Fr feeding tube can allay concerns. In rare circumstances, an on-table retrograde pyelogram can be helpful.

If ureteral injury is identified, immediate ureteroneocystostomy is indicated. The cut end of the ureter is pulled into the bladder lumen at a convenient site, spatulated, and sutured to the bladder mucosa. A long submucosal tunnel is not necessary. The vesicourethral anastomosis should be completed first to avoid tension on the ureteral anastomosis. Similarly, if tension is encountered, a Boari flap is preferable to a psoas hitch to avoid undue tension on the vesicourethral anastomosis. Ultimately, this injury remains very rare for experienced surgeons. Heightened operative vigilance is needed when normal anatomic boundaries and tissues have been altered by severe inflammation and fibrosis. For example, in a series of 1500 consecutive open radical prostatectomies, the only case of a ureteral injury occurred in a patient with unrecognized schistosomiasis who had extensive pelvic fibrosis.[9,32]

NERVE INJURY

Injury to the obturator nerve and femoral nerve can occur during pelvic mobilization, and these injuries are discussed in detail in Chapter 40.

Early Postoperative Complications

URINARY LEAK

At our institution, men undergo a cystogram prior to removal of the urinary catheter. The incidence of significant urinary extravasation on postoperative days 3 to 4 versus day 7 is 9.9% and 13.3%, respectively.[46,47] The observation that the overwhelming majority of anastomoses are essentially water tight by postoperative day 3 suggests that a fibrin plug and not collagen deposition allows for early anastomotic integrity. The urinary catheter can be safely removed in cases with slight extravasation on cystogram.[48] While an intraoperative evaluation of the anastomotic integrity may serve to allay surgeon concerns, early anastomotic integrity has been shown to be independent on the degree of intraoperative urinary extravasation noted.[47] Therefore a watertight anastomosis does not facilitate healing of the anastomosis and early removal of the urinary catheter. Fenig and colleagues observed that postoperative blood loss was associated with the degree of extravasation on postoperative cystogram.[49] This same relationship was not true of intraoperative blood loss, a finding that left the investigators to conclude that postoperative blood loss resulted in a hematoma that may cause distraction of the vesicourethral anastomosis. A subsequent study quantifying the volume of the perianastomotic hematoma indicated that all anastomoses are watertight by postoperative day 7 if the volume of the perianastomotic hematoma is less than 37 milliliters.[50] Therefore achieving hemostasis is the primary, if not the only, factor influencing the integrity of the anastomosis.

Men with significant pelvic hematoma typically develop significant bleeding around the urinary catheter between postoperative day 3 to 5 after straining to have a bowel movement. The cessation of bleeding around the catheter is an indication the hematoma has resolved. In most cases of significant postoperative bleeding, the output from the pelvic drains is minimal unless there is significant dehiscence of the anastomosis.

When there is persistent drainage from the pelvic drains it is imperative to determine if the fluid is urine or lymphatic fluid by measuring urine creatinine and glucose. If the pelvic drains or a cystogram demonstrates significant urinary leak, a combination of continued catheter drainage with retropubic drainage should allow closure of the leak in a short time. Pelvic suction drains can be used following radical prostatectomy, but if a leak does occur, consideration should be given to converting to gravity drainage by removing the suction bulb. Additionally, if a leak persists, gradual withdrawal of the drain can ensure that the drain tip has not migrated into the anastomosis. If the patient has significant hematuria, periodic gentle irrigation of the catheter is wise to maintain drainage. Clot retention, or catheter plugging resulting from clot, can cause leakage in the early postoperative period. Leaks persisting for greater than 7 to 10 days are concerning to the surgeon, but a steadfast approach of maximal drainage should be maintained. Repeat exploration is hardly ever necessary.

Complete disruption of the anastomosis resulting from pelvic hematoma or seroma is a rare occurrence. Even in this setting, if the anastomosis is stented with a catheter, healing should occur. Obviously, the likelihood of bladder neck contracture is high with significant disruption of the anastomosis, and if it is relatively early in the postoperative period, consideration should be given to surgical revision of the anastomosis along with drainage of the hematoma or seroma. If significant time has elapsed since the surgical procedure, the surgeon may encounter technical difficulty with the anastomosis because of tissue friability and distortion.

In the setting of fever or pelvic pain accompanying a leak, consideration should be given to the possibility of an undrained pelvic fluid collection. Cross-sectional imaging along with percutaneous drainage can relieve the problem if it is identified.

URINARY TRACT AND WOUND INFECTION

Infectious complications following radical prostatectomy are relatively unusual. The incidence in contemporary series ranges from 0% to 3%, generally consisting of wound infection.[4,9,38,51,52] Early recognition of wound infection is essential to minimize the need for aggressive therapy. Patients generally at risk include those with excessive abdominal pannus and those with large amounts of urinary extravasation.

The use of prophylactic antibiotics in radical prostatectomy is essentially the same as in individuals undergoing other forms of abdominal surgery. Antibiotic coverage should be broad spectrum and directed toward skin flora. We routinely use a first-generation cephalosporin administered at the time of anesthetic induction and maintained for a period of 24 hours after the procedure. Because patients have an indwelling catheter for 1 week postoperatively, the use of urinary tract prophylaxis is advocated by some surgeons following surgery. The use of antibiotics for a prolonged period postoperatively is controversial, and the benefit is not clearly demonstrated. Nonetheless, in view of the fresh incision, the risk of small amounts of urinary extravasation, and the risk of catheter-related secondary infections, we generally administer a fluoroquinolone until 2 days following catheter removal.

Before the surgical procedure, a urine culture is advisable. Individuals with known infection should obviously be fully treated before the operation. These individuals should then have prophylactic antibiotics directed toward the offending organism.

Wound infection can result in any patient, but in general patients with significant urinary extravasation, bleeding, or excessive subcutaneous fat may be at the greatest risk. In individuals believed to be at risk because of obesity, the use of a suprafascial subcutaneous suction drain can prevent seroma formation and limit the risk of infection. Additionally, relatively loose approximation of the skin allows drainage of serous and serosanguinous fluid and thereby limits the risk of fluid collection. Subcutaneous sutures to close the "dead space" should be avoided in this situation.

When infection does occur, it is best treated by opening the incision and allowing healing by second intention. On rare occasions, periodic débridement may be required to remove devitalized tissue. The fascia underlying the infection should be carefully inspected for dehiscence, which is rare with an extraperitoneal lower midline incision. If persistent wound drainage is noted, consideration should be given to the possibility of a urine leak or a pelvic abscess.

PULMONARY EMBOLUS AND DEEP VEIN THROMBOSIS

Thromboembolic complications continue to be a major complication of pelvic cancer surgery. Although the diagnosis and management of deep vein thrombosis and pulmonary embolus are discussed in Chapters 2 and 4, routine preventive measures are an important part of radical prostatectomy. The incidence of deep vein thrombosis or pulmonary embolus in contemporary radical prostatectomy series has varied from 0.4% to 3.1%.[4,6,9,38,51,52] This rate is consistent with the 1–5% reported rate of patients undergoing surgical treatment of cancer of the abdomen and pelvis.[53] Much discussion has centered on the routine use of heparinoid prophylaxis for procedures that place the patient at high risk for venous thromboembolism. In a review of 1373 RRPs, Koya and Soloway and their associates [54] found only three instances of deep vein thrombosis with no clinical pulmonary embolus when they used only sequential compression devices and no heparinoid prophylaxis. Lepor and colleagues[26] found similarly low rates in their series of 1000 cases, and as such the use of prophylaxis remains controversial.

LOSS OF CATHETER

Occasionally, as a result of catheter malfunction or injury, the Foley catheter can fall out following radical prostatectomy. This complication is obviously of more concern 7 hours postoperatively than 7 days afterward. In the very early postoperative period (<48 hours), it is unwise to attempt blind passage of a catheter. The use of a flexible cystoscope with passage of a floppy guidewire and then a Councill-tip catheter is the safest course of action. Although it is not absolutely necessary to perform this procedure while the patient is under anesthesia, it is probably most comfortable for the patient in this early postoperative period.

If one is unable to penetrate the anastomosis, or if the anastomosis is disrupted, then placement of a suprapubic cystostomy under ultrasound guidance can temporize the situation. If no urethral catheter is placed, the patient will be at high risk of bladder neck stricture with a suprapubic tube in place. On rare occasions, if nothing can be passed through the anastomosis, reoperation with replacement of the catheter and revision of the anastomosis are indicated. Although reoperation is hardly ever necessary, when it is indicated and there is at least partial integrity of the anastomosis, an attempt should first be made to pass a catheter transurethrally and manually guide it into the bladder. If this is not feasible, it is best simply to perform a cystostomy and attempt antegrade passage of a catheter to establish the lumen. A wire can then be passed through the catheter for eventual retrograde catheter passage. This technique is preferable to disruption and reconstruction of the vesicourethral anastomosis.

Similarly, in the presence of unusually severe hematuria or clot retention, the surgeon should consider placement of an open or closed suprapubic cystostomy rather than catheter change. Urinary drainage can be maintained with the cystostomy while the nonfunctional urethral catheter continues to stent the vesicourethral anastomosis.

In the later postoperative period (>2–5 days), consideration should be given to leaving the catheter out as long as the patient is not in urinary retention. A retrograde urethrogram can confirm closure of the urethra. Alternatively, at this later stage, gentle passage of a catheter is usually possible at the bedside. For those patients falling in between (1–2 days), an attempt at bedside flexible cystoscopy with passage of a wire is usually acceptable, but blind passage of a catheter should be avoided. An unsuccessful attempt can be followed by one while the patient is under anesthesia.

For a discussion of risk factors and management options regarding lymphoceles following pelvic lymph node dissection, please refer Chapter 40.

Delayed Postoperative Complications

IMPOTENCE

Erectile dysfunction following radical prostatectomy was the primary impetus for the development of the modified anatomic approach to RRP described by Walsh. Before the anatomic description of the neurovascular bundles containing the cavernosal nerves, erectile function after radical prostatectomy was rare. Now, with the application of nerve-sparing techniques, investigators report potency in 63% to 68% of men undergoing bilateral nerve-sparing procedures and in 41% to 50% of those undergoing unilateral nerve-sparing operations.[2,4,6] A more rigorous and reliable assessment of erectile function was reported by Marien et al.[55] All men signed informed consent to participate in a longitudinal prospective outcomes study where sexual function was captured at baseline and predefined time points during follow-up using validated self-administered questionnaires and the operating surgeon was not involved in data acquisition, entry, or retrieval. This study reported potency rates of 61% and 47%, respectively, in men undergoing bilateral versus unilateral nerve sparing procedures. Most reported series are from centers of excellence, and the reported rates of potency from community-based series are often lower, ranging from 11% to 30%.[1,56,57]

The assessment of postoperative potency is a critical factor in determining outcomes in prostate cancer surgery. Use of a validated instrument for the measurement of sexual function is critical.[58] Potency is clearly not a binary variable, and it should be treated as a graded phenomenon. Decreased preoperative erectile function is an important determinant of the likelihood of postoperative erections after nerve-sparing surgery.

Several factors influence the likelihood of retaining erectile function postoperatively. Age is a primary determinant of the success of bilateral nerve-sparing prostatectomy in preserving potency adequate for sexual intercourse. The potency rate following bilateral nerve-sparing radical prostatectomy for men <50 years old has varied from 86% to 91% compared with 75% to 80% in men in their 50s, 58% to 60% in men in their 60s, and 25% to 42% in men >70 years old.[2,4,6,59] Although it is difficult to quantitate, preoperative erectile function may be the greatest predictor of age-related return of potency. Historically, preservation of potency was reported at 18 months. Lepor and associates observed that 19.8% of men will experience marked to moderate improvement in erectile function between 2 and 4 years.[60] Longer-term studies have shown further improvement in potency in a small cohort of men up to 7 years.[61] Those men who exhibit long-term improvement in erectile function are those whose erection has shown signs of return. Men with no erectile function at 2 years are unlikely to achieve any functional return of erection.

In addition to patient characteristics contributing to postoperative erectile dysfunction, certain technical factors aside from cavernosal nerve preservation may contribute to this outcome as well. We believe that excessive traction, manipulation, or local cauterization of the neurovascular bundles can greatly influence the likelihood of return of function. Recognition of the nerve bundle and careful preservation of its surrounding tissues are exceedingly important in avoiding nerve injury. Neurapraxia caused by traction or thermal injury may reverse, but the increasing suggestion is that prolonged periods of postoperative erectile dysfunction may increase the likelihood of permanent impotence.

On occasion, when dividing the dorsal venous complex and or lateral periurethral tissues, the surgeon encounters bleeding in the space lateral to the urethra. This complication is most often the result of a lacerated venous branch that is partially retracted beneath the levator musculature. Care should be exercised to avoid electrocautery and or placement of deep suture ligatures during attempts to control such bleeding. The placement of sutures should be limited to tacking the vessel to the surrounding levator muscle with a 3-0 or 4-0 absorbable stitch under direct vision. Deeply placed stitches in this location can cause unseen injury to the ipsilateral neurovascular bundle or continence mechanism.

As described in the previous two editions of this text, in order to avoid traction injury to the cavernosal nerves during apical retraction of the gland, we have used a modified approach to the nerve-sparing technique of Walsh. Following division of the deep dorsal venous complex, the lateral prostatic fascia is identified on the anterolateral aspect of the prostate (Fig. 42.3A). The prostatourethral junction is developed by bluntly pushing the overlying levator fibers off the apex with a Kitner dissector. The fascia is incised while it is elevated from the prostate capsule with a right-angle clamp. Care should be exercised to avoid injury to the prostate capsule during this maneuver. Once incised, the lateral edge of the incised fascia is lifted away from the gland and a plane is developed between the prostate and the lateral prostatic fascial contents (inclusive of the cavernosal nerve bundle). The plane is developed with blunt and sharp dissection along the prostatic apex and the prostatourethral junction. In this fashion, the nerve is completely freed from the prostatic apex before division

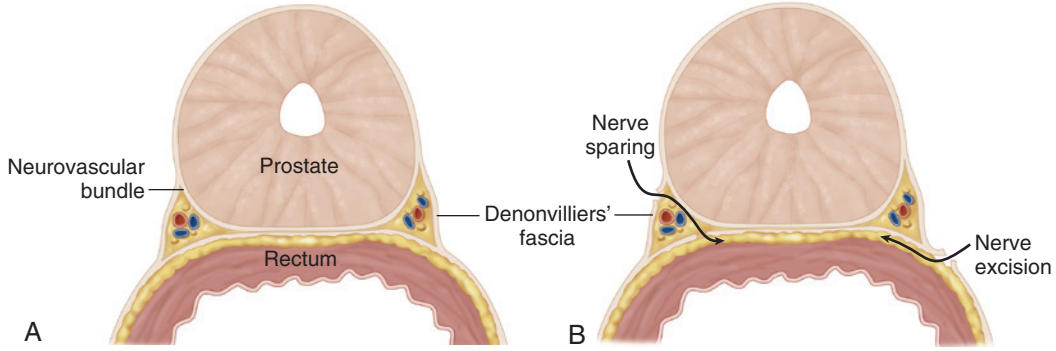

Figure 42.3 The neurovascular bundle dissection can be carried out for either preservation or wide excision. A, Anatomically, the neurovascular bundle is carried and is separated from the prostate by decussation of the lateral prostatic fascia and from the rectum by Denonvilliers' fascia. The lateral prostatic fascia extends over the lateral rectum dorsal to the position of the neurovascular bundles. B, In nerve preservation, the lateral fascia is released on the anterolateral surface of the prostate and then is rolled off the posterolateral aspect of the gland until Denonvilliers' fascia is exposed. On release of the neurovascular bundle, an incision in the posterior layer of Denonvilliers' fascia overlying the anterior rectal wall allows complete separation of the prostate from the bundle. Entry into the plane posterior to Denonvilliers' fascia allows elevation of the prostatic apex from the rectum such that no tension is placed on the nerves after division of the urethra and retraction of the prostatic apex. (Modified from Goad JR, Scardino PT. Modifications in the technique of radical retropubic prostatectomy to minimize blood loss. Urol Clin North Am. 1994;2:75.)

of the urethra or retraction of the prostatic apex (see Fig. 42.3B).

The plane between the lateral prostatic fascia and the prostate should develop easily with a blunt sweeping motion, but occasionally sharp dissection is necessary. On lateral reflection of the fascia from the posterolateral prostate, exposure should be medial to the neurovascular bundle to allow perforation of Denonvilliers' fascia and entry into the perirectal space (see Fig. 42.3B). Carrying the plane circumferentially around the prostate can make division of the posterior urethra and rectourethralis quite simple. Occasionally, the plane is adherent, and in this circumstance consideration should be given to the possibility of extraprostatic cancer advancement or simply residual fibrosis from the prostate biopsy. In these cases, the posterior plane should be developed following division of the urethra, and one should consider intraoperative frozen sections from the lateral and apical margin bed.[62]

Much attention has been focused on penile rehabilitation using behavioral and medical therapy to increase likelihood of potency following RRP. There is increasing evidence that smooth muscle atrophy may occur during the process of nerve regeneration. Animal studies have shown that the use of phosphodiesterase inhibitors preserves smooth muscle function following iatrogenic trauma to the cavernous nerves.[63] The controversy is whether similar efficacy is achieved with daily or on-demand phosphodiesterase inhibitors. Numerous authors reported significantly improved potency using phosphodiesterase-5 inhibitors following radical prostatectomy employing both on demand regimens as well as daily administration, immediately after the procedure, and continuing during the postoperative period.[64,65] At our institution, we routinely prescribe daily sildenafil 50 mg or tadalafil 5 mg for the first year postoperatively for these patients. We believe that sexual intimacy may also "atrophy" during the recovery of erectile function. Therefore we recommend early intervention with intracavernous injections in couples motivated to resume sexual intercourse.

INCONTINENCE

Incontinence remains the most feared and frustrating complication of radical prostatectomy for both patient and surgeon. Although contemporary surgical series report markedly improved rates of total continence compared with earlier series, a small percentage of cases still result in debilitating incontinence for the patient. Further underscoring the frustrating nature of the complication is the absence of any reliable preoperative or intraoperative predictors of postoperative continence.[66]

Contemporary surgical series report rates of continence ranging from 80% to 97%.[2,4,6,16,38,67–69] The definition of continence is variable likely due to surgeon experience and technique. The definition of continence should not be total continence since 14.2% of men report some degree of urinary leakage preoperatively.[66] Lepor and Kaci correlated responses to validated questionnaires assessing level of postprostatectomy continence and patients, self-assessment of continence.[66] At 2 years following surgery, 100% of men who reported occasional urinary leakage, or using a single protective pad over 24 hours, considered themselves continent. Therefore it is reasonable to use this definition of continence but requires careful explanation and counseling to men preoperatively to reinforce this definition of continence. Age may also influence continence. Catalona and colleagues[4,6] reported a 96% rate of continence in men <70 years old compared with a rate of 87% among those >70 years old. In contrast, however, Lepor et al. did not observe a significant correlation between age and restoration of continence.[16] Once again, the reports of incontinence rates are generally from centers of excellence in radical prostatectomy, and community-based series often report lower rates of total continence.[1,38–40,57,58]

The influence of nerve sparing upon continence remains controversial. Marien and Lepor examined return of continence in 1110 potent men in their longitudinal prospective outcomes study and reported no relationship between extent of nerve sparing or potency restoration with continence rates.[70]

In attempting to minimize the risk of incontinence in the postoperative setting, preservation of the external striated sphincter is of paramount importance. Minimizing the blind passage of clamps, periurethral dissection, and aggressive hemostatic suturing in the area of the external sphincter is critical for preservation of the sphincter. For this reason, we prefer to perform the apical dissection sharply with no passage of clamps. All suture ligatures are placed directly under vision, and no excessive efforts are made to control venous oozing in the periurethral area.

As described in the previous two editions of this text, following division of the dorsal venous complex as described, the membranous urethra is exposed. By leaving the puboprostatic ligaments largely intact, the normal suspension of the urethra to the symphysis is preserved. There is increasing evidence that continence is related to urethral length. Efforts should be made to maximally preserve the full thickness of the "spongy" tissue of the urethra along with its surrounding sheath. This goal is accomplished by limiting anterior sharp dissection to the point at which the catheter can first be palpated. This palpation allows precision in this incision and presents a distinctive advantage of open radical prostatectomy. Thinning of the anterior urethra, a potential pitfall of our technique of dorsal vein division, is avoided in this fashion.

As described, we perform our nerve-sparing procedure before division of the urethra. On completion of the procedure, the nerve bundles have been released from the posterolateral aspect of the prostatourethral junction. With gentle retraction on the prostatic apex, the lateral urethra is exposed, and division of the urethra is begun 5 mm distal to the prostatourethral junction (Fig. 42.4). The anterior two-thirds of the urethra are divided, exposing the catheter below. The anterior and lateral anastomotic sutures are placed at this time to incorporate urethral sponge and mucosa in each suture pass. Next, once the catheter has been divided, the posterior urethra is exposed. We believe that passage of the posterior sutures is best performed at this time to facilitate inclusion of the rectourethralis and urethral mucosa in the suture passage. Because the neurovascular bundle on either side of the urethra has already been released, passage of the posterior anastomotic sutures is possible at this point.

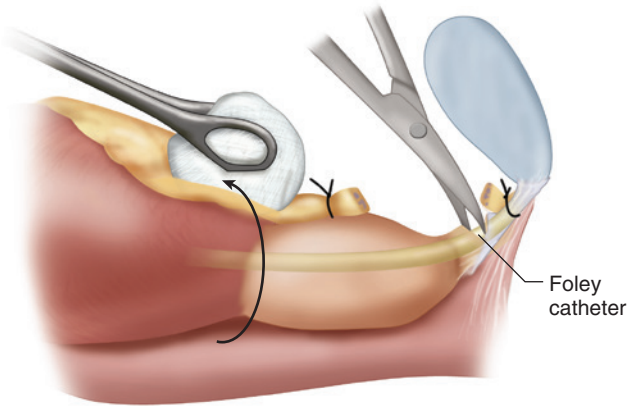

Figure 42.4 Division of the membranous urethra. The urethra is divided anteriorly following full release of the neurovascular bundles. Care is taken to preserve the full thickness of the urethra by cutting through the wall in a single stroke rather than layer by layer. In this fashion the urethral catheter is exposed. (From Tareen B, Godoy G, Taneja SS, Complications of Radical Retropubic Prostatectomy, in Complications of Urologic Surgery: Prevention and Management, 4th Edition, Taneja SS (ed), Saunders Elsevier, Philadephia, PA, 2010.)

When the surgeon assesses the patient with incontinence postoperatively, a careful historical evaluation should be performed to determine the nature of the incontinence. As discussed later, preexisting detrusor hypertrophy, instability, and decreased bladder wall compliance may contribute to postoperative voiding dysfunction. On occasion, these conditions can result in urge-related incontinence. The management of stress urinary incontinence following radical prostatectomy is discussed in Chapter 50. In general, surgical treatment of stress incontinence should be withheld until conservative treatment has failed for 10–12 months. In cases of severe incontinence lasting ≥6 months, complete resolution of incontinence is unlikely, and earlier intervention may be considered.

BLADDER NECK CONTRACTURE/ ANASTOMOTIC STRICTURE

Bladder neck contracture or vesicourethral anastomotic stricture is not an uncommon complication of radical prostatectomy; it occurs in 0.5–17.5% of cases.[4,20,52,68,71–73] The definition of an anastomotic stricture is variable. Some experts do not consider an "anastomotic obstruction" that is effectively managed by a single dilation to be a stricture. In most series, if anastomotic stricture is defined as any requirement for dilation, the rate is approximately 5–10%. This complication usually manifests within 3 months of catheter removal.[73] Anastomotic strictures may develop in men who undergo a technically flawless procedure associated with an uneventful recovery. There is some evidence that a subset of men who develop increased scarring of the surgical incision are predisposed to develop anastomotic strictures suggesting there may be genetic predisposition to scarring when the skin or bladder/urethra are approximated.[72] On occasion, late bladder neck contractures are noted, and consideration to the diagnosis should be given whenever patients complain of worsening incontinence, increased urgency or frequency, or decreased urinary stream.

Multiple factors may contribute to early contracture of the anastomosis including anastomotic urinary extravasation, poor mucosal approximation, suture reaction, and ischemia. A large review from the Cancer of the Prostate Strategic Urologic Research Endeavor (CaPSURE) database showed that men who developed stricture were older and had a higher body mass index.[71] Another report suggested increased postoperative blood loss predisposed to anastomotic stricture formation.[73] Although these factors are self-explanatory, some, such as ischemia and poor mucosal apposition, may not be easily recognized postoperatively. Attention to these issues is most important intraoperatively during completion of the anastomosis. Excessive thinning or mobilization of the bladder neck, particularly when rolling an anterior bladder wall tube, can cause ischemia and should be avoided. Sutures with nonreactive characteristics such as the absorbable monofilament poliglecaprone 25 (Monocryl) should be used.

Up until recently, many surgeons advocated mucosal apposition to decrease risk of anastomotic stricture. This led to tapering of the bladder neck with a mucosal everting stitch to avoid stricture in the tapered segment of the bladder neck. Anastomotic sutures can be positioned in the lumen of the bladder neck for further eversion of the mucosa to maximize mucosal apposition at the anastomosis. None of these efforts to evert the bladder mucosa is performed during robotic radical prostatectomy, without any evidence of increased incidence of anastomotic strictures. In fact, it has been suggested that an advantage of the robotic approach is a lower incidence of anastomotic strictures.[74] During the robotic approach, little effort is made to narrow the bladder neck. Stricture rates following open radical prostatectomy approach that of the robotic approach if bladder neck reconstruction is minimized.[75] We continue to evert the bladder neck mucosa for hemostasis and not to influence anastomotic stricture rates.

MINOR COMPLICATIONS

Inguinal hernia is another proposed complication of RRP, with a proposed incidence of 10–20%.[76,77] The cause has been elusive and has led many investigators to speculate that a lower midline incision in and of itself is the reason for the increased incidence of inguinal hernias. Stranne and colleagues[77] compared a survey population of various lower midline procedures versus a nonoperated group of patients and found significant differences in incidence at 24 months for development of inguinal hernia. Lepor and Robbins[78] reviewed 1300 patients undergoing RRP and showed a 13% incidence of inguinal hernias in this population, a finding suggesting that underdiagnosis of hernia on the preoperative examination was the likely reason for previously higher reported rates of postprostatectomy inguinal hernia. By repairing these clinical hernias at the time of radical prostatectomy using a preperitoneal approach,[26] these investigators found the postoperative incidence of hernias to be only 8%.[78] The question remained whether these hernias were caused by the open surgical approach or were they present but not detectable on physical examination. Valsalva MRI and upright transinguinal ultrasonography have been shown to detect clinically occult hernias.[79] If hernias are identified using Valsalva MRI inguinal ultrasound, the incidence of postprostatectomy hernias is reduced to <1%.[80] Therefore open radical prostatectomy does not cause hernias but rather transforms clinically insignificant hernias to clinically discernable hernias.

Urine loss during sexual intercourse or ejaculation is an often-overlooked complication of RRP. Studies often focus on volume of urine loss and correlate this with greater bother and more significant lifestyle changes.[81] Abouassaly and Gill and their colleagues[82] described their experience with postprostatectomy ejaculatory urine loss in 26 patients and reported that although the amounts of urine lost were typically small, they had a major impact on quality of life and led to a great deal of embarrassment and anxiety. Koeman and associates[83] were surprised to find that seven of 14 patients who complained of "weakened orgasm" in their series also complained of involuntary urine loss. In our experience, the incidence of climacturia decreases over time.[84,85] Men considered incontinence during sexual activity to be a major problem 22.4% and 12.1% of the time, at 3 and 24 months, respectively. In some cases, climacturia occurred independent of stress incontinence. Interestingly, when stress incontinence and climacturia co-existed, the climacturia often resolved following a male sling or artificial sphincter placement.[84,86–88] It remains unclear if climacturia will respond to similar surgical intervention if it occurs without stress incontinence.

Change in orgasm following RRP is another complication that is often not discussed with the patient or is lost when focusing on whether that patient will have potency. Other than the "dry orgasm," many patients believe that their orgasm is "weakened" or different in duration. One could hypothesize that lack of prostate and seminal vesicle contraction may contribute to this phenomenon.

The rate of *fecal incontinence* was reported to be ≤5% in men undergoing RRP who participated in a telephone survey in a study by Bishoff and colleagues.[88] Although rates of this complication are typically proposed to be higher in patients undergoing radical perineal prostatectomy, other investigators suggested that the rates of fecal incontinence noted by Bishoff and colleagues were considerably lower and that no significant differences existed between RRP and radical perineal prostatectomy in this regard.[87] A study of outcomes showed no difference between bowel symptoms in patients undergoing watchful waiting and those in patients undergoing RRP.[89]

Salvage Prostatectomy

Selection of candidates for radical prostatectomy following radiation can be difficult. In general, the operation results in relatively low rates of cancer control, although with proper selection, some investigators have reported 10-year clinical cancer-free survival rates of 60–70% and biochemical recurrence-free survival rates of 30–43%.[62,90,91] Investigators have estimated that as many as two-thirds of these patients have advanced pathologic disease (pT3a or greater).[39,62] Stephenson and Eastham[92] proposed that the 5-year progression-free rates for salvage RRP are 86%, 55%, and 28% for patients with preoperative prostate-specific antigen levels of 4 ng/mL, 4 ng/mL to 10 ng/mL, and >10 ng/mL, respectively.[62]

A higher likelihood of rectal injury is noted in patients undergoing salvage surgery than in those patients undergoing primary radical prostatectomy, with reported rates ranging from 6% to 15%.[39,40,93] Fibrotic reaction often ablates the plane posterior to the prostate, and to avoid injury to the rectum the surgeon should use sharp dissection to develop the plane. In patients with known proctitis or rectal devascularization resulting from radiation, strong consideration should be given to a diverting colostomy in the setting of rectal injury. In a properly prepared bowel, it may be acceptable to repair the injury primarily, but given the propensity for poor wound healing in the irradiated field, the surgeon should have a low threshold for proximal diversion. One option is to repair the defect primarily, but to raise a loop of sigmoid colon to a suprafascial position. If the rectum heals without difficulty, the loop can be dropped back into the abdomen and the fascia closed in a relatively

minor operation. If the rectal injury does not heal, a Turnbull-style loop stoma can be matured at the bedside.

In addition to intraoperative difficulty, individuals undergoing postirradiation prostatectomy are prone to higher rates of incontinence and deep vein thrombosis than are patients undergoing primary prostatectomy. Most groups report rates of incontinence >50%. For this reason, careful selection with regard to the possibility of cancer cure should be a fundamental tenet of salvage prostatectomy. We have not been strong advocates of the idea of palliative resection for locoregional control in this setting and believe that patient selection based on oncologic tenets is essential.

Chapter 42 Questions

1. A 64-year-old man with a history of bilateral inguinal hernia repair with mesh as well as a history of diverticulitis undergoes open radical prostatectomy for a cT1c Gleason 3+4 prostate cancer. On digital rectal examination his prostate gland is approximately 50 grams in size. A preoperative multiparametric MRI demonstrates a significant intravesical lobe. During preparation of the dorsal vein complex (DVC) for ligation and division, he is found to have a significant anterior and retropubic gland. Which of the following maneuvers is most helpful as a next step?
   a. Straightening the operating table
   b. Wrap a tourniquet at the base of the penis to temporarily decrease blood flow to the DVC to assist division
   c. Catheter traction during DVC division
   d. Increase electrocautery current to 70 and attempt to coagulate the DVC stump
   e. Divide the puboprostatic ligaments to mobilize the prostate posteriorly

2. Which of the following are advantages of preoperative Epogen administration prior to undergoing open radical prostatectomy?
   a. Preoperative increase in hematocrit of ~10%
   b. Decreased rate of intraoperative blood loss
   c. Higher postoperative hemoglobin as compared to men donating preoperative autologous blood
   d. Earlier return of continence by 3% on standardized self-reported questionnaire
   e. Lower rate of allogeneic transfusion compared to men donating autologous blood preoperatively

3. A 56-year-old man with a BMI of 38 undergoes radical prostatectomy for a Gleason 7/10 prostate cancer. His surgery is uneventful, but on attempting reconstruction, the bladder neck will not reach the urethral stump. A Tanagho tube is constructed and allows for re-approximation and completion of the anastomosis. Which of the following delayed complications is he at higher risk for developing?
   a. Delayed return of urinary continence
   b. Erectile dysfunction
   c. Detrusor overactivity
   d. Anastomotic leak
   e. Bladder neck contracture

4. A 56-year-old man with a BMI of 28 undergoes radical prostatectomy for a Gleason 7/10 prostate cancer. His surgery is uneventful. Approximately 1 year following surgery he reports that he is voiding well and notes only occasional drops of urine when he drinks alcohol. He is able to achieve erections sufficient for intercourse when using PDE5 inhibitors. His PSA is undetectable. On routine examination, you note a reducible right inguinal hernia. Which of the following measures may have assisted in preventing the development of this inguinal hernia?
   a. Pfannenstiel incision
   b. Upright transinguinal ultrasonography
   c. Valsalva MRI
   d. b and c
   e. All of the above

5. A 65-year-old man with a history of DM, HTN and BPH is found to have Gleason 4+4 in 4/12 cores. He has a history of a cholecystectomy and his staging workup is negative. He undergoes an uncomplicated open radical prostatectomy. His final pathology demonstrates pT2cN0 Gleason 4+4 prostate cancer with negative margins. His catheter is removed on postoperative day 10. Two weeks later he reports fluid leakage per rectum. He denies fevers, chills, nause, or vomiting. What is the appropriate next step in his management?
   a. Low residue diet
   b. Begin empiric therapy for *Clostridium difficile* colitis
   c. Insert a urethral catheter
   d. Pelvic exploration, washout, and diverting colostomy
   e. a and c

6. Which of the following surgical steps should be avoided in order to minimize long-term impact upon urinary continence?
   a. Aggressive hemostasis of venous ooze in the periurethral tissue
   b. Sharp division of the urethra
   c. Maintain puboprostatic ligaments
   d. Place anterior anastomosis sutures under direct vision, following division of anterior urethra
   e. Maximal preservation of urethral tissue

Case Study 1

A 52-year-old man with a history of hyperlipidemia and hypothyroidism is found to have a PSA of 3.7 ng/mL when he applies for life insurance. He reports at initial evaluation that he experiences nocturia ×1, has some decreased erectile function, and does not use PDE5 inhibitors. He is otherwise satisfied with both his urinary and sexual function. He undergoes a prostate biopsy that demonstrates Gleason 3+4 in 2/12 cores.

He elects to manage his disease by undergoing an open radical prostatectomy with bilateral pelvic lymph node dissection. The case is uncomplicated with an estimated blood loss of 550 mL. Due to a prominent intravesical lobe, the bladder neck is tapered using an anterior tennis racket approach. His bladder neck mucosa is everted. Following completion of the anastomosis, irrigation demonstrates no leak. His postoperative hematocrit slowly drifts down and he requires 2 units, postoperative transfusion. His pelvic drain output increases on postoperative day 2.

1. Which of the following is the likely cause of his anastomotic leak?
   a. Bilateral nerve sparing
   b. Urethral length
   c. Intraoperative blood loss
   d. Bladder neck repair
   e. Postoperative blood loss

2. What is the next step in managing this leak?
   a. CT abdomen and pelvis
   b. Initiate total parenteral nutrition
   c. Re-exploration and correction of leak
   d. Continued catheter and monitoring of drain output
   e. Placing the catheter on gentle traction

3. On postoperative day 4 his catheter falls out during ambulation. What is the next management step?
   a. Suprapubic cystotomy
   b. Attempt gentle replacement of catheter
   c. Trial of void
   d. Flexible cystoscopy
   e. Re-exploration

4. The patient's catheter is replaced, and approximately 1 week later his drain output remains high. He undergoes a cystogram that demonstrates no evidence of extravasation from his vesicourethral anastomosis. He then undergoes a CT urogram that demonstrates a partial transection of his left ureter and concomitant urine leak. There is mild hydronephrosis. What is the next best management step in this setting?
   a. Continued observation
   b. Retrograde stenting
   c. Percutaneous nephrostomy
   d. Immediate ureteral reimplantation
   e. Nephrectomy

Answers

1. **e.** Routine division of the puboprostatic ligaments is not recommended. However, for situations where the prostate gland may be anteriorly displaced (via size or prior scar as is possible in this case), incision of the puboprostatic ligaments may drop the gland posteriorly and facilitate distal control. Restricting division only to the region needed to obtain improved access to the DVC is recommended as preservation of the ligaments prevents vein stump retraction and further assists in control.
2. **c.** Preoperative Epogen administration for 7–14 days in men with a preoperative hematocrit <48% results in an increase in the hematocrit of 3%. This approach resulted in a higher postoperative hemoglobin for those receiving Epogen as compared to men who donated autologous blood, while demonstrating no short- or long-term negative effects on cardiovascular or oncologic safety.
3. **e.** Bladder neck shortening is a problem most commonly encountered when wide resection of the bladder neck is carried out. A Tanagho tube refers to anterior relocation of the bladder neck opening by incising laterally on either side (3 and 9 o'clock) and then tapering posteriorly (6 o'clock). This creates a more anterior urethral or bladder neck attachment, thereby removing tension through increased bladder mobility. Anterior bladder tubes such as this risk ischemia to the mucosa and the anastomosis, thus increasing the risk of bladder neck contracture. Obesity is a separate risk factor for bladder neck contracture.
4. **d.** Open radical prostatectomy, like many lower abdominal surgeries, has been correlated with inguinal hernia development, although a cause has not been elucidated. Routine use of preoperative upright transinguinal ultrasound or Valsalva maneuver to identify occult preoperative inguinal hernia allows for repair at the time of prostatectomy, which has been reported to reduce incidence of postprostatectomy hernia to <1%. Open radical prostatectomy can be performed through a Pfannenstiel incision; however, this has not been shown to decrease rates of inguinal hernia postoperatively.
5. **e.** Unrecognized rectal injury presents the greatest risk of rectourethral fistula outside of salvage prostatectomy. Injuries most commonly occur during apical dissection and may be unrecognized if hemostasis is inadequate during this dissection. If a rectourinary fistula does develop and the patient is otherwise well, an initial attempt at conservative management can be attempted using bladder drainage and a low-residue diet. Complicated cases or patients with a history of radiation will likely require use of a temporary diverting colostomy.
6. **a.** Preservation of the external striated sphincter and surrounding tissue is of critical importance in preserving continence. Efforts to limit dissection in the periurethral tissue, including aggressive hemostasis of the periurethral bleeding veins, risk damage to the sphincter and surrounding innervation. During open radical prostatectomy, palpation of the urethra enables the incision on the urethra to be as close to the prostate as possible, thereby maximizing urethral length. Nerve sparing should be completed prior to urethral division to further assist in lateral urethral dissection and division, further preserving urethral length.

CASE STUDY 1

1. **e.** While an intraoperative evaluation of the anastomotic integrity may serve to allay surgeon concerns, early anastomotic integrity has been shown to be independent of the degree of intraoperative urinary extravasation noted. Anastomotic healing appears to be related to postoperative hematoma. Achieving hemostasis is the primary factor influencing the integrity of the anastomosis.
2. **d.** Conservative management of his urethral anastomosis at this time is recommended as he likely developed a post-operative pelvic hematoma that resulted in a distraction in his anastomosis. With continued catheter drainage, the leak will likely close.
3. **d.** In the early postoperative phase, it is usually reasonable to allow the patient an attempt at voiding. However, in this situation, given the anastomotic leak, it is best to perform a catheter replacement using a cystoscope. At this stage this can be attempted without anesthesia, but if available anesthesia will minimize patient discomfort and optimize likelihood for catheter replacement.
4. **c.** Ureteral injury during radical prostatectomy is rare. However, the risk for injury is greater when performing bladder neck division and reconstruction or when performing extended lymphadenectomy (above the iliac bifurcation). Techniques to aid in avoiding ureteral injury include employing indigo carmine intraoperatively or cannulating the ureteral orifices with feeding tubes at the time of anterior bladder neck division.

SECTION VIII

Complications of Reconstructive Surgery

43 Complications of Ureteral Reconstructive Surgery

MITCHELL HUMPHREYS and SEAN MCADAMS

CHAPTER OUTLINE

Surgical Anatomy
Etiology and Epidemiology of Ureteral Injury
Diagnosis and Preoperative Planning
General Surgical Considerations
Surgical Management
Ureteroureterostomy
Ureteroneocystostomy (Ureteral Reimplant)
Vesicopsoas Hitch (Psoas Hitch)
Boari Bladder Flap
Renal Descensus (Nephropexy)
Buccal Mucosal Graft for Ureteroplasty
Transureteroureterostomy
Intestinal Interposition (Ileal Ureter)
Autotransplant
Ureteroenteric Anastomotic Stricture
Transplant Anastomotic Stricture
Ureterolysis
Postoperative Stenting and Drainage
General Complications and Management
  Urine Leakage
  Ureteral Stricture
Chapter 43 Questions and Answers

KEY POINTS

1. The ureteral blood supply to the proximal and midureter branches medially from the renal, aortic, gonadal, and lumbar arteries, while the pelvic ureter is perfused laterally from iliac branches.
2. Antegrade and retrograde ureteral imaging are needed to define the location and length of proximal and midureteral strictures. Bladder capacity should be measured preoperatively when psoas hitch or Boari bladder flap are being considered.
3. Surgical exploration may reveal less viable ureter than expected. Surgeons must be prepared to use additional maneuvers or alternative procedures to provide a tension-free anastomosis. These include vesicopsoas hitch, the Boari bladder flap, and downward nephropexy.
4. Early anastomotic strictures after renal transplant or urinary diversion are typically ischemic in nature. Endoscopic interventions for strictures >2.0 cm are unlikely to be successful, and ureteral reimplantation is an appropriate initial intervention.
5. Iatrogenic thermal injury from vessel sealing devices may have a delayed presentation. If diagnosed acutely, thermal injuries should be managed with excision of the ureteral segment with 1 cm margins prior to repair.
6. An indwelling ureteral stent should be left for all ureteral reconstructive procedures, as well as external drainage to monitor for anastomotic leakage.
7. Transureteroureterostomy is contraindicated in recurrent stone formers or in patients with history of urothelial carcinoma of the ureter or renal pelvis. The donor ureter should travel above the level of the inferior mesenteric artery to avoid impingement. Ureteral stent should travel from the bladder to the donor ureter.
8. Complete ureteral strictures can be bridged with a combination of Boari bladder flap and downward nephropexy. Ileal ureter and renal autotransplant are alternatives, though nephrectomy should be reserved for kidneys with relative function <15%.
9. Absorble suture should be used for a psoas hitch procedure with care taken to avoid entrapment of the femoral or genitofemoral nerves. Symptoms of nerve entrapment may resolve when suture dissolves.
10. Ileal ureter is contraindicated in patients with Cr of 2.0 mg/dL or greater, or with history of inflammatory bowel disease, radiation enteritis, or intestinal absorption disorders.
11. Reconstructive surgery of the ureter has entered the era of robotics with similar efficacy to open procedures in the hands of experienced surgeons. Surgical approach should be determined based on patient interests and surgeon skill set.

Reconstructive surgery of the ureter may be necessitated through trauma, cancer, recurrent stone disease, iatrogenic injury, or congenital abnormalities. The goals of ureteral reconstruction are to restore continuity, resolve obstruction, and preserve renal function while minimizing morbidity. Given that the ureter travels a significant distance through the retroperitoneum, there is variance in the management of injuries at different locations, and surgeons must understand the diverse reconstructive techniques.

This chapter reviews the surgical anatomy of the upper and lower ureter, the etiology of ureteral injury, provides a framework for procedures to consider depending on the type and location of the ureteral pathology, and discusses preoperative and intraoperative considerations and the identification and management of intraoperative and postoperative complications. Complications arising from iatrogenic ureteral injury are additionally covered in detail in Chapter 14, while complications arising from traumatic injuries of the ureter are reviewed in Chapter 15. While it is not possible to detail all reconstructive surgeries, the tenets of successful ureteral surgery will be discussed with regard to the most commonly employed procedures. Robotic-assisted laparoscopic ureteral reconstructive procedures are detailed in Chapter 35. In the current era, each of the discussed procedures has been performed laparoscopically and robotically and considerations unique to these approaches will be noted.

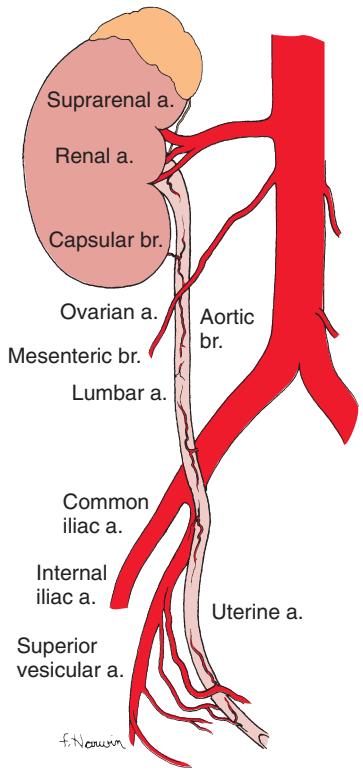

Figure 43.1 Blood supply of the ureter. Perforating arterial branches to the upper ureter emanate medial to the ureter, whereas those to the lower ureter emanate laterally. (From Smith RB, Skinner DG, eds. Complications of Urologic Disorders. Philadelphia: WB Saunders; 1976:131.)

Surgical Anatomy

The length of the ureter is typically 22–30 cm, with a normal luminal diameter of 1–3 mm, depending on its location[1,2] The three areas of physiologic narrowing are the ureteropelvic junction (UPJ), the crossing over of the bifurcation of the iliac arteries, and the ureterovesical junction (UVJ). Ureteral injuries can occur throughout the entire length of the ureter, though the proximal ureter may be more prone to severe injury or disruption since it has less muscular support and fewer mucosal cell layers than the distal or intramural ureter.

Starting from the kidney, the ureter lies posterior to the hilar vessels. As it travels caudally, the ureter courses posterior to the gonadal vessels and anterior to the iliopsoas muscle, then crosses the bifurcation of the common iliac artery as it enters into the pelvis. The pelvic ureter comprises the distal one-third of the ureter. Here the peritoneum is adherent to the ureter anteriorly. In males, the vas deferens loops anterior to the ureter, prior to the ureter entering the bladder. In females, the ureter courses posterior to the uterine arteries found in the broad ligament, running approximately 2 cm lateral to the uterocervical junction and then closely approximates the vagina prior to reaching the intramural bladder.

Ureteric arteries and arterioles travel longitudinally in the adventitia of the ureter. The blood supply to the proximal and midureter branches medially from the renal, aortic, gonadal, and lumbar arteries, while the pelvic ureter is perfused by branches laterally from the iliac artery and its branches (vesical, uterine, hemorrhoidal arteries) (Fig. 43.1).

Etiology and Epidemiology of Ureteral Injury

Understanding the mechanism of injury and patient factors is critical to conceiving a successful surgical approach. Ureteral injury or obstruction may result from urothelial cell cancer, nephrolithiasis, retroperitoneal fibrosis, radiation, infection (tuberculosis, schistosomiasis), blunt or penetrating trauma, or iatrogenic causes. Ureteral trauma is discussed elsewhere in this text. Strictures from urothelial cell cancer are typically managed by excision of the entire ureter and renal unit, and reconstructive procedures (most commonly partial ureterectomy with primary ureteroureterostomy or reimplant) are limited to low-grade distal ureteral lesions. Wolf et al. defined a stricture as ischemic when it follows surgery (e.g., hysterectomy) or radiation therapy, whereas the stricture is considered nonischemic if it is secondary to stone passage or a congenital abnormality. Ischemic strictures tend to be associated with fibrosis and scar formation and thus are less likely to respond to endourologic interventions.[3] Long strictures may result from conditions such as tuberculosis, schistosomiasis, amyloidosis, malakoplakia, and leukoplakia,[4] making a thorough patient history and physical important to diagnosis and management.

Iatrogenic injury to the ureter has become more common with the increase in endourologic procedures and laparoscopic surgery. Contemporary expert series of ureteroscopic complications estimate a perforation rate of 1–5%[5] of

which 0.2% require open surgery, and an incidence of delayed stricture of up to 5%.[5,6] Ureteroscopic surgery is performed at such high frequency that it is currently the most common cause of iatrogenic ureteral stricture.

Ureteral injury, and its management, is discussed in detail in Chapter 14. The incidence of ureteral injury in contemporary series with colorectal or gynecologic surgery has been reported as between 0.1% and 7.6%, with over 80% of injuries being unrecognized at the time of procedure.[7] A Cochrane review found patients were nearly 2.5 times as likely to experience a ureteral or bladder injury with a laparoscopic hysterectomy compared to an open procedure.[8] With the da Vinci robotic surgical system (Intuitive Surgical, Sunnyvale, CA), ureteral injury has been found to occur in 1.7% of hysterectomy cases.[9] During hysterectomy, the ureter is most commonly injured during the ligation and transection of the uterine artery. Entrapment of the ureter may also occur with closure of the vaginal cuff.

Iatrogenic ureteral injury can result from electrocoagulation or ultrasonic instruments, staples, loop sutures, or trocars. When called into an operating room to assist in assessment for injury, it is important for the urologist to understand the mechanism and energy source of the injury. Loop sutures can often simply be cut or removed, whereas complete or partial transection from a thermal device will require more involved surgical management. Thermal damage may result from the steam generated from the application of electrical current, or from inadvertent contact with the ureter by a "hot" instrument. The injury effect may take days to develop, and thus recognition is typically delayed.

Intraoperative cystoscopy is useful to detect ureteral injuries such as entrapment and transection and facilitates immediate correction and potentiates avoidance of late morbidity. Gilmour found intraoperative cystoscopy identified about 90% of unrecognized ureteral injuries during gynecologic surgery, 69% of which were easily managed, most by simply removing a suture.[10] Methylene blue or 10% sodium fluorescein dye can be given to aid in cystoscopic evaluation of ureteral efflux, and retrograde pyelography or ureteroscopy can be confirmatory when there is concern for injury. Intraoperative cystoscopy may not be useful for detection of thermal damage or ischemia secondary to their typically delayed presentation.

Diagnosis and Preoperative Planning

The time to recognition of ureteral injury or stricture is variable and dependent upon the type and severity of the injury, ranging from days to weeks.[11] Patients with ureteral transections resulting in urine extravasation may present with a urinoma in the immediate days after surgery and can experience ileus secondary to chemical peritonitis. Ureteral entrapment may be asymptomatic or patients may present within 1 week with flank pain or possibly with fever due to pyelonephritis. Thermal injuries result in delayed tissue necrosis and may be diagnosed as long as 3 weeks after surgery. Ureteral strictures can take months to develop and thus may result in minimal symptoms or even cause asymptomatic "silent obstruction."[12]

Once an injury is recognized, thorough evaluation and careful surgical planning are paramount to successful repair. In most cases retrograde urography and attempted stent placement, utilizing ureteroscopy when needed, serve as first-line therapy. They provide understanding of the extent and level of the injury and aid in operative planning. When unable to place a retrograde stent, proceed with placement of a nephrostomy tube with antegrade urography and consider an immediate or delayed attempt at antegrade stent placement. External drains should be placed for fluid collection when a patient is symptomatic or when an infected urinoma is suspected. When injury presents in an otherwise stable patient within less than 1 week from the injury, immediate repair should be considered. If the patient is unstable, has evidence of infection, or if it has been greater than 1 week since the injury, delay of repair for 6 weeks is recommended to allow time for resolution of inflammation.

The function of each kidney and the anatomy of both ureters should be evaluated preoperatively. Preoperative nuclear renography assesses the relative function in the ipsilateral renal unit. If the relative function is less than 15% and the insult has been chronic, and/or the repair risks the contralateral renal unit, then nephrectomy should be considered. Patients undergoing ureteral reconstruction may have residual hydronephrosis and reflux after surgery, and having a preoperative renogram provides a functional baseline for monitoring treatment success and the need for additional intervention when postoperative imaging is equivocal. For proximal and midureteral strictures, ureteral anatomy is best defined with a combination of antegrade and retrograde contrast studies (Fig. 43.2). Chronic indwelling ureteral stents may cause artificial dilation of the obstructed ureteral segment. In our opinion, preoperative

Figure 43.2 Simultaneous antegrade and retrograde ureterography demonstrating a left midureteral injury from L4 to the pelvic brim with proximal hydroureteronephrosis. This injury resulted from emergent bowel surgery.

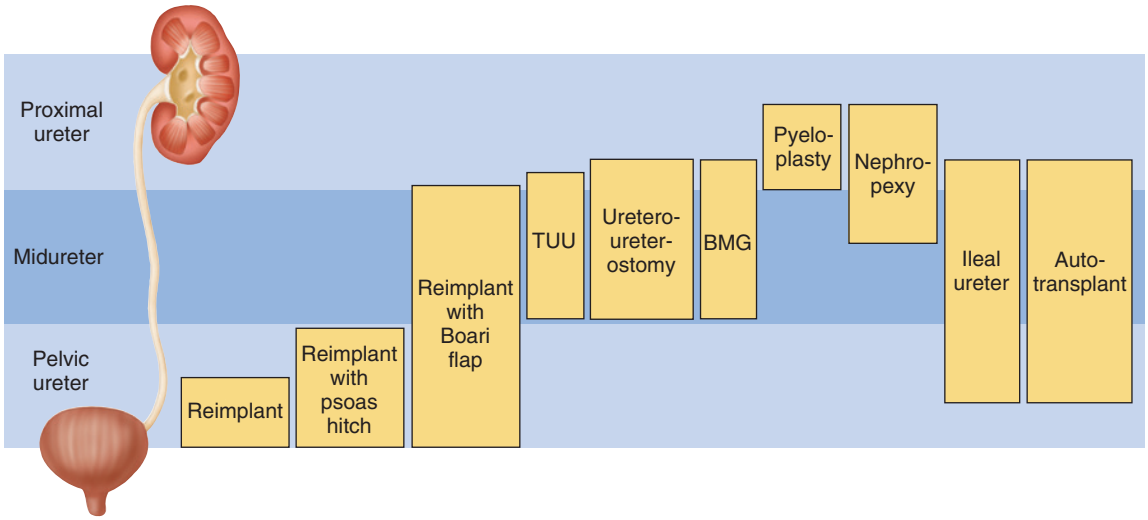

Figure 43.3 Options for surgical reconstruction of the ureter based upon the location of injury. TUU, transureteroureterostomy; BMG, buccal mucosa graft.

stent removal with nephrostomy tube substitution and repeat imaging after 1–2 weeks allow for resolution of artificial dilation and more accurate identification of stenotic segments. Since ureteral reimplant is most likely for pelvic ureteral injuries, antegrade ureterography or the delayed urography phase of a computed tomography (CT) scan provides sufficient information. Bladder capacity should be determined preoperatively if considering a bladder flap procedure, with alternative procedures considered for low-capacity bladders.

General Surgical Considerations

The surgical approach varies based upon location, mechanism of injury, medical history, and other patient factors. Fig. 43.3 provides an overview of options for surgical reconstruction on the ureter based upon the location of injury. Thoughtful planning of patient positioning, incision type, and wide draping for open procedures permits exposure to the entire ureter and renal unit if necessary. For laparoscopic and robotic procedures, a common pitfall is placement of the ports such that proximal dissection is limited. This can be an issue when unanticipated renal mobilization with nephropexy is needed, or when viable ureter is found to be more proximal than anticipated. Contraindications to elective ureteral reconstructive surgery include an untreated urinary tract infection or a bleeding diastasis.

The first intraoperative consideration when repairing the ureter is locating the area of ureteral injury. Urinary leakage and fibrosis can result in loss of normal tissue planes and medialization of the ureter. Generally, it is preferable to locate the ureter distally or proximally to the injury in an area with normal tissue planes, encircle it, and follow the ureter to the area of injury. If a nephrostomy tube is in place, antegrade fluid injection can aid in identification. The next important consideration is the mechanism of injury. For example, the majority of gynecologic injuries occur to the distal ureter. In such cases we identify the ureter entering the pelvis when traveling anterior to the common iliac vessels. The injury will almost always be distal to this location. In all cases, known landmarks should be utilized for ureteral identification.

Excessive mobilization or mishandling of the ureter can result in ischemia and necrosis or ureteral stricture. When reconstructing devitalized ureter, it is critical to only include viable ureter in the anastomosis. Devitalized ureter can be identified by pallor, friability, thick periureteral scarring, and lack of bleeding from the cut edges. Box 43.1 lists the tenets of successful ureteral reconstructive surgery that apply to all procedures detailed in this chapter, regardless of approach.

Box 43.1 Tenets of Ureteral Reconstructive Surgery

- Preserve the native ureteral blood supply (adventitia) by careful mobilization.
- Debride edges of injured ureter until bleeding noted; do not compromise, and be prepared to perform any number of reconstructive procedures.
- Spatulate the ureteral edges to achieve a widely patent anastomosis.
- Mucosa-to-mucosa apposition is critical for optimal healing and reducing the risk of urine leak.
- The anastomosis should be tension free, water tight, and performed over a ureteral stent. Avoid ureteral torsion with the anastomosis or ureteral kinking from other structures.
- Use only absorbable suture within the urinary tract to avoid risk of calcification seen with permanent suture.
- Isolate the repair from processes of infection or fibrosis with (omental) tissue flaps.
- Place an external drain at the operative site to monitor and control any potential urine leak.

Surgical Management

URETEROURETEROSTOMY

Ureteroureterostomy (UU) is utilized for short upper and midureteral defects that are 2–3 cm long or shorter

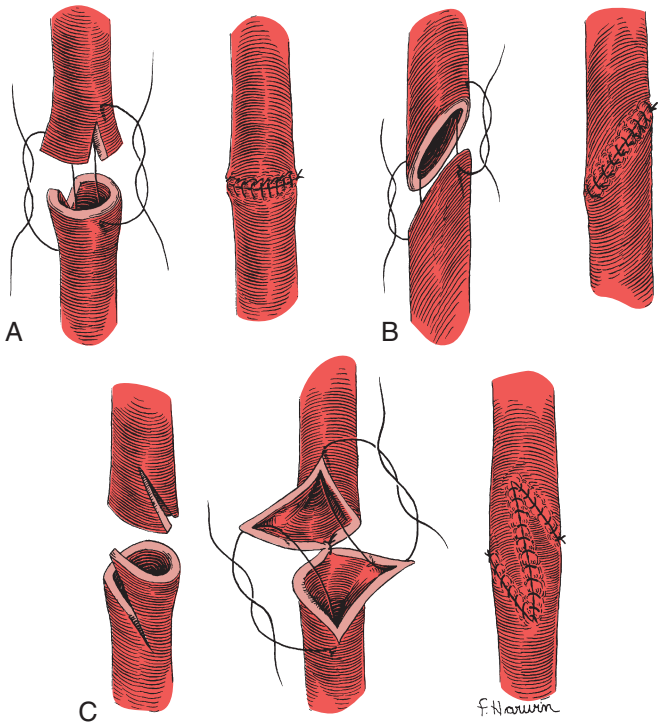

Figure 43.4 Ureteroureterostomy: techniques to maximize luminal diameter. A, Spatulation of ureteral margins. B, Oblique anastomosis. C, Z-plasty technique. (From Smith RB, Skinner DG, eds. Complications of Urologic Disorders. Philadelphia: WB Saunders; 1976:137.)

strictures that have failed endoscopic intervention. It is critical to have a tension-free repair with UU to avoid stricture formation. The determination of whether the ureter can be sufficiently mobilized after excision of the diseased portion to perform a tension-free UU cannot be made until the time of surgery. Concomitant renal mobilization with nephropexy can help reduce anastomotic tension. The location of the stricture will guide the surgical skin incision or port site placement for laparoscopic procedures, bearing in mind that the ureter will need to be mobilized both proximally and distally. After debridement of nonviable tissue, each ureteral segment is spatulated for approximately 5 mm, at 180 degrees apart. Fig. 43.4 demonstrates anastomotic techniques to maximize luminal diameter. Success rates greater than 90% are reported for open surgery[13,14] Lee et al. reported success in 11 of 12 patients undergoing robotic UU with concurrent nephropexy at a mean of 10 months' follow-up for a mean stricture length of 2 cm.[15]

URETERONEOCYSTOSTOMY (URETERAL REIMPLANT)

Ureteroneocystostomy indications include vesicoureteral reflux, distal ureteral obstruction, and transection involving the distal 3–4 cm of the ureter. Both refluxing and nonrefluxing methods exist and extravesical and intravesical surgical approaches have been defined. In a retrospective review of adults undergoing reimplant, no significant difference in preservation of renal function or subsequent stenosis was identified between refluxing and nonrefluxing techniques.[16] The efficacy of laparoscopic and robotic reimplant is well established[17] and has been associated with reduced blood loss and hospital stay.[18] Due to the common adoption of robot-assisted prostatectomy, many urologists are comfortable performing this procedure robotically given the similar setup and familiar pelvic anatomy. Compared to prostatectomy, robotic ports are typically shifted slightly cephalad.

VESICOPSOAS HITCH (PSOAS HITCH)

The psoas hitch procedure involves mobilizing the urinary bladder toward the ipsilateral ureter and securing the bladder to the ipsilateral psoas tendon, with a goal of shortening the needed ureteral length and reducing tension on the ureterovesical anastomosis. The technique is most commonly used for reimplantation after injury or excision of the distal one-third of the ureter and can be used to bridge defects of up to 6–8 cm. Psoas hitch may also be used in conjunction with other maneuvers, such as Boari bladder flap or renal mobilization, when the viable ureter is more proximal. Relative contraindications to psoas hitch include a fixed bladder secondary to a history of pelvic radiation, a contracted bladder, or untreated bladder outlet obstruction. Preoperative cystogram or cystometrogram may be helpful in determining bladder capacity.

Intraoperatively, the bladder is filled with approximately 200 mL of fluid. After bladder mobilization the surgeon should confirm the ability for the bladder dome to reach over the ipsilateral iliac vessels to the psoas muscle. The contralateral superior vesical artery may be sacrificed to aid in mobilization if necessary. An anterior cystotomy is then made, classically in the oblique direction. Alternatively, a transverse incision provides the flexibility of closing the bladder in a longitudinal (Heineke-Mikulicz) fashion to gain additional cephalad reach of the bladder. A traction suture on the distal ureter will help with ureteral delivery into the bladder with minimal manipulation to the ureteral tissue. The ureter should be delivered through a second incision at the superolateral aspect of the dome of the bladder and not to its orthotopic location to allow the straightest course for the ureter. The psoas hitch sutures are then placed and secured prior to completion of the anastomosis to reduce anastomotic tension. A minimum of two interrupted or figure-of-eight slowly absorbing sutures are placed into the bladder detrusor muscle and then superficially into the psoas muscle, including the psoas minor tendon when identified. All sutures should be placed before any are tied to reduce the risk of tearing the muscle or bladder when placing subsequent sutures. Over tightening of the hitch sutures can result in ischemia to the psoas muscle fibers.

The ureter is spatulated anteriorly, and the anastomosis is performed with interrupted 4-0 absorbable suture. The posterior ureter should be anchored with suture to the detrusor muscle. The remaining sutures should approximate bladder and ureteral mucosa and not include the detrusor muscle. Externally, the ureteral adventitia can be secured to the bladder wall with interrupted suture for additional reinforcement. The bladder is then closed in two layers to ensure watertight closure, and a Foley catheter is left in place for 7–10 days with a cystogram prior to removal.

Urinary extravasation is the most common complication and typically resolves with maximal urinary drainage and time. Injury to the femoral nerve or the genitofemoral nerve, though uncommon, can result from placement of the psoas hitch sutures. The femoral nerve runs deep within the psoas major muscle (PMM), emerging caudally to the typical location that a psoas hitch is anchored. However, on rare occasions, if the hitch sutures are placed too deep into the PMM, the nerve may become entrapped. Patients may present with leg weakness, gait difficulty, or complain of inability to climb stairs. On exam, reduced strength will be noted with hip flexion and knee extension. Additionally, decreased sensation of the anteromedial region of the thigh can be seen and the patellar reflex may be abnormal. If suspected, the diagnosis can be confirmed with neurology consultation and electromyogram. The genitofemoral nerve runs along the ventral aspect of the psoas muscle parallel to the ureter and is more commonly at risk for entrapment when placing hitch sutures. Symptoms of entrapment or destruction of this nerve are numbness to the ipsilateral anterior thigh and lateral scrotum in males, or mons pubis in females. In a small case series of femoral nerve injuries after psoas hitch, Kowalczyk et al. described eventual resolution of symptoms in patients in whom absorbable suture was used, but persistence of injury symptoms and the need to reoperate when nonabsorbable suture was used.[19] Physical therapy and early mobilization are beneficial when nerve injury is first suspected.

BOARI BLADDER FLAP

The Boari bladder flap (BBF) has been widely used for ureteral reconstruction for decades and is the next maneuver to consider when psoas hitch alone will not provide a tension-free anastomosis. BBF with psoas hitch can bridge a distance of 12–15 cm. The obvious advantage of this technique is that it does not endanger the contralateral renal unit or the intestinal tract, as do other reconstructive options. Also, its use is not limited by renal function, ileal disease, or recurrent stone disease. BBF is most commonly used for strictures involving the lower two-thirds of the ureter with success rates of 71–91%.[20,21] Morey et al. reported BBF success rates in 90% of 20 patients at 1 year in a series of both distal and proximal ureteral strictures, done in combination with nephropexy for proximal strictures.[22]

The bladder should first be mobilized and distended to identify the location and length of the bladder incision. Care must be taken to avoid injury to the ipsilateral middle and inferior vesical arteries that provide blood supply to the flap. To avoid ischemia the minimum width of the base of the flap should be 4 cm, with a goal of a 3:1 ratio of flap length-to-base width (Fig. 43.5). A rough measurement of the ureteral defect should be taken after debridement of nonviable tissue with subsequent marking of this distance on the bladder prior to incision. A U-incision is typically made but an L-incision allows a spiral flap when needed for longer defects. A psoas hitch at the base and the cephalad end of the Boari tube helps to stabilize the anastomosis.

The ureteral anastomosis can be executed as an end-to-end anastomosis to the tubularized flap, or by tunneling the implant into the posterior aspect of the flap, approximately 1 cm distal to the apex, prior to tubularization. While there is no evidence to support improved outcomes with a nonrefluxing anastomosis, this option avoids the intersection of the bladder closure suture line with the anastomosis and may reduce the risk of urinary extravasation. Two-layer closure of the tubularized flap is recommended and the previously mobilized peritoneum can be used to cover the anastomosis.

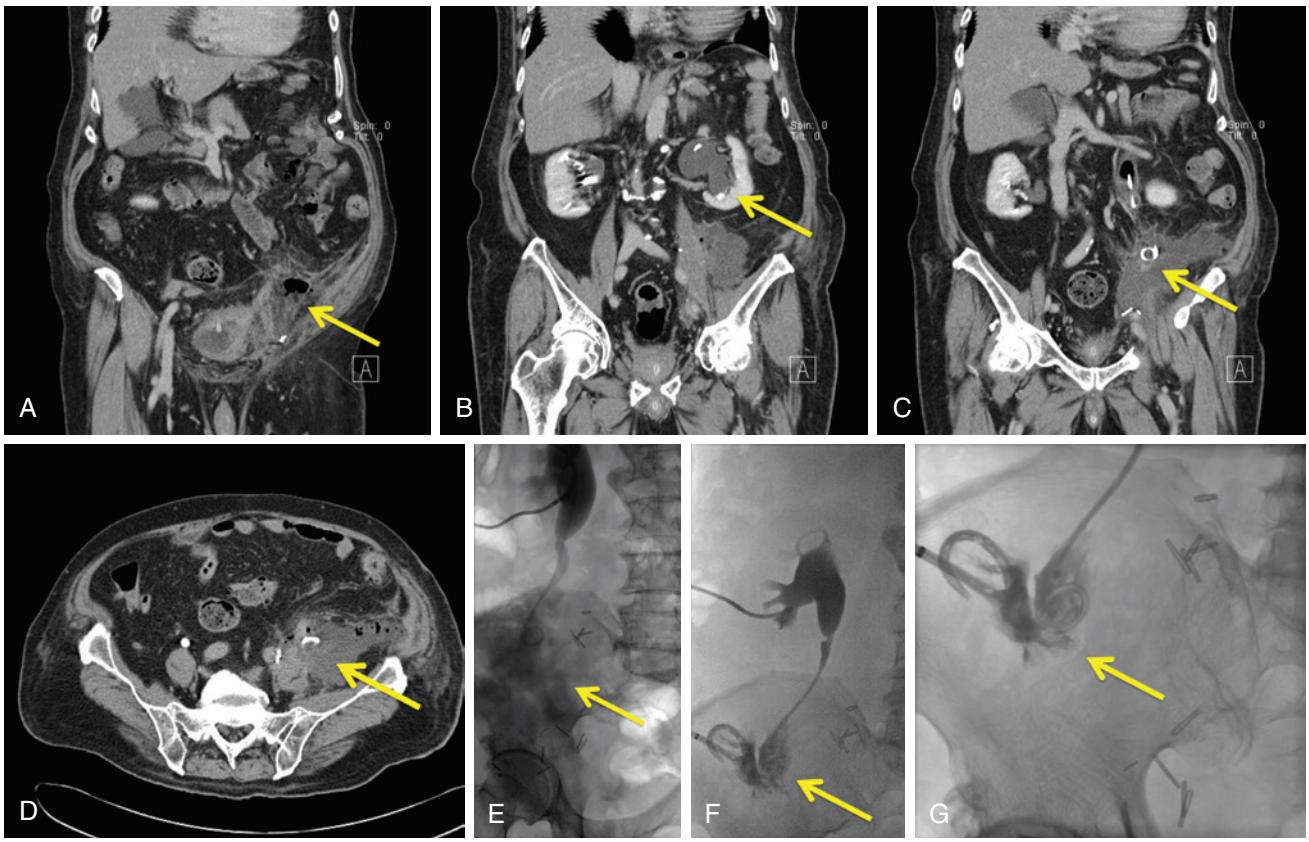

Figure 43.6 A 78-year-old male underwent a distal ureteral resection for a urothelial cancer isolated to the distal ureter. He presented with fever and worsening left lower quadrant discomfort 10 days postoperatively. He is noted to have leukocytosis and tenderness over the left lower quadrant. A CT urogram is obtained demonstrating (A) inflammation with fluid air surrounding the Boari flap (yellow arrow), (B) proximal left hydronephrosis (yellow arrow), and (C and D) the distal "j" of the ureteral stent in a large urinoma (yellow arrows). A left nephrostomy is placed, and antegrade nephrostogram (E) demonstrates free extravasation of contrast in the pelvis (yellow arrow). A percutaneous drain is placed in the urinoma (F and G) demonstrating the pigtail and distal stent to reside in the same cavity, without communication to the bladder flap (yellow arrows). (Courtesy of Samir Taneja, MD.)

Minimally invasive laparoscopic or robot-assisted techniques for BBF in the treatment of the middle and distal ureter have been reported with good results,[23,24] noting decreased blood loss and hospital stay[18] compared to open reconstruction. Such techniques are technically challenging for proximal or long ureteral strictures that require both the bladder and the kidney to be mobilized, but hybrid techniques such as laparoscopic mobilization of the kidney with open BBF and ureteral reimplant are available options. The da Vinci Xi system (Intuitive Surgical, Sunnyvale, CA) provides multi-quadrant access ability without the need for re-docking of the robot and may permit access to a greater span of the ureter compared to previous robotic systems.

Complications of BBF include bladder pedicle ischemia with resultant necrosis, stenosis of the bladder tube (flap), postoperative bowel obstruction, and urinary extravasation (Fig. 43.6). The incidence of complications is difficult to estimate, as contemporary series each include less than 20 patients[18,22–24] and list rates ranging from 8% to 25%. Injury to the contralateral ureter must be avoided during bladder mobilization or bladder defect closure. De novo irritative voiding complaints related to change in bladder capacity and configuration are reportedly rare and readily managed with anticholinergics,[22] but studies including postoperative urodyamic assessment are lacking.

RENAL DESCENSUS (NEPHROPEXY)

Renal descensus, or nephropexy, is employed as an adjunct to other procedures, namely to UU and BBF to eliminate anastomotic tension.[22] Nephropexy is commonly utilized with UU to bridge distances of 3–4 cm, though up to 8–10 cm of length can be obtained by completely mobilizing the kidney and affixing it to the iliac fossa. Caudal mobilization is limited by the anatomy of the renal vein, and thus greater mobilization is possible on the left. Mobilization includes dissection of the proximal ureter from its paraureteral tissue including perforating blood vessels. Sparing the perinephric and perihilar fat in the space formed by the upper ureter, renal artery, and the lower pole of the kidney typically ensures that the ureteral blood supply from the renal artery is maintained. Damage to this area, referred to as the "golden triangle" in transplant surgery,[25] leads to ischemia and may explain why 70% of transplant ureteral strictures occur in the distal third of the ureter.[26]

BUCCAL MUCOSAL GRAFT FOR URETEROPLASTY

Buccal mucosa is an excellent free graft due to a thin lamina propria with an abundant capillary network and

is commonly used by urologists in urethral reconstruction with excellent established long-term outcomes. The graft is harvested from the inner cheek or the inner lip, and graft lengths of 6 cm can be obtained. Buccal mucosal grafts (BMGs) for the repair of ureteral strictures have been described in several case series. This technique has utility for situations when an ileal ureter or autotransplant would otherwise be employed, namely for long proximal ureteral strictures. Several variants have been described, including dorsal or ventral onlay grafting and interposition of a tubularized segment with end-to-end anastomosis.

Unlike a flap, a graft is transposed onto new tissue without its native blood supply. Complications unique to a graft therefore relate to the ability to "take," or establish a new blood supply from surrounding tissues. Judicious debridement of the injured and ischemic tissue along with thinning or "defatting" the graft will increase the ability of the graft to take. An omental wrap is recommended to augment the vascularity and reduce the risk of ischemic complications such as stricture and dehiscence.[27] Graft contraction can occur, so it is recommended to make the graft size generous compared to the defect and then trim the graft as needed at the time of placement.

Another unique concern with this procedure comprises the complications and perioperative management related to the harvesting of the BMG. Care must be taken to avoid Stensen's duct (from the parotid gland) or harvesting tissue too close to the exterior lip as this can result in mouth contracture. BMG harvesting should be performed by urologists with experience in urethroplasty or by a maxillofacial surgeon. Morbidity in BMG harvest is minimal, with a complication rate reported at 3–4%.[28] The most common complications include donor site pain, scarring, perioral sensory defect, and jaw opening impairment.[29,30] Perioral numbness at 6 months has been reported in up to 26% of patients.[30]

TRANSURETEROURETEROSTOMY

Transureteroureterostomy (TUU) is a proven means to manage long-segment distal and midureteral disease or injury when reimplantation is not possible. TUU should be considered when psoas hitch with BBF is not an option due to an immobile bladder or the presence of a hostile pelvis. TUU requires a sufficient length of viable ureter to reach the contralateral ureter. As always, the surgeon and patient should be prepared for alternative (and more involved) interventions should the pathology extend more proximally than anticipated.

The inherent risk with TUU is exposure of both renal units if an anastomotic complication occurs or if obstruction occurs distally in the recipient ureter. For this reason, TUU is absolutely contraindicated in the presence of transitional cell carcinoma of the ureter or renal pelvis and in patients with recurrent urolithiasis, and should be avoided in those with a history of genitourinary tuberculosis, reflux or obstruction of the recipient ureter, severe chronic renal insufficiency, or recurrent pyelonephritis of either renal unit. The surgeon should be aware of ureteral duplication or other anomalies that may affect the approach.

The donor ureter should be sufficiently mobilized without compromising blood supply. A retroperitoneal tunnel is made to pass the injured (donor) ureter to the contralateral side. En bloc transfer of the ipsilateral gonadal vessel may improve the blood supply to the transposed ureter. It is important for the donor ureter to course gradually downward toward the recipient ureter to permit dependent drainage and when possible travel above the level of the inferior mesenteric artery to avoid impingement between the aorta and the inferior mesenteric artery. Such impingement can result in fibrosis and stricture and have a delayed presentation of obstruction as many as 2–4 years after surgery.[31,32] Mobilization of the recipient ureter site should be minimized to reduce trauma and preserve blood supply. A 1.5-cm ureterotomy is made on the recipient ureter and the donor ureter is spatulated 1.5–2 cm. The end-to-side anastomosis should be without tension, watertight, and should not cause torsion or angulation of the recipient ureter. The requisite urinary stent should travel from the bladder to the donor ureter so as to bridge the anastomosis. Alternatively, two smaller caliber stents (4.8Fr) can be placed up each proximal ureter and down the common ureter into the bladder. A postoperative KUB can confirm stent position.

Complications range from 6% to 25% in contemporary studies of open TUU.[32,33] Noble et al. reviewed 253 procedures performed at their institution for both benign and malignant diseases that affected the distal ureter. Transient leak occurred in 16 (6%) patients and there was a complication of the common ureter distal to the TUU in five patients.[34] Long-term follow-up of both renal units is mandatory given delayed presentation of stricture, and particularly if there is a possibility of the common ureter being affected by the process that caused initial insult (radiation fibrosis, pelvic malignancy, etc.).

INTESTINAL INTERPOSITION (ILEAL URETER)

Intestinal interposition is a proven technique for repair of extensive ureteral injuries when other reconstructive techniques are unable to be utilized for repair or in the case of salvage procedures after previous ureteral surgery. It may be favorable in cases of radiation-induced ureteral stricture disease since the vascular supply to the bowel tends to be preserved. While both colon and appendix have been utilized, ileum is the most common intestinal interposition. Historically the ileal ureter was utilized as a "stone chute" for recurrent stone formers. With advancements in endourology this is no longer a primary indication, but it does make ileal ureter a favorable choice in patients with a need for ureteral reconstruction and a history of nephrolithiasis.[35] The ileum can be configured in a "figure of seven" or "reverse 7" orientation for bilateral ureteral disease, or the appendix can be used as a substitution for the right ureter with use of the ileum on the left. Ileal ureter should be avoided in individuals with renal insufficiency and a serum creatinine >2 mg/dL due to the metabolic derangements that can result from urine resorption.[36,37] It is also contraindicated in patients with Crohn's disease, radiation enteritis, or intestinal absorptive disorders. Bladder emptying should be adequate to avoid bladder obstruction from mucus build up. Complete intracorporeal ileal ureter has been demonstrated laparoscopically[38] and robotically.[39]

Intraoperatively it is important to measure the length of diseased segment that will be replaced. The goal is to have a tension-free repair, with a straight ureter. Redundant

ureter can cause kinking and obstruction, leading to dilation and increased urinary resorption. It is ideal to minimize the length of ileum that is used because the bowel retains its absorptive properties. Thus, consider performing the procedure in conjunction with a Boari bladder flap and psoas hitch to shorten the segment of bowel that is required. It is advised to harvest a slightly more generous length than needed and subsequently trim the tissue rather than harvest too short of a length of bowel and be faced with an anastomosis under tension or the need to harvest a second segment. The terminal ileum should not be utilized as its exclusion from the gasterointestinal tract can result in B_{12} deficiency and malabsorption of bile salts. The bowel segment should be flushed to clear excess mucus and be connected in an isoperistaltic direction. Failure to do so could result in urinary stasis, ureteral dilation, and exacerbation of urinary reabsorption. The ileal ureter should be posterior to the bowel anastomosis, and on the left should pass through a defect in the mesentery into the retroperitoneum that is large enough (about 5 cm) to avoid ischemia to the mesentery of the ileal ureter. If viable ureter is present proximally and the patient is not a stone former, the ureter can be anastomosed to the ileal segment in an end-to-side fashion. Otherwise, the ileum is sewn directly to the renal pelvis. The distal anastomosis can be freely refluxing, as this has not been associated with renal deterioration.[36]

Success rates are reported at 81–100%.[36,37,40] Thirty-day minor complications (Clavien grade I–II) have been reported in upward of 40% of patients.[35] Notable long-term complications reported by Armatys et al. in 99 renal units[35] included a 3% anastomotic stricture rate and a 6% fistula rate. A history of radiation was cited as a risk factor for complication. Bowel obstruction is a complication more common to this procedure compared to other options for ureteral reconstruction and must be managed expectantly. Resorption of urine by the ileal segment can lead to a chronic worsening of renal function and hyperchloremic metabolic acidosis.[35] In two retrospective analyses patients did not experience worsening renal function after ileal ureter, and a third demonstrated serum creatinine decreased or remained stable in 75% of cases.[35,36,41] Long-term follow-up in these patients should include annual ultrasound, metabolic panel, and a B_{12} level. Patients presenting with recurrent pyelonephritis or worsening renal function after ileal ureter should be assessed for urinary retention or high pressure voiding and managed as needed.

AUTOTRANSPLANT

Renal autotransplant should be considered as one of the last options before nephrectomy for patients that have profound ureteral loss, have a solitary kidney or severe renal insufficiency, or have failed other attempts at repair. Indications are similar to ileal ureter; however, decreased renal function and history of inflammatory bowel disease are not a contraindication as with ileal ureter. Preoperative renal angiography (CT angiography) is necessary to delineate the vascular anatomy. Iliac artery angiography should be considered in patients with severe vascular disease to rule out significant atherosclerosis of the recipient vessel. Similarly, iliac venography is recommended to rule out venous obstruction in patients with longstanding retroperitoneal fibrosis or radiation. The nephrectomy is commonly performed laparoscopically[42] and the remainder of the procedure is carried out in an open fashion according to the standard concepts of renal transplantation, typically with the aid of a transplant surgeon. If the proximal ureter is short a BBF with pyelovesicostomy can be performed. During nephrectomy, effort must be made to provide as great a length of vein and artery as possible to improve the ease of implantation.

Early postoperative complications include bleeding from the vascular anastomosis, renal artery or vein thrombosis, distal extremity embolization, or urinary extravasation. Renal artery or vein thrombosis may result from hypotension in the postoperative period and should be ruled out in cases of oliguria following autotransplantation of a solitary kidney. The diagnosis is made with duplex renal ultrasound, and, if confirmed, immediate salvage surgery should be considered. Urinary extravasation is the most common complication from autotransplantation though placement of a double-J stent at the time of surgery diminishes this risk. The most common late complications include renal artery stenosis, ureteral stricture, and ureterovesical reflux. Renal artery stenosis may be manifested by hypertension or impaired renal function. Diagnosis is made by renal scan and CT or traditional angiography. Ureteral stricture can be managed as discussed elsewhere in this chapter. Long term, approximately 10% of renal units will be lost following autotransplantation.[43,44]

URETEROENTERIC ANASTOMOTIC STRICTURE

Benign ureteroenteric anastomotic stricture occurs in 3–14% of patients and more commonly involves the left ureter.[45–47] The etiology is typically ischemia and may be related to over mobilization or skeletonization of the ureter. Angulation of the left ureter under the superior mesenteric artery may also contribute. Several studies have failed to demonstrate a significantly different rate of stricture between Bricker and Wallace anastomosis types,[46,48] though nonrefluxing anastomoses likely have a higher rate of obstruction.[49] The typical presentation can include flank pain, infection, decreased renal function, and hydronephrosis, and confirmation of obstruction is made with nuclear renography, or lack of ureteral reflux on loopography. Stricture may present within months of surgery but occurrence at up to 6 years has been described.[50] Endourologic attempts at stricture management are best approached antegrade with intestinal diversions, partly due to the technical challenges of a retrograde approach. Success rates of balloon dilation are estimated at 30% or less.[51,52] Endoscopic incision has better outcomes, approaching 50–80%, though success rates are poorer on the left side.[47] Particularly on the left, one must be cautious with full-thickness endoureterotomy as the pathway of the ureter may abut the sigmoid mesentery or the iliac vessels. Given these concerns, open or robotic[53] repair of left ureteral stricture repair can be considered as an initial approach. It is critical to be familiar with the anatomy of the urinary diversion to avoid damage to the vascular pedicle or contralateral ureter. The same tenets of ureteral surgery apply to this procedure, including a tension-free, watertight anastomosis with internal stenting and external drainage. If the viable ureteral

length is insufficient an additional segment of bowel may be required as an interposition. Success rates of up to 80% have been reported with open repair, citing strictures longer than 1 cm and left-sided strictures as risks for failed repair.[47]

TRANSPLANT ANASTOMOTIC STRICTURE

Ureteral obstruction occurs in 2–10% of renal transplant patients postoperatively, may present within the first few weeks, and typically presents within the first year. Obstruction in the early postoperative period is often transient and successfully managed with stenting alone, whereas obstruction occurring after 3 months typically requires surgical intervention to achieve resolution.[54] Similar early ureteral complication rates of 2.1% and 2.8% have been demonstrated with the extravesical Lich-Gregoir and the intravesical Politano-Leadbetter ureteral implant techniques.[25,55,56] Transplant ureters may at times be sewn to native ureters when ureteral length is inadequate. Initial management of transplant ureteral obstruction is to ensure adequate drainage of the renal unit with nephrostomy tube or indwelling ureteral stent. Endoscopic intervention with balloon dilation has success rates of approximately 50%, and rates are slightly higher with laser or electroincision of the stricture. If initial endoscopic intervention fails, the success rate of a repeat endoscopic procedure is closer to 25%.[57] Understanding the transplant anatomy and abiding by the tenets of ureteral reconstructive surgery should guide the surgeon toward successful reintervention. Complications are similar to those with autotransplant albeit the patient is immunosuppressed and is completely reliant on the transplanted kidney.

URETEROLYSIS

Ureterolysis consists of removing fibrous tissue off the length of the ureter that has resulted from retroperitoneal fibrosis. Such fibrosis occurs for various reasons, most commonly idiopathic, and causes scar tissue formation along the aorta and iliac arteries that eventually grows around the ureter resulting in medialization and obstruction. On imaging the ureter may not appear dilated due to encasement, but hydronephrosis is typically present and the obstruction is confirmed with diuretic renogram. The process may be unilateral or bilateral. Along with ureterolysis, mobilization of the abdominal and pelvic ureter away from the inflammatory process with lateralization or intraperitoneal transposition and preferably with an omental wrap is recommended to prevent recurrence or progression. Omental wrap also increases blood flow to the ureter. Ureterolysis may be done in an open or laparoscopic (robotic) fashion. Success rates approximating 83–92% are reported,[58–60] with laparoscopic ureterolysis providing similar outcomes and shorter convalescence compared to open surgery.[59] A ureteral stent should be placed preoperatively to aid in ureteral identification and remain for 2–4 weeks. With complete mobilization, the ureter is dependent on its proximal and distal blood supply, and thus is at risk for ischemic stricture, particularly if injury to the adventitia of the ureter is made during the often challenging dissection. A clean plane of dissection of the fibrous tissue from the ureter will decrease the recurrence of obstruction. Ureterotomy is a common complication (11%) that may be immediately identified and repaired.[61] Major complications such as injury to the iliac or great vessels can occur. Omental wrap of the ureter has been suggested to increase the rate of late intestinal obstruction in open ureterolysis,[62] though contemporary laparoscopic studies have not described this complication.[59,61] When dissection proves challenging, or a section of the ureter has been obliterated, ureterolysis may be combined with Boari flap, nephropexy, ileal ureter, or autotransplantation.

POSTOPERATIVE STENTING AND DRAINAGE

Generally, placement of an indwelling ureteral stent for all surgical procedures involving a ureteral anastomosis or extensive mobilization of the ureter is recommended. For ureteroneocystostomy and ureteropelvic junction repairs, it is helpful to place a longer stent than necessary to keep the stent coil away from the anastomosis while suturing. Stent migration can occur in a dilated ureter or with excessive manipulation of the repair and is typically confirmed by imaging when patients become symptomatic. Nephrostomy tube placement can be considered if migration occurs early in the postoperative period, to avoid risking injury to the ureteral anastomosis with retrograde stent manipulation. Indwelling stent duration for most ureteral surgery is 4–6 weeks. Suppressive antibiotics for indwelling ureteral stents are not routinely recommended, but one can consider oral antibiotic prophylaxis before stent removal to reduce the risk of bacteremia.

Nephrostomy tubes are often in place at the time of surgery. The decision to remove a nephrostomy tube at the time of surgery is surgeon preference, but it may be preferable to maximally drain the renal unit until the success of the repair can be determined. The nephrostomy tube may be removed after a "capping" trial without significant pain or leakage around the tube, or after nephrostogram to confirm antegrade drainage. Removal under radiologic guidance is recommended when an indwelling stent is in place, to ensure that the indwelling ureteral stent is not displaced into the nephrostomy tract, as this could result in urine leak and fistula formation.

External drains are a useful adjunct in ureteral reconstructive surgery procedures and serve to monitor and control potential urine leaks. Drains should be placed in a dependent area and not directly over the site of an anastomosis, as this may exacerbate a urinary leak. Leakage should be suspected with persistently high outputs and can be confirmed by checking fluid creatinine levels. If a leak is detected, maximal drainage should be continued, including bladder drainage. In the era of minimally invasive surgery drains are often removed prior to hospital discharge on postoperative day number 1 or 2, before leakage from ischemic necrosis would typically present. Without drainage, leakage may result in urinoma, with some patients remaining asymptomatic while others present with flank pain or abdominal pain, fever, or ileus. When suspected, CT of the abdomen and pelvis with delayed phase (urogram) is the study of choice. Delayed images may reveal the presence and location of the urine leak. Prolonged maximal drainage of the urinary system will provide opportunity for resolution. CT or ultrasound-guided

percutaneous drainage of any urinoma may be appropriate, and mandatory if infection is suspected. When a suction drain is present and in proximity to the anastomosis, suction can be stopped to encourage urine to drain via the natural or reconstructed pathway. Prolonged urinary leakage from the anastomosis may require the placement of a nephrostomy tube for proximal urinary diversion.

A Foley catheter is typically left in place after ureteral repair and is mandatory after BBF. For surgeries not involving a cystotomy, the Foley is typically removed on postoperative day 1. The external drain should be monitored for an increase in output after Foley removal. If the increased drain output is confirmed to be urine, prolonged bladder drainage is needed. Similarly, if patients develop symptomatic flank pain after Foley removal, continued drainage is appropriate. A cystogram can be done prior to Foley removal to ensure healing for surgeries involving a cystotomy, particularly in patients with a history of radiation, diabetes, or immunosuppression.

GENERAL COMPLICATIONS AND MANAGEMENT

Urine Leakage

Urinary extravasation that is persistent from the time of surgery is likely due to a technical error and usually heals with prolonged drainage. For significant or persistent leaks, a nephrostomy tube may need to be placed in addition to internal ureteral stenting. With this combination the fistula will heal without stricture development or renal compromise in 63–95% of cases.[63–66] In contrast, leakage that begins several days after surgery may be attributed to ischemic necrosis. Drainage remains the mainstay of management though there is an increased risk of ischemic stricture formation and a higher likelihood that repeat surgical repair will be needed.

Ureteral Stricture

For most reconstructive ureteral surgery, diuretic renal scan can be performed at 3 months postoperatively to confirm patency of the repair. Recurrent obstruction is a long-term risk, and thus renal ultrasound is recommended every 6 months in the first 1–2 years after repair. Postoperative ureteral stricture formation is confirmed when urography, renal scan, or Whitaker testing confirms obstruction.

Endourologic interventions should be considered when possible following ureteral reconstructive surgery. These may include antegrade or retrograde balloon dilation, hot- or cold-knife incision, laser incision, or incision with an Acucise catheter system (Applied Medical Resources Corp., Laguna Hills, CA). Endoscopic success rates have been discussed previously in this chapter. Generally, endoscopic interventions are less likely to be successful for anastomotic strictures than for strictures secondary to stone disease or iatrogenic injury that occur in an intact ureter because anastomotic strictures are most commonly ischemic in nature. Balloon dilation and endopyelotomy rely on full-thickness fracturing or cutting of the urothelium and healing by secondary intention via re-epithelialization. This process requires an adequate blood supply. Whereas strictures in the native ureter benefit from a dual blood supply from the caudal and cephalad portions of the ureter, a ureter implanted into the anti-mesenteric aspect of a bowel segment, a recipient ureter, or bladder flap will have a tentative blood supply from the recipient structure, making healing by re-epithelialization after endoscopic intervention less likely.

Chapter 43 Questions

1. A 62-year-old woman develops a 3.0-cm benign ureteral stricture at the left ureteroileal anastomosis 7 months after a radical cystectomy and neobladder. The left renal function is 30%. The next step is:
   a. Endoscopic laser incision
   b. Endoscopic balloon dilation
   c. Metallic stent placement
   d. Open surgical repair
   e. Re-evaluation in 3 months

2. A 21-year-old man with a history of multiple ureteroscopic interventions for recurrent nephrolithiasis has left flank pain. He is afebrile, and serum creatinine (Cr) is 1.1 mg/dL. CT urogram is negative for stones but demonstrates left hydronephrosis and a 7-cm ureteral stricture from the left UPJ to the midureter. Lasix renal scan shows left renal function of 40% and T ½ of 40 minutes after diuretic administration. The next step is:
   a. Ileal ureter
   b. Transureteroureterostomy
   c. Nephrectomy
   d. Endopyelotomy
   e. Bucal mucosa graft

3. A 38-year-old woman underwent Boari bladder flap (BBF) with nephropexy for a chronically obstructed left kidney secondary to a 6-cm midureteral stricture that developed after left ovarian cyst excision 1 year previously. She subsequently developed nonresolving urinary leakage from the proximal portion of the BBF and she is currently managed with a left nephrostomy tube. Her serum Cr is 1.6 mg/dL, and the left kidney provides 55% function on functional renal scan. Her medical history is notable for Crohn's disease. The best option is:
   a. Ileal ureter
   b. Nephrectomy
   c. Renal autotransplantation
   d. Primary repair of the Boari flap
   e. Conversion to a double 'j' ureteral stent

4. A 54-year-old woman undergoes robotic Boari bladder flap with right ureteral reimplant for ureteral injury involving her entire right pelvic ureter. An indwelling ureteral stent was placed. Foley catheter is removed on postoperative day 1 and she subsequently develops urinary urgency and severe right flank pain. External drain output is low and consistent with serum Cr. The first step is:
   a. Nephrostomy tube
   b. Antibiotics
   c. Scheduled anticholinergic
   d. Replace Foley catheter
   e. Surgical laparotomy

5. A 34-year-old woman has left hydronephrosis on renal ultrasound 6 months after a robotic extravesical left ureteral reimplant. Serum Cr is 0.8 mg/dL. She has no flank pain and completely empties her bladder with voiding. The next step is:
   a. Cystoscopy with retrograde pyelography
   b. Diuretic nuclear renal scan
   c. Observation
   d. Voiding cystourethrogram (VCUG)
   e. Percuteanous nephrostomy tube placement

6. A 43-year-old woman undergoes a vesicopsoas hitch with right ureteral reimplant for a distal ureteral injury noted at the time of abdominal hysterectomy. Two 2-0 absorbable sutures are used to secure the detrusor muscle to the psoas major muscle. Postoperatively she notes right leg weakness and difficulty climbing stairs that is persistent at her 1-week follow-up. The next step is:
   a. MRI of the lumbar spine
   b. Antibiotics
   c. Referral to physical therapy
   d. Operative removal of the psoas hitch sutures
   e. Posterior tibial nerve stimulation

7. A 48-year-old woman undergoes abdominal radical hysterectomy. Routine cystoscopy by the gynecology service before conclusion of the case fails to identify left ureteral efflux, despite methylene blue administration. Exploration reveals ureteral entrapment from suture ligation of the left uterine artery. The best management is:
   a. Excision of distal ureter with reimplantation
   b. Excision of entrapped ureter with ureteroureterostomy
   c. Removal of suture
   d. Removal of suture with placement of indwelling ureteral stent
   e. Ureteral balloon dilation of the area of narrowing

8. A 36-year-old woman undergoes robotic-assisted hysterectomy. The surgeon identifies the distal left ureter is partially entrapped in a vessel sealing device while applying bipolar energy and stops applying the energy. Grossly the ureter appears to have sustained a 25% partial transection. The best management is:
   a. Robotic ureteral reimplant
   b. Primary closure of the ureteral laceration without narrowing the diameter
   c. Place a ureteral stent
   d. Observation with contrast imaging in 2 weeks
   e. Transureteroureterostomy

9. A 36-year-old female underwent laparoscopic hysterectomy for uterine fibroids. She developed left flank pain 3 days later and a nephrostomy tube was placed for confirmed distal ureteral injury. This was removed after 4 weeks. She now presents 1 month later with nausea, vomiting, and left flank pain. She is afebrile. CT urogram suggests a small distal ureteral leak and resultant 2-cm urinoma. What is the next step?
   a. Cystoscopy, retrograde pyelogram, and retrograde stent placement with Foley catheter
   b. Nephrostomy tube
   c. Placement of a nonsuction external drain

d. Ureteral reimplant
e. Antibiotics and re-evaluation in 2 weeks

10. Ureteral stents used during the management of idiopathic retroperitoneal fibrosis:
    a. Are removed immediately after ureterolysis
    b. Do not help identify the ureters during ureterolysis
    c. Are placed without difficulty most of the time
    d. All of the above
    e. None of the above

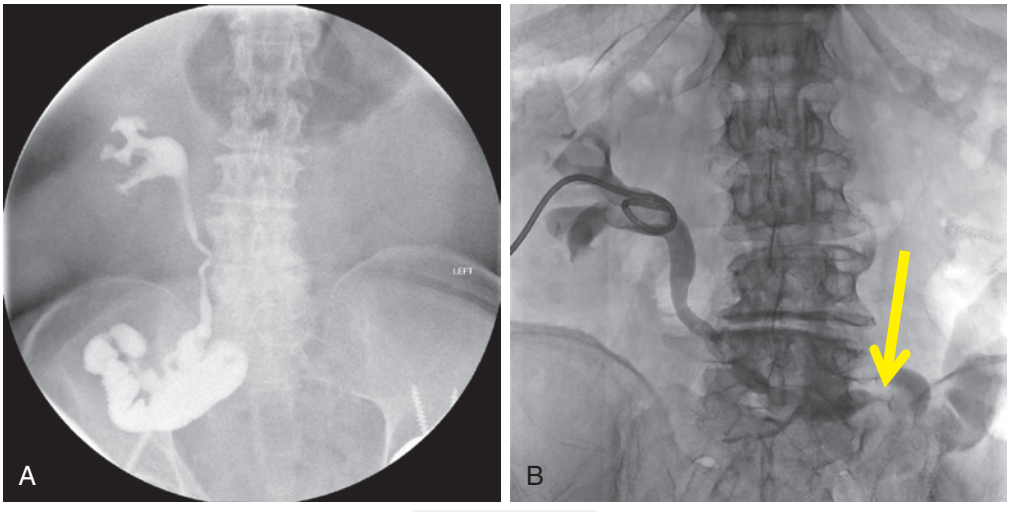
Case Study 1

A 78-year-old man with multiple comorbidities develops a 3.0-cm ureteral stricture at the left ureteroileal anastomosis 5 months after a radical cystectomy and ileal conduit were performed for muscle invasive bladder cancer. Bricker anastomoses were done. Ureteral margins were negative for carcinoma. Cr is 2.0 mg/dL and the left renal function is 45% with T ½ > 40 minutes on diuretic renogram.

1. What is the most likely etiology of his stricture?
    a. Ureteral cancer
    b. Ischemia from anastomotic tension or devascularization
    c. Use of a Bricker anastomosis instead of a Wallace style
    d. Poor renal function
    e. Suture ligation

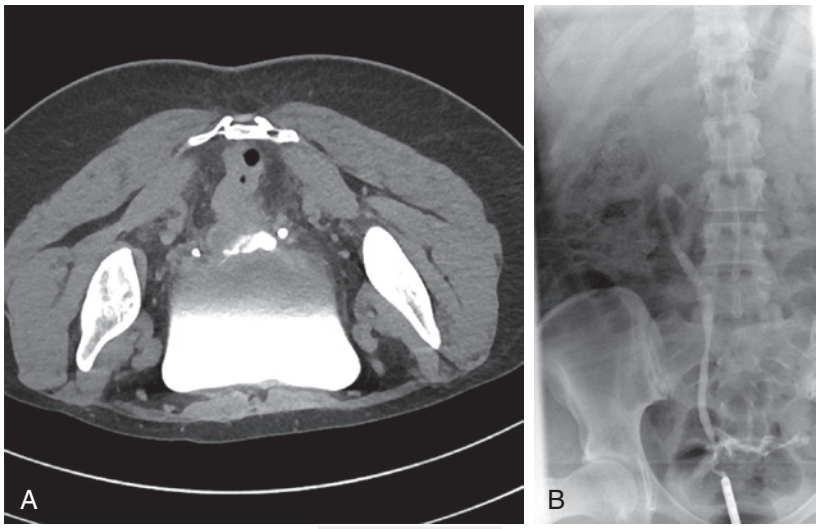
2. He has had two episodes of pyelonephritis and urosepsis in the past 2 months with ureteral stent in place, and thus a nephrostomy tube was placed. Loopogram and antegrade nephrostogram images (Case Fig. 43.1) are seen below. The best option is:
    a. Metallic stent placement
    b. Endoscopic balloon dilation
    c. Transureteroureterostomy
    d. Robotic ureteral reimplant into ileal conduit
    e. Total conduit revision

Case Study 2



A 35-year-old female underwent robotic hysterectomy for uterine fibroids. She presents 3 weeks later with abdominal pain, nausea, and vomiting. CT scan suggests a 2.0-cm fluid collection in the pelvis.

1. What is the next step?
    a. Delayed contrast imaging
    b. Interventional radiology guided drain placement
    c. Nephrostomy tube
    d. Consult gynecology
    e. Pre-emptive ureteral stent placement



2. Delayed contrast imaging is obtained and demonstrates urine leak (Case Fig. 43.2) from the distal right ureter. Retrograde stent placement is not successful so a nephrostomy tube is placed and symptoms resolve. She is planned for operative reconstruction 1 month later. What is the best procedure?
    a. Boari bladder flap with ureteral reimplant
    b. Primary ureteral repair (ureteroureterostomy)
    c. Psoas hitch with ureteral reimplant
    d. Antegrade stent placement and prolonged bladder drainage
    e. None of the above

A robotic extravesical ureteral reimplant with psoas hitch is performed. On postoperative day number 1, the patient notes numbness over the right anterior thigh and the right aspect of her mons pubis.

3. What is the probably etiology of her symptoms?
    a. Entrapment of the femoral nerve by psoas hitch suture
    b. Entrapment of the genitofemoral nerve by psoas hitch suture
    c. Lithotomy position
    d. Bladder spasms
    e. Osteomyelitis

Case Figure 43.1

Case Figure 43.2

Answers

1. **d.** Once disease from cancer recurrence is ruled-out, the most effective means to address a longer stricture (>2.0 cm) is with open (or robotic) repair. This early ureteroenteric stricture (less than 1 year postoperatively) is likely due to ischemia from devascularization and/or angulation of the left ureter under the inferior mesenteric artery. Endoscopic treatment will not likely be successful for a long ischemic stricture. Chronic ureteral stenting is not preferred in younger patients.
2. **a.** Ileal ureter should be considered for long (>4.0 cm) proximal ureteral defects in patients with serum Cr <2.0 mg/dL. It also facilitates stone passage and is thus a preferred option for a recurrent stone former. Endoscopic approaches may be effective for shorter strictures (1–2 cm or less). Transureteroureterostomy is contraindicated in those with nephrolithiasis and would not be possible due to the proximal nature of the stricture. Nephrectomy should be a last resort and classically is reserved for kidneys with <20% function on diuretic renal scan. Other options for this patient would include autotransplantation or buccal mucosal graft.
3. **c.** Nonresolving leakage from the BBF is most likely due to ischemia of the flap. A tension-free primary repair is unlikely to be feasible. Ileal ureter is contraindicated in patients with inflammatory bowel disease. Nephrectomy is reserved for kidneys providing <15% renal function though this is not an unreasonable approach in patients that have already undergone and failed reconstructive surgery. An attempt at renal autotransplantation is preferred in this patient with depressed renal function.
4. **c.** The patient is experiencing bladder spasms, which are common after a significant incision of the detrusor muscle as with BBF. The indwelling ureteral stent permits reflux to the kidney resulting in flank pain. Foley catheter placement may improve her symptoms, but in the absence of urinary leak should not be replaced unless anticholinergics prove unsuccessful.
5. **b.** Hydronephrosis after ureteral surgery may be related to obstruction, reflux, or residual from chronic dilation. VCUG can evaluate for ureteral reflux, though studies have demonstrated that reflux is not detrimental to long-term renal function. Diuretic renal scan should be used to assess for functional obstruction in patients with normal renal function when postoperative imaging is equivocal. We routinely perform a renal scan on all patients postoperatively to monitor for treatment success. Cystoscopy is more invasive, and observation risks permanent damage to the kidney if obstruction is present.
6. **c.** The patient's symptoms may be related to femoral nerve edema from retractor compression of the psoas muscle or could be secondary to nerve entrapment from the hitch sutures. Early mobilization and referral to physical therapy are beneficial to recovery for either mechanism. If entrapment is the issue, symptoms should be expected to eventually resolve since absorbable suture was used. If permanent suture was used a return to the operating room would be appropriate.
7. **d.** Ureteral entrapment that is immediately identified can be resolved with suture removal. If the ligation had a delayed recognition, the areas of the ureter may become fibrotic or ischemic putting the patient at risk for stricture, and making excision more appropriate. Ureteral stenting is preferred, as suture ligation will likely result in edema postoperatively that could result in temporary obstructive symptoms.
8. **a.** Primary closure can be appropriate for partial lacerations of the ureter, though in this case the thermal energy from the vessel sealing instrument could result in further injury to the tissue with delayed necrosis. Thus, excision of the injured area with a minimum of a 1-cm margin is the best option. A ureteral stent can permit healing of a partial laceration such as from endoscopic injury, but success is less likely with thermal injury for the above reasons and the current operative setup is favorable for an immediate repair.
9. **a.** Cystoscopy with retrograde pyelogram will help define the level and significance of the ureteral injury and potentially allow placement of a ureteral stent. Stenting the ureteral injury may allow primary healing.

If retrograde stent placement is not successful, nephrostomy tube placement is appropriate and antegrade stent placement could be considered. The urinoma is small and may resorb if the ureteral defect is bridged. Drainage of the urinoma should be done if physical symptoms persist after renal drainage or if there is any evidence for infection.

10. **c.** Placement of ureteral stents in retroperitoneal fibrosis (RPF) is typically not challenging, a contrast to obstructive processes caused by malignancy. Stents are placed preoperatively to aid in ureteral identification and mobilization and should remain in place for a minimum of 2–4 weeks after ureterolysis.

CASE STUDY 1

1. **b.** This early ureteroenteric stricture (less than 1 year postoperatively) is likely due to ischemia from devascularization and/or angulation of the left ureter under the inferior mesenteric artery. Ureteral cancer recurrence this early is unlikely with negative ureteral margins, but should be ruled out. Several studies have failed to show a statistically significant difference in the rate of ureteral stricture when comparing Bricker and Wallace style anastomoses.
2. **d.** Once disease from cancer recurrence is ruled out, the most effective means to address a longer stricture (>2.0 cm) is with open (or robotic) repair. Endoscopic treatment will not likely be successful for a long ischemic stricture. There are no data to suggest that metallic stents will reduce the risk of infection. Transureteroureterostomy puts the uninvolved renal unit at risk. The best option is to reimplant the ureter. Robotic reimplant may provide shorter convalescence and expedite recovery for this gentleman.

CASE STUDY 2

1. **a.** The fluid collection could be postoperative or could be a urine leak. The next step is to confirm the presence of urine leak and the level of ureteral injury. This can be done with cystoscopy and retrogrades, or nephrostomy with antegrade imaging, but a delayed phase of the CT is less invasive. Drain placement with fluid sampling would confirm the urine leak but provide no information about the location of the leak and is premature at this point for a small collection.
2. **c.** The delayed contrast imaging demonstrates that the distal ureteral injury is very close to the bladder. Retrograde imaging demonstrates a leak, but contrast reaches the proximal ureter suggesting there is not a complete transection. After nearly 2 months, this ureteral injury is unlikely to heal over a stent. Ureteroureterostomy is for proximal and midureteral strictures. Boari bladder flap is unnecessary for such a distal ureteral stricture. The ureter could likely be directly reimplanted into the bladder with such a distal injury, though a psoas hitch will reduce anastomotic tension.
3. **b.** The femoral nerve runs within the psoas major muscle, and the genitofemoral nerve runs anterior to this muscle. Either has the potential to be entrapped with psoas hitch. Femoral nerve injury would result in reduced hip flexion and knee extension that presents as gait difficultly, particularly with ascent of stairs. The most common nerve injury in the lithotomy position is to the peroneal nerve, resulting in temporary drop foot. The symptoms described in this case are consistent with entrapment of the genitofemoral nerve and will likely eventually resolve if absorbable suture was used.

44 Complications of Renal Transplantation

NICHOLAS G. COWAN, JEFFREY L. VEALE, and H. ALBIN GRITSCH

CHAPTER OUTLINE

Basic Operative Procedure
Surgical Challenges
Multiple Vessels
Perioperative Anticoagulation
Severe Recipient Peripheral Vascular Disease
Poor Graft Perfusion
Bleeding
Immunosuppression Toxicity
Cardiovascular Disease
Urologic Complications
Urinary Extravasation
Obstruction
Reflux
Hematuria
Vascular Complications
Hematomas
Renal Artery Stenosis
Renal Artery Thrombosis
Renal Vein Thrombosis
Deep Vein Thrombosis and Pulmonary Embolism
Lymphocele
Arteriovenous Fistula
Graft Rejection
Chapter 44 Questions and Answers

KEY POINTS

1. As the demand for kidney transplantation continues to rise, urologists will increasingly be called on to participate in donor and recipient care.
2. The allograft ureter receives blood supply solely from the renal artery; therefore, preservation of all the arterial branches (especially lower pole arteries) is essential to ensure viability of the ureter.
3. A stented ureteroneocystostomy has four times fewer urologic complications than a non-stented ureteroneocystostomy.
4. If a urine leak is caused by an ischemic sloughed ureter, endoscopic management merely delays definitive treatment. Therefore early surgical exploration and repair is usually the best solution.
5. Recipients who develop recurrent pyelonephritis after transplantation with confirmed reflux on imaging studies initially should be treated with long-term antibiotic prophylaxis. If this approach is not effective, then an endoscopic or open procedure may be indicated.

Minor complications can quickly become life threatening for immunosuppressed patients after renal transplantation. More than 100,000 patients are currently on the national kidney transplantation waiting list, and approximately 450,000 patients are on dialysis.[1] Thus, the demand for kidney transplantation continues to rise. In 2013, approximately 11,878 deceased donor and 5721 living donor kidney transplants were performed in the United States. Community urologists and general surgeons will increasingly be called on to participate in donor and recipient care. Early recognition of renal transplant complications can prevent serious morbidity and mortality. This chapter focuses on how to prevent and treat the complications of renal transplantation.

Basic Operative Procedure

To avoid renal transplant complications, patients should be carefully screened for cardiac disease and severe peripheral vascular disease. However, because the most common causes of end-stage renal disease are diabetes and hypertension, many patients already have these problems. Patients with progressive renal insufficiency should be referred to a nephrologist and kidney transplant program well before they need renal replacement therapy.

A retroperitoneal lower abdominal incision is used to expose the iliac vessels. The donor kidney is prepared by removal of the perinephric adipose tissue and ligation of small branches off the renal vessels. The donor kidney is

kept ice cold until the time of reperfusion by wrapping a gauze pad with crushed ice saline around it. The renal vein or vena caval extension graft is anastomosed to the external iliac vein, and the renal artery is anastomosed to the iliac artery. If possible, a patch of the donor aorta is used to facilitate the arterial anastomosis. Intravenous furosemide and mannitol are administered to reduce ischemia reperfusion injury. The ice pad and the vascular clamps are removed. Once hemostasis is achieved, the graft is carefully positioned to avoid kinking of the vessels. The ureter is passed beneath the spermatic cord and is anastomosed to the bladder mucosa with a stented extravesical approach. A submucosal tunnel is created to prevent reflux.

Surgical Challenges

MULTIPLE VESSELS

In deceased donor transplants, multiple arteries can be kept on a Carrel aortic patch; occasionally when the arteries are far apart, a section of the Carrel patch can be excised and re-approximated. However, when a living donor kidney has multiple arteries, these need to be anastomosed individually to the recipient or to one another so that one accommodating donor artery can be anastomosed to the recipient. If two arteries are approximately the same size, we prefer to use the "pair of pants" technique before anastomosing to the recipient vessel. When the vessels are of different caliber or length, an end-to-side technique may be the most appropriate option. Other options for multiple arteries include: (1) using the recipient's inferior epigastric artery in an end-to-end fashion with a donor artery and (2) harvesting the recipient's internal iliac artery and using it to accommodate multiple donor arteries. If the surgeon has exhausted these options, most transplant centers have a bank of vessels from deceased donors that can aid in the vascular reconstruction. In any event, a lower pole branch should always be preserved to avoid ureteral necrosis.

If multiple donor renal veins are available, the largest should be used and the others can be ligated because of internal venous collateralization. If two veins are approximately the same size, they can be sewn together with the "pair of pants" technique or individually anastomosed to the recipient's iliac vein. For right deceased donor kidneys, it is helpful to include the vena cava to extend the venous length.

PERIOPERATIVE ANTICOAGULATION

Anticoagulation is required for patients with mechanical cardiac valves, atrial fibrillation, and other diseases that increase the risk of venous thrombosis and pulmonary embolus. For patients admitted for deceased donor renal transplantation who are receiving warfarin, the international normalized ratio (INR) should be corrected to <2.5 at the time of the operation. Patients with a history of a coagulopathy or an increased risk of anastomotic thrombosis (peripheral vascular disease or multiple small vessels requiring vascular reconstruction) are anticoagulated with heparin. To limit the risk of postoperative bleeding a small bolus of 500 U followed by a continuous infusion of 100 U per hour has been successful in preventing graft thrombosis.

SEVERE RECIPIENT PERIPHERAL VASCULAR DISEASE

Even after computed tomography (CT) and magnetic resonance imaging (MRI) studies, as well as a thorough history and physical examination, a transplant surgeon may discover severe peripheral vascular disease affecting the pelvic vasculature at the time of the surgical procedure. Most calcified vessels have a soft spot along the external or common iliac artery that can accommodate the donor artery. Noncrushing Fogarty shodden vascular clamps can occlude areas with plaque with less risk of intimal injury. In rare cases the artery can be occluded internally with two Fogarty embolectomy catheters, and the balloons are deflated and removed when the assistant throws and ties down the last suture.

POOR GRAFT PERFUSION

On release of the vascular clamps the renal parenchyma should be pink and have appropriate turgor. Arterial signals should be detectable by Doppler probe in the hilar branches of the renal artery and major sections of the parenchyma. With deceased donor allografts, perfusion is frequently patchy but this resolves in approximately 10 minutes. The pulse in the renal artery should be palpably similar to that of the external iliac artery. The allograft must be positioned to avoid kinking of the vessels. If the hilum is positioned medially, the risk of vascular injury during percutaneous biopsy is reduced. Planning the final renal position and determining the best location before vascular anastomosis may reduce difficulty with graft positioning. Rarely, the graft may need to be placed low in the pelvis or intraperitoneally. This positioning makes renal allograft imaging and biopsy significantly more complicated, and revision of the vascular anastomosis should be considered. Arterial spasm can be relieved by topical or intraadventitial injection of papaverine or verapamil; however, this must be done with caution because of the risk of hypotension and heart block.

BLEEDING

Loss of <250 mL of blood is usually possible by careful hemostasis during exposure of the iliac vessels, ligation of small branches off the allograft vessels, and meticulous placement of the anastomotic sutures. Blood loss can be diminished by flushing the donor vessels with heparinized saline solution, following the preparation of the allograft and ligating the sites of extravasation. If blood loss is significant at the time of reperfusion, the vascular clamps should be reapplied and the graft carefully inspected.

Anastomotic bleeding can usually be controlled with fine suture ligatures. If the vessels have torn, it may be necessary to take down the vascular anastomoses and reconstruct the vessels on the back table. For this reason, the nursing staff should be instructed to leave the back table set up until the operation has been completed. In addition, do not infuse Collin's or UW (University of Wisconsin) solution into the transplant renal artery when the allograft is in situ and the venous anastomosis is complete. Otherwise the patient may develop heart block and cardiac arrest because of the high potassium content of these solutions. Oozing

from the anastomosis usually stops with gentle pressure and the application of cellulose gauze.

IMMUNOSUPPRESSION TOXICITY

The immunosuppressive medications used in renal transplantation may exacerbate or induce complications such as malignant disease, infections, diabetes mellitus, hematologic disorders, neurotoxicity, and metabolic disorders. Surgeons involved in the care of renal transplant patients must be aware of these complicating factors because they may have an impact on the optimal surgical management. Unlike heart or liver transplantation, dialysis provides an alternative renal replacement therapy. If severe complications occur, the recipient's life may need to be saved by discontinuation of immunosuppression.

CARDIOVASCULAR DISEASE

Patients with end-stage renal disease have a substantial risk for cardiovascular disease. Diabetes is the most common disease leading to renal transplantation, and almost all patients with renal failure develop hypertension. Additional cardiovascular risk factors associated with end-stage renal disease include increased extracellular fluid volume, anemia, high plasma levels of homocysteine, and thrombogenic factors. Additionally, uremia may accelerate atherogenesis and proteinuria is associated with hyperlipidemia. Patients who are undergoing dialysis and who are taking calcium salts as phosphate binding agents may develop vascular calcifications, which can complicate the technical aspects of the transplant operation.[2] Secondary hyperparathyroidism and a calcium × phosphate product of over 70 are risk factors for calciphylaxsis. Hyperphosphatemia is often associated with scleral hyperemia, pruritus, and peripheral vascular disease due to dystrophic crystallization. Cardiovascular risk factors are exacerbated by immunosuppression that can cause glucose intolerance (corticosteroids and calcineurin inhibitors) and hyperlipidemia (sirolimus and calcineurin inhibitors). Cardiovascular disease is the leading cause of allograft loss and death after transplantation. Prevention and careful preoperative evaluation rather than treatment are the best ways to avoid cardiovascular complications.

Urologic Complications

URINARY EXTRAVASATION

Ischemia of the distal ureter, the most common cause of urinary extravasation, results in leakage at the ureterovesical anastomosis. The allograft ureter depends on blood supply solely from the renal artery; therefore, preservation of all the arterial branches (especially lower pole arteries) is essential to ensure viability of the ureter. Careful procurement of kidneys and the practice of leaving the shortest length of ureter that allows for a tension-free ureterovesical anastomosis also help to ensure an adequate blood supply to the distal ureter. A stented Lich-Gregoir ureteroneocystostomy has the lowest incidence of urinary extravasation and other urologic complications.[3–5] It is helpful to distend the bladder with antibiotic solution before ureteral implantation. The bladder mucosa should be mobilized sufficiently to allow the ureter to swell without constriction in the antireflux tunnel. The anastomosis can also be tested for leakage by gently refilling the bladder. This brief procedure also ensures that the ureter has been anastomosed to the bladder because anastomosis to an ovarian cyst, the vagina, and thickened folds of peritoneum have been reported.[6]

Figure 44.1 Cystogram demonstrating a bladder leak. Note the small-capacity bladder in a patient who was anuric for approximately 10 years.

In general, most cases of urinary extravasation occur soon after transplantation and manifest with allograft tenderness and decreased urinary output. Increasing wound drainage is also a frequent finding. The diagnosis can sometimes be made by ultrasound examination but is confirmed by creatinine analysis of the draining fluid, by nuclear medicine scan, or by cystogram (Fig. 44.1). Occasionally, upper urinary tract extravasation from a calyx, the renal pelvis, or ureteral injury is best diagnosed by a contrast imaging study or an antegrade nephrostogram. Small leaks in the bladder may be treated with Foley catheter drainage. Antegrade stent and nephrostomy tube placement may also provide sufficient drainage to allow closure of a very small leak. If the leak is caused by an ischemic sloughed ureter, endoscopic management merely delays definitive treatment. Therefore, early surgical exploration and repair are usually the best solutions. The type of repair depends on the level of the leak and the vasculature of the tissues. A bladder leak can be closed primarily, with a Foley catheter left in place for ≥1 week and confirmation of closure by repeat cystogram. Ureteral leaks are best treated by resection of the distal ischemic segment and reimplantation into the bladder over a stent. If the length of ureter is inadequate, then cystopyelostomy (sometimes requiring a psoas hitch or Boari flap) and ureteroureterostomy to the recipient's native ureter are both viable options.

OBSTRUCTION

Common causes of allograft ureteral obstruction include Foley catheter blockage, blood clots, ureteral edema, ischemic ureteral fibrosis (stricture), kinked ureter or extrinsic compression from a lymphocele, urinoma, and hematoma.

Other less common causes of obstruction include stones, prostatic hyperplasia, neurogenic bladder, abscess, rejection (which includes the ureter), and urethral strictures. Obstruction may be painless because of the absence of innervation to the renal allograft. However, obstruction should be suspected in any patient with an unexplained decrease in urine output, enlargement or tenderness of the allograft, and a rising serum creatinine level. Increasing hydronephrosis on ultrasonography is suggestive of obstruction, but this sign is not always present (Fig. 44.2). Low-grade dilation of the collecting system in the early postoperative ultrasound scan may occur with vigorous diuresis or edema and resolves. A mercaptotriglycylglycine (MAG3) diuretic renal scan is useful to determine whether physiologic obstruction is present.

Rapid relief of obstruction can be achieved by placement of a percutaneous nephrostomy tube and antegrade stenting. If obstruction is present, the serum creatinine concentration should decrease following this procedure. Some minor obstructive processes may resolve over time with proximal diversion and stenting. Stones, blood clots, and strictures <1 cm can often be treated endoscopically.[7] More complex obstructions require open repair. Strictures >2 cm require excision and reimplantation of the remaining healthy ureter into the bladder or native ureter as described in the previous discussion of urinary extravasation (Fig. 44.3). Extrinsic ureteral obstruction from a lymphocele, hematoma, or urinoma can generally be successfully treated with external drainage.

Often obstruction can be avoided. Elderly men who have been anuric while undergoing dialysis may have unrecognized prostatic hypertrophy. Following transplantation, this population of patients may benefit from an alpha-blocker or a 5α-reductase inhibitor. If one clinically suspects a voiding abnormality, a post-void residual determination should be obtained to detect urinary retention. Transurethral resection of the prostate (TURP) should not be performed unless the recipient has adequate urine output, because a "dry TURP" can lead to bladder neck contracture or urethral strictures. The complications of endoscopic surgery can be reduced by waiting until the renal allograft has recovered and the patient is receiving a reduced dose of immunosuppression. Self-intermittent catheterization has the least risk for urinary tract infection until the cause of voiding dysfunction has been evaluated and treated. Long-term indwelling catheters should be avoided if possible.

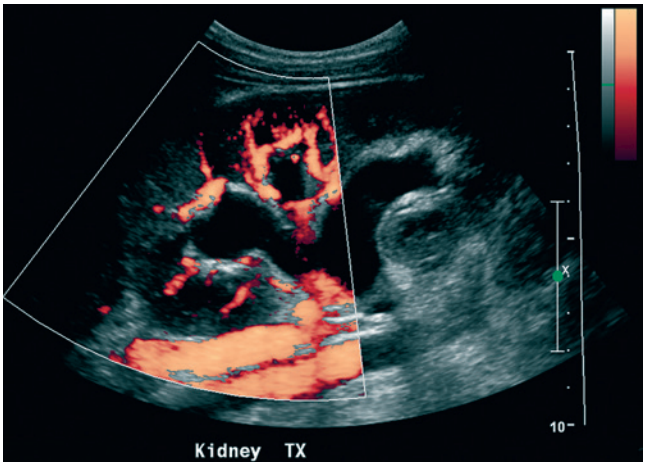

Figure 44.2 Hydronephrosis on renal ultrasound. This image suggests obstruction of the renal allograft. Note the decreased flow to the cortex of the kidney, and the prominent iliac vessels on the power Doppler image.

REFLUX

Although it is not a complication in and of itself, avoiding reflux into the allograft is theoretically desirable to reduce the pressure effects and pyelonephritis that may lead to impaired graft function. Some investigators have supported this theoretical advantage.[8–10] However, this finding has not been confirmed by others.[11–16] Urinary reflux into the renal allograft is usually identified during evaluation of recurrent urinary tract infections and is usually painless. A detrusor tunnel that is five times the diameter of the ureter should be attempted when possible. Most renal transplant surgeons prefer to use the stented Lich-Gregoir extravesical technique.[17,18] When ureteral length is compromised or when the patient has poor bladder capacity, a refluxing anastomosis is an acceptable option. Recipients who develop recurrent pyelonephritis after transplantation with confirmed reflux on imaging studies

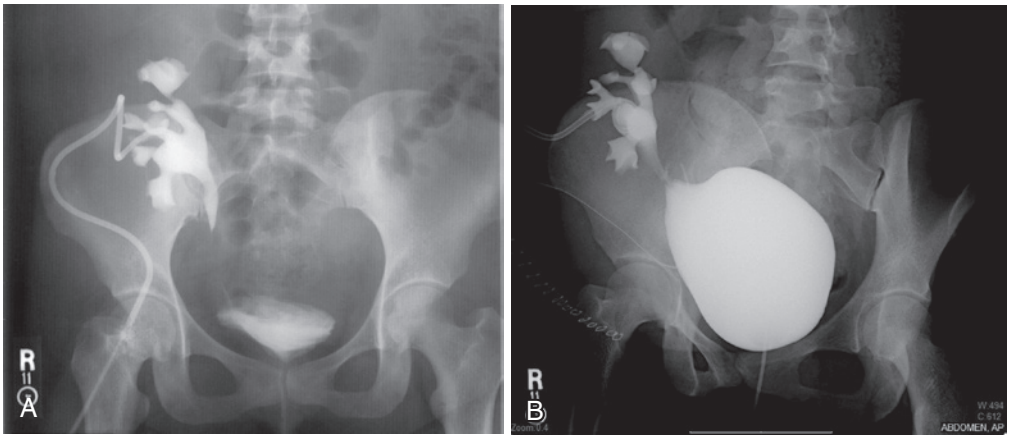

Figure 44.3 A, Anterograde nephrostogram of a distal ureteral stricture that manifested with a rising creatinine 6 months after allograft rejection and 5 years after renal transplant. B, Anterograde nephrostogram after urinary reconstruction with pyelovesicostomy.

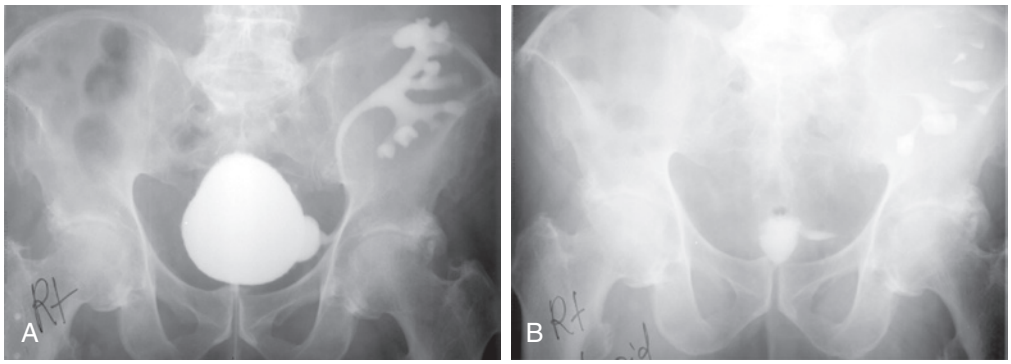

Figure 44.4 Voiding cystourethrogram. A, Reflux into the transplanted collecting system, with a diverticulum at the site of the ureteral anastomosis. B, Note some retained contrast after voiding.

(Fig. 44.4) should initially be treated with long-term antibiotic prophylaxis. If this approach is not effective, then an endoscopic or open reconstructive procedure may be indicated. Videourodynamics can be helpful to identify underlying bladder dysfunction and to determine the optimal corrective treatment.

HEMATURIA

In general, most renal transplant recipients develop some form of hematuria in the early postoperative period. Mild hematuria tends to resolve spontaneously over a couple of days. Moderate hematuria may develop into clots that can block the Foley catheter and occasionally require gentle manual irrigation or continuous bladder irrigation to resolve. If continuous bladder irrigation is not enough to clear the hematuria, then cystoscopy with fulguration is required.

The source of the bleeding is usually the ureteric stump. Vessels of the ureteric stump should be ligated with absorbable suture before creation of the ureteroneocystostomy. Urokinase with its natural anticoagulation properties may be responsible for some persistent hematuria. Hematuria beyond 6 months following transplant should have a complete evaluation.

Vascular Complications

HEMATOMAS

Perioperative bleeding is usually caused by small vessels in the renal hilum that may not have been identified intraoperatively because of vasospasm. Close observation of vital signs and serial hematocrit determinations are necessary in the early postoperative period to detect bleeding. Most small perirenal hematomas are asymptomatic, although larger hematomas can produce significant flank pain, lower extremity edema, and venous or ureteral obstruction. Hematomas in the retroperitoneum often tamponade and can be treated conservatively; however, expanding hematomas and more than four units of blood usually require exploration.

Massive bleeding may occur with graft rupture or anastomotic leaks. Graft rupture may result from swelling from ischemia reperfusion injury or severe rejection.[19] An intraoperative biopsy specimen of the ruptured allograft should be obtained. If the renal parenchyma appears viable, the graft should be wrapped with polyglactin mesh; if hemostasis can be achieved, allograft nephrectomy may not be necessary.[20] Late anastomotic bleeding is rare unless the anastomosis is infected. In this case, allograft nephrectomy is almost always required. If necessary, the iliac artery may be ligated without loss of limb, and the resultant claudication may be relieved by a surgical bypass procedure.[21] During surgical exploration of hematomas, one should resist the temptation to remove blood clots that have dissected into the retroperitoneal fat, unless active bleeding is noted in the area, because it becomes increasingly difficult to achieve hemostasis in this region. Ultrasound examination reliably detects perinephric fluid collections, but CT provides a much better assessment of the extent of blood dissection into adjacent tissues (Fig. 44.5).

If one elects to manage the bleeding conservatively, then aspirin and anticoagulant medications should be discontinued if possible. Blood transfusions are administered to maintain a hematocrit of ≥20%. Uremia inhibits platelet function, and most patients undergoing dialysis have abnormal bleeding times.[22] The intravenous administration of 0.3 μg/kg of 1-desamino-8-D-arginine vasopressin (DDAVP) causes the release of factor VIII from endothelial storage sites and may promote coagulation, although the effect is largely absent after 8 hours and DDAVP may induce tachyphylaxis. Daily intravenous conjugated estrogen (Premarin) infusion of 0.6 mg/kg for 5 days also reduces the bleeding time in uremic patients.[23] Vitamin K deficiency is fairly common in patients with renal failure and a poor nutritional state, and other coagulation parameters should be evaluated and corrected.

RENAL ARTERY STENOSIS

One of the most common vascular complications is transplant renal artery stenosis (TRAS), with a reported incidence of 1.6–12%.[24–27] Most cases of TRAS occur within 3 years after transplantation. The presenting signs suggestive of TRAS include poorly controlled renin-mediated hypertension, increasing peripheral edema, decreased allograft function with or without the use of angiotensin-converting enzyme inhibitors, and the presence of a bruit over the allograft. Renal artery stenosis is suspected on ultrasonography when the peak systolic velocity is >200 cm per second

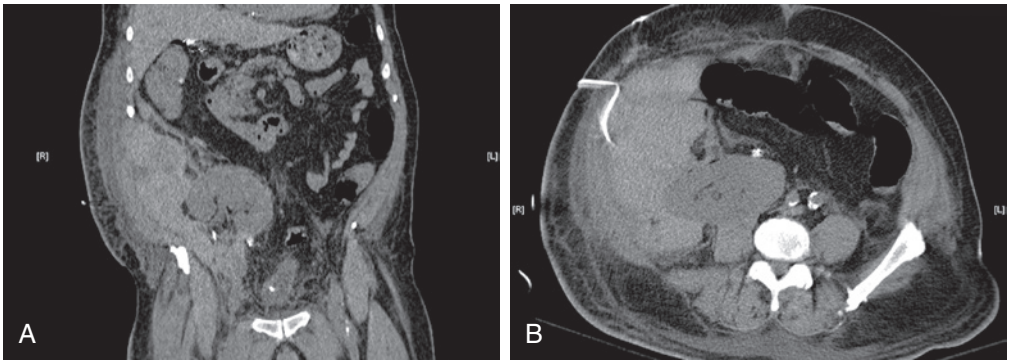

Figure 44.5 A, Coronal noncontrast CT scan of a large hematoma lateral to the renal allograft. B, Transverse noncontrast CT scan demonstrating that even a well-positioned drain does little to prevent hematoma formation.

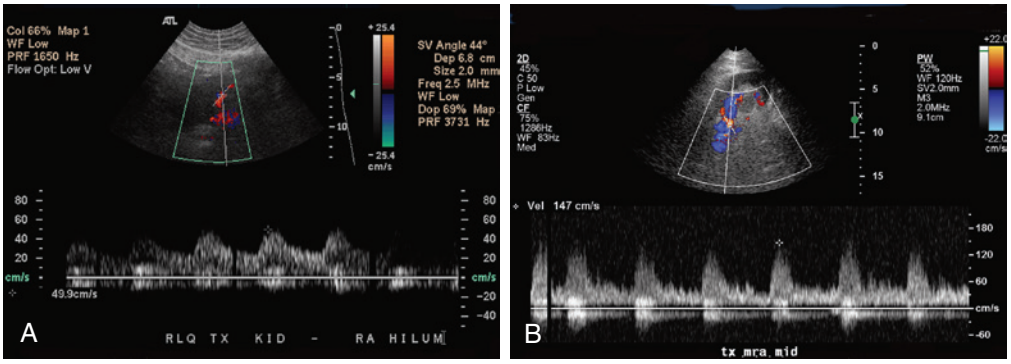

Figure 44.6 A, Doppler ultrasound scan of the renal hilum showing decreased velocity (49.9 cm/second) and loss of the early systolic peak tardus-parvus waveform. B, Normal velocity and waveform.

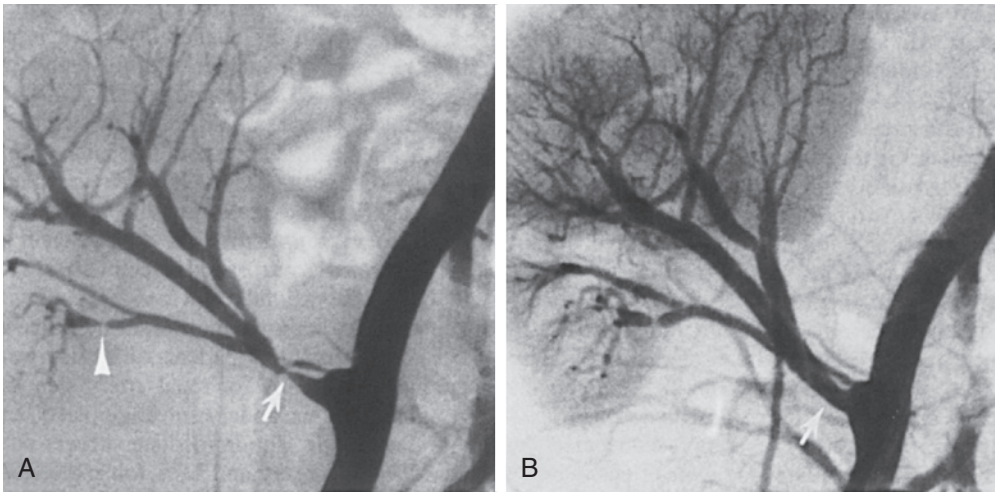

Figure 44.7 Percutaneous transluminal angioplasty of transplant renal artery stenosis. A, Severe stenosis of the proximal allograft renal artery (arrow) demonstrated on an external iliac arteriogram. The end-to-side Carrel patch anastomosis with the external iliac artery is widely patent. Also note the marked stenosis in the lower pole intrarenal branch artery (arrowhead). B, After balloon angioplasty, the proximal renal artery is widely patent (*arrow*). (With permission from Jordan ML, Holley JL, Zajko AB. Renal vascular hypertension in the transplant patient. In: Novick A, Scoble J, Hamilton G, eds. *Renal Vascular Disease*. London: WB Saunders; 1996:279.)

with turbulence. A tardus-parvus Doppler arterial waveform is also highly suggestive of TRAS (Fig. 44.6).[28] Elevated peak systolic velocities in the renal transplant artery are common in the early postoperative period and will often normalize on serial examination.[29]

Angiography remains the gold standard, although CT angiography and magnetic resonance angiography (Fig. 44.7A) can also be used to make the diagnosis. The risk of contrast administration needs to be considered in patients with marginal renal function. In some cases, carbon dioxide angiography can be used to minimize the load of nephrotoxic contrast material. Evidence has linked gadolinium contrast to the development of nephrogenic systemic fibrosis in patients receiving dialysis.[30]

Box 44.1 Causes of Transplant Renal Artery Stenosis

Recipient artery atherosclerosis
Donor artery atherosclerosis
Anastomotic stricture resulting from faulty suture technique
Arterial injury during donor nephrectomy
Kinking of the renal artery
Disparity in donor-recipient vessel size
Rejection of the donor artery
Vascular clamp injury
Perfusion pump cannulation injury

Any factor that leads to intimal injury or turbulent blood flow can result in stenosis, and clinicians should try to avoid the potential causes of TRAS listed in Box 44.1. If stenosis is diagnosed in the first postoperative month, then surgical revision of the anastomosis is usually the best option. Beyond this time period, percutaneous transluminal angioplasty (PTA) (see Fig. 44.7B) is usually the preferred treatment. When compared to treatment with PTA alone, treatment by means of stenting alone or with pre-balloon dilatation demonstrates superiority in various outcomes including patency rate (73% vs 90.4%), reintervention rate (18.9% vs 9.1%), and technical success (93.1% vs 97.1%).[31,32] Surgical correction may rarely be necessary after failed PTA or for lesions that are not approachable by angioplasty. An intraperitoneal approach to the vessels provides the best exposure. The surgical techniques for revascularization of TRAS include the following:

1. Resection of the stenotic segment and direct arterial reanastomosis
2. Transection of the transplant artery distal to the anastomosis and end-to-side reimplantation
3. Bypass with autologous saphenous vein or Gore-Tex graft
4. Open dilation
5. Vein patch angioplasty.

The immediate technical success rate of surgical correction is between 55% and 92%, with graft loss in ≤20% and a mortality rate of ≤5.5%.[33]

RENAL ARTERY THROMBOSIS

Renal artery thrombosis is most often seen in pediatric recipients. The incidence is increased in transplant recipients with thrombotic tendencies (anticardiolipin antibodies, protein C or S deficiency, or thrombocytosis). This complication can also occur in kidneys that have donor vascular disease or kidneys with multiple small arteries requiring complex bench surgical intervention before implantation (horseshoe donor kidneys, pediatric en bloc donor kidneys). Renal artery thrombosis typically occurs within the first 72 hours after transplantation.

At the time of transplant the renal allograft vessels must be carefully inspected for intimal integrity. Fine vascular suture material should be used to create an intimal approximating anastomosis. If the allograft does not perfuse properly, the vascular clamps are reapplied to the recipient vessels, the anastomosis is taken down, the kidney is flushed with chilled Ringer lactate solution containing 1000 U/L of heparin, and the anastomosis is carefully redone. If extensive reconstruction of the recipient vessel is required, the allograft should be removed and placed back in the ice-cold preservation solution on the back table. In transplants that have an increased risk of arterial thrombosis it may be helpful to give 500 U of heparin before suturing the arterial anastomosis. Continuing the heparin at 100 U per hour for the duration of the hospitalization with daily acetylsalicylic acid on discharge may also help to prevent this complication in those patients with significant risk factors.

If delayed arterial thrombosis occurs, it is rarely possible to make the diagnosis in time to salvage the graft, and this complication is usually associated with severe acute rejection. The patient may experience a sudden cessation of urine flow without any discomfort. Thrombocytopenia and hyperkalemia may occur as platelets are consumed in the graft with a sudden elevation in creatinine. The diagnosis of renal thrombosis is confirmed by ultrasonography or renal scan with no blood flow to the allograft. If the diagnosis is made immediately, then the patient is rushed to the operating room for emergency open arteriotomy and thrombectomy. Unfortunately, most grafts that sustain arterial thrombosis are lost and require allograft nephrectomy.

RENAL VEIN THROMBOSIS

Renal vein thrombosis generally occurs in the early postoperative period. Some causes of renal vein thrombosis that should be avoided include kinking or angulation of the renal vein, stenosis of the venous anastomosis, intraoperative or postoperative hypotension, hypercoagulable state, acute rejection, deep vein thrombosis with extension into the allograft, and renal vein compression by a perinephric fluid collection. Prophylactic heparinization as discussed in the previous section on arterial thrombosis may also be beneficial for transplant recipients who have an increased risk for renal vein thrombosis. If venous thrombosis occurs intraoperatively, the allograft will appear cyanotic and swollen. A clot may be palpable in the renal vein.

Thrombectomy and revision of the anastomosis should be attempted as in arterial thrombosis. The vascular clamps should be carefully reapplied so that a segment of the thrombus is not dislodged into the systemic circulation. Delayed renal vein thrombosis is usually diagnosed by Doppler ultrasonography and may be confirmed by renal scan or venography. Late renal vein thrombosis (occurring >4 weeks after transplantation) is usually a result of propagation of deep vein thrombosis into the renal vein. Thrombolytic therapy with intravenous streptokinase or anticoagulation may occasionally be useful. The diagnosis of late venous thrombosis is usually made after a period of prolonged allograft ischemia, and nephrectomy is indicated.

DEEP VEIN THROMBOSIS AND PULMONARY EMBOLISM

Pulmonary embolism is the most common preventable cause of death among hospital patients in the United States.[34] Estimates of venous thromboembolic event incidence within the first year following kidney transplant vary widely, but most large series estimate the rate at 1–3%.[35] Variation in reported

rates is likely due to variable methods of prophylaxis and detection. Possible risk factors for venous thromboembolism include stasis from clamping of the vein, endothelial injury from creation of the vascular anastomosis, pelvic dissection, diabetes, calcineurin inhibitors, immobility, elevated homocysteine level, and decreased venous emptying secondary to urinoma, hematoma, lymphocele, or positioning of the kidney. We recommend placement of pulsatile compression stockings before the induction of anesthesia and removal of these stockings when the patient is ambulating. Chemoprophylaxis with subcutaneous heparin may be added for high-risk recipients. Low-molecular-weight heparins may be considered but should be used with extreme caution as some of these are renally cleared. One alternative is dalteparin, which has been successfully used and is not dependent on renal function for metabolism.[36]

LYMPHOCELE

Lymphatic collections are usually found medial to the renal allograft and may occur in 36% of transplants.[37] The lymphatic collection arises from the lymphatics surrounding the iliac vessels that are divided during mobilization or renal hilar lymphatics of the donor kidney. Some lymphoceles may produce pain, ureteral obstruction, voiding symptoms, and renal or iliac vein compression leading to deep vein thrombosis or leg swelling. The diagnosis is confirmed by ultrasound examination (Fig. 44.8) and aspiration of the fluid using sterile technique. Lymphatic fluid is usually clear with a high lymphocyte count, high protein content, and creatinine concentration similar to that of serum.

Small, asymptomatic lymphoceles do not require treatment. Aspiration alone may resolve the problem, but repeated aspiration is discouraged because it may lead to infection and rarely results in permanent decompression. Percutaneous closed-system catheter drainage with instillation of sclerosing agents, such as povidone-iodine (Betadine)[38] or fibrin glue,[39] has been successful. Loculated lymphoceles, collections adjacent to the renal hilum, and those that are inaccessible for safe puncture are best treated by marsupialization into the peritoneal cavity. This procedure may be accomplished by a laparoscopic or open surgical approach.[37,40] The transplant ureter, which is often incorporated into the wall of the lymphocele, must be identified and carefully preserved. A cystoscopically placed ureteral stent or intraoperative ultrasound scan may be beneficial. The peritoneal opening must be large enough to prevent bowel herniation. Omentum is usually placed in the opening to prevent closure.

The incidence of lymphoceles can be reduced by minimizing the pelvic dissection and ligating lymphatics. Avoiding the immunosuppressant agent sirolimus in the early postoperative period may also help to reduce the incidence of this complication. Additionally, placing a drain at the end of the procedure and leaving it for the initial postoperative course has been shown to reduce lymphatic collections.[41]

ARTERIOVENOUS FISTULA

In renal allografts, arteriovenous fistula formation most commonly follows renal transplant biopsy. Other causes of arteriovenous fistula include trauma, infection, rupture of an aneurysm, and injury to segmental renal vessels before organ recovery. In these latter cases, segmental renal infarction of the parenchyma subtended by the injured vessel may also lead to urine leak from the underlying calyx. An arteriovenous fistula may manifest with hypertension, hematuria, or a bruit over the allograft. The diagnosis is confirmed by color duplex ultrasound examination (Fig. 44.9) or angiography (Fig. 44.10). Most post-biopsy fistulas are small and resolve spontaneously. Localized pressure with the ultrasound probe may diminish flow enough to allow localized thrombosis. Angiography with selective embolization of the feeding vessel is the treatment of choice for persistent clinically significant fistulas.[42] The incidence of arteriovenous fistula may be reduced by correcting the bleeding time and platelet count before performance of ultrasound-guided biopsy of the renal allograft cortical tissue.[43]

Graft Rejection

Only kidneys from identical twin donors have no risk of rejection, require no immunosuppressive medication, and may continue to function for >40 years. Almost all other

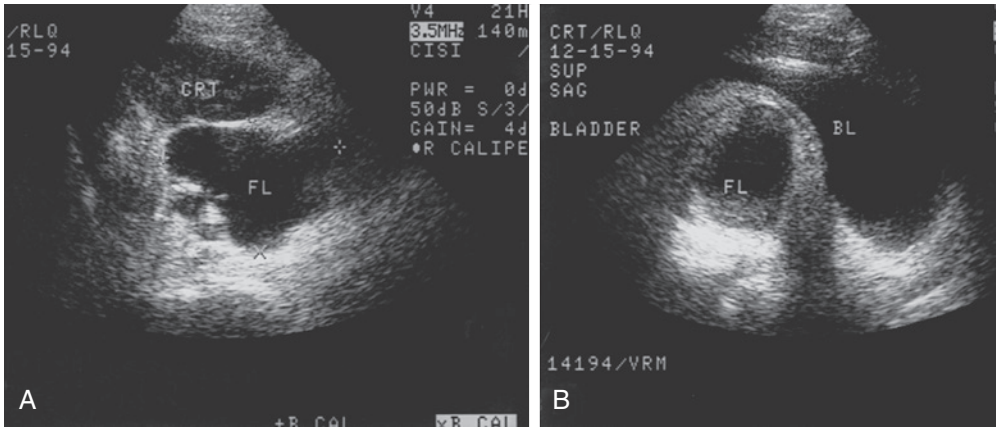

Figure 44.8 Renal allograft ultrasound with a lymphocele. A, The lymphocele (FL) is medial to the renal transplant (CRT). B, The lymphocele extends into the pelvis and displaces the bladder (BL). Attempted sclerosis of this lymphocele with povidone-iodine (Betadine) initially failed, but treatment was successful with an open peritoneal window procedure.

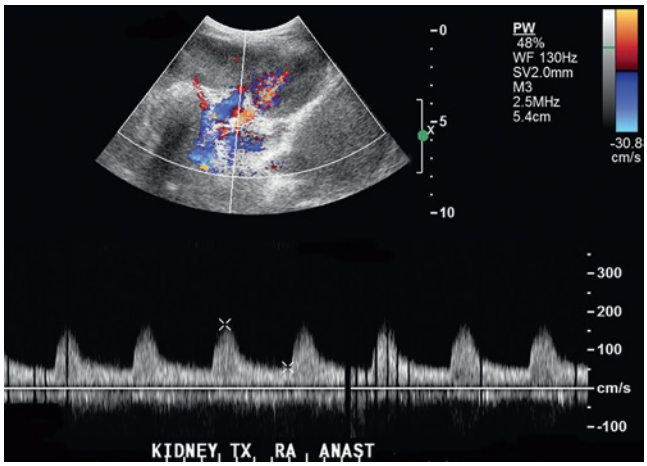

Figure 44.9 Doppler ultrasound scan of renal allograft after biopsy. Note the speckling of colors within the upper region, a finding suggestive of a fistula because blood is flowing in various directions.

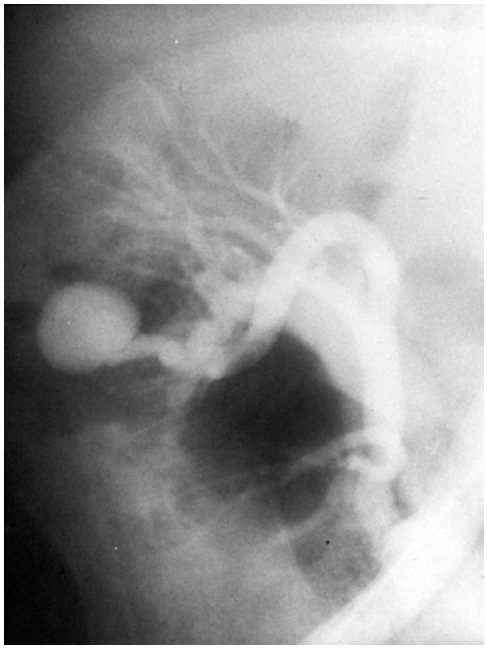

Figure 44.10 Angiogram of an arteriovenous fistula after renal allograft. Note visualization of the renal vein before the nephrogram phase. This fistula was treated with selective embolization.

donor kidneys eventually succumb to rejection and require immunosuppression. Allograft rejection is classified into three major categories: hyperacute, acute, and chronic.

Hyperacute rejection usually begins immediately after perfusion. The transplanted kidney, after initially perfusing well, may become cyanotic, soft, and edematous. One must exclude other causes of insufficient arterial blood supply including positional kinking of the vessels, intimal flap, or hypotension. The diagnosis is confirmed by an intraoperative biopsy of the kidney that shows polymorphonuclear leukocytes in the glomeruli and peritubular capillaries with widespread vascular thrombosis. This type of rejection results from preformed cytotoxic antibodies reactive to endothelial cells of the graft.

Hyperacute rejection can usually be prevented by testing the recipient serum for antibodies reactive to donor lymphocytes with a cross-match test. This test is typically performed before each renal transplantation. Recipients with a positive cross-match test result or blood type incompatibility have undergone successful transplantation with plasmapheresis, intravenous immunoglobulin, and potent immunosuppression. Treatment of hyperacute rejection is disappointing and is generally associated with graft loss.

Acute rejection occurs in 10–40% of allografts within the first year after transplantation.[44,45] With current immunosuppression, the only presenting sign is usually a rise in the serum creatinine level. The diagnosis is confirmed by allograft biopsy. The differential diagnosis includes dehydration, ischemia reperfusion injury, drug nephrotoxicity, obstruction, and pyelonephritis. Acute rejection is often the result of an insufficient immunosuppression regimen or poor patient compliance. New methods of monitoring the immune response may allow the clinician time to increase immunosuppression and reverse the process before significant damage to the allograft occurs.[46] Approximately 90% of acute rejections are cell mediated and are characterized by lymphocytic invasion of the interstitium and tubular epithelium. Ten percent of acute rejections show evidence of antibody-mediated rejection, characterized by complement deposition (C4d) in the peritubular capillaries. Vascular rejection signifies arterial inflammation and can result from either cell-mediated or antibody-mediated rejection. Standardized criteria for grading renal allograft biopsies have been developed and are used to guide additional immunosuppressive therapy.[47]

Acute rejection within the first year after transplantation can be successfully reversed approximately 80% of the time.[2] Acute cellular rejection is treated by high-dose methylprednisolone, by antilymphocytic antibodies, or by increasing the dosage of calcineurin inhibitor medications. For antibody-mediated acute rejection, most clinicians favor rapid removal of the circulating antibodies by plasmapheresis and the neutralization of the remaining antibodies with intravenous immunoglobulin.

Chronic rejection is identified in most renal transplants after a few years. Renal allograft biopsies show evidence of accelerated atherosclerosis, interstitial fibrosis, and tubular atrophy. The pathogenesis is not fully understood but both antigen-dependent and antigen-independent mechanisms of vascular injury are implicated. The serum creatinine concentration slowly increases until the allograft fails. Although immune factors including acute rejection play a role in the development of chronic rejection, the newer term *chronic allograft nephropathy* more accurately describes the multifactorial nature of this disease. Hypercholesterolemia, hypertension, immunosuppression nephrotoxicity, ischemia reperfusion injury, and infection have all been associated with the same pathologic findings. Many clinical trials are now being designed to determine whether this process can be stopped or prevented. Increasing immunosuppressive treatment is usually not advised.

Chapter 44 Questions

1. The percentage of patients with end-stage renal disease who are candidates for renal transplantation in the United States is approximately:
   a. 10%
   b. 20%
   c. 40%
   d. 80%
   e. 100%

2. An anuric patient on hemodialysis for 3 years has bloodshot eyes and complains of itching. A likely cause is:
   a. Allergic reaction to heparin
   b. Glaucoma
   c. Uncontrolled hypertension
   d. Poor adherence to diet recommendations
   e. Excessive fluid consumption

3. How should post-biopsy fistulas initially be treated?
   a. Medications to control hypertension
   b. Fresh frozen plasma and platelet transfusion
   c. Angiography and embolization
   d. Open exploration and repair
   e. Allograft nephrectomy

4. Antibody mediated rejection is confirmed by renal allograft biopsy with the histologic finding of:
   a. Lymphocytic infiltration of renal tubules
   b. Dense deposits in the glomerulus
   c. Complement fragment C4d deposition in peritubular capillaries
   d. Thickening of Bowman's capsule
   e. Arteriolar sclerosis of the arcuate arteries

5. The most common etiology of allograft failure within the first year following renal transplantation is:
   a. Cardiac event resulting in death of patient
   b. Graft thrombosis
   c. Acute rejection
   d. Recurrence of diabetic nephropathy
   e. Hypertensive nephrosclerosis

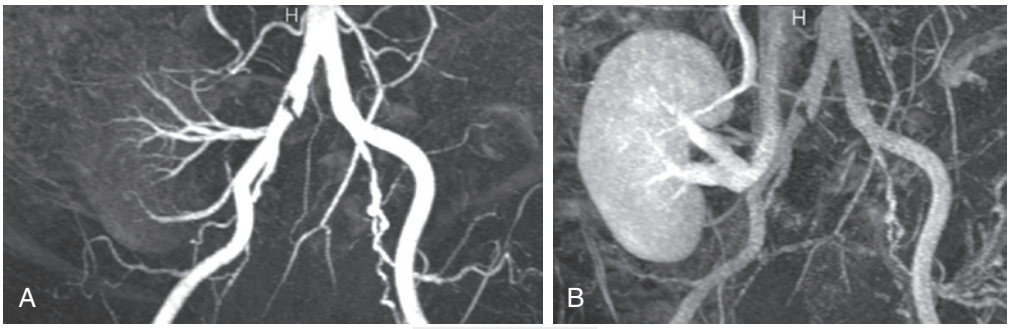
6. Flushing of the in situ allograft artery following completion of the venous anastomosis with either Collin's or UW solution can result in:
   a. Decreased risk of acute tubular necrosis
   b. Decreased risk of delayed graft function
   c. Increased risk of heart block
   d. Increased risk of hypokalemia
   e. Increased risk of graft thrombosis

7. Immunosuppressive regimens commonly used in renal transplantation are associated with which of the following?
   a. Decreased rates of malignancy
   b. Improvement in glycemic control
   c. Increased risk of ischemia stroke
   d. Diminished risk of viral and bacterial infections
   e. Nephrotoxicity

8. A 27-year-old female presents with hydronephrosis of her allograft and an elevated serum creatinine 9 weeks following deceased donor renal transplant. Her bladder is decompressed on ultrasound. A percutaneous nephrostomy tube is placed and an antegrade nephrostogram demonstrates a 2.2-cm distal ureteral stricture. The most appropriate management of the ureteral stricture is:
   a. Internalization of the nephrostomy tube with periodic stent exchanges
   b. Cystoscopy with balloon dilation of the ureteral stricture and stent placement
   c. Antegrade endoscopy with laser incision of the ureteral stricture and stent placement
   d. Resection of the ureteral stricture with reimplantation into the bladder and stent placement
   e. Conversion of the nephrostomy tube to a nephroureteral stent with follow-up antegrade nephrostogram

9. Renal artery stenosis is suggested by transplant duplex ultrasonography when the following finding is identified:
   a. Mid renal artery systolic velocity of 170 cm/s
   b. Intrarenal resistive index of 0.7
   c. Tardus-parvus arterial waveform
   d. Anastomotic end-diastolic velocity of 20 cm/s
   e. Iliac artery peak systolic velocity of 140 cm/s

10. The most common form of early rejection in renal transplant recipients is:
    a. Hyperacute rejection
    b. Cell-mediated acute rejection
    c. Antibody-mediated acute rejection
    d. Acute tubular necrosis
    e. Vascular rejection



Case Studies

CASE 1

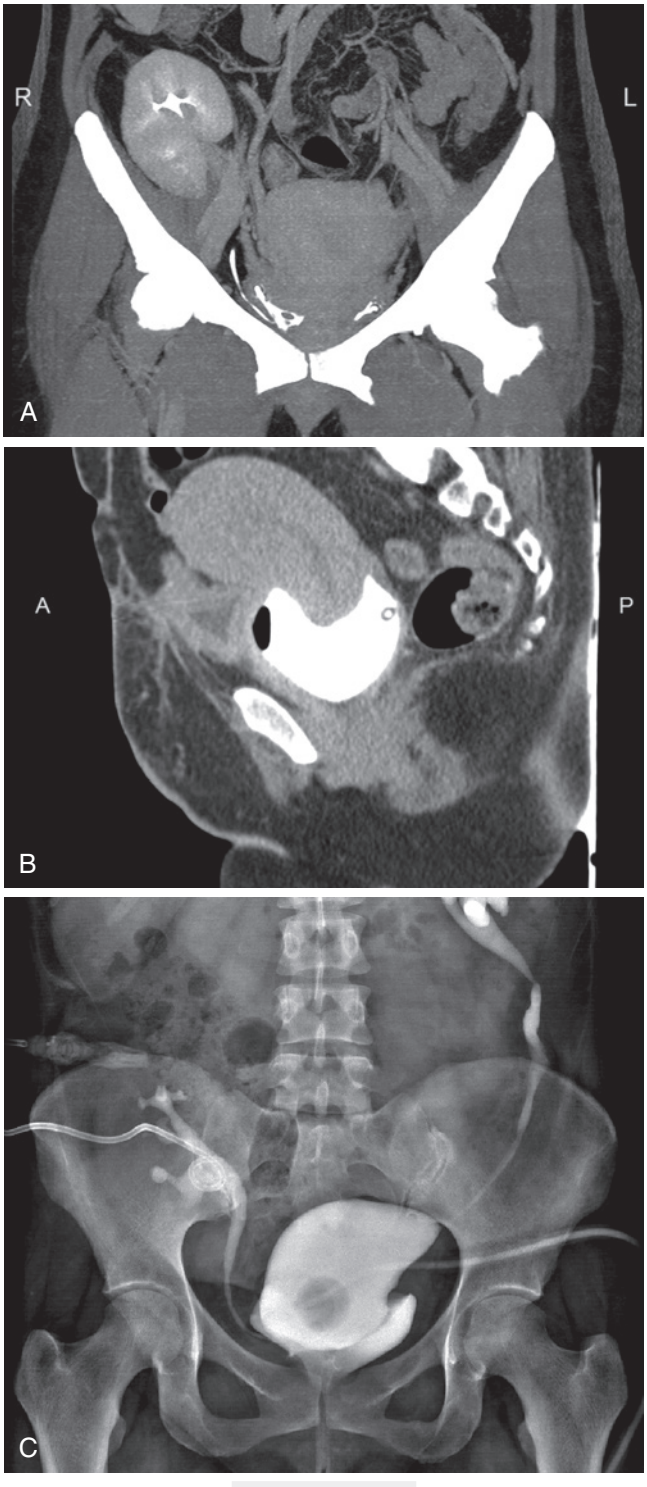
A 62-year-old male with a past medical history significant for hypertension undergoes an uneventful living unrelated renal transplant into the right iliac fossa. Postoperatively he complains of fatigue and cramping in his right buttock, thigh, and calf that is brought on with ambulation over distances of about 100 feet. The pain is relieved with rest. Prior to his transplant he was able to walk 1.5 miles without difficulty. His vitals are unremarkable. His serum creatinine has trended down following surgery and is now at 1.4 mg/dL. Case Fig. 44.1.

1. Which physical examination findings are consistent with this patient's symptoms?

a.	Right pulses: Fem- 1+, PT- 2+	Left pulses: Fem- 2+, PT- 2+
b.	Right pulses: Fem- barely palpable, PT- 2+	Left pulses: Fem- 2+, PT- 2+
c.	Right pulses: Fem- barely palpable, PT- absent	Left pulses: Fem- 1 +, PT- absent
d.	Right pulses: Fem- barely palpable, PT- absent	Left pulses: Fem- 2+, PT- 2+
e.	Right pulses: Fem- 2+, PT- absent	Left pulses: Fem- 2+, PT- 2+

Case Figure 44.1

2. Based on the patient's symptomatology, where would you expect to find a lesion?
   a. Transplant renal artery
   b. Right common iliac artery
   c. Right internal iliac artery
   d. Right external iliac artery
   e. Right superficial femoral artery



3. What imaging study is most likely to yield a causative finding while avoiding risk of toxicity to the transplant kidney?
   a. Angiography (aortogram with runoff)
   b. CT abdomen/pelvis with IV contrast
   c. MR angiogram abdomen/pelvis with gadolinium
   d. Transplant duplex ultrasound
   e. MAG3 with flow and function

4. An MR angiogram of the abdomen and pelvis is obtained with representative images shown (see Case Fig. 44.1). The most likely explanation for the cause of this patient's vascular lesion is:
   a. Proximal extension of a renal arterial thrombosis
   b Renal vein thrombosis with proximal extension
   c. Mycotic infection of an atherosclerotic lesion
   d. An intraoperative injury resulting from a vascular clamp
   e. Renal arterial stenosis with turbulent flow proximally

CASE 2

A 41-year-old female presents for surgical evaluation as a renal transplant candidate. Her urologic history is notable for a urogenital sinus treated with bladder neck reconstruction, continent urinary diversion, and urethral reconstruction. She has had progressively worsening kidney function due to her congenital urologic anomalies and is now on hemodialysis. She still makes urine and denies urinary incontinence, incomplete emptying, or recurrent urinary tract infections.

1. In preparation for her renal transplant, which study/studies would be most beneficial for identifying physiologic and/or anatomic abnormalities that may negatively impact the outcome of her surgery (Case Fig. 44.2)?
   a. MAG3 scan
   b. Video urodynamics
   c. Cystoscopy
   d. CT abdomen/pelvis
   e. Uroflow and post-void residual

Case Figure 44.2

2. You are about to begin the ureteral reimplantation portion of the transplant and are considering the various surgical techniques available. Which form of ureteral reimplantation has been demonstrated to have the lowest complication rate?
   a. Unstented Taguchi
   b. Unstented Lich-Gregoir
   c. Stented Polatano-Leadbetter
   d. Stented Taguchi
   e. Stented Lich-Gregoir

3. A ureteral reimplant is performed without the aid of bladder distention as a catheter could not be placed preoperatively due to a very narrowed introitus and urethral meatus, which is high and posterior to her pubic bone. Her pelvis is scarred from her prior reconstructive surgery. A suprapubic tube is used to drain her bladder postoperatively. One month after surgery her suprapubic catheter is removed and she notices progressive onset of urinary incontinence that is not preceded by urgency, cough, or sneeze. As part of her workup a CT urogram was obtained with a representative coronal and sagittal image is shown (See Case Fig. 44.2).

   Based on these images in Case Fig. 44.2, what is the most definitive treatment for this patient?
   a. Ureteral reimplantation
   b. Initiation of clean intermittent catheterization
   c. Timed voiding
   d. Placement of suprapubic catheter with periodic exchanges
   e. Placement of percutaneous nephrostomy tube and Foley catheter

Answers

1. **b.** In the United States there are approximately 450,000 patients on dialysis and 100,000 candidates on the national deceased donor waiting list for kidney transplantation (22%). Patients with a living donor are generally listed for a deceased donor organ as a back-up plan.
2. **d.** Patients with renal failure are not able to eliminate potassium and phosphorus. A common problem for dialysis patients is hyperphosphatemia when they do control the consumption or GI elimination with binders. The deposition of calcium phosphate crystals leads to irritation of the conjunctiva and skin. Deposition in small blood vessels can lead to tissue necrosis or calciphylaxsis when the calcium × phosphorus product is greater than 70.
3. **a.** Approximately 70% of post-biopsy fistulas close spontaneously within 18 months.
4. **c.** Complement deposition in the peritubular capillaries by immunofluorescence and detection of donor specific antibody in the serum is diagnostic of antibody-mediated rejection. This is an important distinction since the treatment is different than acute cell-mediated rejection.
5. **a.** Cardiac events resulting in death (with a functioning allograft) are the most common cause of allograft failure within the first year following renal transplant.
6. **c.** Both Collin's and UW preservation solutions contain high levels of potassium. Direct infusion into a recipient's intravascular space can result in hyperkalemia, heart block, and cardiac arrest.
7. **e.** Modern immunosuppressive regimens utilizing calcineurin inhibitors (cyclosporine, tacrolimus) and steroids have side effect profiles which include increased risk of malignancy and infections, glucose intolerance, and hyperlipidemia. Although administered to prevent rejection and subsequent allograft rejection, these regimens can also lead to nephrotoxicity resulting from renal vasoconstriction and chronic interstitial fibrosis.
8. **d.** Strictures >2 cm in length should be primarily managed with excision and reimplantion. Additional techniques such as a Boari flap or psoas hitch may be utilized to facilitate reimplantation. Endoscopic management of transplant ureteral strictures is best reserved for distal ureteral strictures <1 cm in size. Direct vision internal ureterotomy, typically with a laser, is the preferred endoscopic technique.
9. **c.** Renal artery peak systolic velocities of >200 cm/s, turbulent renal artery blood flow, and a tardus-parvus Doppler arterial waveform are all suggestive of transplant renal artery stenosis. A tardus-parvus Doppler arterial waveform appears as a small amplitude waveform with a prolonged systolic rise when compared to the normal arterial waveform, which has a sharp systolic upstroke peak.
10. **b.** Cell-mediated acute rejection is the most common form of early rejection in renal transplant recipients and is confirmed with a biopsy. This form of rejection is characterized by lymphocytic invasion of the interstitium and tubular epithelium.

CASE 1

1. **d.** This patient has both buttock and calf claudication and therefore would be expected to have diminished femoral and pedal pulses on the affected side. He had no symptoms of left lower extremity claudication and therefore would be expected to have a palpable left femoral and tibial pulse on exam.
2. **b.** The right common iliac artery is where you would expect to find an arterial lesion based on this patient's symptoms of buttock, thigh, and calf claudication. Thigh and buttock claudication predominate when an arterial lesion is present in the aortoiliac area as the internal iliac artery must also have diminished blood flow to produce these symptoms. Lesions of the external iliac artery and superficial femoral artery will spare the buttock and typically cause only thigh or calf pain. A lesion of the transplant renal artery would be unlikely to result in symptoms of claudication.
3. **c.** An MR angiogram abdomen/pelvis has a high sensitivity for detection of intravascular lesions while avoiding the risk of contrast-induced nephropathy to the newly transplanted kidney. Additionally, MR angiogram avoids the need for intravascular access required for angiography and is not operator dependent like a duplex ultrasound.

While duplex ultrasound may suggest the location of a vascular lesion it will not define the anatomy as clearly as an MR angiogram. A MAG3 scan would not provide you with detailed intravascular anatomy.

4. **d.** These images (Case Fig. 44.1) demonstrate focal dissection in the middle part of the right common iliac artery with an intimal flap. The most likely explanation for this dissection is an intraoperative vascular clamp injury. Vascular clamp injuries following renal transplant are rare and can present with lower extremity claudication or remain asymptomatic with only mild graft dysfunction noted on labs. Diagnosis is suspected with an abnormal duplex ultrasound and can be confirmed with an MR angiogram, CT abdomen/pelvis with contrast, or angiography. If severe peripheral vascular disease is noted intraoperatively, then noncrushing Fogarty shodden clamps can provide vascular control with less risk of intimal injury.

CASE 2

1. **b.** In patients with complex urologic history, urodynamics may further clarify the type of lower urinary tract dysfunction and offer the opportunity for medical or surgical optimization prior to renal transplant. Ensuring optimal bladder function prior to transplant may help minimize any negative influence on graft function.
2. **e.** A stented Lich-Gregoir ureteral reimplant has been shown to have the lowest complication rate in terms of urine leaks, urine obstruction, and hematuria.
3. **a.** The bladder is seen anterior to the uterus in the sagittal view and the vagina is actually filling with contrast. Contrast was retained in the vagina due to her narrowed introitus resulting from prior surgeries. At the time of her transplant the ureter was reimplanted into the vagina, and definitive management involves reimplantation into the bladder. Bladder distention typically aids in the identification of the bladder wall; however, in this case the maneuver could not be performed due to inability to place a catheter preoperatively. This patient underwent ureteral reimplantation and the VCUG (Case Fig. 44.2C) shows contrast traveling down the ureter and into the bladder. During the voiding phase contrast can be seen refluxing up her transplant ureter and left native ureter. Contrast is also pooling into her vagina. She was continent of urine following her reimplantation.

45 Complications of Conduit Urinary Diversion

ALEXANDER P. KENIGSBERG, JAMIE A. KANOFSKY, and SAMIR S. TANEJA

CHAPTER OUTLINE

Preoperative Considerations
Selection of Bowel Segment
Selecting the Length of Bowel
Selecting the Site of Stoma
Extracorporeal Versus Intracorporeal Laparoscopic Urinary Diversion
Complications
Conduit
Calculi
Malignant Disease
Bowel
Stoma
Parastomal Hernia or Prolapse
Stomal Stenosis
Ureterointestinal Anastomosis
Ureteroileal Anastomotic Leak
Anastomotic Strictures
Fate of the Kidney
Pyelonephritis and Renal Damage
Refluxing Versus Nonrefluxing Anastomoses
Double-barreled Wet Colostomy
Bacteriology of the Ileal Conduit
Other Potential Complications
Chapter 45 Questions and Answers

KEY POINTS

1. In performing radical cystectomy, the urinary diversion is the most common source of morbidity.
2. Careful selection of the bowel segment based upon mesenteric arcades is essential in avoiding bowel ischemia or bowel anastomotic leak.
3. In preparing the bowel, the distal mesenteric incision will provide the greatest length to the stoma in reaching the skin.
4. Stomal preparation prior to abdominal wall transposition may avoid stomal retraction.
5. Care of the stoma, stomal hygiene, and periodic inspection by an enterostomal therapist may help the patient avoid eventual stomal stenosis.
6. Both Bricker- and Wallace-style ureterointestinal anastomotic techniques can be associated with low morbidity, but a tension-free anastomosis with careful attention to ureteral vascularity is essential for success.

In 1851 Sir John Simon of London attempted open ureterosigmoidostomy in dogs. He reported that the operation was "almost always fatal, and it was plain that the peritoneum would be exposed to much hazard."[1] Although urinary diversion can be dated back to 1851, it was not until 1950 that Bricker[2] reported on the use of ileum for "bladder substitution after pelvic evisceration." Although ileal conduit is the simplest and most popular of diversions, complications are frequent.[3] The surgeon should discuss the options as well as the advantages and disadvantages of conduit and continent diversion with the patient well before the operative day. Critical factors to consider include the patient's age and performance status, manual dexterity, body habitus, motivation and desires, expected long-term functional status, bowel condition, bowel length, prior surgery or radiation, and renal reserve.

Construction of the urinary conduit carries the potential for a great number of unforeseen events. Complications can be divided into two categories, early (≤30 days of the surgical procedure) and late. The rate of early complications has been reported to range from 20% to 56%,[4] and such complications include intestinal obstruction, fistula formation, leakage from the ileal-ileal or ureteroileal anastomosis, wound infection, wound dehiscence, loop necrosis, and pyelonephritis. The incidence of late complications reportedly ranges from 28% to 81%,[4] and these complications include intestinal obstruction, pyelonephritis, renal deterioration, ureteroileal strictures and obstruction, stomal stenosis, parastomal herniation, calculi, metabolic abnormalities, and the development of carcinomas.

In evaluating quality of life issues, Turner and colleagues[5] found that 88–95% of patients were satisfied overall,

whereas 17–19% of patients were bothered by impaired body image. With regard to sexuality, 30% of patients reported decreased libido, whereas 20% felt less sexually attractive.[6] Hart and associates[7] reported frequent difficulty in caring for the collection device in 57% of their patients who had undergone ileal conduit procedures. Dutta and colleagues[8] found that 85% of patients undergoing ileal conduit would make the same choice of urinary diversion again.

The choice of urinary diversion remains controversial from a quality-of-life perspective. A 2005 meta-analysis by Porter and Penson[9] found insufficient evidence to conclude that one form of urinary diversion is superior to another. A more contemporary meta-analysis including five additional studies, three[11–13] of which demonstrated an improved quality of life among patients undergoing orthotopic neobladder rather than ileal conduit, led Ghosh and Somani to conclude that patients with orthotopic neobladder had significantly improved quality of life. An ileal conduit remains, however, an appropriate and often preferable option to orthotopic neobladder, due to individual patient preferences and selection considerations, such as renal function and a patient's ability to comply with neobladder maintenance.

In our experience, patients undergoing conduit diversion often experience a reduced quality of life, or depression, in the initial period following surgery, largely due to a perception of altered body image and limitation of normal routine activities. With time, individuals seem to adapt and by 1–2 years following the procedure, most patients do not greatly complain of any limitations or altered self-perception. Those individuals who have chronic difficulties in caring for the stoma, or experience poor appliance fit and urine leakage, will generally have a harder time adapting and remain depressed. Among patients with preoperative debilitation due to bleeding, pain, or voiding difficulties, conduit diversion may greatly improve quality of life and outlook, even in the early postoperative period.

Preoperative Considerations

Complications related to major intraabdominal surgery include those secondary to anesthetic, cardiac, pulmonary, and thromboembolic events. Prevention of such complications is discussed elsewhere in the text. Preoperative patient selection and proper evaluation by a cardiologist or pulmonologist may be necessary.

In today's age of managed care, most patients undergo bowel preparation at home. Wolff and colleagues[14] found little difference between aggressive antibiotic preparation and a minimal preparation of enemas, dietary restrictions, and mechanical lavage. This finding suggests that aggressive preparation can be safely avoided, thus reducing the risk of perioperative colitis. We routinely use a 2-day bowel preparation in which patients are started on a clear liquid diet 2 days before the surgical procedure. Magnesium citrate is prescribed for 2 days preoperatively along with two saline laxative (Fleet) enemas the night before the operation. Alternatively, 1 day preoperatively, patients are asked to drink ≤1 gallon of polyethylene glycol and electrolyte solution (GoLYTELY) until the stool is clear. The classic use of antibiotic preparation is discouraged.

SELECTION OF BOWEL SEGMENT

Based on early experience, the use of jejunum in urinary reconstruction has fallen out of favor. Although functional results are not significantly different from those seen with ileum, tremendous metabolic complications arise secondary to water and salt loss. Golimbu and Morales[15,16] used both canine and clinical models to evaluate jejunal conduits. These investigators reported on a series of 30 jejunal conduits used in patients with a history of prior radiation, multiple pelvic surgical procedures, or poor condition of the distal ureters, ileum, or colon. They found that the major complications with use of jejunum were electrolyte abnormality and water loss. However, the resulting hypochloremic, hyponatremic, and hyperkalemic metabolic acidosis, generally accompanied by dehydration, usually responded to increased salt and fluid intake. Despite these findings, jejunum is rarely used today because of the great consequences of fluid shifts, and this method should be considered only when no other option is viable.

The use of ileum and colon has similar functional and metabolic outcomes. In general, those patients with metabolic abnormalities are found to have hyperchloremic metabolic acidosis secondary to luminal bicarbonate loss and active hydrogen ion or ammonium reabsorption.[17] Factors influencing the severity of the metabolic abnormality include the contact time of urine and bowel (conduit length), the drainage of the conduit (adequate stoma), and the underlying renal function of the patient. Other metabolic conditions include encephalopathy from elevated ammonia, weakness from hypocalcemia, neuromuscular dysfunction from hypomagnesemia, and osteomalacia or growth delay in children. Patients with osteomalacia specifically develop bony pain, muscle weakness, decreased phosphate, increased alkaline phosphatase, and excess osteoid in the bone. The physiologic features and management of the metabolic abnormalities accompanying ileal or colon diversion are discussed in detail in Chapter 5. In general, the acidosis is easily treated by one of a variety of medications.[18]

Although functional and metabolic results of colon and ileal conduits are generally similar, Mogg[19] initially described the technique of the colon conduit to be superior to that of ileal conduit because of the thicker musculature, infrequent peristalsis, and the need for less intraperitoneal manipulation. In his review of 48 cases, Mogg found complications in 16 patients: four patients developed stones, two developed ureteral stenosis, eight had stomal ulceration, and two developed urinary peritonitis.

Morales and Golimbu[20] evaluated 46 colon conduits, of which 39 were constructed using transverse colon. In their study, these investigators observed a 15% mortality rate. Early complications included intestinal obstruction in three (6.5%), intestinal anastomotic leak in two (4%), and bilateral ureteral obstruction in one (2%). Late complications included acute pyelonephritis in eight (17%) and stomal prolapse in six (13%), with four (8.5%) of these patients requiring surgical repair. In addition, six patients (13%) had ureterointestinal anastomotic obstruction. In evaluating the patients' upper urinary tracts, 32% of normal kidneys showed deterioration postoperatively, 37% of preoperatively abnormal renal units improved, and 25% of preoperatively abnormal renal units deteriorated. The

investigators used an intraluminal nipple to achieve an antirefluxing mechanism, and no patient with antirefluxing ureters developed renal damage.

Complication rates with ileal conduit diversion have been similar to those observed with colon conduit. Jahnson and Pedersen[21] reported on 124 patients with ileal conduits followed for ≤20 years. Of the 124 patients, 48% had early complications including urine or intestinal anastomotic leaks, urinary or intestinal obstruction, wound dehiscence, infection, or cardiovascular misadventure. These investigators noted a 6% mortality rate in the perioperative period (four deaths from septicemia, two from myocardial infarction, and one from uremia). Jahnson and Pedersen also found an association between preoperative radiation therapy and the rate of wound infection. In addition, the investigators reported a late complication rate of 52%, including 22% of patients with ureteroileal obstruction or stricture.

Singh and associates[22] evaluated 93 patients undergoing ileal conduit for benign disease and looked at the complication rate after an average of 5 years. These investigators reported a mortality rate of 2.1%. Complications again were related to the stoma (31%); 10% of patients developed a parastomal hernia, and 4.3% developed stomal retraction and stenosis. These investigators reported complications of the ureteroileal anastomosis in 7% of the patients. In addition, 34% of patients had upper urinary tract dilatation, 10% with bilateral changes.

More recently, Shimko and associates[23] evaluated the records of 1057 patients who had undergone radical cystectomy with primarily ileal conduit diversion (1.1% received colon) with a median follow-up of 6.3 years. They found an average of 2.3 complications per patient, occurring at a median of 1.1 years postoperatively. Patients developed bowel complications in 20.3% of cases, 20.2% had renal complications, 13.9% developed a parastomal hernia, 2.1% developed stomal stenosis, and 9% of patients required a reoperation. The authors also noted that stone-related complications occurred in 15.3% of patients who underwent conduit diversion.

In general, it appears that ileal and colon conduit diversions have similar outcomes. Because of the technical ease of ileal diversion, this remains the segment of choice. The decision to use colon is usually based on the condition of the ileum or distal ureters as a result of pelvic irradiation or prior surgical intervention, the length of ureter resected at the time of operation, or the presence of inflammatory bowel disease in the terminal ileum. When the surgeon performs en bloc resection of the colon or rectum, a sigmoid colon conduit may eliminate the need for two bowel anastomoses, or any anastomosis if a colostomy is to be constructed. Finally, if an upper abdominal stoma is required, the transverse colon can be used to reduce the technical difficulty associated with bowel mobility. In patients undergoing colon conduit, barium enema should be adequate to rule out the possibility of colonic malignant disease or other abnormalities. In patients undergoing ileal diversion, barium enema is not necessary, but it may be helpful in ruling out potentially obstructive distal abnormalities.

An effort is underway to reduce concerns regarding bowel-related complications of urinary diversion through tissue engineering. Bivalacqua and colleagues[24] have demonstrated successful implantation of tissue-engineered neourinary conduits (NUC), produced by seeding smooth muscle cells onto a PLGA scaffold, in a porcine model. As a result of these promising results, multicenter phase I trials are underway to assess the safety of NUC in humans. Many questions regarding the use of tissue-engineered conduits remain, however, including which materials are best used to construct these conduits, and which surgical techniques are best utilized to maintain conduit blood supply and patency.

SELECTING THE LENGTH OF BOWEL

As mentioned previously, the length of bowel used can be a critical determinant of the severity of metabolic abnormality associated with the pouch. A length of 10–12 cm serves as a general guideline. In obese patients with a large amount of abdominal wall to traverse, a longer segment should be isolated. Lengthening and mobilizing the distal conduit can be achieved either through aggressive division of the mesentery (with care taken to preserve the proximal ileocolic branch) or, as a preferred method, resection of a segment of bowel immediately distal to the conduit (Fig. 45.1). Another option in the management of a short distal mesentery is the use of a Turnbull loop stoma. In this technique, a "knuckle" of the distal conduit is brought through the fascial opening. The antimesenteric border is incised, thus allowing circumferential maturation without any tethering from the distal mesentery.

The surgeon should pay careful attention to the anatomic lie of the conduit after maturation of the stoma. The intraabdominal portion of the conduit should be relatively straight, with no kinking or twisting to impair luminal drainage. A red rubber catheter left in the length of the conduit can allow the conduit to heal in a straight fashion.

In individuals with a thin abdominal wall or small body habitus, as short a segment as possible should be used. Preserving good length of the ureters can allow the ureterointestinal anastomoses to "rise" along the lateral abdominal wall and can thereby minimize the intraabdominal length of the conduit. Tension on the ureteroileal anastomoses can be avoided by fixation of the proximal segment of the conduit to the sacral promontory or by a lateral retroperitoneal incision.

In patients with impaired renal reserve, as noted by elevated serum creatinine concentration or creatinine clearance <50 mL/minute, the surgeon should make every effort to limit the conduit to as short a length as required by the abdominal wall thickness. Although cutaneous ureterostomy is an option in patients with renal insufficiency, it is generally preferable to interpose at least a short segment of bowel to avoid the stomal retraction and stenosis seen in cutaneous ureterostomy. Even with significant renal impairment, the patient should have only limited worsening of renal function if the conduit is constructed with the intention of keeping the transit time of urine as short as possible.

SELECTING THE SITE OF STOMA

Selection of the stoma site is probably the most important preparatory step for conduit surgery. Ultimately, the stoma predicts the long-term success or failure of the operation.

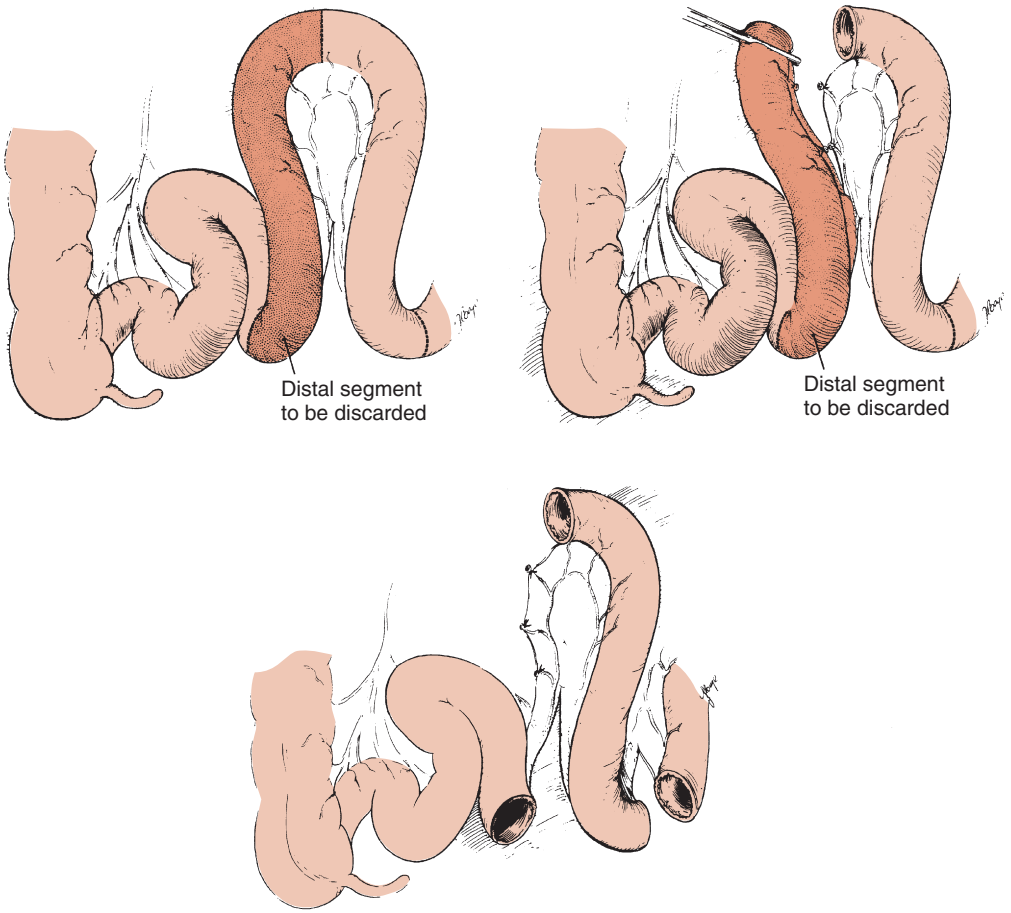

Figure 45.1 Daniel's technique of discarding the distal half of the loop in creating an isolated segment. (From Ehrlich R. Ileal conduit. J Urol. 1973;109:994.)

The position of the stoma should be marked preoperatively to ensure adequate fit of the stomal appliance and ease of stomal care on the part of the patient.

Marking of the stomal site should be done with the patient lying down, sitting, and standing, with an attempt to find a flat area on the abdomen. A permanent marking pen or subcutaneous puncture with a needle can be used to mark the planned stoma site preoperatively. Care must be taken to avoid the belt line, abnormal skin creases, and deformities such as scars, bony prominences, valleys, or ridges. Patients should be given the option of wearing a simulation stoma preoperatively, and the surgeon should evaluate the patient carefully to ensure adequate manual dexterity. The stoma should be within the rectus muscle, generally below the umbilicus, on top of the infraumbilical fat mound, and it should be well within the patient's visual field (Fig. 45.2).[25]

On rare occasions, a supraumbilical site should be chosen to avoid a protuberant abdomen. This allows the patient to see the stoma clearly and to change the stoma appliance. If such a site is chosen, the conduit is generally brought completely into a retroperitoneal location behind the right colon. The mesentery of the isolated segment can be placed in a retrocolic position or brought through the right mesocolon to place the conduit in the right paracolic gutter. Alternatively, a transverse colon conduit can be used.

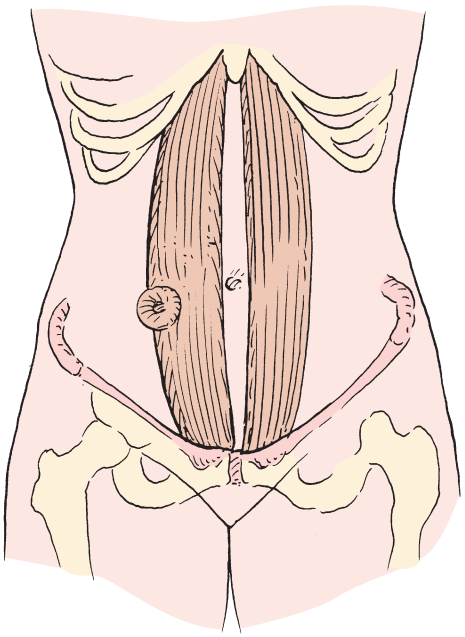

Figure 45.2 Stomal placement. Ample margins from adjacent protuberances and deformities are imperative.

Before entering the operating room, the patient must be adequately prepared for the future conduit and its care. The advent of stomal therapists in the 1950s greatly reduced the incidence of stomal complications and permanent defects.[4] When evaluating whether preoperative teaching and marking had any benefit, Bass and colleagues[26] found that those patients who received preoperative teaching had fewer total stomal complications (32.5%) compared with patients who had no preoperative teaching (43.5%). Thus, we strongly encourage that all preoperative teaching and stomal marking be performed by an enterostomal therapist.

EXTRACORPOREAL VERSUS INTRACORPOREAL LAPAROSCOPIC URINARY DIVERSION

With the expansion in use of robotic laparoscopic techniques, many surgeons are choosing to perform radical cystectomy robotically, a practice that consensus guidelines have deemed a reasonable alternative to open radical cystectomy.[27] Early robotic-assisted radical cystectomy (RARC), as described by Menon and colleagues,[28] utilized extracorporeal techniques for construction of the urinary diversion, primarily as a way to limit operative time. Initial studies evaluating the safety and efficacy of intracorporeal urinary diversion (ICUD) showed high rates of complications associated with ICUD relative to extracorporeal urinary diversion (ECUD),[29] largely attributed to the learning curve, which led many surgeons to continue using extracorporeal techniques.

Subsequent investigations into use of intracorporeal techniques for the construction of urinary diversions have been more promising. Ahmed and colleagues from the International Robotic Cystectomy Consortium (IRRC)[30] studied 167 patients who had undergone ICUD, 106 of whom were given an ileal conduit. Compared with a group of 768 patients who had undergone ECUD, patients undergoing ICUD had comparable operative times. The authors also found that patients who had undergone ICUD had significantly fewer postoperative complications at 90 days and also significantly fewer postoperative gastrointestinal complications, such as ileus. They also noted a lower rate of readmission at 30 and 90 days, but acknowledged, however, that there was likely a selection bias for patients in the ICUD arm of the study.

Koupparis and colleagues[31] were able to replicate these encouraging findings in their own patient cohort. Their study demonstrated lower complication rates for patients with ICUD than for those with ECUD (31% vs 48%). They also evaluated recovery times from the procedures, finding that patients with ICUD had significantly shorter hospital stays than those who underwent ECUD (8 vs 13 days). The length of stay in this case may reflect geographic variation in hospitalization practices. In our experience, uncomplicated open cystectomy and ECUD results in a typical hospitalization of 4–6 days, with an occasional range of up to 10 days among patients experiencing significant ileus. Whether reductions of length of stay can truly be achieved with ICUD remains controversial and is likely heavily influenced by regional variations in surgical approach, experience, and care pathways.

With possible advantages to ICUD, particularly in terms of length of hospital stay, fluid loss, and complication rates, the matter of the learning curve becomes quite important for surgeons considering use of the technique. Desai and colleagues[32] conducted ICUD on 37 patients and evaluated and found a significant decrease in console time between the first nine and last 10 cases in which the procedure was performed. Others[33,34] have reported the learning curve for intracorporeal techniques to be 30 cases.

Ultimately, many questions remain about the benefits and safety of ICUD. While recent studies have yielded encouraging results, prospective trials will be useful toward determining whether ICUD or ECUD will yield the more favorable postoperative complication profile. Ultimately, it may be difficult to separate the effects of laparoscopic cystectomy from ICUD in evaluating length of stay and complication rate, with the exception of evaluating those complications specific to the diversion.

Complications

CONDUIT

Necrosis of the conduit is a rare but disastrous complication. It invariably results from acute ischemia of the conduit, usually secondary to mesenteric injury, twisting, or an inadequately identified blood supply. In the early postoperative period, it is not unusual for the stoma to appear dusky. This discoloration is often caused by venous congestion arising from compression of the segment by local edema above the fascial opening. Within a few days, this phenomenon usually resolves. Drainage is maintained by use of a red rubber catheter inserted beyond the level of the fascia and brought out through the stoma. The red rubber catheter can usually be removed 48 hours postoperatively.

When selecting a bowel segment, the surgeon should identify a clear arterial supply that will be preserved following mesenteric division. This should be separate from the ileocecal artery to maintain blood supply to the bowel anastomosis. The mesentery should be handled carefully, and while the conduit is positioned, no twist or stretch of the mesentery should be present. In closing the mesenteric defect above the conduit, the surgeon should avoid laceration or incorporation of the arteries within the conduit mesentery.

Acute necrosis of the conduit usually manifests with a dusky, oozing stoma and may be accompanied by metabolic acidosis, hyperphosphatemia, or early shock. Alternatively, the patient may not be ill, but the dusky appearance of the stoma may persist for several days postoperatively. In cases of severe acidosis despite a normal-appearing stoma, one should consider a subfascial segmental infarct of the conduit, which can occur on rare occasions. The usual course of action consists of early exploration with resection and replacement of the conduit or diseased segment. Chronic ischemia of the conduit can occur and usually results in a rigid, poorly compliant conduit or stomal stenosis. Chronic ischemia may manifest with upper urinary tract dilatation resulting from poor drainage of the conduit. In this case, surgical intervention with repeat diversion is usually indicated.

Calculi

The incidence of calculi formation in patients with ileal conduits is 5–20%.[35–37] These calculi are usually renal in

origin, but stones can also form within the conduit itself. Of note, Gilbert and colleagues[38] found a lower incidence of urolithiasis among patients who received a conduit urinary diversion relative to those with continent urinary diversion. The proposed mechanism of stone formation involves a combination of urinary stasis, contact with bowel, and infection, and reduced urinary stasis could help explain Gilbert and associates' findings. Delayed or incomplete emptying of the conduit allows for longer contact times between urine and the intestinal mucus. This situation results in enhanced and increased chloride and bicarbonate exchange, with subsequent metabolic acidosis. Hypercalciuria develops as the bone-buffering mechanisms try to correct the acidosis. When hypercalciuria occurs in the presence of alkaline urine, stone formation is favored. Additionally, infections with urea-splitting organisms release ammonia and may facilitate chloride-bicarbonate exchange and further stone formation.[37,39] Prevention of calculus formation is usually directed at serum alkalinization with bicarbonate (Sholh's solution) or potassium citrate (Urocit-K), prevention of residual urine (catheterization as needed), prevention of infection with urea-splitting organisms (antibiotics), urinary acidification agents (vitamin C), and thiazides to enhance proximal tubular calcium reabsorption.

In addition, stones have been reported to form from retained staples or nonabsorbable sutures. Thus, the surgeon should make an effort to exclude or excise all staples from the bowel lumen during construction of the conduit. The distal staple line of the resected bowel should be completely excised, and the proximal staple line can be excised or excluded from the lumen using Parker-Kerr sutures (a running horizontal mattress stitch) of 2-0 polyglactin 910 (Vicryl). On rare occasions, a staple may erode into the conduit lumen and may cause stone formation.

Upper tract calculi may be treated with extracorporeal shock wave lithotripsy, percutaneous nephrolithotomy, or retrograde techniques, if access is possible. Extracorporeal shock wave lithotripsy may be difficult to perform because these stones are usually infectious, large, and difficult to clear. Cohen and Streem,[40] however, reported a 95% success rate with extracorporeal shock wave lithotripsy (occasionally, second therapy was needed). Percutaneous nephrolithotomy has a success rate of 100% and is the method of choice for large renal calculi.

Calculi that develop within the conduit may be treated with endoscopic techniques employing laser lithotripsy. Access can be obtained with a flexible cystoscope or, in larger conduits, with pediatric endoscopes. Stones arising from an exposed staple or staple line should be broken prior to the attempt to extract, in order to avoid perforation of the adherent bowel wall. The causal factors in conduit stone formation must also be investigated, and any staples should be removed endoscopically if they are identified.

Malignant Disease

Carcinoma within the conduit has been reported since the development of urinary diversions. The first case of ureterosigmoidostomy-associated cancer was reported in 1929, and the incidence of cancer following ureterosigmoidostomy has been reported to range between 6% and 29%.[41] In fact, the risk of developing adenocarcinoma after ureterosigmoidostomy is 400 to 7000 times that of the general population. Husmann and Spence[41] found that 26 years after diversion, 70% of patients had developed adenocarcinoma. However, the rate of carcinoma developing within colon and ileal conduits is <1%.[42] Since 1950, four cases of adenocarcinoma developing in an ileal conduit have been reported.[43,44] The rarity of these cases is likely, in part, the result of the infrequency of primary small bowel tumors.

The origin of adenocarcinoma in bowel conduits is unclear. Gittes[45] found that carcinogenesis of ureterosigmoidostomy depended on the presence of urine, feces, urothelium, and a healing anastomotic suture line. He assumed that the use of bowel segments interposed into the urinary tract would not lead to tumor formation in the absence of feces. This theory has since been challenged. Other hypotheses include chromosomal abnormalities, *N*-nitrosamines, oxygen free radicals, infection, and chronic inflammation. Malignant transformation in these cases may also be an early event.[42]

Three cases of carcinoid tumor arising in an ileal conduit have also been described in the literature.[46,47] Transitional cell carcinoma developing in the conduit has been reported as early as 9 months postoperatively. Mulholland and coworkers[48] reported finding grade 2 transitional cell carcinoma arising from the bowel mucosa at a site completely separate from the ureter. In any patient undergoing creation of an ileal conduit, the upper urinary tracts must also be followed as well because of the 2–9% rate of upper urinary tract transitional cell carcinoma following cystectomy.[49]

BOWEL

Bowel complications occurring after conduit surgery are generally related to the ileal resection and anastomosis. When constructing an ileal conduit, the surgeon selects a segment approximately 10–15 cm proximal to the ileocecal valve. Despite preservation of the terminal ileum, malabsorptive syndromes can arise, particularly if long segments of bowel are resected. Diarrhea in the early postoperative period is often the result of prolonged antibiotic use and bile salt malabsorption. This complication generally improves spontaneously in ≤4–6 weeks. The patient should be encouraged to drink fluids liberally and should avoid the use of motility-suppressing agents. A culture for *Clostridium difficile* should be obtained. In rare cases of severe or persistent diarrhea, oral cholestyramine can be used to form bulk and decrease transit time.

Vitamin B_{12} deficiency can arise from poor absorption following ileal resection. Levels should be monitored periodically starting 6–12 months postoperatively. Individuals developing anemia at prolonged intervals following surgery should be evaluated for vitamin B_{12} deficiency.

Anastomotic leak, bowel obstruction, and ileus are common problems following ileal diversion and are discussed in detail in Chapter 11. Early recognition is paramount in avoiding the necessity for bowel resecting or ileostomy.

STOMA

Construction of the stoma is perhaps the most critical aspect of conduit surgery because the stoma is the most

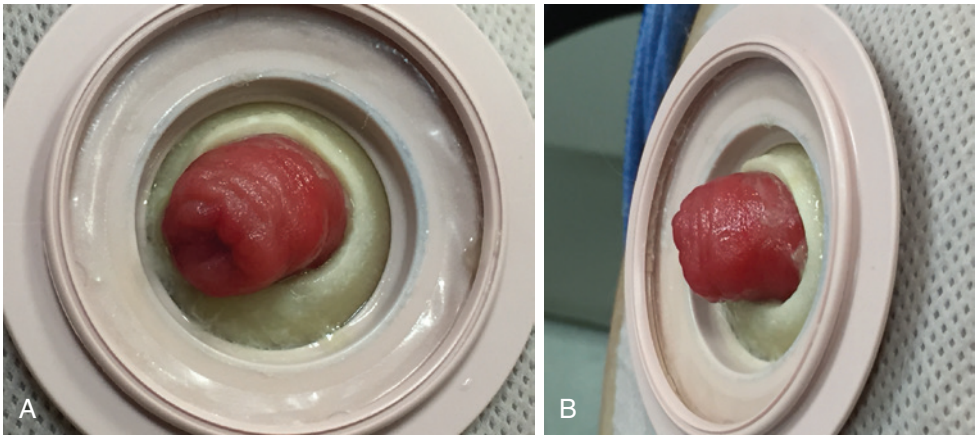

Figure 45.3 Properly constructed ileal stoma with (A) good appliance fit. B, The stoma protrudes approximately 1.5–2.0 cm from the abdominal wall, allowing proper fit of the stomal appliance. Less than 1/8 inch of skin is exposed circumferentially. The stoma protrudes into the appliance.

likely site of complication. In addition, the stoma greatly influences the patient's quality of life. Preparation of the stoma site, transposition of the bowel segment through the abdominal wall, and maturation of the stoma should be carried out with great caution and meticulous attention to detail. In patients in whom a conduit will undoubtedly be constructed, preparation of the stoma site can be carried out before the midline incision is made. This technique allows the surgeon to align the abdominal musculature in anatomic position with the skin opening, to use the preoperatively marked stoma site without confusion, and to be fresh and alert at the time of site preparation.

Regardless of surgical technique, the essential points of stomal preparation include an abdominal wall opening that can accommodate the conduit without ischemia but is snug enough to provide support, passage through the rectus sheath to avoid herniation next to the stomal opening, and adequate protuberance and maturation of the stoma to ensure good fit of the appliance (Fig. 45.3) Although a comprehensive discussion of technique is beyond the scope of this chapter, those points critical in preventing complication are discussed.

Early complications relevant to the stoma are generally related to poor vascularity, as discussed earlier. Delayed or late complications of the stoma are common, and these include parastomal hernia and prolapse, stomal retraction, local dermatitis, and stomal stenosis. As a result, stomal complication is the most common cause of reoperation after conduit surgery. In Bricker's[50,51] evaluation of the complications of 543 ileal conduits, stomal complications were responsible for reoperation 26% of the time. Cass and associates[52] found that 57% of all reoperations were for stomal problems. Klein and colleagues[53] from the Cleveland (Ohio) Clinic reported their results and noted a 5% overall stomal revision rate. These investigators also found no difference in the complication rates when they compared end stomas with loop stomas.

Cheung[54] analyzed 322 stomas, of which 123 were ileal conduits. The overall complication rate from the stoma alone was >60%, and transverse colostomy had the highest rate of complications at 73%. The overall rate of stomal complications with ileal conduits was 62.6%. With an average 6 years of follow-up, Cheung identified stenosis in 7.3%, parastomal hernia in 27.6%, prolapse in 4.1%, and excoriation in 20.3% of his patients. The average time to stenosis was 128 months, whereas the average time to herniation was 22 months; 23% of all stomal hernias occurred within the first year.[54]

Parastomal Hernia or Prolapse

The reported incidence of clinically evident parastomal hernia ranges from 4.5% to 13.9%[55] for ileal conduit surgery, although the rate of radiographically diagnosed parastomal hernia has been reported to be as high as 50% 2 years postoperatively.[56] Potential contributing factors include obesity, wound infection, chronic cough, steroids, malnutrition, and abdominal distention. Most patients are asymptomatic, but 10–20% may have symptoms, including pain, poor-fitting appliances, poor cosmesis, and potential bowel strangulation.[57] Early studies indicated a higher rate of parastomal hernia in patients receiving an end ileostomy rather than a loop ileostomy. Subsequent analyses have shown similar rates of parastomal hernia between the two methods.[53,56]

Parastomal hernias arise when a gap exists between the intestinal segment forming the stoma and the surrounding tissue.[58] The fascial defect may be created by tangential forces working on the circumference of the opening that can stretch the fascia.[57] Most commonly, incorrect placement of the stomal opening lateral to the rectus fascia results in gradual opening of the surrounding fascia. Sjodahl and colleagues[58] evaluated 130 patients with intestinal stomas and found the incidence of parastomal hernia to be 2.8% in patients with stomas brought through the rectus muscles compared with 21.6% in patients whose stomas were placed lateral to the rectus muscles. In the operating room, the surgeon should note that the entire fascial opening is within the body of the rectus sheath. Creating the fascial opening before making the midline incision can assure the surgeon that all fascial layers are aligned. Placement of reinforcing sutures between the bowel serosa and the posterior layer of the abdominal fascia can be considered (in either interrupted or continuous fashion), but it is unclear if this reduces stomal hernia incidence. If done, care should be exerted to ensure no kinking or obstruction of the conduit lumen occurs, and that the placement of

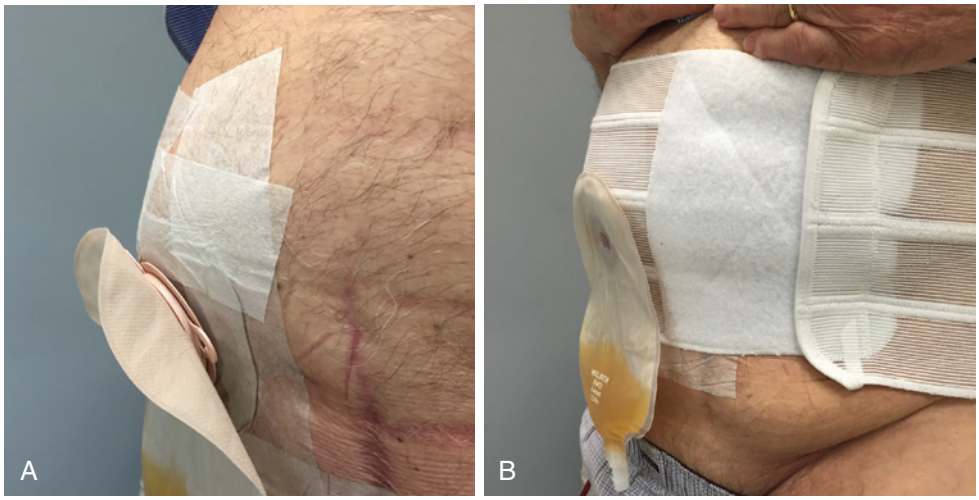

Figure 45.4 A patient with a largely asymptomatic parastomal hernia (A), which is not resulting in any stomal retraction or difficulty with appliance, and no proximal obstruction or pain. (B), A stomal belt and abdominal binder can aid in preventing progession of the hernia and discomfort during activity.

sutures in the posterior fascia does not cause stomal retraction at the skin level. In general, if such sutures are to be placed, they should be placed 3–4 cm proximal to the stomal maturation.

Repair of parastomal hernias can be difficult and should be attempted only if the patient is symptomatic. Conservative options include support belts or appliances to keep the hernia reduced and appliances that eliminate the need to repair the hernia operatively (Fig. 45.4). Surgical options can become complicated and include relocating the stoma to a new site or repairing the fascial defect, either primarily or with the use of synthetic material. The surgeon should realize, however, that untreated parastomal hernias usually worsen, and earlier repair may be technically easier.

Rubin and associates[59] reported on 94 parastomal hernias repaired surgically. These investigators found a 76% incidence of recurrence after fascial repair compared with a 33% incidence after stomal relocation. For patients with recurrent parastomal hernias, fascial repair with synthetic material had the lowest recurrence rates (33%). Overall, 72% of patients developed additional abdominal hernias at the old stoma site, recurrent parastomal hernias, or herniation at the laparotomy incision site. The morbidity associated with surgery was also high; 63% of patients had at least one postoperative complication. These investigators concluded that parastomal hernia is rarely life threatening, and repair should be avoided if possible because of poor success rates and high rates of morbidity and recurrence.

In another approach to repairing parastomal hernias, reported by Kaufman,[60] the stoma is relocated without a laparotomy incision. The stoma is dissected off the skin and is dissected to its base. Any adhesions are freed. A cruciate incision is made on the patient's contralateral side, and the stoma is delivered to this new site with the use of long sponge forceps and dissection from the herniated side. Such an approach is somewhat blind, and the surgeon should exercise caution in selecting patients with minimal intra-abdominal reaction or adhesion.

A technique described by Leslie[61,62] uses a suprafascial synthetic wrap to close the hernia defect. A skin flap is elevated from medially to laterally to expose the underlying fascia for 10–15 cm circumferentially around the stoma. The stomal skin is left intact. The fascial defect is exposed, the peritoneum is opened, and the conduit and fascial edge are freed from all intraperitoneal contents. The fascial defect is then closed directly or with interposed absorbable mesh. Once the fascia is closed, nonabsorbable mesh is wrapped around the bowel segment and is tacked only to the fascia, approximately 8–10 cm away from the conduit. Slight overlap of the edges allows the protuberance of the stoma to be retained by gathering up the bowel centrally. The synthetic material used should be chosen carefully and should not be tacked to the bowel because it has the potential to erode into the conduit over time. Gore-Tex appears to be the material of choice.

The role of prophylactic mesh to reduce the incidence of parastomal hernia is a relatively new field of investigation with promising early data, primarily from the general surgery literature.[63–66] Investigations into its applications in the context of conduit urinary diversion are limited. Styrke and colleagues[67] conducted a 10-year case study in which they placed mesh anterior to the peritoneum, not anchored by sutures, in 114 consecutive patients receiving ileal conduits. Parastomal hernias were noted in 14% of patients at mean follow-up of 35 months, with no mesh-related complications in any of the patients. Donahue and colleagues[68] offered prophylactic mesh to 40 patients with a BMI >30, finding a radiographic parastomal hernia rate of 18%, but a clinically apparent parastomal hernia in one patient and no mesh-related complications. Prospective studies, which are currently underway, are necessary to determine whether prophylactic mesh is safe and effective and stratify the patients for whom it is most appropriately used.

In considering use of therapeutic or prophylactic mesh placement, caution should be exerted to avoid direct contact of the mesh edge with bowel serosa. A concern remains, in our view, for mesh erosion into the conduit lumen over time, and long-term follow-up of the previously discussed studies is critical before widespread adaptation of the approach.

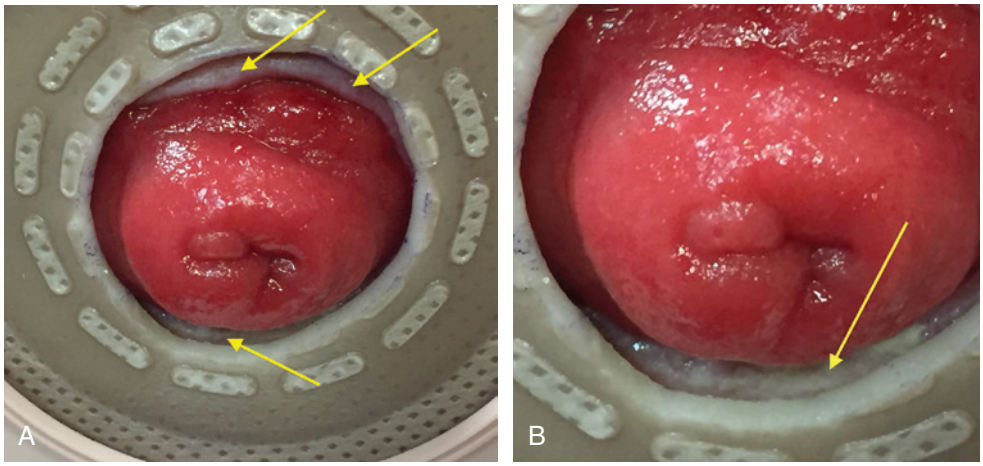

Figure 45.5 A poorly fitting stomal appliance, either due to improper preparation of the wafer or flattening of the stoma, results in (A) exposure of the surrounding skin (yellow arrow) to urine pooling and, ultimately, (B) hyperkeratotic changes (yellow arrow). These changes precede eventual stomal stenosis.

Stomal Stenosis

Stomal stenosis has a reported incidence of from 0.7%[55] to 19%. Frazier and associates[69] reported on 675 cases performed at Duke University (in North Carolina) in the 1970s and 1980s. These investigators found a 2.8% incidence of stomal stenosis. Factors contributing to the development of stomal stenosis include fascial or muscular constriction, ischemia of the stoma, shape and retraction of the stoma, alkaline urine, hyperkeratosis, and local skin changes.

The most common pathophysiologic features of stomal stenosis usually start soon after the surgical procedure. Poorly fitting appliances, often the result of stomal retraction, can cause skin ulceration and irritation that can eventually lead to hyperkeratosis of the local skin (Fig. 45.5). This complication ultimately results in stenosis (Fig. 45.6). Additionally, leaking of the stoma underneath the appliance can cause local skin irritation (Fig. 45.7A) and superficial excoriation (Fig. 45.7B).

Alternatively, stenosis can occur at the level of the fascia in response to an inadequate opening, which over time may result in kinking of the conduit. Abdominal wall muscular spasm in patients with neurologic disease can cause a similar situation. This complication usually responds to antispasmodic medications. When stomal stenosis exists, it can start a cascade of events leading to obstruction, dilatation with reflux, urinary tract infection, sepsis, and renal damage.

When fashioning the stoma, the surgeon must assess for adequate blood supply and adequate mucosal nipple above the skin to guarantee proper fitting of the appliance. The matured stoma should extend 1–2 inches above the skin edge for proper appliance fit. If the stoma is too long, this can impair drainage within the bag. Appliances should be no more than 1/16 to 1/8 inch larger than the stoma to minimize urine contact with the skin. Proper maturation of the stoma and selection of the appropriate site for stomal placement are the most critical factors in determining the success of the stoma.

The presence of a bulky mesentery can prevent proper maturation of the stoma. Placement of maturing sutures in positions directly next to the mesenteric edge can allow the

Figure 45.6 Terminal stomal stenosis (arrow).

distal bowel edge to fold over the mesentery. Ligation of ≤5 cm of the distal mesentery to prevent bowing of the stoma has been advocated by some investigators, but it does have the increased risk of stomal devascularization and associated problems and is not usually necessary. *Defatting,* or removal of excess lateral fat from the edge of the mesentery, can be performed by gently teasing away the fat along the bowel wall. Care must be taken to avoid laceration of the mesenteric vessels that lie centrally within the mesenteric fat. The tendency to tuck excess mesentery beneath the skin edge should be avoided because it creates a large mound next to the stoma and causes difficulty with the fit of the appliance.

Anchoring the conduit to the rectus fascia to prevent stomal retraction is controversial. In general, if no tension is present on the intraabdominal portion of the conduit, no retraction should occur. Obesity and postoperative distention can obviously affect this situation. We place two to three sutures from the edge of the anterior rectus fascia opening to the seromuscular layer of the conduit as it passes

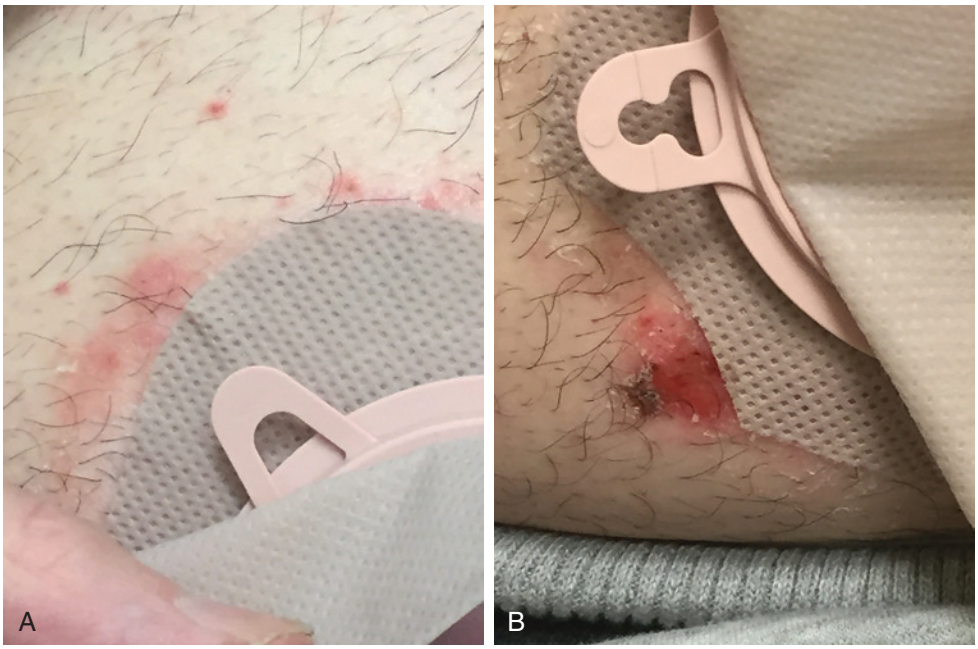

Figure 45.7 Leakage of urine beneath the stomal appliance can lead to local skin irritation: (A), superficial skin irritation, and (B), excoriation.

through the fascia. Additional sutures can also be placed in the posterior rectus sheath. These stitches should not be under traction or they may risk bowel wall ischemia.

We reported a modified technique of stomal maturation before abdominal wall transposition of the conduit or stoma.[70] We observed that this modification allows more symmetric eversion, tension-free anastomosis, and less likelihood of stomal retraction. Since the initial report in 2009, we have institutionally adhered to the "Taneja technique" of stomal maturation. The technique is begun by defatting the distal 4 cm of mesentery to allow circumferential eversion of the stoma using four seromuscular sutures (Figs. 45.8 and 45.9). The bowel intussusception is locked in place with through-and-through sutures from the lumen to the external stomal surface, and the mesentery is then tucked under the everted bowel edge to ensure that no retraction of the stoma occurs along the axis of the mesentery (Fig. 45.10A). Finally, the matured edge of the intussusception is anchored to the dermis circumferentially while sutures from the fascial edge are placed to the seromuscular layer 2–3 cm proximal to the matured edge of the stoma to prevent retraction (Fig. 45.10).

Hyperkeratosis is characterized by thickening and hardening of the skin and proliferation of the epithelium. This complication can be treated with catheter drainage to avoid urinary contact with the skin, in combination with the application of a heat lamp 12 inches from the skin twice daily. External beam radiation therapy has also been reported to be beneficial in severe cases of hyperkeratosis.[48,71] Bacterial and fungal infections can initiate stomal deterioration. Continued exposure to alkaline urine can cause stomal encrustation, stomal epithelialization, and eventual stomal stenosis.[25,72] Treatment options include 500 mg of vitamin C four times a day or 0.25% acetic acid washes twice a day. Early local skin care accompanied by urinary acidification is essential to prevent progression of the problem and can often reverse it. If combined with significant stomal retraction, early revision with excision of the hyperkeratotic skin may be advisable.

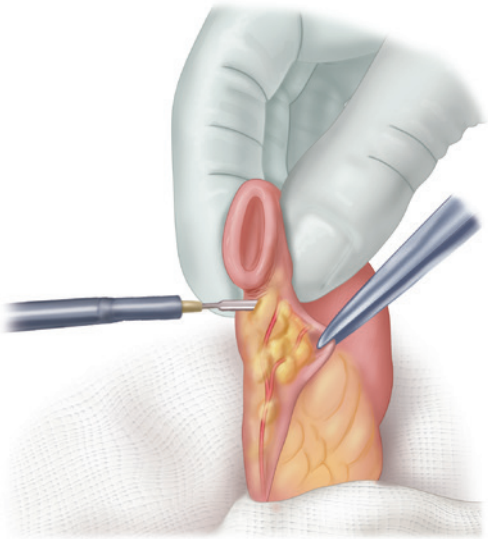

Figure 45.8 The Taneja technique of stomal maturation. Technique of mesenteric defatting. The thickness of the mesentery is reduced by excising excess fat, but the central vascular arcades are preserved.

The techniques for surgical revision of a stenotic or retracted stoma are many. In general, repair can be performed locally through a circumscribing incision at the stoma site (Fig. 45.11). The conduit wall is identified in the subdermal tissues, and the conduit is then freed completely to the level of the fascia. Great care should be exercised in avoiding the mesentery of the bowel. The fascia is freed from the conduit wall, and the bowel is then mobilized intraperitoneally. Extensive conduit length can be achieved in this fashion. The distal stenotic segment of the stoma is then excised along with hyperkeratotic local skin, and rematuration of the stoma is performed (Fig. 45.12). To

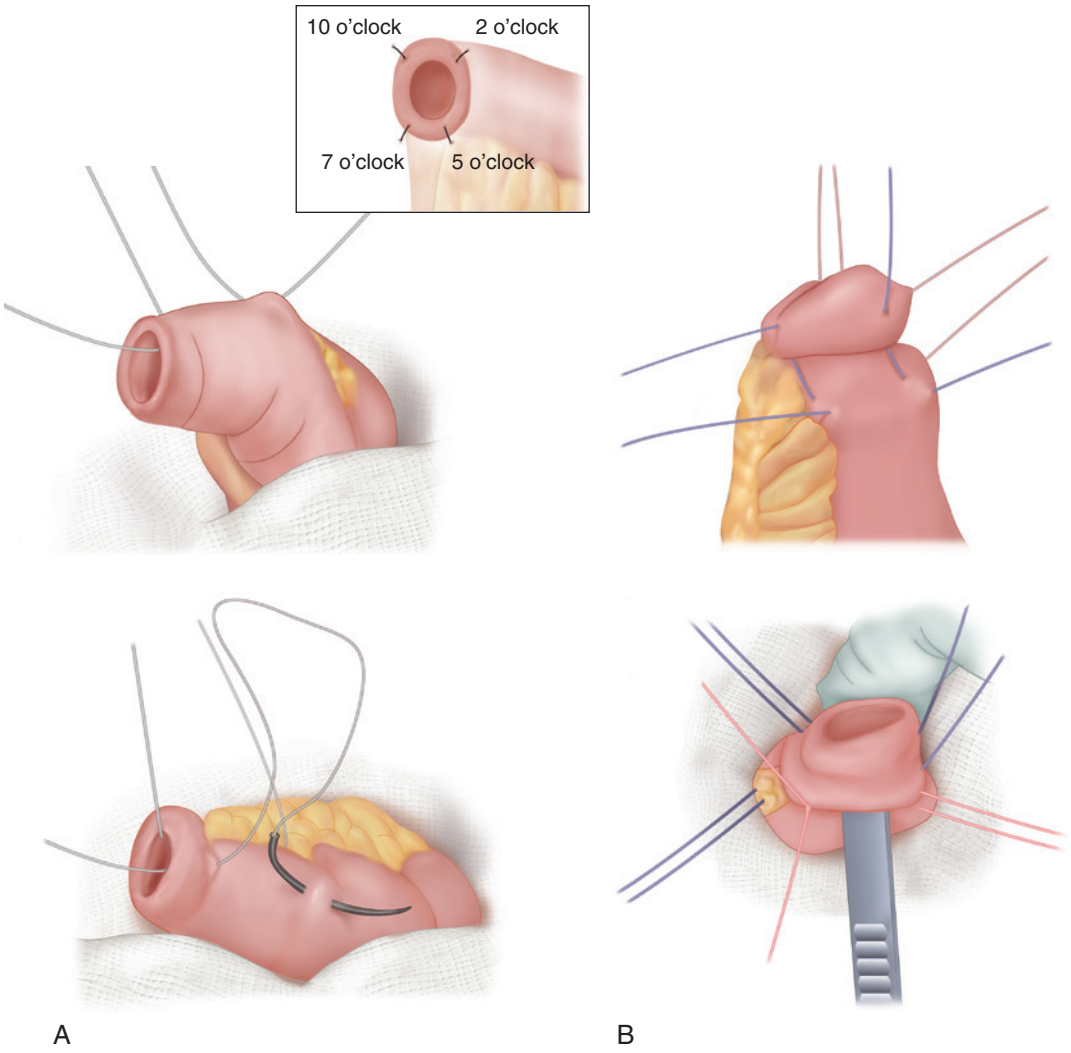

Figure 45.9 The Taneja technique of stomal maturation. A, Creation of stoma by mucosal eversion and distal bowel intussusception. Sutures are placed from the cut bowel edge to the seromuscular layer approximately 4 cm proximal to the edge. B, If one considers the mesenteric position at 6 o'clock, the everting sutures are placed at 2, 5, 7, and 10 o'clock to maximize eversion to the mesenteric edge and to avoid the necessity for suture placement in the mesentery.

facilitate intraperitoneal mobilization, the fascial opening can be extended, but careful closure must then be performed to avoid subsequent herniation.

Alternative techniques of dealing with an incomplete stenosis involve incision of the stenotic ring with either direct reanastomosis to the skin or rotation of a secondary skin flap into the defect (Figs. 45.13 and 45.14). The shortcoming of these techniques is that they do not address the problem of stomal retraction. On rare occasions, full laparotomy is required to achieve adequate conduit length for stomal maturation. A preoperative loopogram can provide critical information in determining the intraperitoneal availability of redundant conduit.

URETEROINTESTINAL ANASTOMOSIS

During mobilization of the ureter, preservation of the periureteral adventitia is essential to ensure adequate blood supply to the ureter. Before creating the anastomosis, the surgeon must ascertain adequate length from each ureter. In addition, when placing the stoma on the right, the surgeon must pass the left ureter beneath the sigmoid mesocolon with gentle angulation and must be careful to avoid kinking the ureter. These are the basic tenets of constructing the ureterointestinal anastomosis.

Numerous anastomotic techniques exist, and to a large extent, the segment of bowel used, the dilatation of the ureters, and the preference of the surgeon are the deciding factors. Bricker's[2] initial description of the ureteroileal anastomosis employed an end-to-side (ureter-to-bowel) approach with wide spatulation of the ureter. Wallace[73] subsequently reported an end-to-end anastomosis in which the two ureters were converted to a single lumen and were anastomosed to the proximal end of the bowel. Creation of an adequately sized well-vascularized lumen, mucosa-to-mucosa apposition with watertight closure, and sufficient mobilization of the ureter to reduce tension on the anastomosis are necessary. Ultimately, the comfort of the surgeon with an individual technique is likely the greatest predictor of success.

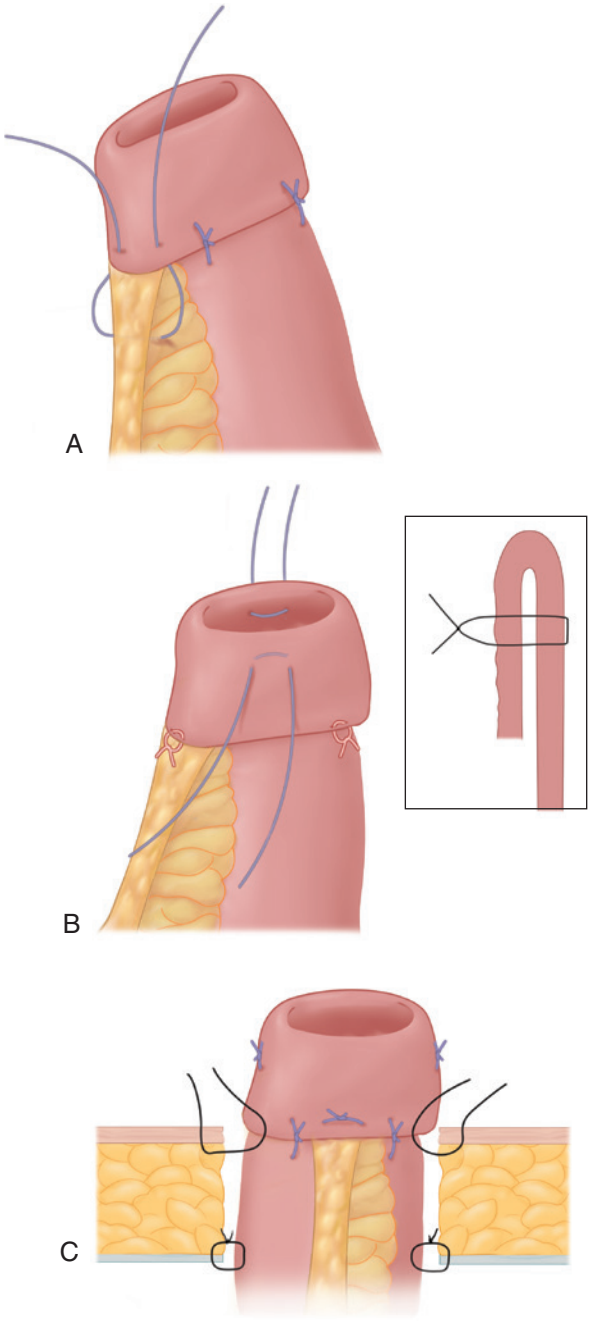

Figure 45.10 A and B, The Taneja technique of stomal maturation. Eversion over the mesentery is performed by suturing to the mesenteric edge with a U-stitch (inset in B). The stomal intussusception is held in place with through-and-through sutures from the lumen to the exterior surface. C, On abdominal wall translocation, the stomal edge is anastomosed to the skin and fascial sutures are placed approximately 3 cm proximal to the everted stomal edge.

Various techniques for ureterocolonic anastomosis have been described. The technique most commonly used for conduit diversion, however, is antirefluxing tenial anastomosis. As discussed later, the necessity for antirefluxing anastomoses remains to be validated in this setting. The use of a stent in the ureteroileal anastomosis is a subject of great controversy. We routinely use a stent for the following reasons:

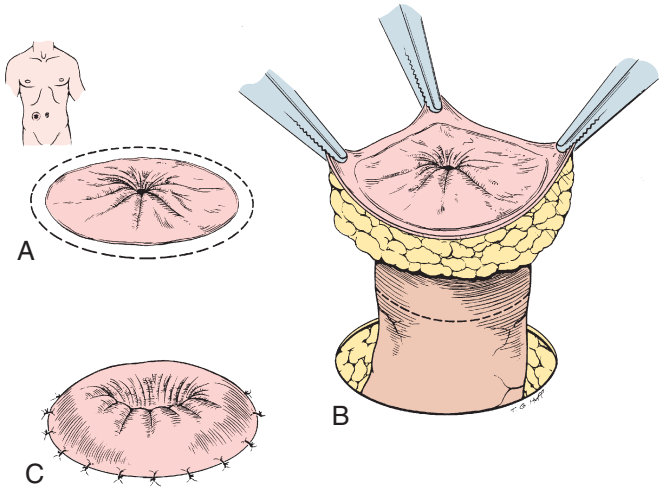

Figure 45.11 Reconstruction with distal amputation. A, Circumferential incision is made around the stoma. B, Mobilization of stoma and distal conduit and amputation of distal segment are performed. C, New stoma is fashioned.

1. It ensures the patency of the anastomosis, specifically in the immediate postoperative period when edema is present at the site.
2. It provides access to the kidney and collecting system if retrograde studies are needed.
3. It enhances stomal drainage when long, externally draining stents are used.

Numerous urinary diversion stents can be used, including a single-J stent or a double J stent with external extension. We prefer the double J variety because it ensures some urine in the conduit and thus prevents a completely dry anastomosis in the early postoperative period.

Regan and Barrett[74] compared the incidence of stricture and leakage in stented and unstented anastomoses. Those patients who were stented had lower rates of stricture and leakage compared with patients who did not have stents. This was a small study with relatively short follow-up, and the influence of technical factors and selection bias cannot be excluded. Individuals with stents in place may be at a high risk of ascending pyelonephritis and urosepsis in the postoperative period. For this reason, these patients should be administered antibiotic prophylaxis for the duration of stenting, and the stents should generally be removed by postoperative day 5–7. Although it is not clear that ureteral stenting is required for ureterointestinal anastomoses, it appears that the potential benefits far outweigh the potential harm.

Ureteroileal Anastomotic Leak

Ureteroileal anastomotic leak (extravasation) is reported to occur in 1.9–5.5% of conduits but alarmingly has an associated mortality rate of ≤48%.[75] The factors contributing to the occurrence of leakage include poor surgical technique, prior radiation therapy, recurrent cancer, stomal edema or obstruction, extraluminal hematoma or seroma, and pelvic abscess. During the normal postoperative course, a small amount of leakage from the anastomosis may occur, but this often resolves without any sequelae. Intraoperatively, the surgeon should make every effort to create a watertight

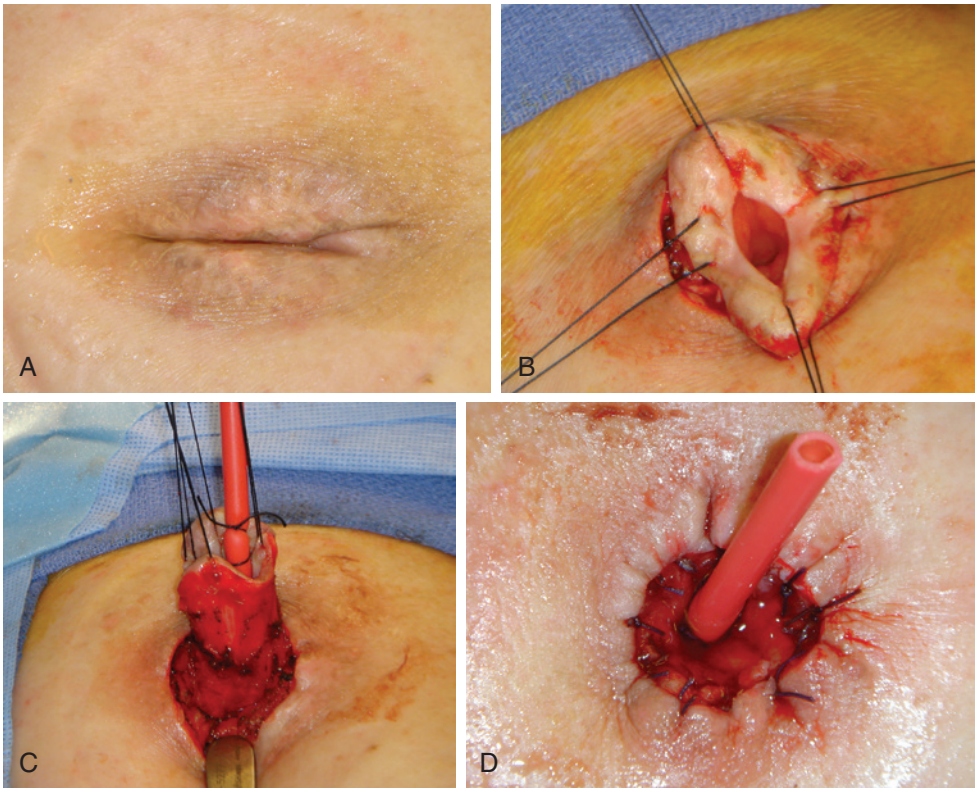

Figure 45.12 Demonstration of stomal revision. A, Completely stenotic stoma due to chronic retraction and inflammation. B, Excision of the stenotic ring by placement of stay sutures in the scar and elevation of the distal conduit. C, Lengthening of the conduit through mobilization beyond the rectus fascia. anastomosis so as to prevent a perianastomotic urinoma, which may become secondarily infected.

We routinely use a Bricker-type anastomosis in our conduit diversion procedures. During spatulation of the ureter, three directly juxtaposed 4-0 chromic anchoring sutures are placed at the apex, or corner, of the spatulation. Generally, this is the most dependent portion of the anastomosis and thus is the most likely to leak. Interrupted sutures are then placed circumferentially 3–4 mm apart. An indwelling stent is always used.

Significant urinary leakage should be suspected in the presence of increased drain output with decreased output from the stoma. Other signs and symptoms may include proximal hydronephrosis or flank pain if no stent is used,

sepsis, ileus, bowel obstruction, urinary drainage from the wound, elevated serum ammonia, or elevated blood urea nitrogen (BUN) without a concomitant elevation of the serum creatinine concentration. This last sign is the result of absorption of urine in the peritoneal cavity. Additionally, the creatinine level in the drainage fluid can also be measured. When the drainage fluid is urine, the creatinine level is generally markedly higher than is the serum creatinine. In a study of 1120 ileal conduits, Hensle and colleagues[76] found elevated BUN to be the most reliable indicator of a urine leak (20 of 21 patients).

Once concern of a leak exists, localization of the leak with a loopogram, intravenous pyelogram (IVP), computed tomography (CT) scan, cine loopogram with real-time fluoroscopy, or injection of contrast material into the ureteral stent can be helpful. CT loopogram may also help to localize the extent of leakage. The leakage commonly originates from the ureterointestinal anastomosis but can also originate from the middle or back of the loop. In our opinion, loopogram with real-time fluoroscopy is most helpful in defining the nature and severity of the leak. In the study by Hensle and colleagues,[76] left ureteral anastomosis was the most common site of leakage. One must also examine the stoma because edema may cause stomal obstruction with increased intraluminal pressure, increased back pressure, and eventual leakage.

When the diagnosis has been established, a conservative approach should be used initially. This approach includes ensuring of adequate drainage with a catheter in the stoma (on low suction if needed), drainage of the collecting system with either percutaneous nephrostomy tubes or ureteral stents, nutritional support, and antibiotic prophylaxis. Early leaks in the stented ureter can be observed initially, provided the patient has no signs of sepsis. Cross-sectional imaging should be used to rule out the presence of an undrained urine collection, which can compress or stretch the anastomosis and thus prevent its ultimate closure. High-output leaks in the presence of a stent should be managed initially by percutaneous drainage of the kidney to minimize urinary extravasation. In the absence of a ureteral stent, it is unlikely a major leak will seal without percutaneous drainage of the kidney and urinoma. Antegrade stenting is an option, but the surgeon should exercise extreme caution to avoid further disruption of the anastomosis.

Delayed leaks occurring >7–10 days postoperatively are often the result of ischemic ureteral necrosis. Early attempts at conservative therapy are still worthwhile, and percutaneous nephrostomy is an important adjunct to such therapy. If the leak continues as a high-output fistula despite proximal drainage, it may require early exploration because this finding suggests major ureteral necrosis. If proximal drainage reduces or abrogates fistula output, surgical repair is still likely necessary. However, waiting for 6–10 weeks to allow inflammation to subside is wise.

If the patient does not respond to conservative therapy, early surgical exploration and repair must be attempted. Hensle and colleagues[76] suggested repair after 72 hours if no improvement is noted, whereas Coleman and Libertino[77] suggested waiting ≤3 weeks. In the study by Coleman and Libertino, leaks in seven of 10 patients resolved after 3 weeks, whereas three of 10 patients required open revision. The decision to wait must be based on the patient's condition, the size of the leakage, the output volume, the presence of persistent infection, and the presence of signs of improvement.

In repairing an early leak, surgical exploration usually includes creating a new anastomosis. Simple placement of additional sutures in a preexisting anastomosis is rarely successful and is ill advised. Stent placement in the new anastomosis is strongly advised. The previous opening in the ileum should be identified and closed. To facilitate intraoperative dissection and mobilization, a Foley catheter with 3–5 mL in the balloon can be placed in the conduit. Antegrade stenting of the ureters is also helpful in localizing, mobilizing, and repairing the anastomosis.[77] The surgeon should anticipate very friable tissues, and the repair should focus on identification of a viable, minimally inflamed ureteral edge, mucosal apposition, and tension-free anastomosis. Watertight closure is often not possible because of the condition of the tissues. Eyre and associates[75] recommended sending the distal ureter for frozen section during repair, to assess tissue necrosis or small vessel occlusion. However, this condition may be difficult to assess in the presence of acute inflammation.

Patients with a delayed urine leak (10–14 days) usually have ischemic necrosis. This complication can involve a variable length of ureter and, in severe cases, can extend all the way to the renal pelvis. The technique of repair should be based on the length of the defect. Complete resection of the devitalized ureter must be performed with creation of an ileal interposition, transureteroureterostomy, or renal autotransplantation. Minimal-to-moderate gaps can be closed by mobilization of the proximal conduit itself. In patients with significant ureteral necrosis, critical illness or sepsis, or multiple comorbidities, the surgeon should give strong consideration to nephrectomy if the contralateral kidney is adequately functioning. Before surgical exploration, a renal scan may be performed to assess bilateral function, if necessary. Bowel preparation should be performed, if possible, based on the patient's overall condition.

Anastomotic Strictures

The incidence of ureteroileal strictures ranges from 1.5% to 18.4%.[35] For example, Bricker[50] found a 3.75% incidence of reoperation for ureteroileal obstruction in his initial 54 cases. In addition, Cass and colleagues[52] and Frazier and associates[69] reported stricture rates of 6.5% and 7%, respectively. Madersbacher and colleagues[78] noted upper urinary tract obstruction in 13 of 131 (10%) patients as a result of stenosis at the ureteroileal anastomosis, and Gburek and associates[79] reported a 5% rate of stricture in 66 patients, their most common late complication of ileal conduit creation. More recently, Gilbert and associates[38] noted a ureteroileal obstruction rate of 8% at 2 years, as well as an increased incidence among patients receiving a conduit diversion rather than a continent diversion. The possible causes of stricture formation include tension at the anastomosis, devascularization and ischemia of the ureter, prior radiation therapy, prior leakage, and infection. In the setting of prior leakage, dense reaction surrounding the ureteroileal reimplantation results in extrinsic scarring of the anastomosis. Stricture at the anastomosis should be considered in any patient with decreased renal function (increased serum BUN and creatinine levels), hydronephrosis, flank pain, decreased urine output, fever, or sepsis.

The diagnosis of ureteroileal anastomotic stricture can be made with ultrasound, CT scan, IVP, and loopogram. IVP and loopogram can localize and define the length of the stricture. Newer techniques, including three-dimensional reconstructed spiral CT scan, CT urogram, and magnetic resonance imaging urogram, may also be used if available. In patients with poorly functioning or nonfunctioning kidneys, antegrade pyelography is often necessary to define the stricture. Hudson and colleagues[80] reported a rate of correlation between loopogram and IVP of 81%. Although reflux on a loopogram can rule out stenosis, the absence of reflux does not confirm obstruction. In a study by Hudson and colleagues,[80] 84% of obstructed kidneys were on the left, likely the result of extensive left ureteral mobilization and angulation or tension of the left ureter as it crosses behind the sigmoid mesentery. One must also be concerned with recurrent cancer as a cause of stenosis because carcinomas tend to develop at the ureterointestinal anastomosis.[81]

Initially, the conduit should be examined endoscopically to rule out recurrent malignant disease. In patients with established percutaneous access, antegrade endoscopy can further aid in defining the nature and extent of the stricture. The surgeon is then faced with choosing between endoscopic and open treatment. Endoscopic management by antegrade or retrograde methods is discussed in detail elsewhere in the text. Although endoscopic management is increasingly popular, high failure rates are noted unless the stricture is short and uncomplicated.

In the setting of an uncomplicated, short (<1 cm) stricture, most patients should be managed initially with an attempt at endoscopic treatment. The lumen of the stricture should be identified endoscopically. For endoscopic repair, we favor an antegrade approach because the patient is left with a nephrostomy tube as a safety mechanism. If endoluminal ultrasound technology is available, this technique is generally useful. Blind cutting procedures should be avoided because the anastomosis is often directly next to bowel or vascular structures. The ureter should be stented for 6 weeks following stricture incision. If the stricture is >1 cm long, it may be wise to consider open repair initially.

During open reimplantation of a strictured ureteroileal anastomosis, it is best to place an antegrade stent to the level of stricture. The distal ureter is often encased in fibrotic reaction, particularly in the setting of previous leak or infection, and placement of antegrade stents can allow the surgeon to identify the ureters in an otherwise nondiscernible surgical plane. A catheter is placed in the conduit for similar reasons. The distal ureter must be mobilized, but extreme caution should be taken to avoid devascularization of the healthier proximal ureter. In cases of severe periureteral scarring, it is often preferable to excise the stricture, limit mobilization of the proximal ureter, maximally mobilize the conduit, and bring the conduit to the more fixed segment of viable ureter. We also recommend sending the distal ureteral margin for frozen section pathologic evaluation. If malignant disease is identified, a larger segment of ureter should be resected to achieve a cancer-free ureteral margin. For long stricture defects, numerous surgical options exist, including ileal interposition, transureteroureterostomy, renal autotransplantation, and, on rare occasion, nephrectomy.

When the ureteroileal stricture is identified late and the residual renal unit is nonfunctioning, nephroureterectomy is the treatment of choice. This is particularly true in the setting of underlying urothelial malignant disease because a nonfunctioning obstructed upper tract moiety is difficult to follow-up for recurrent malignant disease.

FATE OF THE KIDNEY

During the preoperative evaluation, the status of the patient's renal function should be evaluated by sending blood for BUN and creatinine. One of the primary goals of conduit surgery is the preservation of renal function. In patients with a serum creatinine level >2.5 ng/mL or significant renal disease on radiographic studies, a short conduit should be created to help decrease stasis and to minimize electrolyte abnormality.

Pyelonephritis and Renal Damage

The rate of early pyelonephritis ranges from 1.8% to 3.1%, whereas the rate of late pyelonephritis ranges from 3.1% to 13%.[35,69] A reduction in the incidence of pyelonephritis has been reported in contemporary series, perhaps owing to improved technique and better perioperative antibiotics. In early series, Bricker[50,51] observed that ≤33% of his patients suffered from early pyelonephritis. Madersbacher and colleagues[78] noted that 23% of their patients who had ileal conduits had symptomatic urinary tract infections severe enough to lead to hospital admission. These investigators observed acute or recurrent pyelonephritis in 15 of 131 (11%) patients; this complication was associated with postrenal obstruction caused by anastomotic strictures, stomal stenosis, or urolithiasis in 13 of these patients. Recurrent urinary tract infections without clinically overt pyelonephritis were seen in 10 of 131 (7%) patients, and urosepsis occurred in five (4%) patients, associated with upper tract dilatation in four of these patients. Gburek and associates[79] observed pyelonephritis as an early complication in 6% of their patients and as a late complication in 2% of their patients.

Gilbert and associates[38] followed a cohort of 1565 patients, 80% of whom received an ileal conduit. Within 5 years, over 16% of patients suffered renal failure or impairment. The authors also noted a higher incidence of these renal complications among patients who received a conduit diversion rather than a continent diversion. This may reflect a selection bias, as patients with preexisting kidney disease, or risk factors for such, would be less likely to undergo continent diversion. Regardless of the findings of the study, conduit is still considered the diversion of choice in patients with limited renal reserve preoperatively.

Refluxing Versus Nonrefluxing Anastomoses

The question whether a nonrefluxing ureterointestinal anastomosis has any added benefit in conduit surgery has been the topic of much debate. Although early experiments suggested renal compromise in the setting of a refluxing moiety,[82] little clinical evidence exists to support this view. Kristjansson and associates[83,84] found no difference in glomerular filtration rate or stricture between refluxing and nonrefluxing anastomoses. A 15% rate of ureterointestinal stricture was noted in each group. Both bacteriuria and renal scarring were more common among refluxing anastomoses. Several investigators demonstrated improvement

in hydronephrosis in the majority of patients when nonrefluxing anastomoses were used.[85,86] Stein and associates[87] reported on 105 children who were followed up for 16.3 years after construction of a nonrefluxing colon conduit. These investigators noted a 65.3% incidence of pyelonephritic changes, a rate comparable to that found in other studies, which reported a rate of change in children of ≤68%. More recently, a randomized controlled study comparing refluxing and nonrefluxing anastomosis in orthotopic neobladders by Skinner and colleagues[88] demonstrated no difference between the two techniques with regard to UTI or renal function, but noted that nonrefluxing anastomoses required a statistically significant higher rate of diversion-related secondary surgical procedures.

In adults, a conduit with freely refluxing ureters is preferable, mainly for ease of follow-up. Studies show no significant difference in renal damage and, most importantly, no difference in long-term glomerular filtration rates when comparing nonrefluxing and refluxing conduits. In patients with refluxing conduits who have persistent pyelonephritis with renal damage, the physician may consider revision to a nonrefluxing colon conduit.

DOUBLE-BARRELED WET COLOSTOMY

The double-barreled wet colostomy (DBWC) is an optional method of urinary diversion for patients in need of total pelvic exenteration (TPE), in an effort to avoid two stomas. DBWC was first described by Carter[89,90] in 1989 and involves a single stoma site for both fecal and urinary diversion. With this technique the sigmoid colon is divided 10–15 cm distal to the site that is to be used as a loop colostomy. This loop ostomy is brought up through the fascia, rectus muscle, and left abdominal wall, and the ureters are reimplanted into the distal colonic segment. The small intestine is left intact, and no gastrointestinal anastomoses are created with this method.

This technique improves upon the morbidity (notably wet diarrhea output) and mortality (up to 9%) seen with the original ureterocolostomy described by Brunschwig and Pierce.[91] The double-barreled technique also carries advantages to the technique of using two separate stoma sites, used frequently in the wake of Brunschwig's findings, due to the fact that DBWC only requires maintenance of one stoma site and that the small bowel remains uninterrupted, with no gastrointestinal anastomoses.

Kecmanovic and colleagues[92] analyzed the records of 38 patients who underwent DBWC, finding a postsurgical morbidity rate of 15.7% with no treatment-related mortality. They did, however, note that two patients had late postoperative complications, which included stenosis of the ureterocolonic anastomosis and conduit necrosis. Chokshi and colleagues[93] compared outcomes of 43 patients who underwent DBWC to 10 patients who received IC in the context of total pelvic exenteration. While they found a higher rate of DBWC morbidity than Kecmanovic (possibly due to a stricter definition of postoperative morbidity), they reported no significant differences in morbidity or mortality as compared to conduit. Interestingly, they noted that 26% of patients with DBWC developed enteric fistulas while none did in the IC group. The two groups had no significant differences in terms of incidence of pyelonephritis, urinary leaks, or urinary fistula.

While prospective studies are needed to further compare the complication rates and quality of life associated with DBWC to other forms of urinary diversion, DBWC appears to be the best diversion option for patients requiring TPE, given early studies demonstrating comparable or improved complication profiles to the alternatives and the relative advantage of a single stoma site.

BACTERIOLOGY OF THE ILEAL CONDUIT

Guinan and colleagues[94] reported on the bacterial milieu of the ileal conduit. The native ileum before creation of a conduit was sterile in nine of 10 patients, and one of 10 grew fungus. Postoperatively, 74% of conduits had urine cultures demonstrating bacterial growth. The most common infectious organism was *Proteus* followed by *Pseudomonas* and *Escherichia coli*. These investigators found IVP changes in 67% of infected conduits but no significant correlation between urinalysis and culture results. The changes seen were most pronounced in the presence of *Proteus* or *Pseudomonas* infection.

In general, we do not treat asymptomatic urinary tract infections in patients with conduits, in order to avoid selection of antibiotic resistance over time. We do recommend treating patients with significant asymptomatic bacteriuria ($>10^5$ organisms) in the setting of *Proteus* and *Pseudomonas* infections. Obviously, aggressive treatment is indicated in individuals with pyelonephritis or systemic signs of illness such as fever or leukocytosis. The surgeon must ensure that the conduit is adequately draining, to minimize reflux and the potential for pyelonephritis in the patient with asymptomatic bacteriuria.

OTHER POTENTIAL COMPLICATIONS

The incidence of duplex ureters found on autopsy is 0.3–2.5%.[95,96] The presence of this condition, if unknown preoperatively, can greatly compromise the outcome of conduit surgery. Careful examination of preoperative imaging studies is essential for the recognition and management of the duplicated ureter. When this condition is recognized, the ureters can be implanted separately or together with a Wallace-type anastomosis. Another unfortunate but uncommon complication is conduit-enteric fistula. The finding of decreased output, severe watery diarrhea, and fecaluria can lead to the diagnosis of a fistula.[97]

Stomal varices are another rare and problematic complication. Varices are usually seen in patients with cirrhotic or metastatic liver disease. These patients usually present with gross hematuria coming from the mucocutaneous junction and can usually be treated by correcting the underlying coagulopathy.

Occasionally, the use of coagulation or techniques to oversew the varices may be necessary. Transjugular intrahepatic portosystemic shunts have been used to correct the underlying portal hypertension and to stop the bleeding in these patients.[98]

Chapter 45 Questions

1. A patient presents with a reducible parastomal hernia 1 year after conduit urinary diversion. He denies pain, but is concerned because an inguinal hernia he had 3 years previously required immediate intervention. The most appropriate next step is:
   a. Repair the fascial defect with mesh
   b. Recommend the patient try a support belt
   c. Relocate the patient's stoma
   d. Repair the fascial defect primarily, without mesh
   e. Change the patient's stomal appliance

2. A patient with multiple sclerosis develops stomal stenosis at the level of the fascia. What is the most appropriate next step in managing this patient?
   a. Balloon dilation of stenotic segment
   b. Relocation of the stoma
   c. Change the patient's stomal appliance
   d. Trial of antispasmodic medication
   e. Surgical excision of stenotic segment

3. A patient with an ileal conduit presents with a urine leak 11 days after radical cystectomy. The most likely cause of this complication is:
   a. Ileal segment necrosis
   b. Urine eroding through conduit staple line
   c. Improper surgical technique in formation of ureteroileal anastomosis
   d. Erosion of preexisting stone through ureteroileal anastomosis
   e. Ischemic ureteral necrosis

4. Which of the following strategies is most effectively employed in patients with limited renal reserve undergoing conduit urinary diversion?
   a. Shortening the length of the conduit
   b. Antirefluxing ureteroileal anastomosis
   c. Placing the conduit on tension
   d. Freely refluxing ureteroileal anastomosis
   e. Parker-Kerr sutures

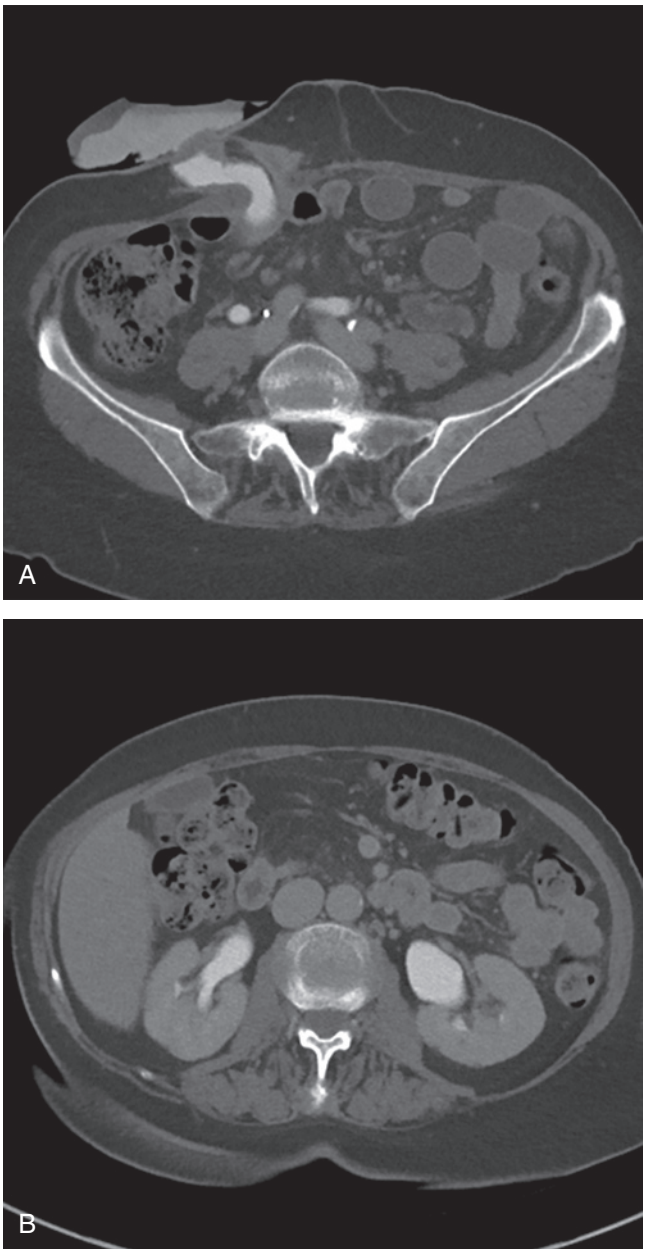
5. Which of the following describes the best initial management of a ureteroileal stricture?
   a. Observe for 4 weeks
   b. Surgical excision of stricture
   c. Endoscopic examination to rule out recurrent malignant disease
   d. Reimplantation of strictured ureteroileal anastomosis
   e. Retrograde stenting of anastomosis

6. In patients with a duplicated ureter, what is the most appropriate course of surgical management?
   a. Excision of the upper moiety
   b. Excision of the lower moiety
   c. Nonrefluxing anastamosis
   d. Wallace anastomosis
   e. End-to-side anastomosis of lower moiety to upper moiety

7. All of the following are early signs of conduit necrosis EXCEPT:
   a. Dusky-appearing stoma
   b. Hyperphosphatemia
   c. Metabolic acidosis
   d. Stomal retraction
   e. Oozing from stoma

8. A patient who underwent ileal conduit urinary diversion 1 year previously comes in with hyperkeratotic skin, but no signs of decreased urine outflow. What is the appropriate next step in management?
   a. Catheter drainage of conduit
   b. Surgical excision of hyperkeratotic skin
   c. Cauterization of the hyperkeratotic skin with silver nitrate
   d. Alkalinization of the urine
   e. Change the stomal appliance

9. A 77-year-old patient who has previously undergone radiation for prostate cancer treatment has now been diagnosed with muscle-invasive bladder cancer. He lives independently, but notes that he requires help with some activities of daily living. Which of the following is the most appropriate urinary diversion for this patient?
   a. Ileal orthotopic neobladder
   b. Indiana pouch
   c. Ileal conduit
   d. Transverse colon conduit
   e. Double-barreled wet colostomy



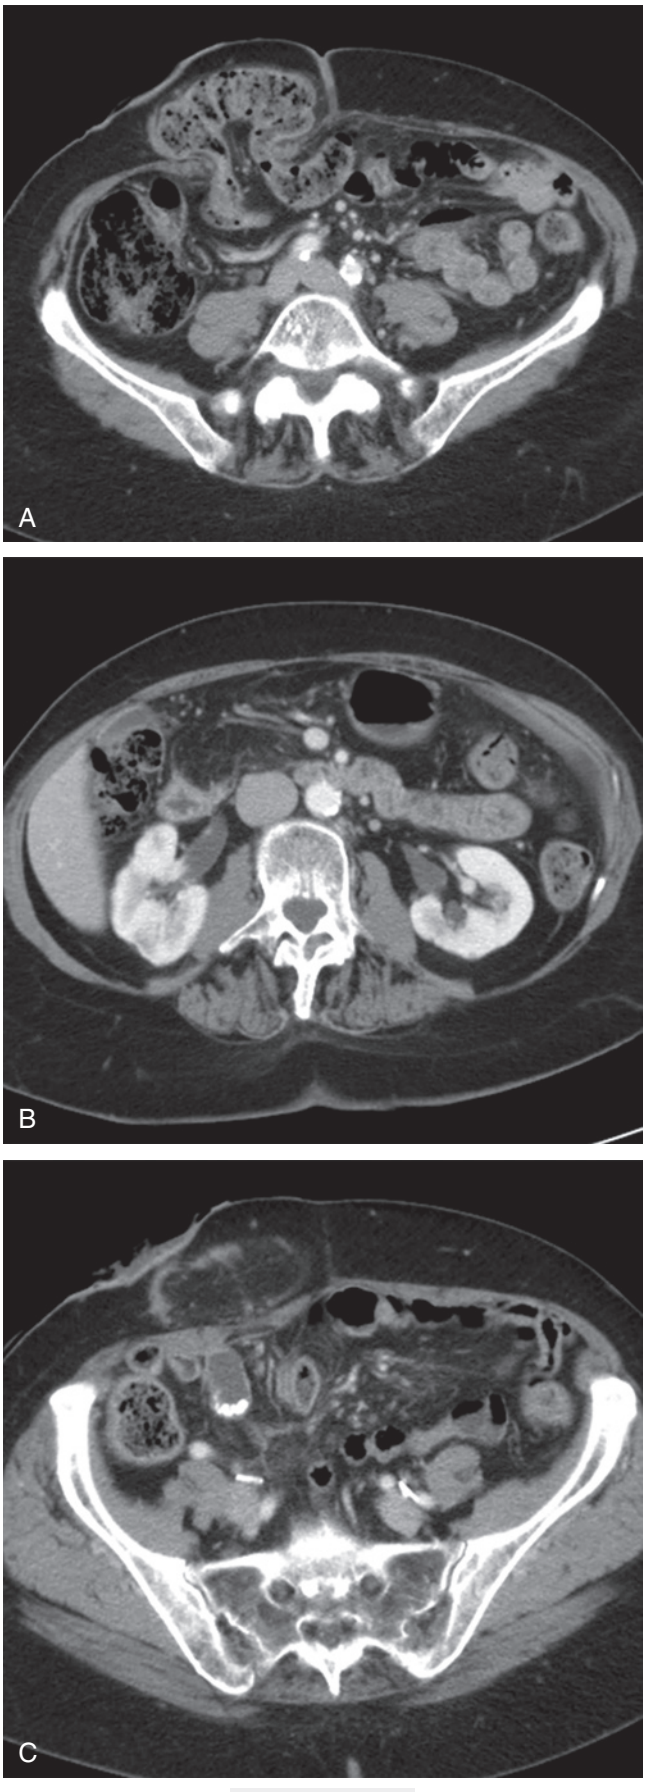
10. An obese patient is noted intraoperatively to have increased tension on his conduit. All of the following techniques can be used to elongate the conduit EXCEPT:
    a. Turnbull loop stoma
    b. Proximal mesenteric incision
    c. Distal mesenteric incision
    d. Defatting
    e. Abdominoplasty

Case Study 1

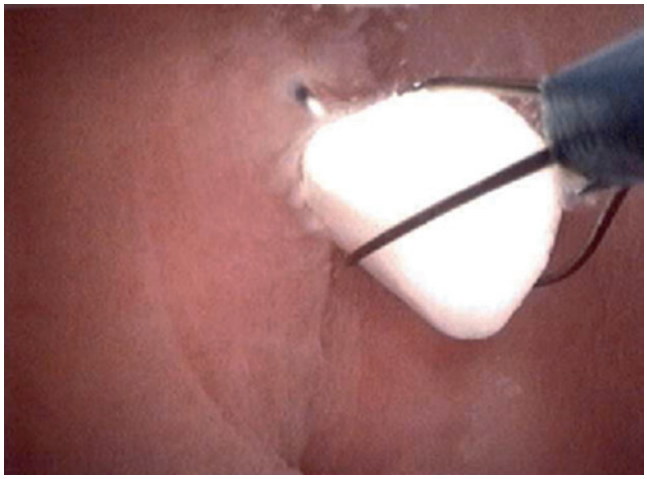
A 75-year-old woman who underwent radical cystectomy and ileal conduit diversion 5 years ago presents for follow-up care 2 years postoperatively with a stable, easily reducible parastomal hernia that she developed roughly 1 year after surgery. She has not noticed any changes in urine output. She denies changes in bowel habits.

1. A follow-up surveillance CT scan (Case Fig. 45.1) shows a parastomal hernia, but no proximal hydronephrosis. Urographic phase CT is as follows:

   The best management option for this patient is:
   a. Surgical revision of stoma
   b. Have patient manually reduce stoma four times per day
   c. Send patient to general surgeon
   d. Consider use of a belted abdominal binder
   e. Intermittent catheterization of stoma



Case Figure 45.1



2. Two years later the patient returns. Her parastomal hernia is slightly increased from the previous visit. She has undergone a surveillance CT (Case Fig. 45.2) demonstrating worsening of the hernia, stable upper tracts, and several small stones in the ileal conduit.

   The most appropriate next step in management is:
   a. Continue conservative management of parastomal hernia
   b. Cystoscopy of the ileal conduit and surgical treatment of stones
   c. Stomal revision
   d. Potassium citrate
   e. Conversion to colon conduit

3. The patient is brought for surgical treatment of her stones and the image (Case Fig. 45.3) is captured:

Case Figure 45.2

Case Figure 45.3

Which of the following steps could have been taken to lower the risk of stone formation?
a. Urine acidification
b. Use of nonabsorbable sutures
c. Parker-Kerr suture
d. Phosphate supplementation
e. Potassium citrate

4. Which of the following is the most likely mechanism of stone formation in this patient?
a. High calcium diet
b. Renal failure leading to secondary hypercalcemia and subsequent hypercalciuria
c. Urinary stasis leading to increased chloride and bicarbonate exchange with compensatory hypercalciuria
d. Metabolic alkalosis secondary to urinary retention
e. Excessive oxalate ingestion

5. If the patient were to develop recurrent symptomatic stones, which of the following would be the most appropriate treatment option?
a. Timed catheterization of the stoma
b. Stomal revision
c. Surgical treatment of the stones
d. Conversion to a continent cutaneous diversion
e. Dietary calcium restriction

Case Study 2

A 68-year-old male undergoes an uncomplicated cystoprostatectomy and ileal conduit diversion. In the recovery room, his stoma is dusky and purple, and he is oliguric and mildly tachypneac. His labs demonstrate, normal electrolytes, mild lactic acidosis and a hemoglobin of 9.7.

1. The most likely explanation for his dusky stoma is:
a. Myocardial infarction
b. Venous congestion
c. Portal hypertension
d. Mesenteric ischemia
e. Infarcted conduit

2. Over the next 2 hours, his stoma becomes darker and begins to ooze dark blood. He remains mildly tachypneic, but is hemodynamically stable with normal blood pressure and heart rate of 82. A blood gas shows improvement in his metabolic acidosis, but mild acidosis remains. If concerned regarding ischemia of the conduit, the next step is:
a. CT abdomen
b. Remove sutures in stomal maturation
c. Loop endoscopy
d. Laparoscopic evaluation of the conduit
e. Re-exploration and revision

3. In managing a stoma with edema and venous congestion, the most important early postoperative maneuver is:
a. Lowering blood pressure
b. Incision of the stoma
c. Placement of loop catheter
d. Diuresis
e. Percutaneous nephrostomy diversion

Answers

1. **b.** Surgical repair of parastomal hernias is difficult and not indicated unless the patient is symptomatic. Rubin and associates[59] found that 76% of patients recurred after fascial repair and 33% after stomal relocation, with 63% of patients suffering a postoperative complication. Given the high morbidity associated with revision surgery, conservative measures are indicated for patients with asymptomatic parastomal hernias.
2. **d.** Patients with neurologic conditions can develop stenosis from muscular spasm causing a kinking of the conduit. These conditions are often responsive to antispasmodic medication. This conservative measure should be tried before considering surgical intervention.
3. **e.** Patients with a urine leak 10–14 days after surgery usually have ischemic ureteral necrosis. Conservative measures can be attempted first, with some authors suggesting that patients can wait up to 3 weeks for surgical intervention, as many of these leaks self-resolve.
4. **a.** A shorter conduit length reduces the amount of contact between urine and the bowel, thus reducing metabolic abnormalities associated with the conduit. Antirefluxing ureteroileal anastomoses have not been shown to improve renal outcomes relative to patients with freely refluxing ureteroileal anastamoses for patients undergoing conduit diversion.
5. **c.** After a ureteroileal stricture has been diagnosed, the first step of management is endoscopy to rule out recurrent malignancy. Most strictures under 1 cm can be repaired endoscopically, and a stent should be placed by antegrade approach and remain for 6 weeks. Strictures over 1 cm are more likely to require open surgical revision.
6. **d.** In patients with a duplicated ureter, a condition which should be diagnosed preoperatively with imaging, either a Wallace anastomosis or separate implantation with Bricker anastomoses for both ureters is indicated. A Wallace anastomosis is best used, however, in that it allows reimplantation without separation of the duplicated ureter.

7. **d.** While the stoma can appear dusky in the days immediately following surgery, persistent duskiness is likely a sign of conduit necrosis. In cases of conduit necrosis, the patient should be brought back to the operating room for exploration, resection, and replacement of the conduit.
8. **a.** Alkaline urine is one of the major causes of hyperkeratosis. A catheter should be placed to avoid urine contact with the skin and a heat lamp used twice daily 12 inches from the skin. Further, oral vitamin C or acetic acid washes can be utilized to acidify the urine and site of hyperkeratosis.
9. **d.** Urinary diversions involving segments of ileum are less than optimal in this patient. Previous pelvic irradiation can cause damage to the distal ileum and thus make the tissue more friable and less amenable to healing. Due to the patient's age and functional limitations, orthotopic and continent cutaneous diversions are not ideal, as the patient may not be able to handle the regular management of these diversions. The transverse colon is the segment of bowel farthest away from this patient's radiation site, and transverse colon conduits have similar functional outcomes to ileal conduits.
10. **b.** While some authors have called for a distal mesenteric incision to reduce tension on conduits, the technique does carry an increased risk of devascularization of the diversion. It should be noted that while defatting is a useful technique for lengthening the conduit, it is important that the mesentery is not tucked under the skin edge, as this can lead to poor appliance fit and ultimately stomal stenosis.

CASE STUDY 1

1. **d.** Conservative management is indicated in the case of a nonsymptomatic parastomal hernia. The lack of hydronephrosis on urographic phase CT indicates only a mild obstruction, and the patient only needs to be given something for decompression of the conduit. Stomal revision has a high rate of failure and carries with it additional surgical morbidity.
2. **b.** Up to 20% of patients with urinary conduit develop stone formation. Potassium citrate may be appropriate in the prevention of stone formation. In this case, however, the patient has evidence that stones are causing obstruction and thus they should be treated. Stomal revision is unnecessary at this time, although the patient should continue efforts to decompress the parastomal hernia.
3. **c.** The stone has formed along a retained staple in the conduit. A Parker-Kerr suture helps prevent contact between the staple line and urine, which may lower the risk of calculi formation. Urine alkalinization with Shohl's solution or potassium citrate could have been useful in the prevention of this stone. Nonabsorbable sutures, like retained staples, are implicated in stone formation.
4. **c.** Urinary stasis is believed to lead a metabolic acidosis, in which bone is used as a buffer. This subsequently leads to hypercalciuria and stone formation in the conduit. There are no signs that this patient has renal failure, and her diet is unlikely the primary driver of stone formation. In fact, dilatation of the conduit, noted in 2013, is suggestive of urinary stasis due to mild obstruction.
5. **b.** While catheterization is useful in the prevention of stone formation, it is an insufficient measure in the treatment of a patient with recurrent symptomatic stones. In this case, the patient should undergo stomal revision to remove the obstruction caused by her parastomal hernia. Surgical treatment of recurrent stones is not indicated, as the patient is likely to require frequent intervention.

CASE STUDY 2

1. **b.** In this patient, the uncomplicated nature of his surgery along with his clinical presentation makes simple venous congestion the most likely cause of his stomal discoloration. While ischemia is feasible, in the absence of systemic signs of infarcted or ischemic bowel such as hemodynamic instability, severe acidosis, or electrolyte disturbance, it is less likely. Simple observation with fluid resuscitation is appropriate.
2. **c.** In this case, given the general low suspicion of ischemia, re-exploration would not be indicated. Loop endoscopy can provide a sense of whether ischemia is present by determining if subfascial mucosa is pink or dark and dusky. Pink mucosa below the fascia would indicate venous congestion of the distal conduit due to edema and entrapment at the fascial level. This will generally resolve with conservative management.
3. **c.** Placement of a loop catheter will ensure adequate drainage of the conduit, thereby allowing a gradual decline in edema, distal obstruction, and venous congestion, while avoiding loop distention and secondary stress on the proximal suture lines.

46 Complications of Continent Cutaneous Diversion

EILA C. SKINNER and DIMITAR ZLATEV

CHAPTER OUTLINE

Introduction
Prevention of Complications
Application to Robotic Surgery
Early Complications
Urine Leak
Necrosis of the Efferent Limb of the Pouch
Problems Related to Catheterization
Urinary Infection
Bowel Fistula to the Pouch and Other Bowel Complications
General Medical Complications and Complications Unrelated to the Diversion
Late Complications
Infections
Incontinence
Pouch Stones
Kidney Stones
Ureteral Pouch Obstruction
Stomal Stenosis and Difficulty With Catheterization
Conversion From a Continent to a Noncontinent Diversion
Afferent Antireflux Mechanism
Acute Pouch Rupture
Parastomal Hernia
Late Malignant Diseases
Conclusions
Chapter 46 Questions and Answers

KEY POINTS

1. Patient selection is critical to ensure that the type of diversion planned is appropriate for the patient from both a medical and a psychological or social standpoint.
2. Attention to the following technical details during construction of the reservoir can avoid many potential complications:
   - Careful isolation of the segment to be used for the reservoir and complete detubularization of the segment.
   - A direct ureteroileal anastomosis carries the lowest risk of subsequent stenosis.
   - The continence (efferent) limb should be short and straight, and the continence mechanism should be tested during construction to ensure complete continence and ease of catheterization.
3. Early urine leak should be managed with aggressive catheter irrigation, percutaneous drainage of any urinoma, and diverting nephrostomy tubes as needed. Reoperation should be avoided.
4. Most continent cutaneous reservoirs are chronically colonized with bacteria but symptomatic infections are unusual. Late asymptomatic bacteriuria should not be treated.
5. Incontinence from cutaneous continent reservoirs usually requires surgical repair. The exact diagnostic and treatment approach depends on the type of continence mechanism used.
6. Pouch and kidney stones can occur in all types of cutaneous diversions and are usually amenable to endoscopic or percutaneous management.
7. Acute pouch rupture is a rare but potentially fatal complication. Early recognition and surgical exploration are key to successful management.
8. Stenosis of an ileal antireflux mechanism may manifest with silent bilateral hydronephrosis and renal insufficiency.
9. Patients with continent cutaneous reservoirs should have annual evaluation to check for pouch and renal stones or upper urinary tract obstruction.

Introduction

Complications related to radical cystectomy and urinary diversion are very common, occurring in up to 70% of all patients, with 10–15% of complications classified as high-grade.[1,2] Many complications are related to the cystectomy and bowel resection and are common to all types of diversion. These are discussed in Chapter 41. Approximately half of early complications and three-fourths of late complications are related to the diversion itself.[3] Attempts to compare complication rates between the three main types of diversion have shown conflicting results. Although some series have shown no difference in early complications,[4,5] a recent study of patients undergoing robotic cystectomy with extracorporeal diversion showed that continent cutaneous diversion was associated with higher early and late complications compared with both ileal conduit and orthotopic neobladder, as well as an increased likelihood of open surgical revision for late complications. Nonetheless, as the main advantage of continent cutaneous diversion is being generally dry from the beginning after surgery, many patients are willing to accept the increased risk of complications and surgical revision in exchange for avoiding diapers or an external appliance. This chapter focuses on the management of both early and late complications related to continent cutaneous urinary diversion.

Patients undergoing cystectomy should undergo comprehensive preoperative assessment and counseling regarding options for diversion and expectations regarding recovery. Patients being considered for continent cutaneous diversion must have adequate cardiac, pulmonary, and renal function (GFR >40) and be motivated and able to adequately care for themselves and the pouch.[6] Many different techniques are available for constructing a continent form of urinary diversion, including orthotopic neobladders as well as continent cutaneous diversions. Continent cutaneous diversion is specifically indicated for male and female patients undergoing cystectomy who are candidates for continent diversion but in whom an orthotopic neobladder is either contraindicated or not desirable. These indications include the following:

1. The patient prefers continent cutaneous diversion.
2. The external urethral sphincter is incompetent.
3. Severe urethral stricture disease is present.
4. The patient is unwilling or unable to catheterize through the urethra.
5. The patient has chronic bladder or urethral pain or severe interstitial cystitis.
6. The patient has known prostatic stroma invasion with urothelial cancer (relative contraindication to orthotopic diversion).
7. The patient has had previous radical prostatectomy or high-dose radiation therapy to the area of the bladder neck (relative contraindication for orthotopic diversion depending on the severity of the scarring encountered during the surgical procedure).
8. Frozen section biopsy of the urethral margin is positive for urothelial cancer.

Many complications are common to all types of diversion (e.g., early urinary leak and ureteral obstruction), but others are unique to continent cutaneous diversion. These diversions are constructed from isolated colon or ileum with a large variety of continence mechanisms. A full discussion of the various techniques is beyond the scope of this chapter. The following discussion focuses on the most common forms of continent cutaneous diversion, including the Indiana pouch and its variations,[7] the right colon pouch with appendix or tubularized ileal stoma,[8] and the cutaneous T-pouch.[9] The Indiana pouch cutaneous diversion has been recently described in conjunction with robotic-assisted cystectomy, with no significant difference reported in functional outcomes and early and late complications over standard open series.[10] We also discuss the complications associated with the cutaneous Kock pouch,[11] a diversion now rarely performed in the United States but one that still can cause challenging complications in patients who had the diversion in the past. Metabolic complications associated with the use of bowel in the urinary tract are covered elsewhere (see Chapter 5).

Prevention of Complications

Careful surgical technique is the key to minimizing complications related to the continent diversion. The choice of bowel segment must allow for adequate pouch volume. In general this requires approximately 44 linear cm of small bowel or 26 to 30 cm of colon for the reservoir portion. If the available colon length is <26 cm, an additional patch of ileum should be used to enlarge the reservoir.

The segment chosen for the reservoir must be isolated carefully to avoid compromise of the vascular supply of either the reservoir or the remaining bowel. This maneuver is most difficult in patients who have had previous bowel resection. In these patients, it is crucial to take down the previous bowel anastomosis rather than choosing a new site. When a new site is chosen, the risk of vascular compromise of the segment between the old and new bowel anastomoses is high. If appendix is to be used, it is examined for adequate length and girth, and the tip is amputated to ensure that the lumen is patent into the cecum as sometimes the lumen can be obliterated in older patients. Care must be taken not to damage the main blood supply to the appendix during mobilization.[8]

The segment chosen for the reservoir must be opened along its entire length to allow for a low-pressure reservoir (Fig. 46.1).[8,12] In general the segment should be folded and closed to construct a reservoir that is as spherical as possible and provides the maximum volume for the surface area used to minimize the intraluminal pressure. It is critical to use only absorbable suture (or absorbable staples) to close the reservoir because any permanent suture or staples may become a nidus for stone formation. Closure of the pouch in one or two layers should be watertight, and this can be tested intraoperatively.

An antireflux mechanism is generally believed to be important in cutaneous continent diversion because of the very high rate of bacterial colonization.[13] Some of the commonly used antireflux mechanisms include tunneled ureteral anastomoses, the ileocecal valve, the Kock intussuscepted nipple valve, or an extraserosal tunnel (T-pouch).[14,15] Some authors have also reported good results with a refluxing anastomosis.[16]

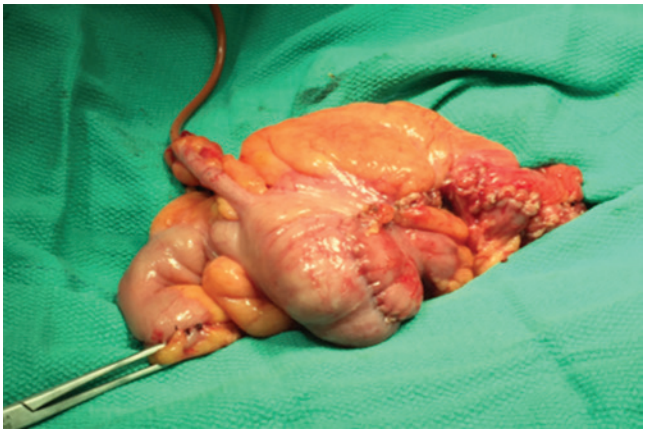

Figure 46.1 Segment of right colon and distal ileum isolated for a right colon pouch with appendix stoma. The entire right colon segment should be incised along one of the taeniae coli to detubularize the bowel completely. The afferent limb distal ileum (held by an Allis clamp) is closed with a Parker-Kerr stitch and otherwise left intact for implantation of the ureters. The appendix (cannulated by a red Robinson catheter) will serve as a catheterizable stoma to the umbilicus. The ileocecal valve acts as the antireflux mechanism.

The choice of technique for the ureteral anastomosis depends on the bowel segment used. We use a stay suture for manipulating the ureter during the anastomosis and avoid grasping it at all with forceps. The ureteral anastomosis with the lowest early and late stenosis rate is the end-to-side ureteroileal anastomosis, with <3% long-term stenosis.[17] This has been our standard anastomosis in the Kock pouch, the Studer and T-pouch ileal neobladders, and the right colon pouch with appendix stoma (using the distal ileum as the afferent limb). A similar direct nontunneled anastomosis to the colon carries a 6% to 7% stenosis rate.[16] The LeDuc method appears to have the lowest stenosis rate for antirefluxing techniques, although results have varied.[18] Tunneled anastomoses into the tinea of the colon carry a rate of stenosis of 10% to 12%.[17] Previous ureteral surgery or radiation therapy increases the risk of subsequent stenosis. In patients who have undergone previous pelvic radiation, it is wise to take the ureters well above the field of radiation and to attempt to use a nonirradiated segment of bowel for the implantation.

Construction of the catheterizable efferent limb and stoma requires careful attention. Regardless of the continence mechanism used, the length of the efferent limb has no impact on continence. Therefore, it should be as short and straight as possible to avoid any redundancy above or below the fascia that could contribute to difficulty with catheterization. At each step in construction of the efferent limb, the surgeon should pass a catheter to ensure that it is smooth and without obstruction.

Stomal stenosis can be minimized by making a V-shaped flap when opening the skin and dropping the skin flap into the spatulated antimesenteric side of the efferent limb when it is matured to the skin.[19,20] This maneuver is performed whether the stoma is in the right lower quadrant or at the umbilicus. With an umbilical stoma it is helpful to excise the majority of the umbilical scar to reduce the risk of later stenosis.

Finally, thoughtful placement of catheters, stents, and drains can minimize problems related to urinary leak in the early postoperative period. All bowel segments excrete a large amount of mucus early on, and this needs to be managed so that catheters continue to drain. We routinely use a 24Fr stiff two-way hematuria catheter to drain the reservoir, placed percutaneously several centimeters away from the stoma. Only a small 12Fr or 14Fr red Robinson or Foley catheter is placed through the stoma as a placeholder. A Foley is less likely to be dislodged but it needs to be protected so that the balloon is not pulling against the continence mechanism. We use 8Fr pediatric feeding tubes to stent the ureters, and they are tied to the larger hematuria catheter within the reservoir so the feeding tubes and hematuria catheter are removed together once the pouch has healed. Alternatively, stents can be passed up to the kidney and then brought into the pouch and out through the pouch wall and skin to drain externally. Finally, a suction drain is placed in the pelvis near the reservoir to drain any urine that might leak from the suture line. This drain may be left in place until the pouch is healed. Nursing staff and later the patient and family are instructed to irrigate the large catheter regularly to keep it free of mucus.

Application to Robotic Surgery

Adaptation of the continent cutaneous diversion to robotic approaches has been recently described. Torrey and colleagues reported on 34 patients who underwent robotic-assisted radical cystectomy followed by laparoscopic mobilization of the colon and extracorporeal construction of an Indiana pouch, with the goal of minimizing the required surgical incision.[10] In this series, early and late complication rates, including hospital stay and transfusion rates, were not improved compared to those reported in open series. A systematic evaluation of factors contributing to complication rates in robotic-assisted cystectomy with extracorporeal diversion showed that continent cutaneous diversion was associated with increased early and late complications compared to ileal conduit or neobladder diversions.[1] Goh and colleagues recently described one of the first techniques for a completely intracorporeal robotic-assisted Indiana pouch construction.[21] The majority of series of robotic-assisted cystectomy published to date include very few cases of continent cutaneous diversion.[22]

Early Complications

Diversion-related complications account for approximately 40% of the total early complications observed in patients undergoing cystectomy and continent diversion.[3,23] The incidence of early complications is not increased with continent diversion compared with ileal conduit.[24–26]

URINE LEAK

It is very common to have some degree of urine leak from one of the suture lines in the pouch during the first few days after the surgical procedure. This is not a true

complication as long as the urine comes out the drain. The leakage may persist for days to weeks but nearly always heals with time as long as good catheter drainage is maintained. More frequent irrigation of the pouch catheter may hasten resolution of the leak. Sometimes the drain is too close to the pouch and is acting as a wick, and a few centimeters withdrawal of the drain can resolve this problem.

An undrained leak is potentially serious and may present with abdominal distention, ileus, decreased urine output, fever, or rising blood urea nitrogen. In this situation, the following measures should be taken:

1. A gravity cystogram under fluoroscopic guidance to confirm proper position of the catheter. This study can also identify the site of extravasation.
2. Computed tomography (CT) scan to evaluate for a large fluid collection in the abdomen or pelvis. If a collection is identified, an additional drain should be placed percutaneously under image guidance. The site of leakage may also be identified if the CT scan is done with intravenous (IV) contrast in the excretion phase.

Diversion of urine with unilateral or bilateral nephrostomy tubes may be required if the leak is severe and persistent, appears to be arising from one or both ureters, or if urine is draining from the wound or has fistulized to another site (e.g., bowel anastomosis or vaginal cuff). This diversion of urine away from the pouch facilitates healing at the site of leakage. The nephrostomy tubes may be left in place for several weeks if necessary. Antegrade studies can confirm resolution of the leak before the tubes are removed. This measure nearly always resolves even the most difficult leak, so it is crucial that the surgeon performing continent diversion have skilled interventional radiologists available to assist in these situations.

A basic principle of management of urinary leaks in the early postoperative period is to avoid attempting open surgical repair. Open exploration and primary repair are extremely difficult in this early period as a result of intense inflammatory reaction. These procedures are rarely successful in achieving a watertight repair. The only situation requiring reoperation is a large, undrained leak that is not amenable to percutaneous drainage. Any repair of a persistent leak should be delayed if possible to 8 to 12 weeks after the initial surgical procedure, once inflammation has had an opportunity to decrease.

NECROSIS OF THE EFFERENT LIMB OF THE POUCH

Necrosis of the efferent limb of the pouch should be an extremely rare event if care is taken in mobilizing the bowel and constructing the catheterizable efferent limb. The most distal portion of the efferent limb or appendix has the most tenuous blood supply, so slight duskiness at the mucocutaneous border is not uncommon shortly after the surgical procedure. However, if there is concern that the limb looks necrotic, a flexible cystoscopy can be performed. No intervention is necessary if healthy mucosa is encountered in the efferent limb. Reoperation with construction of a new efferent limb is required in patients with total necrosis of the limb.[23]

PROBLEMS RELATED TO CATHETERIZATION

Mucus production is universal in continent diversions made from small or large bowel. All cutaneous pouches should be regularly irrigated to clear the mucus. Mucus plugging of catheters can usually be managed by aggressive irrigation. Gross hematuria with clots rarely complicates a continent diversion during the initial healing phase. Continuous irrigation and correction of any coagulopathy are helpful, and rarely an endoscopic evaluation to identify and cauterize a bleeding vessel might be necessary. If a catheter is dislodged or must otherwise be replaced in the early postoperative period, a fluoroscopic cystogram should be performed to confirm proper position of the new catheter.

URINARY INFECTION

Febrile urinary tract infections are relatively common in patients in the early postoperative period, especially while catheters are still in place. In a review of 27 perioperative mortalities in cystectomy patients over a 30-year period, eight cases were caused by overwhelming sepsis. Many of these patients had urine or bowel leak, and all had reoperations during their hospital course.[27] Fungal infections and resistant bacterial infections have become more common in hospitalized patients and can cause significant morbidity and death, especially if not recognized early. Long-term antibiotics have not generally been used because of induction of highly resistant organisms, but we will reintroduce antibiotics at the first sign of fever. We often also add antifungal medications to the treatment of hospitalized patients who become febrile or have leukocytosis after the first week in the hospital in the absence of other obvious sites of infection, even before the urine culture grows yeast. One must suspect resistant organisms in acutely ill postoperative patients and treat them accordingly.

BOWEL FISTULA TO THE POUCH AND OTHER BOWEL COMPLICATIONS

A fistula to the pouch is heralded by the presence of fecal material in the urinary drainage bag or drain, possibly associated with fever or pain. It is generally caused by a leak from the bowel anastomosis or a missed bowel injury. The recommended initial management in the early postoperative setting is bowel rest with parenteral nutrition. CT scan is advisable to ensure that an undrained abscess is not contributing to the problem. Again, early surgical exploration is difficult in the setting of inflammatory postoperative reaction and should be avoided in favor of delayed repeat exploration and repair if the fistula does not resolve within 4 to 6 weeks of bowel rest.[28] An asymptomatic fistula is occasionally identified on routine postoperative imaging. In the absence of symptomatic infections or diarrhea these can be managed conservatively.

Other early bowel complications include prolonged ileus, partial or total small bowel obstruction, gastrointestinal bleeding (usually resulting from stomach or duodenal ulcers), *Clostridium difficile* enterocolitis, and pelvic abscess caused by a bowel leak. The problems are common to all types of urinary diversion and to most other major abdominal surgical procedures involving bowel resection. The

incidence of prolonged postoperative ileus has been markedly reduced in recent years by adoption of ERAS (enhanced recovery after surgery) techniques, including avoidance of bowel preparation, careful fluid management, minimized narcotics, and the addition of alvimopan, a μ-opioid antagonist.[29] Management is nonoperative whenever feasible, with endoscopic and percutaneous techniques used as needed. Taken together, these types of gastrointestinal complications account for approximately 30% of all early complications in patients undergoing cystectomy and diversion.[1,2]

GENERAL MEDICAL COMPLICATIONS AND COMPLICATIONS UNRELATED TO THE DIVERSION

Many early postoperative complications result from cystectomy itself rather than from the specific type of diversion performed. These complications include hemorrhage, thrombotic events, and medical complications such as cardiac or pulmonary problems. Patients undergoing cystectomy and diversion have an average age of almost 70 years, and an increasing proportion of our patients receiving treatment are older than 80 years of age. Previous smoking behavior often contributes to significant cardiac and pulmonary comorbidities in these patients. Other problems that increase complications include diabetes, poor nutrition, obesity, limitations to mobility, and renal insufficiency. General medical problems account for over half of the early complications observed following cystectomy.[3] It is important to optimize the patient's other medical conditions preoperatively whenever possible.

Late Complications

INFECTIONS

Colonization of the urine with bacteria is always present in patients with a continent cutaneous reservoir on intermittent catheterization.[6,26,30] Conversely, late serious infections such as pyelonephritis and sepsis are relatively rare in the absence of upper tract obstruction or stones. *Therefore, it is very important not to subject patients to unnecessary antibiotics for asymptomatic bacterial colonization.* Patients and their primary care physicians need to be instructed in this principle.

Patients with cutaneous diversion who have symptomatic infections should be evaluated for completeness of emptying, hydronephrosis, and the presence of stones in the pouch or in the kidney. Occasionally patients with no anatomic abnormality may develop recurrent symptomatic infections that cause pain over the pouch or fevers, often preceded by very foul-smelling urine. This presentation appears to be much more common in patients with a history of interstitial cystitis than in patients with malignant disease. Daily pouch irrigation with saline solution (or even a very dilute bleach solution) should be recommended. Chronic low-dose antibiotic suppression may be helpful. A useful approach for patients who suffer recurrent symptomatic infections is to have them take a very short course of antibiotics (e.g., 2–3 days of a sulfonamide or fluoroquinolone) at the first sign of symptoms, no more than once or twice per month. Longer-term antibiotic use risks colonization with highly resistant organisms.

INCONTINENCE

Incontinence in a continent cutaneous diversion affects on average 15% of patients and can occur at any time.[31] Occasionally what is interpreted as urine leakage is actually mucus drainage from the efferent limb (which is unavoidable) or failure to pinch the catheter on withdrawal, thus leaving a small amount of urine in the efferent limb. Persistent leakage, however, is due to a failure of the continence mechanism. Endoscopic injection of bulking agents has been described, but resulted in complete resolution of leakage in a minority of patients.[32,33] Although some patients may opt for more frequent catheterization, a pad, or an external collection device as management of smaller leaks, most patients with significant leakage ultimately require open surgical repair.[34] The diagnostic approach prior to surgical correction depends on the type of urinary diversion that had been constructed, but generally includes endoscopy of the pouch and a cystogram with drainage views. Urodynamic studies should be considered in pouches constructed from colon, which is more likely to have high-pressure waves and be amenable to pouch augmentation with a patch of ileum.

The following are some considerations for each type of diversion:

1. *Kock pouch to skin*. These procedures are now rarely performed in the United States, but some older patients still have a cutaneous Kock pouch and may require treatment. Incontinence results from incompetence of the intussuscepted nipple valve possibly caused by extussusception of the valve, stones on the nipple valve, or a fistula through the midpoint of the valve (e.g., by traumatic catheterization). Flexible endoscopy allows retroflexion of the scope and identification of the problem at the efferent valve. Detubularized ileal reservoirs generally have reliable low-pressure systems, so urodynamic evaluation is not necessary. Occasionally an extussuscepted nipple valve can be restapled to the back wall of the pouch, or a stone can be removed and the nipple repaired. However, it is often preferable to replace the efferent continence mechanism completely with a new limb (e.g., using a T-limb or the Mitrofanoff principle).[34,35]
2. *Indiana pouch and its variations.* Incontinence in this type of right colon pouch is generally the result of incompetence of the reinforced ileocecal valve. It may also be caused by a high-pressure reservoir, especially if the colon was not adequately detubularized; thus urodynamic studies should be performed prior to a planned repair. Repair may be accomplished by mobilizing the pouch and reinforcing the ileocecal valve with additional Lembert silk sutures around the base, with the addition of an ileal patch onto the pouch if high-pressure contractions were seen on urodynamic study.[36] Alternatively, a new efferent limb can be constructed. Temporary improvement may occasionally be achieved with endoscopic subcutaneous injection of collagen around the base of the efferent limb near the ileocecal valve.

3. *Appendix or tapered tunneled ileal segment.* Incontinence in these systems is unusual, but it may result from loss of the reinforced tunnel at the base of the appendix or erosion of the appendix from an indwelling catheter. Again, flexible endoscopy and urodynamic studies to identify high-pressure contractions are helpful in defining the problem. Repair may be achieved by constructing a new tunnel at the base of the appendix (using the Mitrofanoff principle) or by making a new efferent limb with a tapered ileal segment. Injection of collagen in the submucosa at the base of the appendix has also occasionally been helpful.
4. *Extraserosal tunnel (T-limb).* Incontinence is usually caused by loss of the extraserosal tunnel, as occurs when the permanent silk backing sutures pull through the serosa, most likely due to trauma from daily catheterization.[14] It may be difficult to recognize this situation convincingly on a cystoscopic examination or cystogram because the problem is on the outside of the reservoir. Urodynamic studies should be performed preoperatively if the pouch was made from colon to identify high-pressure contractions. To repair the continence mechanism, either the tunnel can be reinforced with a new set of backing sutures or an entirely new efferent limb can be constructed.

POUCH STONES

Stones can develop in any continent diversion, with an incidence that varies between 5% and 10% and increases over time.[37] The incidence is highest in pouches constructed using surgical staples (such as the Kock pouch),[36] but it is also seen in pouches without any foreign body[38] and is related to mucus production, chronic bacterial colonization, and incomplete emptying. As a result, all patients with a continent diversion should be followed with at least yearly plain radiographs, CT scan, or cystogram for surveillance of stones while still small and amenable to endoscopic management.

There is a higher incidence of stones in continent cutaneous diversions than in neobladders, probably because of a higher rate of bacterial colonization and elevated post-void residual of urine leading to stasis.[39] The incidence appears to increase with longer follow-up, and patients with a history of one pouch stone have a high recurrence rate and should be followed more diligently. These patients should also be encouraged to irrigate their catheters more regularly and may benefit from potassium citrate supplementation to reduce future stone formation.[39,40]

Stones in a pouch should be suspected in a patient with hematuria, pain, difficulty with catheterization, urinary incontinence, or recurrent symptomatic urinary tract infections. The stones are almost always radiopaque and can be identified on cystogram or CT scan without contrast. It is crucial for the urologist to review these films personally, as many radiologists are unfamiliar with the anatomy of this type of reconstruction and may easily miss the presence of stones in the pouch on plain films (Fig. 46.2). It is more straightforward to identify small pouch stones on CT scan, though these may be missed as well (Fig. 46.3). MRI is not sufficiently sensitive for detecting stones in the reservoir.

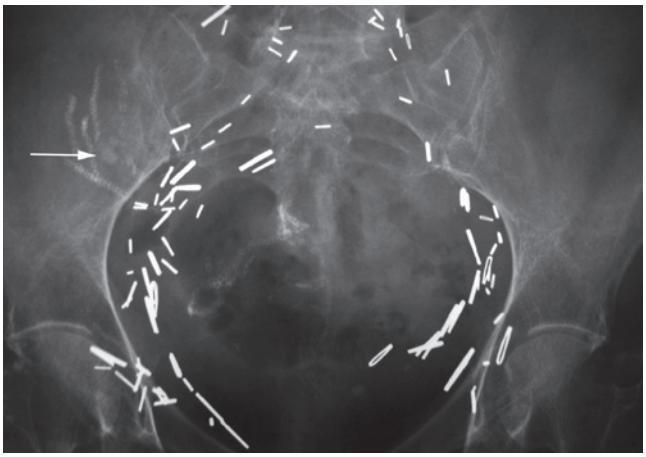

Figure 46.2 Small stones are faintly visible overlying the surgical staples on the efferent intussuscepted Kock ileal nipple valve (arrow). These stones can be missed by an inexperienced radiologist.

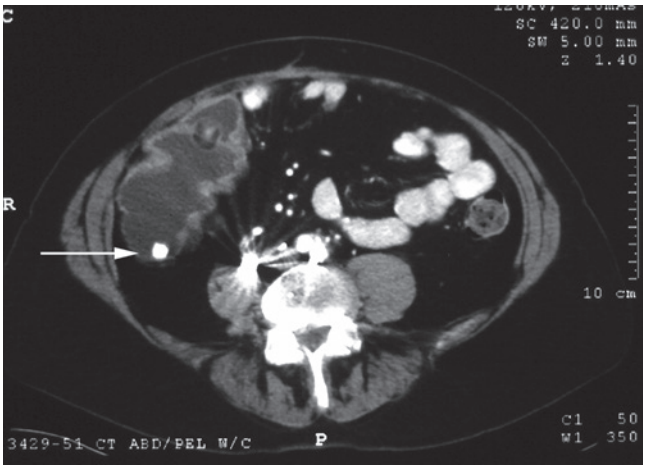

Figure 46.3 CT scan without contrast in the reservoir depicting a 1-cm stone (arrow) in the pouch.

If left untreated, these stones inevitably increase in size and tend to harden in consistency as more stone deposits in layers. Therefore pouch stones should not be observed but rather treated by complete removal at the time of initial diagnosis. The goal of treatment is to remove all fragments without damaging the pouch or its continence mechanism. Fortunately, most pouch stones can be removed endoscopically by using techniques similar to those for removal of large bladder or kidney stones. The availability of versatile endoscopes, both rigid and flexible, and of efficient energy sources such as electrohydraulic, ultrasonic, and pneumatic lithotriptors and holmium lase has allowed efficient fragmentation and removal of stones even through small stomas. Extracorporeal shock wave lithotripsy is not recommended for pouch stones because of the need to remove all fragments to prevent recurrence.

Small stones can be easily retrieved with a flexible cystoscope inserted through the stoma. Such scopes are approximately the same caliber as the catheters used to empty the pouch. Basket removal or lithotripsy followed by basket removal can be performed safely without significant concern

for damaging the continence mechanism. However, because these scopes are smaller than their rigid counterparts, the smaller working channel makes them less efficient for treating larger stones.

For large stones, a rigid scope such as an offset rigid nephroscope or cystoscope provides a large enough channel to break up and remove the stone fragments efficiently. This technique is preferable to flexible endoscopy, and a rigid scope can generally be inserted safely through a stoma under direct vision. Aggressive manipulation of a rigid scope within the efferent limb should be avoided. An Amplatz type access sheath can be used to protect the continence mechanism from damage from repetitive insertion of instruments during the course of the procedure. This device does dilate the efferent limb and stoma, but provides safe access into the pouch without damaging either the mucosa of the efferent limb or the continence mechanism. Use of continuous flow irrigation facilitated by this device decreases the pressures within the pouch, allows for efficient irrigation of stone fragments, and improves visibility during the procedure. The development of permanent incontinence after endoscopy through a stoma is extremely rare.[41] Some patients may find it difficult to catheterize immediately after endoscopic manipulation because of the presence of edema, a complication more likely with rigid than flexible endoscopy. It may be helpful to leave a catheter in the efferent limb for 24 hours after the procedure to allow the edema to subside.

Rigid endoscopy of the stoma should be avoided in certain situations. Appendiceal stomas tend to be too narrow for most rigid scopes and the angle entering the pouch limits manipulation. Small stones in such pouches can be removed with a flexible cystoscope. Larger stones or stones in a difficult location within the pouch are better managed percutaneously.[42,43] This procedure can be safely accomplished as long as one is careful to identify a spot where the pouch is up against the abdominal wall without the intervening bowel. When a percutaneous catheter had been used perioperatively, use of this old scar is generally safe. If any doubt exists, ultrasound or CT scan should be used to identify a safe passage for percutaneous access.[44] Once access is obtained, the tract can be dilated either by balloon dilation or sequential manual dilators. An Amplatz sheath along the percutaneous tract allows access to the pouch and facilitates irrigation and removal of stone fragments. All stone fragments must be extracted or irrigated out of the pouch at the end of the procedure because they may not pass through the catheter and subsequently stick to bowel mucosa and become a nidus for additional stone formation.

Patients who are not followed up with at least annual radiographs may present with very large stones (Fig. 46.4). When stones are more than 3–4 cm in diameter, endoscopic management is difficult and inefficient. In these rare situations, the stones are best managed with a simple open cystotomy lateral and superior to the stoma.[45]

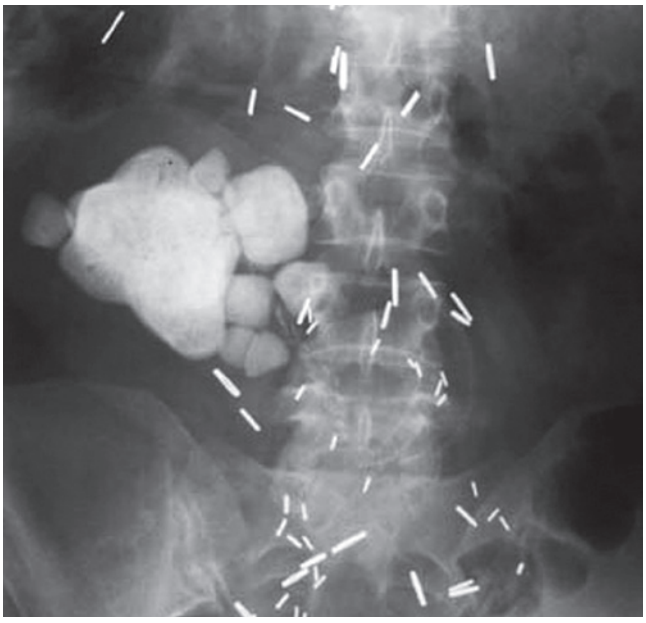

Figure 46.4 Large stones in a continent cutaneous reservoir. These stones are best removed through a small open incision lateral and superior to the stoma rather than with endoscopic techniques.

KIDNEY STONES

Kidney stones are a known complication of urinary diversions for a variety of reasons. Metal staples from a Kock pouch nipple valve may reflux up into the kidney and form a nidus for stone formation. Metabolic derangements from the interposition of intestinal segments and chronic bacterial colonization with urease-producing bacteria can predispose patients to stone formation as well.[46,47] In patients with cutaneous reservoirs, treatment options for managing kidney stones include extracorporeal shock wave lithotripsy and percutaneous nephrolithotomy.[45] In rare instances, retrograde ureteroscopy can be performed through the stoma but the altered anatomy makes access to the upper collecting system extremely difficult and unreliable.

Treatment options depend on the size and location of the stones. Although no absolute size criteria have been determined for this patient population, extracorporeal shock wave lithotripsy is more effective for smaller rather than larger stones. Overall success rates for extracorporeal shock wave lithotripsy have been variable, with overall success rates ranging up to 80%; however, more than 40% of patients required multiple treatment sessions.[48] Larger stones, staghorn calculi, and stones within the ureter are more reliably managed percutaneously either through percutaneous nephrolithotomy or antegrade ureteroscopy.

URETERAL POUCH OBSTRUCTION

The management of ureteroileal stenosis is covered in detail in Chapter 45. As mentioned earlier, the type of ureteral anastomosis is directly related to the risk of subsequent obstruction, with antireflux techniques conferring the highest rates of stenosis. The lowest rate reported is the Leadbetter technique with interrupted ureteroileal anastomoses.[49] Ureteral obstruction can be discovered incidentally, can occur many years after the diversion, and can be asymptomatic. Therefore, patients with urinary diversion need lifelong follow-up for hydronephrosis, even after the risk of recurrent cancer is past. Obstruction may also

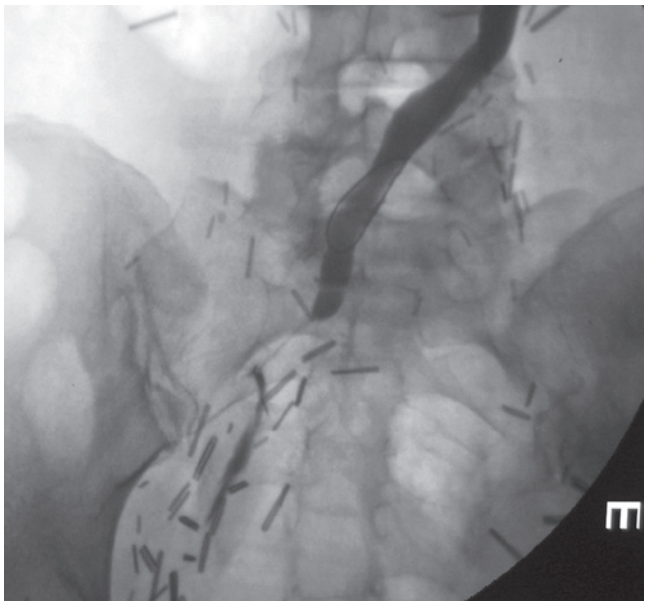

Figure 46.5 Ureteroileal stricture seen on an antegrade nephrostogram. Only a faint sliver of contrast material is seen passing through the stricture. These strictures are more common on the left side and are usually due to ischemia of the distal ureter. Nonetheless, cytologic examination and brush biopsy should be performed to rule out recurrent urothelial carcinoma.

manifest with pain, infection, or renal insufficiency. The differential diagnosis includes ischemic stenosis and recurrent cancer. These disorders can be differentiated to some extent by their appearance on CT urogram or antegrade nephrostogram (Fig. 46.5), cytologic study, or endoscopic biopsy.

Open repair is still considered the gold standard of treatment, with long-term success rates between 76% and 93%.[50–53] However, the morbidity of such repair can be significant, and therefore endoscopic techniques are usually the first line of treatment.

Endoscopic management of ureteral strictures in continent cutaneous diversion usually requires an antegrade approach because it is very difficult to access the obstructed anastomosis from the reservoir. Various endoscopic treatment modalities have been described, including balloon dilation, endoureterotomy, and metal stenting. Success rates vary widely and depend on several factors. Wolf and associates reported the importance of renal function on success rates after endoscopic treatment of nonmalignant ureteroenteric strictures, with endoureterotomy failure in all patients with ipsilateral renal unit function of less than 25%. These investigators also observed that repeat endoureterotomy after a failed procedure was considered only when at least a partial radiographic response occurred and when steroid injections were used.[54] In a review of the literature on endoscopic treatment modalities for ureterointestinal strictures after radical cystectomy, Kurzer and Leveillee concluded that favorable characteristics for success after endoureterotomy included age <60 years, a right-sided stricture, length <1 cm, mild to moderate dilation, use of a ≥12Fr stent, and stenting for >6 weeks.[55] Cumulative success rates showed that balloon dilation had the worst outcome at 18%, in contrast to endoureterotomy at 63% and metal stenting at 83%. No specific cutting modality (i.e., laser, electrocautery, cold knife) appears to have an advantage over another. These investigators also pointed out that an open repair after multiple endoscopic attempts had a lower success rate and higher morbidity than did an initial primary repair.[55] In a recent study involving 74 patients treated for nonmalignant ureteroileal strictures, Schondorf and colleagues reported than open surgical intervention produced better overall results than minimally invasive endoscopic intervention (91% for open vs 26% for endoscopic), particularly for strictures greater than 1 cm (86% for open vs 6% for endoscopic).[52] The authors concluded that the success rate of endoscopic intervention was acceptable only for ureteroileal strictures of 1 cm or less (50%) and that ureteroileal strictures greater than 1 cm should be primarily managed by open surgical revision.[52]

STOMAL STENOSIS AND DIFFICULTY WITH CATHETERIZATION

Stomal stenosis and difficulty with catheterization in the absence of stenosis at the skin occur in 10% to 30% of patients.[31] Stomal stenosis at the level of the skin is particularly common when the appendix is used for the efferent limb, presumably in part due to compromised blood supply at the appendix tip.[20,56] Location of the stoma at the umbilicus can also commonly lead to stenosis. The following sequential steps may be attempted to manage this problem:

1. Office dilation with female urethral sounds, with stoma catheter placement for a few days for additional passive dilation of the skin
2. Office incision of the stenotic skin edge or excision of built-up scar tissue
3. Outpatient Y-V plasty of the stoma by dropping in a new flap of skin
4. Formal revision of the stoma.

Formal revision of the stoma, although more involved, is also the most successful in difficult cases and has the best long-term results. As the efferent limb (appendix or ileum) has usually lengthened significantly several months after the original surgical procedure, it can be mobilized down to the fascia, the old mucocutaneous border excised, and a freshly spatulated stoma constructed with an interposed flap of skin.

Difficulty with catheterization is one of the most vexing problems for patients with a continent cutaneous diversion and causes significant anxiety. When not due to stenosis at the skin, it is usually due to tortuosity of the efferent limb in its course from the skin to the pouch, as true stenosis of the efferent limb other than at the skin level is rare. Often the source of the problem can be diagnosed by simply observing the patient self-catheterizing or catheterizing the patient in the office with the pouch full. Endoscopy of the limb can be helpful in identifying the problem, though it can be challenging in the office setting.

Complete inability to catheterize despite multiple attempts is an emergency. Unfortunately, most emergency physicians have little experience with these types of diversions and are unable to troubleshoot the problem. The urologist should thus not delay in becoming involved. A first attempt should include catheterization with a small 14Fr

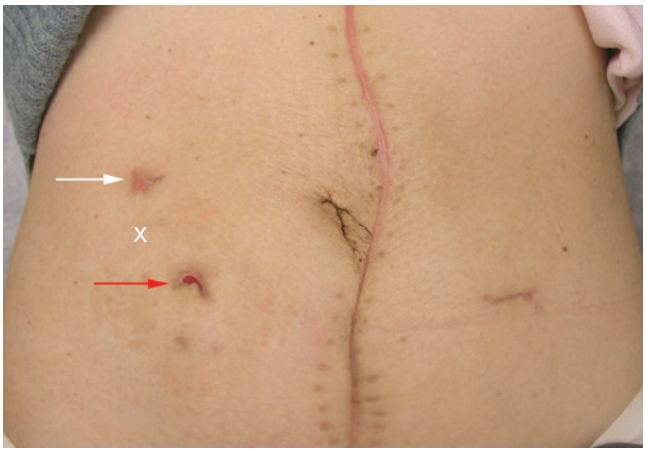

Figure 46.6 Photograph of the abdominal wall of a patient 6 months following cystectomy and nephroureterectomy with a right colon pouch and an appendix stoma. The stoma (red arrow) is located in the right lower quadrant. The scar from the perioperative percutaneous catheter drain that has been removed is lateral and superior to the stoma (white arrow). It is generally safe to drain a pouch percutaneously in the area marked (white X) because no intervening bowel should be present between the stoma and perioperative drain site.

or 16Fr coudé-tip catheter with sufficient lubrication. Flexible endoscopy with passage of a wire is occasionally successful if the stoma is open at the skin level. If these initial attempts fail, the overdistended pouch should be drained percutaneously. This maneuver relieves the patient's pain and may straighten out a kink in the efferent limb. The procedure can be done safely percutaneously with a long 18-gauge or 16-gauge angiocatheter (such as those used for central line placement) a few centimeters to the right and superior to the stoma, given that the right colon and small bowel usually lie medial to the reservoir (Fig. 46.6). A test pass can be made with a fine spinal needle, or bedside ultrasound guidance can be utilized if the location of the pouch is unclear. Once the tip of the angiocatheter is in the pouch, the needle can be removed and the pouch emptied through the soft plastic catheter. If catheterization through the stoma is still unsuccessful with the pouch less distended, a wire can be placed through the angiocatheter and the tract dilated to allow percutaneous placement of a catheter for temporary drainage until the stoma can be surgically repaired.

If the stoma is wide open at the skin but the catheter hangs up inside before entering the pouch, this is usually caused by tortuosity of the limb or an outpouching just above the fascia rather than by a true stricture within the efferent limb. Changing catheters can often solve this problem. Straight red Robinson catheters are the least expensive and the easiest for patients to find at medical supply shops. However, coudé-tip catheters or stiffer catheters (e.g., those made by Coloplast Corp., Minneapolis) may be more successful for negotiating a tortuous efferent limb or overcoming a lip at the fascia. The patient should try several different catheters to see which one works most easily. Sometimes patient position affects the ease of passing the catheter; however, because it is not practical for the patient to catheterize only lying down every effort should be made to find a solution that works with the patient in the seated or standing position.

If changing catheters does not resolve the problem, then open surgical revision is required. We usually take down the entire stoma, mobilize the pouch through the old midline incision, resect excess length of the efferent limb, and reconstruct the stoma. This surgical procedure is significant and one should ensure that all other aspects of the diversion (e.g., continence mechanism, ureteral anastomoses) are working properly or can be repaired at the same time. The surgeon should be prepared for the possible need to cut a new segment of bowel to construct an entirely new efferent continence mechanism.

Complete reconstruction of the continence mechanism may require several different techniques and should be performed by a surgeon with wide experience in continent diversion. Useful techniques include using a tapered ileal segment tunneled into a new tinea of a right colon pouch by a Mitrofanoff technique or construction of an ileal patch with a tapered extraserosal tunnel using the T-pouch technique.[15] Both these mechanisms can be added to a mature right colon reservoir after the old nonfunctioning efferent limb is excised. If the pouch was originally made from ileum, a new T-limb efferent limb can be constructed using a new short segment of ileum.

CONVERSION FROM A CONTINENT TO A NONCONTINENT DIVERSION

Very rarely, the patient and surgeon decide that the best management of a problematic continent diversion is to convert it to a continuously draining conduit. Unfortunately, this is not a simple undertaking and can be more complex than fixing the continent diversion. It is unsatisfactory simply to excise the efferent continence mechanism and connect the pouch itself to the skin because this mechanism tends to make a poor stoma, has a high risk of herniation or prolapse, and empties poorly. If an afferent limb is present (e.g., with a Studer pouch or a right colon pouch with the ureters implanted into the distal ileal segment) then the reservoir may be discarded and the afferent limb brought up as an ileal stoma. Care must be taken not to compromise the blood supply to this segment when the rest of the reservoir is excised. In the absence of an afferent limb (e.g., with an Indiana pouch), it is best to discard the pouch and construct an ileal conduit from a new segment of ileum.

AFFERENT ANTIREFLUX MECHANISM

The need to provide an antireflux mechanism is controversial because of the very high rate of bacterial colonization in these reservoirs.[6] Commonly used antireflux mechanisms include the Kock intussuscepted nipple valve, tunneled ureteral anastomoses, the ileocecal valve, or an extraserosal tunnel (T-pouch). However, these mechanisms (with the exception of the ileocecal valve) have a significant risk of late upper tract obstruction because of stenosis of the antireflux valve or ureteral stricture, and good results have been reported with direct refluxing anastomosis.[16,36]

The Kock pouch used an intussuscepted ileal nipple valve that is a very effective antireflux mechanism. Initially, few

problems were related to this mechanism other than occasional stones on the surgical staples used to maintain the nipple valve. However, with long-term follow-up investigators discovered that late stenosis of the nipple valve was common, sometimes occurring 10 years or more after construction of the reservoir.[57] This problem can remain silent until the development of significant bilateral hydroureteronephrosis or even renal failure. The diagnosis is made on antegrade study, which depicts a dilated afferent limb and delayed emptying into the reservoir. Endoscopically, these stenotic nipple valves look white and scarred, with only a pinpoint opening that may require intravenous methylene blue to identify. Treatment involves intubation with an angled catheter and wire and then incision with a hot knife through the stenotic nipple until free drainage of the afferent limb is accomplished. A balloon incision device can also be used under careful direct vision. The main risk of this procedure is bleeding from the cut edge, which can be avoided by pinpoint coagulation. Incision of the valve is usually very effective in resolving the obstruction, although recurrent obstruction can occasionally develop. Most patients who undergo incision of the valve mechanism experience reflux that does not usually cause problems, likely due to the high-volume, low-pressure mature reservoir.

The T-pouch extraserosal tunnel mechanism was designed in part to address this risk of late stenosis in the Kock pouch by better maintaining an adequate blood supply to the afferent limb.[58] Stenosis is still occasionally observed, especially in patients who were previously irradiated or in whom the distal afferent limb was tapered during construction. Because of this risk, some no longer taper the limb before closing the tunnel over the top of the afferent limb.[59] The absolute risk of late stenosis will not be known until more patients have experienced long-term follow-up. Management is with endoscopic incision, similar to that described earlier for the Kock pouch.

We have also seen occasional afferent limb stenosis that appears to result from fibrosis of the midpoint of the ileal segment itself rather than the nipple valve (Fig. 46.7). These cases closely resemble the late fibrosis and lack of peristalsis seen with very long-term follow-up of ileal conduits.[60,61] As more patients live for many years with these continent diversions, we may find that this problem is more common than currently observed. Management requires replacement of the entire afferent limb with a new segment.

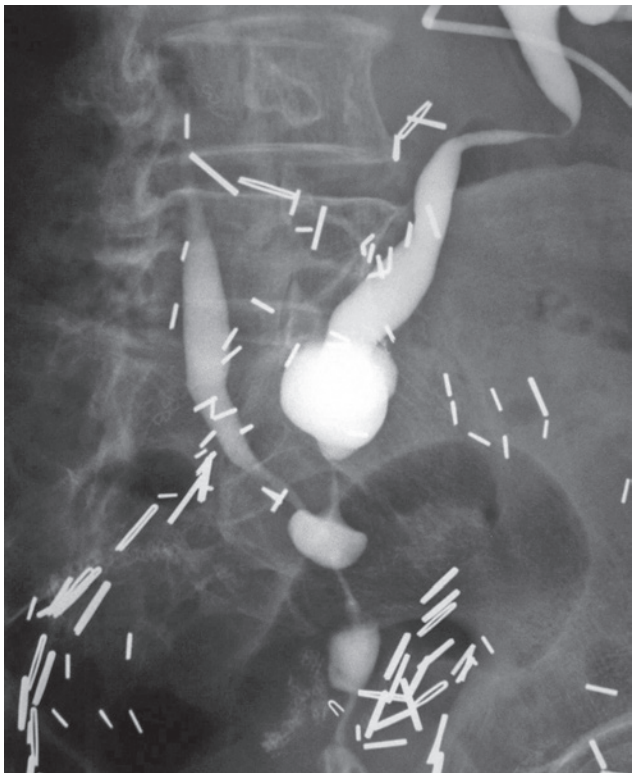

Figure 46.7 Stenosis of the midportion of the afferent limb in a patient with an ileal orthotopic neobladder. The diversion was 11 years old at the time of this diagnosis.

ACUTE POUCH RUPTURE

Spontaneous rupture of a cutaneous continent reservoir appears to be quite rare, although the exact incidence is unknown.[6,62] Mansson and colleagues polled surgeons who performed continent diversion in Scandinavia and reported that 17 patients out of a total of 1070 with cutaneous diversion suffered a spontaneous rupture, for an incidence of 1.6%.[63] Early rupture can very rarely occur in the first few postoperative weeks in a patient who is noncompliant with catheterization. Late rupture does not always have any obvious inciting event and seems to be more likely in patients who have been previously irradiated.

At presentation, the patient generally has acute severe abdominal pain and distention. Attempts to catheterize the pouch may return little urine. Unfortunately, delay in diagnosis is the rule and deaths have occurred in this situation as a result of abdominal sepsis. The diagnosis may be made on cystogram, although false-negative cystograms have been reported.[39] A CT cystogram may be more helpful. Rupture should be suspected in any patient with acute abdominal pain and ascites fluid seen on CT scan, even if actual extravasation is not demonstrated. Surgical repair is generally recommended, especially because the urine in these reservoirs is nearly always colonized with bacteria.

PARASTOMAL HERNIA

Parastomal hernias have been reported in approximately 4% of patients with continent cutaneous diversions, although the incidence may increase in patients with longer follow-up.[64] These hernias can appear with stomas at any location and are more commonly seen in patients who are elderly, obese, or smokers. These high-risk patients often also have ventral midline hernias from the abdominal incision. The parastomal hernia may lead to difficulty with catheterizing or incontinence. Repair when necessary may be attempted with a semicircle of permanent mesh placed around the stoma at the fascia level. This procedure is relatively simple for the patient because it does not require full laparotomy or adhesiolysis. Alternatively, the hernia may be repaired laparoscopically. In either approach, care must be taken to avoid placing the mesh directly against the wall of the efferent limb because that may lead to subsequent erosion of the mesh. Unfortunately, recurrence after these types of repair is not uncommon. The most secure repair

Figure 46.8 CT cystogram depicts no evidence of a urinary leak or fistula.

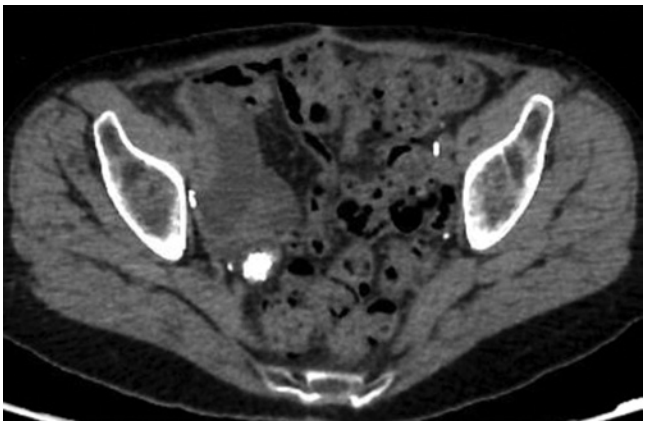

Figure 46.9 CT with a 1.5-cm stone in the pouch.

involves moving the stoma to a new site, a maneuver that requires open laparotomy and complete mobilization of the pouch. This major undertaking may occasionally require construction of an entirely new efferent limb.

LATE MALIGNANT DISEASES

The development of late malignant diseases in ureterosigmoidostomy diversions with a mean latency of 25 years was one of the factors leading to the virtual abandonment of this procedure in the United States. However, late malignant diseases have also been reported in nearly every other type of diversion, both ileal conduit and continent diversions using ileum and colon. The risk of such malignancy is unknown, but it appears to be very low.[65] The primary reason is that most patients undergoing cystectomy and continent diversion today are elderly, have invasive bladder cancer, and have a limited life expectancy.

Late adenocarcinomas have been reported in patients with continent colonic reservoirs, but with much shorter latency than that seen with ureterosigmoidostomy diversion.[65,66] Because the colon is already predisposed to develop benign and malignant polyps, it seems likely that these tumors may have existed before construction of the diversion (Figs. 46.8 and 46.9).

Conclusions

Continent cutaneous urinary diversion offers a reasonable alternative to ileal conduit or continent neobladder in properly selected patients. These operations are technically challenging, and postoperative complications are common. The surgeon undertaking continent cutaneous diversions must have a good understanding of the pathophysiology of these operations and be familiar with the diagnosis and management of their complications.

Chapter 46 Questions

1. A 75-year-old woman with a history of interstitial cystitis and functioning right colon pouch with an appendix stoma to the umbilicus has persistent infected urine despite multiple courses of oral antibiotics. She catheterizes 5 times daily. She does not have fevers but complains of some pain over the pouch and very foul-smelling urine. Renal ultrasound 6 months earlier showed no hydronephrosis. What is the next management step?
   a. Increase frequency of catheterization
   b. Long-term intravenous antibiotics
   c. Conversion to an ileal conduit
   d. Non-contrast CT scan
   e. Daily low-dose antibiotic suppression

2. Stomal stenosis at the level of the skin is most common in which of the following?
   a. Indiana pouch
   b. Right colon pouch with appendix catheterizable stoma
   c. Right colon pouch with tubularized ileal stoma
   d. Cutaneous T-pouch
   e. Kock pouch

3. A 69-year-old man with a right colon pouch and tubularized ileal stoma has increasing difficulty with self-catheterization. On examination, he has a stenotic stoma with built-up white scar tissue around the stoma edge. You are unable to pass a 14-F straight catheter. What is the next step?
   a. Gently dilate the stoma with female sounds and leave a 16-Fr catheter in the stoma taped in for a few days
   b. Flexible cystoscopy
   c. Bilateral percutaneous nephrostomy tubes
   e. Y-V plasty of the stoma
   d. Formal stoma revision for moving the stoma to another site

4. What is management of stomal stenosis at the skin with best long-term results?
   a. Office dilation with female urethral sounds
   b. Placement of a stoma catheter to facilitate passive dilation of the skin
   c. Office incision of the stenotic skin edge
   d. Y-V plasty of the stoma
   e. Formal stoma revision

5. A 65 year-old patient with history of stenosis at the skin requiring stomal dilation in clinic wakes up from significant abdominal discomfort. She cannot catheterize her stoma. By the time she sees you, she is in intense pain from the distended pouch. Catheterization with different sized Coudé-tip catheters as well as attempts at passage of a wire via flexible endoscopy are unsuccessful. What is the next step in management?
   a. Give narcotics, and come back to try again in 1 hour
   b. Placement of bilateral nephrostomy tubes
   c. Percutaneously drainage of the pouch
   d. Emergency revision of the stoma in the operating room
   e. Transfer to a tertiary care center with a surgeon experienced in cutaneous diversions

6. A 72-year-old male with radical cystectomy and right colon pouch with tubularized ileal stoma for muscle invasive bladder cancer 2 years ago comes in for annual evaluation. He has had no difficulty with pouch catheterizations, which he performs at least 5 times daily. He brings in a recent pouch urine culture collected by his primary care provider that reports 100,000 CFU/ml Escherichia coli that is pan-sensitive. He is worried that he has a urinary infection and asks about treatment. He reports no fevers and no pain, and says that his only complaint over the past few months has been foul-smelling urine on a rare occasion. Labs reveal no leukocytosis and serum Cr 1.1 mg/dL that is at baseline. A CT scan obtained earlier today depicted no evidence of kidney or pouch stones, no evidence of recurrent malignancy, and no evidence of upper tract obstruction on renal delayed phase images. What is the next step in management?
   a. 3-day course of fluoroquinolone antibiotic and teach patient daily pouch irrigation with saline solution
   b. 3-day course of fluoroquinolone antibiotic followed by prophylactic antibiotics
   c. Cystoscopy of the efferent limb and pouch in the office
   d. Cystogram of the pouch
   e. Observation

7. A patient with a history of kidney stones and an extraserosal tunnel (T-pouch) continent cutaneous diversion comes in 4 months following his surgery complaining of persistent small volume urine leakage, despite self-catheterization of the pouch at least 5 to 6 times daily. He has no fevers and no pain over the area of the pouch. What is the next step in management?
   a. Observe the patient self-catheterize
   b. Endoscopy of the pouch
   c. Cystogram of the pouch with drainage views
   d. Urodynamics to evaluate to evaluate for high-pressure contractions within the pouch
   e. CT scan to assess for pouch or kidney stones

8. A 67-year-old woman develops fecal material in the urinary drainage bag 2 weeks following cutaneous diversion with a right colon pouch. She has no associated fever and no pain. A CT scan with oral and intravenous contrast depicts no evidence of an intra-abdominal abscess, with a clearly defined fistula between the bowel anastomosis and the reservoir. What is the next step in management?
   a. Cystogram of the pouch with drainage views to better delineate the location of the fistula
   b. Endoscopy of the pouch to evaluate the size of the fistula
   c. Bilateral nephrostomy tubes to divert the urinary stream from the fistula
   d. Surgical exploration and fistula repair for definitive treatment
   e. Bowel rest and parenteral nutrition supplementation

Q9–10. A 68-year-old man has a cystectomy and continent cutaneous diversion with an ileal T pouch, constructed with afferent and efferent tapered ileum with extraserosal tunnels. He is continent and has no trouble catheterizing his stoma. Four years later his serum creatinine level has increased from a baseline of 1.1 to 1.4 mg/dL. His CT scan depicts moderate new onset bilateral hydroureteronephrosis.

9. What is the next step in management?
   a. Increase the frequency of catheterization
   b. Irrigate the pouch daily
   c. Place a permanent catheter in the stoma
   d. Place bilateral percutaneous nephrostomy tubes
   e. Perform endoscopy of the pouch

10. Endoscopy is performed with a flexible cystoscope. Following intravenous administration of methylene blue, the pinpoint sized afferent opening is catheterized with an angled catheter and wire. Retrograde pyelogram depicts bilateral hydroureteronephrosis (more severe on the left) with delayed emptying into the reservoir. What is the next management step?
    a. Placement of a ureteral stent for 6 weeks
    b. Incision of the afferent valve
    c. Left to right transureteroureterostomy
    d. Open excision of the afferent valve and reimplantation of the ureters into the pouch
    e. Conversion to an ileal conduit

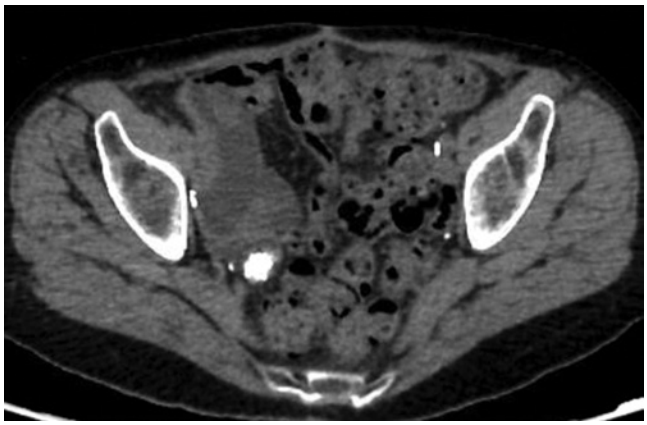
11. A 59-year-old woman a continent cutaneous diversion with a right colon pouch has gross hematuria, abdominal pain, and leakage of urine in between catheterizations. A non-contrast CT scan depicts a 5 mm stone in her pouch with no associated kidney stones. How should this stone be managed?
    a. Urinary alkalinization and observation for the stone to pass
    b. Shock wave lithotripsy
    c. Endoscopic removal through the stoma with a flexible cystoscope and holmium laser
    d. Percutaneous extraction through a puncture between the stoma and the perioperative percutaneous catheter drain
    e. Open surgical extraction of the stones

Case Studies

CASE 1

A 71-year-old woman is diagnosed with a large muscle invasive bladder tumor causing right hydronephrosis. Following neoadjuvant chemotherapy, she is noted to have a partial response by CT scan and undergoes definitive management with a radical cystectomy anterior exenteration continent cutaneous urinary diversion with a right colon pouch and appendix catheterizable stoma. She develops stomal stenosis of the skin 7 months later and is having an increasingly difficult time catheterizing through the stoma. Attempted dilation in clinic with female urethral sounds did not result in improvement with catheterizations. Serum Cr is 1.3 mg/dL, slightly increased from a baseline of 1.0 mg/dL. CT scan depicts no evidence of hydronephrosis or urolithiasis.

Case Figure 46.1



1. What is the next step in management?
   a. Flexible cystoscopy
   b. Percutaneous drainage of the pouch
   c. Bilateral percutaneous nephrostomy tubes
   d. Y-V plasty of the stoma
   e. Formal stoma revision

2. She undergoes Y-V plasty of the stoma and is subsequently able to catheterize without difficulty; however 2 years later she develops progressively worsening urinary leakage in between catheterizations, especially when she is ambulatory. In clinic you observe that she catheterizes with ease and correctly pinches the catheter on withdrawal to avoid backflow of urine. Endoscopy of the pouch is normal and a cystogram with drainage views is shown in Case Fig. 46.1. The next step is:
   a. Observation
   b. Leave a catheter in the pouch for a few days
   c. Urodynamics to evaluate for high-pressure contractions within the pouch
   d. Repeat endoscopy of the pouch in 3 months
   e. Formal stoma revision

3. Filling urodynamics show peak pressure waves of 20 cm water. CT scan shows no hydronephrosis and no urolithiasis. The next step is:
   a. Increased frequency of catheterizations
   b. Leave a catheter in the pouch for a few days
   c. Augmentation of the reservoir with a patch of ileum
   d. Open repair or replacement of the efferent catheterizable continence limb
   e. Conversion to an ileal conduit

CASE 2

A 72-year-old woman with history of anterior pelvic exenteration and construction of an Indiana pouch 4 years ago for high-grade noninvasive bladder cancer presents

Case Figure 46.2

to you with recurrent pain over the pouch for the last 6 months associated with persistently infected urine. She has a known blown-out, nonfunctioning left kidney from a prior ureteral stricture. Her pain resolves with culture-tailored oral antibiotics, but recurs off antibiotics. She self-catheterizes four to six times per day without difficulty. Surveillance with MRI 3 months ago showed no evidence of disease recurrence, no right hydronephrosis, and the known left hydronephrosis.

1. What is the next step in management?
   a. Urodynamics
   b. Daily low-dose antibiotics
   c. Noncontrast CT scan
   d. Increase frequency of catheterization
   e. Left percutaneous nephrostomy tube

2. CT scan of the pouch is shown in Case Fig. 46.2. The pouch stone is 1.5 cm in size. There are no kidney stones. How should this stone be managed?
   a. Dissolution therapy with urinary alkalinization
   b. Endoscopic treatment with a flexible cystoscope and holmium laser
   c. Shock wave lithotripsy
   d. Percutaneous ultrasound-guided stone extraction
   e. Open surgical extraction of the stones

3. The patient undergoes endoscopic laser lithotripsy of the pouch stone. She is lost to follow-up and returns 4 years later with an x-ray of the abdomen that depicts two 5-cm stones in the pouch. What is the best management of these stones?
   a. Dissolution therapy with urinary alkalinization
   b. Endoscopic treatment with a flexible cystoscope and holmium laser
   c. Shock wave lithotripsy
   d. Percutaneous ultrasound-guided stone extraction
   e. Open surgical extraction of the stones

Answers

1. **d.** Patients with cutaneous diversion who have persistent urinary infections should be evaluated for completeness of emptying, hydronephrosis, and the presence of stones in the pouch or in the kidney that represent a nidus for persistence of the urinary pathogen. Stones are almost always radiopaque and are best identified on a noncontrast CT scan.
2. **b.** Stomal stenosis at the level of the skin is particularly common when the appendix is used for the efferent limb, presumably in part due to compromised blood supply at the appendix tip. Stomal stenosis can be minimized by making a V-shaped flap when opening the skin and dropping the skin flap into the spatulated antimesenteric side of the efferent limb when it is matured to the skin. This maneuver can be performed whether the stoma is in the right lower quadrant or at the umbilicus.
3. **a.** The initial step in management of stomal stenosis at the level of the skin is office dilation with sounds and placement of a catheter in the stoma for additional passive dilation. If this does not improve self-catheterization, subsequent steps are office excision of the scar tissue or surgical repair with outpatient Y-V plasty of the stoma or formal revision of the stoma.
4. **e.** All of the choices are steps in the management of stomal stenosis at the level of the skin; however, formal revision of the stoma is the most successful in difficult cases and has the best long-term results. The efferent limb (appendix or ileum) is mobilized down to the fascia, the old mucocutaneous border excised, and a freshly spatulated stoma constructed with an interposed flap of skin.
5. **c.** Complete inability to catheterize despite multiple attempts is an emergency. If initial attempts at access of the pouch are unsuccessful, the overdistended pouch should be drained percutaneously to relieve the patient's pain. The procedure can be done safely percutaneously with a long 18-gauge or 16-gauge angiocatheter. If the location of the pouch is unclear, a test pass can be made with a fine spinal needle or bedside ultrasound guidance should be utilized.
6. **e.** This patient has asymptomatic bacterial colonization of the pouch, which is essentially universal in patients with a continent cutaneous reservoir on intermittent catheterization. It is very important not to subject patients to unnecessary antibiotics for asymptomatic bacterial colonization. Patients and their primary care physicians need to be instructed in this principle.
7. **a.** Persistent incontinence from cutaneous continent reservoirs affects an average 15% of patients and usually requires surgical repair. However, on occasion what is interpreted as urine leakage is actually mucus drainage from the efferent limb (which is unavoidable) or a small amount of urine left in the efferent limb after failure to pinch the catheter on withdrawal. Thus, an important initial step prior to proceeding with a diagnostic approach for anticipated surgical correction is to observe the patient catheterizing to determine if this is done correctly.
8. **e.** A fistula to the pouch is generally caused by a leak from the bowel anastomosis or a missed bowel injury. In this patient, it is most likely due to a leak from the bowel anastomosis given its proximity to the pouch. The recommended management is bowel rest with parenteral nutrition. Early surgical exploration is difficult in the setting of inflammatory postoperative reaction and should be avoided in favor of delayed repeat

exploration and repair if the fistula does not resolve within 4 to 6 weeks of bowel rest.

9. **e.** The most likely cause of bilateral hydronephrosis in this setting is stenosis of the afferent limb where it inserts into the pouch. This is easily identified on endoscopy which will show a pinpoint opening where the afferent limb empties into the pouch.
10. **b.** The Kock pouch used an intussuscepted ileal nipple valve as a very effective antireflux mechanism. Although there were few early complications related to this mechanism (occasional stones on the surgical staples used to maintain the nipple valve), a notable late complication was stenosis of the nipple valve. This problem can potentially remain silent until the development of significant bilateral hydroureteronephrosis or renal injury. The first step in management is endoscopic evaluation of the pouch – the stenotic nipple valve appears white and scarred, its pinpoint opening usually requiring intravenous methylene blue for identification. Treatment involves intubation of the opening with an angled catheter and wire followed by incision of the afferent valve with a hot knife through the stenotic nipple until free drainage of the afferent limb is accomplished. This is usually very effective in resolving the obstruction, and open surgical revision is rarely required.
11. **c.** Pouch stones should not be observed because they are unlikely to pass via the efferent limb and inevitably increase in size as more stone deposits in layers. The recommended treatment is complete removal at the time of initial diagnosis, which for a stone this size can be efficiently performed with laser lithotripsy and stone basketing via a flexible cystoscope. Extracorporeal shock wave lithotripsy is not recommended for pouch stones because of the need to remove all fragments to prevent recurrence. Open surgical repair is reserved for pouch stones larger than 3–4 cm in diameter.

CASE 1

1. **b.** A patient with acute inability to drain a continent cutaneous reservoir is often in acute pain by the time of treatment. If simple dilation of the stoma or negotiation of a smaller catheter is not possible, draining the pouch percutaneously can often relieve pressure and allow time to negotiate a catheter in. If an angiocatheter is used a wire could be passed and used to place a temporary suprapubic catheter if necessary.
2. **c.** The cystogram shown depicts no evidence of urinary leak or urinary fistula. On the basis of the diagnostic evaluation, this patient has urinary incontinence. Incontinence in a diversion with an appendix catheterizable stoma is infrequent but usually requires surgical repair. It may be due to loss of the reinforced tunnel at the base of the appendix or erosion of the appendix from an indwelling catheter. Prior to surgical management, urodynamic studies to identify high-pressure contractions are helpful in defining the problem and to delineate the type of surgical repair.
3. **d.** Augmentation of the reservoir is not indicated in the setting of low-pressure contractions within the pouch. However as persistent leakage is due to a failure of the continence mechanism, increased frequency of catheterizations or an indwelling catheter are insufficient and formal stoma revision is required. Surgical repair consists of either making a new tunnel at the base of the appendix using the Mitrofanoff principle or constructing an entirely new efferent limb with a tapered ileal segment (see Case Fig. 46.1).

CASE 2

1. **c.** Patients with cutaneous diversion and persistent infections should be evaluated for the presence of pouch or kidney stones. Stones are not well seen on MRI and are best identified with a noncontrast CT scan.
2. **b.** Pouch stones are unlikely to dissolve or pass. The recommended treatment is complete removal at the time of initial diagnosis. This stone is small enough to be efficiently treated with laser lithotripsy and stone basketing via a flexible cystoscope. Extracorporeal shock wave lithotripsy is not recommended for pouch stones because of the need to remove all fragments to prevent recurrence. Percutaneous management is reserved for larger stones or stones in a difficult location within the pouch.
3. **e.** When patients with continent cutaneous diversion are not followed up with at least annual radiographs, they may present with very large stones in the pouch. Endoscopic or percutaneous management is inefficient for stones that are larger than 3–4 cm in diameter. The best management is a simple open cystotomy lateral and superior to the stoma (see Case Fig. 46.2).

47 Complications of Orthotopic Neobladder

SANJAY G. PATEL and MICHAEL S. COOKSON

CHAPTER OUTLINE

Patient Selection and Contraindications to Orthotopic Diversion
Surgical Complications
Bowel Complications
Urethral Anastomotic Complications
Ureterointestinal Anastomotic Complications
Urolithiasis
Urinary Tract Colonization and Pyelonephritis
Fistulas
Voiding Dysfunction
Urethral and Pelvic Tumor Recurrence
Neobladder Rupture
Chapter 47 Questions and Answers

KEY POINTS

1. Proper patient selection is probably the single most important factor in determining the ultimate success or failure of orthotopic neobladder diversion.
2. Absolute contraindications to orthotopic neobladder include significant renal disease, severe hepatic dysfunction, inflammatory bowel disease, radiation enteritis, sphincter dysfunction, severe urethral stricture disease, inability to manage neobladder care, and any compromise of oncologic control.
3. Most neovesical-urethral anastomotic leaks will spontaneously close with conservative management; however, it is critical to evaluate for outlet obstruction due to mucus retention to prevent neobladder perforation.
4. Ureterointestinal strictures are less prevalent with a refluxing anastomosis. Such strictures are optimally approached in an antegrade fashion for initial endoscopic management and will likely require surgical correction.
5. Patient counseling about potential neobladder voiding dysfunction including nighttime incontinence, stress incontinence, and hypercontinence must be thoroughly addressed preoperatively so that functional outcomes are aligned with patient expectations.

Since the 19th century, urologists have used intestinal segments for reconstruction of the urinary tract following extirpative surgical procedures. However, objectives have evolved from a simple diversion of urine with preservation of renal function to the anatomic and functional preservation of volitional voiding without altered body image. In fact, the desire to afford patients with a near-normal state of voiding by preserving the natural continence mechanism while eliminating a cutaneous stoma or absolute requirement for intermittent catheterization led to the development of orthotopic urinary diversion. Orthotopic bladder substitution, first pioneered by Lemoine[1] in the early 20th century and popularized by Camey and LeDuc,[2] has been extensively refined[3–6] to a procedure with excellent patient satisfaction and acceptably low morbidity.

Many techniques exist for creation of an orthotopic neobladder.[7–12] Ileum is the bowel segment of choice because of ease of construction, lower storage pressures, less urine absorption, and lower mucus production as compared with large bowel. The most commonly performed ileal reservoirs fall into one of two types: the U-shaped ileal neobladder as described by Studer and associates[13] and the W-shaped reservoir that was initially described by Hautmann and colleagues.[3,10] Basic requirements for an acceptable orthotopic urinary neobladder include a capacious, low-pressure reservoir that provides acceptable continence without compromising cancer control. Both the Studer and Hautmann configurations are easily constructed using an afferent limb or chimney that facilitates the ureteroileal anastomosis.

As contemporary surgeons have become more familiar and dexterous with robotic surgery, robotic radical cystectomy has increased in utilization. While the cystectomy portion is generally performed intracorporally, many surgeons are reluctant to perform the urinary diversion intracorporally due to the technical challenges and increased operative times required. Intracorporeal robotic neobladder diversion techniques have been refined and are typically performed using a modified Studer technique,[14] and their frequency will increase over time.

Multiple large published series and reviews have reported the surgical complications and long-term outcomes of open orthotopic neobladders.[15–17] Robotic intracorporeal

neobladder diversion has been shown to have similar complication rates to that of open series.[18] Randomized studies comparing open and robotic neobladder diversions have yet to be performed and may ultimately answer if the robotic technique offers an advantage over open techniques. Most potential complications, including the diagnosis and treatment options outlined in this chapter, are generally applicable to all methods of orthotopic neobladder diversion. As discussed in further detail, typical early postoperative complications are similar to those seen with other types of urinary diversion and can include persistent urine leak, pyelonephritis, and bowel complications such as ileus and small bowel obstruction. Late complications can include ureteroenteric and neovesical-urethral anastomotic stricture, urinary fistula, and urolithiasis. Additionally, the issues and complications unique to orthotopic neobladder, including patient selection concerns, voiding dysfunction, and incontinence, are addressed.

Patient Selection and Contraindications to Orthotopic Diversion

Fortunately, we practice urology in an era when bladder cancer has become a survivable disease for a substantial percentage of patients and the long-term outlook is a component of the algorithm for the consideration of treatment options. With improvements in anesthesia and surgical technique, radical cystectomy is feasible even in patients of advanced age and with significant comorbid conditions.[19–21] In choosing to perform an orthotopic neobladder, proper patient selection is probably the single most important factor in determining the ultimate success or failure of the procedure. Patients must be cognizant of the medical, physical, and emotional demands of a continent urinary reservoir, must be highly motivated and capable of performing self-catheterization, and must be compliant with the necessary follow-up regimen.[12] Thus, patients with severe mental impairment should not undergo orthotopic diversion.

Preoperative counseling on methods of urinary diversion by a trained wound ostomy continence nurse can aid immensely in both the physical and mental preparations of the patient for the demands of a neobladder and should be obtained for all patients regardless of choice of diversion. The wound ostomy continence nurse should mark the patient for an appropriate stomal site on the abdominal wall in the event that intraoperative factors preclude neobladder diversion and noncontinent diversion is performed.

Although some risk factors that were previously considered contraindications to neobladder, including advanced age, have changed with improved technique,[16] absolute contraindications to creation of an orthotopic reservoir still exist (Table 47.1). Sound oncologic principles should always supersede the preference of diversion, most prominently the achievement of negative surgical margins at the site of the neoanastomosis. In women, orthotopic diversion should be reserved for patients whose tumors do not involve the bladder neck or urethra. In men, involvement of the prostatic stroma or apex is an absolute contraindication to neobladder diversion. Investigators have strongly recommended that frozen section analysis of urethral margins be performed intraoperatively before construction of an orthotopic diversion.[22] Orthotopic reconstruction is absolutely contraindicated in patients in whom simultaneous urethrectomy is indicated on the basis of their primary tumor.

Table 47.1 Absolute Contraindications to Orthotopic Neobladder

Medical	Oncologic
Compromised renal function	Bladder neck involvement: female patient
Serum creatinine >2.0 mg/dL or creatinine clearance <60 mL/min	Prostatic urethral or apical involvement: male patient
Severe hepatic dysfunction	Need for simultaneous urethrectomy
Compromised intestinal function	Failure to achieve negative urethral margin
Inflammatory bowel disease	
Radiation enteritis	
External sphincter dysfunction	
Severe urethral stricture disease	
Severe mental impairment	

Significant benign urethral disease such as profound stricture is also considered an absolute contraindication. Furthermore, patients with external sphincter dysfunction, a severely compromised rhabdosphincter, or an incompetent urethra should also be excluded from placement of a neobladder. In addition, severe acute or chronic inflammatory bowel disease affecting the chosen bowel segment is a contraindication to construction of a neobladder.[23] In general, continent urinary diversion should not be performed in patients with significant renal or hepatic impairment.[24–26] Isolated case reports have advocated the use of continent urinary diversions in select patients with renal insufficiency.[27,28] However, the prolonged metabolic acidosis associated with neobladder diversion is generally poorly tolerated in patients with any degree of renal compromise.[29] In most adult patients, neobladder diversion should be performed only if the serum creatinine concentration is <2 mg/dL.[30]

Patients considered for continent diversion should have normal liver function because reabsorption of ammonium and chloride can worsen hepatic impairment and can precipitate encephalopathy.[24,31] Some surgeons consider stress urinary incontinence an absolute contraindication for neobladder diversion.[16] However, as discussed later, techniques for management of stress incontinence in patients with neobladders are increasingly acknowledged.

As mentioned earlier, several factors previously considered inadvisable to selection of patients for orthotopic diversion, such as obesity, advanced chronologic age, prior abdominal surgical procedures, or the presence of metastases in pelvic lymph nodes, when taken individually are no longer considered absolute contraindications.[12,32,33] Indeed, management of bladder cancer in the elderly patient is becoming an increasingly important issue as the general population ages. Clark and colleagues[19] demonstrated that radical cystectomy with orthotopic urinary diversion could be performed even in persons of significantly advanced age without escalating operative mortality or diversion-related complications.

Although patients with increased body mass index have been shown to have higher rates of transfusion[34] and of postoperative complications,[35] investigators generally accept that weight per se does not affect cancer-specific survival

and is not an absolute contraindication for performing cystectomy with continent diversion.[36] Neobladder may be a preferable diversion choice in severely obese patients where increased anterior abdominal adiposity makes it difficult to create a low tension cutaneous stoma. In addition, avoidance of a cutaneous stoma in morbidly obese patients may preclude development of stomal complications including the development of a parastomal hernia. Multiple studies demonstrated that the incidence of local pelvic recurrence with lymph node–positive disease is approximately 11% and the presence of positive lymph nodes by itself should not preclude placement of an orthotopic diversion.[12,33] In patients who have received prior pelvic irradiation, great care must be taken to select a bowel segment out of the confines of the radiated field. Salvage cystectomy with neobladder diversion is a technically challenging procedure but has been demonstrated to be a viable option in selected cases.[21,37–39] However, patients should be preoperatively counseled on reported incontinence rates approaching 25% following salvage cystectomy with neobladder and the possible need for artificial urinary sphincter placement in the future.[12]

Surgical Complications

Proper patient preparation and adherence to meticulous surgical technique are paramount in the prevention of surgical complications. Although controversy existed in the current literature from urologic and colorectal surgery,[40] investigators previously accepted that urologic patients who have an intestinal procedure on unprepared bowel have an increased incidence of wound infections, intraperitoneal abscess formation, and bowel anastomotic leakage when compared with patients who have preoperative mechanical bowel preparation.[30,41] Various methods are employed for mechanical cleansing of the bowel.[42] Current protocols often administer large volumes of an oral polyethylene glycol solution. Not all patients readily tolerate this treatment because of the large amount of fluid that must be ingested, in addition to the nausea, emesis, and abdominal cramping that are frequent side effects of the bowel preparation. Elderly patients may be unable to complete this regimen as a result of these mentioned side effects in combination with dehydration induced by the profuse diarrhea. Thus, some patients may benefit from preoperative admission specifically for bowel preparation. Alternatively, oral sodium phosphate solutions can produce equivalent mechanical cleansing with the consumption of significantly less volume.[43,44] Recent evidence from colorectal and urology literature suggests that there is no increased risk of complications (superficial infections, fascial dehiscence, or anastomotic leakage) in patients not undergoing mechanical bowel preparation.[45] As a result, there has been a move away from preoperative mechanical bowel preparations in patients undergoing cystectomy and urinary diversion.[46,47] Antibiotic bowel preparations are often used in combination with mechanical cleansing and consist of timed doses of neomycin and erythromycin base or metronidazole on the day before the surgical procedure.[48,49] However, articles in the general surgery and colorectal literature have suggested that preoperative bowel preparation with oral antibiotics may be safely omitted in the current era of potent intravenous (IV) antibiotics.[50]

An advisory statement from the National Surgical Infection Prevention Project outlined the use of perioperative antibiotics for prevention of surgical site infections.[51] The working group endorsed infusion of the antimicrobial dose within 60 minutes of incision and suggested that antibiotic prophylaxis be discontinued within 24 hours after the operation. Although the committee did not specifically address urologic surgery, cephalosporins were included in the recommendations for general abdominal, colon, cardiac, orthopedic, gynecologic, and vascular surgical procedures. To decrease wound infection rates in bowel surgery, preoperative IV doses of a second- or third-generation cephalosporin such as cefoxitin, 2 g, should be administered within an hour of incision. For patients with allergies to β-lactam antibiotics, perioperative doses of vancomycin, 1 g IV, in conjunction with clindamycin, 600–900 mg IV, should be substituted. The American Urologic Association Best Practice Statement on Urologic Surgery Antimicrobial Prophylaxis recommends administration of a second- or third-generation cephalosporin or aminoglycoside + metronidazole or clindamycin as first-line prophylaxis.[52] Pariser et al. demonstrated a reduction in postoperative infection rates and subsequent morbidity by changing the perioperative antibiotic regimen prior to cystectomy from cefoxitin alone to vancomycin, gentamicin, and fluconazole based on analysis of prior positive culture data within 30 days of cystectomy during a 2-year time period.[53] Thus perioperative antibiotic regimens may be refined to reflect institutional and regional antibiotic resistance characteristics.

Venous thromboembolism has been recognized in approximately 1–6% of patients undergoing radical cystectomy with orthotopic diversion.[54–58] Studies have advocated the use of venous thromboembolism prophylaxis for major urologic surgical procoedures,[59–61] as underscored by the knowledge of a higher incidence of deep vein thrombosis in patients with cancer.[62] Low-molecular-weight heparin or alternatively low-dose unfractionated heparin should be administered preoperatively and during the length of hospitalization. Graduated compression stockings and intermittent pneumatic compression may be used in conjunction with systemic anticoagulation. Controversy exists concerning the optimal duration of thromboembolic therapy administered for deep vein thrombosis prophylaxis.[59] Continuation of anticoagulant therapy following hospital discharge is determined at the level of the individual patient with special consideration to the patient's history, age, and mobility.[63]

Intraoperatively, strict adherence to general principles such as preservation of intestinal blood supply, gentle handling of tissue, avoidance of spillage of enteric contents, careful orientation of bowel segments, and realignment of the mesentery is critical in the avoidance of bowel-related complications. Occasionally a patient has such significant bowel adhesions or a tethered mesentery that placement of the neobladder within the pelvis becomes unfeasible. Multiple maneuvers are available for attempts to place the neobladder to the proper anatomic location for urethral anastomosis,[10] but in the event these are unsuccessful, continent cutaneous diversion or incontinent diversion with an ileal conduit should be performed.

BOWEL COMPLICATIONS

Early bowel complications are usually related to the bowel resection and subsequent anastomosis. These complications can include anastomotic leak, enteric fistula, bowel obstruction, and prolonged ileus. These entities often manifest in the early postoperative period as wound infections or abdominal abscesses and if undiscovered may progress to sepsis. Fortunately, these complications are relatively uncommon but nonetheless may be a cause of early major morbidity and mortality. This possibility underscores the need for prompt recognition and treatment.

The most common cause of delay in bowel function following intestinal reconstruction is paralytic ileus.[64] The incidence of this complication varies by series, era, and definition but in general approaches 20%. In a series of 304 patients who underwent radical cystectomy, half of whom underwent neobladder diversions, ileus was the most common cause of increased length of hospital stay and was clinically apparent in 18% of patients.[57] Most of these cases resolved with conservative management. Conservative management entails early ambulation, correction of electrolyte abnormalities, and encouraging moderate use of narcotic pain medications. Nasogastric tubes were not used routinely in this cohort and were reserved only for those patients with significant abdominal distention or emesis. Other series also advocated avoidance of nasogastric tubes or their early removal following cystectomy and urinary diversion.[65–67]

Although published evidence is not overwhelming,[68,69] total parenteral nutrition should be considered in patients with prolonged delay in enteral feeding, to avoid subsequent clinical malnutrition and deterioration.[70] More recent series have indicated that early oral or parenteral feeding may not affect the return of bowel function,[71,72] so the use of oral or parenteral nutrition is possibly best reserved for patients with prolonged ileus. Patients who undergo cystectomy should also routinely be treated with a proton pump inhibitor or histamine (H_2) blocker to decrease gastric pH and to facilitate prevention of clinically significant gastric bleeding.[73] Although some surgeons favor the use of metoclopramide as an adjunct to prevent postoperative nausea and vomiting by promoting intestinal motility, no substantial evidence from controlled trials supports this approach.[74]

Bowel obstruction occurs uncommonly in the early postoperative setting, although the historical incidence is between 1% and 15%.[30,64,75] Patients with obstruction may experience any combination of abdominal pain, distention, nausea, emesis, and obstipation. Because mechanical ileus provokes dehydration and electrolyte disturbances, adequate fluid resuscitation, particularly replacement of nasogastric tube output, is critical.

Initial imaging traditionally included flat and upright plain abdominal films to demonstrate distended loops of bowel on the supine view (Fig. 47.1), as well as air-fluid levels on the upright view. An unresolving obstruction may merit imaging with computed tomography (CT) including oral contrast or an upper gastrointestinal series with a small-bowel follow-through to define the point of mechanical obstruction further. As with paralytic ileus, most partial, mechanical, bowel obstructions resolve with conservative management, and only a few patients require reoperation.[56,64,76,77] The most common causes of bowel obstruction

Figure 47.1 Partial small bowel obstruction in an abdominal plain film following cystectomy. Note the substantial dilation of the small bowel and limited air in the distal colon. This patient has a solitary kidney and thus a single ureteral stent emanating from the neobladder.

are adhesions, although fascial and internal hernias can be culpable as well. In addition to careful closure of mesenteric apertures, a novel bioabsorbable membrane of hyaluronate and carboxymethylcellulose (Seprafilm) is available for intraoperative application to diminish the rate of significant bowel adhesions.[78]

Recurrent cancer should always be considered in the differential diagnosis in patients presenting with a late bowel-related complication, even in the absence of demonstrable radiographic findings. When surgical exploration is required, tissue sampling should be obtained to rule out recurrent cancer.

Anastomotic bowel leak or breakdown is a potentially devastating complication that has been reported in urologic reconstruction in 1–5% of patients.[79] Factors contributing to anastomotic breakdown include surgical techniques, bowel ischemia, prior radiation therapy, systemic steroid use, inflammatory bowel disease, and distal bowel obstruction. Attempts to avoid anastomotic breakdown include adequate bowel preparation, irrigation of the bowel segment before manipulation to prevent undue spillage of enteric contents into the peritoneum, use of nonirradiated and well-vascularized bowel, and placement of omentum over the anastomosis.[30,79] Patients with poor nutritional status or chronic pulmonary disease and those who received >2 U red blood cell transfusions also appear to be at higher risk for anastomotic complications.[80]

Unrecognized anastomotic leaks may lead to septic complications including abscess formation, wound dehiscence, and fistula formation. This possibility underscores the importance of early recognition and prompt correction. Fever, leukocytosis, and abdominal pain in the early postoperative period should be aggressively evaluated with abdominal CT scan with oral and IV contrast to delineate the anastomotic leak and any developing abscess. Broad-spectrum

antibiotics should be administered early to prevent the development of sepsis, and patients should be kept without oral intake. Although on many occasions the abscess can be percutaneously drained by interventional radiologic means, the surgeon must maintain a high level of vigilance and suspicion for the potential presence of necrotic bowel, which would require emergency reoperation.[79]

Resection of >60 cm of ileum for neobladder formation may decrease bile acid reabsorption that cannot be adequately compensated for by hepatic production, with resulting bile salt, lipid, and vitamin B_{12} malabsorption and profound diarrhea.[81] Oxalate levels may additionally become elevated and thus increase the propensity for urinary calculus formation. Cholestyramine has been used to bind excess bile acids and to treat diarrhea, but long-term therapy is poorly tolerated.[82,83] Careful attention to preservation of the ileocecal valve and appropriate use of <60 cm of intestine are the best strategies to prevent sequelae of malabsorption.

Orthotopic diversion allows significant prolonged contact of urine with bowel mucosa. When ileum is used for neobladder construction, ammonium, hydrogen ion, and chloride are reabsorbed with wasting of sodium and bicarbonate into the lumen and resulting hyperchloremic metabolic acidosis, which is reported to occur in ≤10% of patients.[24,84] Early postoperative treatment with sodium bicarbonate (2–6 g/day) may assist in preventing the salt-wasting hypovolemic and acidotic state.[16] Patients are usually weaned from these treatments after the first few months because persistent significant acidosis is rare in patients with normal renal function. However, yearly monitoring of electrolyte status can diagnose and help avert long-term complications of acidosis, such as bone demineralization.

URETHRAL ANASTOMOTIC COMPLICATIONS

The ileal neobladder can be complicated by persistent urinary leakage at the neovesical-urethral anastomosis, as manifested by high drain output in the postoperative period. Large series specifically addressing neobladder diversion indicated early urethral anastomotic leak occurrence of between 2.1% and 6.6%, with later ileourethral leakage at <1%.[16] Additional series reported rates of urethral anastomotic leak of approximately 3–7.7%, with only a minute percentage requiring operative intervention.[56,85,86] Neovesical-urethral anastomotic leaks most often spontaneously close with continued drainage and decompression of the neobladder.

When evaluating anastomotic leak, the surgeon must rule out outlet obstruction as a cause. Urinary retention resulting from mucus obstruction occurs between 1.2% and 4.6% of the time and can contribute to anastomotic leakage as well as the rare but potentially devastating complication of neobladder perforation.[16,87] Regardless of whether a suprapubic tube (which incidentally, we no longer routinely use) is placed in the neobladder in conjunction with the urethral catheter, regular irrigation of the neobladder in the initial postoperative period decreases mucus retention and facilitates emptying to reduce neobladder-urethral anastomotic leakage and allow optimal healing.

It is also critical to ensure that the Foley catheter is in the proper position and that it has not migrated out of the neobladder into the urethra. We generally use a 20- or 22Fr Foley catheter with a 10-mL balloon and inflate the balloon to 15 mL to allow a spherical configuration. A larger catheter is necessary to allow for irrigation of mucus or blood clots in the early postoperative period. Occasionally it may be useful to manipulate the placement of the drain lying on the anastomotic suture line to ensure that the drain itself is not perpetuating the leak.[87] A cystogram may be performed before drain or catheter removal to ensure complete closure at the urethral anastomosis. For prolonged urine leakage or in patients who develop metabolic derangements from urinary extravasation, bilateral percutaneous nephrostomy tubes can be placed for temporary diversion along with a Foley catheter and pelvic drain. Prevention of urethral anastomotic leaks may be aided by meticulous mucosa-to-mucosa approximation of a tension-free suture line and avoidance of overdistention of the neobladder resulting from catheter malfunction or mucus plugging.

A later complication of the neovesical-urethral anastomosis is stricture, which often manifests as difficulty with neobladder emptying. The reported incidence of this complication is approximately 2.4–9%.[16,56,58,86,88,89] Failure to empty after orthotopic urinary diversion necessitates cystoscopic and radiographic examination to differentiate between dysfunctional voiding and neovesicourethral obstruction. Dysfunctional voiding commonly results from an unsuitable size or shape of the neobladder; from the position, length, or angulation of the neobladder neck; or from a denervated proximal urethra. In contrast, neovesicourethral obstruction is caused by stricture, distal urethral obstruction, local tumor recurrence, cystolithiasis, or obstructive mucosal valves.[88]

Cystoscopy is the primary diagnostic tool allowing direct visualization of the bladder neck and quantitative assessment of the anastomotic stricture. Other diagnostic modalities such as transrectal ultrasound of the vesicourethral anastomosis, ultrasound of post-void residual, cystography, and CT or magnetic resonance imaging of the pelvis can further assist in differentiating dysfunctional voiding from anastomotic stricture.

Treatment options for anastomotic strictures vary from conservative management with continuous or intermittent catheterization, dilation at the level of the bladder neck, transurethral resection of transurethral incision of the bladder neck with cold knife, electrocautery, or holmium laser. Although many of these strictures can be managed with transurethral incision or resection, it is paramount to sample tissue and exclude recurrent cancer as a cause. In addition, vigilant follow-up is required to identify early recurrent strictures and to ensure proper emptying and prevent neobladder rupture. Patients whose neobladder becomes overdistended as a result of outlet obstruction should be instructed to perform intermittent catheterization to ensure proper emptying because the tonicity of the neobladder may not return to baseline. This approach may also serve to check that the stricture has not recurred and that the anastomosis is widely patent.

URETEROINTESTINAL ANASTOMOTIC COMPLICATIONS

One of the most difficult complications of urinary diversion is breakdown or stricture of the ureterointestinal

anastomosis. Once again, basic surgical tenets are paramount in reducing or preventing anastomotic complications. During mobilization of the ureters, great care must be taken not to devascularize the distal ureter, and adequate length must be achieved to avoid tension on the anastomosis. Care must be taken to avoid kinking of the left ureter as it is passes beneath the mesentery of the sigmoid colon. Additionally, every effort should be made to create a watertight anastomosis with absorbable suture material, to spatulate the ureter to ensure adequate luminal diameter, and to ensure careful placement of apical sutures.

The incidence of ureteroenteric anastomotic leak decreased significantly with the routine use of soft Silastic stents placed across the ureteroenteric anastomosis at the time of diversion.[12,90] This technique is now used almost universally and has a reported rate of urinary leakage of approximately 3%.[56] Studies have investigated placement of self-retaining ureteral stents following neobladder diversion with a similar incidence of complications.[91] Of course, stents alone do not eliminate complications of ureteroenteric anastomosis and can lead to additional complications when they are improperly positioned or are inadvertently sutured to the ureter. Furthermore, obstruction or infectious complications including urosepsis may result from occluded ureteral stents.

Ureteral stents are routinely removed before the removal of the pelvic drain. Anastomotic urinary leakage is suspected when drain output is increased or when urinary drainage from the wound is noted, particularly in the setting of decreased urine output. Suspicion of urinary leakage should trigger prompt assessment. Evaluation of the suspected fluid for creatinine content is usually the first step. If the creatinine concentration in the fluid is higher than that of the serum, further testing should include imaging such as a CT scan or cystogram to identify the site of urinary extravasation. Most often, initial management is conservative, involving adequate drainage of the neobladder, with consideration of placement of a percutaneous nephrostomy tube along with continued closed-suction drainage and close monitoring. If leakage persists, usually antegrade stent placement through the nephrostomy will be attempted. Rarely is surgical intervention necessary in the early postoperative period for this complication.

Urinary leakage at the ureteroenteric anastomotic site can lead to periureteral fibrosis and predispose to stricture formation. Other causes of stricture include tension at the anastomosis, ischemia of the ureter, infection, and recurrence of cancer. The incidence of ureteroenteric stricture is between 2% and 9%. [16,30,56,75,86,92] Ureteral strictures can also occur away from the anastomosis where the left ureter crosses beneath the inferior mesenteric artery.

An exhaustive review of specific ureteroenteric anastomotic techniques is beyond the scope of this chapter, but considerable debate remains about whether a nonrefluxing or refluxing anastomosis is most desirable for orthotopic urinary diversion.[12,87,93] Arguments for provision of an antireflux mechanism include the potential harmful effects on renal function secondary to recurrent pyelonephritis from reflux of colonized urine.[8] Primary opinions supporting a refluxing anastomosis describe a higher incidence of obstruction with the antirefluxing mechanism; these proponents also argue that the neobladder is a low-pressure reservoir and that urine is assumed to be sterile. Studies addressing renal function indicate no detrimental effect on renal function in patients who have neobladders without an antireflux mechanism at an average follow-up of 50 months.[94] However, upper urinary tract deterioration may need to be measured over decades, not months.[12]

Other series additionally indicate a higher level of upper urinary tract deterioration with antirefluxing techniques as a result of stricture formation and obstruction.[95,96] A large cohort with >350 patients who received a Hautmann neobladder with a LeDuc antirefluxing anastomosis had a ureteroenteric stricture rate of 9.3% at average follow-up of 54 months.[97] Abol-Enein and Ghoneim[98] reviewed >300 patients who received a Hautmann neobladder with an antirefluxing serous-lined extramural tunnel technique and reported a 3.8% rate of stricture with unspecified follow-up.

In a series of 166 Kock ileal neobladders in which the ureteroenteric anastomosis was performed with a refluxing end-to-end Wallace technique, the stricture rate was only 0.6% with follow-up of 2.7 years.[99] In a cohort of 32 patients with refluxing ureteroileal anastomosis into a Studer limb, <1% of renal units developed a stricture with 2-year follow-up.[100] Another study examining 130 patients who received either a Studer or a Hautmann neobladder with a refluxing end-to-side Bricker anastomosis found only three ureteroenteric strictures at a mean follow-up of 20 months.[101] Thus the rate of ureteroenteric stricture has varied greatly among the large neobladder series that have incorporated both refluxing and nonrefluxing anastomosis, although the general trend reveals lower stricture rates with nonrefluxing anastomoses.

To date, studies evaluating the different anastomotic techniques that are well designed, prospective, and randomized, with appropriate numbers and long-term follow-up, have not been performed. We believe that a simple end-to-side, freely refluxing anastomosis to an afferent limb of a low-pressure neobladder is sufficient and has an acceptably low rate of anastomotic stricture.

Regardless of the technique used for ureterointestinal anastomosis, prompt diagnosis and treatment of anastomotic strictures are paramount to preserve renal function. Although many patients are asymptomatic and the diagnosis is made by the presence of hydronephrosis on routine surveillance imaging, patients with ureteroneobladder strictures may present with flank pain, pyelonephritis, or renal insufficiency.

Ureteroenteric stricture can be diagnosed with IVP, CT scan, or antegrade nephrostogram if obstruction is of high grade and percutaneous intervention with nephrostomy placement is indicated (Fig. 47.2). It is imperative that tumor recurrence be excluded in these patients before a specific treatment is initiated. This goal is usually accomplished through a combination of radiographic, endoscopic, and cytologic evaluations. In addition, the function of the involved renal unit should be determined, and in patients with poorly functioning units (<15%), strong consideration should be given to the performance of simple nephrectomy.

Several techniques have been used to treat ureteroenteric strictures including balloon dilation, endoscopic incision with both antegrade and retrograde approaches, and open revision.[87,102] In addition to the potential presence of malignant disease, factors considered in determining the optimal operative strategy must account for the length of the stricture

Figure 47.2 Ureterointestinal stricture. Note the dilation of the proximal collecting system above the stricture at the distal ureter in this nephrostogram. Some contrast material still passes through the stricture into the neobladder.

and the history of prior irradiation to the area. Endourologic procedures using balloon dilation have been reported, although success rates are generally no better than 29% with long-term follow-up.[102] Endoscopic incision of strictures has been employed with short-term success rates of approximately 70%.[103] Longer follow-up was not as favorable in this series, which had only a 32% patency rate after endourologic treatment of ureteroenteric strictures at 3 years.

The best results have been seen with short (<2 cm) distal strictures treated when the patient's renal function remains good. Leaving a stent of ≥12Fr for ≥4 weeks also may increase success rates. Data also suggest improved outcome with local injection of steroids (triamcinolone) into the stricture bed following surgical incision. Success was universally poor for endoscopic treatment in renal units with <25% function.

Open surgical correction with excision of the stenotic segment and revision of the anastomosis yields the highest rate of success but with the tradeoff of a technically challenging and potentially morbid procedure. Anastomotic revision is assisted by placement of an antegrade stent abutting or even through the anastomotic stricture to assist in the intraoperative identification of the ureter. This technique is particularly useful in the setting of dense adhesions and fibrosis in which initial identification of the ureter may be difficult. Similarly, a catheter is placed in the neobladder to allow for intraoperative identification. It may also be necessary to revise the contralateral ureteral anastomosis in the event that it is in close proximity to the area of repair. Furthermore, care must be taken during dissection to avoid injury to the contralateral nonobstructed ureter as scarring and fibrosis may distort ureteral anatomy.

After recognition and excision of the ureteral stricture, the ureter is spatulated and reanastomosed to the orthotopic diversion. In general, the neobladder enjoys more redundancy than does the ureter, which is often encased in a fibrotic reaction. It is important to evaluate the excised segment of strictured ureter by frozen section pathologic analysis to rule out malignant disease. In the case of large ureteral defects, ileal interposition, transureteroureterostomy, or even nephrectomy may be necessary. These patients should undergo full mechanical and antibiotic bowel preparation to minimize complications and to maximize intraoperative surgical options.

The success rate of open revision of ureterointestinal strictures approaches 90%.[87,104] Not surprisingly, left ureteroenteric strictures are often more difficult because of the longer course and pathway under the sigmoid mesentery. Right ureteroenteric strictures may in certain circumstances be approached from a completely extraperitoneal approach.

UROLITHIASIS

Urolithiasis in neobladders can be caused by a variety of factors including metabolic derangements, retained mucus, urinary stasis, and chronic infection.[105] Current opinion is that neobladders are less often colonized compared with continent cutaneous diversions unless long-term catheterization is needed.[106] Reservoirs created with exposed metallic staples have a significantly higher incidence of urolithiasis. Series with the orthotopic Kock neobladder in which exposed permanent staples were used to create the intussuscepted nipple valve reported urolithiasis in the range of 30% at 3-year follow-up.[99] The use of absorbable staples for the afferent nipple valve construction in the Kock neobladder reduced the rate of stones to 4%.[107]

More recent series that did not use staples in neobladder construction reported much lower rates of urolithiasis in the range of 0.5–3%.[98,108] For patients with limited stone burden within the neobladder, transurethral techniques may be used, although some investigators favor a percutaneous or open approach to avoid compromising the continence mechanism of the neobladder.[105]

Upper tract calculi are also common complications of urinary diversion. Urinary stasis resulting from chronic dilation is likely a major culprit in stone formation. Most upper urinary tract calculi appear on the left side, a finding suggesting causality with mobilization and transposition of the left ureter.[109] Contemporary treatments include all modalities of management from shock wave lithotripsy to percutaneous nephrolithotomy.[109–112] Planning an operative strategy naturally depends on the stone burden, location, likely composition, and anatomic considerations, as well as the surgeon's comfort with procedures. Retrograde endoscopic management is particularly difficult in orthotopic neobladder diversions even with nonrefluxing anastomoses, and a combination of alternative modalities are often used. Accordingly, almost all ureteral and renal pelvic stones requiring endoscopic intervention are approached by an antegrade percutaneous technique.

URINARY TRACT COLONIZATION AND PYELONEPHRITIS

Bacterial colonization of the neobladder diversion occurs in 40–80% of patients.[113–115] Colonization is strongly associated with both residual urine[116] and the need to perform

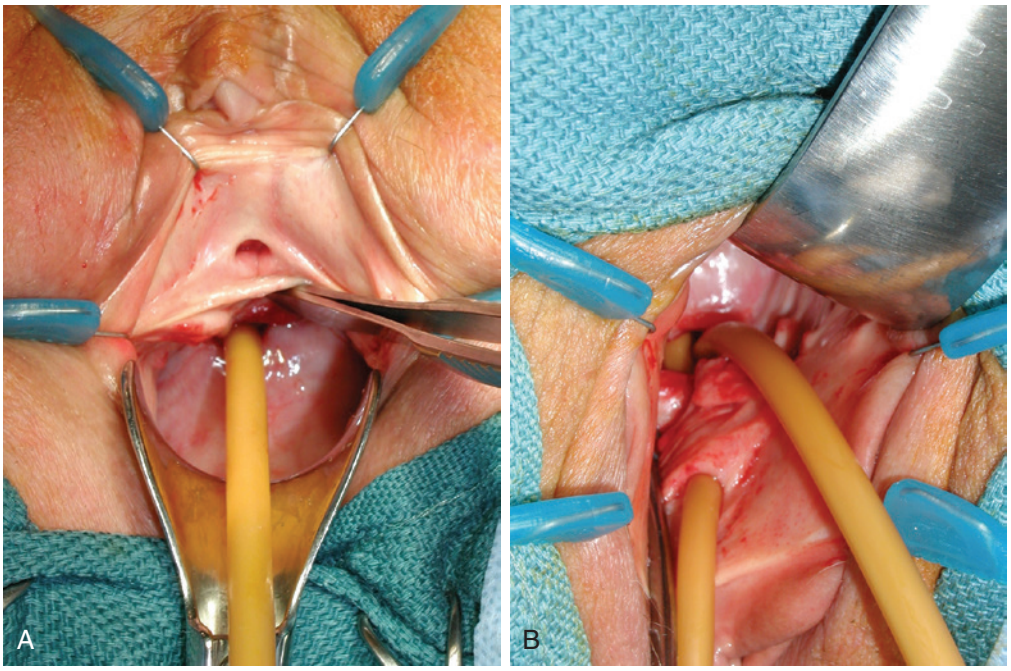

Figure 47.3 Neobladder-vaginal fistula visualized in (**A**) lithotomy and (**B**) prone positions. A catheter is placed into the neobladder through the fistula tract. The urethra is additionally shown catheterized in the prone position.

self-catheterization.[117] Treatment of the neobladder bacteriuria remains a controversial topic in that approximately half of these patients remain asymptomatic from the infection.

In a prospective evaluation of 66 patients with neobladders who were evaluated with urinalysis and culture 2 months to 4 years postoperatively,[114] 55 patients voided normally and 11 performed intermittent catheterization at least once daily as a result of high post-void residual urine. Of the patients who voided normally, 78% had at least one positive urinalysis, and of these bacteria was identified on culture in 50%. Overall, 26 (39%) and 8 (12%) patients had urinary tract infection and urosepsis, respectively. The estimated 5-year probabilities of urinary tract infection and urosepsis in patients who voided independently were 58% and 18%, respectively. Urine culture with >100,000 colony-forming units and female gender were the only factors predictive of urinary tract infection on multivariate analysis. Recurrent urinary tract infection was the only predictor for urosepsis. These investigators recommended prophylactic antibiotics only for patients with recurring urinary tract infections but did not advocate treating patients with a positive urinary culture in the absence of symptoms. However, it is recommended that treatment be pursued in patients with urea-splitting organisms because of the high risk of stone formation.[106]

Approximately 6% of patients with neobladders progress to overt pyelonephritis at some point following urinary diversion.[16] In the absence of obstruction, upper urinary tract infections can be managed with administration of culture-specific antibiotics.

FISTULAS

When indications for orthotopic diversion were initially extended to female patients, surgeons were appropriately concerned about the rate of neobladder-to-vagina fistula.[118,119] Fortunately, neobladder-vaginal fistula formation was reported at <5% in multiple series[98,120,121] (Fig. 47.3). Surgical refinements that decreased fistula formation include the avoidance of overlapping suture lines and the interposition of omentum when the anterior vaginal wall has been incised or partially excised. When oncologic control is not compromised, the ideal technique includes avoidance of entry into the vagina and preservation of the anterior vaginal wall.[121,122] Most fistulas that develop in the setting of a female neobladder require surgical intervention, and they often are not amenable to repair without complete mobilization and subsequent interposition of omentum or myocutaneous flap.

A dreaded complication of neobladder diversion is the development of enterocutaneous or neobladder-enteric fistulas. Mortality is pronounced with these abnormal communications, so diagnosis and treatment must be prompt. As addressed earlier, poor nutritional status, anastomotic leak, devascularization of tissue during the surgical procedure, steroid use, multiple medical comorbidities, and unprepared bowel all contribute to fistula formation.[64] Enterocutaneous fistulas often manifest between 4 and 7 days postoperatively but of course may become apparent at any time during the follow-up. Patients generally present with fever, leukocytosis, metabolic derangements, and signs of cellulitis that progress to frank spillage of enteric contents onto skin.

Broad-spectrum antibiotics should be briskly administered to ward off sepsis, and CT scan of the abdomen should be obtained to rule out intraabdominal abscess. Following supportive treatment and stabilization, a fistulogram may assist in localizing the tract and in determining whether further conservative management is merited. In cases of obvious peritonitis, exploration with or without bowel

diversion is necessary. In the absence of infection, in patients with sufficient bowel rest and supplementation of nutritional status with either a low-residue diet or total parenteral nutrition, 60–80% of enterocutaneous fistulas spontaneously close. For the remainder of patients, operative management is preferable within 6 weeks of the initial diagnosis.

Fistulas between the small or large bowel and neobladder may be more insidious in onset and may manifest with pneumaturia, fecaluria, diarrhea, and general abdominal symptoms. The diagnosis is often confirmed by a traditional or CT cystogram (Fig. 47.4). In the absence of gas-producing organisms, the finding of air in the anterior portion of a noninstrumented patient on CT scan should arouse strong suspicion of this fistula. Again, conservative measures, which in this case include neobladder catheter drainage and bowel rest with TPN, may allow healing of small fistulas,[123,124] but definitive operative management often becomes necessary.[125] At the time of surgical correction, the surgeon should obtain a biopsy sample of the fistula site to exclude recurrent malignant disease as the underlying cause. Rare cases of vascular fistulas with orthotopic diversion have been reported and successfully treated with endovascular repair.[126]

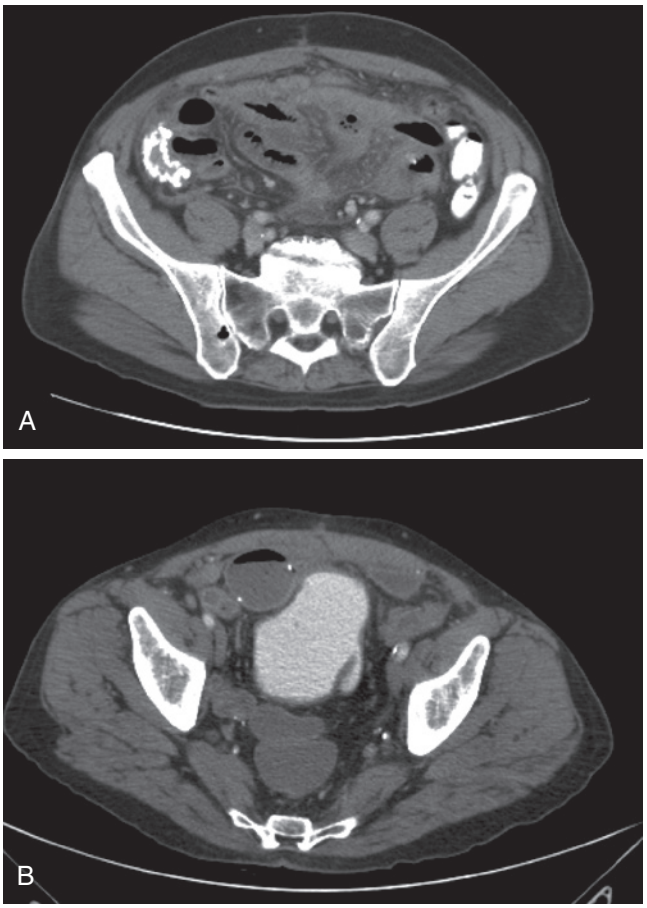

Figure 47.4 Neobladder-enteric fistula on CT cystogram. A, Note the presence of gas in the fluid collection anterior to the neobladder that is suggestive of fistula. B, Cystogram reveals the fistula tract on the left lateral aspect of the neobladder.

VOIDING DYSFUNCTION

The perceived improved quality of life of the orthotopic neobladder as compared with incontinent diversion may be significantly reduced or eliminated in patients with severe voiding dysfunction.[127] Daytime incontinence may range from mild stress incontinence to total incontinence in a small percentage of patients, but complete daytime continence is achieved in close to 90% of patients with neobladders.[16] Approximately 20–50% of patients experience some degree of nighttime incontinence. Alternatively, approximately 8% of patients may develop hypercontinence or high post-void residuals requiring self-catheterization.[87,128] Hypercontinence is more prevalent among women due to overly acute neocystourethral angle from downward migration of the neobladder and is as high as 15% among women.[129] Hypercontinence is also particularly common following an episode of urinary retention in which the bladder may become silently overdistended and may fail to recover its natural tonicity.

A comparison of the severity and incidence of voiding dysfunction among various surgical series is confounded by the variability in definitions, end points, surgical technique, and length of follow-up. Additionally, symptoms have rarely been assessed using validated instruments. With these limitations noted, a review of >2000 patients with orthotopic neobladders did provide a clear characterization of associated voiding dysfunction. This meta-analysis showed that 4–25% of patients with orthotopic neobladders performed intermittent self-catheterization for incomplete emptying. Daytime incontinence was present in approximately 13% of patients.[127]

As with the fashioning of other types of urinary diversion, general surgical principles must be maintained to maximize chances of optimal functional outcomes and to reduce complications. The neobladder must be constructed such that it can accommodate a sufficient volume under low pressure with limited absorption of urine.[12] Intrinsic to the spheroid shape of the reservoir are mathematical principles that dictate the optimal length of bowel to achieve the desired capacity, as pressure is inversely related to the radius according to Laplace's law.[83] Ideally, a segment of bowel 50–55 cm in length is selected. If the segment is too small, the capacity will be low and will risk unnecessary and avoidable incontinence and urinary frequency.[130] Similarly, if too generous a segment of bowel is selected, poor emptying and urinary retention will ensue. Poor emptying can precipitate not only the need for lifelong self-catheterization but also distention and the rare but devastating complication of neobladder perforation.[131,132]

A report of a large series of neobladder emptying failures in men demonstrated an 8% incidence of mechanical dysfunction and a 3.5% incidence of dysfunctional voiding.[88] The investigators indicated that vigilant reservoir emptying to prevent excessive neobladder distention had a more profound impact on voiding function than did the length of bowel used and the corresponding size of the initial pouch.

During cystectomy, particular attention should be directed toward preserving the rhabdosphincter to protect the continence mechanism.[12,133] In men, the apical prostate dissection should be performed in a manner similar to that

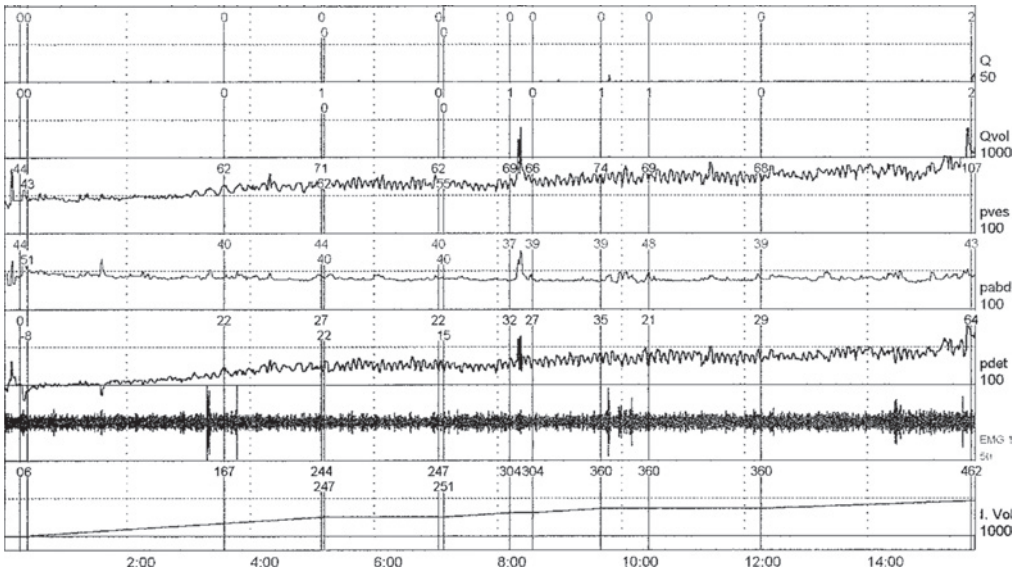

Figure 47.5 Urodynamic tracing of neobladder cystometry in a patient with voiding dysfunction. Note the hyperactivity of the neobladder in the detrusor pressure (pdet) tracing, which reveals neobladder overactivity. EMG, electromyogram; pabd, abdominal pressure; pves, total bladder pressure; Qvol, voided volume.

of radical prostatectomy. In women, the urethra and uninvolved bladder neck are preserved. In addition, a plane of dissection can be carried posterior to the bladder and just above the anterior vaginal wall to preserve urethral innervation. It is also important to handle and preserve vaginal tissues, the levator muscle, and pelvic floor fascia gently. Finally, positioning the neobladder neck in the most dependent portion of the pelvis ensures proper funneling of the bladder outlet on voiding.

Urodynamic study is now frequently used to determine causes of dysfunctional voiding in the patient with a neobladder. Indeed, despite bowel detubularization,[134] uninhibited contractions resulting in incontinence may occur in almost half of reservoirs (Fig. 47.5).[135,136] These patients often benefit from pharmacologic intervention with anticholinergic agents to decrease neobladder overactivity. Women with de novo stress urinary incontinence following neobladder placement may be candidates for placement of a pubovaginal sling in a modified fashion so the areas of previous surgical intervention are avoided.[137]

In addition to aiding continence, careful neurovascular preservation appears to assist with preservation of sexual function in both male and female patients.[138–140] However, some analyses suggest that sexual function–preserving cystectomy may compromise oncologic control.[141]

URETHRAL AND PELVIC TUMOR RECURRENCE

The historical incidence of urethral recurrence following cystectomy is 10%,[142] but urethral recurrence with ileal neobladder in both male and female patients has been reported in the range of 0.5–5%.[58,143–146] This discrepancy is likely the result of both patient selection bias and careful intraoperative evaluation of the urethral margin with frozen section analysis before construction of an orthotopic reservoir.[147,148] Although surveillance cystoscopy or urethral washing for cytologic examination is generally advocated for screening following orthotopic diversion, large series demonstrated that the majority of patients with urethral recurrence actually developed symptoms that led to the diagnosis (discharge, pain, palpable mass) and the presence of positive cytologic findings did not affect stage or survival.[149,150] Additionally, the sensitivity of urethral wash cytology is extremely low.[151]

Most recurrences are detected within 5 years of cystectomy,[152] but lifelong screening is required because urethral tumors have been found ≤15 years after initial surgical treatment.[153] Whether these tumors actually represent recurrences of the original tumor or are a consequence of the field changes known to occur with urothelial cell cancers is unclear. However, once urethral recurrence is diagnosed, treatment depends on the type of recurrence. For invasive urothelial carcinoma, urethrectomy and conversion of the orthotopic diversion to an incontinent diversion are the therapeutic procedures of choice. Patients with carcinoma in situ have been successfully treated with bacille Calmette-Guérin (BCG) with an 83% response rate.[154] Superficial recurrences have also been managed with endoscopic resection.[143,155]

Pelvic recurrences occur in approximately 7% of patients who have undergone cystectomy,[156] but large-scale analyses indicated that local recurrence with functional impingement on the neobladder that requires resection is rare.[16] In one series, Freeman and colleagues[157] found an overall local recurrence rate of 11% in a study of predominantly male patients with orthotopic neobladders. A similar rate of pelvic recurrence (14%) was reported in another series examining patients with unfavorable histologic features.[158] In these series, one-half to two-thirds of patients with pelvic disease recurrence retained adequate neobladder function despite death from the disease. In another study, the type of urinary diversion did not change the risk of complications, the response to salvage treatment, or overall survival in patients with pelvic recurrences.[159] In rare circumstances, an ileal conduit or palliative diversion is necessary because of local tumor invasion of the neobladder.

Among women, the rate of pelvic disease recurrence after anterior exenteration was <5% in two separate studies, but in both series the recurrences were in patients without transitional cell carcinoma.[119,160] In a study of patients with squamous cell carcinoma, the pelvic recurrence rate was 12%.[161] Thus, female patients with squamous cell carcinoma and those with nonurothelial histologic features may be at higher risk for local recurrence and may not be appropriate candidates for vaginal sparing. When the anterior vaginal wall was preserved during cystectomy and neobladder formation among women with transitional cell carcinoma, the local recurrence rate was 5%.[121]

NEOBLADDER RUPTURE

Spontaneous rupture of an orthotopic neobladder has been reported to occur in 1.5–4.3% of patients.[131,162] This complication is most commonly the result of acute or chronic overdistention of the neobladder. However, other causes include instrumentation, catheter trauma, mucus retention, and altered sensorium from drug or alcohol effects. Patients prone to overdistention or excess mucus production must be instructed to be vigilant in continuous intermittent catheterization as frequent as every 4 hours to avoid this uncommon but occasionally life-threatening complication. Patients with orthotopic diversions should be instructed to wear medical alert bracelets to inform medical personnel in the event of an emergency.

The presentation of spontaneous orthotopic neobladder rupture is generally that of acute abdominal pain accompanied by abdominal distention and decreased urine output. In the setting of infection, the patient may present with peritonitis or sepsis. An initial attempt should be made to place a Foley catheter in the neobladder. A cystogram can then be performed to evaluate for extravasation. In addition to a standard CT scan of the abdomen and pelvis, a CT cystogram may be revealing. A high index of suspicion should be maintained if a large amount of free fluid likely representing urine is demonstrated on the CT scan even in the absence of extravasation on cystogram.

The presentation and overall clinical features in part dictate the magnitude of treatment for neobladder rupture. Patients without signs of overt peritonitis or sepsis may be managed initially with conservative measures including catheter drainage, broad-spectrum antibiotics, and careful monitoring of vital signs and urine output.[163] However, patients with altered mental status, intractable pain, hemodynamic instability, or frank peritonitis should undergo emergency surgical exploration. Exploratory laparotomy with drainage of peritoneal urinary ascites and repair of neobladder rupture should be performed. A large-caliber intraperitoneal drain and large-caliber Foley catheter should be placed for postoperative management. Generally, the Foley catheter is removed after 3 weeks, any underlying cause of the complication is corrected, and the patient is monitored closely to ensure that neobladder compromise does not recur.

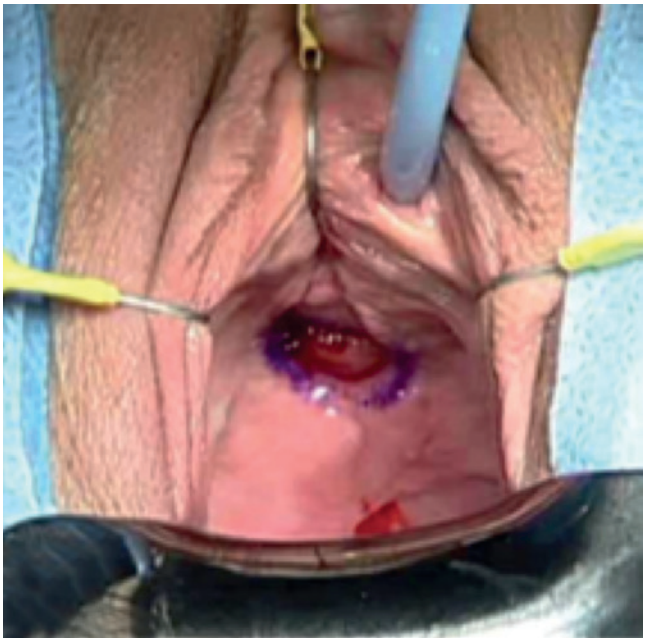
Chapter 47 Questions

1. A 65-year-old man with muscle invasive bladder cancer undergoes radical cystoprostatectomy with orthotopic neobladder. Four months after surgery he notes passage of stool contents per urethra and pneumaturia. He undergoes CT cystogram, which shows a small fistulous connection between his neobladder and sigmoid colon. The patient has stable vital signs and otherwise has no other complaints. He empties his neobladder every 3–4 hours and has a PVR in clinic of 15 mL. He has daily bowel movements and denies constipation. Flexible cystoscopy is performed in clinic, which reveals an erythematous 0.5-cm fistulous connection that has mild evidence of bleeding. Biopsy of this site is negative for recurrence of cancer. What is the next step in the management of this patient?
   a. Cystoscopy and fulguration of the fistula
   b. Surgical exploration with excision of the fistula tract
   c. Bilateral percutaneous nephrostomy tube placement
   d. Bowel rest, total parenteral nutrition (TPN), and urethral catheter placement
   e. Colonoscopy and placement of colonic stent

2. A 70-year-old man undergoes radical cystoprostatectomy for muscle invasive bladder cancer with a Studer neobladder urinary diversion. He presents to the ER 6 months after his procedure where he is noted to have fever of 102.1°F, heart rate of 95, blood pressure of 110/54 mm Hg, white blood cell count of 15.1 × 10^9/L, and an elevation in his serum creatinine level to 1.6 mg/dL. He states he has had worsening left-sided flank pain and fatigue. He has been emptying his neobladder every 3–4 hours without any problems and has a post-void residual urine of 20 mL. CT scan is obtained with the delayed phase as shown in Case Fig. 47.1. He is started on broad-spectrum IV antibiotics. The best next step in the management of this patient is:
   a. Placement of urethral catheter
   b. Cystoscopy and retrograde ureteral stent placement
   c. Left percutaneous nephrostomy tube placement
   d. Surgical exploration and ureteral reimplantation
   e. Urethral catheter placement with a cystogram

3. Which of the following is an absolute contraindication to orthotopic neobladder diversion?
   a. Positive pelvic lymph nodes
   b. Renal insufficiency with serum creatinine of 1.4 mg/dL
   c. Hepatic insufficiency
   d. History of left hemicolectomy
   e. History of transurethral resection of the prostate (TURP)



4. A 70-year-old man with a neobladder urinary diversion is admitted to the hospital after falling down a flight of stairs. He is taken to the ER where his vital signs are within normal limits, with normal CBC and BMP. He is diagnosed with a left clavicular fracture per x-ray imaging. His physical exam is otherwise unremarkable with the exception of a distended abdomen. He undergoes CT scan which shows a large amount of free fluid in his abdomen. The next step in the management in this patient is:
   a. Emergent exploratory laparotomy
   b. Cystoscopy with incision of bladder neck contracture
   c. Percutaneous drain placement
   d. Placement of urethral Foley catheter and cystogram
   e. Percutaneous drain placement with bilateral nephrostomy tube placement

Case Figure 47.1

5. All of the following are causes of stone formation in neobladders except:
   a. Retained mucus
   b. Urinary stasis
   c. Chronic infection
   d. Use of colon instead of ileum for neobladder
   e. Use of metal staples for creation of neobladder

6. A 56-year-old woman undergoes vaginal sparing cystectomy with ileal neobladder creation. She tolerated the procedure well and is discharged home on postoperative day 7. Her pathology revealed a pT1 tumor at the dome of the bladder with 0 of 20 nodes positive for disease. She returns for follow-up 8 weeks later complaining of progressively worsening urinary leakage and is wearing 10 pads per day. She states that her leakage is worse during the nighttime and is not associated with Valsalva. Her post-void residual urine in clinic is 5 mL. Her physical examination is shown in the picture in Case Fig. 47.2 and confirms a neobladder to vagina fistula. The most common cause of early neobladder-vaginal fistula is:
   a. Extravasation of urine
   b. Displacement of urethral anastomosis from hematoma

Case Figure 47.2

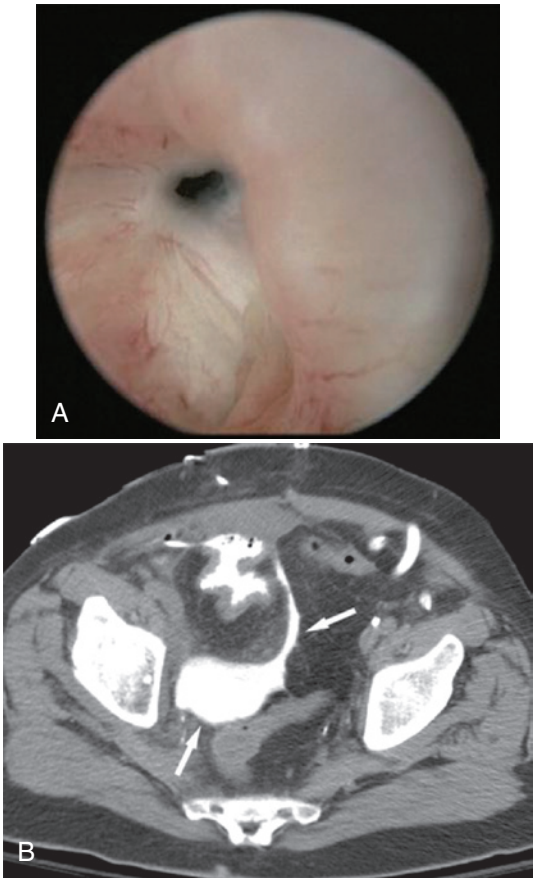
c. Damage to the anterior vaginal wall during cystectomy
d. Disease recurrence at urethral margin
e. Acute neovesical-urethral angle

7. A 70-year-old man underwent neobladder diversion 5 years prior. He presents to the ER with delirium, fever up to 101.9°F, tachycardia to 110, and leukocytosis of 18×10^9/L. His wife tells you that he has been dribbling urine over the last week. His post-void residual is 900 mL. He is started on IV antibiotics. The next step in management is:
   a. Cystoscopy with placement of a guidewire, dilation, and catheter placement
   b. Bilateral nephrostomy tube placement
   c. Open suprapubic tube placement
   d. Open revision of a neovesical-urethral anastomosis
   e. Transurethral resection of a bladder neck contracture

8. A 73-year-old man underwent neobladder urinary diversion. One year later he experiences elevated post-void residuals up to 700 mL with weakening of his stream and is diagnosed with a bladder neck contracture. He undergoes cystoscopy and incision of a pinpoint bladder neck contracture using a holmium laser. The most common cause of his bladder neck contracture is:
   a. Extravasation of urine after neobladder surgery
   b. Prolonged postoperative urethral catheter placement
   c. Recurrent urinary tract infections
   d. Bladder stone formation
   e. Traumatic Foley placement

9. A 68-year-old man with neobladder urinary diversion presents to the ER with a 3-day history of left flank pain and is diagnosed with a 1.0-cm left ureteropelvic junction (UPJ) stone with moderate hydronephrosis and a 1.5-cm lower pole stone. His vital signs are within normal limits, and his pain is controlled with oral narcotics. The management strategy with the highest success rate is:
   a. Cystoscopy and retrograde ureteroscopy and laser lithotripsy
   b. Alkalization of urine
   c. Acidification of urine
   d. Extracorporeal shock wave lithotripsy (ESWL)
   e. Percutaneous nephrolithotomy (PCNL)

10. A 67-year-old woman with extensive cT2 bladder cancer at her bladder neck presents to your clinic for evaluation for ileal neobladder. She has a history of a left hemicolectomy for diverticular disease and her Cr is elevated to 1.6 mg/dL. She has baseline stress urinary incontinence of one pad per day. Which of the following would preclude her from neobladder diversion?
    a. Elevated creatinine
    b. History of left hemicoletomy
    c. Disease the bladder neck
    d. Stress urinary incontinence
    e. Age >65



Case Studies

CASE 1

A 68-year-old man who underwent neobladder urinary diversion 9 months ago presents to the ER with 1-day history of severe abdominal pain. He states that he has had a progressively worsening stream over the last few weeks and has been straining to empty his neobladder. His vital signs in the ER are significant for tachycardia with heart rate of 110 and fever of 101.1°F. His blood pressure is 110/65 mm Hg. On exam his abdomen is diffusely tender to palpation and is mildly distended. The patient's bladder scan shows 900 mL in his bladder. His white blood cell count is 15.1×10^9/L, with an elevation in his serum creatinine level to 1.6 mg/dL from baseline of 0.9 mg/dL. The nursing staff attempt to place a Foley catheter but are unble to do so. Urology is consulted for Foley catheter placement. Bedside cystoscopy is performed and the scope is unable to be passed into the bladder (Case Fig. 47.3A).

1. The next best step in management is:
   a. Bilateral nephrostomy tube placement
   b. Cystoscopy in OR with transurethral incision of the bladder neck
   c. Open suprapubic tube placement
   d. Interventional radiology consult to place a percutaneous suprapubic tube
   e. Cystoscopy with placement of a guidewire, dilation, and catheter placement

After the catheter is placed the patient is admitted for monitoring and administration of IV antibiotics. He continues to have continued abdominal pain overnight. He is afebrile, has normalization of his heart rate, and continues to have a stable blood pressure. CT cystogram is performed (Case Fig. 47.3B).

Case Figure 47.3

2. The best next step in management is:
   a. Exploratory laparotomy
   b. Bilateral nephrostomy tube placement
   c. Broadening of IV antibiotics
   d. Interventional radiology consult to place a percutaneous drainage tube into the fluid collection
   e. Bowel rest with nasogastric (NG) tube placement and total parenteral nutrition (TPN)

The patient clinically improved after drain placement and ultimately had the drain removed 2 weeks later after the drainage was less than 100 mL per day and the creatinine level from the drain was serum. He had a cystogram 3 weeks later that showed no evidence of a leak, and his Foley catheter was removed. One month later the patient states that he is having a worsening urinary stream. Cystoscopy in clinic reveals a recurrent bladder neck contracture. His PVR in clinic is 200 mL.

3. The next best step in management is:
   a. Open revision of bladder neck
   b. Cystoscopy in OR with transurethral incision of the bladder neck and catheter placement
   c. Open suprapubic tube placement
   d. Interventional radiology consult to place a percutaneous suprapubic tube
   e. Cystoscopy with placement of a guidewire, dilation, and catheter placement

Case Figure 47.4

CASE 2

A 54-year-old woman underwent orthotopic urinary diversion 4 year ago. Since her procedure she has had several febrile urinary tract infections, which have been treated with oral antibiotics. Her PVR in clinic is 300 mL. She has been using intermittent catheterization off and on for the last 2 years and admits to being noncompliant with it. Her vital signs in clinic are within normal limits. Her serum creatinine is 0.9 mg/dL. Her UA reveals pyuria with 3–5 WBC/HPF and a urine pH of 7.0. She undergoes a renal ultrasound that shows no abnormalities. Her KUB is shown in Case Fig. 47.4.

1. The next step in management is:
   a. Urinary alkalinization and observation
   b. Exploratory laparotomy and extraction of the stones
   c. Placement of catheter and irrigation with acetohydroxamic acid
   d. ESWL
   e. Conversion of neobladder to ileal conduit

Answers

1. **d.** Conservative management with bowel rest and neobladder decompression with urethral catheter is a good initial strategy in patients with small neobladder-colon fistulas without evidence of distal intestinal obstruction and signs and symptoms of sepsis. Fulguration of the fistula and placement of a colonic stent have not been shown to cause closure of fistulous tracts. Bilateral percutaneous nephrostomy tubes would divert urinary flow, but would not divert fecal flow. Surgical exploration should be attempted in patients who have signs/symptoms of sepsis or peritonitis or in patients who fail conservative measures.
2. **c.** This patient has developed a ureteroenteric stricture (which can occur in 3–8% of patients) with sign and symptoms of sepsis. He will need to undergo urgent decompression of his left kidney with a percutaneous

nephrostomy tube in addition to broad-spectrum IV antibiotics. While placement of a ureteral stent is commonly performed in patients with intact bladders, it is quite difficult to identify the ureteral-enteric orifices within the neobladder. Urethral catheter placement would decompress a ruptured bladder; however, there is no evidence of extravasation of urine on the CT scan. Surgical exploration and ureteral reimplantation would be the best definitive management for ureteroenteric strictures; however, these should be performed in an elective setting.

3. **c.** Reabsorption of ammonium and chloride from the urine in a neobladder can worsen hepatic impairment and can precipitate encephalopathy, and thus hepatic insufficiency is an absolute contraindication for neobladder. Serum creatinine over 2.0 mg/dL is the accepted upper limit for consideration in a neobladder, and thus a creatinine of 1.4 mg/dL is not an absolute contraindication to neobladder diversion. Positive pelvic lymph nodes, history of left hemicolectomy, and history of a TURP are not absolute contraindications for neobladder.
4. **d.** The patient has sustained a neobladder rupture from blunt trauma to his abdomen resulting in urinary ascites. Given that the patient is clinically stable there is no need for exploratory laparotomy. Placement of a urethral catheter and cystogram will drain the neobladder as well as confirm the diagnosis of neobladder rupture and could provide insight into the degree/size of injury. The patient's mechanism and timing of injury does not support bladder neck contracture as the diagnosis usually presents with high post-void residual urine, weak stream, and overflow incontinence. There is no indication for placement of percutaneous nephrostomy tubes.
5. **d.** There is no difference in the stone formation rates between colon or ileal neobladder reservoirs. The remaining answer choices are all associated with stone formation within neobladders.
6. **c.** The image depicts a neobladder to vaginal wall fistula. While care was taken during the initial operation to spare her vagina there was likely an injury to the anterior vaginal wall which resulted in a fistulous connection to the neobladder. Disease recurrence is less likely given the location of the fistula and that her disease was primarily at the bladder dome. Extravasation and displacement of the anastomosis commonly cause bladder neck contractures while an acute neovesical-urethral angle usually results in hypercontinence.
7. **a.** The patient presents with urinary retention secondary to bladder neck contracture and early urosepsis. Bladder neck contracture occurs in 2.4–9% of patients. It is prudent to decompress the neobladder in an expeditious fashion with cystoscopy, dilation, and catheter placement. Once the patient's condition improves, more formal management of the bladder neck contracture can be performed with transurethral incision or resection of scar tissue.
8. **a.** Bladder neck contracture occurs in 2.4–9% of patients with patients presenting with urinary retention and weak stream. A more serious presentation includes neobladder rupture, which requires urgent urinary catheter placement. Causes for bladder neck contracture are myriad, but most commonly result from extravasation of urine after neobladder surgery, which causes inflammation and scarring of the neovesical anastomosis.
9. **e.** The patient has an obstructing 1-cm UPJ stone in the left ureter without signs/symptoms of infection. Retrograde ureteroscopy can be challenging as it is difficult to identify the ureteroeneteric anastomosis orifices. ESWL is an option, but does not have as high stone clearance rates for lower pole stones. PCNL is the preferred management strategy for upper tract stones in patients with a neobladder and has higher stone clearance rates compared to ESWL for lower pole stones.
10. **c.** Absolute contraindication for neobladder include serum Cr >2.0 mg/dL, inflammatory bowel disease (not prior bowel resection), and disease at the bladder neck. Age and mild stress urinary incontinence are not absolute contraindications to neobladder diversion.

CASE 1

1. **e.** The patient has a distended bladder, leukocytosis, and fevers and requires urgent decompression of his neobladder. If the patient was stable, then cystoscopy in OR with transurethral incision of the bladder neck would be a reasonable option with more durable long-term results. Suprapubic tube placement is an option but should only be used if a urethral catheter could not be placed.
2. **d.** The patient has evidence of a neobladder rupture secondary to obstruction from his bladder neck contracture as evidenced by contrast extravasation from the neobladder in the CT scan image. He already has a urethral catheter in place and given that he is hemodynamically stable percutaneous drain placement would be the best option. If the patient was hemodynamically unstable exploratory laparotomy would be the best next step.
3. **b.** The patient has a recurrent bladder neck contracture that recurred despite dilation. The best next step would be to take the patient to the OR and perform an incision of the bladder neck at the 5- and 7-o'clock positions. Open revision of the bladder neck would be quite difficult to perform and would result in poor healing and possible incontinence. Suprapubic tube placement would decompress the neobladder, but would not result in restoring functional voiding to the patient. Repeat dilation of the urethra would likely not be successful given that it failed once already.

CASE 2

1. **b.** This patient has three large stones within her neobladder. Stone formation in the neobladder can occur in a patient with a foreign body, metallic stapes, excess mucus production, and chronic infection. In this case the patient's stones are quite large and will require open or endoscopic removal of the stones.

48 Complications of Bladder Augmentation and Surgery for Neurogenic Bladder

HIMANSHU AGGARWAL, CATHERINE J. HARRIS, and GARY E. LEMACK

CHAPTER OUTLINE

Introduction
Short-term Complications
Long-term Complications
Urinary Tract Infection and Bacteriuria
Stones
Perforation
Carcinoma
Metabolic Disorders
Bowel Dysfunction
Incontinence
Pregnancy
Conclusion
Chapter 48 Questions and Answers

KEY POINTS

1. Bladder augmentation is a safe, well-tolerated, and effective surgery in appropriately selected patients.
2. Prolonged postoperative anastomotic leak, although rare, is a known early complication of bladder augmentation. It can be prevented and ultimately corrected by continuous bladder drainage and regular irrigation with mucus evacuation. Leaks that initially fail conservative therapy may require percutaneous diversion of the upper tract.
3. Stones may be identified in augmented bladders. Regularly removing mucus and appropriately treating urea-splitting organisms in the urine can assist in prevention of stone formation.
4. Perforation of an augmented bladder is a rare but potentially fatal complication. A high degree of suspicion should be maintained for patients with bladder augmentation who become acutely ill. CT cystogram is the optimal study to identify a perforated bladder augment, which requires surgical repair.
5. There is an unclear association between prior bladder augmentation and bladder cancer. Although no standardized guidelines exist for carcinoma surveillance for these patients, annual cystoscopy starting 5 to 10 years after augmentation is recommended. Gross hematuria requires appropriate and timely evaluation in patients who have undergone augmentation.

Introduction

Von Mikulicz first described augmentation of the bladder with the use of an intestinal segment in 1889. It was not until the 1950s, however, that this procedure became more widely used after a report by Couvelaire described augmentation of small, contracted tuberculous bladders. Bladder augmentation is now an accepted technique used to increase bladder capacity.[1] However, with the introduction of onabotulinumtoxinA (BTX) as an effective minimally invasive treatment for overactive bladder in 2000, the overall number of bladder augmentations (also described as augmentation cystoplasty) decreased.[1,2] In the United Kingdom, the number of bladder augmentations decreased from 192 in 2000 to 120 in 2010 and the number performed in the United States decreased by 25% between 2000 and 2009.[1,3] Today, the indications for augmentation cystoplasty (AC) include patients with impaired compliance, small bladder capacity, and refractory detrusor overactivity that have failed behavioral, medication, and intravesical therapies.[4] Although ileum is most commonly used, intestinal segments from the stomach to the colon have been utilized for bladder augmentation.[1]

OnabotulinumtoxinA was initially shown by Shurch et al. in 2000 to improve detrusor overactivity and incontinence in patients with spinal cord injury.[2] Subsequent phase III clinical trials have demonstrated improved urinary incontinence, urodynamic parameters, and quality of life (QOL) in patients with neurogenic bladder.[5,6] These benefits have also been demonstrated in patients with nonneurogenic

overactive bladder.[7] Treatment with BTX requires repeat injections every 3 to 12 months with durable results at 5 years.[8] The most common complications are urinary tract infections (UTIs) and urinary retention. It has been suggested that in patients requiring more frequent injections (<5.1 months), AC may be more cost-effective long term; however, this assumes a low complication rate of less than 14%.[9] Therefore, in patients that fail BTX injections or require frequent injections, AC remains a viable treatment option.

Neuromodulation is another therapeutic option for patients with overactive bladder that have failed conservative and drug therapies and for patients unwilling to take on the risk of intermittent catheterization with BTX. Sacral neuromodulation (SNM) and posterior tibial nerve stimulation (PTNS) are options in patients with nonneurogenic overactive bladder. A 50% improvement is maintained at 5 years in 50% of patients undergoing SNM.[8] Overall continence rates or cure with SNM at 5 years is closer to 15% compared to 80–100% overall continence after bladder augmentation in neurogenic patients and 78–90% in idiopathic detrusor overactivity.[1,8] Overall, it is clear that AC remains a necessary and viable treatment option for overactive bladder despite emerging therapies.

The goal of this chapter is to discuss the presentation and incidence of the various complications seen with AC, techniques to avoid these complications during the initial surgical procedure, and therapies and procedures available to treat the complications. Two distinct populations undergo AC:ß younger patients with neurogenic bladder conditions such as those with spina bifida, and older patients that develop neurogenic bladder conditions later in life, such as after a spinal cord injury or those with small capacity bladders related to radiation or idiopathic causes.

Short-term Complications

Relatively few early complications are specifically related to bladder augmentation surgery. Patients undergoing AC are at risk for cardiovascular, pulmonary, gastrointestinal, and thromboembolic perioperative events as seen with any intraabdominal procedure. A query of the American College of Surgeons National Quality Improvement Program Pediatric Database from 2012–2103 revealed that of the 97 patients that underwent AC alone, 18.6% of patients had a complication within 30 days of the operative procedure. Of these, the most common complications were urinary tract infection (UTI) at 9.3%, followed by wound complications (7.8%) including three superficial infections and one dehiscence. Six patients (6.2%) required transfusion or had a bleeding complication, one patient became septic, and there were eight patients (8.3%) that required reoperation. Reoperations included exploratory laparotomy, cystourethroscopy, revision, and exploration of the intestinal anastomosis. Increased risk of a 30-day event was associated with increased operative time, procedure number, and high surgical risk score. There were no mortalities at 30 days.[10] A mortality rate as high as 2.7% was reported in older literature. The higher mortality rates were also associated with additional surgical procedures. Commonly noted early surgical complications include a 1.9–10.3% risk of bowel obstruction and a risk of a significant wound infection of 6.4%.[11] Bleeding requiring blood transfusion is seen in 3% of patients undergoing AC.[11,12]

Figure 48.1 Cystogram demonstrating an early leak after augmentation ileocystoplasty.

The incidence of early bladder anastomotic leak (Fig. 48.1) after augmentation is extremely low.[13] Two were reported in a series of 133 patients, noted on postoperative days 2 and 5 respectively, and each required surgical exploration and repair.[13] Early leaks are prevented by optimal bladder drainage, which can be achieved with use of both a urethral and a suprapubic catheter. The perivesical space should be well drained. The augmented bladder should be regularly irrigated to evacuate mucus and to minimize the risk of a mucus plug. Mucus plugs can clog a catheter and lead to poor urinary drainage of the newly constructed augment with possible leak at the anastomosis. Small anastomotic leaks that are adequately drained should heal on their own with time. When a trial of conservative therapy fails to heal clinically significant anastomotic leaks, percutaneous drainage of both kidneys and drainage of urinoma, if one is present, are required. Rarely, an ischemic bowel segment can cause anastomotic leak, and in these cases conservative management is not successful. Laparotomy with resection of the nonviable segment and repeat anastomosis are necessary.[4]

Patients with myelomeningocele may be at increased risk for specific complications following AC. The risk of ventriculoperitoneal (VP) shunt infection after AC ranges from 0% to 20%. Appropriate perioperative antibiotics should be given, and any risk of intestinal spillage into the abdominal cavity should be minimized. Urine should be clear of infection preoperatively.[14] Conversion of the VP shunt out of the peritoneal cavity to ventriculopleural shunt can be considered prior to bladder augmentation; however, data regarding this approach are limited.[14] Another technique to guard against shunt infection is the use of the extraperitoneal augment, which allows a significant portion of the

operation to be performed extraperitoneally and thus minimizes exposure of the shunt to potential infection. Symptoms of an infected VP shunt may be vague and mimic partial small bowel obstruction. Other symptoms and signs include fever, headaches, lethargy, change in vision and mental status, and seizures. In addition to significant morbidity, shunt infections are linked to higher risks of future shunt infection and malfunction, intellectual impairment, and even death.[14,15] If shunt infection is suspected, broad-spectrum antibiotics (Vancomycin, frequently in combination with Rifampin) should be instituted and neurosurgical consultation initiated.[15]

Intraoperatively, surgeons should also be able to recognize the signs and symptoms of a latex allergy reaction. This allergy is most commonly seen in patients with myelomeningocele and often manifests as a precipitous drop in blood pressure related to the reaction to the latex in the surgical gloves that are in contact with the intraabdominal contents. Because of the known risk of this potentially life-threatening complication in this patient population, most centers now require surgeons operating on patients with spina bifida to wear nonlatex surgical gloves and to use latex-free catheters and latex-free surgical drains. If a reaction does occur intraoperatively, recommendations include instant interruption of contact with possible antigens (change gloves, surgical drains, and possibly contaminated instruments), copious irrigation of the field, expeditious completion or termination of the surgical procedure, volume expansion, and appropriate resuscitation and management of anaphylaxis by the anesthesia team.

The patient's bladder neck competence should be considered with evaluation for augmentation cystoplasty. If it is found to be incompetent, our preference is to perform a tight fascial bladder neck sling. If the bladder neck is of insufficient length, bladder neck closure may be performed through the abdominal incision for the augmentation cystoplasty. If bladder neck closure is performed, great care must be taken to close in multiple layers, preferably nonoverlapping layers, with interposition such as omentum to prevent fistula formation. The importance of good social support and compliance is magnified in patients with bladder neck closure given the potential mortality associated with the inability to catheterize and a closed bladder neck.[16]

Long-term Complications

Long-term complications of bladder augmentation include bacteriuria/UTIs, metabolic changes, stone formation, perforation of the augmented bladder, bowel dysfunction, incontinence, and the potential risk of tumor formation.[17] A recent study of 2831 bladder augmentations reported a 10-year cumulative incidence of bladder rupture (2.9–6.4%), small bowel obstruction (5.2–10.3%), bladder stones (13.3–36.0%), pyelonephritis (16.1–37.1%), cystolitholapaxy (13.3–35.1%), and re-augmentation (5.2–13.4%).[12]

URINARY TRACT INFECTION AND BACTERIURIA

Bacterial colonization of the urine and asymptomatic bacteriuria is a very common finding in patients with bladder augmentation. Most studies have estimated the incidence to be somewhere between 65% and 100% of patients.[11] The need for intermittent catheterization (IC) certainly predisposes these patients to bacteriuria. Patients undergoing AC for nonneurogenic reasons are more likely to be able to void on their own and therefore have one less risk factor for bacteriuria. Other risk factors for bacteriuria in patients after AC include large residual urine volume and the presence of mucus, which can harbor bacteria.[1,11,18]

Symptomatic UTIs are less common than asymptomatic bacteriuria, with a reported incidence of 4–49%.[19,20] Patients with neurogenic bladder (NGB) may have vague symptoms of UTIs like an increase in spasticity, malodorous or cloudy urine, or symptoms of concomitant autonomic dysreflexia instead of typical symptoms of UTI, such as frequency, urgency, and dysuria. In these cases, obtaining a urine culture and treating based on the culture is appropriate. Because of the lack of clear-cut symptoms, at times it is not always straightforward to determine when antibiotics should be instituted, and in many circumstances asymptomatic patients should be discouraged from treating changes in urine odor and color even if bacteriuria is found on culture. One possible exception to this concept is when urea-splitting organisms are noted on culture. In this case, most clinicians suggest treating bacteria due to the association with renal calculi. A short course of antibiotics of 3–5 days is given. If the patient is symptomatic a longer course of 7–10 days is warranted. Patient education is likely the most important factor in avoiding unnecessary use of antibiotics in this scenario.

Recurrent UTIs can be a significant issue for patients with NGB at baseline before bladder augmentation. It is not always clear whether a postoperative infection in these patients is a continuation of their preoperative bladder disease or whether the infection is the result of the bladder augmentation procedure itself. Nonetheless, despite the need for intermittent catheterization (IC) in patients undergoing bladder augmentation for NGB, these patients have been shown to have fewer instances of postoperative UTI compared with the preoperative state.[21] This finding may be related to secretion of immunoglobulin A by the bowel that prevents bacterial adherence to epithelial cells.[22]

The first step in the management of recurrent symptomatic UTIs is to image the upper and lower urinary tracts to rule out potential sources of infection like stones and foreign bodies. Patients experiencing symptomatic UTIs should be encouraged to irrigate the bladder regularly during IC. This maneuver may help to remove mucus, which may harbor bacteria and make it more difficult to eradicate infections. In addition, patients may benefit from changing IC technique by using single-use catheter kits, though the data supporting this practice are controversial. Similarly, there is little evidence that hydrophilic catheters are helpful in decreasing the risk of recurrent UTI.[23] A recent Cochrane review including 31 different trials regarding IC concluded that there is no convincing evidence that the incidence of UTI is affected by use of aseptic or clean technique, coated or uncoated catheters, single (sterile) or multiple-use (clean) catheters, self-catheterization or catheterization by others, or by any other strategy.[24]

Use of antibiotic irrigations has been advocated to help reduce the incidence of recurrent infections, though data

are lacking. It is our practice to recommend Gentamicin irrigation two to three times weekly for patients who continue to have antibiotics resistant UTI after all other conservative methods fail. Intravesical gentamicin has a low risk of absorption and has been shown to be highly effective. It has prolonged stability without special storage conditions and only severe bladder inflammation can potentially increase transvesical absorption.[25,26]

The use of cranberry supplementation has been shown to have a moderate benefit in the prevention of recurrent symptomatic UTIs in women. Concentrated cranberry supplementation may have a role, and is routinely used, though data relating to clinical practice in the neurogenic subpopulation are lacking.[27]

Suppressive ("prophylactic") antibiotic use has been studied in patients on IC at risk for recurrent UTIs. A recent Cochrane review concluded that for patients on IC, there is limited evidence that receiving prophylactic oral antibiotics reduces the rate of asymptomatic bacteriuria. However, there is weak evidence that use of prophylactic antibiotics can result in a lower incidence of symptomatic bacteriuria. Possible benefits of antibiotic prophylaxis must be balanced against possible adverse effects, such as development of antibiotic-resistant bacteria. These risks cannot be reliably estimated from currently available trials.[28]

STONES

The incidence of stone disease in patients with bladder augmentation using small bowel/large bowel ranges from 10% to 50%[17,29,30] (Fig. 48.2). A higher incidence of stones is noted in patients with continent urinary stomas.[31] Patients with bladder or renal stones have been found to have a 50% chance of recurrence. Of patients with recurrent renal stones, 40% were noninfectious after an initial infectious stone.[32] Compared to patients who are able to void spontaneously, stones are five times more common in patients requiring IC through the native urethra and 10 times more common if IC is performed through a continent urinary diversion stoma.[33] The reason is believed to be secondary to incomplete urinary emptying and urinary stasis that may be seen with this type of reconstruction as well as a higher incidence of bacteriuria in patients who perform IC. Recurrent UTI and concomitant bladder neck surgery also are significant risk factors for stone formation in patients with an augmented bladder.[34,35] Foreign bodies such as exposed staples, usually associated with a continent stoma, can also serve as a nidus of stone formation. A lower incidence of stone formation has been reported in patients with gastrocystoplasty, probably because of lower urinary pH, less mucus production, and a lower incidence of bacteriuria.[36] In a study of children who had undergone AC, bladder stones were found to be most commonly infectious stones with struvite being the most common composition at 55.2%, followed by calcium phosphate (28.7%), and pure carbonate apatite (10.5%). Renal stones were most likely calcium phosphate (46.7%) struvite (36.7%), or pure calcium oxalate (13.3%). Overall, of those with bladder stones, 22.7% also developed renal stones. [32]

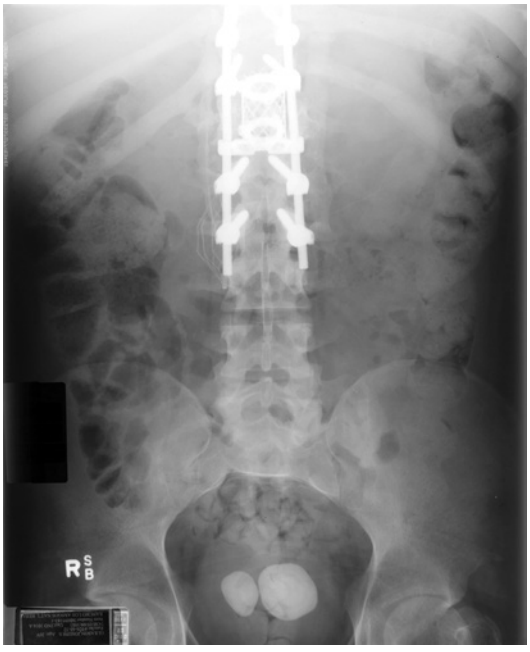

Figure 48.2 Radiographic study of the kidneys, ureters, and bladder. This 45-year-old patient with a T6 spinal cord injury had bladder augmentation 6 years earlier and now has large bladder calculi.

Several groups have studied causes of bladder stone formation. Khoury and colleagues[37] compared the mucus of stone formers with nonstone formers and reported a significantly higher calcium-to-phosphate ($p < 0.05$) ratio in the mucus of the patients who formed stones. This finding suggests that mucus could conceivably be a nidus of stone formation and removal of mucus could minimize future stone formation. Hensle and colleagues[31] investigated a pediatric population after bladder augmentation (with and without stomas) and found a statistically significant reduction (43% vs 7%; $p < 0.001$) in the incidence of stone formation in patients receiving a prophylactic irrigation protocol consisting of 240 mL saline solution and 120–240 mL gentamicin sulfate solution (240–480 mg gentamicin/1 L saline) twice a week.[31] However, use of other mucoregulatory agents (*N*-acetylcysteine, aspirin, urea, ranitidine, and octreotide) to reduce mucus in every patient with augmentation is questionable and is not recommended, as multiple studies including a randomized trial did not show any benefit of routine use of these agents.[38]

Most patients with stones are more likely to be diagnosed during routine radiographic follow-up of their NGB, or perhaps during surveillance cystoscopy. However, common symptoms of stones include hematuria, recurrent UTI, and worsening of incontinence. Treatment of stones is directed at stone removal and can usually be done endoscopically. For large stones, an open or percutaneous procedure may need to be performed. Percutaneous cystolithotomy should be considered in pediatric patients with urethras too small to accommodate standard endoscopic equipment. This consideration is also important in patients who have undergone a prior Mitrofanoff procedure (or other continent stoma such as Monti), which may not allow passage of an endoscope large enough to treat a bladder stone adequately. An Amplatz set can be used to dilate a suprapubic tube tract in preparation for appropriate fragmentation (if needed) with laser or electrohydraulic lithotripsy and removal.[39] It is important to remove all the stone material because any

remaining fragments of stone can serve as a nidus of recurrent stone formation. During any type of endoscopic procedure to remove stones, the potential risk exists of unidentified perforation through the much thinner bowel used to perform bladder augmentation; therefore, a temporary catheter should be left in place postoperatively.

PERFORATION

Perforation is a potentially life-threatening complication following augmentation cystoplasty and is seen in 3–13% of patients[12,13,40–42] Risk factors for perforation of augmentation cystoplasty include a competent bladder outlet that does not allow for a "pop-off" of urine, recurrent UTI, the need to empty the bladder with IC, and chronic overdistention, which is often seen in patients who do not maintain an appropriate IC schedule.[43] Gastrocystoplasty or ileocystoplasty may be associated with lower incidence of spontaneous perforation than other bowel segments.[41,42] Several causes of perforations of the augmented bladder have been evaluated. Bowel ischemia secondary to chronic overdistention and subsequent vascular compromise can lead to rupture.[44] Bowel detubularization, which is essential in eliminating peristaltic waves, has been suggested as a potential source of bowel necrosis and an underlying cause of perforation of the ischemic and necrotic bowel segment.[40] High pressures generated from uninhibited bladder contractions occurring in the augmented bladder also could be the underlying cause of perforation.[44] However, most patients who undergo properly performed bladder augmentation should have a significant and sustained decrease of detrusor pressure to acceptable levels and thus should not be at risk of perforation if an appropriate IC regimen is maintained.[45]

The most common presenting symptom of perforation is acute abdominal pain, though other commonly seen symptoms are nausea, vomiting, oliguria, and fever, as well as shoulder pain secondary to diaphragmatic irritation. Examination should reveal a distended abdomen with peritoneal signs. Patients with NGB may have greater morbidity and mortality associated with perforation because alterations in sensory pathways secondary to their underlying neurologic condition may lead to a delay in recognition. Cystogram may show extravasation; however, ~24% of patients may have normal study results.[13] Because of the lack of initial symptoms in certain NGB patients combined with the potential of a false-negative evaluation, a high degree of suspicion for this injury should be maintained in patients with bladder augmentation who become acutely ill. A CT urogram may be superior to a cystogram in identifying a perforated augmented bladder, although this should not supplant clinical judgment even in the face of a negative study.[43]

Once the diagnosis of bladder perforation is made, patients should receive aggressive intravenous hydration and broad-spectrum antibiotics, and undergo urgent abdominal exploration to repair the injury. The site of perforation is either the junction between the bowel and the bladder wall or the augment segment. Limited reports have described the conservative management of a perforated augmented bladder with catheter drainage of the bladder and percutaneous drainage of any intraabdominal fluid collections. However, because diagnosis of perforation is often delayed in this patient population, conservative management should be reserved for patients who are hemodynamically stable and do not show signs of progression or worsening of their symptoms.[46]

CARCINOMA

The actual risk of cancer in patients with bladder augmentation is not known. However, rates of cancer in patients with an augmented bladder range from 0% to 1.2% at 15 years of follow-up.[11,47] Most tumors are diagnosed within 10 years after the original surgical procedure; however, carcinoma occurring 50 years after AC has been reported as well.[48] Patients undergoing gastrocystoplasty seem to be at higher risk of developing carcinoma.[49,50]

Potential risk factors for tumor formation in bladder augmentation include chronic inflammation of the augment patch, recurrent UTI, and urinary stasis.[51–53] The association of recurrent UTI may be related to the impact of bowel and infection on urinary nitrates that are ultimately converted to nitrosamines. Nitrosamines have been implicated in tumors associated with urinary conduits and ureterosigmoidostomies.[54] Adenocarcinoma is the most commonly identified tumor in augmented bladders and is typically found in the region of the anastomosis of the bowel and bladder;[47] however, transitional cell carcinoma has been reported as well.[47]

A high degree of suspicion must be maintained to make the diagnosis. Patients with an augmented bladder perform regular IC and often have microscopic hematuria of benign origin. However, patients with gross hematuria should undergo prompt cystoscopy. Although no standard guidelines for cystoscopic evaluation and surveillance of these patients exist, a regimen of annual cystoscopy starting after 5 years[55] or 10 years following the augmentation has been proposed.[47] Regular cytologic studies in these patients, to screen for abnormalities, have also been proposed; however, cytologic examination is often unreliable in patients who have undergone AC, secondary to a chronically colonized state.[33]

METABOLIC DISORDERS

Hyperchloremic metabolic acidosis is the most commonly noted metabolic abnormality in patients who have undergone AC with either an ileal or a colonic segment. This finding is secondary to reabsorption of ammonia and ammonium chloride and secretion of bicarbonate by the bowel segment.[20,56] However, symptomatic acidosis requiring oral therapy with bicarbonate has only been reported in 16% of these patients.[11] Treatment of hyperchloremic acidosis consists of administration of alkalizing agents. Prophylactic alkali substitution should be commenced at a base excess below −2.5 mmol/L, with the aim of avoiding the long-term complications of clinically evident acidosis.[57] There is an association between renal insufficiency and an inability to handle excess acid load that leads to symptomatic acidosis in patients undergoing complete urinary reconstruction. Therefore patients with a serum creatinine level above 2.2 mg/dL[58] who require lower urinary tract reconstruction should be advised to undergo conduit rather

than augmentation to minimize the contact time of the urine and bowel.

One potential concern with chronic acidosis is buffering of the acid load by bone, with resulting bone demineralization. This can be a significant issue in children and can potentially affect bone growth. In fact, Mundy and Nurse[59] noted a halving of growth rate in 20% of children undergoing colocystoplasty. Interestingly, a negative impact on linear growth has not been noted in patients undergoing ileocystoplasty.[59,60] The reason for this finding may be that ileum, as opposed to colon, is able to reabsorb calcium. Boylu and colleagues[61] used bone-mineral density to evaluate pediatric patients with and without neurogenic disorders before and after ileocystoplasty. These investigators concluded that any changes in bone-mineral density were related to the underlying neurologic disease and its locomotor consequences. The decrease in bone-mineral density was not thought to be secondary to metabolic changes related to the bladder augmentation.[61]

Gastrocystoplasty can be preferred in patients with underlying renal insufficiency because no additional acid load is generated with augmentation using stomach segment. However, hematuria-dysuria syndrome can occur following gastrocystoplasty. Symptoms include bladder spasms, hematuria, dysuria, and suprapubic or penile pain. This complication has been noted in 26–37% of patients undergoing gastrocystoplasty and is related to irritation of the bladder mucosa from acid produced by the stomach segment used for augmentation. This syndrome can usually be managed with histamine (H_2) blockers.[62,63] Largely due to the high incidence of this syndrome following gastrocystoplasty, this procedure is now only rarely performed.

Vitamin B_{12} deficiency has been reported in adults in whom ileal segments had been used for AC, especially if longer segments (>60 cm) were used.[64] In children, no decrease in vitamin B_{12} levels was observed following bladder augmentation and substitution using ileal segments in most cases after a follow-up period of up to 8 years.[65] However, one study demonstrated an increasing risk of vitamin B_{12} deficiency after the seventh postoperative year when ileal segments had been used.[66] Since large hepatic vitamin B_{12} reserves prevent symptoms of vitamin B_{12} deficiency over a period of 2–5 years even in the presence of severe malabsorption, serum vitamin B_{12} levels should be checked annually starting at year 5 following augmentation. Treatment can be oral and/or intramuscular injection; however, a randomized study demonstrated that oral therapy (2 mg per day) is as effective as parenteral treatment (1 mg intramuscularly).[67]

BOWEL DYSFUNCTION

Chologenic diarrhea due to the loss of bile acids via the large bowel is one potential source of bowel dysfunction following AC. Many of these patients are undergoing cystoplasty for NGB and may have neurogenic bowel dysfunction as well. Other possible causes of bowel dysfunction after AC include colonization of the distal ileum with colonic bacteria after resection of the ileocecal valve, and bile acid malabsorption due to resection of the terminal ileum. This can lead to an increased water and electrolyte load delivered to the colon that cannot be adequately reabsorbed, with resulting diarrhea. In addition, the increased bile acid load can compound the problem by increasing gut motility. Fewer patients with sigmoid augmentation note postoperative bowel dysfunction compared to ileum or ileocecal augments, a finding which appears to strengthen the association of ileal resection with certain types of postoperative bowel disturbances.[68] Despite this association, ileum is much more commonly used since it provides lower reservoir pressures and better compliance than do sigmoid segments.[69]

The overall prevalence of bowel dysfunction after bladder augmentation is not entirely clear from a review of the literature. In a review of 113 patients with 3-year follow-up after cystoplasty, Singh and Thomas[68] noted a persistence of bowel dysfunction in 30% of patients. Complaints included an increase in stool frequency (38%), looser stool consistency (38%), and an increase in episodes of fecal incontinence (23%).[68] Husmann and Cain[70] reviewed 63 patients after a hemi-Indiana augmentation procedure and noted an improvement in fecal continence in 23% of patients, no change in 74%, and worsening of fecal control in 3%. Herschorn and Hewit reviewed 59 patients with a median follow-up of 76 months; 18.6% of patients reported bowel dysfunction, although seven of those 11 patients noted bowel issues preoperatively as well.[71]

Therapy for bowel dysfunction includes a low-fat diet and standard oral antidiarrhea treatment (typically loperamide). Anion exchange resin (cholestyramine) can be used in patients with refractory cases. Since long-term cholestyramine use is associated with poor absorption of fat-soluble vitamins A, D, and K, vitamin levels should be checked regularly. Despite active treatment, bowel dysfunction persists in a significant portion of these patients. Careful counseling and evaluation of bowel function before surgical intervention may decrease the impact on patients' satisfaction postoperatively.

INCONTINENCE
