- assessing the ship performance in damage conditions;
- estimating the risk according to the event tree analysis ETA and matrix type risk model (risk is estimated separately for each scenario of the accident under consideration);
- assessing the risk according to the risk acceptance criteria (risk matrix and in some cases ALARP concept) and safety objectives;
- managing the risk according to the risk control options;
- selecting the design (or operational procedure) that meet the requirements, criteria, limitations, safety objectives;
- optimizing the design (or operational procedure);
- making the decisions on safety, (Abramowicz-Gerigk 2006, Abramowicz-Gerigk 2008b, Abramowicz-Gerigk & Burciu 2013, Arangio 2012, Burciu & Grabski 2011,

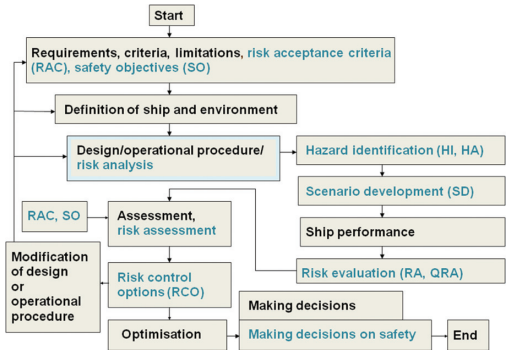

Figure 1. Structure of the method of risk and safety assessment of ships in damaged conditions.

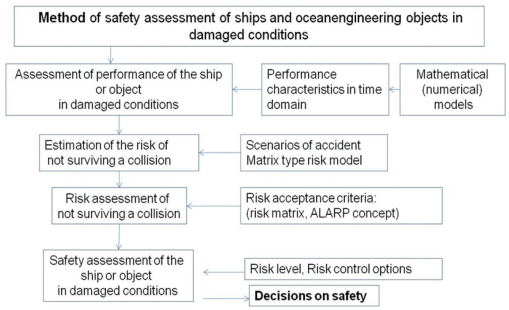

Figure 2. Structure of the SSADC sub-method for safety assessment of ships and oceanengineering objects in damaged conditions.

Gerigk 2004, Gerigk 2005, Gerigk 2006, Gerigk 2008, Gerigk 2010, Gerigk 2012, Nowakowski & Werbińka 2009).

The structure of the SSADC method is presented in Figure 1, Gerigk (2010).

The structure of the SSADC sub-method (see the module called as "Ship performance" in Fig. 1) for safety assessment of ships and oceanengineering objects in damaged conditions is presented in Figure 2, Gerigk et. al. (2012).

3 ASSESSMENT OF A SHIP (OBJECT) PERFORMANCE IN DAMAGED CONDITIONS

Flooding process and floodwater dynamics. The behaviour of a damaged ship is following from three major mechanisms:

– flooding process and dynamics of floodwater,
– interaction between floodwater and damaged ship,
– damaged ship motion in waves.

The flow through the damage (opening or openings) is estimated according to the equation which can be obtained from the Bernoulli's equation for the steady flow of water.

Interaction between floodwater and ship (object) dynamics. The effect of interaction between floodwater and damaged ship motion can be estimated using either the added weight or added force concept. According to the added weight concept, the floodwater should be treated as an added weight with a moving centre of gravity which changes the location of the ship's overall centre of gravity. It should be taken into account that as the total mass of the ship is changed during flooding so the inertia forces should be changed as well. The floodwater does not experience a negative vertical acceleration. In the case of the added force concept the forces due to the floodwater are treated as external forces. The forces due to floodwater should be calculated using the instantaneous acceleration rather than gravitational acceleration and by integrating water pressure at the compartment walls. There are three methods of modeling the floodwater—damaged ship motion interaction as presented in Table 1, ITTC (2011).

There are three methods of modeling the floodwater—damaged ship motion interaction as presented in Table 1, ITTC (2011).

As it is presented in Figure 1 the floodwater dynamics can be predicted using various models ranging from the second order ordinary differential equations through to numerical fluid mechanics (CFD).

Taking into account the modeling of floodwater-ship motion interactions it has been decided to use at this stage of research the quasi-static model first of all. Obtaining the promising results of assessment of performance using this model it has been decided to apply the quasi-dynamic model after that. It such the way it is possible to compare the behavior of the damaged ship applying both the models of the floodwater-ship motion interactions.

The excitation accumulated food water forces should be calculated according to the following assumptions:

– water in the flooded compartment moves in the quasi-static way;

Table 1. Models of the floodwater—damaged ship motion interaction.

	Floodwater treatment	Interaction concept
Quasi-static	Static	Added weight
Quasi-dynamic	Dynamic	Added weight
Dynamic	Dynamic	Added force

– free surface of water in the flooded compartment is flat and moves in different way depending on the model.

The schemes of the floodwater-ship interactions in the case of the quasi-static model with the horizontal free surface in the flooded compartment are graphically presented in Figure 3, ITTC (2011), bibliography (2012). In the case of the quasi-dynamic model the free surface in the flooded compartment is not horizontal. It is flat and changing according to the ship motions in each time step.

Damaged ship (object) motion in waves. Generally, the 2-D strip method or 3-D panel method may be used to calculate the radiation elements within the equations of damaged ship motions together with the direct integration used to calculate the non-linear restoring forces. Some studies calculate the damaged ship motion in 6DoF (six degrees of freedom) domain. At this stage of studies the 3DoF domain has been applied. The roll viscous dumping is added by the use of empirical formulae. The linear memory effect function (added mass and wave damping) is used even for the large amplitude motion and heeling condition, Bertram (2004), Dudziak (2008), Faltinsen (1990), Gerigk (2010), Krężelewski (1982). This issue has been recognized as a serious scientific and research problem to be solved in the future.

Assessing the damaged ship performance it has been anticipated that the ship may have six degrees of freedom in damaged conditions. Although at this stage it is assumed that the most important from the safety of damaged ship point of view are the following degrees of freedom: sway, heave and roll.

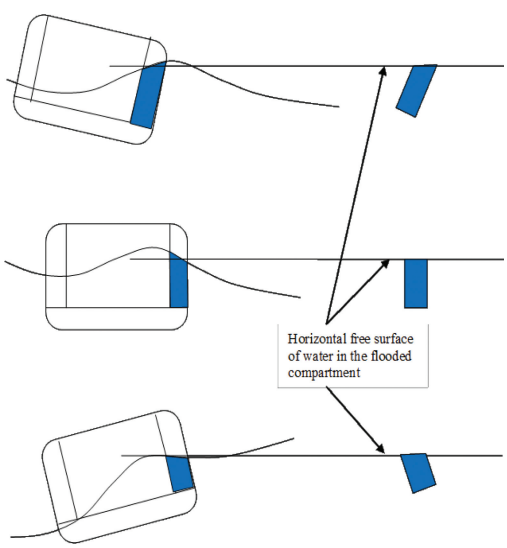

Figure 3. The graphical interpretation of the quasi-static model with the horizontal free surface in the flooded compartment.

4 THE MATRIX TYPE RISK MODEL

The safety case concerns the ships in abnormal/damage conditions when the ship skin is damaged due to the following hazards: collision, grounding, stranding or another reason, Gerigk (2010).

The risk assessment starts from the modeling of the risk contribution tree. For each hazard a separate event tree should be modeled using the Event Tree Analysis ETA, Gerigk (2010).

The holistic approach to ship safety has been applied. According to this approach two major assumptions have been done. First that the system failures can be either the hardware, software, organizational or human failures. The second assumption was that the risk model for assessment of safety of ships in abnormal/damage conditions should be the holistic risk model. The holistic risk model should enable to take into account almost all the possible scenarios development, Gerigk (2010).

From the mathematical point of view the relations between the events within an event tree (ETA) are represented by the conditional probabilities which are the components of the risk formula for each sequence of events (accident scenario), Gerigk (2010).

The basic formula for the risk evaluation associated with the different hazards and scenario development is according to the well known general formulae, Gerigk (2010):

$$R_i = P_i \times C_i \tag{3}$$

where P_i = probability of occurrence of a given hazard; C_i = consequences following the occurrence of the data hazard and scenario development, in terms of fatalities, injuries, property losses and damage to the environment.

The risk model (6) may have four different kinds of losses regarding the Human Fatalities (HF), Cargo and Ship Losses (CS), Environment pollution (E) and Financial losses ($) and for the ship in damaged conditions can be presented as follows:

$$R = P_c \, P_{c/f} \, PoC_{dam} \times C \tag{4}$$

where P_c = probability of collision (hazard); $P_{c/f}$ = probability of flooding having the ship hit from given direction at data position with given extent conditional on collision; PoC_{dam} = probability of capsizing in damaged conditions in given time conditional on having flooding when the ship is hit from given direction at data position with given

extent conditional on collision; C = consequences regarding the fatalities, property (cargo, ship), environment and finance ($C = C_{HF/C}, C_{CS/C}, C_{E/C}, C_{\$/C}$).

The PoC_{dam} probability of capsizing in damaged conditions in given time can be calculated according to the following formulae, Gerigk (2010):

$$PoC_{dam} = P_{c/f/ns} P_{c/f/ns/tts} \tag{5}$$

where $P_{c/f/ns}$ = probability of not surviving conditional on having flooding when the ship is hit from given direction at data position with given extent conditional on collision; $P_{c/f/ns/tts}$ = probability of given time to sink conditional on not surviving the conditional on having flooding when the ship is hit from given direction at data position with given extent conditional on collision.

The PoC_{dam} probability can be estimated during the accident at sea using the following methods, Gerigk (2010):

- binary method;
- method based on definition of the probability of surviving a collision;
- method based on definition of the damage stability;
- method based on definition of the ship performance during the accident.

In the case of the last method the roll function in time domain has been anticipated as a major characteristcs/function enabling the risk assessment, Gerigk (2010).

The risk analysis requires to calculate the conditional probabilities regarding the initial events ZI_i, major events (hazards) ZG_j, intermediate events ZP_k and final events ZK_l which can be treated as consequences. The basic mathematical formula are as follows, Gerigk (2010).

First of all the row matrix of initial events is evaluated:

$$P(ZI) = P(ZI_i) \text{ for } i = 1 \text{ to } n \tag{6}$$

Then the matrix of major events is calculated:

$$MP_{ZG} = P(ZG_j/ZI_i) \text{ for } j = 1 \text{ to } m \tag{7}$$

After that the matrix of intermediate events is calculated:

$$MP_{ZP} = P(ZP_k/ZG_j) \text{ for } k = 1 \text{ to m1} \tag{8}$$

Then the matrix of final events is calculated:

$$MP_{ZK} = P(ZK_l/ZP_k) \text{ dla l} = 1 \text{ do m2} \tag{9}$$

Finally, the row matrix of final events may be estimated as follows:

$$P(ZK) = P(ZI)\ MP_{ZG}\ MP_{ZP}\ MP_{ZK} \tag{10}$$

The above mathematical model is representing the entire risk model called as the matrix type risk model. This model enables to consider almost all the possible scenarios of an accident using an event tree. In the case when the additional events occur the $PoC(C_i)$ probability of occurring the C_i given consequences can be calculated according to the formula presented by Gerigk, Gerigk (2010). The typical additional events may concern the water on deck, air cushions, cargo leakage, additional heeling moments or passenger behavior.

5 APPLICATION OF THE SSADC METHOD

The ship accidents at sea may lead to the loss of life, loss of properties (ship and cargo) and pollution of environment. The modern approach to safety of maritime transportation requires to apply the so-called life-circle approach by integrating the design for safety, safe operation and safe salvage methods. The effective safety assessment methods requires to develop the methods, models and tools for the assessment of risk and safety of ships in damaged conditions.

The SSADC method of safety assessment of ships in damage conditions together with the matrix type risk model enables to assess a ship safety almost for all the possible accident scenarios including the ship survivability at each stage of flooding process including the preliminary, intermediate and final stages of flooding.

Such an approach to ship safety assessment in damage conditions is necessary to predict any further deterioration of the damage condition. If the ship survives flooding and is unable to return to port under own power it is necessary to solve the problems associated with the towing when waiting for an assistance. During the towing the risk and safety assessment of the ship should be permanently conducted (Perera & Soares Guedes 2011, Skjong & Vanem & Rusas & Olufsen 2006, Soares Guedes & Teixeira 2001).

The structure of the entire procedure for the assessment of safety of ships in abnormal/damage conditions during the accident at sea and for the salvage purposes was published by Gerigk, (Gerigk 2010, Gerigk 2012).

The example applications of the SSADC method has been done for two ships and one ocean engineering object.

An example of application concerning a new Multi-Task ship (MT-ship) is presented in the paper.

The MT-ship has the main data as follows:

- length: $L_{BP} = 60{,}0$ m
- breadth: $B = 8{,}0$ m
- heigth to the main deck: $H = 9{,}35$ m

The basic information on the hull form of the MT-ship is presented in Figure 4.

During the safety assessment of the MT-ship in damage conditions the following scenarios were considered to be flooded:

– scenario 1: combined compartment 1
– scenario 2: combined compartment 2
– scenario 3: combined compartment 3
– scenario 4: combined compartment 4
– scenario 5: combined compartment 5
– scenario 6: combined compartment 6
– scenario 7: combined compartment 7

The Mt-ship has no conventional arrangement of internal spaces therefore each combined compartment consists of a few sub-compartments.

The event tree analysis was done for the MT-ship. It is not published, yet,

Generally, thirteen safety functions have been used for each event tree from the MT-ship safety in damaged conditions point of view. Between them are as follows:

– function1 (avoiding the hazard),
– function 2 (hull skin damage (flooding)),
– function 3 (position and extension of damage),
– function 4 (equalization of the ship heel at the preliminary stage of flooding),
– function 5 (loss of the ship stability at the preliminary stage of flooding),
– function 6 (loss of the ship stability during the intermediate stages (and phases) of flooding),
– function 7 (loss of the ship stability at the final stage of flooding),
– function 8 (loss of the ship floatability at the final stage of flooding),

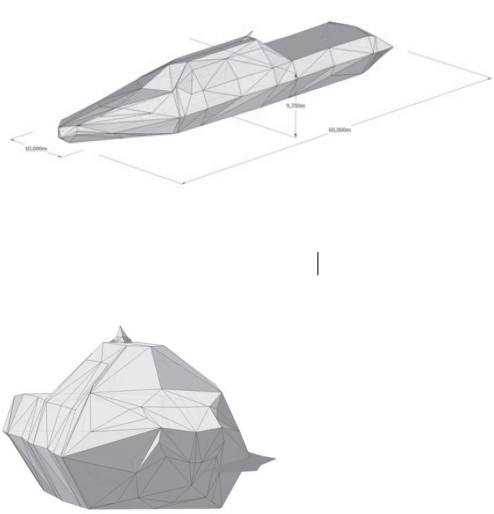

Figure 4. The hull form of the MT-ship.

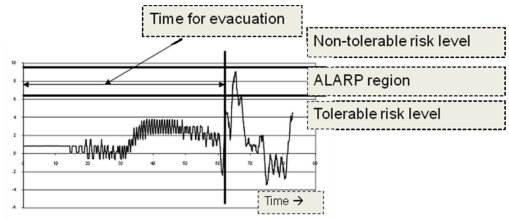

Figure 5. An example of the roll function in time domain and ALARP risk evaluation criteria applied for the assessment of safety of the MT-container ship in damaged conditions.

– function 9 (ship is waiting for assistance),
– function 10 (ship returns to port under own power),
– function 11 (ship returns to port by tow),
– function 12 (ship is continuing the mission),
– function 13 (fire and/or explosion).

Assessing the performance of the damaged MT-ship the following impacts were taken into account, (Abramowicz-Gerigk 2005, Abramowicz-Gerigk 2008a, Gerigk 2004, Gerigk 2005, Gerigk 2006, Gerigk 2008, Gerigk 2010, Gerigk 2012):

– gravitational forces,
– hydrostatic forces,
– excitation Froude-Krylov forces,
– excitation diffraction forces,
– accumulated flood water forces,
– cargo shift forces.

An example of the damaged MT-ship performance data as the roll function in time domain is presented in Figure 5. The vertical axis regards the angle of heel and the horizontal axis concerns the time in seconds. During the conference the latest results of investigations concerning the MT-ship performance data and risk assessment results will be presented.

6 CONCLUSIONS

A few elements of the method of assessment of safety of ships in damaged conditions are presented in the paper. The method is based on the assessment of ship performance and risk assessment.

The key issue to apply the method is to have the proper model for the performance assessment of ships in damaged conditions and risk model for the risk assessment. At this moment the model for the ship (object) performance assessment has been prepared to obtain the three major hydromechanics' characteristics of the damaged ships. These are as follows: sway, heave and roll. For estimating

the sway, heave and roll motions either the quasi-static or quasi-dynamic models presented in chapter 3 may be used. The crucial issue of the damaged ship (object) performance assessment is to decide which hydromechanics' characteristic in the form of the sway (heave or roll) process in time domain should be used to estimate the risk value. For the ships in damaged conditions it is the roll function. At this stage of research the risk assessment can be performed using the ALARP concept. This is to investigate how much time a captain has to evacuate the damaged ship (object).

The current research is associated with further development of the performance procedures of ships in damaged conditions.

The method has the following features:

1. no disadvantages which exist in SOLAS;
2. holistic approach to safety (design, operation, catastrophe, salvage);
3. holistic approach to safety: safety factors (sources of factors: design, operation, management, human factor);
4. holistic approach regarding the risk model;
5. assessment of safety for all the possible scenarios.

The key issue to apply the method is to have the proper matrix type holistic risk model. The proposed risk model enables to estimate the risk level for all the possible scenarios of an accident. The proposed risk model is much more complicated than the models published in literature.

The assessment of damaged ship performance using the CFD based method is the best way to obtain the damaged ship performance characteristics in time domain at the design stage. As an alternative the damaged ship performance may be performed using the model tests.

The current research is associated with further developing the risk models necessary for the ship performance-oriented and risk-based assessment. From the practical point of view the research should bring a model for the computer simulation of the ship salvage process.

The research has been carried out at the Gdansk University of Technology according to support obtained from the Ministry of Science and Higher Education in Warsaw. The author would like to express his sincere gratitude to the above organisations.

Review of risk concepts and perspectives in risk assessment of maritime transportation

F. Goerlandt & J. Montewka
Department of Applied Mechanics, Marine Technology, Research Group on Maritime Risk and Safety, Aalto University, Espoo, Finland

ABSTRACT: Shipping accidents can have severe consequences, causing concerns to various stakeholders. This has led to research into risk assessment methods for the maritime transportation system. This paper presents an analysis of risk concepts and perspectives adopted in 44 methods for risk assessment in maritime transportation. As a methodological framework for analysis, a historical classification of risk concepts and a novel categorization of risk perspectives along the realist-constructivist continuum are applied. Analyses reveal that in the maritime transportation, risk is strongly tied to probability and that a wide range of perspectives is found, from realism over scientific proceduralism to more constructivist views.

1 INTRODUCTION

Risk assessment methods for maritime transportation have received a growing interest in recent years and relevant organizations have provided recommendations to maritime authorities on the use of specific risk management tools (IALA 2009; IMO 2010). In the wider risk research literature, there is a relatively recent focus on foundational issues, with calls for increased discussion, reflection and analysis regarding applied terminology, principles and perspectives (Aven 2012a; Rosa 2010).

Answering to these calls, the aim of this paper is to provide a broad overview and analysis of how risk has been defined, and what risk perspective is taken in methods for risk assessment of maritime transportation. Our main interest is a number of "risk-theoretic" aspects, related to the underlying conceptualizations, perspectives and principles in the sense intended by Aven (2012a). Reflecting on foundational issues in the application area of risk assessment in maritime transportation requires a methodological framework. Two aspects of this framework are introduced in Sections 2 and 3, respectively addressing the risk concept (what risk "is"), and the risk perspective (how risk is "looked at"). While these aspects are closely linked in practical applications, making a clear distinction between these is important from a foundational viewpoint.

In the course of this research, 44 original methods for risk assessment for maritime transportation have been found and analyzed. The methods have been published in scientific journals over a time span of last 40 years, from 1974 to 2013, (Fujii et al. 1974; MacDuff 1974; Hara & Nakamura 1995; Pedersen 1995; Roeleven et al. 1995; Harrald et al. 1998; Fowler & Sørgård 2000; Merrick et al. 2000; van Dorp et al. 2001; Friis-Hansen & Simonsen 2002; Kaneko 2002; Merrick et al. 2002; Rosqvist et al. 2002; Kristiansen 2005; United States Coast Guard 2005; Merrick & Van Dorp 2006; COWI 2008; Przywarty 2008; Klemola et al. 2009; Ulusçu et al. 2009; Debnath & Chin 2010; Kaneko 2010; Klanac et al. 2010; Mermiris & Vassalos 2010; Montewka et al. 2010; van Dorp & Merrick 2011; Qu et al. 2011; Akhtar et al. 2012; Almaz 2012; Blokus-Roszkowska & Smolarek 2012; Montewka et al. 2012; Goerlandt et al. 2012; Jeong et al. 2012; Montewka et al. 2011; Montewka, Ståhlberg, et al. 2010; Sormunen et al. 2012; Rasmussen et al. 2012; Suman et al. 2012; Weng et al. 2012; Burmeister et al. 2013; Mulyadi et al. 2013; Talavera et al. 2013; Ståhlberg et al. 2012; Goerlandt & Kujala 2011).

2 A CLASSIFICATION OF DEFINITIONS FOR THE RISK CONCEPT

As a central part of our analysis concerns the applied risk concepts in risk assessments, a brief review of some basic categories of definitions of the risk concept is provided. The below classification is taken from a historic analysis of the risk concept by Aven (2012b), addressing the question what risk means in itself, i.e. what risk "is".

C1. Risk = Expected value (R = E)

a. The risk of losing any sum is the reverse of Expectation, and the true measure of it is, the product of the sum adventured multiplied by the probability of the loss.

b. Risk equals the expected loss
c. Risk equals the product of the probability and utility of some future event
d. Risk equals the expected disutility

C2. Risk = Probability of an (undesirable) event (R = P)
a. Risk is the chance of damage or loss
b. Risk equals the probability of an undesirable event
c. Risk means the likelihood of a specific effect originating from a certain hazard occurring within a specified period or in specified circumstances

C3. Risk = Objective Uncertainty (R = OU)
a. Risk is the objective correlative of the subjective uncertainty; uncertainty considered in the course of events in the external world
b. Risk is measurable uncertainty, i.e., uncertainty where the distribution of an outcome in a group of instances is known (either through calculation a priori or from statistics of past experience)

C4. Risk = Uncertainty (R = U)
a. In regard to cost, loss or damage
b. About a loss
c. About the happening of an unfavourable contingency
d. Of outcome, of actions and events

C5. Risk = Potential/possibility of a loss (R = PO)
a. Risk is the possibility of an unfortunate occurrence
b Risk is the possibility of an unfavourable deviation from expectations
c. Risk is the potential for realisation of unwanted, negative consequences of an event

C6. Risk = Probability and scenarios/(severity of) consequences (R = P&C)
a. Risk is a combination of hazards measured by probability; a state of the world rather than a state of mind
b. Risk is a measure of the probability and severity of adverse effects
c. Risk is equal to the triplet (s_i, p_i, c_i), where s_i is the ith scenario, p_i is the probability of that scenario, and c_i is the consequence of that scenario, $i = 1,2, \ldots, N$; i.e. risk captures: What can happen? How likely is that to happen? If it does happen, what are the consequences?

C7. Risk = Event or consequences (R = C)
a. Risk is a situation or event where something of human value (including humans themselves) is at stake and where the outcome is uncertain
b. Risk is an uncertain consequence of an event or an activity with respect to something that humans value

C8. Risk = Consequences/damage/severity of these + Uncertainty ($R = C\&U$)
a. Risk = uncertainty + damage
b. Risk is equal to the two-dimensional combination of events/consequences (of an activity) and associated uncertainties
c. Risk is uncertainty about and severity of the consequences (or outcomes) of an activity with respect to something that humans value
d. Risk is the deviations from a reference level (ideal states, planned values, expected values, objectives) and associated uncertainties

C9. Risk = Effect of uncertainty on objectives (R = ISO)

3 FOUNDATIONS OF VARIOUS PERSPECTIVES TO RISK ASSESSMENT

In a risk assessment, risk is described or measured for the purpose of informing a decision, but there are different views regarding how to do this. The foundational view on risk assessment applied in the process of informing a decision is referred to as a risk perspective. It thus does not concern the question what risk "is", but how risk is "looked at" and which processes are applied in making statements concerning risk.

There are important and long-standing debates between opposing philosophical positions related to risk assessment, ranging from realism/positivism to constructivism/cultural relativism (Klinke & Renn 2002; Shrader-Frechette 1991; Rosa 1998).

The realist risk philosophy is rooted in a dualism between the mind and the external material world. Under such a view, knowledge relates to a discovery of the world as it really is and to discover the laws of causality in that world (Jore & Njå 2010). Realists are convinced that a true risk exists and that technical estimates of risk are representations of this true risk, affecting people as predicted by the calculated results regardless of the beliefs or convictions of the assessor (Klinke & Renn 2002).

Constructivism acknowledges that modeling is a cognitive process in which the complexity of the world is reduced to a mental construct, where the analysis does not aim to uncover the truth about risk but provides a reflection of somebody's mental construction conditional to a specific background knowledge, see (Jore & Njå 2010; Klinke & Renn 2002). Important characteristics of constructivism are that there is no reference to a true risk and that different assessors can have different mental constructions.

Extreme constructivists posit that any risk construct is equally valid, i.e. that no mental construction is superior to others, and adhere to a form of cultural relativism (Shrader-Frechette 1991).

Another major schism exists between positivists and cultural relativists in that the former see no role for values in risk assessment, whereas the latter conceive risk assessment as a combination of facts, values and public perceptions (Shrader-Frechette 1991). Rather than an absolute dichotomy between realists/positivists and constructivists/cultural relativists, there exists a continuum between these extremes (Shrader-Frechette 1991).

A schematic version of this continuum has been presented by Jore and Njå (Jore & Njå 2010), in the context of terrorism risk, focusing on the role and use of models and on the interpretation given to the outcome of an analysis.

In Table 1, a novel and extended version of this classification is presented. The description of the perspectives should be seen as an approximation of the general features of some common approaches to risk assessment. In the following subsections the brief overviews of the perspectives are given.

3.1 *Realism and true judgments*

The most realist views rely exclusively on data and engineering models. It is based on the conception that objectivity can only be achieved by application of data, mathematical calculations and engineering models.

Table 1. Risk perspectives in the realist/constructivist continuum.

	Foundational perspective	Risk expression	Risk interpretation
I	Realism Positivism	Model seen to describe true risk	Truth Risk is a property of the world. Based only on "hard" evidence.
II	True judgments	Model seen to describe true risk Expert judgment as truth-approaching Uncertainty sporadically mentioned	Judgment aiming at truth Risk is a property of the world. Based on "hard" evidence and judgment Uncertainty related to imprecision of underlying true risk
III	Probability of frequency Uncertainty quantification	Model seen to describe true risk Expert judgment is truth-approaching Uncertainty is quantified	Judgment aiming at truth Risk is a property of the world. Based on "hard" evidence and judgment Uncertainty related to imprecision of underlying true risk
IV	Precautionary perspective	Model is seen to describe a true underlying risk Direction of bias away from true risk is qualitatively evaluated.	Judgment aiming at truth Risk is a property of the world. Based on "hard" evidence and judgment. Uncertainty related to imprecision of underlying true risk
V	Scientific proceduralism	Model is seen to describe a true underlying risk Model is seen as compromise between stakeholder groups Quantitative and qualitative	Judgment and values Risk is a property of the world. No truth-claims are possible concerning risk judgments. Risk assessment is the result of judgments of both experts and lay people, balancing facts and values. Analytic-deliberative process.
VI	Argument view	Model is seen as an expression of argument Quantitative and qualitative	Judgment Risk results from an interpretation. Based on "hard" evidence and judgment. Adversarial approach.
VII	Uncertainty view	Model is seen as an expression of uncertainty Quantitative and qualitative Broad qualitative uncertainty evaluation	Judgment and uncertainty Risk is uncertainty of an assessor related to events/consequences. Based on "hard" evidence and judgment
VIII	Constructivism Cultural relativism	Qualitative descriptions	Judgment, values and perceptions Risk is a cultural or social phenomenon. Lay people oriented.

In a "true judgment" view, expert judgment is used, but it is applied to estimate a true underlying risk. In this view, expert judgment is seen as an alternative only when there is no data available. Assessments under this view typically rely on heavily on data, calculations and models and less on judgment.

3.2 *Probability of frequency and uncertainty quantification*

Kaplan (1997) proposes the so-called "probability of frequency" approach to risk assessment, based on a risk concept in line with risk definition C6 (R = P&C), where subjective probabilities are used to express uncertainty about true frequentist probabilities. The assessment thus focuses on quantifying uncertainty about an underlying true risk, which is estimated. Kaplan's view is strongly tied to realism, as the risk description focuses on a true risk as determined by experts. Closely related perspectives are those where uncertainty is quantified around a true risk, such as in the traditional Bayesian perspective where uncertainty is quantified in relation to model parameters (Aven & Heide 2009). Such uncertainty quantification can also be done using non-probabilistic representations of epistemic uncertainty (Helton & Johnson 2011). These methods typically consider a risk problem in a highly mathematized form.

3.3 *Precautionary perspective*

Rosqvist and Tuominen (2004) propose a precautionary approach to risk assessment, based on a risk concept in line with C6 (R = P&C). They propose a framework in which risk is quantified using probabilities, supplemented with a systematic analysis of model bias to account for model uncertainty. The bias analysis aims to assess whether the risk estimates are optimistic, realistic or conservative in relation to the true risk of the system (Rosqvist & Tuominen 2004). While starting from a realist conception because a true risk is in focus, uncertainty is assessed through biases in a qualitative way. This less quantity-focused approach is in our view a step towards constructivism in comparison with the perspective by Kaplan (1997). Through the bias analysis, it allows for a more reflective stance towards underlying assumptions and simplifications, which places the risk problem in a wider qualitative context.

3.4 *Scientific proceduralism*

Shrader-Frechette (1991) advocates a middle-way between realism and constructivism which she terms "scientific proceduralism". Its rationale is based on three premises: (i) explanatory power as tested by prediction, (ii) naturalistic approach to theory choice and (iii) testing the predictive and explanatory power of our risk theories and by subjecting risk evaluations to intelligent debate, criticism, and amendment by the scientific community and lay people. Concerning expert judgment, she notes that "[…] there is little reason to believe that experts are always able to calculate actual or *real* risk" (Shrader-Frechette 1991), and that "experts' trust in their probability estimates is typically a function of how much information they have gathered, rather than a function of its accuracy of its predictive success" (Shrader-Frechette 1991). Her views seem to be on the one hand rooted in the existence of a "true risk", because it can be tested by prediction and because the estimation of a probability implies the existence of a "correct" or "true" probability. Thus, scientific proceduralism has strong ties to realism. She also stresses the explanatory power and debate aspects of risk modeling, which are elements of a more constructivist view. The probabilities and risk models can in this sense be understood as tools for argumentation. This aspect of her scientific proceduralism has been influential to conceiving risk assessment as an analytic-deliberative process (Stern & Fineberg 1996).

3.5 *Argument view*

Watson argues for an understanding of risk assessment as "an expression of argument, rather than a revelation of truth" (Watson 1994). The strength of argument depends on the quality of the data, the adequacy of the model and the agreement in expert judgments, and is seen as input on a debate on the safety of a system. Watson thus sees a risk assessment as a translation of the available background knowledge into a tool to inform a decision, placing judgment and argumentation central in the risk description. Watson's view represents a significant step towards constructivism because, unlike the above risk perspectives, there is no reference to a true, mind-independent risk. Expert judgment and subjective probability is not seen as a means to estimate a true risk, but as a means to quantitatively put forward an argumentation. We shall refer to this perspective as "argument view".

3.6 *Uncertainty view*

Aven and Renn argue for an uncertainty-based view on risk and risk assessment, where risk is conceptualized in line with definition class C8 (R = C&U). In their view, risk assessment is an expression of an assessor's uncertainty about the occurrence of events and the consequences. Risk assessment can always be performed, as it is seen as a tool to describe uncertainties rather than a tool to uncover the truth. Their view has a strong constructivist basis: "[…] risk does not exist independent of the assessor, as the uncertainties need to be assessed by somebody […] Uncertainty is not real, it is a construct of human imagination to cope

with potential future outcomes that can become real" (Aven & Renn 2009). However, they stress that their risk perspective is not a relativist social construction, because the events/consequences refer to an objective world (they can become real) and because the assessment can be based on the best available scientific data, models and judgment (Aven & Renn 2009). This view is similar to Watson's in that no "true risk" is conceived to exist and its measurement is a reflection of somebody's mental construct in light of evidence available to him/her (Aven 2010). In this perspective, more stress is placed on the importance of uncertainty in the background knowledge (Aven 2013), both in terms of evidential and outcome uncertainty. In this sense, this perspective is a further step towards constructivism in comparison with the "argument view". We shall refer to this view as the "uncertainty view".

4 HISTORIC OVERVIEW OF RISK DEFINITION AND PERSPECTIVE

In Figure 1, a historic overview of the applied risk definitions is given. It is clear that a wide variety of definitions is applied in practical settings. Of the nine categories, risk definitions in the application area are clustered in the categories C1 (R = E), C2 (R = P), C5 (R = PO) and C6 (R = P&C). Over the years, risk has been strongly tied to probabilities and only weak historic trends can be identified. Risk is considered as the probability of an event in the earliest work in the field, after which such views have disappeared for more than two decades, re-emerging in recent work. From 1995 onwards, the predominant definitions involve both the probability of events and consequences. Both the definition through expected values of probabilities and consequences (C1) as well as the combination of probabilities and consequences (C6) are approximately equally often found. The definition of risk in line with a potential or possibility of a loss (C5) is very sporadically used throughout the history.

Reflecting on the findings by Aven, it is found that the traditional engineering definitions (C1 and C6) and the definitions of decision analysts (C1) are the predominant views on risk, (Aven 2012b). Aven in (2012b) claims that the risk definitions of category C8 (R = C&U), where uncertainty rather than probability is seen as a fundamental component of risk, have recently replaced probability-based conceptualizations in the engineering fields. From our analysis, it is seen that this is not the case for the maritime transportation application area. In fact, such a view on risk is not found.

A more policy-oriented issue is that many applications do not follow the suggested definitions by relevant authorities. In the Formal Safety Assessment (FSA), which is commonly seen as the official guide for risk assessment in the maritime field, risk is defined as "the combination of the frequency and the severity of the consequence" (IMO 2007), i.e. a categorization in line with class C6. While the definitions based on expected values (C1) are close to this view as it consists of the same elements, the definitions in line with C2 and especially C5 represent significantly different risk classes. The ISO-definition, seeing risk as "the effect of uncertainty on objectives", is not applied in the application area.

In Figure 2, a historic overview of the risk perspectives in the application area is shown. It is seen that strong realist conceptions are found from the early work in the application area to the present day. Risk perspectives in line with the "true judgment" view have been present since the mid-1990s and are approximately equally often found as the strong realist views since that time. Views in line with the "probability of frequency" approach to risk assessment, where uncertainty is quantified around a true risk are relatively rare in the application area, starting from the mid-2000s. Only two such methods are found: one applying a traditional

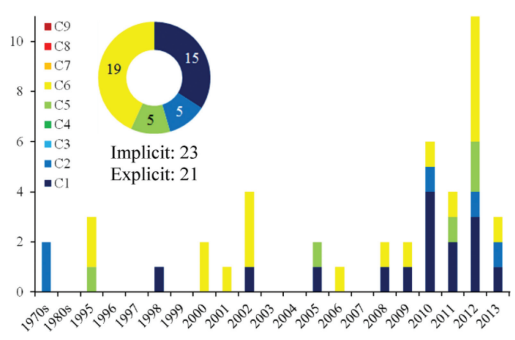

Figure 1. Historic overview of applied risk definition. Risk concept classes as introduced in Section 2.

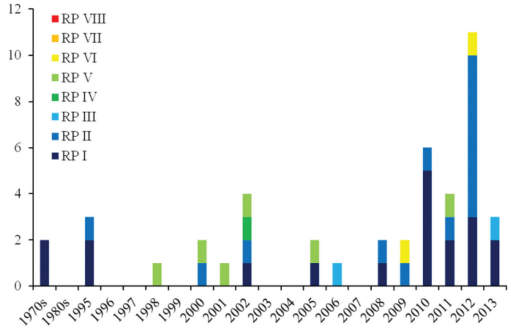

Figure 2. Historic overview of foundational Risk Perspective (RP). Classification on realist-constructivist continuum according to Table 1.

Bayesian approach and one applying Dempster-Shafer evidence theory to quantify uncertainty about model parameters. The precautionary view is only found once, in the early 2000s, and hence represents somewhat of an outlier view in the application area. There is relatively more work in line with the scientific proceduralism view on risk assessment, from the late 1990s onwards. The argument view, where expert judgment is taken as a core element of the risk description, represents a minority of the perspectives on risk assessment.

The historic overview clearly shows that a wide range of perspectives has been applied in risk assessments for maritime transportation. Most of the work is rooted in the idea that a true, mind-independent risk exists in line with realist perspectives on the continuum of Table 1. Using different modeling approaches, the majority of the methods aim to estimate this true risk. While the use of expert judgment has gained steady support, many of the applications rely heavily on accident and traffic data. Even when judgment is applied, it is considered to be truth-oriented. From the overview, it is also found that constructivist views, where the assessment is seen rather as a reflection of an assessor's interpretation of the system risk, are rare. The uncertainty view, where an assessor expresses his uncertainty about the occurrence of events and consequences, is not found in the application area.

5 RELATION BETWEEN RISK DEFINITION AND RISK PERSPECTIVE

In Figure 3, the applied risk definitions are grouped per risk perspective. It is observed that definitions of risk of classes C1 (R = E) and C6 (R = P&C) are found across the realist-constructivist continuum. Definitions in line with C2 (R = P) are mostly found in the realist part of the spectrum. Definitions C5 (R = PO) are also linked to more realist conceptions.

This implies that the adopted definition does not necessarily provide much information regarding the foundational perspective. E.g. risk definitions based on expected values (C1) can lead to very realist perspectives on risk if such a definition is taken to literally mean that risk as a concept is equal to an expected value, as e.g. in (Kaneko 2002; Mermiris & Vassalos 2010; Akhtar et al. 2012; Montewka, Ehlers, et al. 2010). However, the same definition can be used in a more stipulative sense, to define risk measures as in e.g. (Harrald et al. 1998; Ulusçu et al. 2009). The risk concept is then implicitly understood more widely, but the C1-definition is seen as useful in the specified context.

Nonetheless, if a risk definition is posited without reflection on the underlying risk concept or the applied risk perspective, misunderstandings can easily occur. The presence of a range of competing underlying views on risk assessment, all applying similar terminology, signals that possible disagreements on adopted approaches run deeper than a semantic discussion on applied terminology.

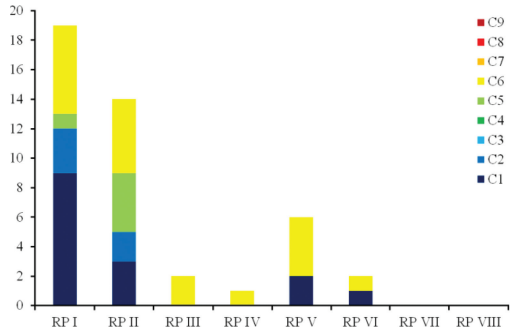

Figure 3. Overview of risk definition (C) in relation to Risk Perspective (RP).

6 DISCUSSION

Our analysis of the adopted perspectives in risk assessment of maritime transportation shows that many competing views on risk analysis exist, as argued by other risk researchers (Shrader-Frechette 1991; Klinke & Renn 2002; Rosa 1998; Jore & Njå 2010). While this has not received much attention in the application area, our analysis shows that this is also the case in risk assessment for maritime transportation. This this is not merely a matter of defining the word "risk", but a matter of more deep running philosophical positions.

In the field of maritime transportation, risk assessment is overall very strongly tied to probabilities, both in relation to the adopted definition as in the applied risk description. This may be at least in part due to the definition in the Formal Safety Assessment (FSA), as "the combination of the frequency and the severity of the consequence" (IMO 2007).

Much work is rooted in the realist-oriented perspectives on risk assessment, with much fewer applications in line with scientific proceduralism or more constructivist conceptions. However, adopting a constructivist-based view to risk assessment requires an adaptation of the expectations of risk assessment as a tool to inform a decision, which has repercussions also in judging the risk acceptability or the decision regarding the adopted risk management strategy.

In many applications, risk is not defined. In light of the existence of a plenitude of conceptual classes in the general risk research field and in the application area, an implicit assumption that the term is sufficiently self-explanatory is in our view unfortunate.

7 CONCLUSIONS

Our findings confirm earlier research claiming that somewhat of a terminological and conceptual chaos exists the risk research field. Four distinct classes of risk definitions are found in applications, mostly considering probability as a component of risk. While applications are based on a wide range of perspectives on the realist-constructivist continuum, most work is positioned on the realist part of the spectrum, focusing on a true, mind-independent risk.

It is hoped that some insights gained from the analysis can serve to illustrate the need for more focus on foundational issues concerning risk assessment in the application area. We are convinced that further conceptual refinements would benefit the practice of risk analysis in the maritime field.

ACKNOWLEDGMENT

This study was conducted as a part of EU funded project on Human Factors in Risk-based Ship Design Methodology—FAROS (2012–2015) (Grant no. 314817), the FP7 program. Merenkulun säätiö from Helsinki is appreciated for the travel grant.

Risk based assessment on increased gas safe machinery spaces of liquefied natural gas fuelled ship

Xiao Jian Li & Rui Ping Zhou
School of Energy and Power Engineering, Wuhan University of Technology, Wuhan, Hubei, China

ABSTRACT: A new concept of machinery spaces called increased gas safe machinery spaces (hereafter Increased Type) of liquefied natural gas fuelled ship is introduced in this paper. This paper develops a practical methodology to assess that kind of machinery spaces based on risk based technology. According to the methodology, the sources of leaks of the gas supply system are firstly identified using Fault Tree Analysis (FTA). Then the frequencies of leakage, ignition and failure of ventilation and detection in risk assessment are estimated from generic historical statistics and with FTA and Event Tree Analysis (ETA). Based on that, frequency analysis of hazards, such as failures of pipes, valves, filters, fans and detectors, under different failure modes, is carried out. As for consequence evaluation, consequence areas of different types of outcome like flash fire, jet fire and vapor cloud explosion are logically preceded from the mechanism of each possible outcome. After all the steps above, risk of each identified hazard is determined and the risk of the machinery spaces ultimately is summarized. In addition, the tolerability of Risks is developed, which determines whether the risk is acceptable, unacceptable or needs risk management as low as reasonably practicable.

1 INTRODUCTION

The potential of LNG to be a 'fuel of the future' for the shipping industry is a hot spot almost daily. There is no doubt that LNG ticks the box in terms of emissions reductions compared to conventional fossil fuels (Michael D. Tusiani and Gordon Shearer 2007). But the expansion of LNG as a fuel into the mainstream shipping industry throws up a combination of technological and regulatory challenges that the industry must address.

It's well known that IACS have provided insight over the past year on the drivers for adopting LNG as a fuel, examining the Classification issues of technology, safety and the regulatory framework. Inherently gas safe machinery spaces and ESD protected machinery spaces have been accepted (IMO 2009; GL 2010; ABS 2011; DNV 2012), which can reach the existing levels of safety of conventional machinery spaces. In addition, recently, a new concept called increased gas safe machinery spaces (CCS 2013), whose safety level was not clear, was creatively put forward to meet the current demand of diesel-LNG dual fuel conversion for existing ships by China Classification Society. Based on that, to accelerate its extensive application, it's extremely necessary to develop a feasible assessment methodology.

2 ARRANGEMENT OF INCREASED TYPE

Figure 1 is the sketch of the arrangement of Increased Type according to *Rules for Natural Gas Fuelled Ships (2013)*, merely showing the portside, which is set as the object of risk assessment.

It's significant to know that pressure in gas supply lines within machinery spaces is less than 10 bar. Full penetration butt joint is one of the obvious features of Increased type. In addition, anywhere in machinery spaces including GVU is covered by two sets of gas detectors. As far as ventilation is concerning, the air space within the machinery spaces and GVU are equipped with mechanical extraction ventilation having a

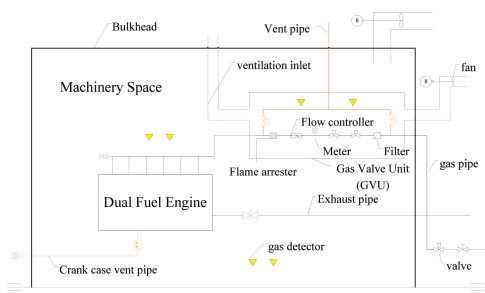

Figure 1. Increased safe machinery spaces arrangement.

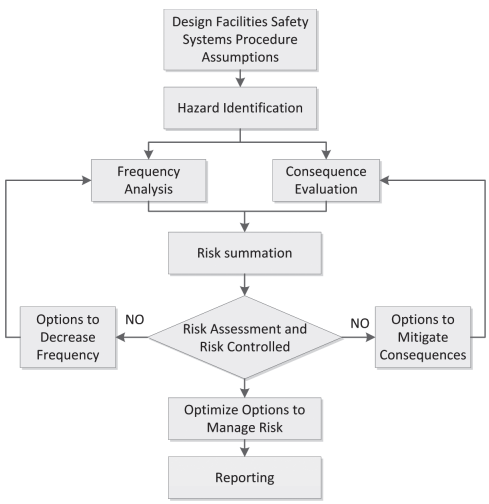
capacity of at least 30 air changes per hour for Increased Type.

3 RISK ASSESSMENT METHODOLOGY

3.1 *Steps in risk assessment*

Risk based Assessment is a scientific methods or tools and processes used to manage the risk of a component or system, which normally carried out using a formal process. The main steps are hazard identification, frequency analysis, consequence assessment, risk summation, risk assessment, and risk management. Figure 2 summarizes those steps.



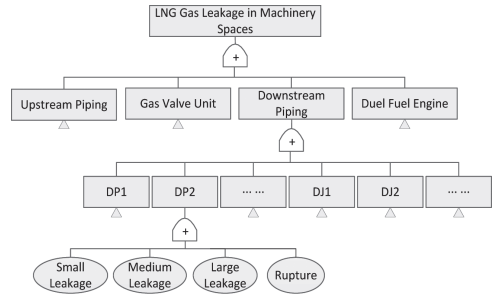


Figure 2. Basic steps in risk assessment.

DP1-Downstream Piping 1; DP2-Downstream Piping 2; DJ1-Downstream Joint 1; DJ2-Downstream Joint 2

Figure 3. FTA for hazard identification.

3.2 *Hazard identification*

A hazard is a source of harm that interacts with people or things in a negative manner. Hazards may be identified through accident history, judgment of knowledgeable individuals or some technical process such as FTA.

The determination of hazards for LNG begins with an understanding of the properties of the fuel. The following characteristics are important to identifying LNG hazards: storage parameters, tendency to form combustible mixture, ignition and explosion characteristics, means of controlling combustion and environmental effects.

Vaporized LNG fuel within the gas supply system in the machinery spaces presents non-toxic gas state, temperature and pressure of which should be recognized. It can be seen that flammability plays a major hazardous role during the LNG fuel's supplying. Thus, gas leak, the base of flammability, should be emphasized during hazard identification. A typical model of sources of leakages are showed in Figure 3. The gas supply system is divided into four units including Upstream Piping (UP), Gas Valve Unit (GVU), Downstream Piping (DP) and Duel Fuel Engine to identify hazards logically.

3.3 *Frequency analysis*

Frequency information is required to match the event specification and consequence calculation. In general, leak frequencies of hole sizes (small, medium, large, rupture), see Table 1, in risk assessments are estimated from generic historical leak statistics, which works well for common items (pipes, valves, pumps, etc.) that have been collected and provided by COVO (Rijnmond Public Authority 1982; Crossthwaite P.J., Fitzpatrick, R.D. and Hurst N.W. 1988), DNV (DNV consulting 2005) and API (API 2008).

The event tree approach (Fig. 4) is used to track outcomes from gas leakage and branch outward based on binomial choices on possible outcomes (e.g., ignition yes/no). Using the equation (1), (2), (3) can determine the final probabilities of every estimated outcomes.

$$pvce_{v,n} = pf_{v,n} \cdot pov \cdot pod \cdot poop \cdot poi(1 - poii) \cdot pvcedi \quad (1)$$

$$pff_{v,n} = pf_{v,n} \cdot pov \cdot pod \cdot poop \cdot poi(1 - poii) \cdot pffdi \quad (2)$$

$$pjet_{v,n} = pf_{v,n} \cdot pov \cdot pod \cdot poop \cdot poi \cdot poii \quad (3)$$

where $pvce_{v,n}$ = the probability of a vapor cloud explosion given a vapor release associated with the nth release hole size; $pf_{v,n}$ = the release frequency associated with the nth vapor release hole size; pod = the probability of abnormal

detection; poop = the probability of outer wall failure; $poi_{v,n}$ = the probability of ignition given a release; $poii_{v,n}$ = a vapor release associated with the nth release hole size; pvcedi = the probability of VCE given a delayed ignition of a release of a flammable vapor associated with the nth release hole size; pffdi = the probability of flash fire given a delayed ignition of a release of a flammable vapor associated with the nth release hole size; $pff_{v,n}$ = the probability of a flash fire given a vapor release associated with the nth release hole size; $pjet_{v,n}$ = the probability of a jet fire given a vapor release associated with the nth release hole size.

3.4 *Consequence evaluation*

Consequence assessment is the main part of risk based assessment and models for different outcome types-dispersion, flash fire, jet fire, vapor cloud explosion are presented in the later sections. As the Figure 5 shows, consequence areas, component damage areas and personal injury areas concluded, of each identified hazard with a range of hole size is determined based on LNG gas properties and ambient condition.

Table 1. Release hole sizes used in frequency analysis and consequence evaluation.

Release hole number (n)	Release mode	Range of hole size (mm)	Specific release hole diameter, d_n (mm)
1	Small	0–6.35	$d_1 = 6.35$
2	Medium	>6.35–50.8	$d_2 = 25.4$
3	Large	>50.8–152.4	$d_3 = 101.6$
4	Rupture	>152.4	d4 = min [D,406.4]

3.4.1 *Release rate*

There are two regimes for flow of gases or vapors through an orifice: sonic for higher internal pressures and subsonic flow for lower pressures. After analyzing, the release rate of LNG gas supply system is computed using Equation (4), which is based on discharge of gases and vapors at subsonic velocity through an orifices.

$$W_n = \frac{0.9}{1000} \cdot \frac{\pi \cdot d_n^2}{4} \cdot P_s \sqrt{\left(\frac{k \cdot MW}{R \cdot T_s}\right)\left(\frac{2}{k+1}\right)^{\frac{k+1}{K-1}}} \tag{4}$$

where W_n = the theoretical release rate associated with the nth release hole size[kg/s]; d_n = the diameter associated with the nth vapor release hole size[mm]; Ps = Is the storage or normal operating pressure[kPa]; K = Is the release fluid ideal gas specific heat capacity ratio; MW = the release fluid molecular weight[kg/mol]; R = the universal gas constant = 8314 [J/(mol·K)]; Ts = the storage or normal operating temperature[K].

3.4.2 *Vapor cloud explosion*

In the machinery spaces, a vapor cloud explosion can occur as a result of a delayed ignition of LNG gas that disperses. The TNT equivalency method can be used to estimate the overpressure VCE producing. This method determines the amount of available energy in the cloud and relates this to an equivalent amount of TNT using Equation (5):

$$W_{TNT} = \frac{\eta \cdot mass_{vce} \cdot HC_v}{HC_{TNT}} \tag{5}$$

where W_{TNT} = the energy released in an explosion expressed as equivalent mass of TNT[kg];

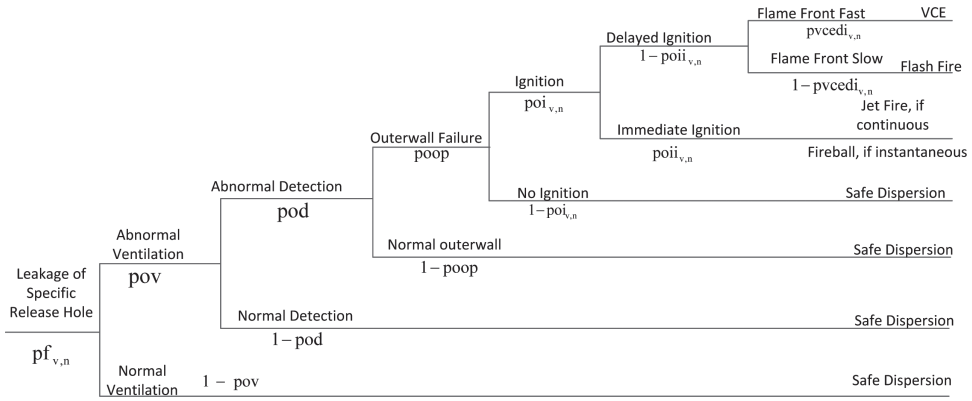

Figure 4. ETA used in machinery spaces.

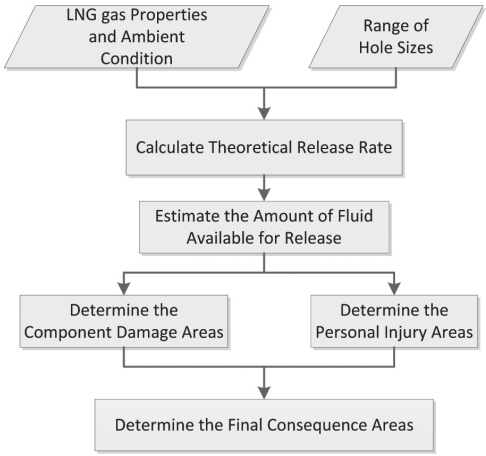

Figure 5. Consequence analysis procedures.

$mass_{vce}$ = the mass of flammable material in the vapor cloud used in the VCE calculation[kg]; η = the explosion yield factor; HC_{TNT} = the heat of combustion of TNT ≈ 4648 [kJ/kg].

$$P_{SO,n} = 100 \cdot \left(\begin{array}{l} -0.059965896 + \frac{1.1288697}{\ln[\bar{R}_{HS,n}]} - \frac{7.9625216}{\left(\ln[\bar{R}_{HS,n}]\right)^2} \\ + \frac{25.106738}{\left(\ln[\bar{R}_{HS,n}]\right)^3} - \frac{30.3967}{\left(\ln[\bar{R}_{HS,n}]\right)^4} + \frac{19.399862}{\left(\ln[\bar{R}_{HS,n}]\right)^5} \\ - \frac{6.8853477}{\left(\ln[\bar{R}_{HS,n}]\right)^6} + \frac{1.2825511}{\left(\ln[\bar{R}_{HS,n}]\right)^7} - \frac{0.097705789}{\left(\ln[\bar{R}_{HS,n}]\right)^8} \end{array} \right) \quad (6)$$

where $P_{SO,n}$ = the side-on overpressure associated with the nth release hole size[kPa], 34.5 kPa for component damage; $\bar{R}_{HS,n}$ = the Hopkinson's scaled distance used in the blast calculations associated with the nth release hole size.

Using the Equation (6), (7) can determine the safe distance (xs_n^{vce}) from the vapor cloud explosion for component damage, with the side-on overpressure ($P_{SO,n}$) of 34.5 kPa. For personal injury, the safe distance can calculated be based on the Equation (8) and the Pr value can be set at 0.5.

$$\bar{R}_{HS,n} = \frac{xs_n^{vce}}{W_{TNT}^{1/3}} \quad (7)$$

$$Pr = -23.8 + 2.92 \cdot \ln[1000 \cdot P_{SO,n}] \quad (8)$$

where xs_n^{vce} = the safe distance from the vapor cloud explosion for component damage associated with the nth release hole size[m]; Pr = the probability value, typically set at 0.5 (50% probability).

Once the safe distances, $xs_{cmd,n}^{vce}$ and $xs_{inj,n}^{vce}$, are determined, the following equations is carried out for personal injury area and component damage area for each of the release hole size.

$$CA_{cmd,n}^{vce} = \pi \cdot \left(xs_{cmd,n}^{vce}\right)^2 \quad (9)$$

$$CA_{inj,n}^{vce} = \pi \cdot \left(xs_{inj,n}^{vce}\right)^2 \quad (10)$$

where $xs_{cmd,n}^{vce}$ = the component damage consequence area for VCE associated with the nth release hole size[m^2]; $xs_{cmd,n}^{vce}$ = the safe distance from VCE for component damage associated with the nth release hole size[m]; $CA_{inj,n}^{vce}$ = the personal injury area for VCE associated with the nth release hole size[m^2]; $xs_{inj,n}^{vce}$ = he safe distance from VCE for personal injury associated with the nth release hole size[m].

3.4.3 *Flash fire*

Flash fire, like VCE, can occur as a result of a delayed ignition of a vapor cloud. However, unlike VCE, the flame speed is relatively slow and overpressures do not occur. The consequence are for personnel from a flash fire, $CA_{cmd,n}^{flash}$, is merely the flammable cloud boundary. As for the flammable cloud boundary, it can be determined using the Gaussian Models, with the LFL set 0.05 at and the UFL set at 0.15 for LNG gas. Equation (11) determines the component damage consequence area for flash fire.

$$CA_{cmd,n}^{flash} = 0.25 \cdot CA_{inj,n}^{flash} \quad (11)$$

where $CA_{cmd,n}^{flash}$ = the component damage consequence area for flash fire associated with the nth release hole size[m^2].$CA_{inj,n}^{flash}$ = the personal injury consequence area for flash fire associated with the nth release hole size[m^2].

3.4.4 *Jet fire*

Jet fires or fireball occurs as a result of immediate ignition of LNG gas from the gas supply system. As all the release type of the leakage in machinery space is continuous after analyzing, the consequence of fireball is not evaluated in this paper. For jet fire, the main deleterious effect is the heat flux produced by the jet fire.

The amount of energy radiated by the jet is a fraction of the total combustion power of the flame, as Equation (12) shows.

$$Qrad_n^{jet} = 0.35 \cdot W_n \cdot HC_v \quad (12)$$

where $Qrad_n^{jet}$ = the total energy radiated from a jet fire associated with the nth release hole

size[W]; HC_v = the heat of combustion of vapor fuel[J/kg].

The received thermal flux at some location away from the jet fire can be calculated with the Equation (13). The acceptable distance away from the jet fire is determined by the thermal radiation limit, 12.6 kW/m^2 for individual death and 37.8 kW/m^2 for component's damage.

Once the acceptable distance, $xs^{jet}_{cmd,n}$ and $xs^{jet}_{inj,n}$, are calculated, Equation (14) and Equation (15) are used to determine the jet fire consequence area.

$$Ith^{jet}_n = 0.5 \cdot Qrad^{jet}_n \cdot \frac{1}{4\pi \cdot xs^2_n} \tag{13}$$

$$CA^{jet}_{cmd,n} = \pi \cdot \left(xs^{jet}_{cmd,n}\right)^2 \tag{14}$$

$$CA^{jet}_{inj,n} = \pi \cdot \left(xs_{inj,n}\right)^2 \tag{15}$$

where Ith^{jet}_n = the radiant heat flux received at a distant receiver location from a jet fire associated with the nth release hole size[W/m^2], 12.6 kW/m^2 for individual death and 37.8 kW/m^2 for component's damage; $CA^{jet}_{cmd,n}$ = the component damage consequence area for a jet fire associated with the nth release hole size [m^2]; $xs^{jet}_{cmd,n}$ = the safe distance from the jet fire flame surface for component damage associated with the nth release hole size[m]; $CA^{jet}_{inj,n}$ = the personal injury consequence area for a jet fire associated with the nth release hole size [m^2]; $xs^{jet}_{inj,n}$ = the safe distance from the jet fire flame surface for personal injury associated with the nth release hole size[m].

3.5 *Risk summation*

The risk of some identified hazard which can be calculated using the Equation (16), (17), (18) that is the weighted average of jet fire, VCE and flash fire consequence area.

$$R^{flam}_{cmd} = \sum_{n=1}^{4}\left(\begin{array}{l} pjet_n \cdot CA^{jet}_{cmd,n} + pvce_n \\ \quad \cdot CA^{vce}_{cmd,n} + pflash_n \cdot CA^{flash}_{cmd,n} \end{array}\right) \tag{16}$$

$$R^{flam}_{inj} = \sum_{n=1}^{4}\left(\begin{array}{l} pjet_n \cdot CA^{jet}_{inj,n} + pvce_n \\ \quad \cdot CA^{vce}_{inj,n} + pflash_n \cdot CA^{flash}_{inj,n} \end{array}\right) \tag{17}$$

$$RS_i = \max\left[R^{flam}_{cmd}, R^{flam}_{inj}\right] \tag{18}$$

where R^{flam}_{cmd} = the risk concerning component damage[m^2/year]; R^{flam}_{inj} = the risk concerning personal injury[m^2/year]; RS_i = the final risk concerning hazardous area of an identified hazard [m^2/year];

As all the hazards of the in the machinery space are assumed as relatively independent events, the total risk of the machinery space can be determined using the Equation (19) (20).

$$R_i = RS_i \cdot (U_{cmd} + p_{inj}U_{inj}) \tag{19}$$

$$R = P_{all} \cdot U_{all} = \sum R_i \tag{20}$$

where R_i = the total risk of an identified hazard [\$M[①]/year]; U_{cmd} = the equipment economic value per square meter of the machinery spaces[\$M/m^2]; U_{inj} = 1\$M/m^2, conservatively assuming 1death for every hazardous square meter; p_{inj} = 1/S, conservatively assuming one crew stay in the engine spaces at any time, 'S' is the gross area of the engine spaces[m^2]; R = the total risk of the machinery spaces [\$M/year]; P_{all} = the gross probability of fire and explosion of machinery spaces, [1/year].

U_{all} = the total consequence of fire and explosion of machinery spaces, [\$M/year].

3.6 *Tolerability of risks*

Two graphic forms to convey risk result—individual risk contours and societal risk F-N curves are recommended by the Rijnmond Public Authority (1982). Compared with individual risk, Societal Risk expressed in an FN-diagram allows a more comprehensive picture of risk. Moreover, each type of accident (e.g. fire and explosion) can make use of Societal Risk expression (IMO 2007). Therefore, a kind of F-N curves (Fig. 6) is recommended, which is taken from a public environmental impact statement, published on the Hong Kong Environmental Protection Department Environmental Impact Assessment (EIA) website (DNV 2007). However, F-N curves merely focus on

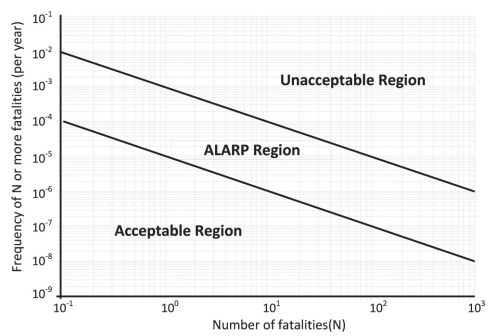

Figure 6. F-N curves.

①It refers to million dollars.

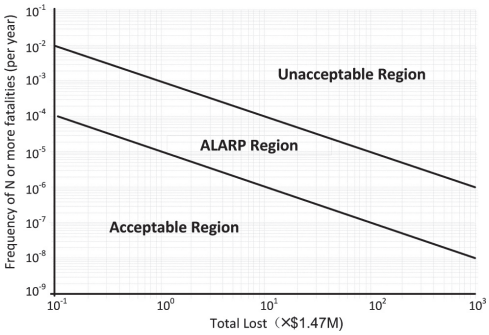

Figure 7. F-TL curves.

human fatalities without considering financial loss. It's worth combing human fatalities and financial loss together into a new type curves deriving from F-N curve assuming that a fatality correspond to 35 lost life-years, the median value correspond to $1.470.000 (DNV 2000). The new type of curves can be called F-T.L. curves. See Figure 7. As F-T.L. curves show, the ALARP zone refers to as low as reasonably practicable-a tolerated zone of risk, only if all reasonable measures have been taken to reduce or mitigate the risk.

As for engine spaces of LNG gas fuelled ship, it's critical to determine which zone the total risk of machinery spaces locate, equation (20). According to Figure 6(b), equation (21), (22) can be deduced.

$$\log10(P_{all}) + \log10(U_{all}/1.47) \le \log10(10^{-5}) \quad (21)$$

$$\log10(10^{-5}) \le \log10(P_{all}) + \log10(U_{all}/1.47) \le \log10(10^{-3}) \quad (22)$$

Thus, for acceptable zone, it should meet the equation (23) deriving from equation (21). In the similar way, for ALARP zone, it should meet the equation (24) deriving from equation (22).

$$R = P_{all} \cdot U_{all} \le 1.47 \times 10^{-5} = R_{lower\,\lim it} \quad (23)$$

$$R_{lower\,\lim it} = 1.47 \times 10^{-5} \le R = P_{all} \cdot U_{all} \le 1.47 \times 10^{-3} = R_{lower\,\lim it} \quad (24)$$

4 DISCUSSION

The introduction of alternative fuels for marine design presents a challenge for commercial ship industry. The novel designs and technologies of increased safe machinery spaces put forward by CCS is not covered by current standards needs to meet adequate levels of safety. This research develops a practical methodology to assess increased safe machinery spaces, which will contribute to the perfection of relevant specifications, rules or standards.

1. This methodology takes over the basic framework of risk based technology (Fig. 2) and some limitations or issues are noteworthy.
2. The risk of fire and explosion in increased gas safe engine spaces of LNG gas fuelled ship is merely discussed in this research. However, risks outside, like collision, tank explosion, freezing damage and stranding and so on, are exclusive, which deserve further study.
3. As leaking orifice is divided into four ranges, small, medium, large and rupture, and generic historic data may be not able to meet the requirement, interpolation method (Yu L. J., Duo Y. Q. and Shi Li Chen. 2007) could be applied to the frequency analysis of this methodology.
4. A factor influencing consequence is ignition. Different type of ignition would lead to different consequences. If the release is immediately ignited at the release point, then outcomes will be jet fire for gas leakage. If the ignition is remote or delayed in time, then flash fire and Vapour Cloud Explosion (VCE) are possible. Currently, several empirical formulae (Spencer H, Daycock JH and Rew PJ 1998; Bai YZ et al. 2010; Ronza A, Vilchez JA, Casal J 2007) have been developed to estimated ignition likelihood. John L. However, Woodward and Robin M. Pitblado (2010) point out that a flammable cloud has a probability of ignition that depends both on its flammable extend and the number, strength and duration of coverage of local ignition sources, which needs further research to define probability of ignition accurately.
5. As for flash fire and vapour cloud explosion, the hazardous areas are determined by flammable cloud boundary, which can be calculated by CFD codes, like CFX and Fluent. However, due to the large amount of calculation, Gaussian Models can be an alternative method to analyse flammable cloud boundary at the expense of the precision.

Semi-qualitative method for ship collision risk assessment

W. Zhang, J. Montewka & F. Goerlandt
Department of Applied Mechanics, Marine Technology, Research Group on Maritime Risk and Safety, Aalto University, Espoo, Finland

ABSTRACT: In this paper we introduce a method for the assessment of the complexity of ship-ship encounters, linked with the risk level of such encounters. The method combines traffic data obtained from the Automatic Identification System and experts' judgment. The collected data describes maritime traffic over the Northern Baltic Sea, including the Gulf of Finland, which is potentially one of the most heavily trafficked sea areas in the world.

Based on the method, we develop a risk model, which differentiates between four types of ship-ship encounters, associating a risk level to each of them. The encounters are of the following types: normal encounter, collision avoidance, close-encounter and accident. The obtained results reveal that the areas of the highest risk are related to the waterways crossing between Helsinki and Tallinn, as well as approaches to harbours. The risk model developed here can be used for efficient data screening for encounters of various risk levels as well as for the comparison of traffic situations from various time epochs.

1 INTRODUCTION

Maritime transportation is the main transportation mode for both domestic and international trade. It is estimated that 90% of the world trade volume is carried by sea (IMO 2008). While major shipping accidents are relatively rare occurrences, their consequences can have devastating effects measured in human or economic losses and in terms of damage to the marine environment. Worldwide, groundings, collisions and fires are the most frequently occurring accident types (Soares & Teixeira 2001). However, in local sea areas with high traffic intensity such as the Gulf of Finland and the Singapore Strait, ship-ship collisions are one of the most frequently occurring accident types (Kujala et al. 2009; Weng et al. 2012).

In response to stakeholder concerns regarding the safety of maritime transportation, various approaches to ship collision risk have been proposed. Where the risk is seen as a measure of safety. Some studies concern probabilistic risk assessment and management. Such methods are aimed at probabilistically identifying areas of high ship collision risk e.g. using statistical methods (Friis-Hansen & Simonsen 2002), traffic simulation (Goerlandt & Kujala 2011) and combined accident statistics and ship domain analysis (Montewka et al. 2012). Another studies concern operational risk assessment, where ship collision risk is considered in real-time dynamic traffic situations onboard vessels or in Vessel Traffic Service (VTS) centers. Various methods for decision support in collision avoidance have been proposed, e.g. based on fuzzy ship domains (Kao et al. 2007; Pietrzykowski & Uriasz 2008; Gucma & Pietrzykowski 2006), or statistical models (Mou et al. 2010).

However most of these methods rely on scarce accident statistics, predictive traffic flow methods (Fowler & Sørgård 2000) or simulation techniques (Goerlandt & Kujala 2011), which necessitate assumptions on what constitutes a vessel encounter. This may lead to an unreliable identification of risk areas, as discussed in (Goerlandt & Kujala 2014). Therefore, the method presented in this paper utilizes non-collision information from actually observed traffic to assess system risk and avoid assumptions, which may question the reliability and validity of the method.

The model presented in this paper follows an approach determining a Risk Indicator reflecting the complexity of ship-ship encounters in a given sea area. The logic behind is that the more complex a meeting between two ships is the more difficult is to handle the situation as the number of simultaneous goals gets higher and tenser (planning, conducting and assessing the efficiency of the evasive action), navigators may begin to operate in a higher stress mode, which contributes to the higher probability of making an error, see for example (Hollnagel 1998; Yang et al. 2013). Therefore, we introduce the complexity of an encounter as a Risk Indicator.

The method presented in this paper applies experts judgment and micro-level ship traffic data

as obtained from the Automatic Identification System (AIS) as background information. From this, a set of traffic metrics is deduced, which are combined in a collision Risk Indicator.

The developed model behaves as expected, which has been proven in a series of tests, presented in the paper. The analysis of the collision risk for the maritime traffic over the Northern Baltic Sea shows very good agreement of the obtained results with the previous studies.

The remainder of the paper is organized as follows: Section 2 introduces conceptual basis for the Risk Indicator. In Section 3 the Risk Indicator is formulated and in subsequent section it is quantified and the behavior tests are carried out. Section 5 demonstrated the results of collision risk assessment with the use of the Risk Indicator for the Northern Baltic Sea. In Section 6 we discuss the developed model and the obtained results, whereas Section 7 concludes.

2 CONCEPTUAL BASIS

2.1 *Risk concept and perspective*

In risk research literature, there is increasing focus on the theoretical basis of risk assessment, particularly in terms of the adopted conceptual risk definition and the adopted perspective on how risk is described (Aven & Zio 2013). The work presented in this paper adopts the view that risk can conceptually be defined as "the possibility of an unfortunate occurrence", see e.g. (Aven 2012). This concept can be summarized as follows:

$$Risk = Po(A) \tag{1}$$

where $Po(A)$ signifies the potential of occurrence of A, where A stands for the event of interest, which in this context is a ship-ship collision.

The risk perspective, which aims at the description of risk, adopts a situation-dependent indicator (I). The indicator describes how possible the occurrence is in a particular context, which can be summarized as:

$$Risk \sim I(A) \tag{2}$$

$$I(A) = f(S) \tag{3}$$

where $I(A)$ signifies the indicator of the occurrence of event A, expressed either quantitatively or qualitatively. The indicator I depends on a set of system states S, in the context of this paper these are the traffic metrics—distance between two meeting ships, the relative speed and the difference in their headings—deduced from the micro-level ship traffic data.

2.2 *Traffic conflict technique*

The indicator-based risk perspective is compatible with the methodological framework of the Traffic Conflict Technique (TCT). This technique, originally proposed in road traffic safety analysis (El-Basyouny & Sayed 2013; Sacchi et al. 2013; Young et al. 2014), has recently been applied in navigational risk assessment, see for example (Debnath & Chin 2010). Relying on scarce accident statistics, predictive traffic flow methods (Fowler & Sørgård 2000) or simulation techniques (Goerlandt & Kujala 2011) which necessitate assumptions on what constitutes a vessel encounter may lead to an unreliable identification of risk areas (Goerlandt & Kujala 2014). Therefore, the method presented in this paper utilizes non-collision information from actually observed traffic to assess system risk.

The concept of the TCT is rooted in the idea that not only accidents, but also all conflict situations, i.e. situations in which traffic system users encounter one another such that accidents can occur, provide insight in the system risk level. The hierarchy of different levels of nearness to an accident encompasses undisturbed passages, conflicts of various severity, near misses and accidents. This hierarchy has been conceptually presented as a pyramid (Hyden 1987) or a diamond (Svensson 1998). The most significant advantage of the TCT is the fact that vessel conflicts of various severity levels occur more frequently than collision accidents, such that more information about the system risk level can be obtained in shorter time periods (Debnath & Chin 2010).

In this paper we introduce a method for detecting and classifying the ship-ship encounters, using AIS data, and experts judgments. Subsequently the method is adopted to develop a risk model, which quantifies the risk level over a sea area in tempo-spatial manner, associating the magnitude of Risk Indicator with the level of complexity of an encounter. The model attempts to convert available data into information first, and then information to understanding. Data serves here as the input to the risk assessment model, information contains the risk description, which is based on the data,

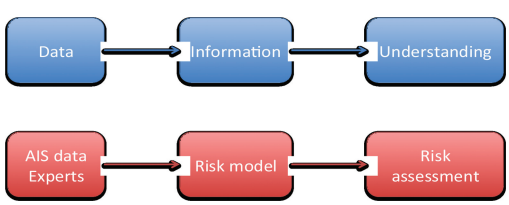

Figure 1. A systematic way of transforming available data into understanding of the analysed system.

and understanding relates to the process of risk assessment and obtained results, see for example (Aven 2013; Montewka et al. 2014) and Figure 1.

3 FORMULATION OF RISK INDICATOR

In this chapter, the methodological framework is provided for the developed model, which detects and ranks the complexity of ship-ship encounters. First, the available micro-level ship traffic data, as obtained from the Automatic Identification System (AIS), is outlined. Subsequently, the process and outcome of an expert elicitation related to the development of a quantitative Risk Indicator (I). The latter is a measure of risk in the sea area, based on detection of vessels encounters and their complexity. Then, the mathematical formulation of the indicator is presented, both in regards to the model structure and model parameters. Finally, the obtained results need to be clustered to arrive at qualitative Risk Indicator. Thus, the purpose and rationale of the applied clustering technique is outlined.

3.1 *Micro-level ship traffic data: Automatic Identification System (AIS)*

The AIS system identifies every vessel equipped with an AIS transmitter, individually, along with its specific position and movements, enabling a virtual picture to be created in real time. The data is transmitted at an interval of about 3–10's, and a number of key parameters are recorded. The data used in this paper was obtained from HELCOM (Baltic Marine Environment Protection Commission—Helsinki Commission), and it covers the Northern Baltis Sea, including the Gulf of Finland and a period of two months: May and July 2011. The raw data includes fundamental navigation information such as time, latitude, longitude, speed, course, heading, etc, see (US Department of Homeland Security 2013).

3.2 *Risk indicator*

Risk Indicator, developed in the course of this study, utilizes two types of data: first, judgement of experts (nautical officers and captains with the record of at least 5 years of sea service), second, AIS data. The former is used to define the structure of the mathematical model for Risk Indicator, whereas the latter quantifies the model parameters. Both are described in the following subsections.

3.2.1 *Determining the model structure*

Risk Indicator is intended to measure the risk through the complexity of an encounter between two ships at sea, both being under way. This type of encounter is regulated by the International Regulations for Preventing Collisions at Sea, (IMO 2003). In this paper we measure the encounter complexity through the available time that officers have to perform the evasive action and the magnitude of that action. The time available is directly determined through the distance between two meeting ships and their relative speed, whereas the magnitude of action is assessed based on the difference in ships headings. Beside, two ship encounter, there exist multiple-ship encounters, however they are out of the scope of this analysis.

Risk index takes its value from a range of [–n, n]. A positive value indicates that the encounter may require an action from an officer in charge to ensure safe passage of the ships. A negative value indicates a safe situation, where action is not required. The Risk Indicator presented here comprises three interrelated elements, as follows: 1) the distance between two ships; 2)the rate of change of the distance in the course of encounters, measured by the relative speed between two ships; 3) the relative orientation of two ships, described by the difference between their headings.

Such a triplet attempts to describe the complexity, thus the risk level, of an encounter between two ships.

Distance

As distance alone does not describe the complexity of an encounter, it must coexist with other parameters. However, for the purpose of this study, we assume that an increased distance between two ships corresponds to a decreased complexity of an encounter. Thus, distance and complexity are inversely proportional in the mathematical model describing I.

$$I \approx f(Distance)^{-1} \tag{4}$$

Relative Speed

The rate of change of distance between two ships is another relevant factor in the model. This can be described by relative speed, which is calculated based on true headings of two ships and their actual speeds, as depicted in Figure 2. The higher the relative speed, the less time an officer has to address and solve the situation. Therefore, the existence of a positive correlation between the two parameters is assumed. It is not yet clear, however, what kind of relation best describes the correlation.

$$I \approx f(Relative\ speed)^{2} \tag{5}$$

However, in certain encounters like overtaking, a high relative speed may be preferable, as this shortens the time of the manoeuver. In such situations the above relation does not hold, therefore it would

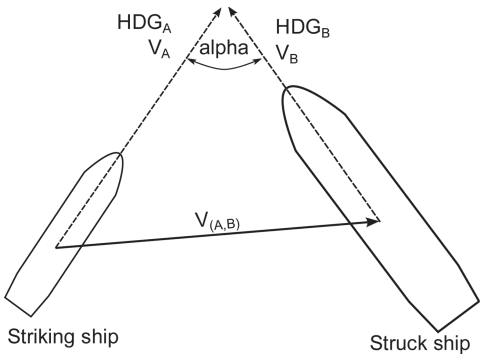

Figure 2. The relations between ships headings, their actual speed and the resulting relative speed.

be desirable to introduce alternative relations and measure their effect on the Risk Indicator. The anticipated effect of the changes in this parameter of the model outcome is elaborated in the discussion part of the paper.

Phase

Through phase we specify the relative location of two vessels and the magnitude of course alteration that is anticipated to perform collision evasive action. The range of phase is [–180,180], where a negative indicates that the encounter is not of interest to navigators, as the ships are receding from each other. Positive phase indicates that the ships are approaching one another. The interpretation of this parameter is given in Figure 3.

$$I \approx f(Phase) \tag{6}$$

Considering the range of phase, $f(Phase)$ is periodic function, and the period is 2π

$$f(x) = f(x + 2\pi) \tag{7}$$

A negative phase corresponds to a situation, where there is no risk of collision. For the positive phase, the collision risk exists and varies with the time, as two encountering ships approach each other. We can define $f(x)$ as an odd function, that is

$$f(-x) = -f(x) \tag{8}$$

The function describing I would contain three parameters, bound with the following relationships:

$$I \approx f(Distance)^{-1},\ (Relative\ Speed)^2,\ g(Phase) \tag{9}$$

where $g(Phase)$ is a periodic and odd function. The mathematical model quantifying the I is presented in the following section.

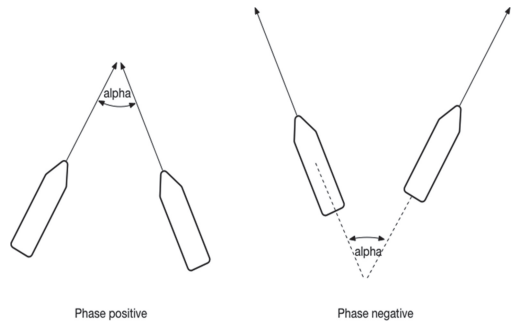

Figure 3. Interpretation of parameter "phase". On the left phase is positive, on the right it is negative.

3.2.2 *Formulation of the Risk Indicator*

It is known that every periodic function $x(t)$, with T denoting its period, can be expanded into a Fourier series:

$$x(t) = \sum_{k=-\infty}^{+\infty} a_k \cdot e^{jk\left(\frac{2\pi}{T}\right)t} \tag{10}$$

Here,

$$a_k = \frac{1}{T}\int_T x(t) \cdot e^{-jk\left(\frac{2\pi}{T}\right)t} \tag{11}$$

Since $f(x)$ is an odd function, considering

$$e^{j\theta} = sin\theta + j \cdot cos\theta \tag{12}$$

Thus $f(x)$ can be described as a sine series,

$$f_0(x) = \sum_{-\infty}^{+\infty} b_k \cdot \sin(kx) \tag{13}$$

In order to reduce the complexity of computation, we use the first two terms of the Fourier series only, that is,

$$f_o(x) = b_1 \cdot sinx + b_2 \cdot sin\,(2x) \tag{14}$$

In light of the previous discussion, the following expression can be stated for Risk Indicator (I):

$$I(x,\ y,\ z) = ((kx^{-1} + my^2)(b_1 \cdot \sin(z) + b_2 \cdot \sin(2z)) \tag{15}$$

where, x represents Distance, y represents Relative speed, z represents Phase.

3.2.3 *Parameter estimation*

To estimate the paramters of the equation quantifying the Risk Indicator, we selected data samples from some typical encounters. Then, we applied the least squares method to obtain the numeric values for the parameters.

For this purpose we predefined two distances. The first is 6 NM, which is the usual observation range of shipborne radar in high seas, the second is 1 NM. For these two ranges, we propose the values for the Risk Indicator, as follows:

1. The absolute value of I at 6 NM range should take some small value, let's take 5:

$$E(I(x,y,z))|_{x=6} = 5 \tag{16}$$

where E is mathematical expectation.

2. The absolute value of I at 1 NM range, is taken as 100:

$$E(I(x,y,z))|_{x=1} = 100 \tag{17}$$

In a short distance like 1 NM, some factors like phase have more influence than in a longer distance like 6 NM, and can not be ignored. Then, traffic scenarios containing phase in the range of [165, 180] are chosen in calculation.

There are four parameters that need be calculated to quantify the Risk Indicator (k, m, b_1, b_2). Since phase involves direction and course, b_1 and b_2 are supposed to be 1. Then, the other two parameters can be estimated by the method of least squares.

$$f = \min\left(\sum \Delta I_i\right) = \min\left(\sum_i^n a_i (k x_i^{-1} + m y_i^2)\right) \tag{18}$$

Let

$$\begin{cases} \dfrac{\partial f}{\partial x} = 0 \\ \dfrac{\partial y}{\partial x} = 0 \end{cases} \tag{19}$$

That is,

$$\left(\sum_i^n a_i^2 x_i^{-2}\right) k + \left(\sum_i^n a_i^2 x_i^{-1} y_i^2\right) m = \sum_i^n a_i x_i^{-1} I_i \tag{20}$$

and

$$\left(\sum_i^n a_i^2 x_i^{-1} y_i^2\right) k + \left(\sum_i^n a_i^2 y_i^4\right) m = \sum_i^n a_i y_i^2 I_i \tag{21}$$

Eventually,

$$k = \frac{\sum_i^n a_i x_i^{-1} I_i \sum_i^n a_i^2 y_i^4 - \sum_i^n a_i y_i^2 I_i \sum_i^n a_i^2 x_i^{-1} y_i^2}{\sum_i^n a_i^2 y_i^4 \sum_i^n a_i^2 x_i^{-2} - \left(\sum_i^n a_i^2 x_i^{-1} y_i^2\right)^2} \tag{22}$$

$$m = \frac{\sum_i^n a_i x_i^{-1} I_i \sum_i^n a_i^2 x_i^{-1} y_i^2 - \sum_i^n a_i y_i^2 I_i \sum_i^n a_i^2 x_i^{-2}}{\left(\sum_i^n a_i^2 x_i^{-1} y_i^2\right)^2 - \sum_i^n a_i^2 x_i^{-2} \sum_i^n a_i^2 y_i^4} \tag{23}$$

4 QUANTIFICATION OF RISK INDICATOR

In this section we present the results of the quantification of the parameters of Risk Indicator and then we demonstrate the results of the behaviour tests, performed for the proposed model for several, preselected encounters.

4.1 *Quantification of the parameters of Risk Indicator*

Risk Indicator's parameters are determined with the use of data sampled from over 1500 various encounters recorded duering May and June 2011, adopting the procedure descirbed in Section 3.2.3. The encounters were sampled in a way, that the whole range of distances between 1 NM and 6 NM has been covered, see Table 1 for some exemplary data sample.

The following parameters describing the Risk Indicator has been found by (22) and (23): k = 36.84 and m = 3.81E – 4. Considering $b_1, b_2 = 1$, the final equation describing the Risk Indicator is as follows:

$$I(x,y,z) = (36.84x^{-1} + (3.81e-04)y^2) \times (\sin z + \sin(2z)) \tag{24}$$

4.2 *Classification of Risk Indicator*

To classify the traffic scenarios of different value of Risk Indicator, into meaningful categories, attempting to reflect the risk level, cluster analysis

Table 1. Traffic data sample.

Scenario	Dist (km)	Relative speed (NM/hour)	Phase (deg)
36	5.6	13.6	56.8
	5.3	13.6	56.8
63	1.7	7.3	179.3
	0.9	3.0	178.8
89	5.5	26.1	83.9
	5.1	25.1	83.9
91	1.5	8.4	179.8
	0.9	12.2	179.8

is performed. In this study we anticipate four risk levels, follows:

1. regular encounter—distance between ships is less than 6 NM, but far more than 1 NM.
2. collision avoidance—Ship-ship distance is more than 1 NM but not large enough.
3. close-encounter—ship-ship distance is close to 1 NM, manoeuvre is necessary.
4. risk encounter—ship-ship distance is less than 1 NM, significant course alteration or speed change is deemed necessary.

Cluster analysis is a class of statistical techniques that can be applied to data that exhibit "natural" groupings. Cluster analysis sorts through the raw data and groups them into clusters. A cluster is a group of relatively homogeneous cases or observations. Objects in a cluster are similar to each other. They are also dissimilar to objects outside the cluster, particularly objects in other clusters.

For the purpose of this study we used *K*-means clustering, which is a method of vector quantization. *K*-means clustering aims to partition *n* observations into *k* clusters in which each observation belongs to the cluster with the nearest mean, serving as a prototype of the cluster. This results in a partitioning of the data space into Voronoi cells. *K*-means clustering algorithm can be described as follows:

Given a set of observations $(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n)$, where each observation is a *d*-dimensional real vector, *k*-means clustering aims to partition the *n* observations into *k* sets $(k \le n)\ \mathbf{S} = \{S_1, S_2, \ldots, S_k\}$ so as to minimize the within-cluster sum of squares:

$$\arg\min \sum_{i=1}^{k} \sum_{x_j \in S_i} \left\| x_j - \mu_i \right\|^2 \tag{25}$$

where $\boldsymbol{\mu}_i$ is the mean of points in S_i.

In Table 2 the preliminary results of classification are show, where the corresponding ranges of Risk Indicator are found for each encounter type. However precise categories need lots of traffic scenarios as training data. This will be executed in further study.

Table 2. Risk range to safety level in ship-ship encounter.

Risk Indicator range	Encounter type
<50	Regular encounter
50–100	Collision avoidance
–500	Close-encounter
>500	Risk encounter

4.3 *Behavior tests of the Risk Indicator*

The behaviour tests attempt to check, if the developed Risk Indicator behaves as supposed, when input variables are changed accordingly. For this purpose we selected numerous traffic scenarios, representing the predefined four types of encounters. For each scenario we calculated Risk Indicator and compared it with the selected traffic situations. With this exercise we gained confidence in proper behavior of the Risk Indicator model and proper recognition of various encounters.

5 ASSESSMENT OF COLLISION RISK IN THE NORTHERN BALTIC SEA APPLYING THE RISK INDICATOR

Finally, we carried out the assessment of ship collision risk for the Northern Baltic Sea, with the use of the Risk Indicator introduced here. For this purpose we utilized the traffic data for May and July 2011 with the primary aim to assess the historic collision risk level in various locations of the Northern Baltic Sea in order to draw a spatial risk map for the analyzed sea area.

In Figure 4 all the encounters are plotted for the Northern Baltic Sea, and Figure 5 contains information for the Gulf of Finland. Four levels of risk, stemming from the four encounter types, are marked with different colors. Green means regular encounter, blue is collision avoidance, yellow stands for close-encounter, and red means risk encounter. The areas where the Risk Encounters occur are related to the waterways crossing between Helsinki and Tallinn, as well as approaches to major harbours. The former finding is expected, as there is a broad agreement among experts about riskiness of this area. Previous studies for this sea area support the findings, see for example (Kujala et al. 2009; Goerlandt & Kujala 2011; Montewka et al. 2012). The harbours approaches were recognized by the risk model presented here as locations of increased risk. This is mostly related to the close distance at which the ships are passing and the situations where a pilot boat approaches a ship to transfer a sea pilot. Despite the close distance between these two ships, such cases are considered safe, and the ship-ship collision risk is low. The model shall be further improved in order to detect such cases and classify them accordingly. As for now, the model classifies them as risk encounters, this unnecessarily increases the number of such encounters.

The locations of ship-sip meetings classified by the model as Close Encounters correlate with the locations where Risk Encounters were detected. This is an interesting finding, strengthening the arguments for the justification of the previous type of encounters. Most of meeting of this type occur

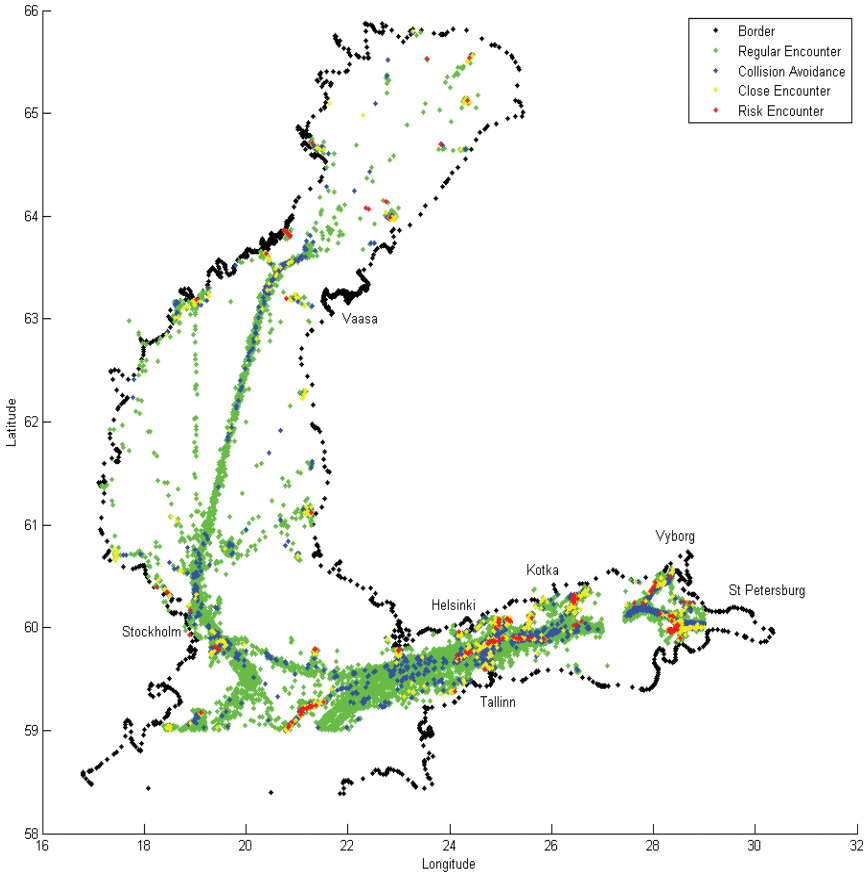

Figure 4. Preliminary risk assessment for ship-ship collision in the Northern Baltic Sea.

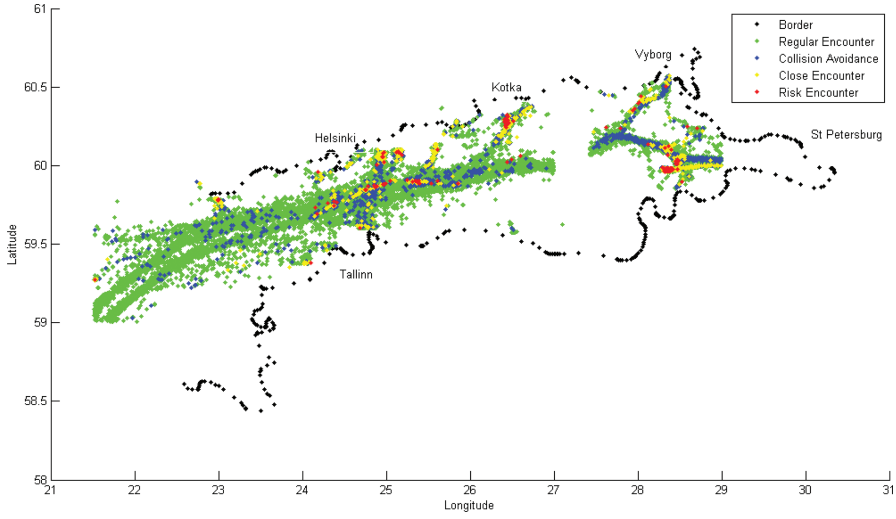

Figure 5. Preliminary risk assessment for ship-ship collision in the Gulf of Finland.

in the waterways leading to harbours. This seems sound, as the navigable space is usually limited in such locations, two types of meetings are predominant—overtaking and passing on reciprocal courses. This implies evasive actions at close range. Such an encounter may be of less risk than the same encounter in the open sea. In the former case the officers are aware of the situation and aware of the action of another ship. In the latter case, the situation may be more ambiguous, and officers more confused, which results in the increased probability of wrong performance. Nevertheless, the data presented in Figure 9 about this type of encounters correlates with the sound judgement and background knowledge about the potential places where the traffic is complex.

The encounters belonging to the type Collision Avoidance are distributed in a random fashion in the Gulf of Finland. However certain routes can be defined in the Sea of Bothnia, and the majority of encounters are happening along these routes. In the Gulf of Bothnia the number of encounters significantly drops, compared to the other sea areas, and they are concentrated along the waterways leading to main harbours of the Bay of Bothnia.

The spatial distribution of the last type of encounters, namely Regular Encounter, shows almost random nature of this encounter in the Gulf of Finland. However, for the Sea of Bothnia the location of detected encounters correlates with the major shipping lanes. Despite almost zero level of collision risk of this type of encounters; they are plotted to form a background picture. By determining the number of this type of encounter we get a reference point to calculate the share of other three types of encounters, as presented in Table 3. It is evident, that the type 4, which is of the highest risk, takes 0.84% of the total number of encounters. Actually, it is less, as the miss-classified cases increases it, as discussed earlier. Type 2 takes 4.3% and type 2 takes 7%. Such a distribution of encounters of various risk levels is in line with the pyramid hierarchy of an accident, as discussed in (Hyden 1987).

Table 3. Results of ship collision risk assessment for the Northern Baltic Sea.

Encounter type	Amount	Share [%]	Color code used in Figures 4, 5
1—Regular encounter	33,456	87.83%	Green
2—Collision avoidance	2,666	7.00%	Blue
3—Close-encounter	1,651	4.33%	Yellow
4—Risk encounter	319	0.84%	Red
Total	38,092	100%	–

Table 4. Results of ship collision risk assessment for the Gulf of Finland.

Encounter type	Amount	Share [%]	Color code used in Figure 4
1—Regular encounter	25,361	90.21%	Green
2—Collision avoidance	1,573	5.60%	Blue
3—Close-encounter	979	3.48%	Yellow
4—Risk encounter	199	0.71%	Red
Total	28,112	100%	–

Despite the problems of miss-classification, the hierarchy detected and the spatial distribution of encounters seem reasonable.

6 DISCUSSION

The model assessing the Risk Indicator introduced in this paper features novelty in how an encounter between two ships in the open sea is looked at. Unlike most of the existing approaches it combines three parameters, which are relevant to collision risk: distance between meeting ships, their relative speed and the difference in their headings. The latter indicates the magnitude of action required to solve the meeting situation. These parameters have been thoroughly described in Section 3, therefore in this section only the outstanding issues are addressed.

First is the form of relation between these three factors. The type of relation between Risk Indicator and distance or phase is relatively clear, as discussed earlier. However the function binding Risk Indicator and relative speed may raise concern. In the model we adopt the quadratic dependency, however there is no strong arguments for such a selection. Basically any other kind of relation is equally probable, this brings the uncertainty to the model, which in future can be addressed by alternative hypotheses testing, and studying the effect of the changes on the levels of Risk Indicators and their spatial distribution.

On the other hand, in the adopted form of Risk Indicator model the equation parameters for distance and relative speed are summed. The accompanying factors k and m take the values, which are 4 orders of magnitude apart. This leads to a situation, where the distance between two meeting ships is weighted more than their relative speed. Therefore, in the presented Risk Indicator model the effect of relative speed is not as important as the effect of distance.

Another issue is related to the size of encountering ships, which may affect the distance at which

the ships pass. In case of small vessels the safe passing distance is most probably shorter than in the situations where large ships are involved. Therefore, ship size shall be accounted for in the future studies.

Neither the effect of hydro meteorological conditions like the wave height and visibility has been included. However, the collected data refers to May and July, which are rather favourable months in the Baltic Sea. The time of the day has not been considered either. However over May and July the length of the day is on average 18 hours for the Gulf of Finland and even longer for the Sea of Bothnia and Bothnian Bay. This means, that our study focuses mainly on daytime conditions.

7 CONCLUSION

In this paper we propose a new method for ship-ship collision risk assessment in the large sea areas, applying the concept of Risk Indicator, which has been defined and developed for the purpose of this study.

The Risk Indicator considers the following factors influencing the complexity of an encounter thus collision risk: the distance between two ships, the relative speed of two ships and the difference in course of two encountering ships. The risk model developed here differentiates between four types of ship-ship encounters, associating a risk level to each of them. The encounters are of the following types: normal encounter, collision avoidance, close-encounter and accident.

The method applies experts' judgment together with micro-level ship traffic data obtained from the Automatic Identification System corresponding to the Northern Baltic Sea and summer season (Many, July 2011).

Finally, the risk model has been applied for the assessment of ship collision risk in the Baltic Sea and the obtained results have been benchmarked with other available risk models existing in the literature and the existing background knowledge on the phenomena analyzed. The benchmarking results show that the proposed model correctly classifies the various encounter types and the spatial map of risk levels for the maritime traffic in the Northern Baltic Sea corresponds to the actual traffic and the areas, which are known for featuring the increased collision risk.

The presented model can be used for efficient data screening for various types of encounters as well as for the comparison of traffic situations from various time epochs. The latter is especially relevant, as changes have been made, and the effect of these changes needs to be quantified in a post assessment strategy.

RAPP method: Failure analysis and risk determination in automobile fleets within the case study electric actuator

Stefan Bracke & Sebastian Sochacki
Chair of Safety Engineering and Risk Management, University of Wuppertal, Wuppertal, Germany

ABSTRACT: The increasing complexity of product functionality and manufacturing process parameters often leads to complex failure modes during the product life cycle. These field information are the basis for risk analysis and damage case prognosis with the goal of an early risk detection and leads to the possibility of nearby interactions, e.g. product and manufacturing optimisation or recall action. This paper outlines the essential procedure of the new developed method "Risk Analysis and Prognosis of complex Products (RAPP)". The main focus of the RAPP method is the detection, visualisation and prognosis of risks and damage cases depending on their life span variables regarding to a product fleet—based on a risky production batch—in field. The theory and application of the RAPP method is explained within an automotive case study electric actuator based on a synthetic data set, which includes real effects of typical field failure behaviour.

1 INTRODUCTION

The development and manufacturing of technically complex products as well as capital goods are confronted to central challenges: The increasing complexity of product functionality and manufacturing process parameters often leads to complex product damage symptoms and failure modes during the product life cycle. In case of this paper technically complex products are meant to be electronic goods, home appliances, consumer electronics or automobiles. These products are manufactured in series with an amount of middle up to a high production batches (statistical population), for example $N \geq 100$ products per day. After the sales of such production batches the products are passed into the use phase. The term product fleet denotes each production batch with the same construction stage (same grade of upgrade/innovation stage) of a component.

During the usage phase a huge amount of operational data (operating time, operating temperature, load characteristics etc.) regarding each product is generated. A special type of operational data collection can be found in case of failure occurrence during the usage phase of such components. For instance the time of damage appearance, the failure mode as well as the life span at the failure occurrence is recorded. These field informations are the basis for risk analysis and damage case prognosis with the goal of an early risk detection, visualisation and prognosis. Finally, it leads to the possibility of nearby interactions e.g. product and manufacturing optimisations or recall actions.

As part of the research work the RAPP approach (Risk Analysis and Prognosis of technical complex Products) has been already developed (Bracke 2013): In this paper, the RAPP method is now developed in a comprehensive extended procedure. The overarching goal of the RAPP method is the analysis of product fleet risks in the use phase depending on their life span variables regarding to certain failure modes.

2 GOALS OF THE RAPP APPROACH

The challenges and requirements of a risk analysis and risk prognosis based on the RAPP approach with regard to product fleets in the use phase are as follows:

a. Detection of specific risks regarding to a product fleet in field, which is based on a risky production batch.
b. Prognosis of the future amount of units at risk depending on their life span variables (e.g.: operating, switching cycles, operating time or operation parameters).
c. Visualisation of the determined risk as a basis for further decisions (e.g.: recall actions, garage actions).

This paper demonstrates on the one hand the developed theoretical background of the RAPP method and on the other hand an application of the shown RAPP steps due to the automotive engineering case study electric actuator. The case

study is based on a synthetic field data set. The creation of these data and information was based on characteristics with respect to real damage case data sets. The result of the RAPP method application is the estimation of the risk regarding the product fleet during the usage phase based on a detected failure mode. The data set includes e.g. field operating times, kilometrage and observation time based on the car-level.

3 RAPP APPROACH AND CASE STUDY: BASE OF OPERATIONS

The basis of every risk analysis constitutes two parts (Bracke & Haller 2011): On the one hand the knowledge of the damage case at a certain observation period and on the other hand the empirical product use phase behaviour. The observation of both data base is independent from each other.

The knowledge of the damage case includes data and information regarding the amount of damaged components as well as data of the life span variables regarding the point of observation, when the damage of each component appeared in the use phase (e.g.: operating hours, operation cycles, start and shut down activities). In addition, external conditions (e.g.: temperature, air humidity) have to be analysed and documented (Persin et al. 2013).

The knowledge of the empirical product usage phase behaviour includes data and information regarding the determination and mapping of the products' life span variables. This data is based on independent observations regarding the damage cases: The data base is collected from the whole—not damaged—product fleet in the field during the usage phase. This means that the data are not censored.

The precondition with regard to the RAPP approach is the correlation between the progression of the analysed failure mode variable and the chosen life span variable. This can be verified with the help of the Spearman's rank correlation coefficient (Sachs 2002).

An excerpt of the data and information of the case study electric actuator regarding the damage case and the empirical product use phase behaviour is shown in Table 1.

Table 1. Excerpt of data and information of the automotive case study electric actuator regarding damage cases and product fleet (synthetic field data set).

Nr.	Data array	Format/content
Information regarding the product fleet		
1.1	Production batch (automobile fleet)	$N_{PF} = 15.833$
1.2	Production period	03.2011–06.2011
1.3	Kilometrage profile of the product fleet regarding the life span of the product	Log-Normal distribution (parameters: μ; σ)
Field damage case information		
2.1	Observation time of concerned automobile fleet in field	12 months
2.2	Failed electric actuators up to observation time	$n = 211$

4 RAPP METHOD: OVERVIEW, PRINCIPALS AND STATISTICAL TOOLS

The essential procedure of the RAPP method (Risk Analysis and Prognosis of complex Products) includes five steps A–E, which are shown in Figure 1 (Bracke 2013). The single steps of the method and the used statistical tools are summarised in an overview in this chapter and explained in Table 2.

A detailed application of the RAPP method based on the theoretical steps is explained within the automotive case study electric actuator in chapter 5. The main goal of step A is the detection of the failure mode related to the product life span variables and the statistical mapping and prognosis of the Failure Mode (FM). Base of operations is data out of the technical analysis of damaged components and field data (e.g. guarantee/goodwill database).

The focus on step B is the empirical mapping of the product fleet (PF) behaviour based on the failure mode related life span variables (step A). The goal of step C is the estimation of the critical area regarding the failure mode related life span variables by definition of a range using the borderlines of important quantiles of the failure mode and the product fleet distribution models. The step D of the RAPP method focuses on the determination of the risk in product fleets in terms of a detected failure mode. Furthermore, step D considers the

Figure 1. Overview of the RAPP method (Bracke 2013).

Table 2. Essential procedure of the RAPP method.

	Step	Data Bases, statistical tools, procedure
Step A: Mapping and prognosis of the failure behavior		
No.	Action	Statistical tools and data bases
A1	Analysis of failure mode related life span variables	Technical analysis of damaged components
A2	Determination of life span variable's correlation	Spearmans ς; Kendalls τ
A3	Analysis of the behaviour development of the failure mode	Distribution models; e.g. Weibull distribution (two parameter model: b, T)
A4	Prognosis of the parameters of the statistical model of the Failure Mode (FM)	Regression analysis; coefficient of determination r^2
A5	Analysis and mapping of clearing effects: e.g. replacement part operations	Consideration of market charging via distribution models
Step B: Mapping field load profile		
No.	Action	Statistical tools
B1	Analysis of the life span variables of the Product Fleet (PF)	Correlation analysis between technical analysis and product fleet
B2	Empirical mapping of the life span variable development	Distribution models; e.g. log-normal (parameters μ, σ)
B3	Analysis and mapping of clearing effects: e.g. product fleet reduction	Consideration of market scrap influences via distribution models
Step C: Estimation of the critical area		
No.	Action	Statistical tools
C1	Determination of critical areas (quantiles)	E.g.: 50%, 95% 99%-quantile of FM and PF models
C2	Mapping of life span variable quantiles regarding failure mode and product fleet	E.g.: $l_{CLL\text{-}CUL} = \lvert Q_{PF\text{-}LL;0.05} - Q_{FM\text{-}UL;0.95} \rvert$
Step D: Risk analysis and risk prognosis		
No.	Action	Statistical tools
	Risk analysis	
D1	Risk probability in product fleets regarding actual point of time, based on critical areas	Overlap of FM and PF distribution models results in risk probability P_{FM}
D2	Determination of function "Damage Appearance (DA)"	Overlap of FM and PF distribution models results in density function f_{DA}
D3	Analysis of risk probability and damage appearance peaks development [retrospective]	Regression analysis at different points of time t_x leads to damage appearance function
D4	Analysis of significant changes: risk in-/decrease	Significance tests (e.g.: Mann-Whitney U-Test; Siegel-Tukey-Test, Fisher-Test) and confidence intervals
	Risk Prognosis	
D5	Risk probability regarding future points of time [future]	$P_{Prog\text{-}PF}$
D6	Prognosis of risk probability and Damage Appearance (DA) peaks development [future]	f_{DA}
D7	Determination of clearing effects: e.g. product fleet reduction/replacement part operations	Consideration of market charging distribution models
Step E: verification of risk analysis and—prognosis		
No.	Action	Statistical tools
E1	Field observation regarding to the risk point of time	Determination of failure rate λ and products at risk n
E2	Simulation of the failure and the product fleet behavior	Monte Carlo simulation

estimation of the retrospective and the expected risk development within the product fleet. The last step E of the RAPP method is the verification of the risk analysis and prognosis (step D) based on field observation and Monte Carlo simulation methods. The application of step E regarding the case study electric actuator is part of future research works.

5 RAPP RISK-ANALYSIS AND—PROGNOSIS WITHIN THE CASE STUDY

5.1 *Step A: mapping and prognosis of the failure mode*

Out of the field data base a density function is generated to represent the statistical area of the empirical Failure Mode (FM). A common

distribution model to approximate such failure modes is the three parameter Weibull distribution (density function (1)). An advantage to approximate such failure modes using a three parameter Weibull distribution is the interpretation of the utilised parameters (t_0 = failure-free time; T = characteristic lifetime; b = shape parameter; (Bertsche 2008)). The estimation of the parameters is done by state of the art methods such as Trust-Region method (Celis et al. 1985) or Maximum-Likelihood-Estimator (Meyna & Pauli 2010).

$$f(x)_{FM} = \frac{b}{T-t_0}\left(\frac{x-t_0}{T-t_0}\right)^{b-1} \cdot \exp\left(-\left(\frac{x-t_0}{T-t_0}\right)\right)^{b} \quad (1)$$

Regarding the case study, the point of time of field data analysis is early (12 Month in Service (MIS); Table 1), when the failure behaviour is not comprehensive known. Based on this special case, the use of an approach, which considers an additional prognosis of changing failure behaviour, is useful: The given damage cases within a limited observation period can be splitted into a certain number of classes (e.g. quarter division: 3, 6, 9, …, 24 months in service). With the use of each location parameter T, the mean value as well as the shape parameter b, the prospective parameters of the failure behaviour regarding the second year (24 month in service) can be calculated by using non-linear regression methods (Fig. 2).

A paradigmatic example is shown in Figure 2. The abscissa represents the Month in Service (MIS) regarding to different field observation times, whereas the ordinate reflects the estimated values of the parameters regarding the Weibull distribution models. If the gradient of the regression functions converges to zero, the parameters are not changing and therefore it is assumed, that the failure behaviour is constant. According to the risk prognosis point of time (MIS point, RAPP method step D), it is possible to choose the predicted parameters based on Figure 2.

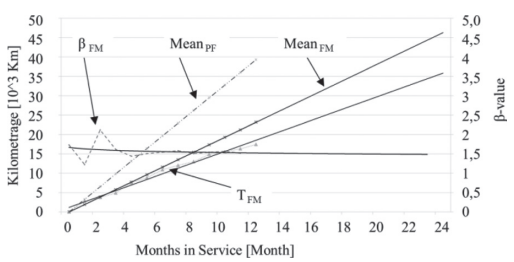

Figure 2. Estimation of Weibull parameters T, b, $t_0 = 0$ and arithmetic mean value x, using non-linear regression methods for prognosis of the comprehensive failure mode, product fleet field observation time 24 months in service; exemplified by the case study electric actuator.

5.2 *Step B: mapping field load profile*

A kilometrage profile can be generated (Table 1) out of the empirically known field data of the Product Fleet (*PF*). An important criterion is the timeframe between the product approval (e.g.: car registration) and the failure occurrence, the latter describes the risks observation point inside the RAPP method.

In many cases distribution functions for mapping a product fleet kilometrage profile can be described with the help of a log-normal distribution (2) (Sachs 2002), normal distribution as well as the Weibull distribution model (1).

$$f(x)_{PF} = \frac{1}{x \cdot \sigma \cdot \sqrt{2 \cdot \pi}} \cdot \exp\left(-\frac{(\lg(x)-\mu)^2}{2\sigma^2}\right) \quad (2)$$

5.3 *Step C: estimation of the critical area*

The estimation of the critical area has to be evaluated by limiting the two density functions within the given one-sided quantile (Q) of each function. A typical one-sided quantile in case of the automotive industry (Lower Limit LL = 0.05/Upper Limit UL = 0.95) is used in the constituted case study. Therefore, the left-sided failure mode distribution was limited by using a 0.05 quantile (Q_{LL}) and the kilometrage distribution by applying a right-sided 0.95 quantile (Q_{UL}). In case of a right-sided failure mode, the quantile borders have to be switched. The schematic visualisation of the critical area within the case study electric actuator is shown in Figure 3, (Bracke 2013).

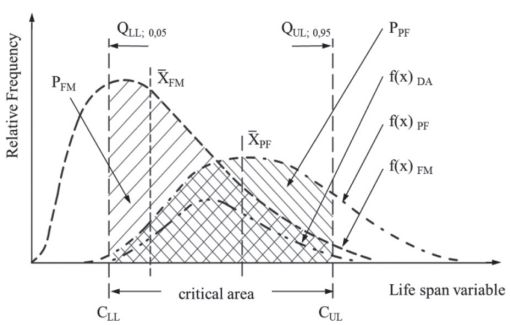

Figure 3. Visualisation to determine the critical area [$c_{LL} = Q_{LL;0.05}$; $c_{UL} = Q_{UL;0.95}$] as well as the overlapping of $f(x)_{PF}$ and $f(x)_{FM}$ to determine the risk parameters P_{RPF} and $f(x)_{DA}$ (Bracke 2013).

5.4 *Step D: risk analysis and risk prognosis*

The RAPP approach provides the calculation of three characteristics:

- P_{RPF}: Risk probability regarding the product fleet (Index: *RPF*),
- $f(x)_{DA}$: Probability function of damage appearance (Index: *DA*) and
- $P_{RPF\text{-}Prog}$: Prognosis of the future risk probability (Index: *RPF-Prog*).

Besides the kilometrage function $f(x)_{PF}$ and the failure mode function $f(x)_{FM}$, the introduced characteristics are visualised in Figure 3.

The calculation of the RAPP characteristics is as follows: The risk probability of the critical product fleet P_{PF} can be estimated using the failure occurrence probability P_{FM} (Integral of $f(x)_{FM}$ (1) regarding to the critical area, step C) and the product fleet kilometrage probability P_{PF} (Integral of $f(x)_{PF}$ (2) regarding to the critical area, step C).

$$P_{RPF} = \mathrm{P_{FM}} \cdot \mathrm{P_{PF}} = \int_{C_{LL}}^{C_{UL}} \frac{b}{T-t_0}\left(\frac{x-t_0}{T-t_0}\right)^{b-1} \cdot \exp\left[-\left(\frac{x-t_0}{T-t_0}\right)^{b}\right] \cdot \int_{C_{LL}}^{C_{UL}} \frac{1}{x \cdot \sigma \cdot \sqrt{2\cdot\pi}} \cdot \exp\left(\frac{(\lg(x)-\mu)^2}{2\sigma^2}\right) \tag{3}$$

The function $f(x)_{DA}$ describes the failure occurrence probability of the product fleet in dependence on a life span variable (e.g.: kilometrage). With this specific characteristic the failure occurrence probability can be determined (4) at any point of observation time with respect to an appropriate life span variable. Furthermore, the probability to find one unit at the point of observation can be easily calculated by finding the maximum of the failure occurrence function (5).

$$f(x)_{DA} = \frac{\mathrm{b}}{\mathrm{T}-\mathrm{t_0}}\left(\frac{x-t_0}{T-t_0}\right)^{b-1} \cdot \exp\left[-\left(\frac{x-t_0}{T-t_0}\right)^{b}\right] \cdot \int_{C_{LL}}^{C_{UL}} \frac{1}{x \cdot \sigma \cdot \sqrt{2\cdot\pi}} \cdot \exp\left(\frac{(\lg(x)-\mu)^2}{2\sigma^2}\right) \tag{4}$$

$$f'(x)_{DA} = 0 \tag{5}$$

The probability $P_{RPF\text{-}Prog}$ maps the prognosis in the field of expected damage cases in the future at a specific point of observation time t_{RP}. The general procedure is identical to the determination of the first risk characteristic P_{RPF}. The difference is the adjustment of the product fleet's kilometrage function $f(x)_{PF}$ in relation to the prognosis point of time and thus the renewed determination of the left-sided lower quantile $Q_{LL(Prog);0.01}$. In case of additional changing failure behaviour, the adjusted failure mode function and its appropriate quantile have to be considered.

Referring to equation (3) the probability $P_{RPF\text{-}Prog}$ can be calculated as follows:

$$P_{RPF\text{-}Prog} = P_{FM\text{-}Prog} \cdot P_{PF\text{-}Prog} \tag{6}$$

In the presented electric actuator case study the risk analysis and prognosis based on the RAPP method is using the field data set regarding the first twelve MIS. Afterwards, the results of the risk prognosis are compared to the real failure behavior at the point of time 21 MIS. The results of the RAPP risk analysis and the respective risk prognosis (step D; Fig. 6) are shown in Table 4.

Regarding to Figure 3 the following Figure 4 and Figure 5 shows the overlapping of the den-

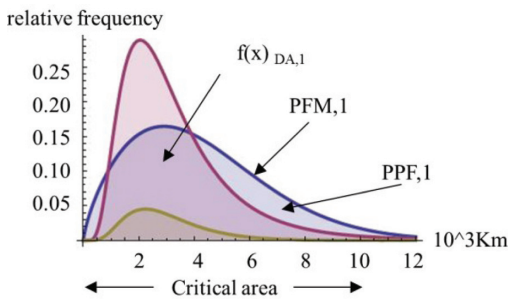

Figure 4. Visualisation of the overlapping $f(x)_{PF}$ and, $f(x)_{FM}$ and the product of both to determine the risk parameters $f(x)_{DA}$ after one MIS.

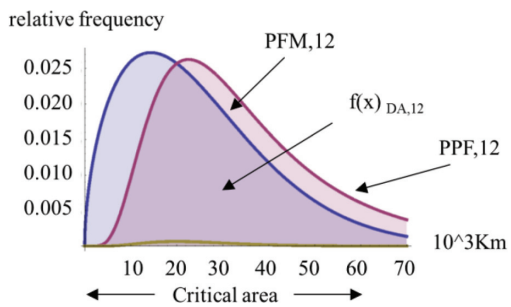

Figure 5. Visualisation of the overlapping $f(x)_{PF}$ and, $f(x)_{FM}$ and the product of both to determine the risk parameters $f(x)_{DA}$ after twelve MIS.

sity functions of cars based on the electric actuator failure mode (Weibull distributed, (1)) and the associated product fleet (Lognormal distributed, (2)) after one and twelve MIS.

After the first MIS the major section of the product fleet is moved in the range of cars with electric actuator failure mode (82.03%). The peak $f'(x)_{DA,1}$ is at 2,239 kilometres. At the beginning of 12 MIS regarding the product batch the fleet moved to a mean kilometrage of 23,179 kilometers. The risk analysis in product fleet (P_{RPF}) dropped from 82.03% to 31.58% by simultaneous increasing the range of the critical area (4,780 to 83,880 kilometres). Comparison of $f'(x)_{DA,1}$, $f(x)_{PF,1}$ and $f(x)_{FM,1}$ with $f'(x)_{DA,12}$, $f(x)_{PF,12}$ and $f(x)_{FM,12}$ shows a proportional process, therefore it can be assumed, that the failure behaviour is not completely developed. Additionaly the dispersion of $f(x)_{FM,i}$ and $f(x)_{PF,i}$ have a similar development which is an indicator (in conjunction with a linear arithmetic mean development) for a random failure behaviour. But it can be received that a short quantity of cars is in the critical area (max 71.04%) of the electric actuator and could breakdown in higher kilometrage. The following Table 3 summerises the results regarding the risk analysis at 1 MIS and 12 MIS.

The extrapolation of the Weibull distribution parameters of $f(x)_{FM,1\text{-}12}$ show a prognosis of the electric actuator failure behaviour after 21 MIS based on the prognosis of the shape and location parameters (Fig. 1).

Table 3. Results of the RAPP risk analysis after one and twelve MIS; case study electric actuator.

Risk characteristics	Result
Results after one month in service	
$P_{PF,1}$	82.03%
Note: Risk analysis in product fleet; observation point of time: 1 MIS	
$P_{PF,1}$: c_{LL}/c_{UL}	0.00/12.26 [10^3 km]
Note: Critical area regarding to the life span variable within 1 MIS observation time	
$f'(x)_{DA,1}=0$	2.239 10^3 km
Note: Damage appearance, 1 MIS	
Results after twelve months in service	
$P_{PF,12}$	71.04%
Note: Risk analysis in product fleet; observation point of time: 12 MIS	
$P_{PF,11}$: c_{LL}/c_{UL}	4.78/83.88 [10^3 km]
Note: Critical area regarding to the life span variable within 12 MIS observation time	
$f'(x)_{DA,12}=0$	23.179 10^3 km
Note: Damage appearance, 12 MIS	

Table 4. Results of prognosis from focus of failure mode and proportion of cars at risk compared with the fair values after 21 MIS.

Risk characteristics	Result
Prognosis of the damage appearance	
$f'(x)_{DA,Prog,21}$	32,338 km
Note: Damage appearance prognosis: 21 MIS	
Real values of Damage appearance	
$f'(x)_{DA\,21}$	24,765 km
Note: Damage appearance 21 MIS	
Risk probability prognosis	
$P_{RPF,\,Prog,21}$	17.81%
Note: Risk probability prognosis: 21 MIS	
Real values proportion of the risk probability	
$P_{RPF,21}$	12,57%
Note: Risk probability 21 MIS	

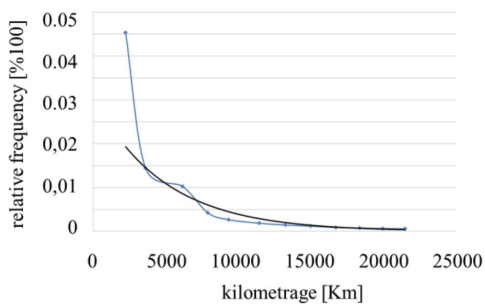

Figure 6. Visualisation of the maxima of damage appearance density function $f'(x)_{DA,1\text{-}12}$.

The determination of the function "damage appearance" (4) for each month in service $f(x)_{DA,1\text{-}12}$ shows the centered area of the $P_{RPF,1-12.}$ After finding the maximum with (5) the x-value of $f'(x)_{DA,1\text{-}12}=0$ expose the focus of kilometrage from the electric actuator for each month. Figure 6 presents $f(x)_{DA,1}$ till $f(x)_{DA,12}$.

Primarily, it can be observed that the y-value of the $f'(x)_{DA,1\text{-}12}$ are very small, therefore it is difficult to show $f(x)_{FM,1\text{-}12.}$ $f(x)_{PF,1\text{-}12}$ and $f(x)_{DA,1\text{-}12.}$ in one plot. In the first month the focus of the failure mode ($f'(x)_{DA,1}=0$) can be located at 2,239 kilometres. In the following months the focus increases proportionately while the dispersion of $f(x)_{DA,2\text{-}12}$ gets disproportionately higher. With the increase of the range of $f'(x)_{DA,1\text{-}12}$ the validity of focus of the failure mode gets lower. The black line describes a possible model fit by using an exponential function. The following Figure 7 compares the failure mode focus (damage appearance, (5)) with the proportion of cars from P_{PF} in the critical area of P_{FM} ((6)) for each month.

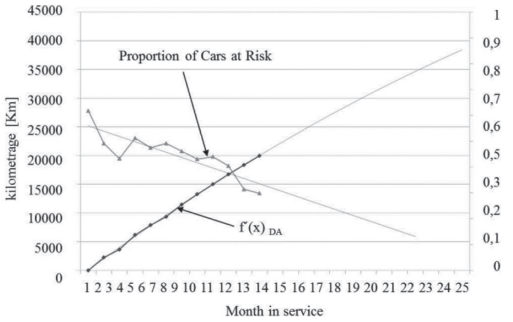

Figure 7. Prognosis of the damage appearance focus ($f''(x)_{DA} = 0$) and the proportion of cars from P_{PF} in the critical area P_{FM} based on 12 MIS.

According to Figure 7 it can be observed, that the damage appearance is changing to linearly a higher kilometrage. The prognosis shows the increase trend of failure mode focus regarding the kilometrage for the next 13 MIS (Total: 25 MIS). Comparison of the prognosis with the real values of 21st MIS based on field data shows a related behaviour, but overrates the real occurrence. The reason is the increase of the dispersion after twelve months in service and the following MIS.

The critical area of the risk probability regarding the product fleet has a linear course. Comparing the prognosis with real values 21 months in service the risk probability will be overrated after the period of observation. While the damage appearance gets higher simultaneously the proportion of cars at risk gets lower which is an indicator that the overlapping of P_{FM} and P_{PF} gets smaller. The following table summarises the important results and values of the Figure 7.

The results of the 21 MIS prognosis regarding to the real behaviour of the failure mode after 21 MIS leads to significant deviations. In this case the damage appearance prognosis as well as the risk probability prognosis overrates the failure behavior. Taking into account of the difficultness of random failure behavior the RAPP method gives well oriented results to forecast of the failure behaviour.

6 CONCLUSION

This paper outlines the RAPP method and its application within the electric actuator case study for determination of risks in product fleets within the usage phase. The focus is the analysis and prognosis of the field failure behaviour of a defect electric actuator unit based on product field data. The results lead to a visualised risk analysis and prognosis on the basis of the existing failure mode and the product fleets life span variables at a certain point of observation. Furthermore, the estimation of the risk prognosis with respect to the expected damage cases within the product fleet is feasible. The comparison of the RAPP method versus industrial state-of-the-art methods (Eckel 1977) has not been verified yet and is an inherent part of future research work.

The advantages of the present procedure are: The RAPP method, in comparison to the industrial standards of risk prognosis methods, considers a direct link of different dimensions (e.g. operating time, switching cycles) causing a specific damage case and the product's life span variables without a mathematical conversion. Thus, the method generates the possibility of direct visualisation of damage cases (failure behaviour) and life span areas at a specific point of observation time to estimate the existing risk potential. The visualisation includes the critical area between a product's life span variable and a present failure mode, which can be calculated by using p-quantiles of the failure behaviour probability function and the empirical life span variables. Furthermore, the adjusting empirical life span variable as related to the failure behaviour can be visualised properly and analysed subsequently. Finally the developing of the damage appearance regarding the predicted behaviour of the failure mode and the product fleet is calculable.

The disadvantages of the shown procedure are: The fitted density functions of the empirical failure modes and the product fleet's life span variables are fundamental for the presented method. Thus the deviation due to different probability functions and the fitted model itself can lead to different results of the risk analysis. The current research results due to different probability functions show a marginal influence in the result. However, some case studies led to adverse risk prognosis based on small critical areas, which is also a part of the future research work.

ABSTRACT: Different methodologies for tsunami risk assessment have been developed, namely for reconstitution of previous hazardous events and for planning awareness and alert systems and civil protection resources. The vulnerability analysis is frequently based on simulations using precursor impact damages and on modeling hydrodynamic floods. Our innovative approach is applied on two distinctive coastal Atlantic areas, with urban and rural/natural context from Setúbal and Figueira da Foz counties. We presented a deepened methodology for assessing vulnerability to tsunamis in its social, structural and morphological component that results of new inputs that distinguish this from previous studies. The tsunami inundated areas were obtained from tsunami numerical modeling. The morphological and structural analysis is based on field work element collection using a matrix with 18 parameters. For the social impacts evaluation, a multi-components analysis is performed, using 47 socio-economics variables, expressing the expected impacts. A composite territorial index of vulnerability is presented and mapped.

1 INTRODUCTION

The evaluation of the degree of exposure and vulnerability to natural disasters in the last decade has seen a notable increase (Wisner et al., 2004; Douglas, 2007). Even after the 2004 India Ocean Tsunami, and more recently the 2011 Japan Tsunami there has been a focus on the hazard process assessment and mapping through physical models (Liu et al., 2007; Santos et al., 2007; Santos, 2011; Satake et al., 2011; Singh et al., 2012). Other approaches have been focusing on the analysis of territorial vulnerability resulting from past impact in predicting future events (Dominey-Howes and Papathoma, 2007; Dall'Osso et al., 2009; Dominey-Howes et al., 2009; Hart and Knight, 2009; Dominey-Howes et al., 2010). On the other hand, several studies have been pointing the importance of conceptual requirements and technical problems for territorial vulnerability assessment, like the scale analysis (Fekete et al., 2010; Kienberger et al., 2013), the perception of natural and technological risks (Tavares et al., 2011), the supporting data (Papathoma et al., 2003; Silva and Pereira, 2014) and the comparativeness of models (Smit and Wandel, 2006), to develop detailed territorial approach and strong risk analysis. Furtermore, different authors underlined the vulnerability assessment and territorial coping capacity on tsunami affected areas based on natural scope (Taubenböck et al., 2008; Kaplan et al., 2009; Hart and Knight, 2009), according the building fragilities (Papathoma and Dominey-Howes, 2003; Ghobarah et al., 2006; Dominey-Howes et al., 2010; Omira et al., 2010; Leone et al., 2011; Reese et al., 2011) or empathizing the support capability (Post et al., 2009; Freire et al., 2013). In addition, an enlarged understanding of vulnerability related with natural hazards has been enhanced (Turner et al., 2003; Cutter et al., 2003; Cardona, 2004; Adger, 2006; Douglas, 2007; Mendes, 2009) emphasize not only in the impacts and coping post events, but also the long term recovery capacity and the adaptation to the reframed conditions.

In this study two coastal areas of Portugal were selected (Fig. 1): Figueira da Foz, located in the central region of Portugal and Setubal located nearby Lisbon. Therefore, the objective of this study is to propose a multidimensional vulnerability analysis for coastal areas with a potential

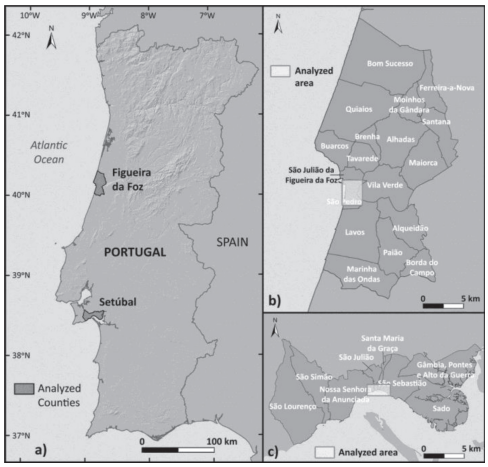

Figure 1. Location of the two studied areas: a) Portugal framework; b) Figueira da Foz; c) Setubal.

tsunami hazardous impact. First is calculated the morphological index of vulnerability (Mv) that combines the different physical and occupation characteristics of the analyzed area. Secondly, is calculated the structural vulnerability index (Bv) that estimates the vulnerability of the different potentially affected buildings. Thirdly, the social vulnerability (Sv) that analyzes the socioeconomic characteristic of the study area is calculated.

Finally, is calculated the Composite Index of Vulnerability (CVI) that aggregates the three indices previously calculated.

The main goal is to assess a potential tsunami impact by considering the coastal natural scope, the existing building characteristics and the societal capability, in the sense of (Deneulin and McGregor, 2010).

2 METHODOLOGY

The tsunami inundated areas used in this study are based on the worst case scenario which is the 1755 Lisbon Tsunami. This is an innovative approach because these results were obtained from the tsunami numerical modeling carried out by Santos et al. (2012) and Santos & Koshimura (2013).

Then, a multidimensional vulnerability analysis for the two coastal areas is proposed. Furthermore, this study presents a new methodological approach to evaluating the structural, morphological and social vulnerability to tsunamis. This methodology was supported on the collection and assessment of large data from fieldwork and databases. The data processing and analysis were supported by statistical tools for a composite vulnerability index characterizing the potential inundated areas. For the process associated with the morphological component analysis a total of 5 parameters (Table 1) were taken into consideration, in particular by adapting the coastal vulnerability index (Pendleton et al., 2010) and the physical vulnerability index presented in Ismail et al. (2012).

A matrix was built for the data acquisition and evaluation of the parameters. In this matrix, to each parameter was assigned a value ranging from −1 to +1, with positive values representing an increase in vulnerability, and negative values a decrease in vulnerability.

After assigning values to each of the different parameters, the morphological vulnerability index was calculated, ranging from "very low" to "very high". Regarding the structural component, the potential affected buildings by the tsunami inundation were analyzed. A total of 13 parameters were included in the matrix, which characterize the buildings in its structural, architectural and occupational tools (Table 2). On the other hand, the data acquisition was based on fieldwork in order to collect several intrinsic characteristics of the building and the surrounding areas.

Furthermore, in the structural component new parameters were introduced related to the

Table 1. Morphological assessment parameters (Mv).

Morphological assessment parameters

Existence of underground floors
Foundations type
Occupation form
Number of utilization units
Average number of daily visitors or residents per unit of use
Occupation floating
Built form plan
Emerged building height in relation to the wave

occupation of the buildings that are not included in the previous methodologies presented by Dall'Osso et al. (2009) and Ismail et al. (2012). The introduction of parameters "form of occupation", "number of units for use"; "average daily number of persons present or visitors per unit of use" and "floating occupation" allow complementary analysis of buildings including through its functional distinction seasonal and occupational, thereby enhancing the analysis. For each attribute is assigned a value that vary from –1 to +1, whereas positive values represent an increase of vulnerability and negative values a decrease of vulnerability. The parameters included in the structural component do not influence the building's vulnerability in the same way. For this reason it was necessary to assign weight for the different parameters. Weights have been calculated via pair-wise matches between each of the factors, using M-Macbeth3 software, that is a platform for multi criteria analysis and decision making processes (Bana e Costa et al., 2004; Bana e Costa & Chagas, 2004). After assigning values to each of the different parameters, the index of structural vulnerability was calculated, ranging from "very low" to "very high". The methodology for assessing social vulnerability was based on the methodology performed by Cutter et al. (2003), Mendes (2009), atribuir Schmidtlein et al. (2008) and Chen et al. (2013) using factor analysis performed in SPSS. Initially were collected a total of 172 variables of social, economic, demographic and the ones related with buildings in the studied areas. Social vulnerability was analyzed by using factor analysis, which allows the elimination of redundant data, their standardization and their grouping factors. The analysis was performed for a total of 15 municipalities and 88 parishes. As a result, the correlation matrix of data was evaluated, where all the data with a correlation higher than 0.7 were removed. A factor analysis was performed until a set of parameters was obtained to validate the sample. These parameters are: KMO of 0.717, more than 0.6 communalities and a variance rate of 78% (Comrey & Lee, 2009).

From this analysis, the initial 172 variables were reduced to 47, which are grouped in Table 3.

Table 3. Social vulnerability variables (Sv).

Group of variables	Number of variables
Agriculture	3
Buildings/sccommodation	19
Economy	6
Population	13
Services	3
Social support	3

After the factor analysis was calculated the social vulnerability for each parish based on SoVI® classification of Cutter et. al. (2003), ranging the vulnerability from "very low" to "very high". After calculating the morphological, structural and social vulnerability a Composite Vulnerability Index (CVI) was calculated, which integrates the three components with the following formula:

$$\mathrm{CVI} = Mv + Bv + Sv \quad (1)$$

where Mv = weighted sum of the morphological parameters; Bv = weighted sum of the structural parameters; and Sv = factorial analysis scores of the social vulnerability.

The final composite vulnerability index, was obtained by the simple mean of three parameters. The index ranging from "very low" to "very high", based on standard deviation, according to the categories: "very low": <–1 SD; "low": [–1, –0.5 [SD; "moderate": [–0.5, +0.5 [SD; "high": [0.5, 1 [SD; "very high": ≥1 SD.

3 STUDY AREAS' CHARACTERIZATION

The municipality of Figueira da Foz is located in the central coastal area of Continental Portugal and has an area of 379 km^2 (Fig. 1a). According to the 2011 Census (INE, 2011) the county records a population of 62,125 inhabitants, divided unequally by 18 parishes with a population density of 163.3 (hab/km^2). In this study the area of Cabedelo, the industrial zone of the port of Figueira and Cova-Gala were analyzed (Fig. 1b). These areas are located on the left bank of the Mondego river, belonging to the parish of S. Pedro. The choice of Figueira da Foz was justified by the fact that of the existence of historical accounts related to the 1755 Lisbon Tsunami (Santos et al., 2009; Santos et al., 2012), the high seasonal population dynamics and the existence of a major harbor and industrial zone along the coast. The analyzed area in Figueira da Foz is characterized by low altitudes between 0 and 8 m with gentle slopes and the existence of dunes. In terms of the sediment consolidation, the area is characterized by the existence of unconsolidated sediments, beaches and mudslides. With regard to land use and occupation the area presents natural/agricultural areas and salines, and an industrial area that includes Cabedelo, industrial harbor. This study area also included artificialized spaces with residential urban fabric, health and social equipments in Cova Gala, on the left bank of the river Mondego.

The second study area has an urban occupation that belongs to the Setúbal city, which is located in the Sado estuarine region (Fig. 1c). According to

the 2011 Census (INE, 2011) the municipality of Setúbal has a population of 121 185 inhabitants distributed by 8 parishes with a population density of 520.1 (hab/km^2) and has an area of 172 km^2. The choice of Setúbal is justified by the fact of the existence of historical accounts related to the 1755 Lisbon Tsunami (Santos & Koshimura, 2013), reporting the existence of many fatalities and severe damage, the urban area is located on low altitudes of about 4 m, and the existence of marinas and an important harbor. The area is mostly represented by alluvial deposits and landfills, observing generally low altitudes (between 3 to 4 m) and very low slopes. The land use and occupation area is characterized by urban fabric and close to the shoreline by harbor and leisure facilities

4 RESULTS AND DISCUSSION

4.1 *Morphological vulnerability*

The morphological differentiation of vulnerability's mainly result in the distance to the coast, verifying in general, a decrease of vulnerability with increasing their distance (Fig. 2). The Figueira da Foz area also presents "moderate" to "high" levels of vulnerability in the estuarine area related with flat zones and narrow channels (Fig. 2a). For the Setúbal area, namely artificialized, the differentiation of morphological vulnerability results from the distance to the shoreline and the low slope, showing a general decrease of vulnerability with increasing their distance (Fig. 2b).

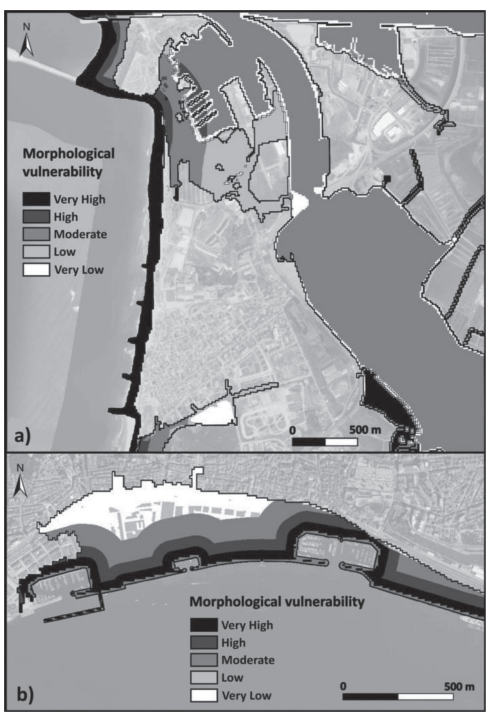

Figure 2. Morphological vulnerability: a) Figueira da Foz; b) Setúbal.

4.2 *Structural vulnerability*

In the analyzed area in the municipality of Figueira da Foz there were identified a total of 47 buildings potentially affected by the occurrence of a tsunami similar to the 1755. Making an analysis of all the buildings evaluated is concluded that 42% present the following categories: warehouses, shipyards, workshops and outhouses, 30% have take an exclusively residential typology, 13% are industrial buildings, 11% are commercial buildings and 4% represent fabric allocated to services. However, it could be identified two distinct zones within the study area: the Cabedelo zone and the industrial harbor are clearly dominated by industrial buildings, warehouses and buildings belonging to shipyards. Further southern in the Cova-Gala the residential buildings dominate. The different land occupation shows two zones for the structural vulnerability. Also noted was the camping, that was not affected by the tsunami inundation. However, it could be isolated because the only access to it could be completely inundated. The structural vulnerability varies from "high" vulnerability to "low" vulnerability, but where most of buildings (85%) are classified with "moderate" vulnerability. (Fig. 3a).

The analyzed area in the municipality of Setúbal presents an urban riverfront downtown, where are located the recreational and fishermen docks, and also the equipments of Setúbal harbor. The area is bounded on the north by the historic city center and to the south by the Sado estuary. A total of 468 potentially affected buildings were identified, mostly with commercial use or assigned to administrative services (60%). A number of 135 buildings (29%) has mixed function, (ie, residential and commercial use), and only 54 (11%) have an exclusively residential typology. This area also presents two distinctive structural vulnerabilities based on the buildings characteristics, separated by the main city Avenue. One to the north, where the buildings has residential function, among which are some properties degraded in narrow streets located in the historic city center; and another area to the south, where stands out the buildings connected to the two main economic activities characteristic of this riverside area—the shops and restaurants connected to the fishing industry, and the port of Setúbal. As presented on

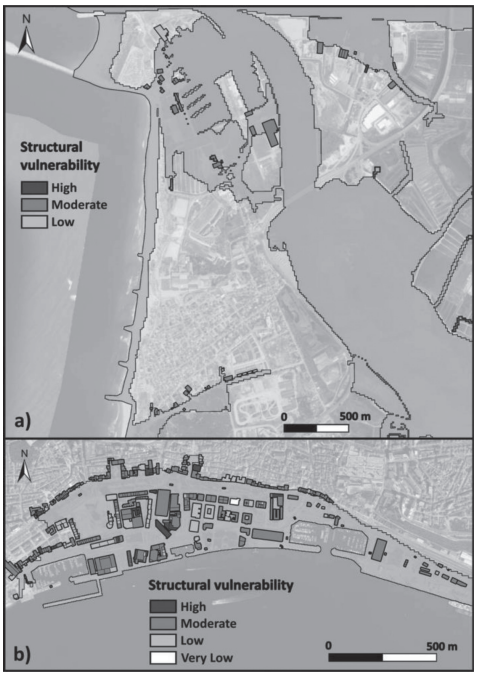

Figure 3. Structural vulnerability: a) Figueira da Foz; b) Setúbal.

the Figure 3b the structural vulnerability of the buildings range from the "very low" vulnerability to the "high" structural vulnerability.

4.3 *Social vulnerability*

For the social vulnerability analysis it was considered the entire county areas (Figueira da Foz and Setubal). Then, the obtained results were projected for the two studied areas. In the Figueira da Foz the social vulnerability for each parishes varies between "low" vulnerability and "very high" vulnerability (Fig. 4a). In the municipality of Setúbal the social vulnerability varies between "very low" and "high" vulnerability (Fig. 4b). In general, the municipality of Figueira da Foz has a social vulnerability higher than the municipality of Setúbal. Regarding to the specific analyzed area part of the municipality of Figueira da Foz, the Cabedelo zone and Cova Gala (located in the parish of S. Pedro) present a "very high" social vulnerability. In the municipality of Setúbal the analyzed area is divided in 4 parishes, which present different social vulnerability rates. The parishes of Nossa Senhora da Anunciada and São Sebastião have a "high" social vulnerability, the São Julião parish presents a "low" vulnerability and the Santa Maria da Graça parish presents a "very low" social vulnerability rate. The studies

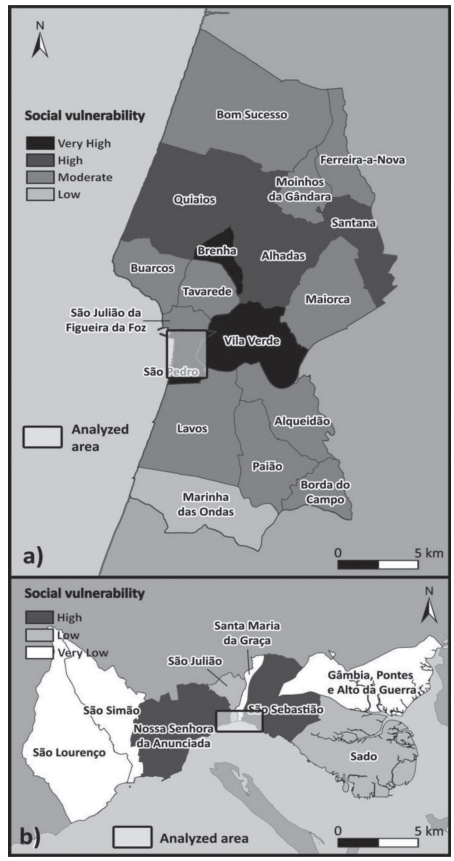

Figure 4. Social vulnerability: a) Figueira da Foz; b) Setúbal.

areas show that social vulnerability rates are very marked by administrative boundaries, as a result of demographic, social and economic variables.

4.4 *Composite vulnerability index*

After calculating the morphological, structural and social vulnerabilities, the Composite Vulnerability Index (CVI) was calculated. This new index combines all the previously calculated indexes. The results in Figueira da Foz study area are: mean = 0.465, and the standard deviation is 0.026. The results also show that the CVI present the highest values in front impact zone (Fig. 5a), with a decrease in vulnerability, with rare exceptions, to the inland of the study area, attending to an indirect relationship between vulnerability and distance to the shoreline. In the analyzed area the CVI varies from "very low" to "very high" (Table 4). 8% of the area is classified as "very high" vulnerability, corresponding almost exclusively to the coastal

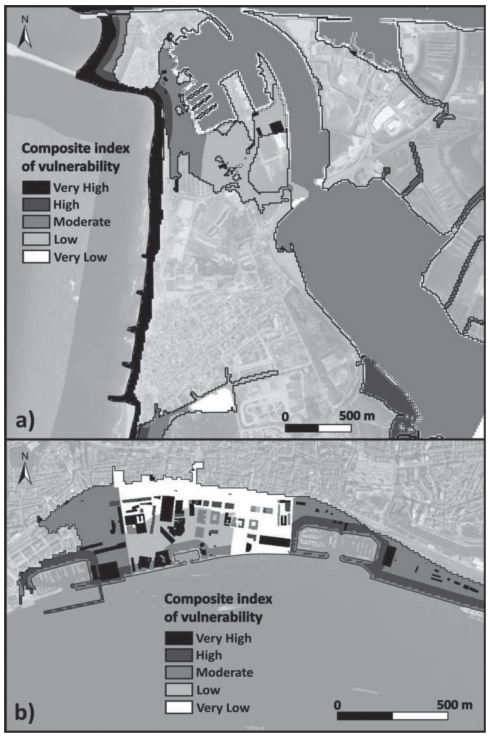

Figure 5. Composite Vulnerability Index (CVI): a) Figueira da Foz; b) Setúbal.

Table 4. Classification of Composite Vulnerability Index (CVI) to Figueira da Foz.

Standard deviation classes	Classification interval	Nominal classification
<–1 SD	0.394–0.439	Very low
[–1, –0.5 [SD	0.439–0.452	Low
[–0.5, +0.5 [SD	0.452–0.478	Moderate
[+0.5, +1 [SD	0.478–0.491	High
≥+1 SD	0.491–0.696	Very high

area and some buildings. With "high" vulnerability rate is classified 4% of the area, which corresponds to the stretch near the coastline and saline areas. 73% of the area presents "moderate" vulnerability that corresponds to the zones near de Mondego river and the harbor zone. With "low" vulnerability (10%) and "very low" vulnerability (5%) are identified the inland areas mostly in the south of Cova Gala and in the fishery and industrial zones.

The results in Setubal study area are: mean is 0.439, and the standard deviation is 0.084.The results of the CVI in Setúbal study area (Fig. 5b)

Table 5. Classification of Composite Vulnerability Index (CVI) to Setubal.

Standard deviation classes	Classification interval	Nominal classification
<–1 SD	0.287–0.356	Very low
[–1, –0.5 [SD	0.356–0.398	Low
[–0.5, +0.5 [SD	0.398–0.481	Moderate
[+0.5, +1 [SD	0.481–0.523	High
<+1 SD	0.5228–0.7028	Very high

show an increase of the vulnerability of the buildings, mainly in western and eastern zones, where the majority of buildings present a rating of "very high" vulnerability. Also noted is a large area in the central zone classified as "low" and "very low" CVI, which is a result of the positive social and economic characteristics of the population, expressed by the social vulnerability index. In this area de importance of the morphological component is still present, namely by the parameter that refers to the distance to the shoreline parameter, standing out essentially on the western and eastern zones with a stretch of high vulnerability around the shoreline.

Analyzing the cartographic output (Table 5), 13% is classified as "very high" composite vulnerability index, corresponding exclusively to buildings. With "high" CVI is classified 15% of the area, which corresponds to the band around the coastline, as well as some buildings. Most of the area (37%) has "moderate" composite index. The "low" (11%) and "very low" vulnerability (24%) CVI rates are presented on the central zone, but representing very few buildings.

5 CONCLUSIONS

The multidimensional approach presented in this article allowed the introduction of new parameters that differentiate it from previous methodologies. The analysis and evaluation of morphological, structural and social vulnerability components allows a comprehensive assessment of the studied areas, which is complemented by calculating the CVI that aggregates all the three vulnerability components. The CVI expresses differences between the two studied areas. In both areas the vulnerability varies from "very low" to "very high". However, there are differences between both. In the Figueira da Foz studied area the CVI is fundamentally influenced by the physical characteristics, namely the distance to the shoreline and the slope. Other parameter that emerge on the vulnerability analysis are the land use occupation characteristics, namely associated with

industrial and harbor activities. In Setúbal the CVI is influenced mainly by the socioeconomic characteristics and the urban fabric, namely by the existence of different types of buildings.

The deepen methodology used for vulnerability analysis made possible a better understanding of local characteristics, highlighting specific parameters or the combination of parameters. The Composite Vulnerability Index (CVI), resulting from structural, morphological and social variables allows to the decision makers a more adequate response. Some specific preparation, reduction and mitigation action or measures related with tsunami impact can be supported by this vulnerability composite analysis.

Monte Carlo simulation and Bayesian Evidence Synthesis

U. Sahlin & Y. Jiang
Lund University Centre of Environmental and Climate Research, Lund, Sweden

ABSTRACT: We can all agree that Monte Carlo simulation is a useful technique to propagate uncertainty through a quantitative model. Besides used for sensitivity analysis, the resulting uncertainty in the output of a Monte Carlo simulation can be used to inform decision making. If so, it must be acknowledged that this is a technique for simulation which needs to be complemented by a conceptual framework that assign a meaningful interpretation of uncertainty in output. Now, the interpretation differs with the chosen perspective of risk. Also, the chosen perspective of risk influences the way uncertainty ought to be treated and assigned to input variables in a Monte Carlo simulation. Bayesian Evidence Synthesis is a framework for model calibration, statistical inference of multiple sources of evidence and quantitative modelling to support decision making. In addition, Bayesian Evidence Synthesis provides means to take qualitative aspects of knowledge into account. Therefore, this framework can be used to conceptually frame a Monte Carlo simulation under, not only the Bayesian, but also a general perspective of risk.

1 INTRODUCTION

Monte Carlo simulation is a technique to propagate uncertainty in quantitative models, but that is all. It does not in itself provide any principles to integrate information or to treat uncertainty. Also, it does not adhere to a certain perspective on risk.

If used for sensitivity analysis, where the effects on outputs by varying inputs are in focus, the interpretation of the results of a Monte Carlo simulation does not depend on the interpretation assigned to its inputs and outputs. Sensitivity analysis is in this sense unproblematic.

The situation of concern is when Monte Carlo simulation is used to quantify uncertainty in quantities in order to inform decisions. It is important to keep in mind that a Monte Carlo simulation should not be associated to a particular framework. Introductory text books and common computer programs for Monte Carlo simulation describe methods to quantify uncertainty in input parameters and provide tools to describe the uncertainty in output. Vose (2008) present different statistical principles and argue for uncertainty being subjective, at the same time as the impression is that principles from classical statistical statistics are seen as the first choice. The tutorial for @RISK (Palisade Corporation, 2013) rightly present the quantification and interpretation of uncertainty in a neutral way e.g. by talking about Monte Carlo simulation as a technique "*to combine all the uncertainties you identify in your modeling situation*" leading to "*results presented in the form of probability distributions*". However, statements like "*you can explicitly include the uncertainty present in your estimates to generate results that show all possible outcomes*" gives the impression of an objective known value that is to be accurately described, and thereby a classical statistical view on uncertainty. A Monte Carlo simulation can be made in a simplistic way, e.g. when input parameters are assigned distributions either as the ones that describe data best or that best describes our belief in the possible range of values of that parameter. There is of course more advanced Monte Carlo simulation which more or less takes into account the issues considered here.

We repeat the point made by previous work (e.g. Aven and Kvaløy, 2002, Rettedal et al., 2000) that the use of a Monte Carlo simulation requires a conceptual framework which assigns an interpretation of the uncertainty in the output. An additional purpose of the conceptual framework is to carry the principles to integrate background knowledge into the assessment of risk. It is therefore important that the conceptual framework also is valid under the chosen perspective on risk. Different perspectives on risk can be divided into classical Bayesian, classical statistical and general (Aven, 2013). In an ideal case, a risk assessor decides which perspective of risk that is valid in a particular situation and supports the integration of knowledge into the assessment by principles consistent with that perspective on risk. The purpose of this paper is not to argue that Monte Carlo simulations often are done or framed in a faulty way, but to test the usefulness of a conceptual framework to guide quantification and interpretation of uncertainty. Instead of asking how to interpret uncertainty in a Monte Carlo simulation, it is more relevant to ask

whose interpretation to consider. Most would say it is the interpretation by the decision makers. In the manual for @RISK we read "*the decision-maker must interpret these probability distributions, and make a decision based on the interpretation*" (Palisade Corporation, 2013). It is then up to the assessor to quantify uncertainty in a way that adhere to the interpretation asked for by the decision maker. More emphasis on, and guidelines that adhere to, scientific principles to assess risk are important to strengthen the value of future quantitative assessments.

Some issues arise. Risk assessment should consider all available information. Thus, a desirable characteristic of a conceptual framework would be to handle multiple sources of evidence. A nice feature offered by Monte Carlo simulation is that it is possible to account for correlations between input parameters. In its simplest form, these correlations are assigned assuming a pair-wise linear association between parameters. However, there are other ways to capture the correlation between parameters based on the same sources of evidence. Some sources of uncertainty are missed when parameters are predictions from other models. For example the link to the source of evidence is lost when not considering uncertainty in parameters that have been predicted by statistical regression models.

Two possibly desirable characteristics of a conceptual framework to embrace a Monte Carlo simulation are to

I) give an interpretation of the output for the MC, and
II) provide principles to quantify uncertainty in input that combines with I.

Bayesian Evidence Synthesis (BES) is a possible framework which provides both an interpretation and principles for treating uncertainty in association to a quantitative assessment model applied with the purpose of inform decision making. The aims of this paper are i) to demonstrate how BES incorporates MC simulations and ii) to reflect how BES works under different perspectives on risk.

The paper is organized as follows. First, the different perspectives on risk are illustrated on a simplified risk assessment is used to illustrate the discussion. Then, we will describe Bayesian Evidence Synthesis and show how it can complement a Monte Carlo simulation. Then, we discuss the suitability of BES to give the conceptual framework for MC-simulation under different perspectives on risk. We end with some conclusions.

2 DIFFERENT PERSPECTIVES ON RISK

Risk is perceived in different ways. Aven (2013) distinguish three perspectives: the classical Bayesian, the classical statistical and the general risk perspectives. These perspectives differs in what the risk assessment is set out to measure, such as actual not yet observed states of a system (classical) or risk assessors subjective uncertainty in not yet observed states of a system (Bayesian and general). The perspectives of risk use different measures to quantify uncertainty, Bayesian probabilities in the Bayesian, relative frequencies in the classical, and any measure (probabilistic and non-probabilistic) in the general. Which perspective is appropriate depends on the context in which it is applied and the strength of the prevailing epistemic situation in the background knowledge. This strength can be judged on to what extent the background knowledge provide the bases to assign probabilities to quantify uncertainty (Aven, 2013).

2.1 *An example*

Below we discuss how a Monte Carlo simulation is used under these perspectives. The discussion is illustrated by a Population Viability Analysis (PVA) which is used in ecological risk assessment of species extinction. Risk is quantified as the probability of a population of a bird, mammal or fish to go extinct within 100 years. The system is defined by the state of the population, N_t, through the variable population size at time t. A population is extinct when N_t is zero, but it may very well be doomed to go extinct given enough small population size. Therefore it is customary to instead look at quasi-extinction, which occurs when the population size falls below an assigned critical threshold N_{qe}.

A PVA is conducted by simulating the population during 100 years and calculate the proportion of simulation runs in which N_t falls below N_{qe} at some point in time. In this example, population dynamics is assumed to follow the Ricker growth function with negative density dependence given by the following model

$$N_{t+1} = N_t \exp\left(\alpha\left[1 - \frac{N_t}{K}\right] + \varepsilon_t \right)$$

This means that population growth is negative when population size exceeds its carrying capacity K. The temporal variability in growth rate at carrying capacity is expressed by Gaussian noise with α and σ^2 as mean and variance, respectively. Given this model structure the knowledge about the population is provided by the parameters $\theta = \{\alpha, K, \sigma\}$ and system's initial state N_0.

The purpose with the PVA is to evaluate current risk of extinction and alternatives to manage this risk. Three management alternatives are compared:

A) do nothing, B) increase carrying capacity by 10%, and C) increase the current number of individuals by 10%.

A Monte Carlo simulation quantifies uncertainty in output given a state of the world according to the parameters in θ. Carrying capacity and population average intrinsic growth are assumed to be constant over time. A two dimensional Monte Carlo simulation is therefore appropriate. The inner loop considers the uncertainty arising from variability in growth rate given by the parameter σ and uncertainty in initial population size N_0. The output is the proportion of population going quasi-extinct, $p_{ext}|\theta$ (Fig. 1a). Thus, the final outcome of the assessment is a proportion or a relative frequency indicating to what extent the population is threatened to go extinct (Fig. 1b). Uncertainties in the parameters of the assessment are considered in the outer loop of the Monte Carlo simulation. The output is a sample of proportions taken over a sample of θ, showing the epistemic uncertainty in the assessed proportion of populations going extinct (Fig. 1c). Note that the output of the MC—simulation is a probability (relative frequency) and that this probability is uncertain, since it is a function of uncertain parameters. A common sensitivity analysis is to explore the role a change in a parameter have on the output (Fig. 2).

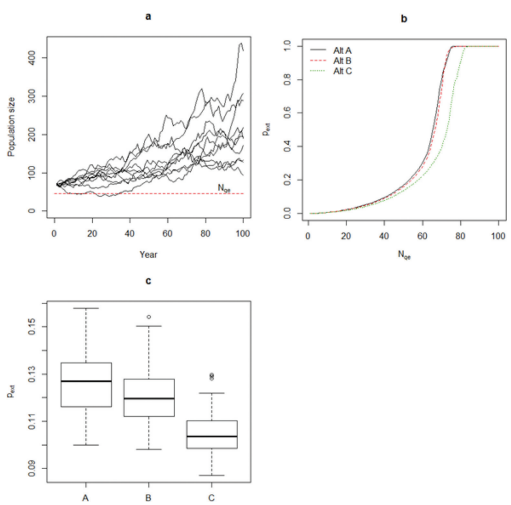

Figure 1. a) Monte Carlo simulations of population size for alternative A. The dash line indicates a suggested threshold of 45 individuals. b) Probability of quasi-extinction (p_{ext}) under different threshold (N_q) for alternative A, B and C with median parameters of MCMC, and c) Probability of quasi-extinction (p_{ext}) for alternative A, B and C for a given threshold ($N_q = 45$) with uncertainty in parameters shown as boxplots.

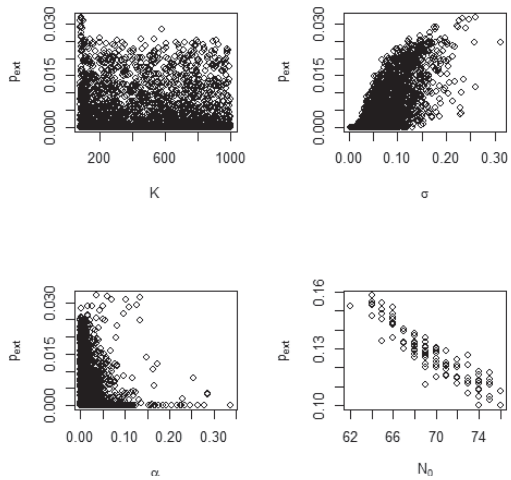

Figure 2. Sensitivity analysis plotting each input parameter to the estimate of risk based on that parameter. The reason p_{ext} differs for N_0 is that the sensitivity analysis is made on the outer instead of the inner two dimensional Monte Carlo loop.

2.2 *The interpretation of uncertainty in output*

Let us first describe some possible interpretations of the output uncertainty from a MC-simulation. A *classical statistical interpretation* of uncertainty in output is found by imagining the assessment as a simulation experiment mimicking a large number of repetitions of the system process that the assessment model is describing (Vose, 2008). An output variable takes different values/states according to a relative frequency. Increasing the number of repetitions will asymptotically approach the probability distribution of the outcome of the system process. This is a possible interpretation of the quasi-extinction probability p_{ext} of the inner loop in the PVA example (Fig. 1b). Those skeptical to this approach argue that that it is not meaningful to talk about a relative frequency when the system process is extremely hard to repeat in the real world, which makes it difficult to talk about true asymptotic probabilities.

Another interpretation of MC output is found when the seeing the simulation experiment as performed under a design corresponding to the assessor's degree of believes in input parameters of the assessment model. Under this *classical Bayesian interpretation*, uncertainty in output is described using knowledge-based probability conditioned on the background knowledge (Aven, 2013).

A separation of variability and knowledge-based uncertainty is important to properly propagate uncertainty in an assessment. There are different ways to reach the knowledge-based probabilities

describing the output of the assessment. One is to, as in the PVA example, use a Monte Carlo simulation that separate variability and knowledge-based uncertainty. If so, the uncertainty in the outcome is subjective probabilities on relative frequencies. The result is a mixture of Bayesian and classical probabilities and is referred to as uncertainty analysis on the classical approach or the *probability of frequency interpretation* (Nilsen and Aven, 2003). This is a possible interpretation of the uncertainty in the quasi-extinction probability resulting from the outer loop of the Monte Carlo simulation in the PVA example (Fig. 1c).

However, the resulting uncertainty consists of a mixture of probabilities (knowledge-based and relative frequencies). Emphasis on one kind of uncertainty in the assessment outcome can be easier in a decision-making context (Aven and Kvaløy, 2002, Rettedal et al., 2000). Variability is relevant for understanding, but of less interest to debate decision alternatives. To "get rid of" variability one can implement it in as process models and parameters expressing stochastic uncertainty at different levels in the assessment. The variability that left unexplained can be treated as a source of knowledge-based uncertainty. Uncertainty in output under this *fully Bayesian interpretation* is simply the assessor's subjective degree of belief. This idea behind this is to adopt a predictive Bayesian approach with focus on inference of observable future system states.

To reach a fully Bayesian interpretation, it may be necessary to reformulate what is the output from the assessment. Returning to the PVA-example there are two options. One option is to show the knowledge-based uncertainty in the system states, here population size, over time. This brings a lot of information that needs to be evaluated further to be of value to the decision maker. Another option is to view the Monte Carlo simulation as a simulation experiment with the purpose to test statements that are important for the decision maker. The statement could for example be if the probability of quasi-extinction is unacceptably high. Let us refer to this as the event A. Regarding 5% as the limit for what is acceptable, our uncertainty about A is $P(A) = P(p_{ext} > 0.05)$. This probability summarizes all knowledge-based uncertainty into a single probability which can easily be communicated to the decision maker.

Some problems with adding the quantification of uncertainty in A as the last step of the assessment are that no consideration is taken to the decision maker's aversion to knowledge-based uncertainty and it can be sensitive to the chosen thresholds in the assessment. Further, the simulation experiment is made within the simplification and assumptions upon which the assessment model is built.

We note that the uncertainty in output from a MC-simulation of an assessment model heavily relies on the assessment model being viewed as appropriate for the application. Model averaging techniques or ensemble modelling can be used to address uncertainty associated to the assessment model. The assessment is then made under a sample of possible assessment models weighted according to our confidence in them being a true representation of the system process.

Even if uncertainty in output is interpreted as subjective degree of belief, it may still be meaningful to talk about uncertainty in this probability. Inaccuracies of the assessment fall back on the limitations of the assessor's knowledge and deliberately made simplifications (Nilsen and Aven, 2003). The former type can be seen as uncertainty in the substance of knowledge. The latter is an example of a wider view on uncertainty associated to the procedures of problem framing and knowledge production, and the sources dependent on the context in which the assessment is made (Maxim and van der Sluijs, 2011). When inaccuracies in the underlying models are high, the bases to assign Bayesian knowledge-based probabilities may be weakened. The added uncertainty that follow from a varying strength of knowledge can refer to different things (Aven 2013), can be seen as qualitative and may or may not be mixed up with probabilities in the Bayesian framework. The general perspective of risk allows different kinds of uncertainties to enter the assessment and allows any kind of quantification.

A classical statistical interpretation of the output from a MC-simulation is suitable when there is enough data to support the assessment (Rettedal et al., 2000). It is not settled to what extent "enough data" implies the existence of empirical data associated to the Monte Carlo simulations inputs and outputs, for which a statistical model can be fitted. If this holds, the assessment model coincides with a statistical model, and the Monte Carlo simulation makes predictions from this model. If no observations for the output have been made, the Monte Carlo simulation can be seen as a simulation experiment. The purpose of such simulation experiment can be to derive relative frequencies on future states varying the input parameters expressing control variables.

The Bayesian and general perspectives on risk ask for interpretations of output uncertainty as knowledge-bases subjective degree of belief, without and with additional assessment of the strength of knowledge, respectively.

2.3 *The input parameters*

Now, we turn to the quantification of uncertainty in input parameters. First, we realize that

the input parameters for which a Monte Carlo simulation draw samples consists of actual parameters (expressing knowledge of the real world) and state variables, describing the system that is under assessment. In some way or another, a MC involves some kind of control measures, which can be implemented as explicit control variables or by changing the levels on parameters or state variables. In the PVA example, control was implemented by changing the parameter K or the initial state of the system. The mixture of parameters, state- and control variables, makes it difficult to generally talk about the quantification of uncertainty in input parameters in a conceptual framework.

The parameters in the PVA example consist of actual parameters $\theta = \{\alpha, K, \sigma\}$ and a state variable N_0. The assessor is uncertain of the actual size of the current population, and describes this uncertainty as a probability distribution over possible values on N_0. To get informed the assessor can request observations from the current population and use a probability model to arrive at the uncertainty in the size of the population. The probability model of the observation process also has associated parameters, let us call them π. The parameters in θ and π can be fitted from time-series on population sizes using a suitable probability model for the system process.

The parameterizations of π and θ can be made based on both classical statistical and Bayesian principles of inference. The major difference between these two is that the Bayesian framework treat parameters as random variables, while the classical statistical regard them as fixed. Probabilities under the Bayesian framework are subjective and express the assessor's degree of belief. Bayesian inference follows by assigning prior distribution to π and θ expressing one's state of knowledge before observing the data. Bayes rule is then applied to update the beliefs into posterior distribution.

In the classical statistical framework uncertainty in parameters (which are perceived as having a true value) is expressed as relative frequencies resulting from drawing random samples from an underlying population. Some argue for a classical statistical approach since it is seen as objective, and objectivity is a valued characteristic for something based on science. However, risk assessment is seldom objective. It can for example be difficult to motivate a mixture of parameters with uncertainty derived by a classical statistical approach and parameters with uncertainty based on expert judgment.

There are situations where the classical and Bayesian inference result in similar probability distributions. It can be argued that classical statistical methods are easier to use, but that can be dealt with by statistical training focusing on the most widely applicable principles of inference, namely the Bayesian. In his widely used book introducing Monte Carlo simulations Vose (2008) mention both classical and Bayesian principles for inference. It is interesting to note that the presentation of the Bayesian methods discuss the consideration of how data has been observed and state of knowledge: "The amount of information contained in data is dependent on two things: (1) the manner in which the data were collected (observation process) and (2) the state of our knowledge prior to observing the data and the degree to which it compare with the likelihood function" (Vose, 2008). This is not the case in the classical statistics. In fact, the classical statistical framework to quantify uncertainty in input parameters is only valid when there is lot of data on everything. Someone faithful to the classical framework would regard everything not derived from data as assumptions.

In a risk assessment situation, the Bayesian framework is the most suitable to quantify uncertainty in input parameters. It allows for a gradual change between situations with a lot of data, in which Bayesian inference could (if the models are the same) show similar results as the classical statistical, to situations based on expert judgment. Bayesian principles for inference play an important role under a general perspective risk, where a decreasing strength in background knowledge asks for an increased use of alternative probabilistic and non-probabilistic measures.

3 BAYESIAN EVIDENCE SYNTHESIS

3.1 *Description*

Evidence synthesis is a term used for synthesis of results from diverse sources and covers a wide range of analysis approaches (Sutton and Abrams, 2001). Bayesian Evidence Synthesis (here denoted as BES) is a statistical framework for explicitly modeling several related and connected sources of data, in which uncertainty in model parameters are incorporated (Jackson et al., 2013). BES can be seen as a complex meta-analysis (Sutton and Abrams, 2001), where complex means to consider multiple effects from an intervention. Classical meta-analyses are usually based on studies that directly have observed the effect of an intervention. A broader view on meta-analyses allows for studies on effects on a lower level which are combined with quantitative modelling to assess the effect of an intervention on a higher level. In this view, a risk assessment can be seen as a meta-analysis (Linkov et al., 2009). Opening up for a quantitative assessment (or complex computer) model to "measure" effects, makes it possible to synthesize evidence for effects which are difficult, if at all, to empirically observe. In the PVA example, there is for example no possibility of

making a randomized controlled experiment testing which management interventions that best would reduce the risk of that population going extinct. It would be unethical to perform an experiment where populations deliberately are kept at high risk, the results from such experiment would take 100 years before being known, and most importantly, there is only one population to study.

A BES is formulated as a cost-efficiency problem that uses a quantitative system model to evaluate chosen measures of cost-efficiency. Based on the state of knowledge on parameters, the quantitative system model is simulated to produce a distribution for model outputs. The system model depends on one or several parameters, which relate to phenomenon in the real world (Fig. 3). In order to avoid confusion with other types of models in the framework, we refer to the quantitative system model (or complex computer model) as a simulator. The parameters of the real world may or may not be observed directly. However, their influence on what have been, or can be, observed are modelled. In this way empirical observations contribute to evidence. A strong link between the quantitative system model and the models for informing parameters makes BES a methodological framework that in a transparent and defendable way enables conclusions to be made based on available evidence to support decision-making.

Jackson et al. (2013) summarize the steps of BES as follows:

1. Build a Directed Acyclic Graph (DAG) according to the underlying causal relationships,
2. Compute posterior probability distributions,
3. Propagate parameter uncertainty through the model to generate uncertainty distribution for the results required for policy making.

In this way "the distributions of the results give appropriate weights to each parameter value, according to how much evidence there is in the data, thus providing a natural way to calibrate the model against the data".

In our view, the advantage with BES is that it provides a generic conceptual framework for statistical inference with the purpose to inform quantitative model and provide a transparent link to empirical data. This statistical framework applies hierarchical (or latent variable) modelling and distinguish between observation and system processes (Fig. 3). System processes are needed to understand where empirical observations come from. The assessment model (simulator) consists of similar or different system processes as those needed to generate the evidence.

It is acknowledged that observations are associated with errors and show patterns that depend on the way they have been observed. Observation processes are described to formulate the appropriate probability models to allow inference from data. In the PVA example, it may not be possible to completely observe the population since individuals move around and can be difficult to find in their environment. The observation process can be modelled as a Binomial-Count process (Kéry and Schaub, 2012). An observation of Y individuals is the result of a draw from a Binomial distribution of in total N possible individuals in the population and a detection probability p (Fig. 4). The detection

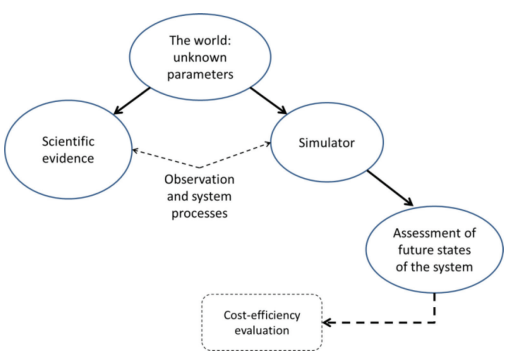

Figure 3. A conceptual graph of Bayesian Evidence Synthesis (modified from Spiegelhalter and Best 2003).

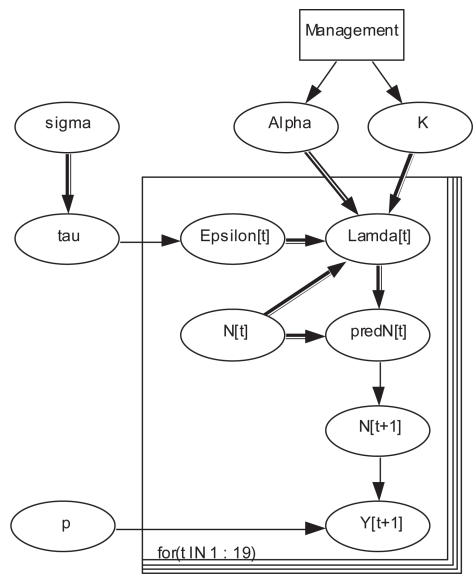

Figure 4. The left hand side of the Bayesian Evidence Synthesis for the PVA example implemented in OpenBUGS showing the links between parameters $\theta = \{\alpha, K, \sigma\}$ and system state variable N_t and between the detection probability p and the observation variable Y_t.

probability can be updated by the Bayesian model or assigned from expert's judgment of the quality of the observation process. In this way, relevant sources of variability and uncertainty are taken into account in a structured way.

Parameterization is seen as calibration of the simulator. Sampling from the posterior of parameters is made using Markov Chain Monte Carlo simulation. The sample can be used directly in the Monte Carlo simulation. Here we ran OpenBUGS (Lunn et al., 2009) from R (R Development Core Team, 2008), which makes it possible to parameterize the model and run the simulator in the R environment.

3.2 *Its use in risk assessment*

Bayesian Evidence Synthesis brings together several methodologies, which more or less are used by risk assessors today. It has its roots in decision analysis within health assessments (Jackson et al., 2013). It is similar to evidence-informed causal modelling and Bayesian Belief Networks (Cox, 2012), and is, in that sense, not a new method. A search on Web-of-Science Core Collection April 4 2014 using the search terms "Bayesian evidence synthesis" generated 237 hits, the first starting from 1995. Adding AND (risk OR safety) reduced the number of hits to 182. The number of publications has grown with time, but not so much for those using the words "risk OR safety" (Fig. 5). The journal of Medical Decision Making had a special issue on Evidence Synthesis 2013. We looked into the papers in three common risk and safety journals. The only paper in the Journal of Risk Analysis using the word "Bayesian Evidence Synthesis" was published 2013. No publication so far in Journal of Risk Research or Safety Science. The search results from this very simple overview indicate that Bayesian Evidence Synthesis is receiving an increasing attention in quantitative risk assessment. The results are limited to peer-reviewed literature only, and perhaps a different picture had been found if searching through actual reports of risk assessments in the gray literature.

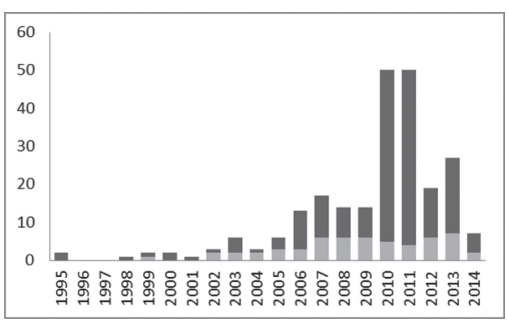

Figure 5. Number of publications related to Bayesian Evidence Synthesis. The bars represent total number of publications with the topic of Bayesian Evidence Synthesis. The light part of the bars represents the number of publications in which the word risk or safety was used as well.

3.3 *Bayesian Evidence Synthesis as a framework for Monte Carlo simulation*

BES has been designed to provide principles for treating uncertainty in association to a quantitative assessment model applied with the purpose of inform decision making. Therefore BES can be a conceptual framework to incorporate MC-simulation, which is the procedure on the right hand side in Figure 3.

A difference between BES and text book type of MC-simulation is how the sample for the MC-simulation is generated. A BES samples from a joint posterior distribution. Thus, there is no shared step where probability distributions of the input parameters of the assessment models must be explicitly specified. Instead, specification occurs at different levels between the actual input parameter and data. Complexity and errors in data is acknowledged by using hierarchical and latent variable modelling to distinguish between actual states and the observations of them. When no data is available, uncertainty of an input parameter is given as priors. Instead of assigning a parameter for an assumed linear correlation, this structure open up for sampling correlative relationships between input parameters informed by the same source of evidence. The text book type of MC-simulation to specify uncertainty in input parameters is easier compared to that of BES, but this procedure is more prone to break the link between underlying data and the assessment output.

A possible critique against BES is that it is a framework to analyze decisions, but not risk. Risk paradigms differ in to what extent risk management is allowed to be part of risk assessment. In some fields management is complex involving management strategies that adapt to the development of the system. If so, decisions and risk is intertwined. An assessment of risk to support decision making come as explicit assessments of risk or are involved in assessments of the impact of risk management interventions on consequences of importance (Cox, 2012). In the former the output of the assessment is quantified observables referring to events and consequences or both (Aven and Eidesen, 2007). The output in the later is quantified efficiency of management interventions. Focus on the efficiency of interventions is common in applications where

consideration of multiple management objectives and conflicting values needs to be taken into account. This is being made without diminishing the importance of cautious management, which is implemented by evaluating efficiency under constraints given by thresholds of acceptance and safety margins on risk. Thus, framing risk assessment in a framework for decision analysis ought not to be a problem.

4 RESULTS

4.1 *Under a Bayesian perspective on risk*

The uncertainty brought by BES is described as weights which have a direct link to underlying sources of evidence. BES presents these weights as the strength of evidence for having a certain output. These weights are interpreted as Bayesian subjective probabilities.

The final outcome of interest is cost-efficiency which summarizes the performances and open up for a comparison of alternative decision alternatives. Thus, focus is more predictive (lower node in Fig. 3) than parametric (upper node in Fig. 3). This does not mean that the final output is a single probability $P(A)$ (see section 2.2). The propagated predictive posteriors of cost-efficiency show the precision, and a narrow distribution can be seen as a qualitatively stronger weight. Our conclusion is that BES supports a Bayesian perspective on risk.

4.2 *Under a classical statistical perspective on risk*

A classical statistical perspective is supported by BES when (i) one can motivate the existence of a statistical model of the processes captured by the simulator and (ii) there is a lot of data to support all parameters in the Monte Carlo simulation. The first condition happens when observations have been, or can (within reasonable time) be made, on similar events that are to be assessed. This would mean that the right hand side in Figure 3 is included in the left hand side. If the second condition is met, classical statistical frequentistic and Bayesian principles of inference result in precise and similar parameters values. Therefore the difference in quantified uncertainty in output, under these two principles, can be small and the BES could be seen as supporting a classical statistical approach.

However, the last condition is difficult to achieve, and most often expert judgments are needed to inform a MC-simulation. Therefore, it is only in exceptional cases when a classical statistical perspective on risk is motivated over a Bayesian treatment of uncertainty. We conclude that BES can support a classical statistical perspective on risk in those rare situations when this is warranted.

4.3 *Under a general perspective on risk*

A risk assessment is subjective, not only in the knowledge put in, but also in the decision taken by the assessor on what and how to make the assessment. The epistemic situation in background knowledge plays a role for what is possible to do. Quality can be considered by evaluating the influence on risk on deviations from the original assessment (Aven, 2013).

We find that BES can be a conceptual framework under a general perspective of risk in which the Bayesian perspective is seen as the base-line. A general perspective, based on Bayesian principles, can be made by allowing for judgment of quality into the quantification of uncertainty. The outcome of a MC-simulation is in fact several outcomes representing different aspects of quality that is taken into account.

The possibility to include judgments of quality is a great advantage with the principles of BES. This is possible since a BES is designed as a framework to combine multiple source of evidence for meta-analysis. Also, new kind of sensitivity analysis can be made. Spiegelhalter and Best (2003) consider the influence of expert judged qualities in three data sources through the observation process models.

Going back to the PVA example, we demonstrate a sensitivity analysis towards the sources of evidence. Consider there are two time-series with observations of the population. One time series is long and one is short. Inference based on the longer is, everything else equal, evidence of higher quality. A BES can be formulated to incorporate both time series by allowing for data-set specific observation processes, here determined by the detection probabilities (Fig. 6). The longer time-series will have a stronger influence on final weights, since it contribute to more data points to the likelihood. This influence can be controlled by assigning strong priors on the detection rates, p_1 and p_2. It can also be made by assuming that one is better than the other. Bayesian MCMC sampling from the posterior will depend on the assumptions made on quality, and the kind of probabilities that come out may be different than the ones where quality is not imposed to the model. Uncertainty is not only presented by probability but also as a sensitivity analysis to aspects of quality. What if the decision makers are sensitive to the choice of time-series in the PVA? The sensitivity of this decision on the cost-efficiency can be evaluated by running the MCMC on a BES based on both data sets, and by removing one data set at

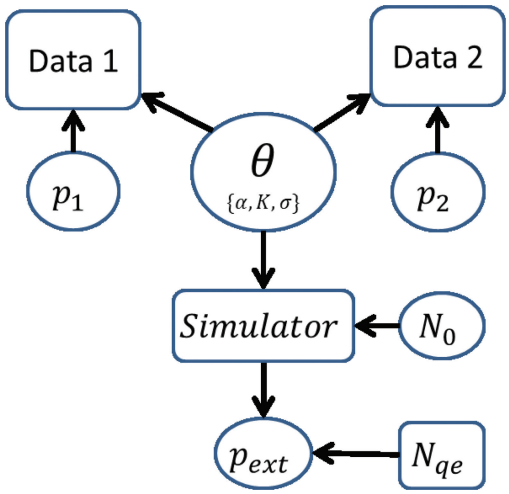

Figure 6. The Bayesian Evidence Synthesis based on two sources of evidence to inform the parameters θ.

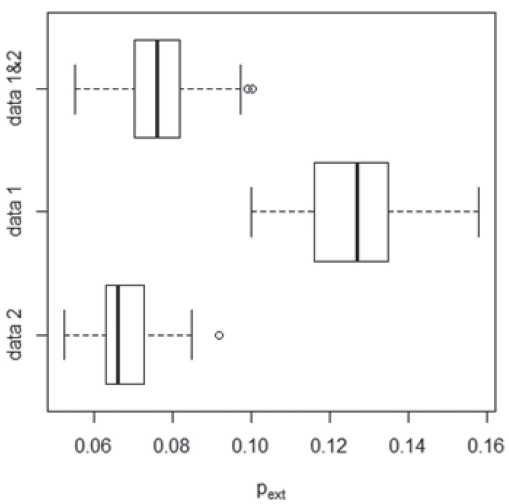

Figure 7. Posterior distributions of quasi-extinction risk informed by two data sets, showing the influence of removing one data set at a time.

a time (Fig. 7). In this example, the risk of extinction was sensitivity to the data set that informed the MC-simulation.

5 DISCUSSION

Here we discuss principles of parametric and predictive inference and views on probability in risk and decision analysis perspectives, with respect to the use of simulations from quantitative model to inform decision making. A difficulty with this discussion is that the term *parameter* and *probability* have different meanings throughout the steps or levels of the assessment process. For example, let X be an input to an assessment model. A probability model is set up to quantify uncertainty in X. This probability model has associated parameters. Under Bayesian inference these parameters are uncertain. In parametric inference the focus is on the uncertainty in these parameters. In predictive inference the focus is on the resulting uncertainty in predictions of X. Here the focus is on uncertainty in the output of an assessment model in which X is an input parameter, thus adding an additional step of prediction. Bayesian probabilities can be used in the inference step and decision analysis, while relative frequencies can exist in the probability models supporting inference or assessment models.

A cause of confusion is the ambiguity of what actually constitute output in a specific Monte Carlo simulation. Again referring to the PVA example, what we use as output could be the states of the system, N_t, the relative frequencies of undesired events, p_{ext}, or the probability that this frequency is unacceptable high $P(A)$. The interpretation of uncertainty may depend on at which of these levels the uncertainty to be interpreted lie.

This discussion uses a typical MC-simulation to illustrate the need of emphasizing foundational issues how to perceive risk and assure quality of the assessment procedure. Students in fields relying on the use of quantitative assessments, such as risk, reliability or system analysis, learn about MC-simulation and different ways to quantitatively describe uncertainty. It is important not to end there, but give the students, and future quantitative assessors, the ability to fully understand what this uncertainty represents and on what scientific principles it can be assessed. We would like to point at Bayesian Evidence Synthesis as a suitable framework to teach predictive statistical principles involving simulations from a computer model. BES is useful both in scientific research and risk assessment and can therefore close the gap between these two highly important processes of knowledge production.

ACKNOWLEDGEMENTS

Amendments of the existing guidance on PSA application to nuclear power plants in Germany

H.P. Berg & M. Krauß
Bundesamt für Strahlenschutz, Salzgitter, Germany

M. Röwekamp
Gesellschaft für Anlagen- und Reaktorsicherheit (GRS), Cologne, Germany

ABSTRACT: The German nuclear regulation has been significantly enhanced by the "Safety Requirements for Nuclear Power Plants" issued in January 2013 and the corresponding "Interpretation of the Safety Requirements for Nuclear Power Plants" issued in December 2013. These enhancements also concern probabilistic safety analyses as supplementary tool for assessing nuclear power plants´ safety. The most recent PSA activities in the frame of Periodic Safety Reviews (PSR) focus on extending Level 1 PSA scope more explicitly to fuel damage states and further improvements with respect to Low Power and Shutdown (LPSD) plant operational states including internal hazards, in particular fire. Moreover, a more complete and systematic consideration of external hazards is intended for full power states. These improvements are in line with recent international activities.

The material for the update of PSA methods and data in the frame of PSR has already been provided in order to issue the intended supplement to the existing documents in 2014.

While probabilistic assessment was mainly used in Germany in the frame of PSR in the past, PSA applications shall be further extended to regulatory oversight activities in the future. The above mentioned Safety Requirements define relative probabilistic criteria to be applied for plant or organizational modifications applied by the licensee or for evaluating events or phenomena which may have a non-negligible effect on PSA results. For these applications a short document is in preparation as well.

1 INTRODUCTION

In general, the nuclear regulatory framework in Germany is a deterministic one with very detailed and comprehensive nuclear requirements, guidelines and recommendations, safety standards and rules incorporated in a corresponding legal hierarchical structure.

In the past, the safety concept of Nuclear Power Plants (NPPs) as well as licensing decisions by the competent authorities and their experts in Germany were mainly based on deterministic principles such as prevention or control of abnormal plant operational conditions and incidents by technical means to ensure high reliability. In the meantime, Probabilistic Safety Analyses (PSA) are mainly applied in the frame of periodic safety reviews and shall supplement deterministic safety demonstrations to verify the balance of the plant design related to safety.

The German nuclear regulatory framework has recently been significantly enhanced promulgating state-of-the-art "Safety Requirements for Nuclear Power Plants" issued by the Federal Ministry of the Environment, Nature Conservation and Reactor Safety (BMU 2013a and 2013b). These enhancements also concern safety demonstrations by deterministic as well as probabilistic safety assessment in more detail.

In this context, PSA shall also supplement deterministic safety demonstrations to assess the safety significance of modifications of Structures, Systems and Components (SSC), measures or procedures as well as of findings that have become known from safety-relevant events or phenomena that have occurred and which can be applied to the nuclear power plants in Germany that are referred to in the scope of application of (BMU 2013a), for which a significant influence on the results of PSA can be expected.

Compared with the unchanged conditions of the plant, modifications of measures, equipment or the operating mode of the plant shall neither result in an increase of the average Core Damage Frequency (CDF) and/or the average frequency of large and early releases (LRF/LERF), for power operation nor for low power and shutdown states, considering all plant internal events as well as all

internal and external hazards including extremely rare man made ones.

Hence, the new German safety requirements contain an implicit definition of quantitative safety criteria: Mean CDF and LERF of full scope PSA Level 1 and 2, respectively, must not increase due to a planned plant modification. However, no absolute value is given, by which the current risk of the plant can be assessed to be acceptable.

The CDF values have been calculated in the frame of the comprehensive (periodic) safety reviews. The results of the latest safety review for the respective NPP are the basis for the comparison in case of modifications.

The fundamental boundary conditions for performing PSA including requirements with respect to their documentation are provided in (BMU 2005). The safety requirements for NPPs in (BMU 2013a) further require that state-of-the-art methods, models and data have to be applied in the frame of PSA.

As far as possible plant specific data have to be applied. If no suitable plant specific data are available from the operating experience, generic data may be used if justified. Such data are provided for common cause failures and fire protection features in (FAK 2005b).

2 UPDATE OF TECHNICAL DOCUMENTS FOR APPLYING PSA IN THE FRAME OF SAFETY REVIEWS

A first set of guidelines and supplementary technical documents providing guidance on the contents and performance of a Periodic Safety Review (PSR), have been issued in 1997.

The PSR, since 2002 called Safety Reviews (SR) for NPPs in Germany, have to be performed at least every ten years. The obligation to submit the results of a SR and evaluation shall not apply if the licensee gives a binding declaration to the regulatory body at the Federal State level stating that operation of the installation will be permanently discontinued latest three years after the dates specified in the German Atomic Energy Act (2013).

For PSA, a revised guideline (BMU 2005) and its corresponding technical documents on PSA methods (FAK 2005a) and data (FAK 2005b) have been developed extending the application area to external hazards for Level 1 PSA for full power operation, to low power and shutdown Level 1 PSA for plant internal initiating events and to Level 2 PSA for plant internal initiating events during power operation.

As a result of the German decision to phase out of nuclear energy until 2022, only two or three SRs remain obligatory to be performed for German NPPs. Therefore, updating the PSA Guideline is no longer be continued and the originally planned comprehensive update of (FAK 2005a) and (FAK 2005b) will not be elaborated anymore.

However, various activities for updating specific topics regarding probabilistic safety analyses have been performed since 2008, in particular with respect to methods with respect to human reliability, external hazards, Level 1 low power and shutdown PSA and some aspects of Level 2 PSA as well as with respect to data on human reliability, common cause failures and reliability of active fire protection features.

It is intended to issue the updated material on methods and data for PSA applications in the frame of SR as a supplementary document in 2014.

In the following, the amendments with respect to Level 1 PSA are presented in more detail.

2.1 *Aspects regarding Level 1 PSA*

2.1.1 *Human reliability*

For performing Human Reliability Analysis (HRA) a specific methodology is required. Different methods are available that can be used depending on the purpose of the analysis and the scope of the methodological approach.

The update of the section on HRA in particular considers issues such as:

- Consistent integration of findings and results on HRA from operational experience,
- Identification of potential vulnerabilities by more detailed modeling,
- Consideration of component failures or system functions representing external contextual factors in the development of a dynamic event flow path with effects on decision making,
- Identification of fundamentally different types of errors such as faulty human actions due to incorrect diagnoses and decisions,
- Errors of commission leading to damage increasing actions.

Moreover, the description of the task, the qualitative analysis and the evaluation of human reliability has been extended.

It is recommended that a detailed human reliability analysis should be applied using advanced methodological approaches reflecting why people act in a certain manner and what action triggers the human error.

In several cases, methods such as THERP (Swain & Guttmann 1983) are applicable, in other cases they are not. Therefore, in the last decade a number of advanced methods and techniques has been developed and according to the objective of the HRA applied to some extent.

In the revised section on HRA "profiles" for several HRA methods are provided, because there are more than one method available being applicable for all kind of questions. These profiles contain a brief description of the underlying procedures of these methods and address the areas of their application to date, their capabilities and limitations as well as cost-benefit aspects.

2.1.2 *External hazards*

Originally, a more comprehensive update of the section on external hazards was planned. To date, the supplementary document, however, will focus on seismic events and external flooding.

Relating to robustness investigations resulting from the stress tests in Germany performed after the Fukushima Dai-ichi reactor accidents, the main emphasis will be on earthquakes and external flooding including a graded approach with respect to flooding events (scope of analysis), possible "cliff-edge effects", checking the parameters currently assumed as well as their superposition and to improve the determination of failure probabilities of permanent or temporary flood protection measures. Moreover, extreme weather conditions are to be addressed. One major activity is the introduction of a procedure to identify the relevant SSSs in case of an earthquake and the benefits of plant walk-downs in this context.

2.1.3 *Level 1 low power and shutdown PSA*

The overall goals of the planned update of the section on low power and shutdown Level 1 PSA in (FAK 2005a) are to provide more precise terms and definitions with particular reference to the different phases of low power and shutdown states in German nuclear power plants (with Boiling Water Reactor (BWR) or Pressurized Water Reactor (PWR)) as well as an adaptation and clarification of the examples for the analyses provided in the document.

Clarification has been given on the specification of operating conditions for Low Power and Shutdown (LPSD) states. A precise definition and identification of initiating events with special consideration of erroneous human actions before such an event occurred has been provided. In addition, a clear definition of the end states of event sequences during low power and shutdown is available. Last not least, Fire PSA methods have been adapted to these Plant Operational States (POS).

Low power and shutdown plant operational states are characterized by several phases, during which either different initiating events can occur or the same initiating events have to be controlled under highly different conditions. The specification of the phases results from the plant specific conditions for processes to take place, together with the current status of the physical parameters during these phases. For LPSD phases, the physical and technical conditions as well as the planned maintenance related and organizational measures may still vary so that a further subdivision with respect to plant operating conditions may be required.

The following definition of an uncontrolled end states has been provided: "Fuel damage states during low power and shutdown operation are characterized by a significant release of radionuclides that may occur due to a loss of fuel cooling and the subsequent heating of the fuel rods or by mechanical damage to the fuel rod cladding. Uncontrolled end states may also result from a loss of reactivity control." Thus, for low power and shutdown states fuel damage states have to be considered instead of core damage states.

Moreover, guidance for performing Fire PSA for LPSD plant operational states is provided and described below.

For each phase during low power and shutdown those compartments or plant areas have to be identified, where fire events may inadmissibly impair items important to safety. In particular, the following changes and enhancements with respect to the input data have to be considered:

- The total compartment inventory of Systems, Structures and Components (SSC) including cables has to be associated to POS in accordance with their safety functions to one of the following three classes (1—no safety relevance, 2—basic event in the PSA plant model, 3—failure may contribute to an initiating event).
- Depending on the POS, changes of the status with regard to fire protection in certain compartments are possible (e.g. BWR containment no longer filled with inert gas). These changes as well as well as changes with respect to fire barriers, amount and distribution of fire loads, effects of maintenance and repair work, changes in the number of persons present and the duration of their presence in certain fire compartments have to be considered for Fire PSA.
- In case of a fire induced loss of the entire compartment inventory, the list of potential initiating events should be adapted and, if necessary, further completed depending on the respective POS.
- For those compartments and/or plant areas identified to be significant within the screening, detailed analyses have to be carried covering the following three analytical steps:
  - Fire occurrence frequency determination:
    For that purpose, the methods in place for full power operational states can be applied, taking into account the changes in fire safety according to the conditions during LPSD.

– Fire damage frequency calculation:
  The methods for full power operation (fire specific event tree analysis) can be applied.
– Fuel damage frequency estimation:
  For this calculation the event tree analysis of the respective initiating event from LPSD PSA can be used. It has to be checked, if those human actions needed for control of initiating events still can be performed in case of fire.

2.2 *Update of data for PSA using German operational experience*

2.2.1 *Data for HRA*

In addition to the activities for facilitating enhanced methods and approaches for PSA, investigations are needed for providing additional or updating data in the areas of human reliability and reliability of fire protection features.

The first activity is aiming to provide additional data for Human Reliability Analysis (HRA) when applying the THERP method. Currently, the data used for HRA in the context of PSA studies mainly stems from the THERP database (Swain & Guttmann 1983), which consists of tables with more than 100 Human Error Probabilities (HEP) for a variety of tasks important to nuclear power plant operation. A persistent problem is the question of whether this generic data is compatible with the operational practice of the power plant in question. Moreover, the amount of data available is insufficient to cover all needs. Therefore, in order to both validate and extend the THERP database, the Federal Ministry for the Environment, Nature Conservation and Nuclear Safety sponsored two research projects to gather human reliability data from the operational experience of German nuclear power plants. For this purpose, a method utilizing the German licensee event reporting system has been developed, which allows, for certain tasks with specific attributes, to determine the number of times a specified task was performed in the past, as well as the number of errors that occurred. Thus, a statistical procedure allows obtaining HEP estimates from these data.

The first project, which ended in 2010, contributed altogether 37 HEP estimates. In all except three cases an agreement within the uncertainty bounds with the THERP database was found; moreover, 21 HEP estimates for which THERP provides no data was contributed.

The methods and results of this project are reported in (Preischl & Hellmich 2013). The second project, which ended in early 2013, continued the activities started in the first one, and moreover contributed human reliability data obtained from tasks which have remained below the reporting threshold of the event reporting system, i.e. they have not yet produced a reportable event, but unambiguously would result in a reportable one in case of an error.

2.2.2 *Data regarding common cause failures*

In (FAK 2005a) methods for quantification of Common Cause Failures (CCF) according to the state-of-the-art at that time are described and generic CCF probabilities for 21 different component types (such as different types of valves, batteries, diesel generators, heat exchangers) are listed (FAK 2005b) based on the operating experience available at this time. This list included all types of components for the time from the start of operation of the German plants until June 15, 1985. For some types of components data of other operating times were available, the most recent ones up to 1998.

However, there was not sufficient operating experience from German plants available for all types of components. Therefore, data from the international operating experience had to be included. These data were mainly based on reports of the IAEA/NEA Incident Reporting System.

In the meantime, the operational experience could be significantly expanded. The operational experience of the operating 17 nuclear power plants in Germany for the period up to the end of December 2010 has been completely evaluated. Since the amount of data has increased the use of foreign operating experience in the determination of CCF probabilities is no longer necessary.

During plant operation components were frequently modified, based on operating experience, new knowledge and new technical developments.

In addition, operational procedures were changed and additional monitoring methods implemented. Therefore, for most component types it is possible to focus only on the operating experience beyond 1990.

2.2.3 *Data regarding reliability of fire protection features*

In the context of modeling plant specific fire event and fault trees, reliability data with regard to fire protections means are required. In (FAK 2005b) technical reliability data for various active fire protection features have been provided resulting from plant specific analyses of the operating experience from different NPPs.

In order to update the already existing reliability data (in particular, failure rates per hours of plant operation) as well as to extend the database covering an additional plant unit the following components and systems installed in six nuclear power plant units at five plant sites:

– Fire detection systems with the corresponding main fire alarm panels, subsidiary fire alarm

boards, detection drawers, detection lines/groups as well as automatic and manual fire detectors,
- Fire dampers and smoke extraction dampers in ventilation ducts with different actuation mechanisms (thermally by fusible link or remote controlled by typically electro-mechanical or pneumatic actuation),
- Fire doors between rooms, partly equipped with electrically hold-open devices, and
- Stationary fire extinguishing systems and equipment including the corresponding extinguishing media supplies, fire water pumps, hydrants, etc.

The data has been evaluated by analyzing the documentation of periodic in-service inspections as well as additional information and reports which resulted from the inspection findings. For more complex systems such as the fire detection systems, in addition to the components' reliability data, fault trees are presented to calculate the system's reliability.

These data are then used in a second step to provide generic data, only based on German operational experience.

The updated and extended generic database covers 104 plant operational years of in total six German NPP units of different type (PWR as well as BWR) and age. These enhancements have increased the level of confidence significantly.

More details regarding the derivation of the new data set are provided in (Forell et al. 2012) and (Forell et al. 2014).

This set of data may also be applied as a-priori information for estimating the reliability of components of a similar design and an equivalent inspection and maintenance practice in the frame of Fire PSA for nuclear power plants in other countries.

3 PSA APPLICATION IN THE FRAME OF PERMANENT REGULATORY OVERSIGHT ACTIVITIES

3.1 *PSA application for the assessment of modifications*

While PSA was mainly used in Germany in the frame of (P)SR in the past as explained earlier, according to (BMU 2013) PSA applications as a supplementary analytical tool to be used in the nuclear regulatory framework shall be further extended.

As already explained in Section 1, due to these new regulations relative probabilistic criteria should be applied for assessing modifications of measures, equipment or the operating mode of the plant.

This results in the extended use of PSA to regulatory issues beyond PSR, such as a regulatory oversight on modifications applied by the licensee or an evaluation of those safety relevant events or phenomena which may have significant effects on the PSA results.

Including probabilistic considerations in the assessment is particularly useful in the evaluation of decision alternatives and strategies. A typical application in the past was the assessment of modifications with respect to in-service inspection intervals.

A recent example is described in (Babst et al. 2014). The licensee has recently requested the regulatory body for approving technical plant modification concerning the spent fuel pool cooling. Major differences of the intended plant modifications compared to the original situation are the number of emergency power supply systems available and the systems used for cooling the spent fuel.

In order to facilitate practical support allowing interpretations and explicit applications of these new requirements, an expert group on PSA in the frame supervisory activities, chaired by the Federal Office for Radiation Protection (BfS), has been established in fall 2012. One topic of discussions is the definition of a significant impact on the PSA results. Moreover, practical examples shall be collected to illustrate a possible risk informed approach.

The intention is to develop a document providing, among others, guidance if e.g. probabilistic considerations within the analyses of plant specific modifications have to be made, but analyses of the current state of the system are not available (e.g. regarding large and early releases of radionuclides, assessment of external hazards in the frame of LPSD PSA or Level 2 PSA).

If possible, the transferability of results for external hazards from full power operational states to low power and shutdown states including plant states representing neither commercial operation nor a formal decommissioning process should be discussed for Level 1 and Level 2 PSA.

3.2 *PSA application for the assessment of operating experience*

Furthermore, guidance shall be developed and examples be provided for the assessment of operating experience in line with (BMU 2013a), because this is generally not covered in the supplementary document on methods and data for PSA discussed in Section 2.

Only in case of human reliability, this aspect has been addressed. For such a retrospective event analysis, a comprehensive root cause analysis has to be performed for determining the causal relationships, e.g. the error mechanisms occurred with the aim of identifying causes that have contributed

to the action errors. This requires, in addition to the identification of the immediate causes, an investigation of the whole process.

Moreover, an example of an enhanced HRA analysis method has been added, which is intended to complement the existing THERP example in (FAK 2005a). As example of an analysis from past operating experience the fire event at the Forsmark NPP has been chosen.

4 CONCLUDING REMARKS AND OUTLOOK

The German Guide on Probabilistic Safety Analysis (BMU 2005) provides fundamental methods and boundary conditions for performing PSA including requirements with respect to their documentation. The recently issued Safety Requirements for Nuclear Power Plants (BMU 2013a) further require that state-of-the-art methods, models and data have to be applied in the frame of PSA.

While in Germany PSA was used in the past mainly in the frame of the ten years (Periodic) Safety Reviews, PSA as a supplementary analytical tool to be applied in the daily nuclear regulatory oversight in case of modifications by the licensee or for an assessment of those events or phenomena for which a significant influence on the results of the PSA results can be expected shall be further extended in the future.

As a result of the German decision to phase out of nuclear energy until 2022, only two or three Safety Reviews remain to be obligatory performed for nuclear power plants in Germany. Therefore, it is intended to provide the updated material on methods and data for PSA applications in the frame of PSR as a supplement to the existing technical documents on PSA (FAK PSA 2005a und 2005b). This supplement will reflect experiences from the German safety review processes and the resulting improvements in line with international developments. It is intended to issue this supplementary document in 2014.

To facilitate practical support allowing interpretations and explicit applications of the new requirements, it is planned to develop a document providing, among others, the definition of a significant impact on PSA results, collecting practical examples to illustrate a possible procedure.

Moreover, guidance should be given for those cases, where more or less detailed probabilistic analyses of plant specific modifications have to be performed, but probabilistic analyses of the current plant state or results of the comparison between unchanged and modified situation are not available (e.g. regarding large and early releases of radionuclides, assessment of external hazards in the frame of LPSD PSA or Level 2 PSA). This document is intended to be issued in 2015.

Focus areas for a Level 2 PSA that supports a site NPP risk analysis

D.M. Helton
United States Nuclear Regulatory Commission, Rockville, MD, USA

M. Zavisca & M. Khatib-Rahbar
Energy Research Incorporated, Rockville, MD, USA

ABSTRACT: The US Nuclear Regulatory Commission is developing a site Level 3 Probabilistic Safety Analysis (PSA) for the two operating nuclear power plants, and associated spent nuclear fuel storage facilities at the Vogtle site. The development of this integrated PSA, along with its intended end-uses, shifts the focus in the Level 2 (accident progression and radiological source term) portion of the analysis toward greater realism. This paper describes ways in which this focus affects the analytical approach. Presently in the US, Level 2 PSAs for operating reactors are most frequently performed in either a simplified manner (to support environmental impact studies), or for comparison with a (safety case-related) figure-of-merit. These applications often rely on simplifying assumptions. The present Vogtle analysis is novel in its scope, encompassing all major radiological sources on the site in concert, while assessing a range of hazards and plant operating configurations. As risk assessment technology advances, as computational capabilities increase, and in light of the multi-unit event at Fukushima Daiichi, this type of PSA activity is expected to proliferate. Interactions between the nuclear safety and risk communities at this stage will facilitate the development of more efficient methods. This paper will describe the approach being taken in several areas of the reactor and the spent fuel pool Level 2 PSA to promote realism in the treatment of the overall site risk. These areas include structural failure characterization, modeling of severe accident phenomena, survivability of equipment and instrumentation, and modeling of accident management actions. Whereas a systems-level view of the subject site design and operation would suggest very little dependency between the two reactors and the SFPs, this paper will make the case that after one or more radiological sources have proceeded to a severe accident (i.e., fuel melting) the detailed overall site accident progression becomes very inter-dependent.

1 INTRODUCTION

The United States Nuclear Regulatory Commission (US NRC) is developing a site Level 3 Probabilistic Safety Analysis (PSA) for the two operating nuclear power plants, and associated spent nuclear fuel storage facilities at the Vogtle site in Georgia, USA. In nuclear power plant risk assessment terminology, Level 3 refers to the modeling of accidents from their initiation to the offsite consequences caused by the accidents (public health effects and property damage). The scope of the Vogtle Level 3 PSA is events caused by both internal and external hazards, excluding acts of sabotage. The development of this integrated (a.k.a., extended) PSA, along with its intended end-uses, shifts the focus in the Level 2 (accident progression and radiological source term) portion of the analysis toward greater realism.

This paper describes ways in which this focus affects the analytical approach. Presently in the US, Level 2 PSAs for operating reactors are most frequently performed in either a simplified manner (to support environmental impact studies), or for comparison with a safety case-related figure-of-merit such as large early release frequency. These applications often rely on simplifying assumptions. The present Vogtle analysis is novel in its scope, encompassing all major radiological sources on the site in concert, while assessing a range of hazards and plant operating configurations.

This paper will describe the approach being taken in several areas of the reactor and the spent fuel pool Level 2 PSA to promote realism in the treatment of the overall site risk. Specifically, the following sections describe the modeling approach in the areas of structural failure characterization, severe accident phenomena, survivability of equipment and instrumentation, and severe accident management. In each section, examples are given where realistic treatment leads to better estimation of site-wide accident interactions. In addition to the interplays between radiological sources within a given modeling area, the paper will also point out

the way in which these different modeling results inherently affect the other modeling areas. Whereas a systems-level view of the subject site design and operation would suggest very little dependency between the two reactors and the SFPs, this paper will make the case that after one or more radiological sources have proceeded to a severe accident (i.e., fuel melting) the detailed overall site accident progression becomes very inter-dependent.

2 STRUCTURAL FAILURE CHARACTERIZATION

In the structural failure characterizations for the reactor and spent fuel pool Level 2 PSA modeling, NRC is relying on a combination of (i) past assessments, (ii) new calculations using three-dimensional finite element analysis in conjunction with statistical data for the failure strain of the liner materials, as well as models for tearing of the liner, and (iii) assessments using engineering criteria. Of particular interest here are the characterizations of containment severe-accident-induced failure and spent fuel pool seismic failure.

Vogtle's physical layout is typical of dual-unit US pressurized water reactors. The two containments are each surrounded by other structures for large portions of the azimuth (the extent varies by elevation), namely the equipment building and the main steam valve rooms. The spent fuel pools are located in-line, between the two reactor containments, with a distinct pool for each reactor. The two pools are normally hydraulically connected to one another through a common cask loading pool, via fuel transfer gates that extend to an elevation just above the spent fuel storage racks. The containment design is typical of pre-stressed concrete containments, having a tendon gallery (square cross-section tunnel) that extends the full 360-degrees of the azimuth, oriented just below the containment's external wall. The tendon gallery is accessed through three vertical shafts: one accessed in the yard (i.e., open to the environment), one accessed through the control building roof, and the other accessed through the equipment building. Numerous electrical and piping containment penetrations exist in both the portions of the containment surrounded by other structures and those leading to the yard. The containment has three access points: the main equipment hatch opens to the yard, the personnel airlock leads to the equipment building, and the emergency airlock leads to one of the tendon gallery access shafts.

The results of the new containment calculations have been compared back to the structural assessments performed by the licensee during the Individual Plant Examination study (1990s), and are also leveraging the failure characterization work stemming from extensive experimental and analytical investigation performed at Sandia National Laboratories (e.g., Petti et al., 2013).

The updated containment analyses estimate that the internal static pressure at which enhanced leakage initiation would occur is roughly the same as estimated in the IPE study (e.g., 7% variation relative to the failure pressure) for the wall-basemat junction, the equipment hatch, the emergency airlock, and the personnel airlock. For the wall-basemat junction failure, the assessments indicate that cracks would develop at the base of the wall and basemat slab and that the likely leakage path would be through cracks in the concrete extending to the tendon gallery under the containment wall (this was not addressed by the IPE analysis). This in turn would pressurize the tendon gallery, potentially failing the doors connecting to the access shaft. The resulting failure area for all of the aforementioned failure locations is expected to be only large enough to prevent further pressure escalation. Based on site-specific MELCOR analyses focusing on long-term molten core concrete interaction, and separately on the results of the structural analysis, this leakage area could range from $2 \cdot 10^{-3}$ m^2 to 0.1 m^2.

From a site Level 3 PSA perspective, the range of potential static over-pressure failures presents an interesting spectrum of possibiilities between environmental radiological releases and habitability/survivability concerns. First, wall-basemat junction failure in to the tendon gallery may cause habitability concerns (temperature, combustible gas, and radiological) in areas near the equipment building tendon gallery access shaft. This in turn has implications for both instrument and equipment survivability and local operator accident management actions, some aspects of which are discussed later. The surrounding structures are relatively compartmentalized, but clearly not designed to accommodate combustion events. Thus, the zone of influence of these habitability and survivability concerns becomes greater if a combustion occurs.

Similarly, other potential failure locations include a mix of release pathways, ranging from those that are preferentially directly to the environment (the equipment hatch), those that are preferentially in to surrounding structures (the personnel airlock), and those that have components of both (the emergency airlock). It's also important to note that the non-catastrophic nature of the rupture will limit the rate of change of containment and ex-containment conditions following failure, which may affect the likelihood of combustion and its effects. While a particular failure location must be assumed for deterministic reactor analysis,

the range of failure locations may be an important modeling uncertainty for the integrated risk analysis.

The spent fuel pool assessments are ongoing as of this writing, but preliminarily indicate that spent fuel pool failure caused by very large seismic accelerations (e.g., accelerations that are an order of magnitude higher than the plant's design basis), were it to occur, would preferentially occur at the bottom of the pool wall. The failure would be oriented such that the associated tear in the spent fuel pool liner would potentially occur at an elevation above the rack baseplate. In terms of propagating effects, the immediate implication is the flooding of areas that surround the backside of the pool wall. Much of this flooded area does not contain instrumentation or other equipment, and does have floor drains. If the drains are not able to keep up with the water flow, the potential exists for the failure of doors leading to internal flooding in areas that contain instrumentation and accident mitigation equipment. This also has the potential to affect both reactor and spent fuel pool accident management actions. In this case, a simplified SFP MELCOR model has been developed to aid in the tracking of conditions within and around the SFP, prior to significant fuel uncovery (at which point a more detailed MELCOR model is employed). These inter-dependencies from a structural failure and physical layout perspective represent important considerations for the integrated site risk analysis.

3 SEVERE ACCIDENT PHENOMENA

MELCOR 2.1 is being used to support the deterministic accident progression modeling in the Vogtle project. MELCOR is a fully integrated, system-level computer code that models the progression of severe accidents in light-water reactor nuclear power plants. MELCOR development is led by Sandia National Laboratories under NRC sponsorship, and is the successor to the Source Term Code package. A broad spectrum of severe accident phenomena in both boiling and pressurized water reactors is treated in MELCOR in a unified framework. These include thermal-hydraulic response in the reactor coolant system, reactor cavity, containment, and confinement buildings; core heatup, degradation, and relocation; core-concrete attack; hydrogen and other combustible gas production, transport, and combustion; and fission product release and transport behavior. In some cases, MELCOR results are used as boundary conditions to standalone tools to investigate specific phenomena (e.g., detonation).

In the Vogtle project, MELCOR is being used for confirmatory reactor Level 1 success criteria and accident sequence development activities (leveraging the licensee's existing Level 1 PSA), reactor severe accident progression (Level 2 PSA) activities, and all aspects of the spent fuel pool deterministic accident progression modeling. When convolving the physical characteristics of the Vogtle plant with the strengths and limitations of MELCOR, it was decided to construct and exercise three MELCOR models. The first represents one unit's reactor and containment in detail, along with a simplified treatment of the surrounding structures. The second represents both spent fuel pools and the fuel handling building, in a detailed fashion. The third model represents one containment, both spent fuel pools, and the fuel handling building in a simplified manner that is conducive to fast-running sequence timing calculations prior to fuel melting. As of this writing, the first and third models have been developed and extensively tested. The second model is currently under development.

Beyond the general need for more models and additional modeling flexibilities, the site risk characterization being developed leads to specific situations where the project scope influences accident modeling decisions. The first example is one that was highlighted by both the Fukushima Daiichi accident, as well as the concurrent NRC State-of-the-Art Reactor Consequence Analysis project (Chang et al., 2012), and involves the modeling of hydrogen (and other combustible gas) generation and transport. Customarily, combustible gasses are tracked within the containment as a potential cause of containment failure. However, when they leak out of containment, they pose a challenge to reactor accident management, site accident management, and as a potential means of instigating or exacerbating an accident at another onsite radiological source (e.g., the spent fuel pool). Given the proximity and inter-connectedness of the auxiliary building, fuel handling building, equipment building, and control building, a combustion event in one of these structures has the potential to cause problems in any of the other. That said, these buildings at Vogtle are generally very compartmentalized, which may limit the zone of influence of a combustion event. However, this compartmentalization makes realistic modeling of such events difficult with the current state-of-practice. Here the project is taking a balanced approach. Pathways between the containment and these structures are modeled and the various elevations of the structures are modeled. However, details about compartmentalization within an elevation (e.g., the breakdown in air space volumes, the failure characteristics of intervening doors, etc.) are not modeled. This allows for statements about the

potential for spatial interactions, without investing the significant resources needed to model the issue in a more sophisticated fashion (which might belie the uncertainties in leakage pathways and combustible gas transport modeling).

As another example of where the project is striving for greater realism, MELCOR results are being used directly in the assessment of accident management actions. This will be discussed in more detail later in the paper; here the focus is on the MELCOR modeling. Since the occurrence of a significant event onsite could impact the effectiveness of diagnosis or implementation activities associated with accident management, it is important to account for such events in the context of the human reliability modeling. Specifically, the onset of core damage, the rupture of the vessel, a combustion event, and the failure of containment are each being tracked closely from both the traditional accident release perspective and as a discrete event that could affect the reliability of the ongoing diagnosis and implementation activities. This situation was seen most clearly in the Fukushima accident, in which combustion events interrupted efforts to restore power, damaged hardware (e.g., a vent valve, fire hoses), injured personnel, scattered radiological material which in turn affected access, and caused evacuation of non-essential personnel (INPO, 2011), (Government of Japan, 2011), and (The National Diet of Japan, 2012).

4 SURVIVABILITY OF EQUIPMENT AND INSTRUMENTATION

The purpose of equipment and instrumentation survivability assessment is to ensure that hardware is not being credited when it would in fact be expected to fail due to the environmental conditions to which it is exposed. Instrumentation survivability is critical to the navigation through severe accident management guidelines because plant conditions (as measured through instrumentation) is the means of establishing accident management priorities and weighing the pros and cons of taking a specific action.

The two main tools for establishing the loads on instrumentation and equipment are the scenario characterization (e.g., stuck-open relief valves, interfacing system pipe ruptures) and the deterministic analyses (in this case the aforementioned three-dimensional finite element analysis and MELCOR analysis). The conditions of interest are humidity, static and dynamic pressure, temperature, and radiation. All of these except radiation are readily calculated by MELCOR, though dynamic temperature and pressure estimation requires additional investigation using separate tools for specific phenomena (e.g., detonation). Near-field radiation can also be estimated based on MELCOR outputs (e.g., see Section 4.3.5 of LaChance et al., 2012), however the Vogtle project handles this more qualitatively. Tentatively, ex-containment equipment not exposed to high radiation fields during design-basis accidents (and thus not subjected to high radiation fields during environmental qualification) is assumed to fail if exposed to such conditions during a given scenario (e.g., equipment near an interfacing system pipe rupture unsubmerged break following core damage). The same general treatment is given for humidity.

Temperature and pressure loads are extracted for various plant locations using the MELCOR results of representative scenarios, in order to develop trends. These loads are compared for various phases of the accident (post core-damage) against the environmental qualifications of the plant equipment and instrumentation within the same location, to estimate whether the equipment/instrument's survival is: (i) likely; (ii) not likely; or (iii) indeterminate. In some cases significant interpretation is required (e.g., the environmental qualifications do not explicitly account for dynamic loads caused by combustion events), which increases the likelihood of reaching an indeterminate finding in those circumstances. A list is made of those that are indeterminate for future investigation, depending on their overall contribution to the release category results. As discussed in the previous section, the MELCOR model is capable of calculating environmental conditions in the containment with high resolution (relative to the spatial resolution of equipment qualification information), and low resolution in the surrounding structures.

As an example of where site integration presents new challenges, consider the case of a hydrogen deflagration in the equipment building (the portion of the auxiliary and fuel handling buildings directly adjoining containment), caused by containment penetration leakage. Such an event has the potential to cause high pressures (and temperatures) in this area of the plant. As is typical of PWR designs, the cabling for ac power and dc control for the spent fuel pool cooling pumps is also located in this general area. Thus, hydrogen (or carbon monoxide) emanating from a reactor accident, migrating in to the equipment building from a containment penetration leak, has the potential to damage equipment and instrumentation used for normal, abnormal, and accident SFP cooling. This type of interaction can only be assessed by investigating the containment leakage paths and environmental loads caused by the reactor accidents, and comparing them on a spatial basis, to the equipment and instrument

environmental capacities of potentially-affected equipment.

A second example posits a similar situation, but in reverse. In the unlikely event that an SFP drainage accident goes unterminated (e.g., due to a large seismic event tearing the SFP liner), the resulting oxidation of SFP fuel in a steam environment can produce hydrogen (the same as a reactor accident), resulting in a hydrogen combustion event. Due to the proximity of the SFP to the auxiliary and control buildings, that has the potential to damage instrumentation used in reactor accident management (e.g., containment purge instrumentation used in controlled venting, hydrogen sampling equipment used in assessing the likelihood of in-containment hydrogen combustion events). This has the potential to adversely affect concurrent accident management activities associated with preventing core damage or mitigating fission product release from the reactor.

5 ACCIDENT MANAGEMENT

The final area of focus in this paper is accident management, which is affected by each of the previous areas. Here, the central focus is the plant's Severe Accident Management Guidelines (SAMGs), with other procedures and guidance (e.g., the Extensive Damage Mitigation Guidelines (EDMGs)) playing a supporting role. Again, the MELCOR results are used to characterize the accident. Specifically, output streams have been built in to the MELCOR model to provide all parameters used by the SAMG diagnostic flow chart and severe challenge status tree, as well as the computational aids that accompany the 12 specific guidelines documents. The exceptions are two guideline entry conditions that are based on projected or measured site doses, which for this project are assessed using trial runs of the US NRC's incident response computer code RASCAL (Radiological Assessment System for Consequence AnaLysis). The plant is being studied as it existed in 2012, so the changes presently being made to the US SAMGs (e.g., see LaBarge et al., 2013) do not apply. Similarly, the changes that will be made in response to ongoing NRC rulemaking related to SAMGs (e.g., US NRC, 2013) also do not apply.

The three basic steps of the human reliability analysis being performed to characterize accident management are identification of those actions to be modeled deterministically (based on a finite number of accident progression analyses), the assignment of screening (or simplified) probabilities that the action is not performed, and the development of more detailed probability bases for a subset of these actions. Identification is based on three aspects of the potential action: priority (relying on the hierarchical nature of the Vogtle SAMGs); duration of time that the entrance criteria for that action are met; and habitability. The screening probabilities are based on a combination of considerations related to: (i) instrumentation availability, (ii) priority, (iii) dependency, (iv) duration of entrance conditions being met, (v) the occurrence of significant accident progression events (vessel failure, containment failure, and combustion events), (vi) familiarity relative to emergency operating procedure and EDMG training, and (vii) survivability considerations. The goal is to then extract the trends and insights from these detailed analyses to inform an otherwise experience-based probabilistic modeling of accident management. The approach for the more detailed probability bases for a subset of the actions is under development.

Again, two examples are given where site integration adds complexity to the assessment of this focus area. The first example simply deals with the fact that the current (circa 2012) site accident management infrastructure is predominantly focused on dealing with a single-unit accident. Most notably, there is a single technical support center, a single operations support center, and (in some instances) a single set of supporting accident management equipment. Having multiple TSCs or OSCs is not inherently necessary, and limitations on staffing and equipment are being addressed through ongoing NRC activities. Nevertheless, it is the case that the accident management response involving more than one radiological source on-site will be coupled. To the extent that there may not be sufficient capacity to deal with multiple events completely in parallel, actions for a given source (be it diagnosis or implementation-oriented) will have to be prioritized within the overall site response. In cases where insufficient equipment exists, a decision will be needed to prioritize the deployment of that equipment (e.g., an ac-independent pump) to one radiological source over another. At best, the timing of the accident is such that it can be used in a serial fashion to try and mitigate the concurrent accidents. Given the potential number of instances where competing demands may exist in the site PSA, it may be necessary to take a retrospective approach (i.e., identify important instances of conflicts once results have been obtained without consideration of conflicts).

The second example is one where an accident at one radiological source creates a habitability challenge in an area needed to take a local action to mitigate an accident at another radiological source. For instance, if all cooling is lost to the SFP and the decay heat in the SFP is high, it will eventually begin to boil. This creates a high-humidity,

high-temperature condition within the fuel handling building. Portions of the fuel handling building are connected to the auxiliary and equipment buildings through normal doors. This potentially inhibits access to these areas, and poses operational challenges for preparing individuals to go in to these areas (fire-fighting turnout gear is typically designed for dry, rather than wet, heat). As such, an action that relies on connecting temporary hoses to a fire-header standpipe in order to refill a tank that will be used as part of a reactor mitigation strategy, could be greatly complicated if that stand-pipe is in the affected area of the auxiliary building. In related existing human reliability analysis guidance (Cooper, 2012) this plays in to the assessment of both feasibility and reliability.

6 CONCLUSION

This paper has described the approach being taken in several areas of the reactor and the spent fuel Level 2 PSA portions of the US NRC's Vogtle site PSA project to promote realism in the treatment of the overall site risk. While there are a number of complex challenges associated with analyzing and preparing for multi-unit nuclear power plant accidents, this paper shows the values of applying the existing tool set, in order to anticipate challenges that may arise, so that they can be contemplated and addressed prior to an accident occurring. As risk assessment technology advances, as computational capabilities increase, and in light of the multi-unit event at Fukushima Daiichi, this type of PSA activity is expected to proliferate within the US and elsewhere. Interactions between technical disciplines within the nuclear safety and risk communities at this stage will facilitate the development of more efficient methods. Interactions will also aid in identifying the potential site complexities that are more likely to manifest themselves for given design types, versus those that are simply theoretical.

ABSTRACT: Technological advancements in area of sensor-based online maintenance systems have made the possibility of repairing some failed safety support systems of Nuclear Power Plants (NPP) such as electrical supply, I&C systems, ventilation systems. However, the possibility of repair during accident situation is yet to be included into PSA level-1. Therefore, this paper presents a scheme of PSA level-1 by implementing an integrated method of Repairable Event Tree (RET) and Repairable Fault Tree (RFT) analysis. The Core Damage Frequency (CDF) is calculated from consequence probabilities of the RET. An initiating event of Decay Heat Removal (DHR) systems of ASTRID reactor is analyzed. The proportionate CDFs estimated with repair and without repair have been compared and found that the recoveries can reduce CDF. In sum, this paper attempts to deal with the possibility of repair of some safety systems in PSA and its impacts on CDF of the NPP.

1 INTRODUCTION

Sodium cooled Fast Reactors (SFRs) present the characteristic of the large thermal inertia of its coolant systems and high coolant temperature (Saez 2013, Lee & McCormick 2011). This characteristic promotes usage of passive cooling systems and also allows for relatively long times for cooling recovery (Nayak & Sinha 2007) during reactor accidents. Particularly, the large thermal inertia allows a sufficient grace period or tolerance time for the possibility to recover failed components in a DHR system. This possibility of repair within a tolerable downtime or grace period has been further boosted by recent developments in the area of sensor-based online maintenance. For instance, the tools of online integrated risk monitoring system can detect the problem rapidly and possible repair can be realized within the time window given by the thermal inertia of DHR systems (Hashemian 2011, IAEA: TECDOC 1999). Robotic repair system in highly automated plants can restore the fault that was not possible by human interventions (Thomas 2012). Efforts are going on in the area of maintenance to repair a component without hampering the normal operation of a complex engineering system.

In addition, the possibility of repairing exists for some failed systems supporting safety of nuclear power plants such as electrical supply, I&C systems, ventilation systems. According to lessons learnt from events related to ventilation systems in the French civil nuclear facilities between 2005 and 2010, 80% of the incidents were the combination of unexpected ventilation shutdown and non-compliance of safety requirement related to dynamic confinement (Berne & Brunisso 2012). These incidents can be prevented by proper design and automated repairation systems. Similarly, some faults in electric supply system can be repaired within a short span of time once diagnosed. The faulty equipment can be plugged out and new one can be plugged in without hampering the normal supply after the detection (IAEA: NG-T-3.8 2012). This can be achieved by using state-of-the-art instrumentation and control systems. Recent technologies in supervisory and control systems provide client-server based digital supervision for efficient plant monitoring & operation functions and high performance controller for preservation of system reliability (Yamamori 2000). Additionally, the use of mobile electrical and cooling equipment available at site or nearby regional centers can make possible the real-time repair of failed safety support systems within a grace period.

The reliability problem of decay heat removal system falls into the category of a tolerable downtime reliability problem in which failure of safety barriers are hazardous if the duration of failure exceeds its tolerable grace period determined by

physical time constraint of the system. The safety of such system can be ensured if repair is performed within that grace period. The reliability characteristics of systems with repairable components have already been dealt in several literatures (Kiureghian et al. 2007 & Barlow 1975). An inhomogeneous state graph model based on semi-Markov process has been used to build component model systems with tolerable down times (Becker et al. 1995). To remove the restriction of constant failure and repair rate in the Markov process, a generalized equations have been derived for calculating the time-dependent unavailability, the failure intensity and the distribution of the time to the first undesired event for components with tolerable down time (Vaurio 1997).

The possibility of repair during accident situation is yet to be included into Probabilistic Safety Assessment (PSA). A PSA method Includes Event tree (ET) to generate accident scenario and Fault Tree (FT) used to quantify the probability of failure of the Safety Barrier (SB). In literature, there are some examples in which FT analysis has been done for systems with repair components. A FT analysis of phased mission systems has been performed with repairable and non-repairable components (Vaurio 2001). The other FT models with repairable basic events have been proposed based on renewal intensity principle and inclusion-exclusion methods (Yuge et al. 2012 & Yuge et al. 2013). However, ET analysis of Initiating Events (IE) with repairable SB has not been dealt before. Therefore this paper proposes a scheme of PSA level-1 for systems with repairable components using a simplified combination of Repairable Event Tree (RET) and Repairable Fault Tree (RFT).

The paper has the following structure. Section 2 describes the proposed scheme of PSA level-1 for systems with repairable components. In Section 3, proposed PSA level-1 method is used to calculate CDF for a system with some repairable components. In Section 3, the results of numerical examples are discussed. Finally, Section 4 concludes the work.

2 A SCHEME OF PSA LEVEL-1 WITH REPAIRABLE COMPONENTS

Probabilistic safety assessment level-1 is a systematic method for investigating the transformation of an undesired Initiating Event (IE) into a set of possible outcomes leading to core damage or not and their core damage consequences in the form of Core Damage Frequencies (CDF). In this proposed scheme of PSA, Repairable Event Tree (RET) is constructed for each IE to follow progression of event sequence through several Safety Barrier (SB) systems protecting the core. To evaluate the success or failure of each SB, a Repairable Fault Tree (RFT) is constructed with failures and recoveries of basic events that could result in the steady-state failure of SB systems. The top event probability of RFT is the probability of a branch path. This process is replicated for other branch path until the consequences. Finally, the sum of probabilities of all consequences provides the core damage frequencies.

2.1 *Repairable event tree analysis*

The proposed RET allows the construction of accident sequences after an initiating event with the possibility of repair of failed SB. The failure of repairable SB can be rectified within a grace period and the failed branch in ET may potentially be converted into success branch. The grace period is determined by physical behavior of the SB. The accident progression beyond repairable failed branch is virtually ceased if the restoration time is less than the grace period. Otherwise, it continues by following binary path sequentially through remaining SBs of the safety system. For non-repairable SB, the accident progression follows the binary tree of success and failure branch. Finally, we get the branch consequences defined by de-coupling criteria of the each branch. Figure 1 represents the proposed scheme of a typical RET.

2.1.1 *Notations and assumptions*

The basic assumptions are:

- Multiple SBs respond to the occurrence of IE in sequential manner.
- Grace period depends on impacts of failure sequences of SB systems on the physical behavior of system.
- Repair of failed items begins without any delay and brings failed SB as good as new without hampering the normal operation of other safety systems.
- SBs may be repairable or non-repairable during accident progression.

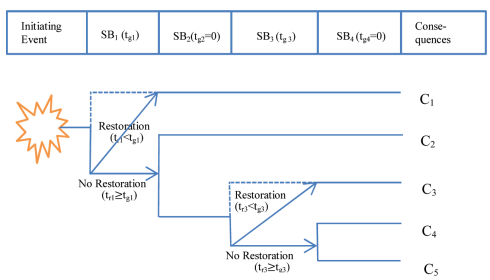

Figure 1. A proposed scheme of repairable event tree.

- Repair time of certain failed SB may be less than or more than its grace period depending on the repair management.

For RET analysis, as shown in Figure 1, the following notations can be taken:

IE = an initiating event harmful to the system
S_i = ith Safety Barrier (SB) along the accident progression
t_{gi} = grace/tolerable time of ith SB to avoid decoupling criteria due to IE and determined based on the deterministic behaviour
t_{ri} = repair time of ith failed SB if repairable
P_{C_k} = Probability of kth consequence C.

2.1.2 *Generation of partially dynamic RET*

Step 1: After occurrence of an IE, check the status of SB, $S_i(i=1, \ldots, l)$;
Step 1.1: If S_i succeeds, create success branch and skip to Step 3.
Step 1.2: If S_i fails, check its reparability. If not repairable, skip to Step 2 otherwise go to Step 1.2.1.
Step 1.2.1: If $t_{ri} < t_{gi}$, turn failed branch into success branch and skip to Step 3.
Step 1.2.2: If $t_{ri} \geq t_{gi}$, create failure branch and skip to Step 2.
Step 2: Move to S_{i+1} and repeat Step 1.
Step 3: Obtain consequence probability P_{C_k} $(k = 1, \ldots, m)$ using RFT analysis.

2.2 *Repairable fault tree analysis*

In general, the fault tree that considers failure and repair of its basic events is termed as Repairable Fault Tree (RFT). In some cases, basic events of RFT may or may not allow repair after failure. In RFT analysis, the outputs of basic events are feed into the immediate upper level through logical gate up to the top level. The failure output of gate can be changed to success output by repair of failed basic event within the tolerable mean down time. Thus the state transition of a gate can be termed renewal process which includes failure rate of gate output and corresponding repair rate (Yuge et al. 2012). The renewal intensities of logical gates are calculated using the mean up time and the mean down time by applying renewal theorem (Barlow 1975, Schneeweiss 1989 & Sherwin 2000).

2.2.1 *Notations and assumptions*

The basic assumptions are:

- The failure and repair of each component are statistically independent and follow exponential distributions.
- Repair is carried out immediately after the occurrence of failure and independent of the repair of other failed components.
- The gates, AND & OR, describe the interactions of state change of components. These two gates are building blocks used to build either a static or a dynamic RFT.
- Steady-State Availability (SSA) of a gate is the ratio of "mean up time" to "mean up time" plus "mean down time" over a long, theoretically infinite, period of all basic events.

For RFT analysis, the following notations can be taken:

λ_i = failure rate of ith component of a gate
μ_i = repair rate of ith component of a gate
P_i = Steady sate failure probability of a SB
A_i = Steady sate availability of a SB
A_{AND}, A_{OR} = SSA of AND & OR gate
v_{AND}, v_{OR} = mean uptime of AND & OR gates
u_{AND}, u_{OR} = mean downtime of AND & OR gates
$\lambda_{AND}, \lambda_{OR}$ = failure rate of AND & OR gates
μ_{AND}, μ_{OR} = repair rate of AND & OR gates

2.2.2 *Steady state probability of logical gates*

Two logical gates, AND & OR, are considered as the building blocks of RFT analysis. The combination of these two gates can be used to model static and dynamic RFT analysis. For example, the Functional Dependency Gate (FDEP), a dynamic gate that includes a trigger event on which other events depends, can be transformed into a static representation of AND & OR gates in RFT analysis.

This paper considers a repairable system's behavior as an alternating renewal process of an up state and down state in which the system failure and the system repair alternate. As the system reaches steady state, the mean time to failure and repair in a cycle also approaches a constant value which does not depend on the system's initial state.

2.2.2.1 AND gate

Steady state availability of an AND gate, as shown in Figure 2a, having n components with failure

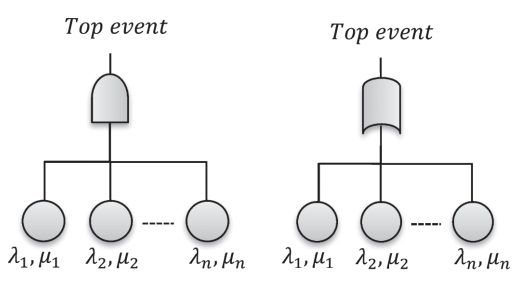

Figure 2. Two basic logical gates for FT analysis.

rate, $\lambda_{i=1,\ldots,n}$ and repair rate, $\mu_{i=1,\ldots,n}$ can be given by following mathematical expressions:

$$A_{AND} = 1 - \Pi_{i=1}^{n} \frac{\lambda_i}{\lambda_i + \mu_i} \quad (1)$$

$$u_{AND} = 1 \Big/ \sum_{i=1}^{n} \mu_i \quad (2)$$

$$v_{AND} = \frac{u_{AND*} A_{AND}}{1 - A_{AND}} \quad (3)$$

2.2.2.2 OR gate

Steady state availability of an OR gate, as shown in Figure 2b, having n components with failure rate, ($\lambda_{i=1,\ldots,n}$ and repair rate, $\mu_{i=1,\ldots,n}$) can be given by following mathematical expressions:

$$A_{OR} = \Pi_{i=1}^{n} \frac{\lambda_i}{\lambda_i + \mu_i} \quad (4)$$

$$v_{OR} = 1 \Big/ \sum_{i=1}^{n} \lambda_i \quad (5)$$

$$u_{OR} = \frac{v_{OR}(1 - A_{OR})}{A_{OR}} \quad (6)$$

2.2.3 *Procedure for analysis of RFT*

Step 1: Construct a RFT based on system configuration and functional logic.

Step 2: Transform dynamic gates, if any, of RFT into a static combination of AND & OR gates.

Step 3: Calculate the equivalent steady state reliability parameters of logical gates such as availability, mean up time, and mean down time using from Eq. (1) to Eq. (6).

Step 4: Determine the equivalent failure rate and repair rate of gates considering the transition of the gate output to be an alternating process as calculated by Step 3.

$$\lambda_{AND/OR} = \frac{1}{u_{AND/OR}} \quad (7)$$

$$\mu_{AND/OR} = \frac{1}{v_{AND/OR}} \quad (8)$$

$$A_{AND/OR} = \frac{v_{AND/OR}}{v_{AND/OR} + u_{AND/OR}} \quad (9)$$

Step 5: Repeat Step 3 and Step 4 for next immediate upper level and up to top level.

Step 6: Estimate the top event probability Pi as a probability of failure by $P_i = 1 - e^{-(\lambda_{AND/OR})t}$ where $\lambda_{AND/OR}$ is the equivalent steady state failure rate of top level gates calculated from Step 4 & 5.

2.3 *Core damage frequency*

The Core Damage Frequency (CDF) can be calculated from the combination of event tree and fault tree analysis. The calculation involves the following mathematical expressions for the proposed scheme of RET shown in Figure 1:

$$P_{C_k} = P(IE) \times (\Pi_{i=1}^{k} P_{i-1})(1 - P_k) \quad (10)$$

$$CDF = \sum_{k=1}^{l+1} P_{C_k} \quad (11)$$

Given, $P_0 = 1$ C_k = the kth consequence ($1 < k < l + 1$), and l is the total number of SB.

3 AN APPLICATION TO PSA STUDIES OF ASTRID DHR SYSTEMS WITH THE POSSIBILITY OF RECOVERY

This paper considered ASTRID DHR systems with an initiating event of primary pump trips to test the proposed scheme of PSA with RET and RFT.

3.1 *ASTRID DHR systems*

The ASTRID consists of four DHR systems namely BCS, RRA, RRB, and RRC, as shown in Figure 3, to deal with decay heat generated in the core and transferred through the hot pool (Saez 2013 & Curnier 2014). In normal conditions, the secondary systems (BCS) transfer the heat from the Intermediate Heat Exchangers (IHX) to the power conversion system. After reactor shutdown, the residual heat can be removed through the secondary loops (BCS) bypassing turbine generator. The use of BCS for residual heat removal is limited to 3 days due to design and operational constraints.

When BCS are not available, the decay heat removal relies on dedicated safety system known

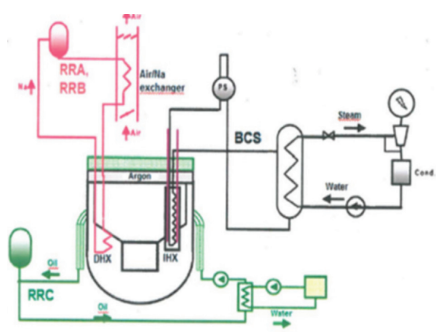

Figure 3. A schematic diagram of DHRS (Curnier et al. 2014).

as RRA, RRB, and RRC (each composed of two redundant trains). Each train of RRA and RRB systems is a Na/Na Decay Heat eXchanger (DHX) and an air/Na exchanger. The two trains of RRB operate in natural convection on both sodium and air sides while RRA trains operate in forced convection with electro-magnetic pumps. Another DHR system, RRC, is also investigated to complement the four DHX circuits. RRC is a diversified system operating through the reactor vault by means of an oil circuit. Figure 3 shows the schematic representation of ASTRID DHR system.

The grace period for repair of failed DHR system depends on the sequences of failure and their effects on the primary sodium temperature rise. A simplified numerical tool has been developed to estimate which transients lead the sodium temperature rise to critical temperature level of 650°C. Figure 4 shows the long term sodium temperature calculations (Gauthe et al. 2013) taking into account of the DHR system operation. In this figure, RVACS is equivalent to RRC of ASTRID DHRSs.

3.2 *An initiating event of primary pump trip*

In the example, an initiating event of ASTRID, trip of a primary pump, is analyzed for the demonstration of introduced scheme of PSA. Figure 5 and Figure 6 show the event tree scheme without repair and with repair of safety barriers. Sodium temperature curve has been calculated for the two sequences of ET and approximate grace periods for each determined for the purpose of performing repair. For the case in which there is no loss of electricity and BCS is working with strength, the grace periods to reach critical temperature and the point of structural damage are found to be 56 hours and 86 hours. For the second case in which there is a loss of electricity and BCS is not working, the grace periods to reach critical temperature and the point of structural damage are found to be 20 hours and 46 hours. If the failure of RRA and

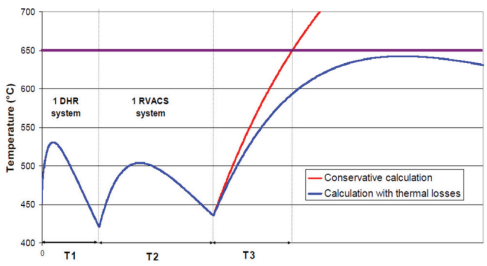

Figure 4. Sodium temperature curve for DHR systems operations (Gauthe et al. 2013).

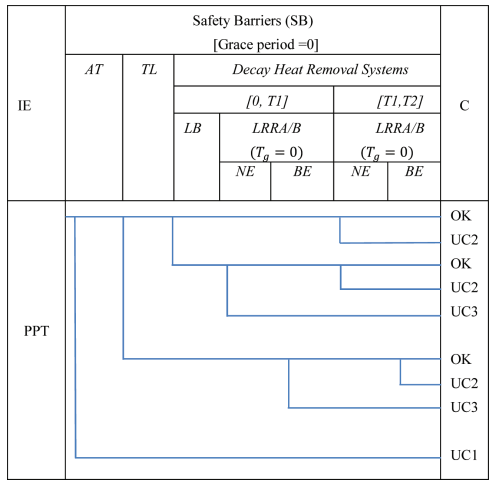

Figure 5. An ET of primary pump failure without repair.

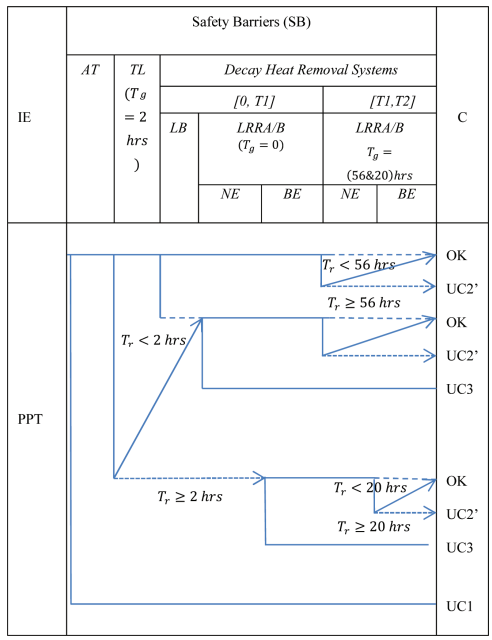

Figure 6. An RET of primary pump failure with some repair.

RRB can be rectified within these grace periods, the number of accidents sequences can lead to the progression towards OK conditions and thus CDF may be reduced significantly.

3.2.1 *Repairable event tree*

Figure 5 & 6 show the event tree of primary pump trip without and with repair possibilities. In Figure 6,

if the repair of failed Electricity loss or RRA/RRB can be done within estimated grace periods, the failure branch can be turned into success branch and failure consequences can be eliminated practically. In Figure 5 & 6, the abbreviations used IE, PPT, AT, TL, LB, LRRA/B, NE, BE, and C, are for initiating event, primary pump trip, automatic shutdown, total loss of electricity, loss of 4 BCS, loss of RRA/B, normal electricity, back-up electricity, and consequences. In Figure 6, grace periods during [T1, T2] for LLR/B are 56 hours for normal electricity and 20 hours for back up electricity.

Table 1 shows the occurrence ratio of UC1, UC2, and UC3 contribution in total CDF due to pump trip event. In case of repair possibility, the probability of consequence, UC2, can be reduced to a lower value after real-time repair, as shown by UC2' in Figure 6. Thus, the CDF can be minimized to a significant value practically. The probability value of UC2' can be calculated by taking into account of modified top event probabilities using RFT analysis. An example of RFT quantification is given in next Section 3.2.2.

The actual value of UC2' is not provided due to the unavailability of repair data of the components of ASTRID DHR. However, the next Section presents a case of RFT analysis of a FT with some recoverable components to estimate the reduction of top event probability.

3.2.2 *Repairable fault tree*

Figure 7 shows the example of a fault tree in which the top event probability or failure probability is calculated as per the procedure of repairable fault tree described in Section 2. In this FT, a dynamic gate, FDEP has been converted into a static tree with a combination of AND gate and OR gate.

Table 2 shows the calculation of top event probability for the FT given in Figure 7. The failure rates and repair rates have been generated randomly for exponential distribution of failure and repair activities. The data set used for [(λ_1,μ_1), (λ_2), (λ_3,μ_3), (λ_4), (λ_5,μ_5), (λ_6,μ_6)] is [(0.16, 0.69), (0.11), (0.22, 0.51), (0.11), (0.05, 0.51), (0.22, 0.11)] per 10^6 hours. For simplification, the time period taken is 10^6 hours. The top event probability for RFT and FT obtained as 0.06 and 0.11, respectively.

Table 1. Contribution of consequences on CDF.

Consequences	Occurrence ratio without repair	Occurrence ratio with repair
UC1	0.14	0.14
UC2	79,89	UC2' (<UC2)
UC3	19.97	19.97
Total CDF	100	UC2' +20.11

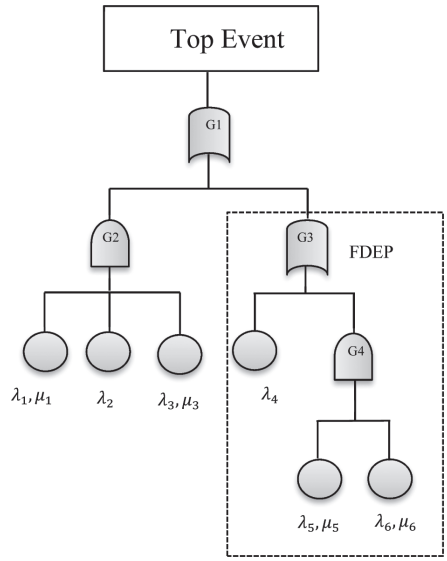

Figure 7. An example of FT with some repairable and non-repairable basic events.

Table 2. RFT results with and without the repair possibility.

	RFT (λ, μ)	FT (λ, $\mu = 0$)
Event probability at G1	$A_{G1} = A_{G2} * A_{G3}$ $v_{G1} = \frac{1}{1/u_{G2} + 1/u_{G3}}$ $u_{G1} = \frac{u_{G1} * (1 - A_{G1})}{A_{G1}}$ $P_{G1} = 1 - e^{-\left\{\frac{1}{u_{G1}}\right\}t}$	$R_{G1} = R_{G2} * R_{G3}$ $P_{G1} = 1 - R_{G1}$
Top event probability (P_{G1})	0.06	0.11

3.3 *Discussion*

The RET & RFT results signify the advantages of repairing failed item within the grace period estimated from the physical response of the item of the DHR system. The conservative grace period can help repair management to accommodate the repair process within the critical time by modifying the design or through introducing innovative design.

From the Table 1, the CDF value, in case of successful recovery of RRA/RRB within the grace period, can be reduced proportionately up to a significant value of the total CDF. In absence of actual calculation of CDF for an initiating event of PPT in Figure 6, the example calculation in

Figure 7 indicates that the top event probability with recovery possibility can be reduced up to 45% with respect to the probability of failure without any repair possibility. Though the reduction in probability failure can vary with the input data of failure rate and repair rate.

However, the future PSA studies of DHR system with repair possibility should consider the common cause failure in RET and RFT analysis to get clearer outline of the benefits. Moreover, the assumptions on exponential failure and repair distribution should be relaxed in RFT quantification as the failure and repair distribution in reality are non-exponential for mechanical and reactive systems.

4 CONCLUSIONS

This paper deals with the PSA level-1studies of a nuclear system with the possibility of recovery of some failed units during accident progressions. A scheme of PSA level-1studies with the combination of partially dynamic repairable event tree and repairable fault tree is introduced. The quantification of repairable fault tree is performed based on the concept of up-time and down-time ratio for steady state system. A case study on the PSA of ASTRID DHR system with an initiating event is performed and found that repair of some units within the grace period during accident progression can reduce the CDF considerably. In future works, the proposed scheme would be implemented using dynamic reliability methods with the considerations of common cause failures and non-linear failure behaviors.

Effect of human factor in the analysis of changes to Limiting Conditions for Operation (LCO) applied to Residual Heat Removal System

S. Martorell, I. Martón, P. Martorell & M. Saiz
Department of Chemical and Nuclear Engineering, Universitat Politècnica de València, València, Spain

ABSTRACT: The objective of this paper is focused on studying the effect of epistemic uncertainty associated to human reliability in the context of the LCO changes. The methodology proposed in RG 1.174 is used in order to assessment and analysis of risk impact of proposed change. An example of application is provided that is centered on the Residual Heat Removal System (RHRS).

1 INTRODUCTION

RG 1.174 (USNRC, 2011) establishes a regulatory framework for the evaluation of risk impact of changes to license basis, RG 1.177 (USNRC, 2011) particularize to change to Technical Specification (TS), in particular Surveillance Requirements (SR) and Limiting Conditions for Operation (LCO). Probabilistic methods have developed to study changes in the TS using Probabilistic Risk Assessment (PRA) results. These regulatory guides establish the need of considering epistemic uncertainties in risk informed decision making, which have addressed in detail in NUREG-1855 (USNRC, 2009).

In addition, NUREG-1764 (USNRC, 2004) provides guidance in order to address human performance aspects of changes to operator actions that are credited for safety, especially those involving changes in the licensing basis of the plant, in the context of the framework depicted in RG 1.174.

The objective of this paper is focused on studying the effect of epistemic uncertainty associated to human reliability in the context of the LCO changes. An example of application is provided that is centered on the Residual Heat Removal system (RHRS).

2 HUMAN RELIABILITY

2.1 *Types of errors*

As part of the PRA for a NPP, a Human Reliability Analysis (HRA) is conducted to determine how human performance affects the safety of the plant. Human Reliability Analysis focuses on estimating Human Error Probability (HEP). With the aim of achieving this, it is necessary to classify the different types of Human Failure Events (HFE) which need to be included in the PRA. According to the ASME PRA-S-2000 (ASME, 2000) one can distinguish between two groups:

- Pre-initiator HFE—human errors committed during actions performed prior to the initiation of an accident, for example, during maintenance or calibration procedures.
- Post-initiator HFE—human errors committed during actions performed in response to an accident initiator

The latter are related to procedural or recovery actions, which contain cognitive tasks (detection, diagnosis), followed by execution tasks (recollection, action).

When an initiator event occurs, the operator performance consists of different phases (Rasmussen, 1986). Human errors in each phase are divided between Errors of Omission (EOO) and Errors of Commission (EOC). Omission errors are related to any human action that should have been performed, but which were not actually carried out. Commission errors are related to human actions that should not be performed, but which in fact are performed (Alvarenga et al. 2011).

The extended Operator Action Tree (OAT) (Kumamoto, 2007) in Figure 1, outlines different human errors for the Post-initiator group

- Slip: The necessary action is recollected correctly, but the action is not performed in time (omission), or is performed incorrectly (commission).
- Lapse: The necessary action is determined by the diagnosis correctly, but the action is not recalled at all (omission), or recalled incorrectly (commission).

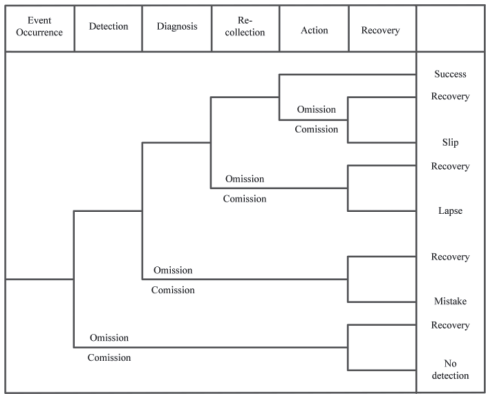

Figure 1. Operator action tree. Extended model (Kumamoto, 2007).

- Mistake: as a result of misdiagnoses, the action is not done (omission), or is done the incorrect action (commission). When the diagnosis does not finish in time, this can be regarded as omission if nothing is done.
- No detection: No action is taken because of a lack of detection (omission), or irrelevant things are performed because of a false detection (commission).

2.2 *HRA techniques*

The birth of the HRA techniques dates back to year 1960. Since mid-80 s several methodologies have been developed, which can be divided into two categories: first and second generation methods (Di Pasquale et al. 2013). Focused on the Post-initiator group, the following review of HR is presented.

First generation methods are strongly influenced by the viewpoint of PRA. These tend to be atomistic in nature, namely, breaking a task into component parts, incorporating the impact of factors such as time pressure, equipment design and stress, known usually as Performance Shaping Factors (PSF). These tools employ the dichotomy omission-commission for human error, and this cognitive model is based on the classification of human behaviour divided into skill-based, rule-based, and knowledge-based (Rasmussen, 1984). Among first generation models, the most remarkable one is Technique for Human Error Rate Prediction (THERP), Swain & Guttmann (1983), which represents the main aspects of these methods generation. Other techniques are Success Likelihood Index Method (SLIM), Embrey et al. (1984); Accident Sequence Evaluation Program (ASEP), Swain (1987); Human Cognitive Reliability model (HCR), Parry et al. (1992). Moreover, The Electric Power Research Institute (EPRI), issued a guidance document for performing HRA known as Systematic Human Action Reliability Procedure (SHARP), Hannaman & Spurgin et al. (1984).

Second generation methods which were first applied in 1990, are based on a cognitive model that is more appropriate to explain human behavior. The focus shifted to the cognitive aspects of humans, the causes of errors rather than their frequency, the study of the interaction of the factors that increase the probability of error, and the interdependencies of the PSF (Felice & Petrillo, 2011). The most representative tools are: Standardized Plant Analysis Risk-Human reliability analysis method (SPAR-H), German et al. (2005); A Technique for Human Error ANAlysis (ATHEANA), NUREG-1624 (2000); as well as Cognitive Reliability and Error Analysis Method (CREAM), Hollnagel (1998).

Finally, the third generation of human reliability methods, started in 2005 and continues today (Di Pasquale et al., 2013), focusing on human performance shaping factors, relations, and dependencies. The only method now defined as third generation is Nuclear Action Reliability Assessment (NARA), Kirwan et al. (2005).

Nowadays, according to NUREG-1792 (USNRC, 2005) and NUREG-1842 (USNRC, 2006), HRA to support PRA uses a mix of techniques from different generations.

3 HEP MODELING

Spanish nuclear power plants have historically used the SHARP methodology to perform HRA. SHARP is not a specific quantification method itself. SHARP is a methodological framework for incorporating human interactions into PRA using a systematic approach. SHARP does not offer explicitly a quantification method, but it gives references to carry out quantification tasks.

Based on the original OAT (Hall et al., 1982), a new structure of the tree is presented in Figure 2, considering the NUREG-1842 (USNRC, 2006).

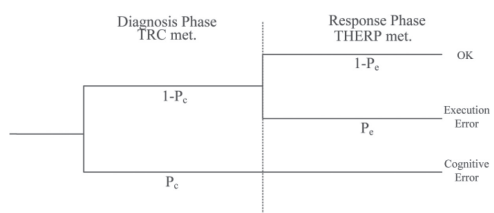

Figure 2. HEP quantification for a post-initiator HFE.

This simplified model decompose the post-initiator HFE in only two phases: diagnosis and response execution phase. As explained in Section 2.1 (Fig. 1), on the one hand the diagnosis phase comprise detection and diagnosis. On the other hand, recollection and action belong to the response execution phase.

HEP quantification can be expressed as:

$$\text{HEP} = P_c + (1 - P_c) P_e \quad (1)$$

where P_c = diagnosis or cognitive error probability, which includes errors due to no detection and mistakes; and P_e = response execution error probability, which includes slips and lapses.

Assuming EOO and EOC on the diagnosis phase as well as response, the most commonly used HRA methods in Spanish plants for post-initiators are:

– Time Reliability Correlation, (TRC), Hall et al. (1983), for the diagnosis phase. The TRC method uses a multivariate lognormal distribution to calculate the probability of an operator successfully responding to a situation within a given time.

This quantification system depends on primarily three factors: available time, whether it is a rule-based action (procedural actions) or a knowledge-based action (non-procedural), and whether the possibility of hesitating exists (Fig. 3).

Furthermore, the TRC method uses the Success Likelihood Indicator (SLI) of the SLIM method (Embrey et al., 1984) to account for the effect of other PSF (i.e. training/experience, workload, stress, procedures, etc.), identified by the experts who are performing the HRA. The influence of the PSF it is reflected as a multiplier which modifies the HEP base value obtained from the curves

– Technique for Human Error Rate Prediction, (THERP), for the response phase. The aim of this methodology is to calculate the probability of the successful performance of the necessary activities for the completion of a task.

THERP involves performing a task analysis to provide a description of performance characteristics of human tasks being analyzed. Results are represented graphically in an HRA event tree, which is a formal representation of the required actions sequence. THERP relies on a large human reliability database containing HEPs, which is based upon both plant data and expert judgments.

As in the diagnosis phase, also THERP applies some PSFs (mainly, experience/training and stress) as a multiplier of the base value.

Among others, these methods are recommended by NUREG-1842 (USNRC, 2006). For this reasons, it will be used both to evaluate the HEP.

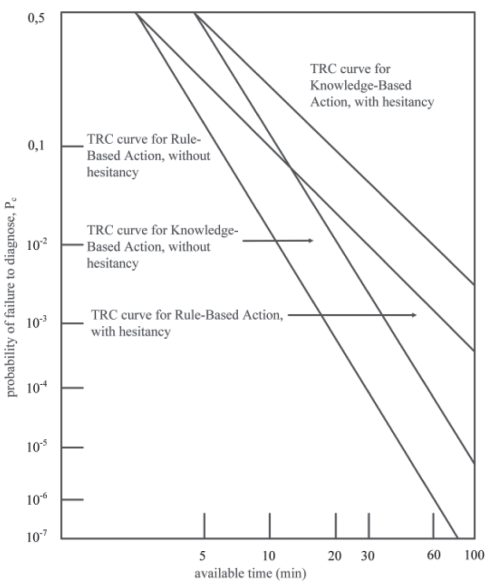

Figure 3. TRC curves for determining P_c.

4 EVALUATION OF RISK IMPACT OF CHANGES TO LIMITING CONDITION OPERATION (LCO)

4.1 *Modeling risk impact*

The PRA model is adopted for risk modeling. RG 1.174 establishes that PRA used should be performed in a manner that is consistent with accepted practices. RG 1.174 states that the quality of a PRA analysis can be measured in terms of its appropriateness with respect to scope, level of detail and technical acceptability. In addition, RG 1.177 requires that the quality of the PRA must be compatible with the safety implications of the TS change being requested and the role the PRA plays in justifying the change.

Thus, the original PRA modeling available should be refined if needed on the basis of the revision of the Capability of the PRA for the particular application to the analysis of changes to Completion Times (CT) and the way in which sources of uncertainty have to be addressed. This should include the identification of not only the usual sources of uncertainty linked to PRA models and data but also the sources of model and parameter uncertainties associated with the assumptions made in CT change evaluation.

RG 1200 (USNRC, 2009) describes one acceptable approach for determining whether the technical adequacy of the PRA used is sufficient to support an application. Specifically, RG 1.200 provides

guidance on the scope of the PRA and the level of detail, among other features.

There are several sources of uncertainty linked to both the inherent capability of the PRA available to quantify the required risk metrics and the additional assumptions made within the PRA application to evaluate the risk impact of the particular CT change.

Random and parametric uncertainties are built into the structure of the PRA model itself. It is this aspect of uncertainty that gives PRA the probabilistic part of its name. They are typically characterized by establishing probability distributions on the parameter values. However, there may be different options or alternatives on how the models should be formulated. Examples include approach to modeling human performance, common-cause failures, ageing of equipment, maintenance effectiveness, etc. This leads to modeling human performance. Human failure events are one of the inputs of the integrated decision-making described in RG 1.174.

4.2 *Revised HRA affected by the change*

In addition, NUREG 1764 provides guidance for use in determining the appropriate level of human factors engineering review of human actions based upon their risk-importance. This guidance uses a graded, risk informed approach that is consistent with Regulatory Guide (RG) 1.174, Rev.1 (USNRC, 2002)

Human actions that are considered more risk-significant receive a detailed review, while those deemed less significant receive a less detailed review. NUREG 1764 uses a two-phased approach to reviewing human actions. Phase 1 is a risk screening and analysis of the affected human actions identified by the licensee to determine their risk-importance and the level of HFE review that is appropriate in Phase 2. The second phase is an HFE review of those human actions that are found to be risk-important.

4.3 *Assessment risk impact*

Risk assessment is proposed by quantifying the usual risk metrics adopted in analyzing CT changes in the literature. It is proposed as a treatment of model and parameter uncertainties based on traditional sensitivity studies and uncertainty assessment respectively, the latter being based on the probabilistic approach for uncertainty formulation and propagation as set by the standard Monte Carlo Sampling technique.

The quantification of the risk impact involves obtaining numerical results from the PRA application, which are then used to calculate the required risk metrics including appropriate treatment of their associated uncertainty.

Basic risk measures applicable in evaluating the risk impact of CT changes are (RG 1.174, USNRC, 2011): 1) Conditional risk given the limiting condition of operation, 2) Incremental conditional risk and 3) Yearly CT risk, which can be formulated, adopting the CDF as a baseline risk measure that can be derived by using a Level 1 PRA, respectively as follows:

$$\Delta CDF_M = CDF_1 - CDF_0 \quad (2)$$

$$ICCDP_M = d_M \cdot \Delta CDF_M \quad (3)$$

$$CDF_M = f_M \cdot ICCDP_M = u_M \cdot \Delta CDF_M \quad (4)$$

Equation 2 represents the condition-specific risk, which represents the increased risk when the equipment is down for maintenance, CDF_1 [year^{-1}], as compared with the reduced risk when the component is known not to be down, CDF_0 [year^{-1}], as compared both with the baseline risk, CDF [year^{-1}]. Equation 3 represents the Incremental Conditional Core Damage Probability ($ICCDP_M$) [dimensionless], also known as single-event CT risk for the downtime, d_M [years], associated with one occurrence of the CT. Equation 4 represents the yearly CT risk associated with the average yearly frequency, f_M [year^{-1}], of occurrences of the CT.

Specifically concerning Technical Specifications, RG 1.177 establishes one more risk metric specific to CT changes for evaluating the risk impact associated with the revised CT, which corresponds to the single-event CT risk after the change, i.e. $ICCDP_M$, which can be derived directly using Equation 3 with the revised downtime, d_M.

The quantification of risk impact of the CT change, adopting the previous risk metrics, has to be performed in such a way that uncertainties are treated in the most appropriate way, which depends on the type of uncertainty. In this paper, special attention is paid to model and parameter uncertainties associated with human performance affected by the LCO change.

4.4 *Analysis of risk impact*

Once the risk impact of the CT change has been assessed as proposed in the previous Section 4.3, it must be compared against the numeric guidelines given in RG 1.174 (see Section 2.4 in RG 1.174). In addition, for CT changes, the risk impact should be compared also against the numerical guidelines presented in Section 2.4 in RG 1.177.

In particular, RG 1.177 proposes adopting two acceptance guidelines for the evaluation of CT changes when using a level 1 PRA. The first one, which is the same acceptance guideline proposed

by RG 1.174 for evaluating whatever change to the LB, uses the baseline CDF and ΔCDF. Thus, the numerical acceptance guidelines are given in RG 1.174 in terms of regions defined in the space of values {CDF, ΔCDF} where the results of the impact on risk of a CT change are placed (see RG 1.174 for a more detailed description of such regions).

RG 1.177 establishes a second acceptance guideline specific for evaluating the risk associated with changes to CT. It corresponds to the single-event CT risk metric assessed after the CT change. It establishes that the licensee has to demonstrate that the CT change only has a small quantitative impact on plant conditional risk. For example, an ICCDP of fewer than 5.0E-07 is considered small for a single CT change using a level 1 PRA. Linked to this second guideline, RG 1.177 establishes the ICCDP contribution should be distributed in time so that any increase in the associated conditional risk is small and within the normal operating background (risk fluctuations) of the plant. Clear indication is provided that ICCDP acceptance guideline of 5.0E-07 is based upon the hypothetical situation in which the subject equipment at a representative plant is out for five hours, causing the CDF of the plant, with an assumed baseline CDF of 1.0E-04 per reactor year, to conditionally increase to 1.0E-03 per reactor year during the five-hour period. Based on the previous paragraph, it seems that a conditional increase to 1.0E-03 per reactor year can be used as a reasonable acceptance guideline for the third risk metric. Based on this second acceptance guideline in RG 1.177, one can outline two regions in the space of values {CDF_1, ICCDP} where the results of the impact on risk of a CT change are placed. The region of acceptable changes is located below the boundary point {1.0E-03, 5.0E-07}.

5 APPLICATION CASE

5.1 *Problem description*

This application case is focused on studying the effect of human factor in the analysis of changes to LCO applied to manual starting of RHRS. The methodology proposed in RG 1.174 is used in order to assess and analyze the risk impact of the proposed change.

As mentioned in the RG 1.174, to quantify the risk impact and compare the results extracted with the acceptance criteria it is necessary to address all the sources of uncertainty. On the one hand, the model uncertainties due to the methodologies chosen for modeling the human performance. On the other hand, the parameter uncertainty in terms of HEP log-normally distributed, which is determined through Thermal-Hydraulic Analysis (THA). Finally, following the results, it is propose a change to LCO, specifically in the Completion Time (CT) change of the RHRS.

The accident sequence corresponding to the loss of the Residual Heat Removal System in Operating Mode 4 (OM 4) during cool down operations has been studied (Table 1). The analysis of this sequence is framed within the Low Power & Shutdown PRA (LPRA) of a typical Pressurized Water Reactor (PWR).

In shutdown conditions, one train of the RHRS removes the residual heat from the core. When the loss of one train of the RHRS is produced, the emergency procedures require checking the availability of the redundant RHR train. If the remaining train is not recovered, an alternative way of cooling the core is using the initial water inventory of the Steam Generators (SG), on the secondary. The Auxiliary Feedwater System (AFWS) prevents the SG from drying out. Next, if it is not possible to remove the heat by means of Steam Generators and pressure and temperature limits to restart the RHRS are exceeded, the "Feed and Bleed" function is required. Charge pumps injecting water can recover the lost inventory and maintain the cooling down as the residual heat is evacuated through a pressurizer relief valve or a RHR safety valve. Finally, in all cases it is necessary to restore the RWST to maintain the plant in a stable conditions in the long run.

5.2 *Modeling scenarios*

The LPRA of a typical PWR describes the event tree showed in Figure 4 for the loss of RHRS at OM 4. To evaluate the effect of parameter uncertainty by means of THA, the analysis is focused on the safety functions, the headers of the event tree, W2 and E1.

Safety function W2 consists of ensuring that the redundant RHR train is operational so as to continue removing the residual heat. This task consists of starting the pump of the RHR remaining train and the support systems required. Recently, in the last LPRA carried out, the possibility of recovery the RHR train in service was not taken into

Table 1. Characteristics of operating mode 4.

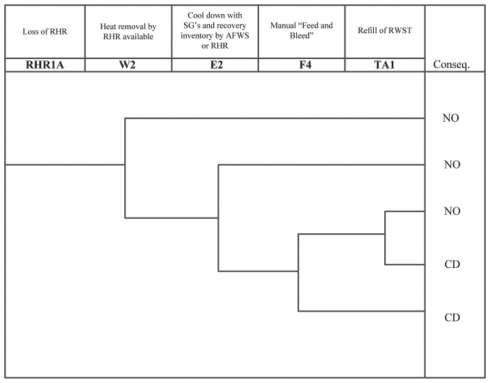

Figure 4. Event tree: loss of RHR at operating mode 4.

account. As a consequence, in OM 4 decreasing power, the pressure and temperature limits to start the standby RHR train exceeded quickly, not leaving any time available for the operator.

The other safety function, E1, states that the SG is an alternative way to evacuate the residual heat. Conservatively, it refers to only two SG whose inventory must be recovered through AFWS motor pumps. This header includes the possibility to restart the RHRS later, provided that the temperature and pressure conditions in the primary allow it.

In spite of what has been explained beforehand, in this application case the possibility of restarting the remaining RHR train is considered. The operator is provided with a specific time window which depends on the moment when the initiator occurs. Moreover, the HEP associated to start the pump is strongly influenced by the available time.

In the first place, the time windows have been extracted, which come from modelling taking into account the time between the start and the end of OM 4. By simulating the accident sequence described, three different time intervals can be considered (Table 2):

- TH1: time to start up the remaining RHR train, between the beginning of OM 4 until the pressure and temperature thresholds of the primary are exceeded to prevent commissioning it.
- TH2: interval to start up the heat removal by means of SG and the AFWS motor pumps to recover the inventory, with the aim of leading the plant to stable conditions.
- TH3: this time window is overlaps with TH2, and appears when the cool down from the SG result in the pressure and temperature conditions which allow to start up again the remaining RHR train.

Therefore, along with TH1 and TH2, the third time window which indicates the available time to evacuate the heat from the RCS through the SG relief valves together with the water injection comes from the AFWS, which is the sum of TH2 + TH3

Table 2. Time windows description.

Time window	Description	Header	System
TH1	Failure of the operator in the RHR restart	W2	RHR
TH2	Failure of the operator in the RHR restart	E1	RHR
TH2 + TH3	Failure of the operator in the start of AFWS motorpumps	E1	AFW

Table 3. HEP obtained for each time window.

Time window	Mean	Standard desviation	95th percentile	5th percentile
TH1	6.170E-01	3.389	1.350E-01	5.228E-03
TH2	3.884E-05	0.233	1.045E-04	6.630E-12
TH2 + TH3	6.642E-04	0.484	3.570E-04	2.322E-09

5.3 *Results of human error probability*

Once the different time windows have been determined by using thermal-hydraulic simulations, these should be evaluated in terms of HEP.

According to the HR modelling explained above, two techniques have been employed to lead the HRA, including it in the LPSA. On the one hand, for the diagnosis phase, the TRC method has been used. The direct influence of the different time windows extracted from thermal hydraulics simulations is directly reflected in the HEP quantification achieved by this technique. On the other hand, the manual or response phase has been carried out by using the THERP method.

The results obtained through HRA showed a HEP log-normally distributed, with the following proper-ties for each time window (Table 3).

5.4 *Assessment of risk impact*

Upon obtaining the HEP distribution for each time window considered, three different cases have been discussed. These are:

- Base case: According to the last LPRA event trees for the accident sequence studied, it is not possible to start the remaining RHR train due to the quick increasing in the RCS temperature and pressure, which surpasses the limits to

Table 4. Impact of the CT change in {CDF_1, ICCDP}.

	CDF_1 (year^{-1})			ICCPD (–)		
Study	Mean	5% perc.	95% perc.	Mean	5% perc.	95% perc.
Base case (CT = 1h)	1.500E-03	3.300E-04	3.730E-03	1.703E-07	3.741E-08	4.238E-07
Sensitivity HEP (CT = 1h)	3.430E-04	1.210E-04	7.930E-04	3.826E-08	1.355E-08	8.849E-08
Sensitivity HEP (CT = 24h)	3.430E-04	1.210E-04	7.930E-04	9.183E-07	3.252E-07	2.124E-06
Sensitivity HEP (CT = 5h)	3.430E-04	1.210E-04	7.930E-04	1.913E-07	6.775E-08	4.425E-07

Table 5. Impact of the CT change in {CDF, ΔCDF}.

	CDF_1 (year^{-1})			ICCPD (–)		
Study	Mean	5% perc.	95% perc.	Mean	5% perc.	95% perc.
Base case (CT = 1h)	7,830E-06	2,300E-06	1,780E-05	2,334E-10	5,125E-11	5,806E-10
Sensitivity HEP (CT = 1h)	7,830E-06	2,300E-06	1,780E-05	5,242E-11	1,856E-11	1,212E-10
Sensitivity HEP (CT = 24h)	7,830E-06	2,300E-06	1,780E-05	1,048E-10	3,712E-11	2,424E-10
Sensitivity HEP (CT = 5h)	7,830E-06	2,300E-06	1,780E-05	1,092E-10	3,867E-11	2,525E-10

recover the system. As a result, the HEP resulting from time windows TH1 and TH2 equals the unit, namely, the failure of the operator is bound to take place. The CT for the base case is 1 hour. This case represents the most conservative estimation.

- Sensitivity HEP case (CT = 1h): it is possible to start the remaining RHR train with a HEP modeling as explained in Section 4.3, using the available times of thermal hydraulics simulations. CT is the same as the base case (CT = 1 hour).
- Sensitivity HEP (CT = 24h): it is the last case, with a CT change consisting of extending it from1 to 24 hours.

The PRA is used to calculate the CDF_1 and CDF_0 basic risk measures, adopting 10^{-13} as the truncation limit. By using Equation 2 it is possible to quantify the conditional risk metric, ΔCDF_M.

Moreover, the maximum allowed downtime has been adopted. 1 or 24 hours for the CT, to measure the second risk metric, $ICCDP_M$ (Eq. 3).

The frequency of entering LCO has been estimated from plant data, i.e. $f_M = 0.00137$ years^{-1}, which is necessary to quantify the yearly CT risk, CDF_M (Eq. 4).

Tables 4 and 5 present the results as a summary of the study for the three different case.

5.5 *Analysis of risk impact*

This section presents the comparison of the results showed in the previous section with acceptance guidelines, reflected on Table 6.

Table 6. Acceptance guidelines.

Risk measure	Risk unit	Treshold	Reference
ΔCDF_M	(1/year^{-1})	1.000E-06	RG 1.174
CDF_M	(1/year^{-1})	1.000E-03	RG 1.174
$ICCDP_M$	(–)	5.000E-07	RG 1.177
CDF_1	(1/year^{-1})	1.000E-03	RG 1.174

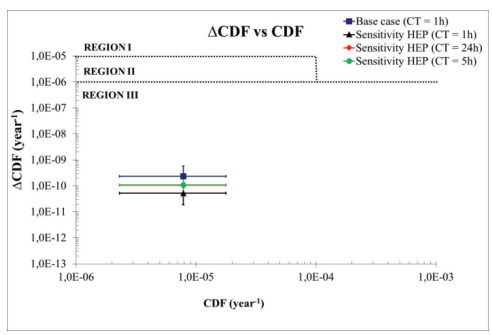

Figure 5. Impact of the CT change in {CDF, ΔCDF}.

In first place, couples {CDF, ΔCDF} have to be placed in the corresponding decision region linked to the first acceptance criterion established in RG 1.174 (USNRC). The mean values for the base case, as well as the sensitivity studies, confirms that the changes remain in the appropriate region, including percentiles (Fig. 5).

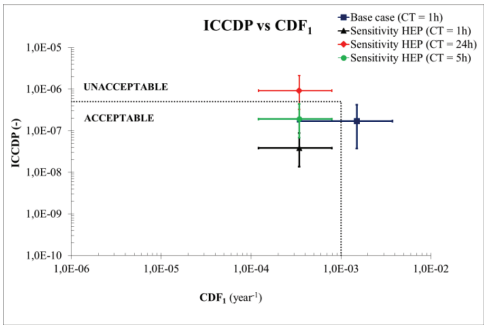

Figure 6. Impact of the CT change in {CDF_1, ICCDP}.

Furthermore, couples {CDF_1, ICCDP} are compared to the second acceptance criterion established in RG 1.177 in a similar way. For the base case, the CDF_1 mean value is out of the appropriate region (Fig. 6). Through modeling human reliability, the sensitivity HEP case satisfies these thresholds, for the mean values, but also for the percentiles. Due to this change, it is possible to extend the CT change, but not up to 24 hours. Using percentile 95%, the most restrictive measure, the maximum CT change which remains the mean value and the percentiles in the appropriate region, as determined by Equation 2:

$$d_M = 5.66h \approx 5h \quad (5)$$

6 CONCLUDING REMARKS

The purpose of this paper is show the effect of uncertainty associated to human reliability in the context of the LCO changes.

An example of application is provided that is centered in a manual starting of Residual Heat Removal System of a typical PWR Nuclear Power Plant. The assumption of more realistic approaches to define the human performance, by means of HRA techniques, allows changes into LCO, which are in the framework of the evaluation of Risk Impact addressed by RG 1.174 and RG 1.177.

The results of the study case shows the improvements following this methodology. Firstly, introducing the HEP distribution, improvements have been achieved in every risk measures. In the case of couples {CDF_1, ICCDP}, including the mean values and the percentiles in the appropriate region which assign the guidelines. Subsequently, is possible to make a change in the LCO of the RHRS, extending the CT from 1 to 5 hours.

Consequently, the paper shows the benefits of the HRA used in the PRA in order to improve and make changes in the LCO of systems, which acquires more importance in critical systems as RHRS.

ABSTRACT: The work presents the application of PSA as a design tool for VVER 440/213 type plant. The reference PSA model based on the state-of-the-art methodology is presented, with a focus on dependency modeling, human reliability, interface between PSA L1/L2, digital I&C modeling. Its application for risk informed decision making is detailed and the main achievements are outlined.

1 INTRODUCTION

Probabilistic Safety Assessment (PSA) represents an important tool in both design and operation of NPPs (e.g., IAEA-TECDOC-1200 and SSR 2/1). In fact, the probabilistic tools extend traditional deterministic analyses providing a better understanding of accidental sequences characterized by combined failures. Additionally, in parallel to deterministic safety assessment, PSA helps identifying plant vulnerabilities and dependencies between systems, examining different design options and prioritizing improvement areas.

The present work describes the application of PSA as a design tool for VVER 440/213 type plant. The reference power plant is Mochovce 3-4 NPPs, currently under completion in Slovak Republic. The corresponding PSA model is based on the state-of-the-art methodology, which includes both national (BNS I.4.2) and international standards (SSG-3 and SSG-4). In Sect. 3, a review of the methodology is provided with a focus on dependency modeling, human reliability, interface between PSA L1/L2, digital I&C modeling. The application of PSA for risk informed decision making is detailed (Sect. 4) and a selection of results is reported in Sect. 5.

2 SCOPE OF PROBABILISTIC SAFETY ASSESSMENT

The section defines the scope of PSA analysis with reference to national legislation and international standards.

2.1 *Initiating event coverage*

In accordance with the requirement of Slovak Nuclear Regulatory Body in BNS I.4.2, the scope of the probabilistic assessment shall cover a complete set of Postulated Initiating Events (PIE), including internal and external hazards. The definition of internal initiating events is based on the IAEA-TECDOC-749 which defines the list of PIEs to be considered for a VVER type reactor. The list is extended to account for the operational experience in other VVERs in general and mores specifically from the operating fleet in Slovak Republic. The analysis of risky manipulation that can cause a man-induced initiating event is also part of the initiating event definition and is based on operational experience on this VVER type.

2.2 *Plant operational states*

The probabilistic safety assessment is developed as an integral PSA model covering all Plant Operational States (POS) of the plant, covering full power, low power and shutdown states. The reference model considers 15 POSs to include the 6 operational modes combined with the typical configurations of the units during maintenance in shutdown states. The determination of these POSs was carried out on the basis of operational experience on other Slovak NPPs and includes plant-specific peculiarities deriving from detail design development.

2.3 *Core damage and large early releases*

Both level 1 and level 2 PSA are developed in compliance with IAEA SSG-3 and SSG-4 in order to

evaluate the scenarios of fuel damage (PSA L1) and radiological releases (PSA L2). The targets for Core Damage Frequency (CDF) and Large Early Releases (LERF) set in BNS I.4.2 for new reactors are respectively 10^{-5} and 10^{-6} per reactor per year (including internal/external hazards), i.e. one order of magnitude below existing and operating NPPs.

2.4 *System coverage and success criteria*

In accordance with the requirement of Slovak Nuclear Regulatory Body in BNS I.4.2 and general international requirements (SSG-3 and SSG-4), the PSA model shall be a comprehensive description of the NPP. In order to have useful information from PSA, a realistic model of the plant is necessary. To account for all relevant dependencies, all necessary support systems are included in the model such as HVAC, electrical supply and heat sink are included in the PSA model. The success criteria for front-end safety systems are derived based on detailed thermal hydraulic analysis specific for the plant and the fuel under analysis, both for core damage and for radiological releases.

2.5 *Input data*

In accordance with BNS I.4.2 and general international requirement, the PSA model implements as far as possible plant specific data for component/system reliability and frequencies. More specifically, for those components similar to those in operation in Slovak NPPs, the corresponding reliability data are used. For completely new technology components, detailed assessment is carried out (see for instance digital I&C in Sect. 3).

3 METHODOLOGY

The section details various aspects of the methodology chosen for the probabilistic assessment.

3.1 *Fault trees and event trees*

The general approach chosen for the PSA model is the large Fault Tree (FT)/small Event Tree (ET). Using this approach, the ET size is kept in manageable size and it is easier to understand the temporal evolution of the progression of accident. On the other hand, FTs form complex structure to include dependencies between various systems. FTs are composed in a modular form that are then suitably used to model functionality of systems considered in ETs to mitigate consequence of initiating events. Specific POSs conditions influencing operability of systems are implemented by using configuration FTs, which are then incorporated in system/sub-system fault threes. This approach enables the use of a limited number of functional events (top FTs linked to the ETs) to model any specific conditions (with reasonable extent) which facilitates development and maintenance of the model.

3.2 *Dependencies*

The functional link between systems is evaluated via a dependency matrix providing comprehensive overview of system relationships including all relevant support systems, such as: HVAC, electrical supply, heat sink, I&C, etc. The modular form of FT as defined in 3.1 enables easy linking of support system modules to catch particular dependencies.

The dependency between a class of components and/or various redundancies is modeled via classical common cause factors, using international best practices (alpha model) and data implementing operational feedback.

3.3 *PSA L1 and L2 interface*

Interface between PSA L1 and L2 is based on bridge tree approach in order to maintain consistency and integrity of the model. The chosen approach groups all core damage sequence from PSA L1 into characteristic typology, generally known as Core Damage End States (CDES) that reflects specific conditions of particular initiating event as well as possible progression of severe accident. The set of PSA L1 consequences in each CDES belong to the same POS and leads to similar initiating events in PSA L2 (e.g. large LOCA, medium LOCA, SGTR, IFSL or transient) with similar boundary conditions (e.g. availability of safety systems).

The bridge trees for PSA L2 reflects specific conditions inherited from PSA L1. Additionally hardware dedicated for severe accident mitigation and plant specific SAMGs are incorporated. Ad hoc FTs

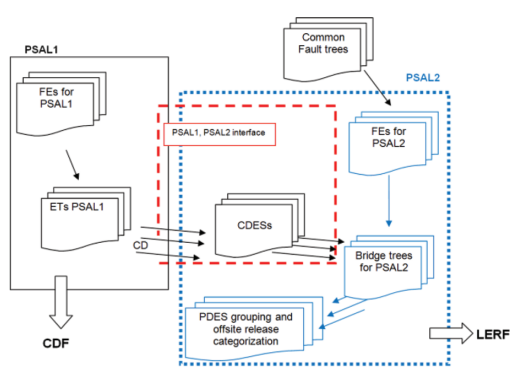

Figure 1. General overview of PSAL1—PSAL2 interface.

are used to model standard PSA L2 activities such as depressurization and cooling of reactor, containment isolation; their modeling is based on the same principles as for FTs of PSA L1.

3.4 *Human reliability*

The list of human action modeled in PSA is defined in accordance with valid EOPs/SAMGs and thermal hydraulic calculation in support for PSA. The evaluation of the human reliability is based on broadly accepted THERP/ASEP methodology (NUREG/CR-1278 and NUREG/CR-4722). The chosen approach is based on critical action concept. Any manual action, evaluated as Compound Human Error Probability (CHEP), can be composed from arbitrary number of tasks that are evaluated as Joint Human Error Probability (JHEP). JHEP is split between diagnosis and manipulation steps that are evaluated as basic human error probabilities. Self-recovery and independent recovery are considered where appropriate and with conservative approach. Recovery actions usually considers at least medium dependency between activities. The uncertainty propagation can be managed analytically as defined in NUREG/CR-1278. As a final verification, CHEPs having high importance are verified by using SPARH methodology as an independent verification.

After evaluation of human reliability, the actions performed by operators in control room are implemented at ET level in PSA L1, enabling a direct evaluation of dependencies between various actions. Activities performed within PSA L2 and by in-situ operators/technicians are implemented at FT level.

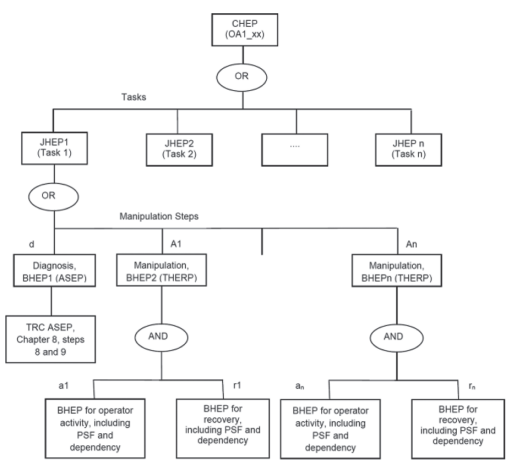

Figure 2. Example of HRA evaluation based on ASEP/THERP.

3.5 *Digital I&C*

The digital I&C considered for the project is new with respect to what is used in previous NPPs in Slovakia. For this reason there is no relevant operational experience from operating Slovak NPPs and the assessment of its reliability is based on the detailed reliability data from relevant suppliers. The reliability of the I&C is assessed based on standard FMEA analysis, followed by a fault tree analysis for reliability estimation. The potential common failure modes are accounted for with suitable common cause factors substantiated with detailed analysis. Input data used for its evaluation are taken from the operational experience of the digital systems operating in other NPPs. Several conservative assumptions (e.g., input reliability data) are considered to ensure that the final result is a bounding estimation.

Due to the complexity of I&C systems its reliability is evaluated by using separate model. Results of this model is then generalized and used as inputs for specific I&C basic events in main model.

3.6 *Symmetric model*

Particular POSs as well specific initiating events can often create asymmetries in the PSA model. The impact of this fact is important mainly for PSA application where for instance it is important to know the impact of the specific unavailability of a component on CDF/LERF. For this reason, the PSA model was adjusted to be symmetric, modeling relevant initiating events as loop-by-loop or system-by-system events.

3.7 *Internal hazard modeling*

The internal hazard modeling in PSA is carried out in accordance with IAEA SSG-3. Following this approach, the evaluation of any considered hazards is divided into various steps:

1. Qualitative screening: based on qualitative criteria, it can be shown that the initiating event cannot impair the safety.
2. Quantitative screening: in case the event has an impact on nuclear safety (either direct or indirect, e.g. through some support system). In such case there can be screened out all initiating events that cumulative contribution to the CDF, which is based on conservative assumptions, does not exceed reasonable threshold. The threshold considered in the framework of this project is set to 10% from safety target for PSA L1.
3. Detailed evaluation: events which cannot screened out based on qualitative and quantitative criteria are consequently included into

detail modeling to estimate their contribution to the CDF.

3.8 *External hazard modeling*

The external hazard modeling in PSA follows indications in IAEA SSG-3. In general, evaluation of external hazards uses similar approach as internal hazards.

In the framework of post-Fukushima stress test activity a thorough design review of the external hazard was carried out, re-assessing the reference level and their corresponding frequency.

4 APPLICATION OF PSA

The application of PSA in various phases of the design of Mochovce 3 and 4 completion project are detailed in the following sections.

4.1 *PSA in the early stage of the project*

The general PSA model was developed in various stages of the project. In preliminary safety analysis report, the model was based on basic design requirement and was used to evaluate the most relevant contributors to CDF and LERF.

PSA was used in this stage mainly as tool for the identification of the risk reduction measures. There were identified several important topic during this stage, such as:

- Hardware modifications (e.g., introduction of new automatic signals to cope with some scenarios in shutdown state where ESFAS actuation can be in maintenance or is disconnected)
- Operational procedure improvement (e.g. operation of water make-up system during cold shutdown to avoid penetration of nitrogen into primary circuit)
- Optimization of technical specifications (e.g. new requirement on availability of safety systems in shutdown states).

4.2 *PSA in detail design development*

During detail design development, the PSA model was regularly updated to reflect the technical modifications implemented in the plant completion. There were several iterations of this process due to successive improvements in several technical areas (e.g., power supply, seismic qualification).

In this phase, PSA was used for:

- Evaluation of design improvements: verification of the impact of a technical solution on the probabilistic figures, including the impact of post-Fukushima stress test measures.
- Definition of selected severe accident scenarios: in accordance with Slovak Decree 430/2011 and relevant international standards (e.g., IAEA SSR 2/1, WENRA Reference Levels), the definition of selected severe accidents shall be carried out also based on probabilistic evaluation.

4.3 *PSA during operation*

During operation, as prescribed in BNS I.4.2 and in relevant international guidelines (e.g., SSG-3 and SSG-4), PSA shall be used for risk-informed decision making purposes, such as safety monitor, in-service inspection optimization and analysis of near-misses. The use of PSA in the evaluation of needs of additional training for critical human action is also envisaged in accordance with BNS I.4.2 and IAEA-TECDOC-1200.

5 MAIN OUTCOMES OF PSA ANALYSIS

The PSA model for MO34 is implemented in Risk Spectrum software. Considering all combinations of POSs and PIEs, the model includes more than one thousand ETs and around two thousands of FTs.

5.1 *Selected results*

The assessment of core damage and large early release frequencies for MO34 NPP demonstrates that safety targets defined in BNS I.4.2 are fulfilled. Additionally, in accordance to general international guidelines (IAEA SSR 2/1, SSG-3, SSG-4), the PSA results show that:

- There is no Minimal Cut Set (MCS) that represents a significant share of the global risk for which additional risk reduction measures would be necessary; for PSA L1, most relevant MCSs are below 3% of the global CDF and for PSA L2 relevant contribution of dominating sequence is below 1%
- Considering the duration of each plant operational states, the risk is well-balanced between power state and shutdown conditions; as it is clear from Figure 3, the improvements due to risk reduction measures makes the hourly risk similar in power and shutdown states
- The risk is reasonably shared between IEs as there is not an initiating event that predominates over the others. As sketched in Figure 4 for power states, the contribution of PIE to CDF is well-balanced. In Figure 5, the rebalancing of the risk before and after design improvements is reported showing their effectiveness to deal with LOCA in shutdown states.

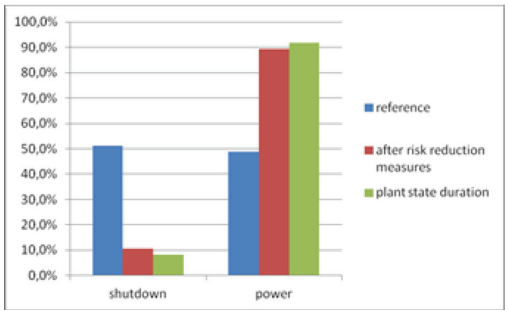

Figure 3. Example of PSA L1 risk repartition between plant operational states.

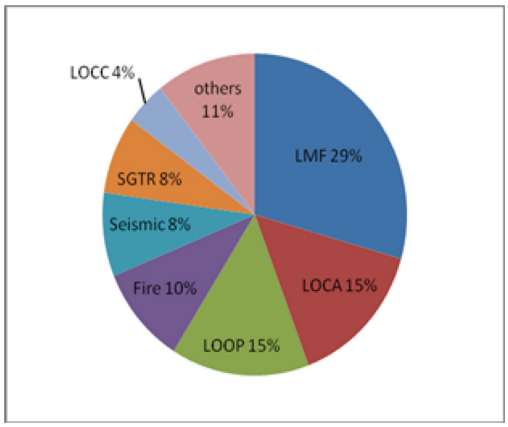

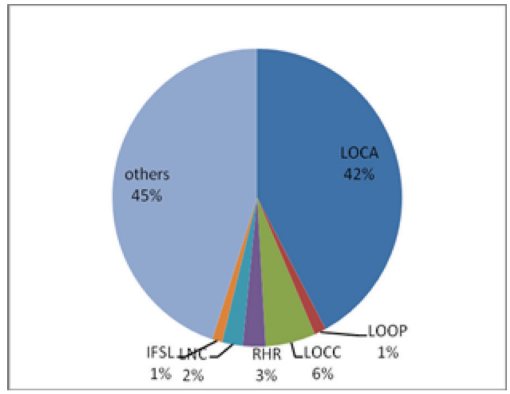

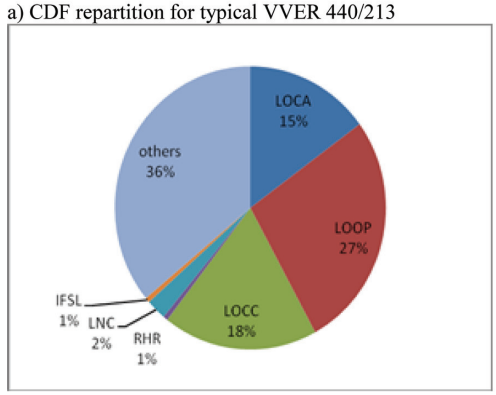

Figure 4. Example of contribution of various IEs to CDF in power state for a typical VVER 440/213 after design improvements and implementation of risk reduction measures.

a) CDF repartition for typical VVER 440/213

b) CDF repartition for after design improvements

Figure 5. Example of contribution of various IEs to CDF in shutdown state (excluding internal and external hazards). The lable "other" refers to the cumulative risk associated to postulated initiating events not directly included in the graphs.

It has to be mentioned that besides the redistribution of the risk, the risk reduction measures (including outcomes of stress test analysis) also helped reducing the global risks and meeting the very challenging targets for new reactors set in BNS I.4.2 (one order of magnitude below existing NPPs). Table 1 provides an estimation of the impact of design improvements (both hardware and operational) on CDF.

Table 1. Estimation of the variation of CDF after design modifications.

State	Δ_{CDF}
Full power	–11%
Shudown	–91%

5.2 *Uncertainty evaluation*

Two types of uncertainties are generally distinguished in PSA analysis, namely epistemic and aleatory uncertainty. Epistemic uncertainty evaluation is assessed during the review of the model and is suitably substantiated in the development and commenting of ETs/FTs. The main assumption of the model are reviewed in the PSA documentation and, where appropriate, a detailed reasoning and/or a sensitivity analysis is provided, with an evaluation of the impact on PSA figures. Aleatory uncertainty is treated by standard means, i.e. associating a probability density function to basic event and propagating uncertainties through the model by means of Monte Carlo simulations. Average error factor ranges between 4 and 5 for power or shutdown state respectively. The main contribution to aleatory uncertainty is due to human-induced events or human actions where the associated

error factor is generally larger due to the inherent variability of the basic events.

6 CONCLUDING REMARKS

In conclusion, general insights from PSA L1 and L2 results show how the implementation of risk reduction measures can be successfully used to meet the stringent probabilistic requirements for new reactors and to reach a well-balanced risk between plant operational states and between initiating events.

Deriving a distribution for accident severity from an F-N curve

J. Braband
Siemens AG, Braunschweig, Germany

H. Schäbe
TÜV Rheinland, Cologne, Germany

ABSTRACT: In an earlier paper, we studied several approaches for modeling the accumulated severity of railway accidents in a certain time interval with the help of a compound Poisson process. The number of accidents can be modeled with a Homogeneous Poisson Process. The distribution of accident severity, however, has not been studied in detail until now.

F-N curves are frequently used to create a relation between accidents having a severity of a certain level or higher on the one side and an admissible number of accidents on the other side. Often F-N curves are used to create safety targets for collective risks.

In this paper, we show that, when an F-N curve is assumed, a Pareto distribution for the accident severity, i.e. for the jump height of the compound Poisson process, is obtained. Using standard statistical methods, we derive a procedure for statistical estimation of the parameters of the jump height. We give one and two-sample tests for testing equality with a given distribution of accident severities or testing equality of two distributions of severity. Moreover, we provide a test for checking whether the hypothesis of the distribution of accident severities holds.

Another application of this approach is the derivation of typical accident categories for use in semi-quantitative risk analyses. We use accident data collected by the European railways over the last decade as a basis for illustrative examples.

1 INTRODUCTION

In an earlier paper, we modeled the accident statistics of railways with the help of a Compound Poisson Process (CPP), see Braband & Schäbe (2011), Braband & Schäbe (2013b).

We first give a generic definition of the problem. We assume a CPP with N_t depicting the number of accidents until time t and $S_1, S_2, \ldots$ an independent, identically distributed (i.i.d.) sequence of random variables describing the severity of the accidents. The sum of all accident severities until time t, $X(t)$ is then distributed as

$$X(t) = \sum_{i=1}^{N_t} S_i. \tag{1}$$

From Birolini (2007), we also know the exact distribution if the jumps are independent and identically distributed (i.i.d.)

$$P\big(X(t) \le x\big) = 1 - F_1(t) + \sum_{n=1}^{\infty} G_n(x)\big(F_n(t) - F_{n+1}(t)\big), \tag{2}$$

where F_i and G_i denote the i-fold convolution of the distribution functions of the time between events and the severity, respectively. The distribution F_n can be motivated to be an Erlang distribution, which is motivated by the homogenous Poisson process describing the number of accidents.

In this paper, we motivate the choice of a distribution G for the jump height of the CPP, i.e. the accident severity. In section 2, we derive this distribution from the F-N curve. It turns out to be a Pareto distribution. In section 3, we give basic statistical information on parameter estimation and testing. This is straightforward, since the Pareto distribution is well known. In section 4, we provide an illustrative example.

2 DERIVATION OF THE DISTRIBUTION

Individual risk is simply the predicted frequency of the undesired outcome. Societal risk takes account of both the severity of the range of possible outcomes and the frequency at which they each are predicted to occur. It is usually presented as a two-dimensional relationship between frequency and cumulative severity of outcome, called an F-N curve. The F-N curve is frequently used for giving target values for maximal numbers of accidents (say F) with N or more accidents. The F-N

curve is used to provide group risks, see e.g. Proske (2008). F-N curves have also been computed from statistics, see e.g. Braband & Schäbe (2011) or used for the definition of risk targets, as e.g. in Rijswaterstaat (2002).

The F-N curve is a curve defined by

$$F = A*Na, \tag{3}$$

where A and a are parameters. F is the "frequency", i.e. the maximal tolerable number for accidents with N or more fatalities. The number of fatalities, N, is mainly measured in FWSI. This stands for Fatalities and Weighted Serious Injuries and has been defined by the European Union, see EC (2009). FWSI values are a sum of fatalities and the number of serious injuries multiplied by 0.1. In this manner, serious injuries are also taken into account. The factor 0.1 arises from experience that normally in accidents about 10 serious injuries occur as frequently as one fatality. Sometimes also equivalent fatalities are used, which take also into account slight injuries with a factor of 0.01. However, the definition of slight injuries is too different at least in the railway sector to allow it to be used in comparisons. Therefore, the smallest severity of an accident in terms of FWSI is 0.1.

Now, from (1) one can derive the probability that an accident occurs with more than s fatalities. It is just

$$Pr(S > s) = A*sa/A*0.1a = B*sa, \text{ with } s \geq 0.1 \tag{4}$$

where B is a new constant. Equation (2) presents the survival function of the distribution function of accident severities with severities of at least 0.1. Therefore, (2) is a conditional distribution function.

Obviously, the probability density of this survival function reads

$$f(s) = a*B*sa - 1 = a*sa - 1/0.1° \text{ for } s \geq 0.1 \tag{5}$$

and zero otherwise.

This is the Pareto distribution, which can be found in standard textbooks, such as in Johnson, Kotz & Balakrishnan (1994). This distribution is typical for the distribution of income.

3 ESTIMATION AND TESTING

When considering the distribution function (3), it is obvious that only one parameter needs to be estimated. The second parameter B is fixed by the requirement that only accidents with at least 0.1 FWSI will be regarded. The estimator of a is given in Johnson & et (1994) as

$$\hat{a} = \log(G/0.1) - 1, \tag{6}$$

where G is the geometric mean of the sample,

$$G = (\Pi\, S_i)^{1/n}, \tag{7}$$

where $\{S_i,\ i = 1, .. n\}$ is a sample of observed accident severity values. The product Π runs over I from 1 to n.

Johnson et al. (1994) mention that $2na/\hat{a}$ has a chi-squared distribution with $2(n - 1)$ degrees of freedom. This property can be used to test whether the sample comes from a certain population with given value a of the shape parameter. As soon as the inequalities

$$\chi^2(2(n-1); 1-\alpha/2) < 2na/\hat{a} < \chi^2(2(n-1); \alpha/2) \tag{8}$$

are fulfilled, one would accept the hypothesis that the sample comes from a population with shape parameter a. Here $\chi^2(2(n - 1);1 - \alpha/2)$ denotes a standard chi-square quantile from the table of the chi-square distribution. With α we denote an error of the first kind of the test.

The result (6) can also be used to provide confidence intervals on a. So the parameter a would lie with probability $1 - \alpha$ within a two-sided confidence interval given by

$$[\hat{a}\chi^2(2(n-1);1-\alpha/2)/(2n);\ \hat{a}\chi^2(2(n-1);1-\alpha/2)/(2n)] \tag{9}$$

Based on this property, it is also possible to construct a two sample test. Assume that $\hat{a}_1$ and $\hat{a}_2$ are estimators from two samples of size n_1 and n_2, respectively. Then,

$$T = (n1\hat{a}2)/(n2\hat{a}1) \tag{10}$$

has an F-distribution with $(2n_1;\ 2n_2)$ degrees of freedom. So, the test would accept the hypothesis of equality of the parameters a if

$$F(2n_1;\ 2n_2;\ \alpha/2) < T < F(2n_1;\ 2n_2;\ 1 - \alpha/2). \tag{11}$$

Another question is, whether the hypothesis holds that a sample of accident severities is distributed according to the Pareto model. Although the F-N curve is widely used for providing target values and sometimes also fits of data have been carried out, this does not prove whether the data really follow a Pareto distribution.

The Pareto distribution is closely connected to the exponential distribution.

If S has a Pareto distribution

$$F(s) = 1 - (s_0/s)^a, \tag{12}$$

then S can be expressed as

$$S = s_0\exp(X_0/a) \tag{13}$$

where X_0 is a standard exponentially distributed variable, see Johnson et al. (1994). Therefore,

$$a^*\ln(S/s_0) \tag{14}$$

has a standard exponential distribution. In the model described, s_0 is known to be 0.1. If one now tests the sample

$$\{X_i = \ln(S_i/0.1),\ i = 1, .., n\} \tag{15}$$

for exponentiality (i.e. with arbitrary mean of the exponential distribution), one has tested the sample $\{S_i,\ i = 1, .., n\}$ for the Pareto distribution.

A study of Ascher (1990) has shown that the score test proposed by Cox and Oakes (1984) seem to be the best one for testing exponentiality against general alternatives. In fact, the Cox and Oakes test is a score test; it tests in the Weibull model for the shape parameter being 1. That means exponentiality since a Weibull distribution with shape parameter one is an exponential distribution.

This test is easily computed. The score statistic is defined as

$$U = n + \Sigma \log(X_i) - n\, \Sigma X_i \log(X_i)/\Sigma X_i, \tag{16}$$

where the sum Σ runs over i from 1 to n. U is an asymptotically normal with mean zero and variance

$$(I_{aa} - I_a\lambda^2/I\lambda\lambda), \tag{17}$$

where

$$I_{aa} = n + \Sigma(\lambda X_i(\log(\lambda X_i)^2, \tag{18}$$

$$I_a\lambda = \Sigma X_i \log(\lambda X_i), \tag{19}$$

$$I\lambda\lambda = n/\lambda^2 \tag{20}$$

$$\lambda = n/\Sigma X_i. \tag{21}$$

Since the X_i are easily obtained from the S_i, the application of this test is straightforward.

4 EXAMPLE

Accident data from Switzerland for Swiss railway accidents have been used. The data have been collected over the last decade. Using formula (6) for accidents with an FWSI value of 0.1 or more, the shape parameter a has been estimated to be 1.8. This is in the region of 1.5 to 2, which is frequently used (see e.g. Braband and Schäbe (2011), and to the value of two, used in Rijkswaterstaat (2002) for providing target data for group risks.

By computing the confidence interval for 95% coverage, i.e. for $\alpha = 1\%$, we arrive with the help of (9) at the interval [1.60; 2.03].

A statistical test carried out for the value "2" would therefore accept the hypothesis. This is due to the fact that, for one sample test, confidence intervals for a parameter can be used for testing, the computations being the same as for obtaining critical values for the test statistic.

The test with the test statistics U in (16) cannot be applied since the data consist of many values with $X_i = 0$, caused by the fact that there are many values with $S_i = 0.1$. Also, the severity values of accidents can sometimes be imprecise, especially when talking about seriously injured persons. This is simply caused by the process of data collection. We apply another method. We just compare the counts of accidents in the following four classes

[0.1; 0,2], [0,2; 1.5], [1.5, 2.5] and [2.5, ∞]

with the computed values for these intervals. This is done with the help of the chi-square statistic

$$H = \Sigma\, (O_k - E_k)^2/E_k. \tag{22}$$

Here, O_k and E_k denote the observed and expected numbers of events in the k-th class. H is known to have a chi-square distribution with $r - 1$ degrees of freedom. With r, the number of calluses is denoted and since one parameter is estimated from the same sample, the number of degrees of freedom is reduced. The computed test statistics is 97, which largely exceeds the critical value of 11.3 for a 1% error of the first kind. This is caused by the fact that in the smallest class, a smaller number of events has been counted that expected according to the parametric model.

5 OUTLOOK

A closer look at the data reveals, however, that while the general decaying shape suggests a Pareto distribution, there might be a better fit when approximating the distribution by a weighted sum of discrete random variables. To intensify this affect we regard Fatalities and Weighted Injuries (FWI), which are often defined by

FWI = <number of fatalities>
+ <number of serious injuries>/10
+ <number of light injuries>/100

Figure 1 shows an example based on a simulation, where the number of fatalities, serious injuries and slight injuries have been drawn for each accident as realizations of independent Poisson random numbers. The dominating number of accidents with FWI zero has been truncated.

Like in real accident data, the typical distribution shape emerges with a kind of step-like structure

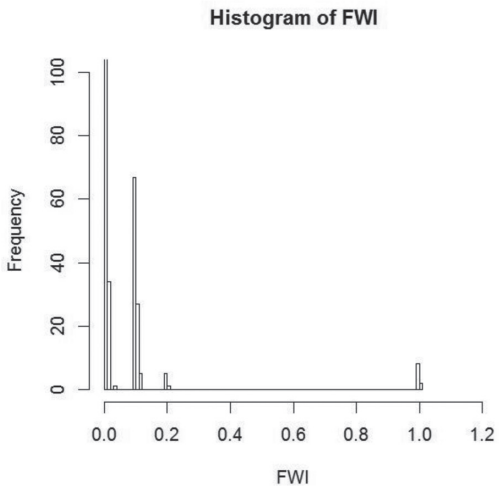

Figure 1. Typical sample FWI distribution.

beginning at 0, 0.1, 0.2 and 1.0. This is due to the fact that the majority of accidents affects only a small number of people, often only one. In practice, however, the number of fatalities, serious injuries and slight injuries would be dependent.

6 CONCLUSIONS

In this paper, we have given a theoretically well founded derivation of the distribution for the jump height of the compound Poisson process which can be used to describe counts of railway accidents. The distribution has been derived from the well-known F-N curve and turns out to be the Pareto distribution. We have used standard statistical textbooks to provide estimation and testing methods. In a practical example, we have derived the shape parameter that falls into an interval for parameters usually used for F-N curves. The distribution type, however, may in fact be more complex due to discretisation effects due the definition of FWI. This needs further research in order to come up with a distribution which fits the data and allows the derivation of optimal tests.

ACKNOWLEDGEMENT

The authors wish to thank the BAV, Bern and especially Hanns Meuli and Roman Slovák, Franziska Rexin from TU Braunschweig, and Rainer Beck, DB AG in Munich, for interesting discussions and giving the possibility to use their data on rail accidents.

Geospatial modelling of rail safety hazards

D.J.K. Griffin
Rail Safety and Standards Board, London, UK

ABSTRACT: RSSB has developed geospatial models (GeoSRM) of rail safety hazards across the mainline rail network in Great Britain (GB). The GeoSRM, shows how risk is distributed across the network, rather than generating a single national estimate for each type of hazard. The GeoSRM is web-based allowing users to submit queries on the risk level for specified regions, routes, hazard types, train operators, services or classes of rolling stock, and display the risk levels overlaid on a map. The pilot model of the GeoSRM is based around three hazardous events: station slips, trips & falls, railway suicides and train derailments. Station slips, trips & falls and suicides are modelled statistically with generalised linear models, taking into account geospatial variation in population characteristics and station properties. Whilst describing the GeoSRM framework in general, this paper focusses on the modelling of train derailments. This takes into consideration the geospatial variation in the frequency of derailments, the probability of derailment escalation and the consequence of any resulting derailment. Derailment causes and escalation probabilities have been linked to the underlying assets that could lead to a derailment e.g. linking derailment due to landslip to presence of cuttings. The paper shows how geospatial risk models can be developed and applied within a railway environment, and how models of this type could be used to inform decision making.

1 INTRODUCTION

Safety performance of the mainline railways in Great Britain has shown significant year-on-year improvements. While there was an average of 18.4 fatalities to passengers and workforce in the five years leading up to 1996/97, in the five years leading up to 2010/11 this figure had reduced to 9.0. This is a reduction of 51%, and is even more significant when it is considered that passenger kilometres have increased by 57% over the same period.

At the same time as safety performance has been improving, the overall cost of the rail industry has been increasing. Since 1996/97 rail industry costs have increased by 60% (at constant prices). Although some of this is a result of the increased train kilometres, it has been reported (McNulty 2011) that there is a 30% efficiency gap between the current industry costs and comparable railways elsewhere in Europe.

A certain proportion of this efficiency gap has been attributed to standards being overly conservative with respect to safety. Where standards have been changed, they often replace the requirement for a risk control with a requirement for a risk assessment to determine if the control is necessary in the given situation. By being able to identify low risk locations or routes and areas where the risk controls deliver little or no additional safety benefit, the industry could achieve significant cost and efficiency savings through the removal of unnecessary/over-prescriptive control measures. It is also increasingly difficult to introduce additional controls to reduce risk that are reasonably practicable, and in many cases they can only be justified for key high risk locations or routes (Griffin & Holloway 2012).

The GB rail industry currently relies on RSSB's Safety Risk Model (SRM) for much of its safety analysis (Dennis & Somaiya 2004). The SRM generates a national estimate of risk for each type of hazard on the network, but it does not show how the risk from these hazards is distributed across the network.

The GeoSRM is a new map-based tool for showing how risk is distributed across the rail network. To demonstrate the concept, the GeoSRM has been piloted on the Wessex route in England. The Wessex route operates a mix of services, whilst dominated by commuter services into London Waterloo station, but also longer distance services to Southampton, Bournemouth, Exeter and Portsmouth.

The pilot also considers just three distinct areas of risk:

- Train derailments
- Suicides
- Passenger slips, trips and falls at stations

These risk areas offer a varied range of hazards that depend on a wide range of spatially varying factors.

The modelling of train derailments follows similar work undertaken by Marsh & Bearfield (2008). It takes into consideration the geospatial variation in both the frequency of derailments and the consequence of any resulting derailment. Derailment causes have been linked to the underlying assets that could lead to a derailment e.g. linking derailment due to landslip to presence of cuttings. The escalation mechanisms modelled include carriages falling on their side, structural collapse and secondary collision. The geospatial factors that affect the event escalation include the train frequency on adjacent lines, presence of structures, switches and crossings and embankments.

The modelling of railway suicides is statistically based, and split into suicides at stations, suicides at level crossings and suicides at other locations. The model considers the size of the local population, characteristics of the local population such as gender, age profile, income and employment levels, health deprivation and disability, education, housing and crime. The model also takes into account train frequency and speed and features of the station such as ticket barriers, presence of staff and CCTV.

Passenger slip, trips & falls are also statistically based with a generalised linear model, accounting for the exposure of passengers to the different parts of the station such as platform, stairs, escalators and concourse. The model takes into account the mix of different types of passenger and locations with particular risk issues, e.g. high use by passengers with luggage, passengers under the influence of alcohol, or propensity for rushing.

This paper focusses on the modelling of train derailments. The next section of the paper deals with the principle of the GeoSRM model and the design decision that have to be made to make the modelling tractable. Sections 3 and 4 deal with the derailment model and the means of calculation, whilst section 5 describes the web interface for the model.

2 GeoSRM PRINCIPLE

The basic principle underlying the GeoSRM is that all risk models are pre-calculated. This enables the web querying to operate with a reasonable degree of responsiveness, as the model is not being recalculated each time the user re-queries the data. There are four basic components, the web interface, the results database, the GeoSRM database and the risk models.

The web interface allows users of the GeoSRM in train operating companies or infrastructure managers to log in to a web based tool. From this tool they can view risk results on a map, create queries and filter the results.

The results database stores all the pre-calculated results from the risk models. The web interface queries this database to generate the data to be displayed. The database contains aggregated data layers so that geospatially coarser datasets are queried where appropriate, depending on the zoom-level of the map.

The GeoSRM database stores all the data required to run the risk models. It is essentially a data warehouse with data having been sourced from a varied range of individual databases. It consists of:

- Track data, defining the track centre line of the network.
- Asset data defining the position of key risk related assets on the railway
- Train data defining the timetable and the movement of the trains across the network
- Safety data defining the rates of precursors, escalation probabilities and event data.

Of the three risk models, the suicides and passenger slips, trips & falls models are statistical and can be implemented within a spreadsheet environment. The derailment model is more complex, based on localised fault and event trees, and is implemented in C++. A schematic of the GeoSRM architecture is shown in Figure 1.

The track is divided into track sections which are explained in more detail in the following section. The derailment and suicides model calculate individual risk values for every train the passes over a track section. This enables the risk from specific causes, at individual locations for just a single train if desired. It does require a large number of individual model evaluations ($\approx 1 \times 10^9$) for the Wessex route.

Derailment risk is calculated for individual sections of track, whilst slip, trip & fall risk is calculated on a station-by-station basis. To enable both these (very different) risk types to be displayed consistently on a map, slip, trip & fall risk is mapped to the individual track sections that pass through the station.

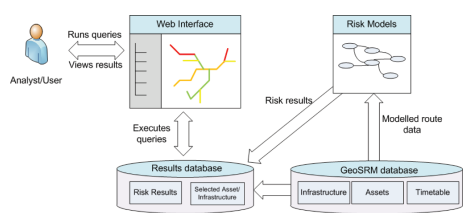

Figure 1. Schematic of the GeoSRM architecture.

2.1 *Track model*

The starting point for the geospatial risk model is the discretization of the track into sections, but first a choice had to be made in terms of which size the sections should be. Large track sections (>100 m) have the advantage that fewer sections are required to cover the network and consequently fewer model calculations. However they do have a number of disadvantages:

– The track sections may need to be represented by a sequence of spatial points to represent the curvature of the track
– More than one asset may be present within a track section, e.g. more than one set of points in a 100 m track section. This will require the derailment model to distinguish between sections with one set of points and sections with two sets of points, as the risk values will be different.
– Risk originating from a single point asset will be smoothed across the whole track section
– Assets may only exist over part of the section, i.e. an embankment might only be present over a fraction of the track section

As it is always possible to "aggregate" risk values to a coarser scale, it was decided to use relatively small track sections, and discretize on a 10 m scale. The Wessex route, which consists of approximately 2,100 km of track was discretized into 211,000 individual track sections. An example of the discretization is shown in Figure 2.

2.2 *Timetable and train data*

To understand risk it is necessary to associate each train in the timetable with the track sections.

There are nearly 3,000 trains operating over a typical day that traverse the Wessex region for at least part of their journey, which includes freight and empty coaching stock movements. The timetable specifies train movements in terms of a sequence of times at fixed timing point locations, with optional platform and routing information.

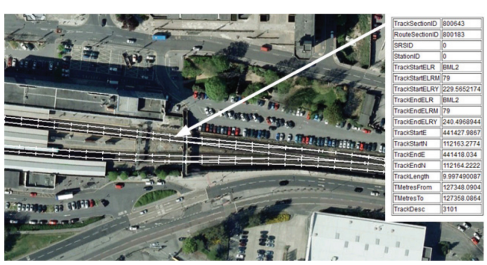

Figure 2. Track sections discretized to 10 m sections (Southampton Central station).

These timing point locations are often stations but include significant junctions en route.

Each train in the timetable was decomposed into a series of journey segments timing point location to timing point location pairs. There were approximately 1,000 distinct journey segments identified, and for each journey segment, the track sections that constitute that segment established. This task is complex, at least for GB timetables, as the timing point to timing point pairs do not necessarily define a unique set of track sections, so there may be more than one way of routing the train.

2.3 *Train loading*

Associated with each train is a "consist" (number and type of carriages) and a loading for the train (number of passengers per carriage). The train loading is taken from modelled passenger demand data, which is based on the concept of demand sections between groups of stations rather than individual stations. It does not identify individual trains but assigns loadings to groups of train. Train journey segments are mapped to these demand sections.

2.4 *Asset data*

The GeoSRM requires information regarding the position of assets on the network. The geospatial position of these assets is normally specified by a mileage along a track. This is then converted to the track sections defined within the track model as well as evaluating the geospatial coordinates of the asset. The assets considered are:

– Switches & crossings
– Level crossings
– Earthworks, such as embankments and cuttings
– Structures, such as over-bridges, under-bridges, viaducts, tunnels, culverts and retaining walls.
– Stations

3 DERAILMENTS

3.1 *Structure*

The derailment model consists of three parts:

– Causal component considering the main causes of derailments
– Escalation component calculating what happens once the train has derailed
– Consequence component which calculates the injuries to those on the train

These three components are discussed in turn in the next three sections.

3.2 *Derailment causal model*

There are 65 precursors within the causal model. These are divided into six groups of causes, namely:

- Rolling stock faults, e.g. axle failure
- Striking an object, e.g. striking items left on line by vandals
- Track faults e.g. track twist, track buckle and rail breaks
- Switch and crossing faults, e.g. points move under train
- Human errors, e.g. signals passed at danger leading to derailment
- Infrastructure failures, e.g. landslip or bridge collapse

Each precursor depends on different geospatial factors, so the causal calculations are illustrated with three examples, track twist, axle failure and landslip.

3.2.1 *Track twist*

The probability of each of these is defined by simple functions. Let $p_{i,j,k}$ be the probability of derailment for the ith track section, jth train and the kth derailment cause. Then for derailment caused by track twist ($k = TTWS$ where $TTWS$ is the index of the track twist precursor), the probability of derailment for the jth train traversing the ith track section is:

$$p_{i,j,TTWS} = \begin{cases} 2.44\times10^{-10} d_i & t_j = P \\ 8.00\times10^{-9} d_i & t_j = FP \\ 2.11\times10^{-7} d_i & t_j = FF \\ 2.44\times10^{-10} d_i & t_j = ECS \end{cases} \quad (1)$$

where d_i is the length of the ith track section and t_j is the train type of the jth train (P = Passenger, FP = Freight of passenger line, FF = Freight on freight only line, ECS = empty coaching stock). The numerical values have been derived from historical rates of occurrence of derailments due to track twist. At this stage of the model development these are national average rates, but future development will make the rates dependent on additional parameters such as track type and condition.

3.2.2 *Axle failure*

For a derailment caused by axle failure ($k = AXL$), the probability of derailment for a single track section traverse additionally depend on the length of the train which determines how many axles it has,

$$p_{i,j,AXL} = \begin{cases} 1.89\times10^{-10} d_i n_j^{AXL} & t_j = P, ECS \\ 2.11\times10^{-9} d_i n_j^{AXL} & t_j = FP, FF \end{cases} \quad (2)$$

where n_j^{AXL} is the number of axles on the train, which depends on the train length (number of vehicles) and the train class, as some trains have just two axles per vehicle.

3.2.3 *Landslip*

In a similar way, the probability of a derailment caused by landslips does not depend on train type but does depend on whether there is a cutting present at the track section,

$$p_{i,j,LNS} = \begin{cases} 2.24\times10^{-9} d_i & X_i^{Cutting} \neq 0 \\ 0 & X_i^{Cutting} = 0 \end{cases} \quad (3)$$

where $X_i^{Cutting}$ is the asset identifier for each cutting. As the track sections are small it is a suitable to treat cuttings as either present or not. In practice what will actually be known, from accident data, is the frequency of derailments f^{LNS}. This frequency has to be apportioned to each of the track sections dependent on whether there is a cutting present and the number of trains that use the track section. Equation (3) can be expressed as follows,

$$p_{i,j,LNS} = \begin{cases} \frac{f^{LNS}}{e^{Cutting}} d_i & X_i^{Cutting} \neq 0 \\ 0 & X_i^{Cutting} = 0 \end{cases} \quad (4)$$

with the distance travelled by all trains in cuttings $e^{Cutting}$ calculated as follows,

$$d_{i,j}^{Cutting} = \begin{cases} d_i & X_i^{Cutting} \neq 0 \\ 0 & X_i^{Cutting} = 0 \end{cases} \quad (5)$$

$$e^{Cutting} = \Sigma_i \Sigma_j d_{i,j}^{Cutting} \quad (6)$$

3.3 *Derailment escalation model*

The escalation model considers the sequence of events following the derailment. For this model the following are considered:

- Train is outside of clearances, so that it foul of its kinematic envelope and could strike a structure or be struck by another train infrastructure failures, e.g. landslip or bridge collapse
- Carriages fall on their side, which increases the degree of injury to the passengers on board
- Derailed train hits a lineside structure

– If train hits a lineside structure then does the structure collapse onto the train?
– Secondary collision with another train on an adjacent line.
– Do the carriages catch fire?

The event tree (Bedford & Cooke 2001, Rausand & Høyland 2004) representing the event escalation is shown in Figure 4, and each of the gates are explained in more detail in the following sections.

3.3.1 *Outside clearances*
The probability of the train maintaining clearances is a simple piecewise linear function of the speed at which the train derails. This is based on an analysis of historical accidents, with different curves for passenger & ECS trains when compared to freight. The relationship is shown in Figure 5.

3.3.2 *Carriage falls on side*
The probability that carriages fall on their side is also modelled as a function of the speed of derailment when the train is not on an embankment. If the train is on an embankment a fixed probability of 0.8 is used instead. These relationships are also shown in Figure 5.

3.3.3 *Hits structure*
For each track section, the distance to next significant structure that could collapse onto the train is determined. Where track sections are bi-directional, this distance depends on the direction that the train is travelling in. Let this distance to the structure be $d_{i,j}^{Struct}$. Assuming a constant deceleration of the derailed train, then the probability of the derailed train hitting the significant structure, $p_{i,j}^{HS}$, is given by,

$$p_{i,j}^{HS} = \begin{cases} 1 & \frac{(v_{i,j})^2}{2a} \geq d_{i,j}^{Struct} \\ 0 & \frac{(v_{i,j})^2}{2a} < d_{i,j}^{Struct} \end{cases} \quad (7)$$

where $v_{i,j}$ is the derailment speed and a is the average deceleration of a derailed train which has been estimated from historical accidents and the relationship between the derailment speed and the distance travelled in a derailed state.

3.3.4 *Structure collapses*
The probability that the structure collapses depends on the speed that the derailed train strikes the structure. This has been estimated based on the assumed average deceleration of a derailed train and again shown on Figure 4.

3.3.5 *Secondary collision*
The probability of a secondary collision depends on the time difference between the time that the train derails and the time that the next train arrives on an adjacent line. The GeoSRM is not a timetable simulation model, so this time is approximated, based on the timetable with random perturbations to ensure that the probability of a secondary collision is a smooth function. The time at which a train traverses a track section is based on the time the train departed the previous timing point, the time the train arrives at the next timing point, and an interpolation between these two times. It does not take into account the acceleration and braking characteristics of the train between these two points, if the timing points represent station stops.

The time of arrival of the next train on an adjacent line $t_{i,j}^{nxt}$ is calculated based on the timetable. Based on the train type of this train (speed and emergency braking capability) and the time to warn the approaching train, the time required for this train to stop short of the derailed train is estimated, $t_{i,j}^{w}$. The arrival time of the next train will follow a distribution to reflect the possibility of late (or early) running. It is not expected that this distribution is symmetrical, but for simplicity a symmetrical triangular distribution is assumed, based around $t_{i,j}^{nxt}$ but with a half-width t^{var}. The probability of a secondary collision is

$$p_{i,j}^{SC} = F_{Tr}\left(t_{i,j}^{w} \mid t_{i,j}^{nxt} - t^{var}, t_{i,j}^{next} + t^{var}, t_{i,j}^{nxt}\right) \quad (8)$$

where $F_{Tr}()$ is the cumulative distribution function of the triangular distribution. The choice of triangular distribution is arbitrary and difficult to justify, although with access to data on actual train movements, empirical distributions of actual train lateness could be derived in future updates of the model. A similar calculation is made for the probability of a secondary collision with the previous train, if it's running sufficiently late so that it arrives after the derailed train—although $t_{i,j}^{w}$ will be different. This is shown in Figure 5.

Two times are calculated, one for where the derailed train activates track circuits on the adjacent line automatically and an additional (longer) time if there is there is a need for verbal communication to warn the approaching train.

3.3.6 *Fire*
The probability of a fire following a derailed train depends on the sequence of events that have already occurred, but not on other location or train specific values. Table 1 lists the values currently used within the GeoSRM. These probabilities are applied to the relevant gates of the event tree displayed in Figure 3.

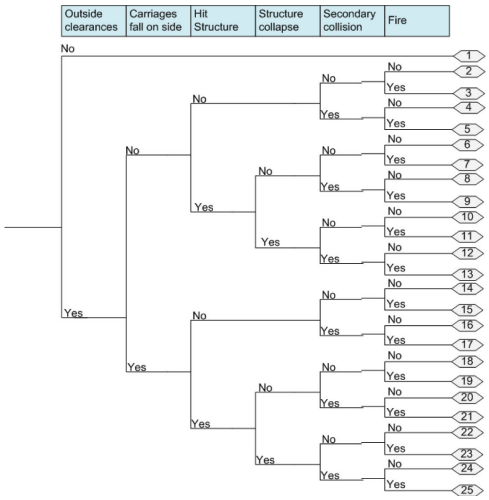

Figure 3. Event tree for the escalation model.

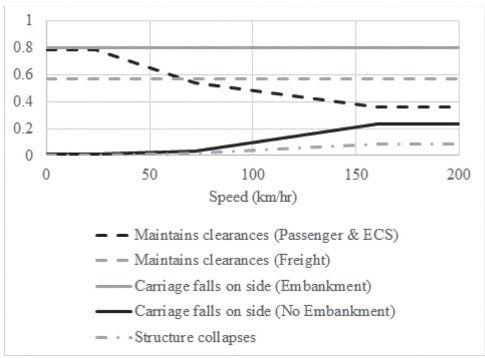

Figure 4. Relationship between probability and derailment speed for escalation events.

3.4 *Derailment consequence model*

The event tree shown in Figure 4 has 25 outcomes (leaves) for which a derailment consequence is required to be calculated. For the SRM, the derailment consequences are calculated manually from available accident history. For the GeoSRM an alternative calculation process was developed based on the concept of an injury atom (Cheng 2009). The injury atoms follow the gates of the event tree and there are 7 in total: base case, maintains clearances, carriage falls on side, hits structure, structure collapses, secondary collision and fire. Each atom is additive so that each of the 25 outcomes is composed of between 1 and 7 of the injury atoms.

Outcome 1 represents a train that derails but maintains clearances and no other escalation events occurs. This outcome has the base case injury atom only. Outcome 2 is based on outcome 1 but with the addition of the maintains clearances injury atom. Outcomes 3 and 4 are similar to outcome 2 but with the addition of the fire and the secondary collision injury atoms respectively. This process continues until outcome 25 which contains all 7 injury atoms. The order that atoms are applied does not affect the result but this requires an injury probability and severity to be defined that is additive for each group of people that are affected.

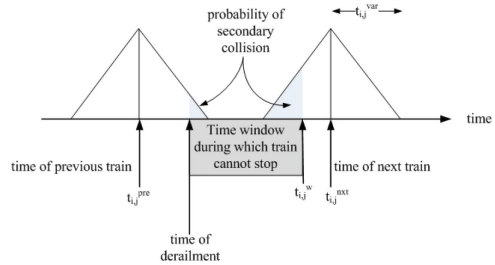

Figure 5. Calculation of the probability of secondary collision.

Table 1. Fire probabilities.

Derailed train	Secondary Train	Probability of fire
Passenger or ECS	None	0.012
	Passenger or ECS	0.03
	Freight Non hazardous	0.05
	Freight hazardous	0.1
Freight	None	0.01
	Passenger or ECS	0.03
	Freight Non hazardous	0.05
	Freight hazardous	0.1

3.4.1 *Injury probability and severity*

In any given train accident there will be a range of injuries from those that are fatalities to those that are uninjured. Injuries are classified into three broad classifications: fatal injuries (death occurring within one year of accident), major injuries and minor injuries. Major injuries are defined in RIDDOR (2013). They cover most fractures, loss of consciousness or other injuries resulting in hospital attendance of more than 24 hrs. All other physical injuries that are neither fatal nor major injuries are classed as minor injuries. Clearly as the speed of the derailment increases, the proportion of the passengers on board the train receiving fatal and major injuries increases. As the total number of passengers on the train is finite, the proportion of minor injuries will start to decrease. To represent

this relationship the consequence is represented by a probability of injury p and a severity of injuries s. Most injuries on trains are caused by secondary impacts and Bell (2001) estimates a relationship between injuries sustained on board the train and accident speed. This relationship can be approximated by a logistic function, using accident speed as a proxy variable for severity. These relationships are shown in Figure 6.

The calculation of consequence at an outcome proceeds as follows. Let C1 be an accident consequence with probability of injury p1 and injury severity s1. Then a new consequence C2 is defined in terms of C1 with the addition of an injury atom. For example consequence 15 in Figure 3 is based on consequence 14 but with the addition of the fire injury atom. The probability of injury and severity of consequence 2 (p_2 & s_2) are based on the probability and severity of consequence 1 (p_1 & s_1), with some additional contribution from the injury atom (p_a & s_a).

$$p_2 = p_1 + p_a - p_1 p_a \quad S_2 = S_1 + S_a \tag{9}$$

Equation 9 assumes that each atom add a fixed additional probability of an injury that is independent of the other atoms that form the consequence. The additional severity is also assumed to be independent of the other atoms. This would seem to be a reasonable simplification given the other uncertainty in the values for these atoms that can be derived from historical accidents.

3.4.2 *Population exposed*

To convert the injury probability and severity to a consequence requires multiplication by the number of people exposed. For derailments there are 6 population groups:

- Passengers on the derailed train
- Workforce on the derailed train
- Passengers on any train involved in a secondary collision with the derailed train
- Workforce on any train involved in a secondary collision with the derailed train

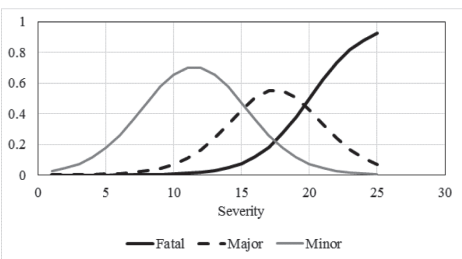

Figure 6. Probability of fatality as a function of accident severity.

- Number of passenger waiting for train at a station
- Number of members of public within 1 km of the derailed train

The last two population groups are only used for derailments occurring within a station and for large fires and explosion involving hazardous goods trains.

4 MODEL CALCULATION

4.1 *Key risk drivers*

An important aspect of the model is to be able to determine what the risk associated with some of the key influencing factors are, termed key risk drivers. These key risk drivers could be basic events of the model but could equally be other quantities that affect event escalation and consequences. For example a bridge might be a key risk driver at a location dues to its effect on both the frequency of derailments and consequence of derailments. It is also necessary that the key risk drivers can be scaled either spatially or across risk precursors, so that the key risk drivers on a route can be calculated. The measure used is the risk reduction importance measure (van der Borst, 2001). The risk reduction importance $\Delta R_{i,j,k}(x)$ for some model parameter x is the difference between risk and the risk with the parameter at some optimum value x^*.

$$\Delta R_{i,j,k}(x) = R_{i,j,k} - R_{i,j,k}(x = x^*) \tag{10}$$

For precursors, the optimum value is simply when the probability of failure is zero. For other parameters the optimum value is more difficult to determine, and has to be defined manually. For example passenger train loading is an important key risk driver at most locations, i.e. the greater the number of passengers on the train then the greater the risk. The optimum value of train loading that minimises risk is zero, but that is not a particularly useful comparison. For the GeoSRM, the optimum value for train loading is chosen so to be the minimum train loading across the network. This ensures that the risk reduction measure is always positive, but at least at one location is equal to zero. The key risk driver $K_{i,j,k}(x)$ is calculated by normalising the risk reduction measure by the risk.

$$K_{i,j,k}(x) = \frac{\Delta R_{i,j,k}(x)}{R_{i,j,k}} \tag{11}$$

The risk reduction measure can be aggregated, spatially, across trains or precursors, and the key risk driver at this aggregated level is the ratio of the

aggregated risk reduction measure and the aggregated risk.

4.2 *Asset risk*

The GeoSRM allows the risk associated with an asset to be determined. Asset risk is defined in a similar way to the risk reduction importance measure used to calculate the key risk drivers. Thus it is the difference in risk between the network with the asset and the risk from the network without the asset.

For example, a set of points is a potential cause of a train derailment, from points moving under the train say. However they can also increase the consequences from a derailment at other nearby locations. If a train derails nearby, but continues to move whilst maintaining clearances, then when the derailed train strikes the set of points, it will immediately go out of line and the consequences will be likely be more severe.

Thus the calculation of asset risk for an asset a is,

$$A(a) = \Sigma_i \Sigma_j \Sigma_k (R_{i,j,k} - R_{i,j,k}(a = \text{null})) \quad (12)$$

where a = null indicates that the asset has been removed from the model input dataset. As the calculation of asset risk requires a full computation of the model within the immediate vicinity of the asset, it is computationally expensive to undertake.

5 GeoSRM WEB INTERFACE

The GeoSRM has been developed as a web application by the University of Southampton. The interface is by default a map that can be zoomed in/out and panned as appropriate. At the moment it is not possible to view the network in a schematic view but this facility may be provided in later releases. The interface consists of three main areas.

The left hand side allows the user to filter the displayed risk, the right hand side that displays the scale and summary results, and the central map area. It is possible to filter by:

- Hazards. Such as derailments, suicide or slip, trips and falls.
- Causes. It is possible to also filter for specific causes of hazards.
- Route. The Wessex route is divided into smaller strategic route sections which can be selected individually or in combination.
- Train. It is possible to filter by both group of train services as well as by class of rolling stock
- Company. Each precursor is assigned a company that controls that risk. Some precursors are shared between two or more companies and in this case all risk controlling companies are assigned. Other companies do not control the risk but are affected by it are also assigned.

Figure 7. Screenshot of the GeoSRM web interface.

The right hand side of the interface displays the results. Results can either be displayed in absolute terms such as fatalities and weighted injuries per year, or normalised. There are a range of possible normalisers that the user can select, such as track km, route km, passenger journeys, passenger km or train km. The colour scale is automatically calculated and is log-symmetrical around some predefined reference value. This reference value sets the middle of the scale and typically could be set to the national average or average over Wessex. By setting this reference value it is easy for the user to see if the displayed risk is better or worse than average.

The central area of the map displays the risk values overlaid on a backdrop aerial imagery. Navigation controls allow the user to zoom in and out of the map. At each zoom levels, the risk values are aggregated to a suitable level to ensure that the information presented to the user is neither in too much detail or too little detail. The pre-calculated aggregation also ensures that the volume of data queried by the tool is minimised, which improves tool performance. A screenshot of the tool is shown in Figure 7.

6 CONCLUSIONS

The GeoSRM demonstrates that it is possible to develop a geospatial risk model for rail safety hazards. The data requirements for such a model are high, and challenges remain in gaining access to the data in a form that is easy to process. Work is ongoing, within Network Rail to develop a Railway Infrastructure Network Model (RINM). This will contain geospatial and schematic layers, but will also contain a logical model that will enable the mapping of trains onto the track sections a

much simpler task. It is anticipated that developing geospatial risk models will be a much more tractable task in the future.

ACKNOWLEDGEMENTS

The author would like to thank South West Trains and Network Rail for their support of this work and for supplying infrastructure data and expertise to enable the models to be developed, and also the UK Department for Transport and their funding of project "T972 Piloting a geo-referenced safety risk model for the rail network in Great Britain", which forms the basis for the work presented in this paper.

Comparing the two methods for judging changes in European railways and in European nuclear safety

N. Petrek
Institute of Railway Engineering and System Safety, Technische Universität Braunschweig, Germany

H.P. Berg
Bundesamt für Strahlenschutz, Salzgitter, Germany

ABSTRACT: In 2009 a new regulation has been implemented by the European Commission which harmonizes the risk assessment process for the European railway industry. This regulation describes the Common Safety Method (CSM) and contains a process for judging the significance of a change. In the area of nuclear safety such a common regulation does not exist to date. In Germany nuclear regulations are issued by the Federal Government although the European Commission enhances efforts to create such a common framework as a reaction to accidents at the Nuclear Power Plants (NPPs) of Fukushima-Daiichi in March 2011. After discussing the regulation framework we compare both methods in detail and explain their similarities and differences and the underlying reasons and how the results can be categorized.

1 MOTIVATION

As part of the harmonization of the risk assessment process in the area of European railway industry a new concept judges the significance of a change. In our paper we will compare this approach of the so-called CSM-Process with the method applied in case of changes of equipment in NPPs. The similarities and differences between both methods are investigated and it is discussed why the method for judging changes in railways uses both risk-based and qualitative criteria in one method.

2 THE CSM-PROCESS FOR JUDGING THE SIGNIFICANCE OF A CHANGE

The CSM regulation of the European Commission (2013a) describes the whole process and defines which changes have to be considered. Article 2 of this regulation which replaces the original CSM regulation (European Commission 2009a) defines that changes may be of technical, operational or organizational nature. Organizational changes must have an impact on the operating conditions or an influence on the maintenance processes. Furthermore, the proposer of the change has to consider the impact on safety of the change. For all changes, which have an impact on safety, the proposer has to evaluate the significance of the change based on six criteria. The CSM regulation describes these six criteria in Article 4 as follows:

- failure consequence: credible worst-case scenario in the event of failure of the system under assessment, taking into account the existence of safety barriers outside the system under assessment;
- novelty used in implementing the change: this concerns both what is innovative in the railway sector, and what is new for the organization implementing the change;
- complexity of the change;
- monitoring: the inability to monitor the implemented change throughout the system life-cycle and intervene appropriately;
- reversibility: the inability to revert to the system before the change;
- additionality: assessment of the significance of the change taking into account all recent safety-related changes to the system under assessment and which were not judged to be significant.

In this context the criteria additionality is not used for judging the significance of the change like the other five criteria. It can rather be interpreted as an instruction how to consider changes, which were already implemented in the same area as the proposed change and were not significant but safety relevant. Apart from the explanation in Article 4 it does not exist any further guidance in the regulation itself how to apply the criteria and how to judge the significance of a change on the basis of the given criteria. This relates to both the

weighting of the criteria and also to the threshold above which the examined change is valuated as significant.

However, the explanation of the criteria clearly reveals that there exists the risk-based criteria failure consequence and four additional criteria, which can be qualified as qualitative. The regulations provide no reasons for the selection of these criteria. Moreover, there is no guidance how to apply both risk-based and qualitative criteria in one method.

Petrek (2014) develops a method how to judge the significance of a change on the basis of the application of all criteria which are given by the CSM regulation. The framework for judging the significance of a change is given in Figure 1. This framework is also developed and explicitly discussed in Petrek (2014). It becomes clear that the consideration of the safety relevance and the analysis of the significance of the change are only two elements of the whole process. These both elements are represented in the light blue box in Figure 1.

The proposed changes are classified in three different categories. If a change does not fall within the scope of the CSM regulation or if a change is not safety related, the CSM process does not have to be applied. However, the application of QM-Procedures is needed, if those procedures are required by the SMS of the company. Besides these QM-Procedures the CSM process distinguishes between the application of own safety procedures and the application of the harmonized CSM risk management process.

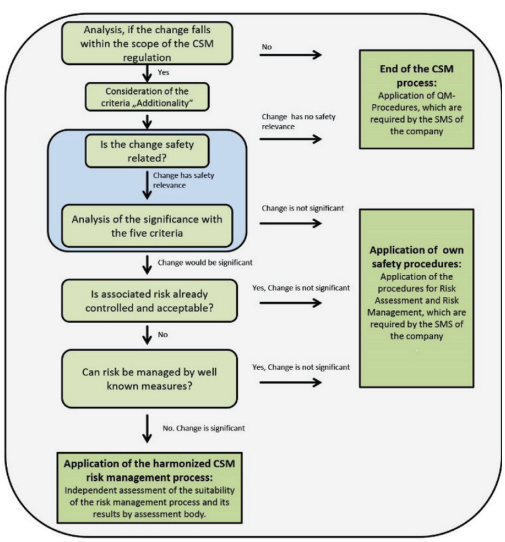

Figure 1. Caption of the framework of the CSM risk management process.

It becomes obvious that the analysis of the significance of the proposed change determines, if the harmonized process has to be applied. Only for significant changes the application of the harmonized risk management process may become necessary. In order to clarify this, further considerations are necessary. This includes the verification, if the associated risk is already controlled and thus acceptable. Only if this is not the case and the risk cannot be managed by well know measures, the proposed change is finally significant and the proposer has to apply the harmonized risk management process. But it should be emphasized that the analysis of the significance does not decide whether any risk management is necessary or not.

The main difference between the harmonized and the own risk management process is the necessity for an independent assessment of the risk management and its results in the application of the harmonized process. Against this background, the role of the qualitative criteria becomes clear. The qualitative criteria are used for the assessment, if the company already has experience with the implementation of the proposed change or not. If this is not the case, it is more likely that the change is significant and an independent assessment of the risk management process is necessary. As described earlier, this role of the qualitative criteria is not clearly given by the regulation itself.

3 JUDGING CHANGES IN NUCLEAR POWER PLANTS

The nuclear technology is, in contrast to the European rail transport, not monitored by European authorities. The licensing and supervision of nuclear installations in Europe is perceived by the respective national authorities.

At European level, so-called safety reference levels have been defined by WENRA (2008, 2013), originally in the context of the definition of safety requirements for nuclear installations of countries which are potential candidates to join the European Union. These reference levels should be adhered to by all member countries of the European Union.

In Part G of these reference levels, the safety classification of Structures, Systems and Components (SSCs) is described. The goal is to identify all safety related SSC and to classify them according to their importance for safety. Part Q reflects changes in a Nuclear Power Plant (NPP) and it is requested that no change reduces the ability of the reactor for safe operation in any form. In addition, national regulations and international agreements within the European Union are supplemented by a directive of the European Commission (2009b) which had to be implemented by July 2011 into national

law. Moreover, a draft amendment to this directive (European Commission 2013b) is under discussion which intends to describe a possible mechanism to develop harmonized European safety regulations.

The licensing and supervision of nuclear installations in Germany is the responsibility of the Federal States (Länder) who are subject of expediency supervision of the Federal Ministry for the Environment, Nature Conservation, Building and Nuclear Safety (BMUB).

In addition to the German Atomic Energy Act (Atomgesetz—AtG) (2013), there exist several national requirements which have to be considered in the approval and supervision process of nuclear facilities. A recent comprehensive update of the German sub-legal nuclear regulations including interpretation has been issued (BMU 2013a and 2013b).

Basically, each NPP in Germany must have a valid operating license. An essential part of this approval is the condition of the AtG to show all changes to the plant and the operation (including changes in the organization) to the competent authority and to examine their safety relevance. Significant changes of systems according to § 7 AtG are subject to approval by the supervisory authority. The implementation of authorizations below this level is subject to a graded supervisory control depending on their safety significance.

The approach in nuclear technology is that all important equipments of a NPP are classified in terms of their safety significance, accompanied by respective requirements and specifications. At the international and national level, there is no detailed classification of SSCs. The procedural rules for the treatment of changes are regulated in operating manuals which are specific for each NPP. The operating manual is part of the approval of the competent authority to start or to continue the operation of the NPP.

In the following, the evaluation of changes in the Federal State of Baden-Württemberg which oversees in total four NPPs is exemplarily described because this Federal State has developed a concept for regulatory supervision of NPPs—the last version is issued last year (UM BW 2013)—and a supervisory manual (UM BW 2011) with a separate detailed chapter describing the regulatory plant change procedure (Landeseinheitliches Änderungsverfahren—LEÄV), already anticipating the safety requirements for NPPs (BMU (2013a).

In this supervisory manual of Baden—Württemberg changes are subdivided into three categories, designated as category A, category B or category C where category A contains the highest requirements and category C the lowest ones. If it is a change in the hardware that also requires a change of the documentation, the higher classification determines the overall classification of the change.

Figure 2 shows the procedure how to classify changes of equipment. In a first step, it must be considered whether the proposed change relates to equipment which is subject to the Atomic Energy Act. In this case it must be examined whether this change is a change in the legal sense. If yes, one has to consider whether a significant change has occurred. According to the supervision manual a change is to be regarded as significant in the legal sense if the change can have more than obviously insignificant effects regarding the safety level of the plant. In this case, the change falls into category A.

Otherwise, it must be checked whether the change is subject to the uniform change process. In this case, the change falls into the category B or category C. For example, changes to safety systems or safety-relevant systems are belonging to category B or C. The decision regarding category B or C depends on the type of change: is it only an exchange by equivalent equipment (components or systems) or leads the change to a deviation in the approved specification.

In the first case it would be a change of category C, in the second one a change of category B.

Therefore, two issues are of vital importance for the assessment of changes in this process.

One is the decision whether a change is a change in the legal sense. This is the case if the planned change is not covered by the previous approvals. If the answer is negative, no further consideration of the change is necessary.

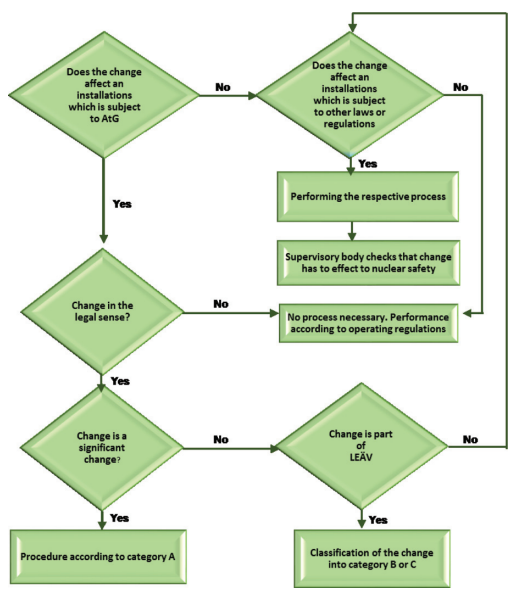

Figure 2. Procedure of classifying changes of equipment in NPPs.

In a next step it is important whether the planned change has to be classified as a significant change. The result of this assessment determines whether a change is classified into category A or category B/ C, respectively.

The importance of a change has to be assessed by comparing the actual plant state with the state after having performed the change. The decisive factor is whether and to what extent the change has safety relevance. The probability of a significant change depends on the impacted area. Changes that affect the design characteristics of the plant or the safety systems are, with a high probability, significant changes and, thus, fall into category A.

In the following it is explained which procedure depending on the classification of the change in one of the three categories is required according to (UM BW 2011).

Category A: If the change belongs to category A, an authorization procedure is required by § 7 of the Atomic Energy Act and pursuant to § 7 paragraph a permit application has to be submitted by the licensee to the supervisory body. The licensing procedure is conducted in line with the Nuclear Licensing Procedure Ordinance (2006). In addition, a probabilistic assessment is required which shows the influence of the change on the Probabilistic Safety Analysis (PSA). It must be explained why the proposed change has no effect on the PSA.

Category B: If the change belongs to category B, it must be supervised by the authority under § 19 of the Atomic Energy Act. A notification of the planned change must be submitted by the licensee to the supervisory authority. The implementation of the change can only take place if the supervisory authority has provided its written supervisory opinion that the proposed change is seen from the perspective of the supervisor as "without any concern or not subject to licensing." The supervisory authority and the technical support organisation (consulted by the regulatory authority pursuant to § 20 of the Atomic Energy Act) monitor and accompany the implementation of the planned changes. In addition, a probabilistic assessment is required as in the case of a change of category A showing the influence of the change on the PSA. It must be explained why the proposed change has no effect on the PSA.

Category C: If the change belongs to category C, it must be monitored by the authority under § 19 of the Atomic Energy Act. An examination of the changes in category C by an expert according to § 20 of the Atomic Energy Act is required. The implementation of the change can only start after the expert has finalised his supervisory report and the authority does not make any objections until the change starts. It is, however, no probabilistic evaluation required as in categories A and B.

Changes that are not subject to the procedure described above are performed by the operator according to its internal written operating procedures without participation of the authorities and experts. The supervisory authority will perform random checks on the basis of the documentation provided by the operator, if he has correctly classified the changes.

Examples of changes are listed in Berg (2011). Basically, it has to be noted that a changes also in other Federal States are classified into one of three categories; however, usually no additional probabilistic reviews have been required so far.

4 COMPARING BOTH METHODS

The detailed description in the last two chapters has shown that the basic procedure of both methods is comparable to each other. Both methods are generally used for judging technical, operational and organizational changes.

In the method of judging changes in nuclear safety the first step is the analysis if the change affects an installation which is subject to the AtG. Additionally, the procedure of Figure 2 contains the examination if the present change is a change in the legal sense. This is the case if the change is not covered by the existing approval of the NPP. For example, a technical plant modification concerning the spent fuel pool cooling using other systems than in the past.

In the CSM risk management process these both steps are enclosed by the analysis if the change falls within the scope of the CSM regulation. This analysis is described in detail in Petrek (2014). For instance a technical change is relevant for the CSM regulation if the change makes use of new technical solutions or if new risks or hazards may arise respectively if existing risks or hazards are altered due to the change.

Both methods distinguish in the described manner between relevant and irrelevant changes for the further procedure.

The next step in both methods is to analyze the significance of the change.

According to Figure 2 for classifying changes of equipment in NPPs the result of this specific step leads to the decision whether the planned change falls into category A or in category B respectively C. As already described in chapter 3 a change is to be regarded as significant if the change can have more than obviously insignificant effects regarding the safety level of the plant. Therefore, the classification of the change is based on the consideration of the safety relevance and the impacted area.

Contrary to this procedure, in the CSM risk management process of Figure 1 the analysis of the safety relevance is only the first step. If the

change is safety relevant, the proposer has to apply the further criteria to assess the significance of the change. According to chapter 2 four of these five criteria are qualitative and do not consider the change itself but rather the implementation of the change. The remaining fifth criterion failure consequence is used for a risk-based consideration of the change.

For clarification, within the procedure of the British ORR (Office of Rail Regulation) for determining the significance of a change the different perspectives of these criteria are combined in a matrix (ORR 2012). This matrix which is basically a type of risk matrix is shown in Figure 3.

The criteria novelty and complexity are interpreted as the uncertainty of outcome, which consider the likelihood that the proposed change will or will not behave as predicted. The uncertainty of outcome represents the Y-axis of the given matrix. The X-axis is defined by the risk-based criterion failure consequence. The X-axis and the Y-axis possess four different categories with the result that the matrix consists of 16 fields, while each of these 16 fields is associated with a significant change, a non-significant change or an unclear result. In case of an unclear result the proposer of the change has to apply the additional criteria monitoring and reversibility in order to determine the significance of the change. This interpretation of the criteria

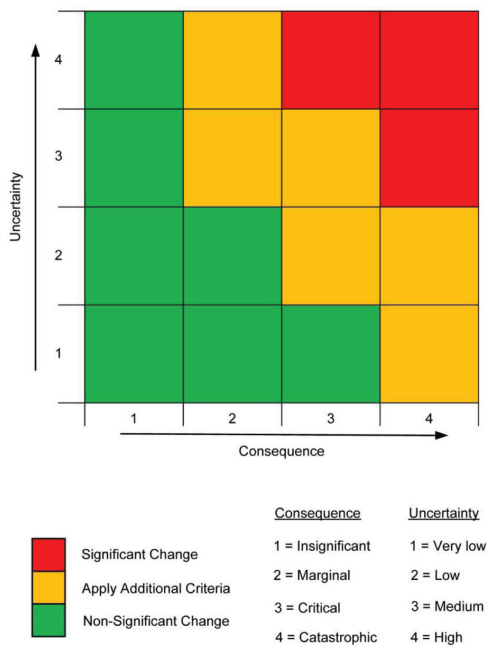

Figure 3. Procedure of the ORR for determining the significance of a change.

in the procedure of the ORR illustrates the role of the qualitative criteria, which is the consideration of the company's experience with the implementation of the change.

In contrast to this procedure, the judgment of changes of equipment in NPPs is done on a risk-based consideration. If the change is not significant, it has to be checked whether the change falls within the uniform change process. Those changes are associated with the categories B and C. The decision between both categories depends on the type of change respectively whether the change leads to a deviation in the approved specification or not. However, in contrast to the procedure of the CSM process a consideration of the existing experience with the change does not take place.

The comparison of the different categories of both methods shows that category A describes the procedure for significant changes and requires an authorization procedure for the implementation of the change. Additionally, a probabilistic assessment which shows a potential impact on the PSA is demanded. On the other hand, those changes which are rated as significant by the application of the CSM process shown in Figure 1 require an application of the harmonized risk management process and also an independent assessment by an assessment body. However, a change which is safety relevant but not significant requires the application of own safety procedures but an independent assessment is not required. In contrast, category B and C of the procedure for changes of equipment in NPPs still require a supervision by the authority respectively in case of category C a monitoring by an authorized expert. Only category B requires a probabilistic assessment which shows the potential influence on the PSA results.

While the significance of a change in the CSM process decides whether an independent assessment is required, the different categories A, B and C decide whether an authorization procedure, a supervision process or a monitoring process is required. Hence, the purpose of the CSM process shown in Figure 1 is to decide whether an independent assessment is required or not. In addition, also for safety relevant but not significant changes a risk assessment is necessary. Therefore, the CSM process does not decide whether any risk assessment is necessary or not.

5 DISCUSSION OF THE RESULTS AND CONCLUDING REMARKS

At first the comparison has demonstrated that the basis structure of both methods is similar. This concerns the initial analysis whether

the proposed change is relevant for the certain method. However, this analysis is divided into two steps within the procedure for classifying changes of equipment in NPPs.

In both methods this initial step is followed by the judgment of the significance of the change which decides what kinds of further risk management procedures are required. At this point is the main difference between both methods which is the set of the qualitative criteria in the CSM process for judging the significance of a change. It became clear that those qualitative criteria are used for the consideration whether the proposer of the change has experience with the implementation of the change.

Furthermore, the consideration of the different categories of both methods has exposed that the significance of a change in the CSM process decides whether an independent assessment is necessary. This aspect represents the main purpose of the CSM process shown in Figure 1.

In contrast, the process for judging changes in nuclear safety always requires at least a deterministic safety assessment to provide the evidence that the respective specifications and nuclear safety standards are fulfilled. Figure 2 describes how to determine the kind of participation of the authority and whether or not a probabilistic safety assessment is required. This is the reason why the method applied in the nuclear field does not contain qualitative criteria which are used for the consideration of already existing experience with the implementation of the change.

In summary, the consideration of changes is seen as a necessary part for the risk management in European railways as well as in nuclear safety.

The comparison clearly showed that there are differences in the processes regarding the role of the proposer of the change and the levels of supervision. While the CSM regulation possesses the level of independent assessment and on the other hand the application of own safety procedures without any participation of an independent assessment body, the regulations in the area of nuclear safety are more restrictive and also more prescriptive limiting the room for maneuvers for the applicant of the change. This is also visible in the fact that all three categories of changes in the nuclear field require a prescribed authorization procedure or a supervision by the authority respectively by the authorized experts but still monitored by the authority.

Combination of technological and economical risk assessment using the Monte-Carlo-Simulation

F. Plinke, D. Althaus, A. Braasch & A. Meyna
Institute for Quality and Reliability Management GmbH, Wuppertal, Germany

ABSTRACT: Economical risks are directly connected with the technological risks. One major problem of a integrated technical and economical risk assessment is the identification of a suitable method, which can combine technological, safety and economical issues in one risk assessment. The Monte-Carlo-Simulation is used in both sciences (engineering & economics) and can be adapted to perform a combine risk assessment. The paper explains the Monte-Carlo-Simulation integrated in a V-model process. Via a V-model the different issues can be partitioned, analysed on a low level (component reliability, safety and price) and later combined to a complete system risk assessment.

1 INTRODUCTION

The architectures of modern systems and components record a gain in complexity and are networked with other systems to a growing extent. The result is an increase of functions, which, at the same time, imposes higher demands on their reliability.

One consequence of these complexity issues is the aggravation of a reliability analysis via classical mathematical and stochastic methods. This is essentially due to complex mathematical expressions, which cannot be solved or only at considerable effort. Furthermore, complex technical dependencies can make classical methods inappropriate. Another reason is that there is just a too high amount of components or subsystems.

The field of application of Monte-Carlo-Simulations comprises illustrating, simulating and analyzing these complex issues in technical and economic areas.

The Monte-Carlo-Simulation is a computer based simulation method that is able to model and analyse even complex interrelations by a series of simulated runs. With the help of random numbers, random events can be generated. Through much iteration of these simulated runs, an estimator can be developed which substitutes the conventional reliability analysis or other analytical calculations.

There are numerous possible fields for Monte-Carlo-Simulation operations, which can be applied for integrated analyses of systems (technical as well as economic analyses).

Selected technical fields of applications are:

- Classical reliability and safety analyses for (highly) complex systems
- Functional analyses for the investigation of degraded functional states (subsystem failures)
- Application in the area of tolerance calculation, especially for non-linear tolerances and tolerance chains
- Simulation of highly reliable systems with extremely low error probability
- Employment in early research and development stages, when a field data analysis cannot be conducted
- Integrated application in the area of product development for validating and securing the development processes.

Selected economical fields of application are:

- Analysis of technical consequences for economic issues
- Targeted risk analysis in consideration of many dynamic risk factors and objects
- Support in the drafting of contracts (especially concerning guarantee and warranty terms and conditions)
- Comparing different contractual strategies using specific simulations
- Analysis of the availability of technical units regarding to logistic questions.

2 MAINTENANCE CONTRACTS

2.1 *Contract types*

Depending on the product type different maintenance and repair strategies are disposed. A simple form for maintenance contracts are time-and-material contracts.

This standard contract type is based on real time and material overhead which is needed to repair a system. Indicating a simple calculation by the maintenance company due to the fact that every work within the repair process is charged. If no costs are capped, the risk for the maintenance company is minimal. Figure 1 describes this simple connection. In this case the "paid" line is identical with the "charged" line.

In some cases special costs are capped to a limit. If this limit is reached any additional costs cannot be charged. The implementation of a material or time cap can be important in contract negotiation. For the customer a special cap is a risk minimizing offer. On the other side if the probability for reaching the cap is very low and if the cap is reached additional costs are low as well, it can be valuable for the maintenance company to offer these types of contracts with caps.

The agreement on special caps can be generalized to a not-to-exceed contract. In this case the maintenance company cuts the costs of all time-and-material-repairs at one point, but however becoming a high risk for the operator. The customer has no additional risk at this point. Figure 2 shows the initial point and the increasing risk value.

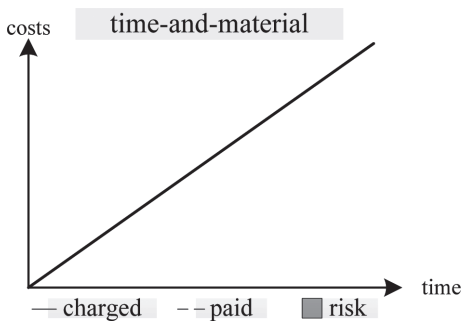

Figure 1. Time-and-material contract.

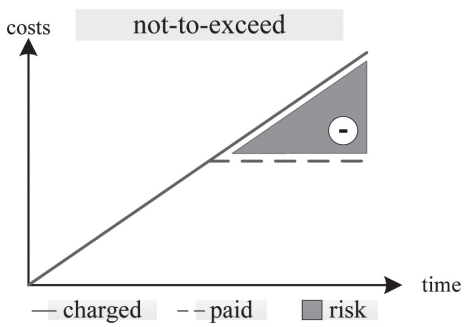

Figure 2. Not-to-exceed contract.

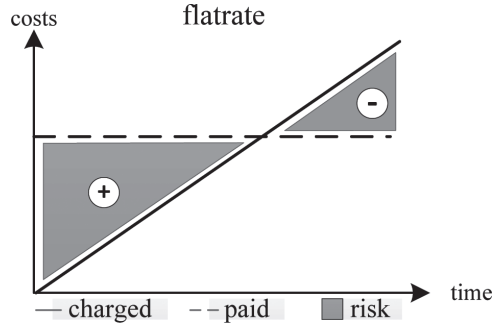

Figure 3. Time-and-material contract.

Another very popular contract type is a flatrate contract. This type is well known in many industries and also common for end-user products or services.

A flatrate based maintenance contract requires a valid period or another limited reference. This can be usage parameters, mileage, usage count or other recordable characteristics. The economical risk is distributed between the maintenance company and the customer and has the highest value in comparison to time-and-material or not-to-exceed contracts.

2.2 *Valid period*

One of the most important agreements in maintenance contracts is the valid period. Especially for high-value products with a regular call for maintenance operations the maintenance offer is a sales appeal. In the last years, e.g. in the automotive industry, the valid period of maintenance services for new cars has raised strongly. Due to different statutory provisions for implied warranty the valid periods differ in European countries.

In the automotive industry the warranty period is raised up to 8 or 10 years from single OEM's. These contracts are flatrate contracts including some caps for wear parts; nevertheless some contracts are even full flatrate contracts with no caps or exclusions.

Due to this extension of the valid period the OEM's and the suppliers are confronted with new challenges in quantifying the new economical risk.

Some of these challenges are

- Warranty costs
- Component dependencies
- Availability of spare parts
- Advances in prices for spare parts or wages
- Higher storage costs

Especially for flatrate contracts theses challenges have to be very carefully considered by the OEM and the suppliers before drawing an agreement of this type of maintenance strategy.

3 RISK ASSESSMENT METHODS

3.1 *Comparison*

To evaluate the most common methods in risk assessment regarding maintenance issues, Table 1 lists the most important properties for this kind of analyses.

Abbreviations:

- CON = Convolution
- PCA = Principal Component Analysis
- NN = Neural Network
- MCS = Monte-Carlo-Simulation

3.2 *Convolution*

Merging of single distributions via continuous or empirical convolution is one of the most common methods in simple risk analysis. For few components with continuous functions the convolution is a proper method, but cannot be used for complex systems with different kinds of data like distribution functions, qualitative data or dependencies. Since not every type of information can be transformed in a distribution function. Moreover it is possible that technical dependencies may occur. In this case the repair of one component requires the change of another. This is a common problem especially due to the failure of older parts. Because of integrated system designs the compatibility of newer versions of the same parts might not be useable with some older hardware.

Using the example of a power window actuator in a car, in some cases the change of electric motor is only possible in combination with the change of rolls and Bowden cables. According to this all components have to be available. Given the case one Bowden cable breaks, the change of one cable is possible without any further effort.

This example of technical dependencies describes the need for a flexible function. The convolution is not flexible enough to integrate such issues in a suitable way.

Table 1. Comparison of different methods regarding to their usability for maintenance issues.

	CON	PCA	NN	MCS
Cont. and discrete functions	+	–	+	+
Expert knowledge	–	–	+	+
Dynamic parameters	+	o	o	+
Techn. or econ. dependencies	–	–	o	+
Rare events	o	–	+	+
Suitable for complex systems	–	o	+	o
Suitable for censored data	o	+	o	o
Tool connectivity	+	+	+	+
Evaluable, documentable	–	–	–	+

3.3 *Principal component analysis*

The principal component analysis is common in the area of economics, to analyze the correlation of different parameters. PCA, in classical meanings, allows only normal distributed parameters and acceptable for many risk assessments as a constraint. For complex systems with exponential, weibull or other distributed components or special economical functions the PCA is not useable.

3.4 *Neural networks*

Neural networks are computational methods based on machine learning and pattern recognition. They are popular in the area of risk assessments because an (almost) unlimited number of variables and parameters can be combined to free defined outputs. One further advantage of neural networks is that in analytical correlations between the variables or parameters have not to be known. A neural network can include different kinds of information. Both continuous and discrete functions can be used as well as expert knowledge. The problem with neural networks for risk analysis is the evaluation of the results. The weighting of the connection between the neurons cannot be reviewed. In addition the correlation function, learned by the neural network can be wrong without any possibility of recognizing it. However the usage of these networks in combination with technical and economical experts presents a good option for quantifying complex risk scenarios in maintenance strategies.

3.5 *Monte-Carlo-Simulation*

The Monte-Carlo-Simulation is a computational simulation method based on random events using the weak law of large numbers. Each simulation run generates a special scenario based on random historical data. One of the advantages of the MCS is the possibility to implement dependencies and qualitative data easily. In addition, the results are comprehensible and can be stored for documentation. Filters can also be inserted directly in order to compare the effects of certain parameters. One disadvantage is the need for much calculation power to perform the simulation runs. Depending on the complexity of a technical system in combination with its economic options the duration of a MCS can be quite long. For simple cases, the MCS can be performed directly in common spreadsheet programs without additional computational algorithm software. However, for complex systems additional software is highly recommended.

4 RISK SIMULATION

The Risk simulation process consists of different steps and layers. Beginning with a system breakdown and level definitions, 3 individual MCS are combined with revenue calculations and derive of measures. Figure 4 describes this process on a general level.

4.1 *V-model*

The risk simulation differs in main parts from classical safety or reliability simulations, which are more and more common in RAMS-processes.

For risk simulations the consideration of the technical and the economical area is needed. At first a system must be described—and programmed—on a technical level. For this description it has proven to be useful to use the top-down approach. Depending on the planned simulation level the system is being decomposed to the lowest data level.

For risk and warranty analyses it is useful to start with the entire system, separating it in functional groups, further in modules and at least in single subsystems with its components. With the MCS different simulation levels are possible and can be integrated in an entire system simulation. The simulation can handle different data levels given the case one functional group, e.g. the engine in a car can only be exchanged in one unit, while another group, e.g. the braking system, can be exchanged on part or component level. In each simulation run, which is one simulated warranty event, it is determined whether a part needs to be replaced or not. The sum of all parts and systems creates a technical requirement list containing all parts which has to be exchanged. Even the kind of exchange like small repair, full repair, part exchange or full exchange can be simulated if suitable data is available. Another technical issue is that the repair or exchange of a system implies the removal of other parts or systems. Especially in modern complex products the space has to be used extreme efficiently. Due to this a simple exchange of a light can presuppose the disassembly of other systems. To predict the costs of warranty events those technical presupposes have to be applied in the risk simulation.

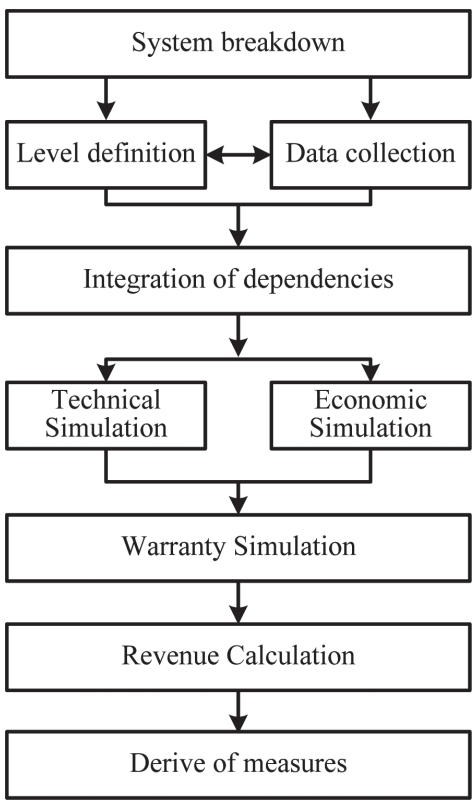

Figure 4. Risk simulation process.

In connection with the technical area, the economic area has to be combined with technical information to generated risk based results. The data needed for the economical input distributions can also be generated out of historical warranty data as well. It is very useful to transform the empirical data into distribution functions, if possible. With this transformation it is feasible to simulate the technical data with more expensive or cheaper costs than occurred in warranty data. A simulation with adapted cost distribution functions indicates the need for reviewing the adapted distribution to exclude implausible simulation results.

The empirical cost information or distribution functions are now connected with the technical requirement list from the previous step on the lowest data level. The part cost for each warranty event can now be aggregated back to subsystems, module groups and functional groups. In addition, a further query checks if the repair of single parts of a unit is more expensive than the exchange of a built unit. Via the MCS it is easy to implement and the results for all simulation runs can be extracted easily. Figure 5 shows the v-model for the MCS risk assessment approach.

Figure 5 shows only three different simulation levels.

If data is available on a higher level of detail or there are more dependency levels, the v-model can be extended accordingly.

4.2 *Input*

Many kinds of data can be programmed in the MCS. One possibility is the usage of field or test

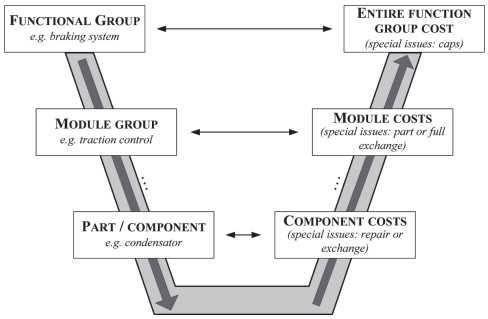

Figure 5. V-model for the technical and economical risk simulation.

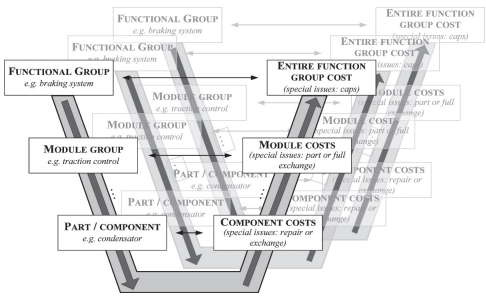

Figure 6. Multiple MCS layers.

data. Also qualitative data and expert knowledge in digital form (yes/no) can be implemented. The simulation can be transformed from the simulation in one-layer into many layers (see Fig. 6).

Different layers can be:

- usage information
- stress information
- individual market or region data
- different warranty rules
- different part versions
- different repair methods

The superposition of the different layers can be programmed via different quantiles of each layer or in different simulations, if asked for a comparison and not an inclusion of different layers.

Another important task in risk assessments is the prognosis of warranty cases and costs of new customers. Depending on different usage and stress factors (in comparison with the list of different layers) every customer has a different failure characteristic and special warranty needs. If the data is on a high quality level and contains different usage and stress information theses data can be adapted to new customers to generate a new customer profile. Also the change of the behavior of a customer can be analysed. In the automotive industry for example data from polluted or hot markets "A" can be used for other regions "C" with similar characteristics. Combined with the knowledge of the special usage behavior from a market "B" which is similar with the knowledge in "C" a customer profile for market "C" can be generated to negotiate a first warranty contract with this customer. This example illustrates the need for high quality data which presents a problem in many industries and at many levels. Due to the fact that this kind of data is not always available the MCS allows changing the simulation level of a single functional group or module very easily. If more detailed data for a special system is available the level can be adapted quickly. Additionally the new data can be used to validate and improve the results of the risk simulation.

4.3 *Revenue calculation*

The simulation of the costs of a warranty event and the statistical conclusions are only one part of the risk assessment process.

Also important is the calculation of the revenues of the warranty arrangement for the maintenance company. To consider this information a database is included in the risk simulation process, containing all warranty rules and maintenance contract details. After the cost simulation every simulation run is filtered by the revenue database which results in the real revenue of a warranty event. Beside the contract and warranty information economical company parameters like marginal returns and handling charges are included as well.

Classic parameters can be:

- Caps on components, parts, modules or systems
- Excluded material for some parts or components
- Different cost sets for special repair processes
- Dynamic parameters changed with the valid period of a maintenance contract
- Special customer parameters
- …

Due to the fact that every simulation run is checked with the revenue calculation and not the final result of the cost simulation, the revenue is also given by a distribution function, on the same level as the cost simulation. This kind of result provides a lot of possibilities for further analyses and derives of measures lowering the risk or increasing the revenue.

4.4 *Measures*

For a holistic risk assessment very flexible outputs and results are of great importance. Next to the result in kind of costs and revenues, also the amount of the contribution of every part or sub-

system to the result is needed to derive measures out of the analysis.

Therefore the MCS is very suitable due to the fact that every simulation run can be stored and analysed.

The most popular presentation of the results is the classic probability function or density. But also tornado graphs containing parts or layer information with high contributions to the entire risk analysis result are useful and can be analysed on a high detailed level. Examples of these presentations can be found in Chapter 5.

5 EXAMPLE

To describe the process disposed above this chapter contains a very simple example with some car components and parts. The values have been changed totally to illustrate the process and the presentation of the results.

In this case study three different functional groups, in one case separated in two module groups which consist of different parts, are going to be simulated (see Fig. 7). The contract type is a flatrate contract, with a valid period of 10 years. The rates are being paid in one year periods with one-tenth of the contract sum.

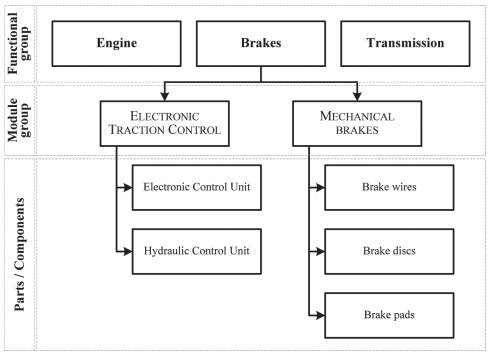

Figure 7. Structure of the example.

One simple technical dependency is given by the fact that, if one brake disc or brake pad has to be changed, the same parts of the other side of the axle have to be changed too. This is premised on safety reasons. If the condition of the brake discs or pads on one axle is clearly different the car can get out of control in full brakings.

The following technical conditions are given for this simple example. There are 3 different part conditions. Condition 1 (C1) is fully ok, only check costs accrue. Condition 2 (C2) is repairable, which means that parts have not to be changed. This condition includes an economical dependency. If the repair of a part is more expensive than the exchange, the part will be exchanged with the price of condition 3 (C3) which is defined as exchange needed.

For every part and condition the cost is defined and connected with the technical simulation of the part condition. Normally this cost information is generated on the basis of field data. In this simple example the costs for C1 and C3 are fix costs, and the costs for the repair (C2) are normal distributed via $N\sim(\mu,\sigma)$ due to the fact that not all repairs are equal in time and material expenditure. For the disc brakes, pads and wires a repair is not possible. These parts can only be C1 or C3. All technical parameters and the assigned costs are given in Table 2. Please remember, that all data for this example have been thinking up free.

The cost for the 10 year flatrate including all warranty issues mentioned above is 4.000€ including contribution margin, handling charges and so on.

Via MCS 1000 random customers are simulated with the aim to get the difference between the flatrate profits versus the warranty costs in years.

Figure 8 shows the simulated empirical distribution of the probability of the amount of warranty costs per contract.

As seen in Figure 8 the probability of a positive end of the warranty contract for maintenance company is about 50%. However, the total result for 1000 customers with a 10 year flatrate contract is clearly negative due to a negative average of the

Table 2. Technical parameters and costs for the simulation.

	P (C1)	Costs (C1)	P (C2)	Costs (C2)	P (C3)	Costs (C3)
Engine	0,89	10€	0,1	N~(5000,1000)	0,01	7.000 €
Brake—ECU	0,79	10€	0,2	N~(500, 100)	0,01	800 €
Brake—HCU	0,89	10€	0,1	N~(300, 50)	0,01	500 €
Brake—Wires	0,70	10€	0		0,30	100 €
Brake—Discs	0,40	10€	0		0,60	50 €
Brake—Pads	0,20	10€	0		0,80	20 €
Transmission	0,98	10€	0,01	N~(2000,800)	0,01	2.500 €

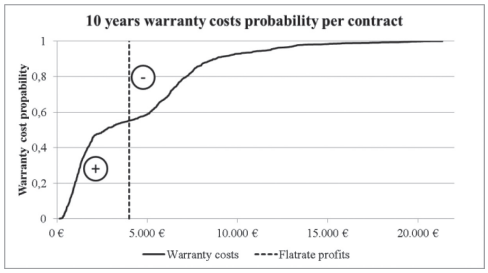

Figure 8. 10 years warranty costs probability per contract.

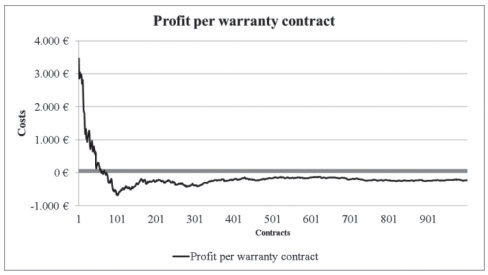

Figure 9. Average profit for all contracts.

Table 3. Summary of the economical simulation results.

	Average	Customers	Total
Flatrate profits	4.000 €	1000	4.000.000 €
Warranty costs	4.234 €	1000	4.234.888 €
Total revenue	–234 €	1000	–234.888 €

relation between costs and profit. Figure 9 shows the development of the average profit for all contracts.

As seen in Figure 5 the average profit in this simulation is almost constant at 400 simulated contracts.

The achievement of the constant value is required for the validation of the simulation results.

In total, this contract type with the given warranty issues and technical dependencies result in the total costs, profits and revenues given in Table 3.

In addition to the total results of the 10 years contract also the regression analysis is also of interest. The regression analysis describes the effect of the single technical components to the final result. The regression coefficients of the simulation for 1000 customers are given in Figure 10 and the input ranked by their effect on the Output Mean is shown in Figure 11.

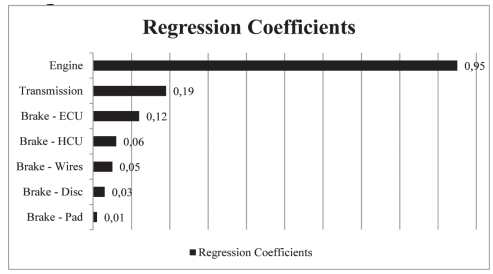

Figure 10. Regression coefficients of the simulation.

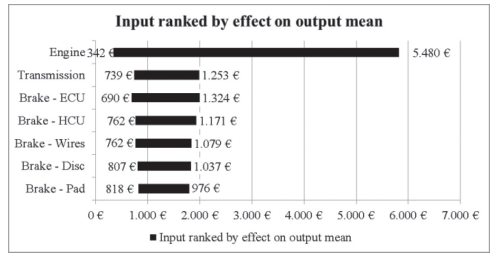

Figure 11. Input ranked by effect on output mean.

It becomes obvious that in this simple warranty cost simulation the influence of the engine status is the dominating parameter. Followed by the ECU & HCU the transmission has a lower impact than expected with regard to the warranty costs. But in combination with the high reliability, the effect is reduced strong.

The input ranked by effect on output mean is a comprehensible description of the risk parameters. The spread of the brake values is in total lower than the spread of the engine costs regarding to the output mean. The range of variation of the engine costs from min. 342€ to max. 5.480€ effect on the output mean confirms the regression analysis and adds the knowledge, that the engine maintenance is a risk but also a chance for profit maximizing.

6 SUMMARY/CONCLUSIONS

Not only technical safety and security issues can influence the risk potential of a product. Also the economical risks depending on the reliability of a product are very important for the manufacturer or the maintenance service company. New contract types are dominating the maintenance market. One example is the automotive industry which highly increasing warranty periods which new risk potential has to be transferred to the suppliers. Also flatrate maintenance contracts for end-users

become more and more popular, with new risks (and chances) for all parties involved.

In classical risk assessment approaches the technical and economical issues are analysed with different methods. The main reason for this is, in addition to the problem to get suitable data, a methodical problem. The methods to analyse technical risks are not compatible with economical issues and vice versa. This paper compares the most common and general methods for complex data analysis and manipulation. It concludes that the Monte-Carlo-Simulation is very suitable for risk assessment issues. The MCS, based on random events, can handle almost any common information (e.g. empirical, continuous, quantative data and expert knowledge). This is one of the major advantages of the simulation method due to the fact that different kinds of information are used in technical and economical issues. To perform a risk assessment with the MCS it is suitable to use an adapted v-model to connect the technical with the economical level. To get versatile outputs, MCS can be inserted in all typical statistic methods which offer a lot of possible output visualizations.

In addition the MCS is useable with conventional business laptops or notebooks and for not very complex technical systems or economical dependencies it is feasible with standard spreadsheet programs.

The results of a systematic study of the risks associated with the transportation of hazardous substances

D. Prochazkova, J. Prochazka & H. Patakova
Faculty of Transportation Sciences, Czech Technical University in Prague, Czech Republic

ABSTRACT: Statistics on traffic accidents annually contain a number of serious accidents involving the hazardous substances on roads and railways, which are accompanied by explosions, fires, leaks of hazardous substances into the environment, or a combination of the two to three mentioned phenomena which have impacts on the protected assets in a traffic accident site, and perhaps as a consequence of internal links and couplings they seriously damage the environment surrounding the accident site. By application of empirical data and procedures of risk engineering it was compiled the check list by which it is possible to determine the critical sites on roads and railways in advance, and it was tested specifically aimed What, If the method, by which it is possible to determine in advance scenarios of impacts of traffic accidents involving the hazardous substances and to determine critical aspects of critical sites from the viewpoint of protection of humans and other public assets.

1 INTRODUCTION

At present it comes up to increasing concern for the protection of human and to the awareness of the public there are entered the issues on security and sustainable development. It is intensifying the interest in recognition of risks and their elimination, respectively, on their elimination on the economic-social acceptable level. The current trend of research in the subject area is the integration of security features with an impact on a wide range of affected areas to complex safety solutions. Today we cannot understand the safety as partial separate segments, but we have to understand it in the complex way, that is, in its real and imaginary form, in all areas of natural or anthropogenic risks.

The basic function of the State is to ensure the security and development of human society, which is not possible without ensuring a safe space in which we live. The basis for safe community is a critical infrastructure, which is understood as a set of infrastructures ensuring the quality of life of the humans. To the critical infrastructure the transport infrastructure also belongs. Its main components are: elements such as terminals, bus stations, railway stations, airport, bridges, tunnels etc.; the traffic physical infrastructures that are made up from the liner constructions and which are important for ensuring the serviceability of a territory under normal, abnormal and critical conditions; and management systems. The subject of the paper is the protection of people from the risks associated with the carriage of dangerous substances by ground roads.

Traffic accidents involving the hazardous substances threaten the people, and therefore, there are subject to the safety management of the territory. For ensuring a safe space in which we live the current relevant international organizations (e.g. the UN, the OECD, the EU, NATO, UNECE), Governments, public administration (administrative authorities, regional and local authorities) have special programme the aim of which is to create a safe space for the 21st century. The real results obtained for the Czech Republic data are shown in next paragraphs.

2 TRANSPORT AND TRAFFIC ACCIDENTS INVOLVING DANGEROUS SUBSTANCES ON THE ROAD

Industry and economy of the countries depend on the hazardous substances that are transported from manufactures to users, to the storages of the waste etc. Hazardous substances are transported by road, rail, water, air and pipelines. Most transportation is done safely. According to the World Road Association PIARC (PIARC 2010), which has been in operation since 1909 and today brings together over 140 countries, the transport of hazardous substances in the EU countries makes up 5–8% of the total volume of traffic. PIARC has kept track of traffic accidents on the road, with the presence of hazardous substances since 30's years of the last century and since the 70's years it records their steep rise, Figure 1.

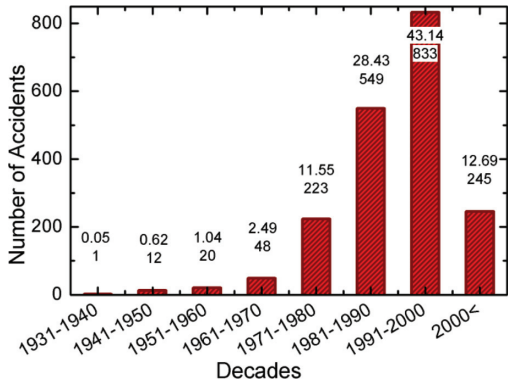

Figure 1. The number of traffic accidents involving hazardous substances (PIARC 2010).

2.1 *Hazardous substances*

Hazardous substances are chemical substances and chemical agents, which accompanies a human in everyday life. By various processes there are from them produced final products, which are part of the nutrition of human or his/her life in many domains, e.g. medicines, hygiene means and equipment, synthetic fertilizers, plastics, synthetic fibbers, etc. At the very beginning it is the mining of raw materials and their subsequent machining. It is followed by transport to the place of processing, storage, production of various intermediate products and, if necessary, transport and storage. Finally, by the various processes there are produced final products.

In each process the chemical substances behave in such a way that corresponds to their nature. Chemical substances have the same properties in the few grams and in many tunes quantities, i.e. in mega kilograms. The severity of the impacts of chemicals on the environment depends on the direct proportion of their quantity. It is, therefore, only on humans, in order to ensure the safe development and use of all chemicals and at the same time at the lowest possible rate cut their unacceptable impacts, both through highly specialized technical discipline, safety engineering and, secondly, also by shoring up the knowledge level of the society as a whole. This means that in human society is promoted a certain safety culture (Prochazkova 2011a, Prochazkova & al 2008).

2.2 *The transport of hazardous substances*

Transport of hazardous substances takes place largely on ground roads what are the liner constructions of transport infrastructure, which is a fundamental part of the critical infrastructure of the territory. They are important for ensuring the service of a given territory under conditions of normal, abnormal and critical. At present there are transported a variety of harmful and toxic chemicals used as raw materials in the industry. The amounts of these chemicals in the transport range from kilograms after dozens of tons. As the possibility of leakage of harmful chemicals in transit is the most dangerous (because in such occurrence it is a lack of specialized catch equipment, on the accident site it is not immediately trained specialized personnel and equipment for the disposal of leakages), and also it is relatively the easiest possibility of puncture of the tank in a car accident, leaks at pumping, overheating, overfill of containers, etc., it is necessary to have this domain regulated by laws, which provide rules for loading, transporting and technical requirements to transport equipment.

Transport on ground roads is according to (Prochazkova & al 2008), codified by a number of provisions, however, it is the fact that so far none legislation does not regulate the transport of chemicals in sufficient details. Therefore, in most of countries it is used a number of international regulations, which, however, are not compatible with other countries' legislations, or each other (Prochazkova & al 2008); therefore, the solution of some problems is long.

Road and rail transport is permitted only to carry dangerous goods as defined in the international treaties, which the Czech Republic is bound and which have been promulgated in the collection of laws. For rail transport, according to the Convention concerning international carriage by rail (COTIF), adopted in Bern on the May 9, 1980, the use of procedure for the international carriage of dangerous goods by rail (RID) and the uniform rules concerning the contract for international carriage of goods by rail (CIM), which regulates the international directive UIC (471-1 in); and for road transport with regard to the international agreement of the ADR (European Agreement concerning the international carriage of dangerous goods) (Prochazkova & al 2008).

2.3 *Knowledge about the accidents with the presence of hazardous substances*

Statistics of road traffic accidents annually, contain a number of serious traffic accidents involving the hazardous substances on roads and railways, which are accompanied by explosions, fires, spills of hazardous substances into the environment, or a combination of two to three phenomena, which has impacts on protected assets in a site of traffic accident and, as a result of internal links and couplings it seriously damaging the

environment and other assets in the wider area of traffic accidents' sites.

Specialized literature contains descriptions of accidents involving the hazardous substances, which caused tens of millions of dollars in damage and great loss of human lives. At accidents on the roads there are threatened humans, property and the environment, that are in the area of ground roads. Figures 2 and 3 show the impacts of the oil train accident that happened on July 6, 2013 in the town of Lac-Mégantic in Canada (Canadian Press Agency 2013). The train, consisting of 5 locomotives, one auxiliary car and 72 loaded oil tankers spontaneously started, derailed, there were several explosions, and the city was flooded with oil and large fires. It was destroyed more than

Figure 2. The impacts of the oil train accident that happened on July 6, 2013 in the town of Lac-Mégantic (Canadian Press Agency 2013).

Figure 3. The impacts of the oil train accident that happened on July 6, 2013 in the town of Lac-Mégantic (Canadian Press Agency 2013).

30 buildings, killed more than 80 people, 10 people remained unaccounted for, evacuated more than 2000 people because of the threat of toxic gases and fire. The next big train accident with presence of oil was on December 23, 2013 in North Dakota (Reuters Agency 2013). Half of the 106 carriages of the train derailed after a collision with another train. After it into the air, it raised a massive fireball. Authorities have evacuated due to heavy black smoke, the adjacent village of Casselton with 2 300 inhabitants.

Authorities ordered residents of a half mile of the remote Casselton to their homes for a time. County Sheriff at the same time recommends to people living within eight kilometres to the South and East of the accident site, to be evacuated. ***All the people in and around 16 km then it was recommended that in this time from they did not ventilate at home.*** After the crash, the causes of which have not yet been found, it went off the track 50 wagons. At least ten of them began to burn. The vicinity was clouded by impenetrable smoke.

According to the data of customs reports in the EU today they also run a trains with oil in Europe, they have 30–50 wagons, i.e. it's not about science fiction, when considering such hazards.

Therefore, the major traffic accidents involving the chemical substances are a subject to the safety management of the territory. Clarifying the causes of traffic accidents involving the hazardous substances is very complex, because it often happens that the safety data sheets, which belongs to the mandatory documentation of vehicles carrying the chemicals, are not complete or entirely absent; sometimes they are only in the language of the carrier (Prochazkova 1993).

On the basis of investigations in the USA and the UK (Lum & Reagan 1995) from the year 1985 the causes of traffic accidents on the roads are divided as follows:

- 57% of the human factor of the driver,
- 27% a combination of factor of the road and the driver human factor,
- 6% a combination of driver human factor and a factor of the vehicle,
- 3% the factor road,
- 3% a combination of factors of the road, drivers and vehicles,
- 2% the factor of the vehicle,
- 1% a combination of road and vehicle factors.

To accident origin they contribute the design of the vehicle, the speed and density of traffic, road design, environs around the road, skill and defects in the behaviour of the driver. In the professional literature, you can now find lots of models showing the factors interconnection, e.g. at work [8] it can be found simple model of the causes of traffic

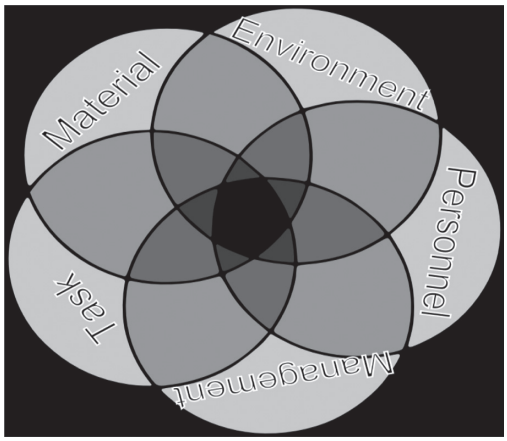

Figure 4. Causes of road traffic accidents (Canadian Centre for Occupational Health and Safety 2012).

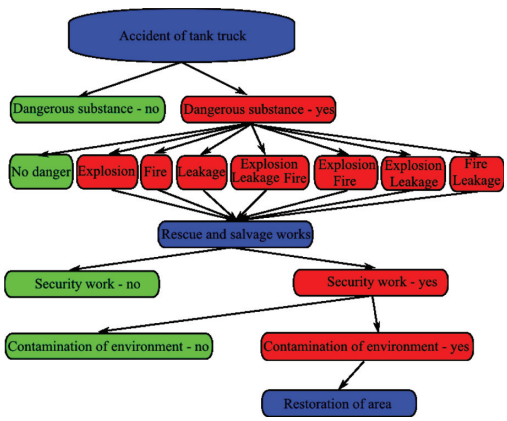

Figure 5. Process model drawn up for the needs of planning activities associated with transportation accidents involving hazardous substances (Prochazkova 2011a).

accidents involving the hazardous substances, Figure 4.

Because at transport the chemicals behave in such a way that matches their nature (Prochazkova & al. 2008), it is necessary to follow every accident involving the hazardous substances from the perspective of ensuring the safety according to the process model, which is shown in Figure 5.

3 DATA AND METHODS USED FOR PROCESSING THE DATA IN A DATABASE

On the basis of current knowledge the safe territory and safe transport in the territory can be ensured only if they are adequately managed and traded-off the risks, i.e. if it proceeds strategically, systematically and proactively (Prochazkova 2011a). Therefore, we have compiled a database of accidents involving the hazardous substances for the Czech Republic (CTU 2013).

The data in the database are evaluated through ordinary methods of mathematical statistics and by the specific methods of risk engineering, i.e. using a specially drawn up a checklist, and What, If method revealing the impacts of accidents involving the hazardous substances on public assets (Prochazkova 2011b). Application of empirical data and procedures of risk engineering the special checklist has been drawn up, which you can specify in advance the critical places on the roads and railways with regard to the transport of hazardous substances (Prochazka 2013).

4 THE RESULTS OF THE RESEARCH ON TRAFFIC ACCIDENTS INVOLVING THE HAZARDOUS SUBSTANCES

We present selected results obtained from investigation by statistic methods and one selected result obtained by risk engineering method; the other results are in the Archives (CTU 2013).

4.1 *The selected results of the statistical surveys*

The analysis of the database of traffic accidents involving the hazardous substances (CTU 2013) shows that there are carrying the different sorts of chemicals: fuel; oil; highly flammable substances; nitric acid; sulphuric acid; lactic acid; phosphoric acid; nitrates; zinc phosphates; manganese phosphates; nickel phosphates; potassium hydroxide; styrene; liquid chlorine; argon gas; formaldehyde; asphalt; lime; powdered PVC etc. There are a total of road accidents involving the hazardous substances hundreds annually and evaluated damage to property associated with the deterioration of the dangerous substance understood as goods associated with them reach hundreds of millions. Other costs are associated with the response (it is often necessary to pump over a hazardous substance, which requires special equipment and technology), clean-up, and renovation of ground roads and with the interruption of the supply chains and stopping the passenger services. These traffic accidents are also accompanied by lighter or heavier injuries of passengers and deaths, damage to roads and property in the vicinity of roads, as well as environmental damage.

On the basis of the source (CTU 2013) they have been drawn up two frequency dependences

for traffic accidents involving the hazardous substances, on the roads, Figures 6 and 7.

Figure 6 shows: the downward trend in the total number of traffic accidents involving the hazardous substances on the territory of the Czech Republic in the years 2007–2010; and the number of traffic accidents involving the hazardous substances depends on the deployment of the main traffic arteries—the most traffic accidents involving the hazardous substances falls annually on the Central Bohemian Region, which is followed by the Southern Moravia Region, Zlin Region, Vysocina Region, Usti nad Labem Region, Liberec Region, the Moravian-Silesian Region and Olomouc Region. The first figure is pleasing. The second figure is in line with the findings of the early 1990s. years (Prochazkova 1993), where as the main source of traffic accidents

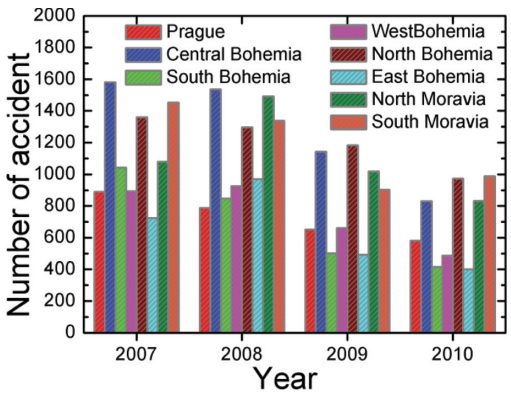

Figure 6. Frequency distribution of traffic accidents with the presence of a hazardous substance on the road for the years 2007–2010, differentiated according to regions.

involving the hazardous; substances was revealed traffic from Asia minor and the Balkans in the direction of Rotterdam, i.e. to the Europe's largest port, in which hazardous substances are translated on the ocean-going ship. This data is in its own way worrying, because the evaluation of traffic accidents involving the hazardous substances in the cited report, made at the turn of the years 1992 and 1993 proposed the need to perform measures, mainly processing and adoption of good legislation for the domain in question, in order to protect the lives and health of people and the environment in the Czech Republic.

From the data in Figure 7 it is an obvious seasonal trend in the occurrence of traffic accidents involving the hazardous substances, i.e. the largest occurrence of traffic accidents involving the hazardous substances is in the summer months, from April to June.

Recorded traffic accidents involving the hazardous substances on the Czech railways show that carrying all sorts of chemical substances: flammable solids substances, substances liable to spontaneous combustion, corrosive substances, poisonous substances and other dangerous substances and articles. The frequency distribution of traffic accidents on the rail with the presence of hazardous substances for the years 1996–2010 is shown in Figure 8. We observe that most of the accidents on the rail with the presence of hazardous substances were in 1997; their number exceeded 700. In the period 1998–2004, the annual number of accidents involving the hazardous substances increases. In the years 2006–2010 there is a decline in the annual number of accidents involving the hazardous substances and, in the years 2009 and 2010 reached under a value of 100, which may, however, be the result of a decline in industrial production, which

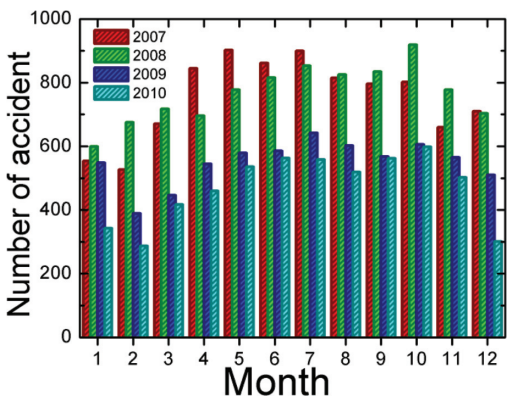

Figure 7. Frequency distribution of traffic accidents involving the hazardous substances for the years 2007–2010, differentiated according to the months.

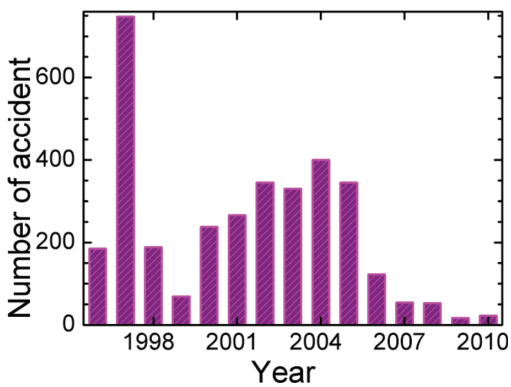

Figure 8. Frequency distribution of traffic accidents involving the hazardous substances for the years 1996–2010.

is naturally linked to the transport of hazardous substances.

Figure 8 shows the frequency distribution of traffic accidents involving the hazardous substances for the years 1996–2010. There were transported flammable, combustible and liable to spontaneous combustion, solid, toxic, corrosive, etc. substances; the most of flammable substances are fuel substances; the second place ranked traffic accidents with the presence of corrosive substances, which is very dangerous, because the substance in the release into the environment pose a great danger to surface and underground water and sewer system; a significant percentage have a traffic accident with the presence of toxic substances, which is dangerous for both people and animals, and the environment (CTU 2013). Further investigation will focus specifically on poisonous substances and explosive substances and performs the simulation possible scenarios of the impacts of accidents in places with large amounts of people and other assets of the human system to identify the places in which it is necessary to perform safeguard measures in the interest of security and further development of the people.

4.2 *Selected results obtained by the What-If method*

To illustrate, there are here the results of the method, What If for the territory in the vicinity of the intersection of the D1 highway and the road "class 1, No. 52", Figure 9, in which according to our database of accidents involving the hazardous substances (CTU 2013) there are frequent accidents with the presence of oil products (mostly fuel—gasoline). The overall look on a given site is shown in Figure 10.

Figure 9. Scheme of territory in the vicinity of the intersection of the D1 highway with the road, class 1, No. 52.

Figure 10. The overall view on the stretch of road No. 52.

The reference section of the D1 highway is located to the South of the city of Brno on 194 km from Praha. In the area it is also departure from the highway, which leads from the North to the centre of the city of Brno and to the South along the road class1, No. 52 in the direction to Vienna. In vicinity of the highway it is a shopping zone with a filling station, then the industrial zone, where mainly dominated technical services and warehouses, supplying the city of Brno. In the zone a railway trail is located. In the investigated area they are also a residential zone and the allotment, along the highway it leads the railroad, and the Leskava River, which flows into the Svratka River. On the road No. 52 in both directions, there are the tram tracks.

The assessment of impacts of traffic accident involving the oil products is performed by the What, If method that is specially modified for the safety management of the territory (Prochazkova 2011b). The results of the evaluation are listed in Table 1.

From Table 1 it follows that recovery after some damage will require a longer period of time, e.g. damage of engineering networks, groundwater contamination, damages as damage of sewer infrastructure need always longer time for renovation; e.g., traffic accident on the D1 highway near the village Kozlov in 2004 caused in the village sewer system a set of explosions that very damaged sewer system (CTU 2013) and renovation lasted several months.

Considering the results of other What, If analyses of traffic accidents with presence of hazardous substances in other urban areas (Prochazkova & al. 2013) it is necessary to solve identified problems. E.g., it is necessary to ensure the readiness of the municipalities with extended competence for overcome of consequences of great traffic accidents with the presence of hazardous substances. They must pay great attention to objects with a

Table 1. Results of What-If analysis of traffic accident with oil products, at the junction of the D1 highway with the Brno-Vienna road, class 1, No. 52, on the territory of the city of Brno. DN—the impacts of a normal traffic accident, NL—other impacts traffic accidents involving the hazardous substances (fuel, oil products); the impacts are listed in the times of 0, 3 and 12 hours and 3 days, taking the time of 0 indicates the time of the accident origin; the symbol ** indicates that no further new impact.

Protected public assets	The impacts
Human lives and health	DN: 0 h-death or injury to participants in a traffic accident, 3 h, 2 h, 3 days ***. NL: 0 h-heavy fires and explosions (highly flammable vapours create with air explosive mixture), thick smoke affects humans and damages human health—vapour with a higher concentration affect as narcotic, provoked the skin, membranes, eyes and respiratory system; 3 h—damage to health by fire with high temperatures; 12 h—damage to health by missiles in a case of leakage of oil products into the sewage and at origin of explosive clouds in the nearest vicinity (there are affected humans in the industrial zone and the shopping area, which is located in the gas station), 3 days ***. ***Numerous losses on humans live as a result of traffic accidents, the subsequent fire and explosions in the sewer system. The place is located in a densely populated area on the outskirts of Brno, where are dense drainage networks.***
Human security	DN: 0 h—stress of drivers in the traffic jam, 3 h—the growing stress of drivers, the disruption of human security in the surrounding municipalities (Moravany, Dolní Heršpice and Přízřenice) and in areas of Brno in which there are detour routes, 12 h ***, 3 days—the inconveniences caused by traffic restrictions due to damage to the ground roads. NL: 0 h-stress to the panic caused by origin of the fire and explosions in the area of the accident, 3 h—stress and panic during the evacuation of the nearby parts of the city of Brno, 12 h—fear from origin of subsequent explosions of the leaked fuel and oil substances, persistent disruption of peace in villages and in urban areas around the detour routes, 3 days ***.
Property	DN: 0 h—damage of ground road due to traffic accidents (road surface, the pillars of bridges, tramway tracks, railways and railway trail) and the buildings in surrounding, 3 h—possible disruption to production in the industrial zone, 12 h ***, 3 days ***. NL: 0 h—damage to the destruction of traffic ground road and buildings in the vicinity due to fire and explosions, 3 h—damage to the destruction of the buildings in the surrounding municipalities and city districts caused by explosions of the leaked fuel and oil substances in the sewer system, then the loss of profit of stores and operators of industrial zone in the evacuated areas, 12 h—persistent loss of profits of stores and operators in the evacuated areas, 3 days—as a result of the destruction of the monitored intersections by the explosion there are over-utilized detour ground roads and factories and plants inside the affected zone are affected by worse traffic situation. *Big losses on buildings, property and ground roads as a consequence of explosions of fuel and oil substances and petrol fumes in an accident side and in the sewer system*.
Environment	DN: 0 h—contamination of Leskava River (Leskava River flows into the Svratka River) and the soil by leakage fuel and oil substances, 3 h—damage to the flora and fauna in the contaminated waters and soils, the deterioration of the atmosphere in the villages on the detour routes, 12 h ***, 3 days—the weakening of the ecosystem due to contamination. NL: 0 h—water contamination (Leskava River flows into the Svratka River), soil and air (in the air a lot of fumes and vapours), damage of greenery due to fire, 3 h—damage to the flora and fauna in the accident site and its surrounding, the persistence of the devastating impacts of fire, 12 h—damage to air quality round the detour routes, 3 days—the weakening of the aquatic ecosystems due to the contamination of surface water and ground water, the destruction of ecosystems as a result of a fire in the accident site and its surrounding. *Long-term groundwater contamination.*
Infrastructure and technology	DN: 0 h—failure of the affected section of the D1 highway (exit 194), road, class 1, No. 52, 3 h—out of function of affected sections of ground roads, trails, 12 h detour routes overload ***, 3 days-decommissioning of the affected leg due to traffic accidents, damage to the detour ground routes due to overload. NL: 0 h—loss of function to destruction of the followed part of the D1 highway and ground road No. 52, 3 h—malfunction of the affected parts of ground roads, possible destruction of ground roads, and other infrastructures and technological facilities due to explosions of petroleum substances and overloading of detour ground routes, 12 h—loss of function of affected sections and overloading the detour ground routes, 3 days—permanent damage to affected areas due to traffic accidents, fires and explosions, damaging the detour ground routes due to overload. *Serious damage to sewers and other utility networks as a result of explosions of vapours oil substances. Paralysis of the transportation infrastructure of Brno.*

(*Continued*)

Table 1. (*Continued*)

Protected public assets	The impacts
Emergency services (police, fire, paramedics)	DN: 0 h—a reduction of the availability of the components of the Integrated Rescue System (IZS), 3 h—reduction of the availability of the IZS components, 12 h ***, 3 days ***. NL: 0 h—a reduction of the availability of the IZS components, 3 h—reduction of the availability of the IZS components, 12 h—a reduction of the availability of the IZS components, 3 days ***.
Supply chains	DN: 0 h ***, 3 h—the disruption of supplies from warehouses in part of Brno the connection of which with Brno is out of function due to damaged ground roads at traffic accident, 12 h ***, 3 days ***. NL: 0 h ***, 3 h, 12 h—disruption of the supply of the Brno from boxed warehouses, 3 days ***.

large number of people (employees and passengers at the time of travel to work and from work from residential parts; transfer to and from schools, shopping malls and medical centres) and also to sites with technologies, which may cause a domino effect. It would be useful if the municipal authorities should have any agreement with schools, hospitals and shopping centres for an emergency case, how best to handle the evacuation, because only a sucker may assume that the task will pulled off by management of objects with a large number of people, or by the Fire Department, that will have to reduce the criticality of the situation and to carry out prompt response to the explosions and fires.

5 CONCLUSIONS

For the protection of the people it is necessary to perform the separate concept of transport, based on a systemic approach that allows keeping up tempo with the technological developments of transport systems that considers the needs of people and transport serviceability, environmental protection and reduces economic damage. Public authority is necessary in co-operation with experts to define the issues which are necessary to solve and to process the relevant studies in the sense of the above recommended procedure—i.e. to determine how the protection of humans will be ensured in places with a high number of people.

After the losses and damage caused by traffic accidents caused by oil trains in the North America in 2013, it is necessary to pay more attention to safety culture and human security. In the event of traffic accidents at settled areas it is necessary to pay great attention to objects with a large number of people and also the sites with technologies, which may cause a domino effect. It would be useful if for any emergency the municipal authorities should prepare agreements with schools, hospitals and shopping centres, how best to handle the evacuation, because this is the way of human survival at emergency situations.

Preference risk assessment of hazardous substances road transportation

D. Rehak, A. Bernatik & P. Novotny
Faculty of Safety Engineering, VŠB-Technical University of Ostrava, Ostrava, Czech Republic

ABSTRACT: Current techniques and methods of risk assessment in the field of hazardous substances road transportation are oriented especially towards assessing the impacts of potential accidents on population and the environment. However, every subject affected has different preferences arising from the nature of his activities. While a carrier prefers maximum profit arising from safety transport, public administration authorities prefer ensuring maximum safety of population and other public estates and properties. At the same time, it is necessary to point out that current legal regulations make a significant drawback in the field of ensuring safety of hazardous substances road transportation. The above mentioned legal regulations do not require risk assessments from the road carriers of hazardous substances. Therefore, carriers do not carry out such assessments, as the data gained from accessible techniques and methods do not provide them with requested information.

Applying the multi-criteria preference risk assessment of hazardous substances road transportation brings a suitable solution to the current situation, as it lies in setting criteria by considering real threats as well as all potential areas of their impact. Subsequent implementation of weight coefficients enables the assessor to prefer his concerns, while the final risk listing provides him with requested information regarding his activities. Realizing such assessment brings complex increase in preventive safety measures in hazardous substances road transportation, since it enables the carrier to realize not only primary risks connected with possible economic loss, but also secondary risks related to the impact on population and other public estates and properties.

From the economic point of view, hazardous substances transportation is a subject of business like any other. However, in comparison with other areas of business, its impacts may be much higher and more serious. In spite of this fact, the risk assessment in the area of hazardous substances road transportation is not required by legislation within the EU. This obligation is only set for stationary sources (Directive 2012).

Moreover, hazardous substances road transportation is a very specific area with a disunited attitude within the issue of risk assessment. This attitude is a subsequence of different preferences of individual interest groups. Owners of transport companies, whose main goal is the maximization of the transport profit, have a different point of view from the public administration authorities who strive for ensuring maximum security of the given transport. There is another point of view, presented by various stakeholders, like purchasers of hazardous substances owning the security certificates or ecological activists. The consequence is a singnificantt diferentiation between the recommended (by the public administration authorities) and the eccepted (by the hazardous substances road transporters) security measures.

On the basis of the above mentioned facts, the authors present a possible solution of the given situation by means of risk assessment of hazardous substances road transportation, where each assessed subject matches identical criteria with various prefecences reflecting his or her interests.

1 MATERIALS AND METHODS

1.1 *Accidents and their impact*

In the past, there have been a number of accidents during hazardous substances transportation around the world, for emample (Oggero et al., 2006):

1. Road accident in Houstonu, USA in 1976, ammonia leakage, 6 casualties, 178 injured; Road accident in San Carlos, Spain in 1978, propylene explosion, 200 casualties,
2. Railway accident in Mississauga, Canada in 1979, LPG explosion and chlorine leakage, 200 thousand people evacuated; railway accident in Montanas, Mexico in 1981, chlorine leakage, 28 casualties, and 1000 injured.

The outcomes of the study show (Guidelines, 2005a) that the accident frequency occurring on roads and railways during hazardous substances transportation has been increasing. At the same time, the outcomes show that more than a half of

the accidents have happened on roads (63%). The most frequent impact of the accidents has been substance leakage (78%), followed by fires (28%), explosions (14%) and gas clouds (6%).

1.2 *Methods of risk assessment of hazardous substances transportation*

Risk assessment of hazardous substances transportation may be realized by means of various methods based on qualitative assessment (estimating merely the consequences of accidents) as well as complicated quantitative methods (which, apart from estimating consequences of accidents, determine probability of accident occurrence).

The European legislation neither determines nor recommends any method in this area. In spite of that, it can be stated that the most suitable methods are those like Chemical Process Quantitative Risk Analysis (CPQRA) and Chemical Transportation Risk Analysis (TRA) issued by the Center for Chemical Process Safety (CCPS) of the American Institute of Chemical Engineers (AIChE).

The CPQRA method (Guidelines, 1999) serves for quantitative estimation of chemical processes risk. It uses a complex of methods in the logical process of chemical processes risk assessment by means of risk measure which is the result of risk summarization of selected undesirable accidents. Sollution is carried out in stages, starting with statement and development of undesirable events of the investigated risk realization and aiming at assessing consequences, impacts and probability of all terminal scenarious of selected undesirable events. At the same time, it includes suggestions for risk reduction. For quantification of consequences and impacts, modeling of physical-chemical processes and phenomena is used (leakages, dispersions, fires, explosions, risk receiver vulnerability—models of burst and response: concentration, function probit, heat radiation, overpressure).

The TRA function (Guidelines, 2005a) states kinds of malfunctions and its frequency for individual types of transport (pipelines, railway, road transport, boats, oceanic crafts), choice of possible accident scenarios, case studies, etc. The method may also be used for mere identification of possible risks. The TRA may help with choosing the type of transport, way of transport, possibilities of combining various types of transport, suitable transport alternatives, the most suitable containers. It can also help develop plans for solving emergencies, managing transport risks, etc. The right application of TRA within the risk management enables one to decide about an alternative way of transport, suitable route, travel limits (speed, weather, time of he day), size of consignment (the total volume), etc.

1.3 *Multicriterial assessment*

Currently there is a whole range of multicriterial assessment techniques, differing in their abilities (e.g. Figueira et al., 2005). Matematically, the decision model can be formulated in the following way (relation 1):

$$\max \quad u_i = \sum_{j=1}^{m} pm_{i,j} \cdot w_j \tag{1}$$

where utility u of variant i, defined as a sum of weighted (w) performance measures pm of the criteria j, is maximized. Definition (1) presumes that the criteria used in the decision analysis are independent of each other (Fishburn, 1965).

Matematical considering of the given assessor or specific interest groups is suitable to be realized by implementing weight coefficients of individual criteria. These weight coefficients might be set by using simple methods (e.g. the method of point llocation, the method of weighed order, the method of alkaline variant, the method of Fuller's triangle) or using more complicated methods based on pairwise comparison which support criteria hierarchy assessment. (Řehák and Šenovský, 2014). The most suitable methods based on pairwise comparison are Analytic Hierarchy Process AHP (Saaty, 2008) or Analytic Network Process ANP (Saaty, 2004), or methods based on utility function quantification or a combination of the above mentioned methods (Weil and Apostolakis, 2001).

2 RESULTS

2.1 *Preferencial risk assessment*

Preferencial risk assessment enables the assessor to implement subjective conditions into an otherwise objective process of risk evaluation. Therefore, it enables the assessor to have a partial influence on the assessment process by preferring certain coefficients to others. This part of the process is important, since every subject perceives certain risks from a different point of view, which subsequently leads to discussion among all stakeholders and to choosing the most suitable security measures.

There are three main groups of stakeholders in the field of hazardous substances road transportation that are entitled to regulate the transport safety:

1. Road carriers of hazardous substances,
2. Public administration authorities:
   a. ministry of the environment,
   b. county council,
   c. affected villages,
3. Other interest groups (e.g. purchasers of hazardous substances or ecological activists).

Preferences of the road carriers of hazardous substances are above all connected with the financial aspect of the transport. The aim of he carrier is gaining a maximum profit from the transport, which is closely connected with the transport safety. In case of an accident the carrier loses the profit as well as the transport vehicle during the repair, which prevents him from earning further profit.

On the other hand, public administration authorities preferences are based on socioenvironmental aspect. The authorities primarily try to ensure maximum safety of population and environment during hazardous substances transportation, considering economic and technological possibilities of the carrier. There are secondary preferences like transport infrastructure security or ensuring transport smoothness.

The last group is formed by other interest groups. Their preferences differ according to their relationship to the carrier. For example, purchasers of hazardous substances, who are holders of safety certificates (e.g. ISO 14 000 or Eco Management and Audit Scheme), prefer the goodwill of supplier companies. As opposed to that, ecological activists strive for maximum environment protection regardless.

2.2 *Multicriterial risk assessment of hazardous substances road transportation*

The essence of multicriterial risk assessment is the right criteria setting. In relation with risk assessment of hazardous substances road transportation, the criteria are divided into three main groups: (Řehák et al., 2014):

1. criteria related to the level of vulnerability of the subjects affected (i.e. population, environment and the road carrier's property),
2. criteria related to evaluating the level of hazardousness of the realized transportation,
3. criteria related to evaluating the level of intended security measures.

2.2.1 *Criterial vulnerability assessment*

Criteria related to assessing the level of vulnerability may be divided into three groups reflecting different vulnerability of the subjects affected:

1. criteria related to population vulnerability assessment, i.e. Occurrence of densely populated areas and Occurrence of buffer zones of water resources.
2. criteria related to population vulnerability assessment, i.e. Occurrence of protected areas and Occurrence of buffer zones of water resources.
3. criteria related to means of transport and cargo vulnerability assessment, i.e. Value of transport technology and Value of the transported cargo.

Occurrence of densely populated areas (V_{POP})—with growing density of populated areas on the hazardous substances transport route there is a potential growth of population vulnerability.

Occurrence of protected areas (V_{PRO})—with the growing number of protected areas on the hazardous substances transport route there is a potential growth of environment vulnerability.

Occurrence of buffer zones of water resources (V_{WR})—with the growing number of buffer zones of water resources on the hazardous substances transport route there is a potential growth of environment and population vulnerability.

Value of transport technology (V_{VT})—carrier's pecuniary loss caused by the damaged transport technology.

Value of the transported cargo (V_{VC})—carrier's pecuniary loss caused by the destruction of the transported hazardous substance.

2.2.2 *Hazardousness assessment criteria*

The level of hazardousness of the realized transport is assessed by means of the following criteria: Hazardousness of the transported substance, Amount of the transported substance, Average age of the transport technology, Average age of the road on the route, Driver's experience and skills and Weather.

Hazardousness of the transported substance (H_{HS})—the level of hazardousness derived from hazardous qualities of the transported substance (e.g. explosiveness, inflammability).

Amount of the transported substance (H_{AS})—the level of hazardousness derived from the amount of the transported substance.

Technical condition of the transport technology (H_{TC})—the level of hazardousness resulting from a bad condition of the transport technology.

Driver's experience and skills (H_{ES})—the level of hazardousness resulting from low experience and bad skills of the driver.

Average state of the road on the route (H_{SR})—outside influence that may have a negative effect on the safety of hazardous substances transportation.

Weather (H_W)—outside influence that may have a negative effect on the safety of hazardous substances transportation.

2.2.3 *Safety measures assessment criteria*

The level of intended safety measures is assessed by means of the criteria of Viability, Effectiveness, Financial demandingness and Time demandingness.

Effectiveness (S_E)—the ability of safety measures to minimize the effect of threat and its impact on the asset.

Feasibility (S_F)—accessibility and utilizability of technological measures to minimize the threat.

Criteria of financial and time demandingness are directly related to the criterion of viability.

Financial Demandingness (S_{FD})—accessibility of financial sources to implement safety measures.

Time Demandingness (S_{TD})—time needed for safety measures realization.

2.2.4 *Criteria specification and indexation*

Specification and indexation must follow after setting the criteria. Specification is based on listing various variants of the given criterion manifestation. Indexation is based on semi-quantitative way of assessment, with selecting a five-grade scale in this case, where 1 presents a low level of vulnerability, hazardousness or measure effectiveness and 5 stands for the highest level. Specific cases of specification and indexation of the criteria of Occurrence of densely populated areas (V_{POP}) and Occurrence of protected areas (V_{PRO}) are elaborated in Tables 1 and 2.

2.3 *Implementation of multicriterial assessment into the risk assessment process*

As it follows from the current methods analysis, the most suitable tool for the hazardous substances road transportation is the TRA method. At the same time it is important to point out that it would be suitable to modify this method with adding the multicriterial assessment, which would make the provided outcomes more suitable for specific users (see Fig. 1).

The basic presumption of successful implementation of interest groups' preferences into the risk assessment process is realistic weight estimation. Based on this, the AHP method (Saaty, 2008), which is often used in practice and reaches good results, was selected. Another significant factor for selecting this method is the fact that it contains mechanisms enabling assessment of measurement consistence by means of the quantity of Consistency Ratio (CR). This quantity indicates the degree of randomness during criteria preference measurement, when the value of 0,1 indicates an acceptable level of consistence and 0,9 corresponds to a purely random choice.

In the first step of the preferential risk assessment it was necessary to set weight of individual areas. In this case, the weight was equally divided among risk increasing areas (i.e. vulnerability and dangerousness) and the risk reducing area (i.e. safety measures). In the second step, individual areas criteria were already assessed by means of the AHP method (Saaty, 2008). For the hierarchy of the above mentioned criteria the following results were reached (see Table 3).

The above mentioned outcomes describe differences in preferences of interest groups, i.e. hazardous substances carrier, public administration authorities and ecological activists, when each of the above nemtioned has a different point of view on the road transportation. Consistence of the set weight coefficients (CR) is the most balanced at public administration authorities. On the contrary, preferences of the road carrier and ecological activists are the least consistent with criteria for setting dangerousness of threats and safety measures.

Table 1. Specification and indexation of the criterion of "Occurrence of densely populated areas".

Specification of the criterion of "Occurrence of densely populated areas"	Index value of the criterion
Population density up to 20 people/ha	1
Population density up to 40 people/ha	2
Population density up to 60 people/ha	3
Population density up to 80 people/ha	4
Population density above 80 people/ha	5

Note: Specification and indexation of this criterion follows from a Dutch manual for risk assessment, the Purple Book (Guidelines, 2005b).

Table 2. Specification and indexation of the criterion of "Occurrence of protected areas".

Specification of the criterion of "Occurrence of protected areas"	Index value of the criterion
Specifically protected areas, regional systems of ecological stability, natural and priority stations	1
Woods, orchard, wineyards, hop-field, loations with livestock breeding	2
Gardens	3
Cultivated farmland	4
Non-cultivated farmland	5

Note: Specification and indexation of this criterion follows from a Czech method of Hazard & Vulnerability Index (Vojkovská and Danihelka, 2002).

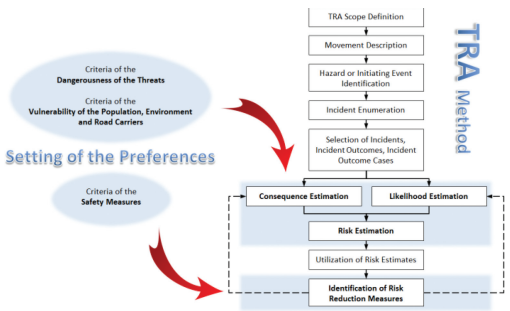

Figure 1. Implementation of preferential criteria in the TRA method.

Table 3. Results of weight calculation of criteria indicating preferences of stakeholders

Area	Area weight	Criterion	Criterion weight (hazardous substances road carrier)	Criterion weight (public administration authorities)	Criterion weight (ecological activists)
Vulnerability of the population, environment and road carriers	0,5	Occurrence of densely populated areas	0,033	0,181	0,088
		Occurrence of protected areas	0,019	0,116	0,189
		Occurrence of buffer zones of water resources	0,067	0,145	0,189
		Value of transport technology	0,252	0,029	0,018
		Value of the transported cargo	0,128	0,029	0,018
	Consistency Ratio (CR)		*0,069*	*0,032*	*0,021*
Dangerousness of threats	0,5	Dangerousness of the transported substance	0,118	0,075	0,205
		Amount of he transported substance	0,041	0,083	0,130
		Technical condition of the transport technology	0,033	0,166	0,054
		Driver's experience and skills	0,226	0,127	0,053
		Average state of the road on the route	0,036	0,034	0,031
		Weather	0,045	0,015	0,028
	Consistency Ratio (CR)		*0,119*	*0,067*	*0,140*
Safety measures	1,0	Effectiveness	0,117	0,584	0,587
		Feasibility	0,148	0,085	0,221
		Financial demandingness	0,666	0,239	0,122
		Time demandingness	0,069	0,092	0,070
	Consistency Ratio (CR)		*0,226*	*0,008*	*0,268*

This fact proves intentional and biased data manipulation in favour of the assessor.

From the set weight of criteria it is evident that road carriers positively prefer the Value of transport technology, the Value of the transported cargo, Driver's skills and experience a in the area of safety measures it is the Financial demandingness of the transport. On the other hand, public administration authorities prefer Protection of population and environment, good technical condition of technology, and high effectiveness of safety measures. The last group is represented by ecological activists who call for environment protection, low dangerousness of transported hazardous substances above all and high effectiveness of safety measures, similar to public administration authorities.

Generally speaking, it may be claimed that, as it was expected, the road carrier's preferences significantly differ from those of public administration authorities and ecological activists. At the same time, it is important to say that the carrier was forced to think more carefully about the propotional value of personal preferences connected with profit maximization and general interest connected with protection of population and environment. The outcome of such movements will be an increasing complex risk which will positively influence the carrier to realize safety measures.

3 CONCLUSION

Hazardous substances road transportation means an important risk, the assessment of which is not required by legislation. Thus, carriers often prefer maximizing profit to transport safety. However, at the same time they are aware of the fact that in case of an accident of their transport not only that the surrounding is endangered (e.g. people, property, environment), but there is also a significant financial loss caused by not delivering the cargo and transport technology damage.

A possible solution to this situation is the preferential risk assessment of hazardous substances road transportation based on modification of the TRA method, enhanced with multicriterial assessment. A method modified in such way enables stakeholders (carriers above all) to implement their own preferences into the assessment process, by doing which the final risk listing includes required information related to the given subject activity. The outcome of such assessment will then be accepting safety measures reflecting the carrier's preferences (e.g. minimization of financial loss connected with an accident), but increasing safety of surroundings and its elements.

ACKNOWLEDGEMENTS

Quantifying MSD risks through Job Hazard Analysis

L. Dement
UL Workplace Health and Safety, TN, USA

ABSTRACT: A proper JHA requires much more than observing a job to see "if it looks hard". The purpose of this study is to break down a task into its component steps, determine the hazards associated with each step, and focus on the ergonomic connection of those hazards. In order to quantify the risks of musculoskeletal disorders, we calculated lifting tasks and compared those to minimal averages. The results indicated that multiple job tasks were in excess of the recommended weight limits for those tasks. Implementing controls is necessary for reduction of these injuries.

1 INTRODUCTION

Nearly 3 million non-fatal workplace injuries and illnesses were reported by private industry employers in 2012 (Bureau of Labor Statistics, 2013) and 4,383 workers died on the job (National Census of Fatal Occupational Injuries, 2013).

Musculoskeletal Disorders (MSDs) accounted for 34 percent of all injury and illness cases in 2012. More specifically, there were 388,060 MSDs in all sectors (private, state and local government) with an incidence rate of 38 cases per 10,000 full-time workers. Injuries and illnesses resulting from repetitive motion involving microtasks resulted in workers taking a median of 23 days away from work to recuperate. MSDs specifically involving the back accounted for 41 percent of the total MSD cases, and shoulder injuries were the most severe accounting for 14 percent of all MSD injuries. It's also important to note that ergonomic risk factors exist in all types of industries. For example, six completely different occupations accounted for more than 25 percent of MSD cases (Bureau of Labor Statistics, 2013).

Regarding Europe, according to the European Agency for Safety and Health at Work, within the EU-27, MSDs are the most common work-related health problems with 25 percent of European workers complaining of backache and 23 percent of muscular pains (EU-OSHA, 2013). Moreover, 62 percent of workers are exposed a quarter of the time or more to repetitive hand and arm movements, with 46 percent to painful or tiring positions and 25% to carrying or moving heavy loads (EU-OSHA, 2013).

Similar to the United States, a plethora of industries are affected by MSDs. The 2013 Liberty Mutual Workplace Safety Index reported the most disabling workplace injuries and illnesses in 2011 amounted to $55.4 billion in direct U.S. workers' compensation costs. This translates into more than a billion dollars spent by businesses each week on the most disabling injuries (Liberty Mutual Insurance, 2014).

Among all the workers who are injured on the job, how many thought to themselves, "I've done this job hundreds of times; I'm not going to get hurt." Until the moment happens to them and it's too late.

Unfortunately, many employees think they are doing the job correctly when in reality they are working in an unsafe manner. This is not to say that the job was done incorrectly to begin with, but over time deviations from the proper procedure can occur. When that happens, workers adapt their work methods to the ever-changing workplace. In time, this can result in at-risk work practices becoming normalized into routine procedures. In an effort of trying to correct these improper deviations, employees will look at the job as a whole and overlook crucial hazards instead of breaking the task down into its component steps. This is a common, worldwide problem.

One answer to this problem is a Job Hazard Analysis. The Occupational Safety and Health Administration (OSHA) define a JHA as "a technique that focuses on job tasks as a way to identify hazards before they occur. The JHA focuses on the relationship between the worker, the task, the tools, and the work environment" (Occupational Safety and Health Administration, 2002).

JHAs are an essential part of a comprehensive safety program. However, the JHA is often overlooked as a particularly beneficial training tool, and without it the potential for injuries and fatalities is elevated. A JHA is not just about identifying hazards and risks. It is a transformative process that illuminates how specific aspects of a job are performed, allowing workers to rate risks associated with each task and prioritize correc-

tive actions to eliminate those risks. Ultimately, it changes workers' attitudes toward their jobs.

2 PREPARATION AND INTEGRATION

It is important to understand which types of jobs are best suited for a JHA. Not all jobs necessarily need one, but many will require a JHA for a deeper appreciation of the individual tasks that comprise the job as a whole. According to OSHA, a JHA is specifically well-suited for jobs (Occupational Safety and Health Administration, 2002):

- with high injury or illness rates;
- with the potential to cause death/severe injuries or illnesses;
- in which a single error could lead to a severe accident or injury;
- that are new to an operator;
- in which there have been changes in equipment, processes or procedures; and
- that are complex enough to require written instructions.

As you're looking at the jobs that are in need of a JHA, consider the methodology. JHAs enable participants to break the task down into to detailed, component steps. JHAs help employees recognize *all* the hazards that are associated with a specific job, in turn reducing the potential for accident or injury.

There is no firmly established template or standard method for a JHA. It's important to use a plethora of methods early in the development process. Direct observation is pivotal in the early stages. It's helpful to take photographs and/or using a video camera to refresh your memory later. The more deeply a job is examined, the greater the likelihood specific hazardous components will become apparent. Interviewing the worker and reviewing the written job description is also crucial to gain a deeper insight into specific job tasks.

Often it isn't until after an injury occurs that the questions start: How did it happen? Why did it happen? Was I doing the job correctly or as I have always done it? The JHA puts a proactive spin on these questions.

It's also important to note, that JHAs can be subjective. For example, what distinguishes a "low/medium/high hazard" from one worker to another? Moreover, what happens to those workers who have pre-conceived notions regarding the job? To one employee, the task might be easy, while to another it's actually quite difficult. What about the many employees who think the job process cannot be changed or improved? This is one of the reasons we recommend involving multiple workers—so various perspectives can be shared and risk perceptions can be aligned.

2.1 *Hazard recognition*

Hazard recognition will assist in identifying perceived, existing, and potential hazards and what will happen if exposure occurs (Roughton & Crutchfield, 2008). The JHA should be designed to answer certain questions that provide insights into specific job tasks and hazards associated with the job.

For example (Occupational Safety and Health, 2002):

- What can go wrong?
- How could it happen?
- How likely is the accident to happen?
- What are the consequences?
- What can be done to eliminate the hazard or reduce it to an acceptable level?

Answers to these questions help ensure the hazard is eliminated or reduced to the greatest extent possible.

3 ERGONOMICS CONNECTION

When conducting a JHA, it's important to realize the variety of hazards that could be present. Many organizations do not effectively identify issues related to ergonomics when conducting a JHA. Breaking down specific tasks is an ideal time to consider ergonomic aspects of the job as a whole.

NIOSH defines ergonomics as, "the scientific study of people at work" (NIOSH, 2013). It is fitting the job to the person in an effort to reduce stress on the body and eliminate possible work-related injuries.

Ergonomic issues affect all types of people and occupations. Occupations such as nursing assistants and registered nurses; laborers and freight, stock and material movers; janitors and cleaners; maintenance and repair workers; and heavy and tractor-trailer truck drivers are among the most vulnerable populations, representing more than 25 percent of MSD cases. In 2012, MSD cases accounted for a median of 12 days away from work compared to nine days for all other types (Bureau of Labor Statistics, 2013).

MSDs can affect workers for sustained periods of time and can recur in the absence of intervention. With ergonomics, it's important to be aware of the risk factors that could lead to injuries. They are:

- Awkward posture
- Force
- Contact stress
- Repetitive motion
- Vibration
- Extreme temperatures

Obviously, awareness of these types of hazards is a pivotal part of the hazard reduction process. In

many instances, quantification is needed to evaluate the hazard and the associated risk, for instance, a worker is constantly bending over and picking up boxes throughout the day. The boxes may be light weight, but the repetitive process of bending over to lift them still has cumulative effects. Using the NIOSH Lifting Equation during a JHA, for example, helps employers and workers better understand body mechanics and risks associated with repetitive lifting.

4 CASE EXAMPLE #1

To better explain the ergonomics connection, let's elaborate on a specific job task that was conducted. For one example, we chose to create a JHA for a rotor inspector, specifically for MSDs. The employee's task was inspecting and stacking rotors in an automobile manufacturing facility. Throughout the day, the employee would grab a rotor from the line, lift the rotor for inspection, and carry it to a pallet three feet away. We broke the task down and to its component steps and quantified the results. The rotor itself, weighed 20 pounds (9.07 kilograms). After watching the worker for an extended period of time, we concluded that approximately six rotors were inspected and transferred per minute. After performing a few calculations, that task equaled 120 pounds per minute (54.4 kilograms) transferred and over 7000 pounds (3175 kilograms) per hour. If the employee works an eight-hour shift, he is lifting over 57,000 pounds (25,854.7 kilograms). Furthermore, from having to walk from the assembly line to the pallets, he is walking around 3.4 miles (5.47 kilometers) per shift.

After breaking this task down, it was evident that it consisted of risk factors such as repetitive motion, awkward posture and force. Quantification also assisted in determining that this job was in need of ergonomic improvements. Using the revised NIOSH lifting equation, we calculated the recommended weight limit for the rotor inspection and stacking. Specifically, we chose the worst position for the task.

The inputs for the example were as shown in the equation calculator below.

Horizontal Location Origin (in.) =	<= 10
Horizontal Location Destination (in.) =	21
Vertical Location Origin (in.) =	0
Vertical Location Destination (in.) =	0
Vertical Travel Distance (in.) =	<= 10
Angle of Asymmetry Origin (degrees) =	0
Angle of Asymmetry Dest (degrees) =	15
Frequency (lifts per minute) =	6
Duration (hrs) =	> 2 but <= 8
Coupling =	Fair
Weight of Object (lbs.) =	20

Calculate

https://www.emcins.com/losscontrol/quick_links/employee_safety_health/ergonomicsNIOSH.aspx.

After computing the total, the results showed the Recommended Weight Limit (RWL) was below the weight of the rotor.

	RWL =	LC	X	HM	X	VM	X	DM	X	AM	X	FM	X	CM
Origin	10.20	51	X	1.00	X	.78	X	1.00	X	1.00	X	.27	X	.95
Destination	4.65	51	X	.48	X	.78	X	1.00	X	.95	X	.27	X	.95

https://www.emcins.com/losscontrol/quick_links/employee_safety_health/ergonomicsNIOSH.aspx.

At the origin (assembly line) of the lift, the RWL for the lift should not exceed 10.20 pounds (4.63 kilograms) and at the destination (pallet) the RWL for the lift should not exceed 4.65 pounds (2.11 kilograms).

4.1 *Results*

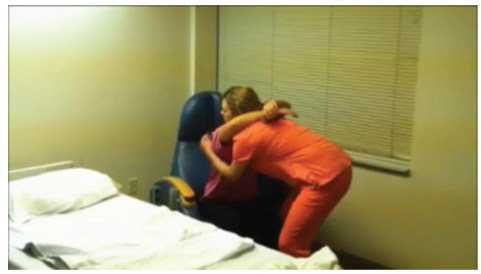
The results show both, the origin and the destination, should require ergonomic controls to be implemented to reduce the stress on the worker. Lowering the frequen cy of the lift and reducing the horizontal distance of the destination would aid in making this lift safer for the employee.

Multiple studies were conducted within the manufacturing environment and all showed similar results. Although the task wasn't extremely taxing on the body for a single lift, the more lifts that were conducted throughout the day could pose serious threats to the health and well-being of the worker.

The way the task is presently being performed, the worker is at risk for MSD injuries involving the shoulder, wrist, back, and possibly the neck. Injuries such as these can pose a serious threat to workers and costs companies in lost time and worker's compensation claims.

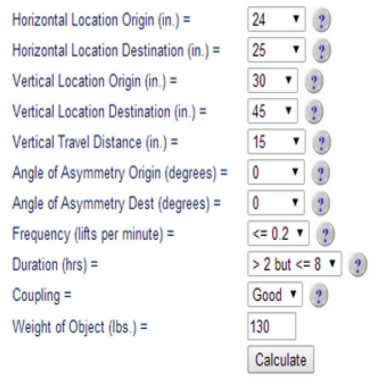
A lift assist would be an ideal control that could be used in this specific task. The lift assist would enable the worker to use less force while picking up and placing the object in its desired location. Virtually all the force of the lift would be diminished by this simple device that can increase productivity and reduce risk of an injury.

5 CASE EXAMPLE #2



A second case that was researched was of a healthcare worker. Numerous times throughout a 12-hour shift, nurses were lifting, pushing, pulling, and transferring patients without any assistance. For this specific example, the most strenuous lift for the nurse was a patient transfer from a chair to the bed. Similar to the rotor example, when conducting a JHA it's important to recognize the ergonomic hazards that are present and could lead to MSDs.

The task in this example begins with the patient in the chair needing to be moved to the bed. In most healthcare facilities, nurses do not have assistance from other nurses or manual lifting assists. When no assistance is available, nurses will do whatever they can to make sure the job is done. This example showcases one of those dangerous tasks.



The patient weighed 130 pounds (58.97 kilograms) while the nurse weighed 140 pounds (63.5 kilograms). Initially, a back compressive force calculation was conducted to find out the force put on the lower back during the most strenuous part of the lift. The results showed the back compressive force on the nurse's lower back was 2014 pounds (913.5 kilograms), which is in excess of the desired back compressive force of 770 pounds (349.3 kilograms).

After calculating the back compressive force for the lift, we decided to run the NIOSH RLE. Although this equation is not intended for patient lifts, it can be used when certain conditions are met, such as the patient is non-combative, the amount of weight the nurse is lifting can be estimated, the lift is smooth, and the lift is fairly consistent. When used for a patient lift, the recommended weight limit changes from the regular 51 pounds to 35 pounds.

There are more variables to consider when lifting a human but to put into perspective the gravity of the lift, we studied the task and chose the most difficult part of the lift to judge. The specific step of the task chosen was as the nurse was bending over to pick up the patient.

In this example, the origin of the lift was approximately two feet away from the body and the destination was two feet one inch. After inserting the other variables, the results showed the RWL were 11.75 pounds (5.33 kilograms) at the origin and 9.96 pounds (4.52 kilograms) at the destination. The patient being 130 pounds (58.97 kilograms) was over the RWL for both tasks.

	RWL =	LC	HM	VM	DM	AM	FM	CM
Origin	11.75	35	.42	1.00	.94	1.00	.85	1.00
Destination	9.96	35	.40	.89	.94	1.00	.85	1.00

Origin	LI =	130	/	11.75	=	11.06
Destination	LI =	130	/	9.96	=	13.05

https://www.emcins.com/losscontrol/quick_links/employee_safety_health/ergonomicsNIOSH.aspx.

5.1 *Results*

The results indicate the task is in need of ergonomic controls such as team lifts and/or manual lifting assists. Reducing the risks with this given job task, and breaking the task down completely, will enable safety and health professionals to further realize the importance of worker health.

Multiple nurses and patient lifts were observed and tested for our research. As with this lift, when one nurse was lifting/pulling the patient, there was greater risk of serious injury. After monitoring nurses for a given period of time, we found many of the nurses had complaints of sore backs, necks, and shoulders.

As is, the patient would have to weigh approximately no more than 11.75 pounds for the job to be considered safe. Another option would be to implement controls such as a lift assists or team lifts when moving patients. These controls will aid in taking the majority of the weight off one individual and dispersing it between multiple nurses or the lift assist.

5.2 *Prioritizing risk*

A matrix that can be used to prioritize risk is another important tool that should be considered when creating a JHA. Risk matrices are used to evaluate the severity and probability of the incident occurring again. Although this can be subjective, it is a valuable tool in determining hazard risk. The matrix below was created for this study and determining the risk associated with specific job tasks.

Risk Matrix	Incident Severity			
Recurrence	Negligible	Marginal	Critical	Catastrophic
Extremely Improbable	L	L	L	M
Unlikely	L	L	M	M
Occasional	L	M	M	H
Probable	M	M	H	H
High Probability	M	H	H	H

5.3 *Benefits*

When properly applied, the job hazard analysis is a tool that enables workers to be more engaged in the job and aware of potential hazards. It assists with the establishment of best practices for performing tasks and implementation of effective safety controls for the specific job. The JHA should be treated as a relevant training instrument designed to raise workplace safety and health awareness. Optimally, it encourages employee engagement and assists in outlining preventative measures (Roughton & Crutchfield, 2008).

The goal for any employer should be to keep workers as safe and healthy as possible. As the JHA becomes more utilized within the organization and workers begin to become more aware of safe practices, higher productivity, lower injury rates, reduced absenteeism, and increased morale should occur. This is also going to enable more communication between the employer and employees and create a positive safety culture.

6 CONCLUSION

The findings of this research show how to quantify a task and determine how unsafe it is. Applying ergonomic principles to these tasks and many others like them, should be a priority and of primary importance for reducing the burden of MSDs in the workforce. Ergonomic issues are overlooked many times within an organization, and by actually putting a number or severity to the task, it enables employers to better understand the relationship between the ergonomic hazard and the worker.

There are many studies that have been conducted, pre- and post-, ergonomic evaluations for the healthcare and manufacturing industries. In almost all instances, the number of injuries and illnesses were reduced, the number of lost and restricted work days were reduced, and workers' compensation claims were reduced.

Overall, the results of this research depict how dangerous these "simple" tasks can be and how easy it is for musculoskeletal disorders to occur.

In both industries, we noticed repeated ergonomic risk factors that were putting workers in hazardous situations. Improper lifting, repetitive motion, awkward posture, force, and contact stress were all prevalent during these routine tasks. As these organizations began implementing JHAs and teaching proper ergonomic awareness, the number of injuries decreased and worker morale and productivity increased. For the short-term, we had positive results from the facilities that had implemented proper ergonomic controls and expect positive outcomes for the long-term as well.

We found the healthcare industry provided a more difficult conclusion. Although the results of the JHA and the quantification of the ergonomic risk factors showed major ergonomic hazards in the healthcare industry that needed to be corrected, actually making those changes in the future will be difficult. This industry deals with time constraints, shortage of nurses, and decrease in staffing ratios which leads to nurses having to do whatever it takes to get the job done; which in some instances might be getting injured performing an improper lift. Due to the majority of nurses being women and the average age being 51.5, muscle strength and intervertebral disc strength have decreased, lowering the maximum recommended weight limit and putting more workers at risk for injury (AMN Healthcare, 2013).

By breaking the task down and evaluating each step, there is a greater potential to recognize all the possible hazards associated with the specific job. JHAs aren't the most "glamorous" aspect of a safety program, but they are an excellent vehicle for training and hazard recognition. The JHA empowers workers to look at their job in a different light—a safer one—by helping them:

- prioritize the jobs and tasks to be analyzed
- break down the job
- analyze each step and identify potential hazards
- identify and implement controls to reduce/eliminate hazards

Finally, the JHA serves workers for the life of their job. These are tools that need to be re-visited and re-evaluated on a regular basis or when a change of a work process or injury has occurred. The JHA is a tool that promotes deeper thinking about the task and a greater understanding of how to rate risk, recognize hazards and work safely.

Practically speaking, the JHA is only going to be truly effective if the organization has made a genuine commitment to putting safety first. From the top down, the importance of a "safe way of life" must be at the forefront. With key elements such as hazard identification, training, employee participation, understanding the risk matrix and learning how to prioritize hazards, the JHA can be the cornerstone of any safety program and a key contributor to a culture of safety in your organization.

ABSTRACT: Risk Analysis (RA) is a meaningful process in every industrial context, particularly referring to major hazard plants. In such sites, input reliability data are generally poor so leading to a partial or incomplete knowledge of the failure process. As a consequence, RA is always affected by the so called *epistemic uncertainty* which presence makes inappropriate the classical probabilistic approach. Therefore, the present work deals with such a kind of uncertainty in the Fault Tree Analysis (FTA) and proposes a new aggregation rule to combine the interval-valued information supplied by a team of experts about each Basic Event (BE). The aggregation leads to an interval which bounds are modelled by fuzzy numbers. Successively, such an uncertainty is properly propagated up to the Top Event (TE) in order to determine the related probability of occurrence. The approach is finally applied and discussed with relation to a Safety Instrumented System (SIS).

1 INTRODUCTION

Risk Analysis (RA) is a fundamental process to prevent accidents and other unwanted events possibly occurring during industrial process activities handling of hazardous materials. It is defined as the process of systematic use of available information in order to identify hazards and to estimate the risk (IEC 60300 1995). Depending on the accuracy required to the analysis, it can be qualitatively or quantitatively carried out. In qualitative methods no explicit quantification of the risk is obtained, whereas in the quantitative ones a numerical calculation of the risk level is addressed.

Quantitative Risk Analysis (QRA) has been in existence for many years particularly in the nuclear industry. Nowadays, QRA is widely used in aerospace, chemical process industries, petrochemical and manufacturing plants even if its detailed application can result very troublesome, time-consuming and expensive. In order to perform a quantitative risk analysis, reliability data are needed. These data have to reflect not only the design features of the employed components, but also the working environment and the adopted maintenance policy. Anyway, in major hazard plants, available reliability data are few and not well documented. As a consequence, the common way of proceeding is to make reference to similar systems/plants or to some worldwide recognized reliability databases. Nevertheless, relying on such data unavoidably affects the accuracy and the precision of the risk analysis results so making them at least questionable. Therefore, this work is focused on the characterization of the uncertainty arising from the poor available information. In literature, uncertainty arising from the intrinsic variability of the failure process under study is known as objective or aleatory uncertainty. On the contrary, uncertainty due to the lack of knowledge about the model characterizing the physical process is known as subjective or epistemic uncertainty (Hoffman & Hammonds 1994, Ferson & Ginzburg 1996, Oberkampf et al. 2004, Sentz & Ferson 2011).

The probabilistic approach is the most widely used method for characterizing both types of uncertainty. However, the purely probability-based approach to risk and uncertainty analysis can be challenged under the common conditions of limited or poor knowledge on the high-consequence risk problem, for which the information available does not provide a strong basis for a specific probability assignment (Zio & Pedroni 2013). This concern has sparked a number of investigations in the field of uncertainty representation and analysis which has led to the development of alternative frameworks that can be grouped in four main categories (Aven & Zio 2011): imprecise probability,

probability bound analysis, random sets (Dempster 1967, Shafer 1976) and possibility theory.

In the present paper, reliability information about the probability of occurrence of each *Basic Event* (BE) are supposed to be supplied by different experts in an interval form. A new aggregation rule is proposed to combine the expressed interval-valued judgments. The aggregation leads to the characterization of probabilities by means of particular intervals named *FUzzy Boundary Interval* (FuBI). Then, the propagation from BEs to the *Top Event* (TE) is performed in order to determine the FuBI related to the TE.

The remainder of the paper is organized as follows. The literature review is supplied in Section 2, whereas the proposed approach is described in Section 3. An industrial application is presented in Section 4 and conclusions are supplied in Section 5.

2 LITERATURE REVIEW

Fault Tree Analysis (FTA) (IEC 61025 1990) is the most used technique in RA to determine the logical sequence of events leading to an undesired one (i.e. the TE) that can imply the occurrence of some hazardous situations. The effectiveness of FTA strongly depends on the accuracy of BE probability estimations. However, real contexts are often characterized by a poor availability of reliability data so that the employment of the classical probabilistic approach can be misleading. Therefore, a meaningful attention has been paid by researchers to theoretical approaches alternative to the probabilistic one. In particular, the possibility theory and the evidence theory, also known as Dempster-Shafer Theory (DST), have been considered as the most promising methodologies to deal with subjective uncertainties about events. In addition, the DST suggests several combination rules to aggregate evidences coming from different sources of information (Sentz & Ferson 2002).

The DST has been mainly applied to design problems (Bae et al. 2004), whereas its application in the reliability field has not yet been widely researched. A methodology to characterize the TE probability of occurrence through the FTA and the evidence theory is proposed in (Curcurù et al. 2012). A continuous frame of discernment, coincident with the interval probability [0,1], is considered and a team of experts is asked to supply the interval-valued probability of occurrence of BEs associated to a stated basic belief mass. Then, supplied information are aggregated by means of the Dempster combination rule and propagated up to the TE. Finally, Belief and Plausibility functions are employed to estimate the uncertainty about the TE probability of occurrence. Advantages arising from using the DST to system safety prediction are outlined in (Limbourg et al. 2008). Authors propose a FTA to investigate upon whether the safety system under study can assure a fixed level of safety. Finally, authors claim that the main advantage of DST lies in its flexibility to handle expert estimates that can be merged, and updated in a comprehensible way.

The application of the possibility theory to the FTA generally reduces to the employment of the classical fuzzy numbers (Zimmermann 1991). Sallak et al. (2006a, 2006b, 2008) propose the fuzzy set theory to evaluate the Safety Integrity Level (SIL) of a Safety Instrumented System (SIS). Authors suggest a fuzzy probabilistic importance measure to identify the SIS critical components aiming at reducing the SIL uncertainty by changing the SIS configuration. A fuzzy based computer-aided FTA tool is presented by Ferdous et al. (2009a). Authors compare the robustness of the fuzzy approach to that one of the classical probabilistic method and claim that the first one is more realistic and robust in handling vague and imprecise basic event data. A hybrid method that jointly propagates probabilistic and possibilistic uncertainties is considered and compared with pure probabilistic and pure fuzzy methods for uncertainty propagation in (Baraldi & Zio 2008). The analyses are carried out on a case study concerning the uncertainties in the probabilities of occurrence of accident sequences in an event tree analysis of a nuclear power plant. A real-time risk assessment method combining Set-Pair Analysis (SPA) and fuzzy theory is proposed by Zhou (2010) and applied to installations storing flammable gas. On the base of data acquired from the safety monitoring system, the likelihood and the consequence of an accident can be evaluated in real-time. In (Ferdous et al. 2009b), fuzzy sets and evidence theory are used to an Event Tree Analysis, and the obtained results are compared to those arising from the Montecarlo simulation. In the fuzzy-based approach, the α-cut method is used to propagate the uncertainty through the tree. In the evidence theory based approach, basic belief masses of each event are aggregated by means of the classical Dempster' and Yager' rules, whereas the three-valued logic structure (Cheng 2000) is used to obtain the total evidence of consequences. Variables involved in a bow-tie representation are modelled by fuzzy numbers in (Markowski et al. 2009). The TE fuzzy probability and the fuzzy probability of consequences are calculated by employing the fuzzy arithmetic in fault and event trees respectively. In (Ferdous et al. 2013), a fuzzy-based and an evidence theory-based approaches are applied to a bow-tie analysis considering the interdependence of input events. The bow-tie approach is also proposed by Khakzad et al.

(2013) to carry out risk analysis of offshore drilling operations and compared with the Bayesian network approach. Strengths and drawbacks of each method are highlighted.

3 PROPOSED APPROACH

The present paper is focused on the implementation of the risk analysis within a major hazard plant. The main innovative aspect of the paper is the proposal of a new combination rule of information supplied by experts with relation to each BE. The aggregation step is a critical phase of the whole procedure consisting of the following steps:

1. information elicitation;
2. information aggregation;
3. calculation of the *fuzzy boundary interval* of each minimal cut-set;
4. calculation of the TE *fuzzy boundary interval*.

3.1 *Information elicitation*

Doubtless, the analyst plays a meaningful role during the information elicitation phase. In fact, the obtained information depends on the way the question is formulated. Experts are often unable to supply a single value about the BE probability of occurrence. Instead, it seems more plausible that experts can characterize each BE by means of intervals in which they estimate the related probability of occurrence could belong to.

In the context here taken into account, the hypothesis made concerns that the only available information is that arising from experts specifically operating in the plant under analysis. Such a hypothesis is particularly true in the specific context of major hazard plants which the paper is focused on.

Therefore, the analyst will ask to the few available experts a synthetic interval-valued information about the BE probability of occurrence.

3.2 *Information aggregation*

Let N be the uncertain parameter on which n experts are asked to express their own interval-valued judgment. Hence, let $N_i = [N_{iL}, N_{iU}]$ be the interval opinion of the ith expert about N, with $i = 1, \ldots, n$. Starting from n interval opinions on N, the aggregation rule reduces the total available knowledge into a single interval which bounds are modelled by means of fuzzy numbers. With relation to a different context, such a particular interval has been defined as *FUzzy Boundary Interval* (FuBI) (Nie et al. 2007). Let $\tilde{N} = [\tilde{N}_L, \tilde{N}_U]$ be a FuBI, with $\tilde{N}_L = (N_{L,Min}, N_{L,Avg}, N_{L,Max})$ and $\tilde{N}_U = (N_{U,Min}, N_{U,Avg}, N_{U,Max})$ triangular fuzzy numbers.

The proposed aggregation rule works as follows:

1. determination of the FuBI support by applying the union operator among the n interval judgments;
2. determination of the crisp part of the FuBI as the intersection among the n interval judgments;
3. assignment of the maximum membership value of the fuzzy bounds to the arithmetic mean of the n lower and n upper bounds of the interval-valued judgments.

Let being so, the bounds of the FuBI, namely $\tilde{N}_L$ and $\tilde{N}_U$, are calculated by means of equations (1)–(6):

$$N_{L,Min} = \min_{i=1,..,n} \{N_{iL}\} \tag{1}$$

$$N_{L,Avg} = \frac{1}{n}\sum_{i=1}^{n} N_{iL} \tag{2}$$

$$N_{L,Max} = \max_{i=1,..,n} \{N_{iL}\} \tag{3}$$

$$N_{U,Min} = \min_{i=1,..,n} \{N_{iU}\} \tag{4}$$

$$N_{U,Avg} = \frac{1}{n}\sum_{i=1}^{n} N_{iU} \tag{5}$$

$$N_{U,Max} = \max_{i=1,..,n} \{N_{iU}\} \tag{6}$$

In order to clarify the structure of the FuBI, Figure 1 reports a simple example of aggregation where two experts are involved.

Therefore, the classical interval representation of the aggregated opinion is limited to the agree-

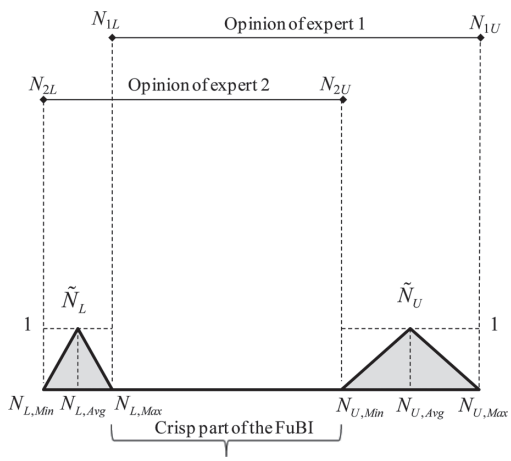

Figure 1. FuBI of the uncertain parameter N.

ment among experts and obtained by the intersection operator, whereas fuzzy numbers are associated to the disagreement part. The way the agreement and the disagreement parts of expert information are handled during the combination phase leads to the FuBI. The aggregation rule is based on the assumption that the interval-valued expert opinions about each BE have a not empty intersection. Namely, it is plausible the existence of an interval on which experts agree. The condition about the small number of involved experts together with that one regarding their specific field of expertise fully support the assumption of not disjoint interval-valued judgments. Analytically, the existence of a not empty intersection is expressed by the following equation:

$$\max_i\{N_{iL}\} < \min_i\{N_{iU}\} \tag{7}$$

As a consequence, there is not any intersection between the lower and the upper fuzzy bounds of the aggregated interval.

Furthermore, experts are supposed to have the same credibility so that equal weights are assigned to them during the aggregation phase. However, if different weights w_i could be assigned to each expert i, equations (2) and (5) turn into:

$$N_{L,Avg} = \frac{\sum_{i=1}^{n} w_i \cdot N_{iL}}{\sum_{i=1}^{n} w_i} \tag{8}$$

$$N_{U,Avg} = \frac{\sum_{i=1}^{n} w_i \cdot N_{iU}}{\sum_{i=1}^{n} w_i} \tag{9}$$

The way the proposed aggregation rule is formulated assures that:

1. the concordance among expert opinions is saved by means of the intersection operator that results into the crisp part of the FuBI;
2. the uncertainty associated with the discordance part of the expert opinions is expressed by means of fuzzy numbers.

Commonly, within the arithmetic interval approach, judgments combination is performed by the classical mean, union or intersection operators. The mean and the intersection operators lead to a reduction of the aggregated interval, namely some values that sources of information consider as possible are ignored. Otherwise, by the union operator the aggregated interval expresses the highest level of uncertainty of the aggregated judgments. In the classic fuzzy approach, each interval information supplied by experts represents the support of a fuzzy number. The choice of the membership function implies an arbitrary alteration of the original information available to the analyst. Let being so, one believes that the suggested aggregation rule modifies the poor available information as less as possible, hence representing a valid alternative to the classical aggregation approaches based on the interval arithmetic or the fuzzy set theory. Furthermore, in comparison with the DST approach, the one suggested here is easier both for the required information and the computational aspect. Therefore, it seems more suitable and applicable to industrial contexts.

3.3 *Calculation of the fuzzy boundary interval of each minimal cut-set*

Once expert assessments with regard to each BE have been aggregated, the next step consists in the determination of the fault tree minimal cut-sets (Rausand & Høyland 2004), together with the calculation of the related probability of occurrence. Let j be a generic BE belonging to the minimal cut-set z, and N_j the related probability of occurrence. Therefore, N_z (i.e. the probability of occurrence of the minimal cut-set z) can be obtained as follows:

$$N_z = \prod_{j=1}^{m} N_j \tag{10}$$

where m is the total number of BEs, supposed to be independent, within the minimal cut-set z. Bearing in mind that the aggregated interval on a generic BE j within z is expressed by means of a FuBI (i.e. $\tilde{N}_j$), as a consequence even N_z is a FuBI. Therefore, equation (10) turns into:

$$\begin{aligned}\tilde{N}_z &= [\tilde{N}_{zL}, \tilde{N}_{zU}] = \prod_{j=1}^{m} \tilde{N}_j = \prod_{j=1}^{m} [\tilde{N}_{jL}, \tilde{N}_{jU}] \\ &= [\tilde{N}_{1L} \otimes \tilde{N}_{2L} \otimes \cdots \otimes \tilde{N}_{mL}, \tilde{N}_{1U} \otimes \tilde{N}_{2U} \otimes \cdots \otimes \tilde{N}_{mU}]\end{aligned} \tag{11}$$

where $\tilde{N}_z$ is the FuBI of the probability of occurrence of the minimal cut-set z. Equation (11) is solved by applying the classical fuzzy arithmetic (Klir & Yuan 1995). In particular, in the present paper the α-cut method is used. Hence, for each level $\alpha \in [0,1]$, the fuzzy lower and upper bounds of the minimal cut-set z, namely $\tilde{N}_{zL}$ and $\tilde{N}_{zU}$ are calculated as follows:

$$\begin{aligned}[N_{zL}^{\alpha}, N_{zU}^{\alpha}] &= \prod_{j=1}^{m} [N_{jL}^{\alpha}, N_{jU}^{\alpha}] \\ &= [N_{1L}^{\alpha} \cdot N_{2L}^{\alpha} \cdot \ldots \cdot N_{mL}^{\alpha}, N_{1U}^{\alpha} \cdot N_{2U}^{\alpha} \cdot \ldots \cdot N_{mU}^{\alpha}] \\ \forall\ \alpha &\in [0,1]\end{aligned} \tag{12}$$

3.4 *Calculation of the TE fuzzy boundary interval*

Once the FuBI of minimal cut-sets have been determined, the TE's FuBI (i.e. $N_{TE}^{\sim}$) is calculated by using the rare events approximation formula:

$$N_{TE}^{\sim} = [\tilde{N}_{TE\,L}, \tilde{N}_{TE\,U}] = \sum_{z=1}^{c} N_z^{\sim} = \sum_{z=1}^{c} [\tilde{N}_{zL}, \tilde{N}_{zU}]$$
$$= [\tilde{N}_{1L} \oplus \tilde{N}_{2L} \oplus \cdots \oplus \tilde{N}_{cL}, \tilde{N}_{1U} \oplus \tilde{N}_{2U} \oplus \cdots \oplus \tilde{N}_{cU}] \quad (13)$$

being c the total number of TE's minimal cuts.

Therefore, using the α-cut method, the fuzzy lower and upper bounds of the TE's FuBI, namely $\tilde{N}_{TE\,L}$ and $\tilde{N}_{TE\,U}$ are calculated as follows:

$$[N^{\alpha}_{TE\,L}, N^{\alpha}_{TE\,U}] = \sum_{z=1}^{c} [N^{\alpha}_{zL}, N^{\alpha}_{zU}]$$
$$= [N^{\alpha}_{1L} + N^{\alpha}_{2L} + \cdots + N^{\alpha}_{cL}, N^{\alpha}_{1U} + N^{\alpha}_{2U} + \cdots + N^{\alpha}_{cU}]$$
$$\forall\ \alpha \in [0,1] \quad (14)$$

Since the top event' FuBI could be difficultly understandable by risk managers or surveillance Authorities, a crisp interval is derived by applying a defuzzification operator to the TE fuzzy lower and upper bounds. For this purpose, the Center of Area (COA) method is applied (Bojadziev & Bojadziev 1995).

4 APPLICATION OF THE METHODOLOGY TO A SAFETY INSTRUMENTED SYSTEM

The proposed methodology has been applied to a SIS in order to evaluate the *Probability of Failure on Demand* (PFD) of a Safety Instrumented Function (SIF).

The international standard ISA-TR84 (ISA-TR84 Part 1, 2002) describes various methodologies for the determination of the PFD. In particular, three techniques, simplified equations (ISA-TR84 Part 2 2002), fault tree analysis (ISA-TR84 Part 3 2002), and Markov modelling (ISA-TR84 Part 4 2002, ISA-TR84 Part 5 2002), can be used to model the interaction and functionality of basic components of a SIS in order to determine the PFD. Anyway, such a standard disregards the uncertainty associated with the input reliability data of SIS components. On the contrary, the proposed methodology, applied to the base case example reported in the ISA-TR84 Part 3, takes into account such an uncertainty and propagates it up to the TE.

In Figure 2 a simplified representation of the system process diagram is reported.

Table 1 synthesizes the system devices and the corresponding BE number. Three experts are here supposed to be involved, each one expressing his/her own judgment about the PFD of SIS components. The bounds of the interval information have been randomly generated around the value reported in the standard. Such values are reported in Table 2, and rounded off at the second meaningful number. The fuzzy bounds of the corresponding aggregated interval, namely the FuBI, are synthesized in Table 3.

The 11 minimal cut-sets of the fault tree are reported in Table 4.

9	12, 14
10	13, 14
11	7

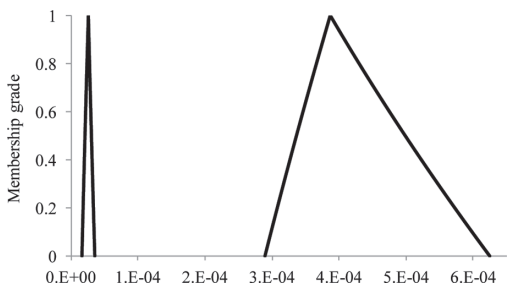

Figure 3. FuBI related to the probability of occurrence of the 5th cut.

As example, the following figure (Fig. 3) shows the FuBI related to the 5th minimal cut-set.

Finally, Figure 4 shows the TE's FuBI, which defuzzified lower and upper bounds are 2.59E-3 and 1.65E-2 respectively.

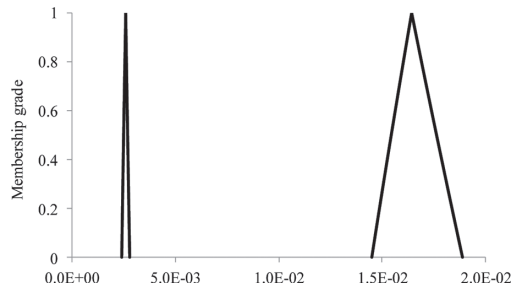

Figure 4. FuBI related to the probability of failure on demand of the SIF.

5 CONCLUSIONS

In the present paper, a new aggregation rule is suggested in order to characterize Basic Events (BEs) by means of a single aggregated interval. Such an interval has been defined as *FUzzy Boundary Interval* (FuBI). In particular, the classical interval representation of the aggregated opinion concerns the concordance among experts, and obtained by the intersection operator, whereas the fuzzy number bounds are associated to the disagreement part. In other words, the uncertainty of each expert about the BE probability of occurrence is modelled by an interval judgment, whereas the further uncertainty arising from the disagreement among experts turns into two fuzzy numbers that bound the aggregated interval.

After performing the aggregation step, the classical fuzzy arithmetic is applied to the FuBI bounds of BEs belonging to the Top Event (TE) minimal cut-sets in order to obtain the TE's FuBI.

Finally, bounds of the TE's FuBI are defuzzified in order to obtain a classical interval. Such an interval can represent a more meaningful and useful information for both the plant risk managers and the surveillance Authorities than that one arising from the classical approach to FTA. In fact, the latter characterizes the TE probability of occurrence by means of a single value that, if on the one hand is easily usable, on the other hand gives to results a certainty that is at least questionable. Instead, considering the uncertainty where it effectively arises from, namely in the probability of occurrence of BEs, and its propagation through the fault tree up to the TE, seems to be a more informative approach.

Furthermore, one believes that the suggested aggregation rule is able to adequately synthesize the available information. In fact, the intersection operator allows at taking into account the concordance among expert judgments and results into the crisp part of the FuBI, whereas the uncertainty associated with the discordance is expressed by means of fuzzy numbers. Furthermore, the totally available information is saved and results into the support of the FuBI associated with each basic event.

Expressing and communicating uncertainty and bias in relation to Quantitative Risk Analysis

F. Goerlandt & J. Montewka
Department of Applied Mechanics, Marine Technology, Research Group on Maritime Risk and Safety, Aalto University, Espoo, Finland

ABSTRACT: In the field of risk analysis, there is a recent focus on foundational issues regarding concepts, terminology and perspectives on risk and there are recent calls on research on how to describe risk. Much of the recent work highlights the importance of uncertainty, and a number of methods have been proposed to assess and communicate uncertainty. This paper starts from an uncertainty-based conceptualization of risk and an existing framework for assessing uncertainty. An overview of propositional attitudes shows that, apart from uncertainty, risk assessment primarily involves the attitude of acceptance. Reflecting on the difference between belief and acceptance, it is argued that often, it is possible to also describe evidential biases. The assessment of bias is subsequently taken as an extension of the existing uncertainty-based risk perspective. Finally, a number of tools are outlined to assess the strength of evidential support and for assessing the direction of bias, both on the level of individual probability assignments and on the overall risk model level. Unlike earlier methods, we assess the various types of evidence separately, showing more transparently what kind of evidential support various probability assignments have.

1 INTRODUCTION

There have been a number of calls for increased focus on foundational issues in risk analysis, addressing concepts, principles and methods when assessing, managing and communicating risk (Aven 2012a).

In this paper, the uncertainty-based risk perspective by Aven (2010) and the framework to assess and communicate uncertainty by Flage and Aven (2009) is taken as a starting point. Reflecting on the nature of the types of propositional attitudes typically found in risk assessments, we propose a modification to the qualitative uncertainty assessment methodology by Flage and Aven (2009) and an extension of the evidence assessment to also include bias, as suggested by Rosqvist and Tuominen (2004).

The paper is organized as follows. Section 2 outlines the adopted uncertainty-based risk perspective and the existing framework to express uncertainty by Flage and Aven (2009). In Section 3, the various propositional attitudes found in risk assessments are considered, indicating that acceptance, along with uncertainty, are the foundational attitudes in risk assessments. In Section 4, an extended uncertainty/bias risk perspective is outlined. In Section 5, a qualitative evidence assessment scheme is proposed, accounting both for uncertainty and bias in line with the suggested risk perspective.

2 UNCERTAINTY-BASED RISK PERSPECTIVE AND UNCERTAINTY ASSESSMENT SCHEME

Recent discussions on foundations of risk analysis have identified a need to clearly distinguish between the concept of risk and ways to describe risk (Aven 2012a). A plethora of risk definitions and concepts is known to exist (Hampel 2006, Aven 2012b), e.g. based on probability (Kaplan 1997), expected values (Campbell 2005), events (Rosa 2010) or uncertainty (Aven and Renn 2009).

For our present purposes, we define the risk concept in line with Aven (2010): "Risk is uncertainty about and severity of the consequences of an activity with respect to something that humans value".

We take the risk description suggested by Flage and Aven (2009) as a starting point, and write (where the symbol "~" means "is described by"):

$$\text{Risk} \sim (A, C, U \mid BK) \quad (1)$$

Here, risk is described by events A and consequences C. The assessor expresses his uncertainty U about the occurrence of A and C based on a background knowledge BK available to him.

Several measures of uncertainty U exist (Helton and Johnson 2011), but for our present purposes we focus on degrees of belief / subjective probabilities P_s as an expression of outcome uncertainty.

A central concern of Aven (2010) is that these subjective probabilities are not perfect representations of uncertainty, because important uncertainties may be hidden in the background knowledge.

Aven (2010) argues that such uncertainties should be made explicit, from which he arrives at a risk description:

$$\text{Risk} \sim (\text{A, C, Ps, EU} \mid \text{BK}) \quad (2)$$

Flage and Aven (2009) suggest following qualitative classification of the strength of evidential support:

Significant uncertainty: one or more of these apply

i. the phenomena involved are not well understood; models are non-existent or known/ believed to give poor predictions
ii. assumptions represent strong simplifications
iii. data are not available, or are unreliable
iv. lack of agreement/consensus among experts

Minor uncertainty: all of these apply

i. the phenomena involved are well understood; models are known to give predictions with the required accuracy
ii. assumptions are seen as very reasonable
iii. much reliable data are available
iv. broad agreement/consensus among experts

Moderate uncertainty exists when conditions are between those of significant and minor uncertainty. Naturally, the classification of these uncertainties in minor, moderator or significant are case-specific and subject to the judgment of the assessor, but the above guidelines are meant to make the reasoning process of the analyst explicit.

In addition to the qualitative uncertainty assessment, the risk description by Flage and Aven (2009) also considers sensitivity S, which relates to the change in the relevant calculated risk measures conditional to changes in the uncertain quantities. This leads to a risk description:

$$\text{Risk} \sim (\text{A, C, Ps, EU, S} \mid \text{BK}) \quad (3)$$

Following classification is adopted for sensitivity:

Significant sensitivity:
Relatively small changes in base case values result in altered conclusions (e.g. exceeded acceptance criteria)

Moderate sensitivity:
Relatively large changes in base case values needed to bring about altered conclusions

Minor sensitivity:
Unrealistically large changes in base case values needed to bring about altered conclusions.

The classification of evidential support in terms of significant, moderate or minor uncertainty as described above provides a good starting point for extending the risk assessment beyond probabilities. However, we find some areas for improvement in the work by Flage and Aven (2009).

First, we find value in providing a qualitative assessment of the various types of evidence per se, which can be rated by an assessor. This approach identifies explicitly which evidence actually is available for the assignment of a subjective probability to the considered variable of interest. The approach by Flage and Aven (2009) in our view leads to some inconsistencies. E.g. when no data is available but the models are based on very well established theories, the classification by Flage and Aven (2009) leads to moderate or even significant uncertainty. However, it is possible that even when no data is available at all to the assessor, the models are so accurate that the uncertainty regarding the evidence is minor.

Second, Flage and Aven (2009) refer to models, assumptions, data and expert judgment as sources of evidence in the background knowledge. However, in characterizing these as evidence for making the assessment, we find it beneficial to consider what propositional attitudes are relevant in the assessor's consideration of these data, models, assumptions and expert judgments as pieces of evidence in making judgments on probabilities.

In particular, a more elaborate discussion on propositional attitudes will indicate that apart from evidential uncertainty, it may also be valuable to consider evidential biases.

3 PROPOSITIONAL ATTITUDES

In the philosophical literature, a distinction is made between several attitudes one can have regarding a proposition. The formalism of propositional attitudes stems from a need for conceptual clarity regarding what sort of attitude or stance one takes regarding a statement (Schwitzgebel 2010). The generic structure of a propositional attitude is as follows:

$$\text{S A that P} \quad (4)$$

The formalism captures an individual's mental state of having some attitude, stance, take or opinion about a proposition or about the potential state of affairs in which that proposition is true (Schwitzgebel 2010). The above structure constitutes of a subject S, an attitude A and a proposition P. For example, in the sentence "the assessor hopes that he will complete the report on time", S refers to "the assessor", A refers to "hopes" (i.e. an attitude expressing a desire concerning a given outcome) and P refers to "he will complete the report on time." Note that

implicitly, it is understood that the attitude A is expressed at a given time t. This further implies that at another time t^*, a subject's attitude toward the proposition may be different. The subject-bound nature of propositional attitudes furthermore shows that different subjects may have different attitudes toward the same proposition P.

In the following sections, a number of important propositional attitudes are briefly considered. It should be noted that the exact philosophical characterization of these propositions is a major challenge for philosophers, with e.g. long-standing debates on the exact nature of knowledge (Lemos 2007). The outlines given below should therefore primarily be seen in a stipulative sense, with the aim of making these broadly different attitudes more in focus in foundational literature on risk assessment, which is (in the authors' view unfortunately) uncommon at present: in standard textbooks on risk assessment, such distinctions are not made (Aven 2010, Bedford and Cooke 2001, Jordaan 2005).

3.1 *Belief*

The attitude of belief (B) can be characterized as follows (Schwitzgebel 2010):

S beliefs that P
if and only if
S has the mental state that P is true.

Beliefs are common attitudes in epistemological contexts, and generally are taken to be truth-oriented. Whether or not a belief is trustworthy depends primarily on the amount and reliability of the offered justification.

Take the following example: "the operator beliefs that the valve is closed". Here, the operator has the mental state that the valve is closed, but this does not mean that the valve really is closed. When asked, he may justify his belief e.g. by saying that the computer system indicates that the valve is closed and that he has just made an inspection during which he has seen that the handle of the valve showed a closed position. Nonetheless, the operator may be wrong in his belief, e.g. when the interior mechanism of the valve is actually cracked, such that the valve leaks.

3.2 *Knowledge*

Clearly, much has been written about the concept of Knowledge (K), and there are major philosophical difficulties in exactly characterizing what knowledge is (Lemos 2007). For our purposes, we adhere to the standard epistemological conceptualization as Justified True Belief (JBT), which can be formalized as a propositional attitude as (Schwitzgebel 2010):

S knows that P
if and only f
(a) S beliefs that P
(b) S has a justification for the belief
(c) P is true

In this account, knowledge clearly is truth-oriented as the propositional attitude is a stronger version of belief, as the proposition is actually true. Note that for S to know P, S must be able to provide a justification.

Take the following example: "the analyst knows that the square of the hypotenuse in a right triangle is equal to the sum of the squares of other sides". This is the well-known Pythagorean theorem, which the analyst may be well-justified to believe as there are no less than 370 proofs for the proposition (Loomis 1968).

Taking however the previous example "the operator beliefs that the valve is closed", the justification provided by the operator may be wrong without him realizing this, see Section 3.1. The valve may in fact really be closed, but neither the indication of the computer system, nor the position of the lever provides the same kind of certainty of justification as the mathematical proof of the Pythagorean theorem. The operator may have very strong justification for his belief, and even if the value really is closed, it is questionable if he can know this in the strict sense of knowledge as justified true belief. Metaphysically, the valve may indeed be closed, but for the operator, the inner mechanism of the valve is not accessible to verify the closed position (and were he to open it, the proposition would be false).

Such considerations naturally lead to the attitude of uncertainty.

3.3 *Two attitudes of uncertainty*

Several conceptualizations of uncertainty exist, often made in light of the nature of the problems dealt with. Levin (2006) proposes an analytical taxonomy of uncertainty, in line with the structure of the propositional attitudes. He distinguishes Outcome Uncertainty (OU) and Evidence Uncertainty (EU).

S is at time t outcome uncertain whether P
if and only if
(a) S believes that either P or ¬P may be true, and
(b) the truth-value of P is non-determinate at t

S is evidentially uncertain whether P
if and only if
(a) S believes that either P or ¬P may be true,
(b) S lacks knowledge of a determinate proposition e_n, and
(c) e_n stands in an evidential relation to P

It should be noted that Levin (2006) acknowledges that this definition should account for the notion that several (i.e. more than two) potentially

true propositions should be considered in uncertainty, and that the reliance on determinism in the definition poses some unresolved metaphysical challenges.

Also, it should be noted that the primary attitude in both OU and EU concerns belief. Thus, while the subject entertains rival hypotheses as being potentially true, of which he is not certain which one to believe exclusively, he has a truth-oriented attitude towards these.

Take the following example: "the operator is uncertain whether a leak will occur from the valve". First, it should be noted that this example concerns a future state of the world, which is at present non-determinate. The operator finds himself in a state of outcome uncertainty. He believes on the one hand that no leak will occur, but as he cannot be certain about future states of the world (such propositions have no true value), he must leave the option open that a leak will occur.

The operator weighs his beliefs according to the evidence available to him. If the computer system indicates a closed valve and if he sees that the lever is on the "closed" position, he has evidence to support the belief that no leak will occur during his watch. However, he lacks knowledge about the maintenance performed on the valve. In line with statement (b), this implies that the operator is in a state of evidential uncertainty because the maintenance clearly has a relation to the possibility of a leak.

3.4 *Degree of belief as an attitude of outcome uncertainty*

The attitude of outcome uncertainty naturally leads to the attitude of Degree of Belief (DB) as:

S beliefs that P to a degree p
if and only if
S beliefs that ¬P to a degree 1-p

It is seen that a subject S can express his outcome uncertainty OU in terms of a degree of belief concerning the truth-content of P.

As with outcome uncertainty, the primary attitude is belief: the subject beliefs P to a degree p. Hence, S is not uncertain about p. This is important, as the subjective degree of belief, also known as subjective probability (Aven and Reniers 2013), is not uncertain for S.

However, S may have poor evidence for making his assignment of degree of belief p. This does not act as an uncertainty about p, but as an uncertainty regarding the evidence on which his assignment of p is based.

The separation between outcome and evidential uncertainty as conceptual attitudes is thus equivalent to a separation between degrees of belief and the strength of evidence for assigning the degrees of belief. Such distinctions between judgment and evidence for judgment are important in the discussion on the risk description in Section 4.

For the assessor, his assigned value of p is not uncertain (he believes it), but this does not mean that the value p is actually true. Other assessors may assign another value p^* which they believe to truly represent their attitude towards P. The assignment of p is a personal judgment, without any reference to the existence of a "true" value p_t. A more elaborate discussion on subjective probability is given by Aven and Reniers (2013).

3.5 *Acceptance*

Acceptance (A) is a very different propositional attitude than the so far considered ones. We adopt the definition and interpretation by Elliott and Willmes (2012):

S accepts that P
if and only if
S presupposes P for specific reasons in the deliberation

Acceptance differs on a number of crucial accounts from belief. One cannot believe at will, whereas acceptance is under one's voluntary control. Furthermore, the degree to which a proposition is worthy of belief depends only on the available evidence, whereas accepting it is context-dependent.

Unlike belief, knowledge and uncertainty, acceptance does not imply any commitment of the subject S that the proposition P is true or even truth-oriented.

The key aspect of definition (A) is the notion of 'specific reasons'. Acceptance is highly context-bound: the reasons for which A is accepted in a first context may not be sufficient for its acceptance in another. In addition, the reasons for acceptance are not necessarily (exclusively) of epistemic nature. This means that the reasons for acceptance may involve value judgments, e.g. when a conservative judgment is invoked as a reason for acceptance.

Take following example: "The assessor accepts that the load-carrying capacity of the crane is 500 kN". Clearly, there may be epistemic justification (reasons) for this acceptance, for instance that calculations using beam theory indicate a capacity of 535 kN. However, the assessor may be justified in invoking value judgments to accept a lower capacity in the calculations than the first estimate of 535 kN. Depending on the purpose of the analysis, i.e. depending on the context, it can be reasonable to value a conservative estimate about which uncertainty is minimized over a possibly more accurate estimate about which uncertainty is

higher. The assessor may do this, because he prefers a calculation which is "on the safe side"—clearly a value judgment. Such a judgment may however be acceptable depending on the aim of the analysis.

More generally, in modeling environments, it is often needed to accept certain assumptions or simplifications. The kinds of assumptions and simplifications made (conservative or optimistic) ultimately rely on non-epistemic value judgments rather than on epistemic justification.

The nature of the justification of the attitude towards a proposition thus has implications as to whether or not there are values involved.

3.6 *Acceptance of evidential bias*

In our context, we define bias as the difference between what is accepted and what is believed, in line with the underlying ideas of Rosqvist and Tuominen (2004). We furthermore define the attitude of Accepting an Evidential Bias (AEB) as follows:

S accepts an evidential bias with regards to e_n
concerning P
if and only if
(a) S accepts that e_n
(b) S beliefs that e_n^*
(c) e_n stands in relation to e_n^*
(d) e_n stands in an evidential relation to P

The central characteristic of accepting an evidential bias is thus that a subject S is prepared to make statements concerning P based on evidences which he does not truly believe. Rather, he accepts evidences, the justification of which may involve value-laden reasons. Yet, the subject is aware of this situation and is able to describe the bias in terms of whether he beliefs that the bias is conservative, realistic or optimistic.

3.7 *Schematic overview*

The brief outline of the propositional attitudes in the preceding sections is summarized according to a number of central characteristics in Table 1.

The overview of characteristics of the various propositional attitudes clearly shows that there are important differences between the attitudes. Belief-based attitudes B, K, OU, EU and DB aim at truth, either an absolute truth as in K or a subjective truth as in B, OU, EU or DB, whereas the attitude of acceptance does not involve a reference to any truth per se. Acceptance depends on the context, whereas beliefs and knowledge do not.

A central characteristic of uncertainty and degrees of belief as opposed to belief, knowledge and acceptance is the simultaneous entertainment of different, mutually exclusive hypotheses regarding a proposition. In belief, knowledge and acceptance, the focus is on one particular proposition. In an attitude of accepting evidential biases regarding a proposition, a subject entertains two different propositions: the believed evidential proposition versus the accepted evidential proposition. This is not the same situation as with uncertainty because in uncertainty, one entertains simultaneous beliefs regarding one and the same proposition.

Table 1. Central characteristics of propositional attitudes.

Characteristic	B	K	OU	EU	DB	A	AEB
Truth-oriented	Y	Y	Y	Y	Y	N	N
Actually true	N	Y	N	N	N	N	N
Dependent on subject	Y	N	Y	Y	Y	Y	Y
Several alternatives	N	N	Y	Y	Y	N	N
Proposition in future	Y	N	Y	Y	Y	Y	Y
Proposition in past/ present	Y	Y	Y	Y	Y	Y	Y
Epistemic justification	Y	Y	Y	Y	Y	Y	Y
Non-epistemic justification	N	N	N	N	N/Y	Y	Y
Context-dependent	N	N	N	N	N/Y	Y	Y

Concerning the element of time, all propositional attitudes except knowledge (defined as justified true belief) can be applied to propositions related to the future, as there is broad agreement among philosophers that statements regarding the future have no truth-content (Hartnack 1959). All attitudes can be applied to propositions related to past or present.

An important distinction exists between belief-based attitudes (B, K, OU, EU, DB) and acceptance-based attitudes (A, AEB). This involves the role of non-epistemic values as justification for the type of attitude taken to a proposition. In the belief-based attitudes, the value judgments of a subject are irrelevant because whether or not one takes something to be true does not depend on whether one sees value in taking it to be true. In contrast, in acceptance-based attitudes, values do play a role as supporting justification. This is related to the attitude of acceptance more being tied to a particular action in a particular context, rather than aiming at the discovery of a true value.

Concerning degrees of belief (subjective probabilities), these may or may not involve values depending on what types of justification (epistemic vs non-epistemic) are invoked as evidential statements on which the degree of belief is based. If these evidential statements only concern attitudes of knowledge, beliefs or evidential uncertainty, non-epistemic values are not present in the

underlying justification of the degree of belief. If however there are attitudes of acceptance and acceptance of evidential bias present in the justification of the degree of belief, these degrees of belief do rely on values.

4 EXTENDED UNCERTAINTY/ BIAS RISK DESCRIPTION

Our recommended risk description can be schematically summarized as follows:

$$\text{Risk} \sim (A, C, P_s, EU, EB, S \mid EJ, NEJ) \quad (5)$$

The risk description is largely similar as the one presented by Flage and Aven (2009), focusing also on the expression of degrees of belief regarding the occurrence of events A and consequences C, using subjective probabilities P_s. As in their framework, evidence uncertainty (the strength of evidential support for the assignment of P_s) and sensitivity S is considered.

However, the methodology for assessing the strength of evidence for assigning subjective probabilities is modified and apart from evidential uncertainty, we also propose a method to assess evidential biases. The assessment of bias is also suggested by Rosqvist and Tuominen (2004) and Rosqvist (2010).

In the above risk description, the assessor makes a judgment regarding his degree of belief P_s about the occurrence of the event A based on the evidence available to him, which enables him to provide a justification J, i.e. P(A|J). This evidence may consist of data, models, theories and judgments. As discussed in Section 3, there exists a variety of propositional attitudes regarding evidential propositions. Evidence can be believed, known or accepted.

Furthermore, there often is a form of evidential uncertainty for the assessor in relation to evidential propositions. Finally, it is possible that the assessor has accepted data, models or judgments the justification of which is (partly) based on values. Hence, the justification may not only of Epistemic nature (EJ), but also may involve of Non-Epistemic nature (NEJ). Hence, the risk description is not necessarily value-free, depending on the nature of the reasons because of which a particular propositional attitude is adopted regarding the evidences. A qualitative assessment of evidential biases can make such value-laden considerations explicit.

Table 2 provides a classification of the various possible attitudes in the evidential categories. It is seen that for all types of evidence, it is possible to accept it as a basis for assigning a degree of belief P_s. For all types of evidence, there may be evidential uncertainty present to lesser or greater degree. In contrast, beliefs and knowledge (defined as justified true belief) are not always appropriate attitudes towards evidence. Some examples will illustrate these points.

Table 2. Propositional attitudes in evidential propositions acting as evidence for the judgment of a degree of belief.

Evidence type	B	K	EU	A	AEB
Data	N	N	Y	Y	Y
Mathematical model	Y	Y	Y	Y	Y
Engineering model	N	N	Y	Y	Y
Theory	Y	Y	Y	Y	Y
Judgments	Y	Y	Y	Y	Y

Experimental or empirical data is, using the concepts of Section 3, typically not believed or known, because it is not in the strict sense true. Experimental data obtained in laboratory conditions can typically be considered reliable, but e.g. accident data or data obtained from accident reports can be based on poor classifications, unreliable or incomplete to varying degrees. Hence, there may be evidential uncertainties related to data, and it may be biased e.g. when severe accidents are believed to be rather well reported, whereas minor accidents and incidents may be underreported.

Mathematical models can be believed and even known, involving no evidential uncertainty. Consider e.g. the Pythagorean theorem: this is a mathematical piece of knowledge. Other mathematical models, e.g. numerical solutions to differential equations, may be accepted rather than believed, and there may be evidential uncertainty e.g. related to the adopted discretization in the numerical solution.

Engineering models typically are not really believed as they represent a simplification of a real system. Models are not true, but are useful in a given context and can thus be accepted. In complex models, there can be evidential uncertainty related to the model structure and parameters. Biases may also be present, e.g. when conservative modeling simplifications are adopted.

Theories may be believed, known or accepted depending on the field of application. Mathematical theories may constitute knowledge, whereas psychological theories, e.g. theories of human error occurrence, may be accepted. There may be evidential uncertainties in theories.

Expert judgments may constitute of beliefs, e.g. a belief regarding the closed position of a valve. If this belief is actually true, it also is knowledge. However, judgments may also be uncertain, e.g. if different experts disagree about their beliefs.

Furthermore, judgments may be accepted, e.g. we may actually believe that not all cars in a crossroad have exactly two passengers, but we may accept this because it is simpler and because we take it that it is a conservative number.

5 TOTAL RISK PICTURE

The risk description of Eq. 5 leads to a systematic look beyond the assigned probabilities, as in the scheme by Flage and Aven (2009). It differs in the tools applied to systematically assess the evidence, and it extends the work by Flage and Aven (2009) by also considering evidential biases.

5.1 *Schematic overview of total risk picture*

The total risk picture consists of a probability model, where subjective probabilities are assigned to events and consequences. This can be achieved using event/fault trees or Bayesian networks.

Apart from the probabilistic risk measurement, a sensitivity analysis is made, identifying the elements in the model to which the risk measure is most sensitive. For those probabilities to which the model is most sensitive, a qualitative assessment of the strength of justification and the direction of bias is made. Finally, the sensitivities, strengths of justification and (when relevant) the direction of biases are grouped in a set of matrices, showing the overall picture of sensitive model elements and their epistemic and non-epistemic justification.

5.2 *Probability evidence assessment scheme*

The total risk picture constitutes subjective probabilities and sensitivities, along with a qualitative description of the strength of evidence and the direction of bias.

A proposed evidence assessment scheme for the evidential support for a subjective probability $P_s(A \mid EJ,NEJ)$ is presented in Table 3, accounting both for epistemic and non-epistemic justification. The scheme may be used to make explicit what type of evidence the assigned probability value is based on, as well as how strong that evidence is believed to be. When relevant, the direction of bias inherent in the evidence can be judged by the assessor.

Naturally, the assigned value in the evidence assessment scheme is in itself a judgment by the assessor. This inherent subjectivity could be an obstacle in communication, but the very nature of risk assessment under the adopted risk perspective is a subjectivist one, see e.g. Aven and Renn (2009).

The real value of the evidence assessment scheme is to increase transparency in the assessment, to make explicit what the various judgments are based on in a systematic manner.

Table 3. Evidence assessment scheme for a particular subjective probability P_s, H = high, M = medium, L = low, C = conservative, R = realistic, O = optimistic.

RISK MODEL ELEMENT "A"				
Strength of evidence	H		M	L
Data				
Completeness				
Reliability/accuracy				
Amount				
Model/theory				
Phenomenon understood		x		
Level of detail		x		
Accuracy of prediction			x	
Judgments				
Expertise of assessor				
Consensus				
Overall score		x		
Evidence bias	C		R	O
Data				
Reporting completeness				
Measurement bias				
Model/theory				
Type of simplifications		x		
Judgments				
Type of assumption				
Overall score		x		

The example assessment scheme concerns a probability which is derived from calculations with an engineering model of a system which is relatively well understood, which is modeled in a high level of detail and leading to reasonably accurate predictions. The evidence bias assessment shows that the type of simplifications is moderately conservative.

Hence, the probability P_s is on based on evidence with low uncertainty and a moderately conservative bias, as also indicated in the table.

The example shows that uncertainty can be minor even if only one type of evidence is available. In case no models or data is available and the assigned probability is purely based on expert judgment, the level of expertise and the degree of consensus may still lead to the conclusion of relatively minor uncertainty related to the probability value.

5.3 *Risk model evidence assessment scheme*

Once the strength of epistemic justification and the direction of evidential bias are qualitatively assessed for the sensitive probabilities in the risk

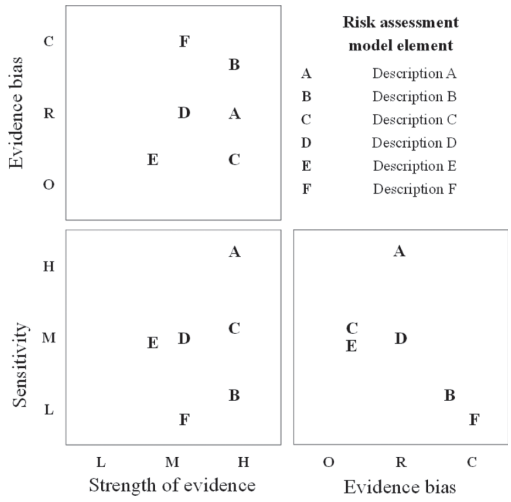

Figure 1. Aggregate risk model evidence uncertainty, bias and sensitivity assessment.

model, this information is aggregated as illustrated in Figure 1.

On the top-right corner, the various risk assessment model elements, i.e. the various subjective probabilities in the risk model, are identified. These are subsequently mapped according to their sensitivity values and their aggregate score in terms of epistemic and non-epistemic justification in a set of matrices.

The aggregation of the strength and possible direction of bias of evidential support for the probabilities in the model, along with the sensitivity score provide insight in the overall evidential support and direction of bias of the entire risk model.

A decision maker could utilize this qualitative assessment along with the quantified risk measures based on probabilities to evaluate how confident he can be about the risk measures. When e.g. an ALARP decision criterion is applied for evaluating the risk acceptability, the broad qualitative assessment guides the decision maker in establishing that the risk is positioned in a given area.

6 CONCLUSION

Informing decisions using risk assessments requires a broad, informative and transparent risk picture. Starting from an uncertainty-based risk perspective, we have outlined an existing framework for expressing and communicating uncertainty related to QRA.

While we find merit in the existing approach, we have proposed a modification to the methodology to qualitatively assess the strength of evidence. Our method directly assesses the strength of the various types of evidence relevant for making the various probability judgments in the risk model, which avoids possible inconsistencies in the existing approach.

Moreover, a more in-depth focus on what kind of attitudes are possible towards evidential statements shows that apart from evidential uncertainty, also evidential biases may be systematically assessed.

The detailed evidence assessment for the various probabilities of which the risk model consists is subsequently aggregated with the sensitivity score, providing a broad insight in the importance of various elements in the risk description, increasing the transparency of the risk assessment.

ACKNOWLEDGEMENTS

The work in this paper is prepared as a methodological support to the risk assessment developments in the WINOIL-project, funded as part of the ENPI Programme. This Programme is co-funded by the European Union, the Russian Federation and the Republic of Finland.

Safety analysis and CFD dispersion simulation of cryogenic release in a deep underground large scale cryogenic installation

E.C. Marcoulaki, A.G. Venetsanos, M. Konstandinidou & I.A. Papazoglou
National Centre for Scientific Research "Demokritos", Athens, Greece

ABSTRACT: This work considers a large installation for neutrino physics experiments, located in specially constructed caverns 1400 meters underground. The installation includes a specially designed heat insulated tank hosting 50 ktons (fudicial mass) of cryogenic argon. The main safety concern stems from the possibility that cryogen may be released from its containment and cause temperature and oxygen concentration conditions that jeopardize human health and/or the cavern integrity. The paper discusses the adopted safety measures and systems, presents CFD dispersion results simulating the uncontrolled release of the cryogen in the underground space, and assesses the potential hazards for the personnel and the cavern.

1 INTRODUCTION

There is significant evidence that very large volume underground neutrino observatories will enable fundamental discoveries in the field of particle and astroparticle physics. Many European national underground laboratories with high technical expertise are currently operated with forefront smaller-scale underground experiments, and there is currently a lot of activity worldwide on the construction of a large-scale facility. The heart of these observatories is a detector consisting of specialized sensitive detection devices submerged into a detector medium. Neutrinos interact with the detector medium, and the particles produced are analyzed to establish the neutrino characteristics. The detector medium can be purified water, liquid argon or organic scintillators.

The analysis presented here is part of an excessive multiyear design study elaborated by a large consortium of neutrino physicists and European construction companies, within the projects LAGUNA (2008–2011) and LAGUNA-LBNO (2011–2014) funded by the European Commission. Among other issues, the study considered (a) the selection of an appropriate location and the conduction of geomechanical investigations, (b) the design and costing of the excavation of underground caverns and tunnels, (c) the design and costing of a tank and its construction plan to host the liquid argon, (e) the design, construction and costing of the detector equipment, (f) the design and costing of on ground and underground processes to fill the tank with argon and (g) to maintain argon at the desired conditions etc. Safety issues have been granted significant attention from the beginning of this study. Several types of risks have been identified and registered, and specific measures were proposed to prevent and mitigate them. More information can be found at the LAGUNA website.

This paper presents in brief the safety assessment of the underground installation at normal operation. In particular, the focus here is on the argon dispersion following a cryogenic release of gaseous argon in the underground premises. The paper is organized as follows. Section 2 gives a general description of the underground installation. Section 3 discusses briefly the quantitative risk assessment leading to the evaluation of accident frequencies. Section 4 presents the phenomenology analysis using CFD simulations of the argon dispersion. Section 6 concludes the work.

2 GENERAL DESCRIPTION OF THE INSTALLATION

The neutrino detector consider here is a specially designed and heat insulated tank with gross capacity 52,300 m^3 filled with cryogenic argon. The tank, and associate processes for argon re-condensation and filtration, as well as cavern air-conditioning, will be located in specially excavated caverns 1400 m underground (see Fig. 1a). The caverns will be at a copper and zinc mine at Pyhäsalmi in central Finland (see Fig. 1b). The location selection was based on various criteria, including the excellent rock characteristics, the absence of nearby nuclear plants and hence of neutrons, the depth of the mine, the low seismicity and the distance from CERN. The latter is ideal for the study of accelerated neutrinos

Figure 1a. Pyhäsalmimine, central Finland.

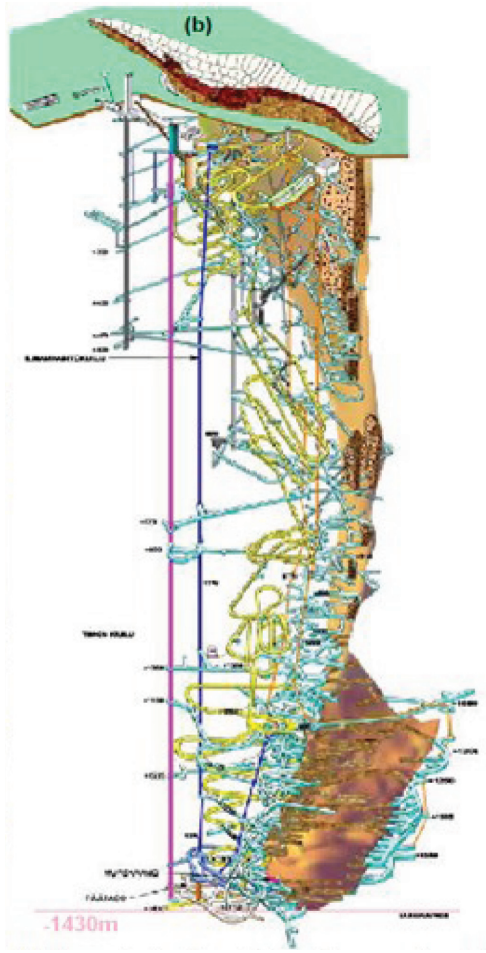

Figure 1b. Present mine layout (http://laguna.ethz.ch).

generated at CERN and aimed towards a detector at Pyhäsalmi. Information on the site selection and characteristics is publicly available in the LAGUNA project deliverables.

At –1400 m (see Fig. 1b) three large caverns will be excavated, suitable for hosting two 50 kton f.m. liquid argon tanks and one 50 kton f.m. liquid scintillator tank (tank caverns). Smaller adjacent caverns will host the process unit equipment (process unit caverns). The tank caverns will be isolated from the process unit caverns and the rest of the mine using lock doors.

The LAGUNA-LBNO project team has provided detailed designs on the location, sizing, cost and equipment types of the on ground facilities and the shafts used for technical infrastructure (like piping, electricity wires). This information is published at the LAGUNA website in strict confidence. The process flow sheet, the argon tank and process unit sizes, the temperature and pressure conditions etc used in the present analysis are also found at the website. In particular, the present work is based on the geotechnical designs and rock mechanical analysis conducted by Kalliosuunnittelu Oy Rockplan Ltd, the tank design and calculations elaborated by Technodyne International Ltd and Rhyal Engineering Ltd, and the liquid handling process design proposed by Sofregaz SA.

The detector medium is argon, kept at cryogenic conditions and vapor-liquid equilibrium at 87 K and 1265 mbar. A detector network and appropriate instrumentation to measure neutrino interactions with argon atoms will be immersed in the argon liquid inside the tank. A ventilation system (pressurizer) and a cavern heating system will work in parallel to maintain the conditions in the tank cavern at 22°C and 1250 mbar.

The neutrino experiments require argon liquid of particularly high purity, so argon liquid will be taken from the tank and processed in a set of filtration units. The argon boil-off produced inside the tank due to heat influx in the tank will be recondensed in heat exchanger units that use nitrogen as coolant. The argon cooling system will also include expansion and compression units arranged in loops that aim to cool down, re-condensate and

reuse the nitrogen coolant, and a nitrogen storage vessel.

The ventilation and heating system units, the pumps, motors and turbines for fluid transmission and processing, and the filtration units will be located in the processes cavern, next to the tank cavern. The heat generated by the instrumentation in the tank cavern and all the equipment located in the process cavern will be rejected finally into the surface atmosphere through a specially built Service Water Cooling System (SWCS). Presently the design of this system comprises a motor driven cooling tower using cooling water from the nearby Lake Pyhäjärvi, and a pipeline running several hundred meters through the rock to transmit the water underground. In case of overpressure in the argon tank, the water cooling system is able to transmit the released argon gas to the mine surface atmosphere.

3 QUANTITATIVE RISK ASSESSMENT

The main concern when storing large quantities of cryogenic argon in a confined space stems from the possibility that Liquid Argon (LAr) may be released from its containment, evaporate, and (a) reach concentrations that can expel oxygen from the air and/or (b) result to extremely low temperatures in the confined space. Two main areas exist where argon is contained and there is a possibility of a Loss of Containment (LOC) and a subsequent release of argon:

a. Tank cavern: Main cavern with the cryogenic argon tank
b. Process unit cavern: Process area where argon is cooled/condensed (if it is in gas phase), filtrated and returned to the argon tank.

A safety analysis along with a Quantitative Risk Analysis (QRA) has been performed based on the existing design details. The QRA includes:

a. an assessment of the various accident sequences leading to Ar release;
b. an estimation of their frequencies; and
c. a calculation of the consequences of Ar release using CFD tools.

This paper discusses briefly the analysis elaborated for tank overpressure, leading to the estimation of accident frequencies, and presents in more detail the CFD results for argon release owning to overpressure in the tank. The release is in the gas phase and can occur either inside the tank cavern, or in the process units cavern, or at the surface of the mine. At this stage of the design, there is lack of information on the precise geometry and equipment arrangement of the process cavern, therefore, only releases in the tank cavern can be simulated. Note that, this is part of the work elaborated on the system quantitative risk assessment, and more information is available in the LAGUNA-LBNO project website.

3.1 *Overpressure and associate safety measures*

Increase of the internal pressure can cause an increase of the stress on the containment exceeding its design limits and resulting in LOC. In the present installation, the critical design feature that might cause a LOC owing to overpressure is the roof of the tank. Its design requires that the overpressure inside the tank with respect to the pressure in the cavern does not exceed the 25 mbarg. It is assumed that, causes that result in a gauge pressure greater than 25 mbarg will result in LOC and in particular in a small break at the gaseous phase of the argon. The pressure increase can be relieved through a set of pressure relief valves (PSVs) installed on the tank. The released Ar is then transferred to the Ar-processes cavern, from where it is transferred to the mine surface through the SWCS and a piping system.

Argon is kept at Vapor-Liquid Equilibrium (VLE) at cryogenic conditions using a cooling system, to remove the heat influx from the cavern air to the argon contained in the tank. Any heat imbalance can cause an increase in the tank internal pressure, leading to LOC and argon release. The heat imbalance may be caused by either an increase in the heat influx or a decrease in the heat removal capacity. Heat flux into the cryogen from the environment will vaporize the liquid and potentially cause pressure build-up in cryogenic containment vessels and transfer lines. Cryogenic fluids have small latent heats and expand 700 to 800 times to room temperature, so even small heat inputs can cause significant pressure increase.

Table 1 reports the safety functions and the safety measures incorporated in the design to prevent

Table 1. Safety measures and safety systems.

Safety functions	Primary safety systems
Maintain heat influx into LAr within design limits	Argon tank insulation
Maintain pressure within tank below the maximum acceptable level	Argon re-condensation system Operator's action to switch off instrumentation
Maintain cavern conditions	Cavern ventilator system Cavern heating system
Relieve extra pressure	Set of tank relief valves
	Support safety systems
	Service water cooling system Electric power

pressure difference beyond the design limit, and the mitigating measures to relieve overpressure and preserve the containment integrity. Systems that directly serve a safety function are called Primary Safety Systems (PSS). For successful operations, the PSSs sometimes depend on other systems that provide support services to them, called Support Safety Systems. Their operation is also safety significant, but only through the impact they have on the operation of the PSS.

3.2 *Accident sequences and frequency of Ar release*

Accident sequences are sequences of events that lead to LOC integrity and hence to argon release. An accident sequence consists of an initiating event that challenges the safety functions/systems of the installation, and of additional events representing either hardware failures and/or human actions that collectively result in a LOC. For the safety systems described above, accident sequences are obtained using Functional Block Diagrams and the associated Event Trees (Papazoglou, 1998).

The results of the event tree analysis are summarized in Table 2. Detailed calculations can be found at the LAGUNA project website. In the case of overpressure in the argon tank, argon gas can be released to the mine surface atmosphere through the pressure safety valves and the service water cooling system. The frequency of such an event has been estimated at 5.74×10^{-1}/year or once every 21 months. This mainly comprises the frequencies of loss of the argon pump in the re-condensation system. The loss of the operating nitrogen loop and the loss of insulation make up for just 1% of the frequency for argon release to the surface. Increasing the reliability of the argon gas pumping system can reduce significantly the expected frequency of this type of release. The frequency of argon release inside the tank cavern owing to overpressure, is almost once every 7 months. This frequency is notably high, but only 17% of this value is attributed to initiating events other than the failure of SWCS components.

The quantitative risk assessment results indicated lack of redundancy in the fluid handling processes. It was, therefore, recommended that the final design incorporates redundancy in the service water cooling system, as well as in the argon side of the re-condensation system. This could reduce the expected frequency of LOC due to overpressure by two to three orders of magnitude. It is noteworthy that, the literature for double walled refrigerated LNG containments suggests a frequency for failure of the roof and vapour release in the order of 3.5×10^{-9}/hr (HSE, 2012). This is the order of magnitude for the contribution of those systems that contain redundancy, like the cavern atmosphere regulating systems, the nitrogen coolant side of the re-condensation system and the loss of insulation events.

4 CFD DISPERSION SIMULATION

4.1 *Assumptions and the modelling strategy*

The ADREA-HF CFD code (Venetsanos et al., 2010) used here has been extensively validated in handling transient dispersion problems involving two-phase cryogenic leaks of fluid heavier than air.

Table 2. Frequencies for loss of containment owning to overpressure.

		Conditional probability of Ar release in			Frequency (hr^{-1}) of Ar release in		
INITIATOR is LOSS of	Frequency (hr^{-1})	Tank cavern	Process area	Surface of mine	Tank cavern	Process area	Surface of mine
LOOP	1.00×10^{-5}	1.5×10^{-4}	3.8×10^{-2}	–	1.50×10^{-9}	3.80×10^{-7}	–
SWCS pump	3.10×10^{-4}	3.65×10^{-3}	8.3×10^{-1}	–	1.13×10^{-6}	2.57×10^{-4}	–
SWCS HX	3.60×10^{-5}	3.76×10^{-3}	9.4×10^{-1}	–	1.35×10^{-7}	3.38×10^{-5}	–
Operating pressurizer train	1.00×10^{-5}	2.00×10^{-8}	–	5.00×10^{-6}	2.00×10^{-13}	–	5.00×10^{-11}
Cavern heating system	3.10×10^{-4}	6.80×10^{-10}	–	1.70×10^{-7}	2.11×10^{-13}	–	5.27×10^{-11}
Ar pump	3.10×10^{-4}	8.60×10^{-4}	–	2.10×10^{-1}	2.67×10^{-7}	–	6.51×10^{-5}
Operating N2 train	5.00×10^{-5}	2.60×10^{-5}	–	6.40×10^{-3}	1.30×10^{-9}	–	3.20×10^{-7}

The ADREA-HF code solves 3D conservation equations for mixture mass, the three Cartesian mixture velocities, the mixture enthalpy and the argon mass fraction. Thermodynamic equilibrium is assumed between phases (HEM model). In this work, the working fluid is a mixture of air and argon. The mixture can be in two-phase flow conditions. The Peng-Robinson equation of state is used to describe argon physical properties (Poling et al., 2001). The computational grids are Cartesian. The irregular cavern/tank geometry is described using the porosity approach, embedded in the CFD code. The argon tank is assumed as solid in all performed simulations. The modelled free volume between tank and cavern is equal to the actual free volume. Regardless of the orifice area, the leak source is assumed to be a single point. The flow direction is fixed, and the flow velocity depends on the orifice area and the volumetric flow rate. The volumetric flow rate depends in turn on the fluid mass flow rate and the conditions (i.e. pressure, temperature, fluid phase).

4.2 *Cavern geometry and tank data*

The tank geometry is defined by two cylinders, the inner and the outer, and is symmetrical in the z-axis. Only the outer tank geometry is used in the CFD calculations. The cavern consists of three sections: a small cylinder (tank base) at the bottom, an elliptical cylinder in the middle, and an ellipsoid part (dome) at the top. The cavern is symmetrical in the x-z and y-z planes. Figure 2 presents the cavern and tank geometry, and the respective dimensions of the cavern and tank components. In reality the tank is placed on a structure made of concrete blocks. The present analysis assumes a solid cylindrical base bellow the tank and free space between the tank base and the cavern bottom.

The calculations of the temperature profiles within the cavern walls tank into account the physical properties of the rock surrounding the cavern. The CDF simulations require a fixed thickness for the cavern wall layer. In the present simulation, this thickness is taken equal to 6 m. Outside this layer the rock temperature is constant and equal to the bulk temperature of the cavern rock. The bulk rock temperature is equal to the temperature of the air occupying the cavern when the accident occurred and the argon was released (i.e. at t = 0). The initial conditions in the cavern before the release are 295 K and 1250 mbara.

4.3 *CFD dispersion results*

The type of release considered here involves the leak of gaseous argon from the tank roof.

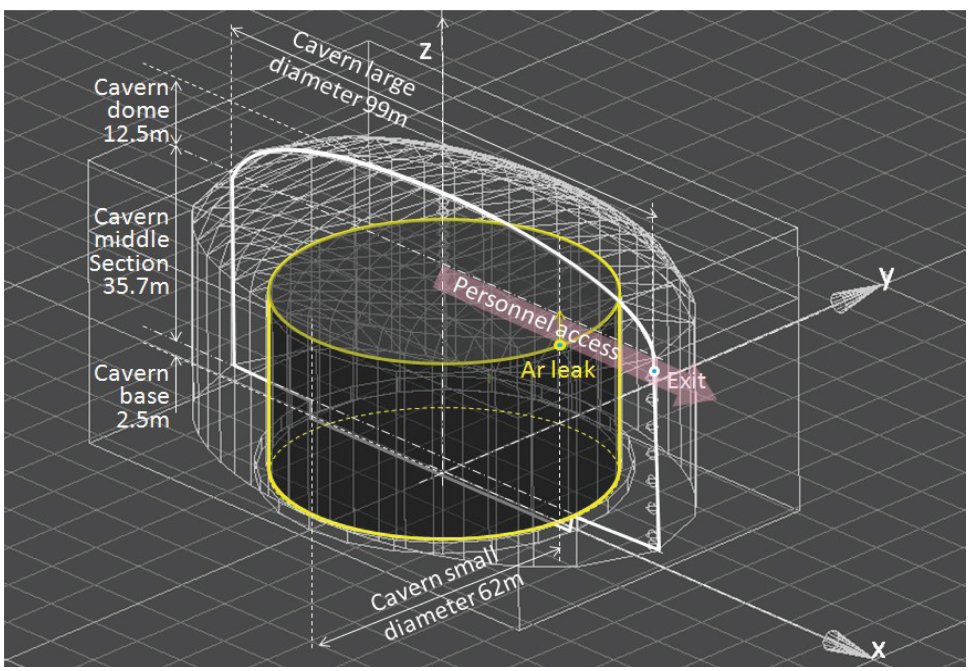

Figure 2. Tank cavern and argon tank geometry.

Table 3 presents the characteristics of this release category. The release location has been set on the cross-section of the top of the outer tank perimeter and the large cavern diameter, on the personnel evacuation route. As the exact location of a break cannot be determined, the location selected here represents the worst case scenario for the personnel safety. The argon mass flow rate is determined based on the initial gas exit velocity determined by the pressure difference and the gas density, and the assumed equivalent break diameter set equal to the boil-off pipe diameter.

Figure 3 gives the argon concentration contours at 1 hour after the release occurrence. The oxygen concentrations are calculated assuming that air consists of 20% oxygen and the gas mixture of air and argon is ideal at this pressure and temperature range. The contours show that one hour after the onset of the release, oxygen is well above 18%.

Table 3. Argon release characteristics.

Parameter name	Value
Orifice diameter	0.244 m
Initial argon flow rate	1.667 kg/s
Argon flow rate slope	0 kg/s^2
Leak location x-axis	27.5 m
Leak location y-axis	0 m
Leak location z-axis	32.5 m
Direction of leak	Upwards, vertical
Argon temperature	89.35 K
Argon pressure	1275 mbara
Argon phase	Saturated vapor
Number of cells (y-symmetry assumed)	44,559
Cell volume (near source)	0.625 m^3

The pressure, argon concentration and temperature profiles in various locations in the cavern free volume during the first 50 hours after the leak occurs are illustrated in Figures 4, 5 and 6, respectively. Concentration and temperature sensors are placed at different heights above the centre of the tank, on the cavern walls near the (x,y) location of the leak and at the (x,y) location of the exit. The exact location of the pressure sensor is near the dome centre. Unlike temperature and concentration, pressure should not change significantly between different locations in the cavern so only one sensor is sufficient. Concentrations are volumetric, so, in ideal gas mixtures, the same numbers hold for molar concentrations.

Figure 5 shows that in the centre of the cavern above the tank the argon concentrations remain below 10% during the first 24 hours, and take two days to go over 20%. Near the cavern walls around the tank the concentrations are significantly higher and reach 10% argon within 5 hours, and 20% within 8 to 10 hours. Therefore, oxygen concentrations are predicted to remain over 18% for a day above the tank and for 5 hours at lower heights. Based on the above concentration results, there is no problem of asphyxiation for this type of release at least up to 5 hours after the release.

4.4 *Qualitative analysis of dispersion results*

The CFD simulations assume that the release rate from a break in the roof of the tank will remain constant for over 50 hours. Clearly, this assumption is not realistic. Figure 4 shows that the pressure inside the tank cavern increases at a rate of 27 mbar/hour. Even if the pressure inside the tank were to remain constant at 1275 mbara (the pressure at t = 0), the cavern pressure will increase from

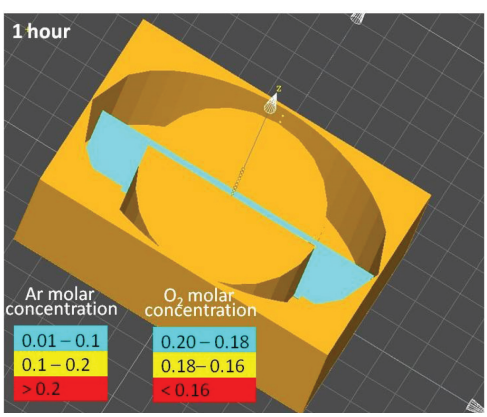

Figure 3. Argon molar concentration contours in the tank cavern at 1 hour after the release.

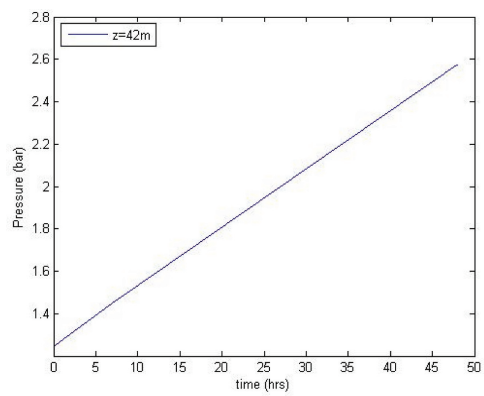

Figure 4. Pressure profile at (x,y,x) = (0,0,42 m) in the tank cavern during the first 48 hrs after the release.

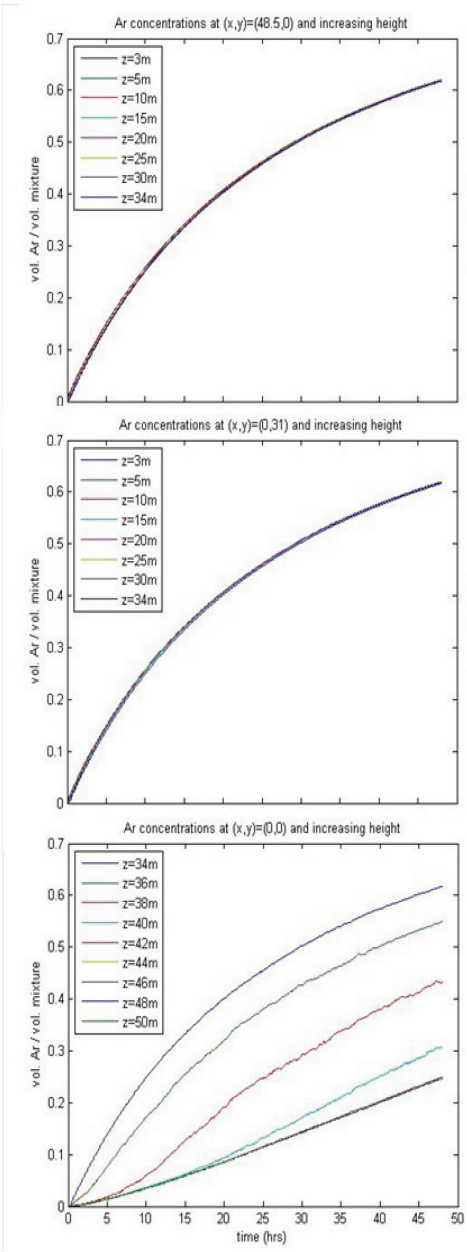

Figure 5. Argon concentration profiles at various locations in the tank cavern during the first 48 hrs after the release.

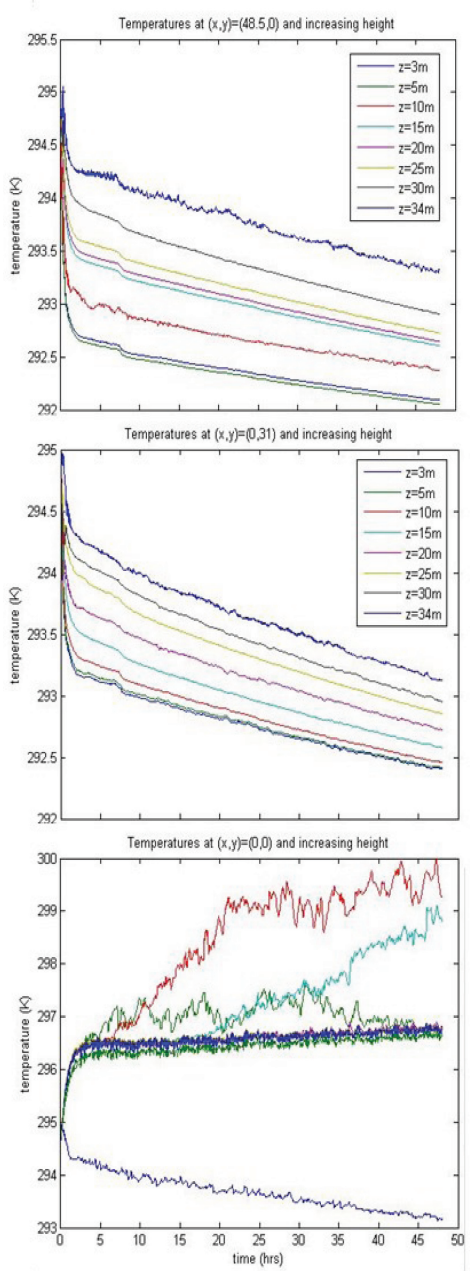

Figure 6. Temperature profiles at various locations in the tank cavern during the first 480 hrs after the release.

1250 mbara to the tank value within about 1 hour. This will effectively stop the release of Ar gas. This time frame is underestimated, since the decrease in pressure difference will reduce the mass rate of Ar release, yielding lower rate of cavern pressure increase. Hence equalization of the pressures will take place later than one hour.

It can therefore be concluded that, if there is personnel inside the cavern when an overpressure break occurs, for at least one hour the conditions

are not dangerous to health and they have adequate time for evacuation.

What will happen after the pressure equalization is questionable since it is not certain what will happen with the re-condensation system. Since the temperature in the cavern remains above 290 K, the heat influx in the tank does not change significantly, so the boil-off remains the same. If the pressure inside the tank increases, a quantity of argon will be released, the pressure in the cavern will increase and the release will stop again. If for some reason the gauge pressure inside the tank drops below –25 mbarg there might be further damage to the roof because of implosion.

Figure 6 presents the predicted temperature profiles. Both the steady-rate-release analysis and the qualitative consideration of the most realistic cases indicate that the temperatures in the cavern won't fall below 290 K.

5 CONCLUSIONS

This paper briefly presented a part of the safety analysis and quantitative risk assessment conducted for an underground installation involving the storage and processing of over 50 ktons cryogenic argon. The installation design is part of an ongoing Pan-European effort to construct a very large scale observatory for particle and astroparticle physics experiments.

The main safety concern in this facility is the loss of containment and the release of the cryogen in the underground premises. Such releases could lead to oxygen deficiency and freezing temperatures, and, therefore, be hazardous for the health of personnel present in the facility. In addition, exposure of the cavern walls to extremely low temperatures for long time periods may alter the rock properties, thus entail significant risks to the cavern integrity.

The study discussed here included a detailed evaluation of accident frequencies and dispersion simulations of argon release due to tank overpressure. The possible release scenarios involve gaseous argon leak inside the tank cavern or the adjacent process cavern. The frequency analysis indicated that there is room for improvement in terms of the fluid handing processes, and suggested specific modifications to increase the system reliability.

The dispersion simulations involved the use of a Computational Fluid Dynamics (CFD) tool suitable for handling Three Dimensional (3D) transient dispersion problems involving two-phase cryogenic leaks of fluid heavier than air. Results are presented for the case of argon gas leak inside the tank cavern due to tank overpressure. A second scenario involving release in the process cavern could not be considered at this stage due to lack of information on the geometry and configuration of the process cavern. The simulation results indicate that the considered release category does not entail risks for human hazards or the underground construction.

Note that, further analysis, not presented here, involves additional types of cryogen release, including the analysis of: (a) a medium size break releasing liquid argon due to rupture of a pipe carrying argon from the tank to the filtration units, and (b) a major failure of the tank resulting in large break (probably along seam lines) also releasing liquid argon. This work is available at the LAGUNA website.

The safety and risk assessment analysis will benefit from the results of an ongoing site investigation (by other members of the LAGUNA-LBNO consortium) will enable a better understanding of how the cavern rock walls will respond when exposed to extremely low temperatures or extremely high pressures for long time periods.

European survey on safety methods application in aeronautic systems engineering

A. Berres, H. Schumann & H. Spangenberg
German Aerospace Center, Lilienthalplatz 7, Braunschweig, Germany

ABSTRACT: After gaining working experience by many years of learning, safety experts work in interdisciplinary teams, sometimes companywide or as a hired specialist. Planes are usually used and maintained over decades. Both scenarios require a safety data exchange over a long time to support development and maintenance. Addressing those needs a survey was developed to evaluate application of safety methods and tools in context of a European project. Based on engineering knowledge and the survey findings, we will show an approach combining system and safety engineering needs. Also recommendations are made for methods and tools applicable for an early integration of safety method. This reduces risk and save cost of projects.

1 INTRODUCTION

Unfortunately, thinking of system errors, defects or failures is not a likeable part of systems engineering. Especially within damaged systems, the loss of resources or lives is at stake. Most engineers are used to develop system functionality and solve problems by finding adequate design solutions without considering the risks (N.G. Leveson 2002). Also the separation for safety and systems engineering during the development worsens the problem. In consequence, the application of safety methods is considered or introduced late in the design process. Furthermore, uncovered requirements and design solutions, not satisfying the required system functionality, are the consequences. Regarding (INCOSE 2011), about 85% of costs are committed within the design stage. Also, requirement changes lead to design changes and costs have to be multiplied by factor 6 during design, by 100 in development and by 1000 in production or test stages (INCOSE 2011).

Cost reduction is possible if safety requirements are considered as early as possible in the development process. Therefore, development phases and applied safety methods have to be understood. With our expertise in systems engineering research projects, we have a clear idea, which methods should and can be applied during early development phases (Berres, Schumann, and Escher 2012). However to help engineers, we would like to follow a pragmatic approach and try to understand which methods and tools were applied during development.

It was decided to start with the development of a survey across the Actuation 2015 partners to find out, which tools for safety assessments are used in industry and academia and may be relevant candidates for further investigation. The identified tools were used to perform a data exchange using our system model PREMISE (H. Schumann and A. Berres 2011). Our system model enabled us to show the early integration of safety methods into the development process in the Actuation 2015 project.

This paper describes the development of the questionnaire, its technical implementation and, of course, the evaluation of the survey results.

1.1 *Actuation 2015*

Before starting with the conducted questionnaire, the project context has to be understood to evaluate the gathered results for the aerospace domain.

Actuation 2015 is a European collaborative research and development project. The project aims to develop and validate a common set of standardized, modular, and scalable Electro Mechanical Actuator (EMA) resources for all actuators and all types of aircraft (Actuation 2015). Safety critical functions for flight control, high lift, landing gear, door, thrust reverser have to be developed.

Actuation 2015 coordinated by Goodrich Actuation Systems SAS gathers 53 partners, including the European key players in the aircraft industry. The consortium includes:

- main European players in actuator and component suppliers
- European players of the business, regional and commercial aircraft industry
- European standardization authorities (CEN)
- Research and test centers from all over Europe, with international reputation in aircraft equipment

development, with past and recognized experience on many aircraft programs (A350, F7X, etc.)
- Universities from several European countries, each of them internationally recognized for the quality of their scientific work, in the field of electric actuation standardization. Several of them have long-term relationship with both aircraft manufacturers and equipment providers.
- SMEs—ten SMEs work in Actuation 2015 and cover a wide range of activities (software, manufacturing and assembly, R&T and test centers, R&T project support).

Considering the project partners and the project goal by conducting the survey, both systems engineering and safety experience of the partners cover the need to find tools and methods for an early integration of safety methods into model based systems engineering.

2 A EUROPEAN SAFETY SURVEY

Various lifecycles of systems engineering are shown in (INCOSE 2011). Identifying applicable safety methods to consider safety methods as early as possible requires the definition of development stages and also the assignment of those methods to the stages. According to (NLR 2013) and in respect to (INCOSE 2011), the following stages are considered for the safety survey: Requirements definition (RD), Preliminary Design (PD), Conceptual Design (CD), Detailed Design (DD), System Design (SD).

For being able to define applicable safety methods, the available methods for systems engineering had to be analyzed. Over the last years, NLR collected more or less all known safety methods and put them into a database (NLR 2013). About 750 methods or techniques are listed therein. Based on the database list, only methods applicable to aircraft and aviation were considered for the survey. However, the database returns 321 safety methods for both applications. To reduce the number of methods, an expert voting was conducted. Safety experts voted the methods impact according to systems engineering stages. The voting of safety methods for the defined development stages adds up as follows:

Requirements design

RHA	Requirements Hazard Analysis
SRCA	Safety Requirements Criteria Analysis

Preliminary design

PSSA	Preliminary System Safety Assessment
PHA	Preliminary Hazard Analysis

Conceptual design

PHL	Preliminary Hazard List

Detailed design

CCA	Common Cause Analysis
BFM	Beta-factor method
CRA	Criticality Analysis or Criticality Matrix
DD	Dependence Diagrams
DMEA	Damage Mode and Effects Analysis
FHA	Functional Hazard Assessment
F(a)HA	Fault Hazard Analysis
FMECA	Failure Mode, Effects and Criticality Analysis
FMES	Failure Modes and Effects Summary
FTA	Fault Tree Analysis
GFCM	Gathered Fault Combination Method
QCT	Quantified Causal Tree
RBD	Reliability Block Diagrams
SM	Shock Method
SSA	System Safety Assessment
SSHA	Subsystem Hazard Analysis
CCD	Cause Consequence Diagrams
CCA	Cause Consequence Analysis
CCFA	Common Cause Failure Analysis
CMA	Common Mode Analysis

System Design

QCT	Quantified Causal Tree
SM	Shock Method
CCFA	Common Cause Failure Analysis
ESD	Event Sequence Diagrams
ETA	Event Tree Analysis
KTT	Kinetic Tree Theory
SHA	System Hazard Analysis

2.1 *Developing the questionnaire*

Based on the safety methods classification, we started to build the questionnaire. To gain valid answers which methods are applied and which methods are pragmatic, we had to answer the following questions:

2.1.1 *Did we find the relevant persons?*

To evaluate the possible impact of an answer, the experience of the participants was considered. Therefore, we designed questions to gain an understanding of the safety experience and expertise in applying safety methods of the answering person.

2.1.2 *Did we identify the relevant processes and standards?*

Known standards and processes as well as their importance and application among users have to be understood. Standards which have to be considered in the future shall be identified.

2.1.3 *Did we find the right applied methods?*

Based on the found classification, we have to ask engineers the following question: “Do you

apply the identified methods during the assigned development stage". Self-developed research safety methods and tailored methods which are derived from standard methods are also to be identified.

2.1.4 *Which tools are applied for the identified methods?*

To understand the requirements of data exchange among tools by using an integrated design model, we need to identify the tools which are used to apply the safety methods. Our main goal is to support the most applied methods and tools, to help engineers during their daily work.

Answering the shown questions lead to 31 questions which compose the "Actuation 2015—safety method questionnaire". A non-functional goal was: A participant shall spend only 15–20 minutes for the survey. The achievement of this requirement was internally proven by our colleagues.

2.2 *Building an online survey*

After creating the questionnaire, we decided to use an online survey approach. Thus, we can gather and evaluate the data faster than using the classical approach by sending "pdf"—questionnaire mails.

By choosing to conduct anonymous survey, privacy and intellectual property issues of the Actuation 2015 members were assured. Furthermore, experts who work under confidential rules were encouraged to exchange their experience.

The main benefits of conducting an online survey are the easy way to deploy the survey and to create electronic reports. They lead to an efficient evaluation of the survey.

2.3 *Selecting of survey technology*

2.3.1 *Requirements on survey technology*

During the development of the questionnaire, the following requirements were identified. The requirements are needed to be able to select the right survey platform.

1. The survey shall be done once and only for this project, reuse of the questionnaire is not necessary.
2. Allowing a user group of max. 300 people.
3. A number of about 50 questions shall be possible, regard to: time spending for the survey shall take only 15–20 min.
4. The survey shall be anonymous to encourage all members to participate.
5. Easy to create, with an easy to understand user interface, to reduce the costs creating the survey.
6. Different possibilities to create questions like single choice, multiple choices, free text.
7. Getting predefined reports after survey.
8. Export report data shall be possible, including the answers of single participants. The export shall support *.csv files to evaluate the data by MS Excel.
9. Survey engines shall be hosted by external providers.

2.3.2 *Market investigation*

An analysis via the internet was done to find suitable platforms (BDC 2013, Survey Software Review 2013, IdealWare 2013, and Ohio State University 2013). We identified more than 30 possible engines. Only the most interesting engines were selected. To be able to understand the capabilities and the functionality of the platforms according to our requirements, a short overview of each platform is given.

SurveyMonkey (SurveyMonkey 2013) is an online hosted survey tool for basic and commercial surveys. The "Free" version might be useful for very small and informal surveys to collect 10 questions and 100 responses per survey. It is limited for customization of the survey look. The "Select" version offers unlimited questions and responses, customizability, skip logic and the ability to export Excel and PDF files. The package's folder structure and "search by title" feature makes it easy to navigate through many surveys. Reports are minimal, but they allow you to export results to another application to do more serious analysis. Higher end "Gold" and "Platinum" versions offer advanced logic features, like question and answer piping, randomization and text analysis for open responses.

SurveyGizmo (SurveyGizmo 2013) offers a low-cost solution with some advanced features. It supports 1000 responses per month, and basic logic as well as a range of more advanced packages. At all levels, SurveyGizmo offers basic piping, fully customizable survey look and feel and the ability to embed images and videos hosted on your own website. More advanced levels offer many randomization options, question options, questions per survey page, and pages themselves, skip logic and more. SurveyGizmo offers an API for integrating survey functionality into websites, blogs and other applications.

QuestionPro (QuestionPro 2013) provides a professional and a free version for creating online surveys. The free version includes: online surveys, micro polls and Ideascale, a feedback collection and voting platform. Also gadgets like Google Analytics and Twitter integration is available. It has a simple wizard approach to create and edit surveys with a large number of question types available. The free version allows an unlimited number of responses, making it ideal for surveys which are small in scope but large in audience, instead it is limited by number of surveys (2) and questions per survey (10).

Murvey (Murvey 2013) helps you create, publish, and manage online surveys easily than you have ever seen before. Murvey is a cloud-based web service that lets you conduct online surveys from a simple and efficient user interface. Creating and publishing the survey only takes a few minutes. Great looking reports can be created as soon as responses start coming in to your survey.

LimeSurvey (LimeSurvey 2013) is a free and open source survey package appropriate for non-profits, looking for advanced survey logic and analysis features. Its range of features includes full customization of survey look and feel, support for 40 different languages, piping, skip logic, a library of available survey questions and blast emailing. The tool has a large support community and is under active development. This is an open source package that can be downloaded for free, installed on your own web server, and customized to your needs by a developer with knowledge of PHP/MySQL. Although the tool itself is free, be prepared to bear the costs for your own web hosting, and the time it takes to properly install, configure, customize and support this product on your own.

Only free or basic versions of the survey platforms where used for our evaluation to reduce cost. To choose the best platform, (Table 1) shows the evaluation of each tool with regard of our requirements.

Shown in Table 1, all tools offer most of the required functionality. SurveyMonkey, SurveyGizmo and QuestionPro provide all required functions by their commercial version only. LimeSurvey covers most of the requirements, but does not provide the infrastructure for the survey. Setting up the required infrastructure was unfortunately not possible in time because of the high effort. Therefore, only Murvey covered all requirements without limitations and was selected for the survey.

2.4 *Implementing the survey*

The implementation of the survey was easy and done in less than 4 hours. To create the survey, mainly the following three types of questions were required.

Table 1. Tool requirements coverage.

Requirement tool	1 2 3 4 5 6 7 8 9
SurveyMonkey	X X O X X X X O X
SurveyGizmo	X X O X X X X X X
QuestionPro	X X O X X X X X X
Murvey	X X X X X X X X X
LimeSurvey	X X X X X X X X O

2.4.1 *Question with single choice*

To create the "single choice question", the question had to be copied from the questionnaire into the question row (grey). Then, possible answer choices had to be copied into the choice field. The created question is shown in Figure 1.

2.4.2 *Question with multiple choice*

A multiple choice question (Fig. 2) can be created like a single choice question. But by selecting the multi choice button, the character of the questions is changed. In the case that additional information is needed, an "other" field can be added. A free text field provides space for an answer, like other standards, given by the participant.

2.4.3 *Question with free-text answer*

In rare cases, a free text answer is necessary. Therefore, a free text field can be used. By selecting the option free-text, copying and pasting the question text into it, the question is easily created (Fig. 3). It is recommended to minimize such questions to reduce the evaluation effort.

After creating all questions from of the questionnaire, a theme can be selected to choose the appearance of the survey. Also an entry text can be realized to introduce the purpose of the survey.

Figure 1. Implementation of single choice questions.

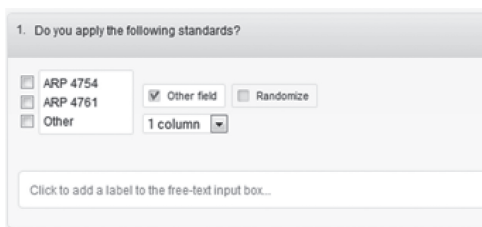

Figure 2. Implementation multiple choice questions.

Figure 3. Implementation of free text answer questions.

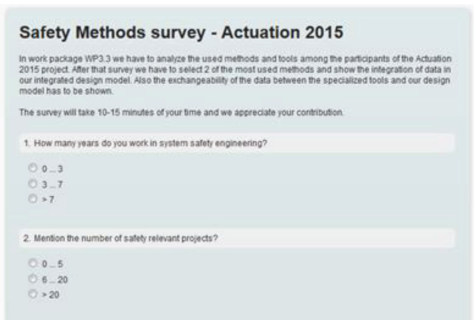

Figure 4. First questions of the online survey.

The following image Figure 4 shows the first questions of the implemented survey.

3 SURVEY REPORT

To conduct the survey, the process was split into two phases. The first phase was a test phase with 30 selected members. Goal of this phase was a test to estimate the number of replies we could expect. Therefor all project member were asked to attend. Our goal was to reach about 10% of the project team. Before starting the survey, the first test group was prepared, by sending the prepared questionnaire. Additionally the purpose of the survey was described. After two weeks, the phase was finished by reaching the goal. Also part of this phase was the evaluation of the questionnaire. The test group was asked to send a feedback. The replies of the test group showed, only minimal adjustments of the questions were required.

After the first phase, the next phase was started. Therefor all project members were asked to contribute to the survey. Again the questionnaire was sent for preparation. A week later, the link to the survey was sent. Because of the holidays took place during the survey time, it was decided to extend the planned two week time span to a month.

The survey was conducted during August and September 2013. All members of Actuation 2015 with a technical background like research, system design or development, were asked to join the survey. As a first result of the survey, only members with a technical background answered. Also, in one case a pdf was send due to technical problems.

3.1 *Did we find the relevant persons?*

As shown in Figure 5, 27% of the members with technical background participated in the survey, by means of filling out or declining the participation.

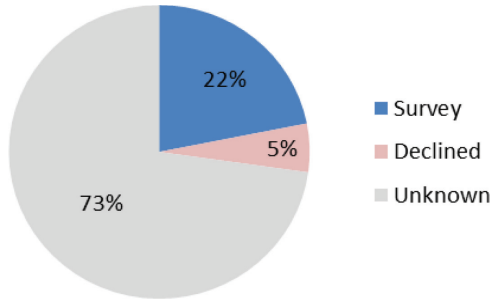

Figure 5. Distribution of participants.

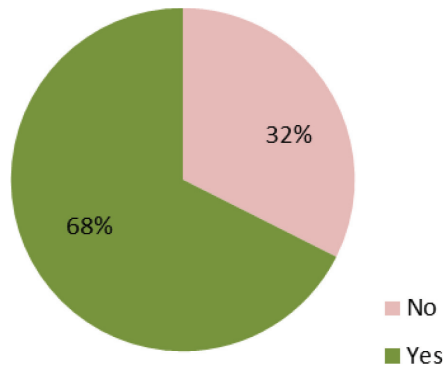

Figure 6. Safety experience.

To distinguish participants with and without safety experience, it was offered to answer only the first question and to leave all others unanswered for participants without experience. Figure 6 shows the distribution of participants with and without experience. Related to Figure 6 and regarding an amount of 68% of participants with safety experience, ~15% of the team with technical background answered the survey while gained safety experience.

To classify the level of experience in beginner, experienced and expert levels, data was classified by years of safety experience, the number of projects attended and a self-assessment of the participant. In Figure 7 the classification results are shown. About half of the participants had gained beginner experiences, i.e. less than 3 years safety experience and less than 5 projects attended. The rest is split equally into experienced with 5–20 years and safety experts with more than 20 year experience and more than 7 projects attended.

The field of work was additionally analyzed. In Figure 8 the expected distribution is shown. Most of the participants work in the field of research, because of the research nature of the project.

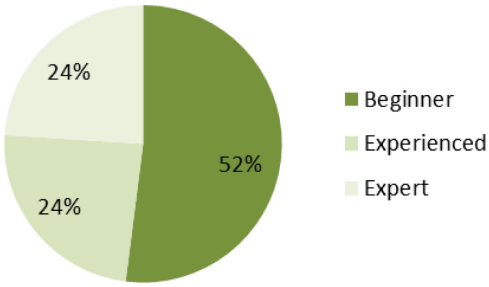

Figure 7. Distribution of safety experience.

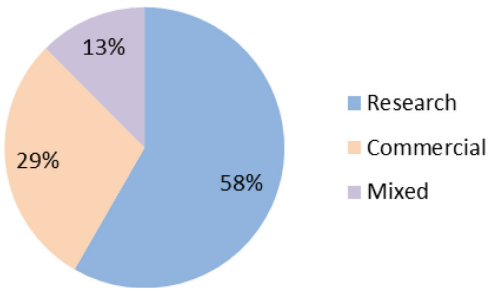

Figure 8. Participants field of work.

In summary about 22% of the project team answered the survey. A good mix of research and industrial experience was found. The participants mainly work in the field of research with a good knowledge of applied standards. They develop new methods, like method driven approaches. At least the participants are experienced in applying safety methods.

3.2 *Applying safety methods*

Regarding the question "Did we find the right applied methods and processes?", analysis of the application of safety standards and methods was done.

In the survey, the following in aerospace mainly employed standards like DO-178b, DO-178c, ARP4754 and ARP4761 were given. In Figure 9 the applied standards are depicted. Also the additionally application of special standards, like ARP 4763 and Mil882, is shown.

Next question to be answered was, to analyze the number of applied methods among the development stages. Figure 10 shows the number of participant applying methods in each development stage.

Unexpected were the results of Concept and System Design stage. One reason may be a different understanding of development stage definition,

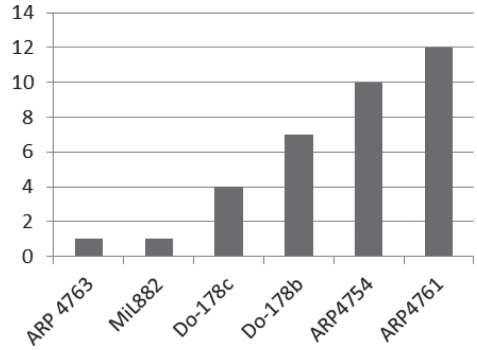

Figure 9. Number of participants applying safety standards.

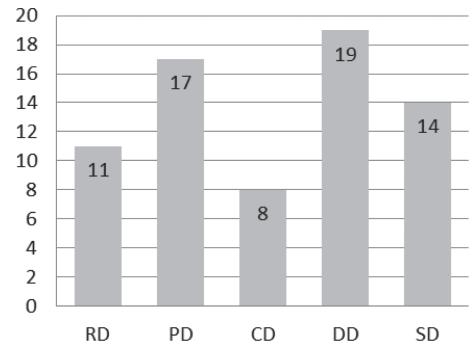

Figure 10. Number of participants applying methods.

applied in systems and safety engineering. Also a reason could be, the different definitions in the applied standards. With regard to (INCOSE 2011), the understanding of what is covered by a development stage depends on the development process. By our expierience made in different domains like aerosapce, aircraft and automotive, merging of stages is recommended. Therefor from the safety engineering perspective Preliminary and Concept Design are merged into a Concept stage and Detailed and System Design into a Detailed stage. This merge is proposed as a safety system engineering process. The number of participants applying safety methods for this recommodation is shown in Figure 11.

Shown in Figure 10, also and according to our expectation, the amount of participants applying safety methods in the early stages is less than in later development stages. This may lead to uncovered safety requirements in the ongoing development process.

Did we find the right methods?

In Chapter 2, applicable methods for each development stage were presented. To validate our classification and assignment of those methods, the

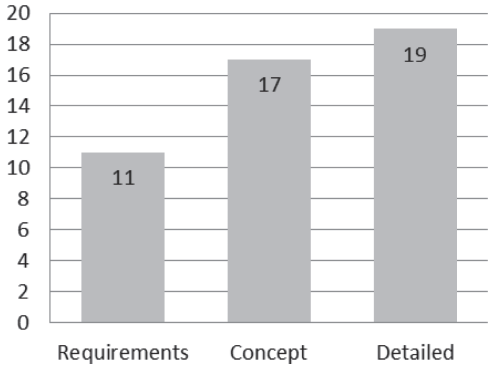

Figure 11. Number of participants applying methods for the recommended merge of development stages.

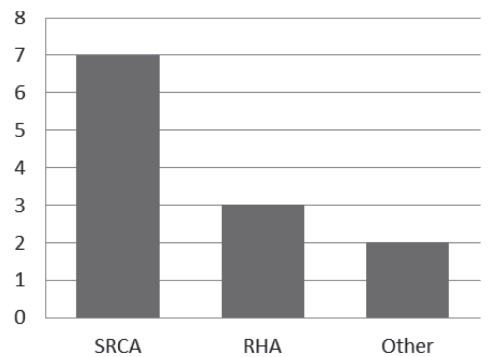

Figure 12. Participants applying methods in requirement stage.

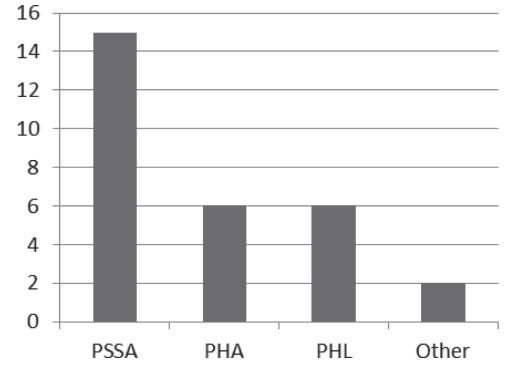

Figure 13. Participants applying methods in concept stage.

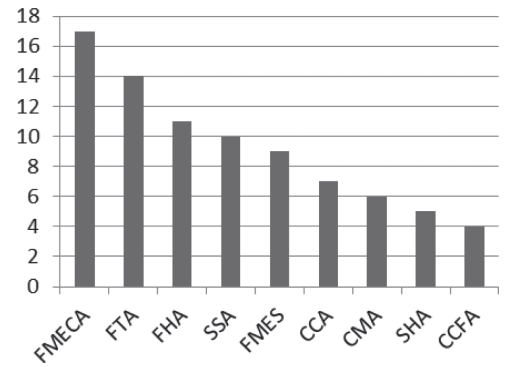

Figure 14. Participants applying methods in detailed stage.

survey answers had to be analyzed. Unfortunately, in the cases that other than the given methods are applied, participants did not mention those methods.

Figure 12 shows the number of participants applying the proposed method during the requirement stage. Besides, only two methods where proposed: SRCA and RHA. SRCA is the most applied method and shall be considered as standard method for the requirement stage.

Regarding the recommended merging, the Concept stage depicted in Figure 13 shows the number of participants applying PSSA, PHA, PHL or other methods. As shown PSSA has a wide user basis: therefore this method is recommended during the concept stage. Note that for the PSSA several methods like FTA and CCA (Common Cause Analysis) are used which are also depicted in Figure 14.

In opposition to the first two stages the detailed stage contains a wide set (~ 30) of applicable methods. The results for detailed stage are presented in Figure 14. As expected nearly all proposed methods were used by the participants, but only methods applied by a minimum of 4 users were presented.

FMECA is the most applied method during detailed stage. This bottom up method can be performed on functional level. But normally it will be performed on part level. On the other hand the second most applied method is FTA. This top down method is usually performed on functional level. One of those methods is recommended, depending on a top down or bottom up development strategy. Applying both methods during a safety assessment leads to coverage validation. In case any function or part is not covered by FMECA or FTA this will be recognized. To complement the safety assessment in this stage additional methods are necessary. Which methods shall be applied, depends on the safety requirement demand by the employed standard.

3.3 *Which tools are applied?*

The safety goals of the applied methods during requirements and concept design are identification

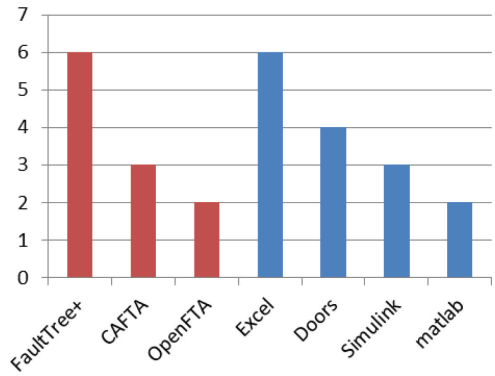

Figure 15. Applied tools.

of hazards, events or risks at system level. Also the assignment of those hazards, events or risks to functions or system elements is required. These methods can be implemented by the use of tables. Common tools providing these functionalities are Doors or Excel. (J. Langheim 2010) shows both tools are used in safety projects. An exchange of data among those tools and our system model PREMISE are implemented easily and shown in (H. Schumann 2010).

Some methods applied during the detailed design like FMECA or FHA can also be implemented in Excel or Doors (Total Quality Management 2013). But others are more complex like FTA. During this analysis a Fault Tree has to be constructed. Implementation of Fault Trees in Excel or Doors is possible but the maintenance is hard and error prone. Therefor a set of tools exists especially for FTA shown in Figure 15.

A little surprise was Matlab and Simulink tool, because those tools are usually applied in systems exploration (Vanderperren and Dehaene 2006). On the other hand implementing a safety method for example risk evaluation on batteries are easily made as shown in (C.G. Wang 2013).

4 CONCLUSION

The survey showed which safety methods are considered in the systems engineering process. But it was also shown that there is a tendency starting late applying safety methods. According to INCOSE 2011, the project risk and effort can be reduced by a factor of 10–1000 by regarding safety requirements early in systems engineering process.

Additionally it was depicted, that most of the methods and standards are well known and applied by experienced engineers. However, new research related methods were applied late or even not. Thus, methods like model based development provide a solution for long term support in development and maintenance.

By defining a systems safety engineering process with three stages, we recommend applying top down safety methods, like SCRA and FTA. Furthermore in the late development stages, bottom up methods like FMECA comply this process. Combining top down and bottom up approaches in the development strategy, a validation is possible. Therefore, by identifying hazardous events of system functions in FTA and identifying hazards and their causes on part level in FMECA, coverage is possible. Also uncovered functions or system parts are detectable.

The recommended tools for safety assessment during the requirements stage are table based tools like Excel or Doors. Both tools are well known in the engineering domain. In the later stages, Matlab Simulink may be used for the evaluation of system and safety aspects. Depending on applied safety methods, specialized tools, comply the safety analysis in those stages.

According to the survey results, the fault tree analysis is the most applied method by safety engineers. Based on this result and the applicability of this method, a demonstrator for data exchange among tools using PREMISE system model was realized. The presentation of this work would exceed this paper and will be presented in an additional publication.

Semi-formal static and dynamic modeling and categorization of airport checkpoints

P. Renger, U. Siebold, R. Kaufmann & I. Häring
Fraunhofer Ernst-Mach-Institut, Efringen-Kirchen, Germany

ABSTRACT: Airport check points are vital infrastructure for secure and safe air transport. They consist of an ever increasing number of components. Also the interactions between the checkpoint components as well as the checkpoint itself and external systems are expected to further increase in the future, e.g. if profiling and more risk based methods are applied. As a basis of analyzing airport checkpoints with respect to security and safety a sufficient system understanding is a prerequisite. The Systems Modeling Language (SysML) is used to accomplish that, which is a system engineering adaption of the Unified Modeling Language (UML). We show how static and dynamic properties of airport checkpoints are modeled using SysML. Aiming at an overall modeling of different airport checkpoint designs, we model a generic airport checkpoint design using SysML. The model comprises standard airports as in operation at many airports today. Throughout the paper, we give a broad outlook how these semi-formal models are applied to new ACP concepts as for example proposed by the famous "airport of the future" project as well as distributed checkpoints, where parts of the screening happens "on the fly" by stand-off screening equipment without intrusion for the passenger.

1 INTRODUCTION

Triggered by the rise of hijacking in the 70 s and the events of September 11th, ever intensified regulations for airport security came into effect, e.g. 107th Cong (2001), European Commission (2002), (2008). Despite the fact that the International Civil Aviation Organization (ICAO) adopts standards and recommendations for the aviation sector, the laws concerning airport security are predominantly national (Nelson and Walker, 2011). This circumstance together with the increased security level has a huge impact on passengers and the aviation business and those businesses that depend on air transport. (Schiphol Group, 2009, AIC Europe, 2010).

Health concerns, loss of privacy and time consuming procedures and queues lead to a negative passenger experience at Airport Check-Points (ACPs). AIC Europe (2010) reported that for European airports security accounts for 35% of airport operation costs. The EU-funded international collaboration project XP-DITE (XP-DITE Project, 2013) is dedicated to the above issues, approaching the ACP from a system level point of view.

This paper does not restrict consideration and modeling of ACPs to the limited number of systems currently compliant with regulations from the EU or the US American Transport Security Administration (TSA). The static and dynamic semi-formal modeling approaches proposed in this paper enable the assessment of future, alternative ACP designs, taking into account common performance indicators and deviations from current regulations. The goal behind the research is also to understand and develop future ACP concepts with the help of the presented modeling techniques and in a second step with executable models to assess the performance of these concepts.

Section 2 reviews the state of the art of airport checkpoint modeling and simulation. Section 3 presents roughly the semi-formal system modeling language. Section 4 shows and explains modeling of conventional and innovative ACP systems. Section 5 concludes and gives an outlook.

2 STATE OF THE ART IN AIRPORT CHECKPOINT SECURITY MODELING

Looking at the literature for airport security, we notice that there are many books treating the very popular subject of terrorism, which always implies aviation security. Also books treating only the subject of aviation security are available (Sweet, 2002) (Seidenstadt and Splane, 2009). A scientific approach to measure, optimize or assess the security or performance of the airport or subsystems like the security checkpoint on an integrated

overall system level is not really covered in the scientific literature.

There are various commercial products available to model and simulate performance of economic and operational aspects. Manataki and Zografos (2010) and (2009) modeled an airport terminal as a flow model with UML for this purpose. Other works focus on time performance of functional areas in the airport. Van Landeghem and Beuselinck (2002), Soolaki et al. (2012) and Nyquist and McFadden (2008) tried to optimize the boarding time while Hsu et al. (2012), van Dijk and van der Sluis (2006) and Park and Ahn (2003) tried to improve the check-in procedure.

2.1 *Airport security analysis tools*

Some regulators have developed their in-house solution for software based assessment of the ACP security level [personal communication]. These tools simulate operational aspects like throughput but also security aspects, e.g. detection rate and compliance with current regulations. Usually these tools have a Monte Carlo approach in common, using several instances of a passenger type with distributions for carried threats and other relevant attributes. TSA developed a Security Checkpoint Optimizer (SCO) software to simulate operational and security performance (Wilson et al., 2007). All these tools have the drawback that the components are thought as statistically independent and no human factors with regard to the ACP staff are taken into account, obviously a major model restriction.

Driven by the Homeland Security, MITRE, a not-for-profit organization chartered to work in the public interest, developed an agent-bases Simulation for the whole airport security. The simulation is covers the attack on an airport. The checkpoint is a part of the whole airport security and registered travelers and other passengers are considered differently (Weiss, 2008).

2.2 *Security screening*

For ACPs, the research seems to be strongly driven by the TSA policy. Papers published in journals often show a connection to a regulation or standard rolled out by the TSA. After the events of 9–11 the TSA required the airports to screen 100% of the checked baggage. This led to a number of publications to help solving this problem with time and budget that is in accordance with the economic requirements (Hafizogullari et al., 2003, Jacobson et al., 2005a, Jacobson et al., 2005b, Leone and Liu, 2003, Sahin and Feng, 2009). The paper from Sahin and Feng (2009) introduces prescreening of passengers to optimize the checked baggage screening. de Barros and Tomber (2007) and Holguín-Veras et al. (2012) used discrete event simulation to examine the checkpoint performance and its impact on design and operation of airport terminals.

Prescreening is another security measure introduced by the TSA that influenced many publications. There was already research in this direction from Jacobson et al. (2001). Along with discussions about the different systems introduced by the TSA, researchers tried to quantify the benefit of prescreening for the security process. Lazar Babu et al. (2006) used linear optimization to assign passengers to different screening procedures with the aim to minimize the risk while the capacity of the screening devices is restrained. This approach assumes that every passenger poses the same risk to the system. The works of Nie et al. (2009), McLay et al. (2006) and McLay et al. (2010) assign a varying thread probability. An example with two lanes with strong and normal checks is done by Nie et al. (2012). Nikolaev et al. (2007) used a greedy heuristic for passenger grouping to minimize the risk with a precedent step in which the security devices are set up restrained by space and budget.

Evolutionary optimization is a less commonly applied mathematical approach. But it allows to optimize cost, delays and risk of a check point at the same time (Concho and Ramirez-Marquez, 2012). Others like Olapiriyakul and Das (2007) used queuing theory to measure time consumption for screening and determine the required staff and equipment. Wang and Zhuang (2011) used also the queuing theory to minimize the waiting lines and game theory to simulate the passengers reaction on waiting lines. To propose better check point designs, Leone and Liu (2011) used the queuing theory to measure the performance defined as screening time of different check point designs. Those standard designs are purposed by the TSA in an older version of the Checkpoint Design Guide, now replaced by (TSA, 2009).

2.3 *Integrated view on the security checkpoint*

Within the work discussed, the level of resolution of airport checkpoints ranges from system level, where the whole checkpoint is characterized by a number of attributes, to component level.

All the publications named above have in common that only one aspect of the ACP is assessed. No publication takes an integrated approach to ACP performance. Modeling presented here aims at an integrated approach, also as basis for simulations, i.e. to cover costs (which includes all operational and capacity aspects), compliance with regulations (which cover all aspects of security), and finally

customer satisfaction. An even more thorough and holistic approach would also include the ethical dimension, which is not always directly linked with passenger satisfaction. The publication which covers cost and security is the one from Nikolaev et al. (2007). The above described approach from (Concho and Ramirez-Marquez, 2012) already covers partly each performance area.

2.4 *Research approach*

Using SysML, this paper models not only the structure and function of current ACP concepts but also possible future configuration as discussed for example in the checkpoint of the future from the International Air Transport Association (IATA).

The purpose of the modelling is to lay the basis of an integrated ACP performance prediction, considering all performance aspects along with security.

The basis of the analysis of ACPs are their models that employ OMG's System Modeling Language (OMG, 2010).

3 SEMIFORMAL SYSTEM MODELING

3.1 *General*

There are many modeling languages that are dedicated to the modeling of systems. The Object Process Methodology (OPM) applies a holistic approach to model complex systems. Main elements of OPM are objects, processes and states (Dori, 2002). It is also one of the state of the art system modeling languages (Grobshtein et al., 2007).

The Architecture Analysis & Design Language (AADL) focuses on the modeling of systems that have to fulfill requirements regarding the demand of space, energy and memory. Therefore it supports the estimation of performance, reliability, and schedulability (Feiler et al., 2006, SAE Aerospace, 2004).

AltaRica is a modeling language that mainly uses hierarchical nodes that contain states and transitions (Griffault and Point, 2006). Among other things it can be used to analyze concurrent processes (Arnold et al., 2000).

3.2 *State of the art in modeling security systems*

SysML is one of the latest semi-formal modeling languages and developed by the Object Management Group (OMG). Derived from a subset of UML and extended with components for system engineering it is a promising candidate for a widely used standard modeling language for complex systems. (Weilkiens, 2008). We have selected SysML to model the airport checkpoint within the overall ACP evaluation approach mainly because of its multi-disciplinary application domain, graphical representation and general acceptance.

SysML was developed to model huge complex systems like an airplane. It is proven to be useful for system design and development. There are books describing system engineering with SysML (Weilkiens, 2008, Debbabi et al., 2010) as well as papers (Hause et al., 2005).

In SysML, the diagram elements for requirements modeling are a completely new extension of UML. Soares et al. (2011) describe requirements modeling for software-intensive systems and propose some extensions to the SysML requirements modeling tools.

Other publications focus more on specific aspects of SysML or system engineering. Some authors focuse on an aspect of SysML like activity modeling. Bahill and Szidarovszky (2009) compared several methods for model driven design including various aspects of SysML and Lopes et al. (2011) used it for the system engineering of smart grids.

Also whole product service systems were modeled, including not only the product understood as engineered system but also the customer service provided to the end user (Durugbo, 2012). Geyer (2012) uses SysML for performance-oriented sustainable building design and showed generic models of typical requirements, design structures and flows of energy and resources. This already shows the applicability of SysML for system analyses.

Beside the main use of SysML in the design and modeling of complex systems, numerous publications describe the use of SysML for system analysis regarding safety our security issues. David et al. (2010) describe a method to assess how the functional design process is linked to reliability techniques with automated model analysis of the SysML model. Grunske and Joyce (2008) used SysML to provide a quantitative security evaluation for component based systems. They created modular attack trees for the components in the system and also transferable attack probabilities between the components to explore vulnerabilities in multiple system components.

SysML does not provide the utilities to test the system or validate it against the requirements. Therefore Linhares et al. (2007) proposed to complement the modeling with petri nets and validate it with the TINA toolbox. A very useful approach when it comes to simulation is the mapping/connection between a conceptual model and the computational process or

simulation program. McGinnis and Ustun (2009) showed this concept using SysML and Arena. Pedroza et al. (2011) presented AVATAR as a SysML environment for the verification of safety and security properties in embedded systems.

3.3 *Requirement analysis and use cases*

To model a system in SysML, which is in our case the airport checkpoint, it is crucial to formulate the purpose or the main function of the system. In case of an ACP this is clearly given. The airport checkpoint should execute screening and inspection procedures to identify dangerous objects in cabin baggage and on persons. This main use case leads to a lot of follow-up requirements. But there are also other SysML use case diagrams like a possible intervention of a law enforcement officer for alarm resolution. In our work we focus on the screening of passengers and their belongings.

3.4 *Block diagrams*

Block diagrams are used to model all components within the system and the relations between them. The block definition diagram (bdd) in SysML defines features of blocks and relationships between blocks such as associations, generalizations, and dependencies. It captures the definition of blocks in terms of properties and operations, and relationships such as a system hierarchy or a system classification tree. A special block named constraint is used to model the constraints on properties of the system.

The internal block diagram (ibd) in SysML captures the internal structure of a block in terms of properties and connectors between properties. A block can include properties to specify its values, parts, and references to other blocks (OMG, 2010). The ibd shows in what role (instances) the elements of the bdd are used in the system.

3.5 *SysML behavior diagrams*

Additional to the structure of the model, diagrams are needed to express the behavior of the ACP. We mentioned briefly the use case diagrams which give the behavior of the system with regard to actors outside the system. Use cases specify the general interaction of the system with a specific user.

The activity diagram (act) shows in more detail what happens inside the system during the operation. It describes which actions are executed and what kind of information or condition has to be fulfilled that lead to the next action. The actions can be operations defined in a block and/or just another activity. The level of detail depends on the model purpose.

Another view on the behavior of the system is the state machine diagram (stm). It describes the configuration of the system with regard to its attribute values. Each set of possible attribute values make up one state. The state machine diagram names some of these states and gives information on what conditions and events lead to another state.

The sequence diagram describes the flow of control between actors and systems (blocks) or between parts of a system. This diagram represents the sending and receiving of messages between the interacting entities called lifelines, where time is represented along the vertical axis. The sequence diagrams can represent highly complex interactions with special constructs to represent various types of control logic, reference interactions on other sequence diagrams, and decomposition of lifelines into their constituent parts (OMG, 2010).

4 SEMIFORMAL MODEL OF AIRPORT CHECKPOINTS

4.1 *Airport checkpoint structural model*

The ACP is a combination of interacting screening and logistical components. The core elements the detection devices to screen people and their baggage for prohibited items. To make screening possible in an organized way and as fast as possible, multiple additional components, here after called logistical components are necessary. Examples are desks for divesting, queuing stanchions or all sorts of barriers. For the operation of an ACP various staff members with different tasks need to be present at the ACP.

4.1.1 *ACP elements in a block definition diagram*

There are many possible main categories of ACP elements. To understand the function of each element a block diagram can be used to group and categorize them.

The ACP as a whole can be modeled by a central block with several connections to subsystems and components, as well as flow ports, in this case two, indicating the passenger flow through the ACP. The important point to notice is that the block definition diagram does not show an actual instance of a system but the elements and their relations in a potential instance of the system.

For one thing, there are subsystems connected with a composition to the ACP. The subsystem called lane is connected via an aggregation to the ACP. The components themselves are connected with a generalization to the block screening device. All detection devices have several attributes and operations they share that are expressed with the generalized component. In addition to the attributes

the detection devices have in common, each device has attributes specific to its technology.

Several components build up a lane. As a component could also exist on its own, the connection to the lane is an aggregation. In contrast, a lane cannot exist on its own because it is dependent on the existence of the ACP. This is expressed by the connection with the ACP in form of a composition.

There are components directly connected to the ACP or first aggregated to a lane and within this subsystem part of the ACP. The idea behind that way of modeling is that some elements like personnel or private screening areas are shared over the whole ACP and therefore over several possible lanes, whereas the elements in a lane are not shared and only used and functioning in the context of a subsystem.

In addition to the components having a screening function, there are structures used to encircle the ACP, organize passenger flow and screening processes. These are also generalized, indicating the similar tasks they fulfill in the ACP.

The path elements through the ACP are special because these are not actual physical elements but an abstract concept to plan and analyze possible ways of the passengers through the ACP. When used for simulation, these model elements are quite important for flow and queuing analysis. The path is connected with a composition to the ACP, which is quite clear because dissolving the ACP would make the path disappear or rendering the concept of paths useless. On the other hand, the path shares some properties with the block logistical structures, as it is also used to guide and control passenger flow.

4.1.2 *Simple ACP lane in an internal block diagram*

In Figure 1. the internal block diagram of a simple ACP is shown. It represents those aspects of an ACP which are commonly seen at airports by regular passengers.

The internal block diagram shows the elements of a system in their role they have to fulfill in the considered instance of an ACP. In this case it is a small ACP consisting only of one lane with some extra elements. The components are instances of their block representation. Each instance fulfills a specific task in the overall system. In the shown example this is the case for the block screener. Depending on the position in the system the screener has to fulfill different tasks.

The block queuing area is also used two times in the ACP. One lane is for priority passengers and the other one for all other passengers. Obviously this leads to shorter waiting times for priority passengers. Both groups share a divesting area, where the flow of passengers and their belongings

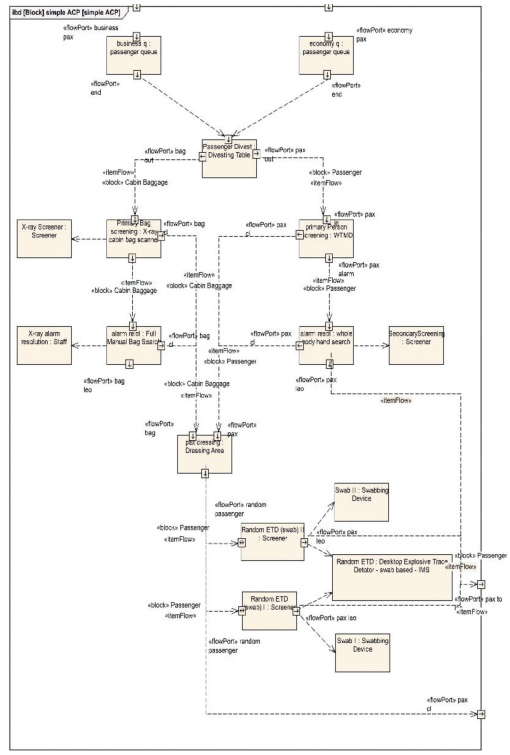

Figure 1. SysML internal block diagram of standard airport checkpoint.

is divided. The baggage goes through an X-ray machine. The X-ray machine depends on a screener as indicated with the arrow symbol used for such a relation between two blocks. After the X-ray there is either an alarm resolution or the baggage is available at the dressing area. If the alarm resolution fails, a Law Enforcement Officer (LEO) takes over and the baggage leaves the ACP not cleared.

On the other path parallel to the baggage the person is first screened with a metal detector. If necessary an alarm resolution is executed by a staff member doing a pat down. If the alarm is not resolved, the passenger leaves the ACP as not cleared and is handed over to the LEO.

Otherwise the passenger reclaims the baggage at the dressing area, where the two paths for passenger and baggage meet. Leaving the dressing area, the passenger is either chosen to be screened for explosive traces or he can move on undisturbed to the gate. The trace detection is performed by two screeners, each using a swabbing device. Together they use the actual trace detector. The passenger is either handed over to the LEO if an alarm was raised or the passenger can proceed to the gate.

The ibd shows the path of passengers and/or bags through the ACP including the junctions and joints. The flow ports indicate both the item, i.e. passenger or bag flowing through, and the status, e.g. alarm cleared.

Thinking already of evaluating the model of the ACP, it is very useful to determine all possible paths a passenger and its belonging can pass. There are blocks with more than one flow port with an outward direction. For simulation some decision logic or probability must be given, determining which flow port is passed by the flow element. In addition to that information, every block has a processing time and capacity in terms of the number of objects it accepts. With the ibd and the mentioned information, first system analysis methods and performance predictions are already supported by the system data modeled with SysML. The data can be used for running a Monte Carlo simulation with a sufficient number of passengers for computing for instance throughput. If queuing theory should be applied the problem of synchronizing the passenger and baggage flow has to be solved first. These examples show that the modelling suffices for the application of performance and security assessment methods.

4.2 *Airport checkpoint behavior modeling*

In the previous section the structure of a simple ACP was presented. Assuming that each component acts independently from the others, the internal block diagram and the description of the components and its attributes are a good basis for a simple analysis and also for running such a model.

In reality the screeners and components react on each other and alter their behavior according to the output of other checkpoint elements. This concept is even more present in so called new and innovative ACPs as discussed in projects like the IATA checkpoint of the future. The present paper does not discuss such ACP concepts with respect to operational or security aspects.

The paper aims at presenting SysML as a modeling tool to represent both structure and behavior, respectively. The structure was discussed in the previous section and in the following sub subsections an activity diagram, a state machine diagram as well as a sequence diagram are shown.

The behavior diagram not presented in this paper is the use case diagram. However this is usually used together with requirements modeling more likely in the planning phases. We focus on SysML modeling for system analysis and evaluation rather than requirements modeling.

4.2.1 *Activity diagram of a simple ACP*

In the activity diagram of the generic ACP, see Figure 2, the principle of independent screening

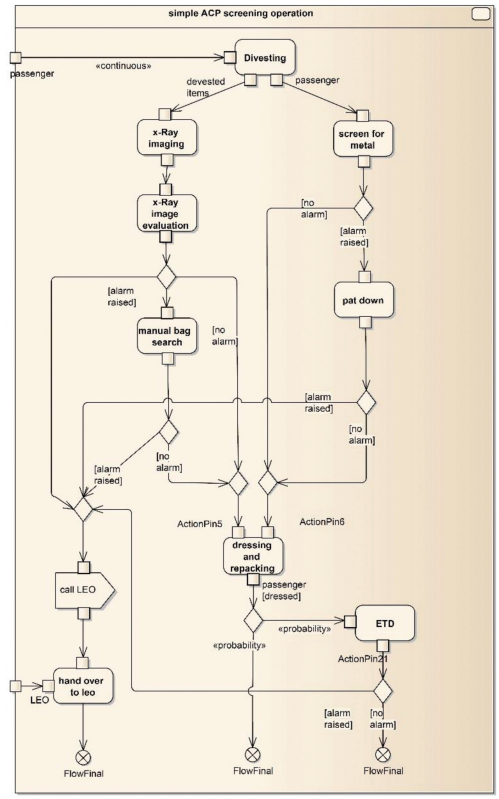

Figure 2. SysML activity diagram of standard airport checkpoint.

equipment lead to nearly no additional information compared to the internal block diagram. The structure of the activities and the connections resembles the one seen in the ibd. As already pointed out in the introduction to this section, this is the case because each component has a single purpose in the ACP and acts independent from the other subsystems in the checkpoint.

The activity diagram adds some information to the process like specifying a continuous input stream of passengers. In the internal block diagram some blocks have one input and two outputs. The flow ports there show the object passing through, however, the logic of the decision is not part of that diagram. The words “probability” or “alarm” and “no alarm” beside the diverging paths indicate the logic behind the decision.

4.2.2 *Sequence diagram for an ACP with sensor fusion on data level*

As explained along with the internal block diagram of a simple ACP lane, the current detection devices do not communicate with each other and each

system provides an independent result with respect to the operation of other components.

In the future, more complicated systems are desired to achieve a more diverse screening process, which reacts on results of other components. Also several results of different screening components are expected to be combined to find a better judgment concerning the status of a screened object, while reducing false alarms. This also allows a faster flow through the ACP as there is no alarm decision after every screening device but only if information has cumulated. If alarm resolution components are less distributed and separated from the main passenger stream, more than it is usual today, the hope is that a significant amount of passengers could go much faster through the ACP.

The sequence diagram of Figure 3 shows the function of such an ACP. The involved components are lined up at the top of the diagram. Each component has a live line attached to it. Between the live lines, arrows indicate signals sent between components. There are arrows indicating synchronized and not synchronized signals. When time advances, the arrows are attached to the life line farther towards the bottom of the diagram.

The diagram describes how the components send their screening information to a central unit. This unit requests a decision on alarm resolution from an extra component. This is the core function of an ACP with sensor fusion on data level.

Additionally, there is the necessity to recognize the passenger at each step in the screening process to make sure that the results of the screening is attached to the right person. Therefore the passenger has to register himself at the entrance of the ACP. Leaving the ACP the result of the screening process is requested and either the exit gate opens and the passenger proceeds to his gate or the passenger is led to a place where alarm resolution is performed. The sequence diagram indicates this decision with a box containing both versions of the behavior divided by a dotted line.

The use of data fusion allows another type of ACP. The function of this ACP is presented in the following sub subsection.

4.2.3 *Activity diagram of a distributed ACP*

In a (theoretical) distributed ACP people move more freely. One realization could be achieved by registration every passenger upon entering and

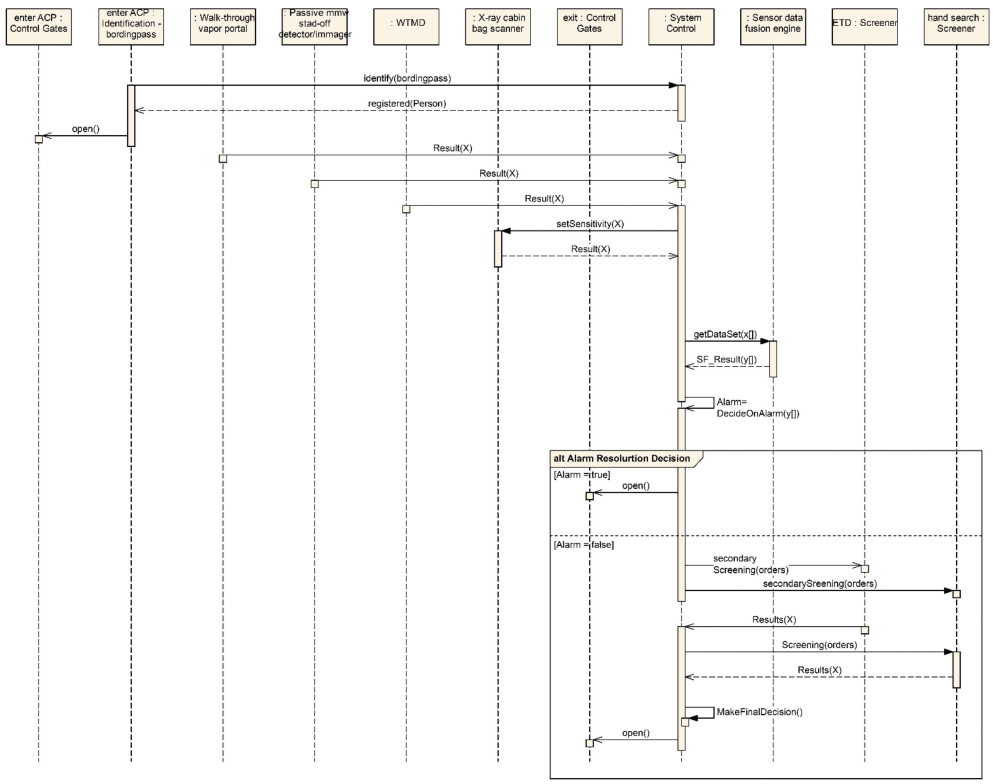

Figure 3. SysML sequence diagram of ACP with sensor fusion on data level.

exiting the *screening* area and making a final decision on alarm resolution upon request from the overall screening system. The screening area itself could be any confined space accessible to the passenger inside the airport, e.g. the check-in hall, commercial area, or passenger lounge.

The screening areas might be equipped with several stand-off detections devises used to screen the people while present in the screening area. Additionally people could be tracked (e.g. biometrically) to connect screening results with persons' identities. A centralized processing unit could merge the results and decides if a further, more thorough screening (e.g. conventional ACP screening) is necessary when leaving the screening area.

The process is modeled with a SysML activity diagram in Figure 4. In this diagram we use the Accept Event Action and Send Signal Action elements to illustrate the communication with the continuous screening part and the exit control mechanism. Parallel to the passenger proceeding to the screening area, the process of tracking and screening is started. This actions are surrounded by an interruptible activity region and are going on till the signal of a leaving passenger is received. This stops the screening and tracking and causes

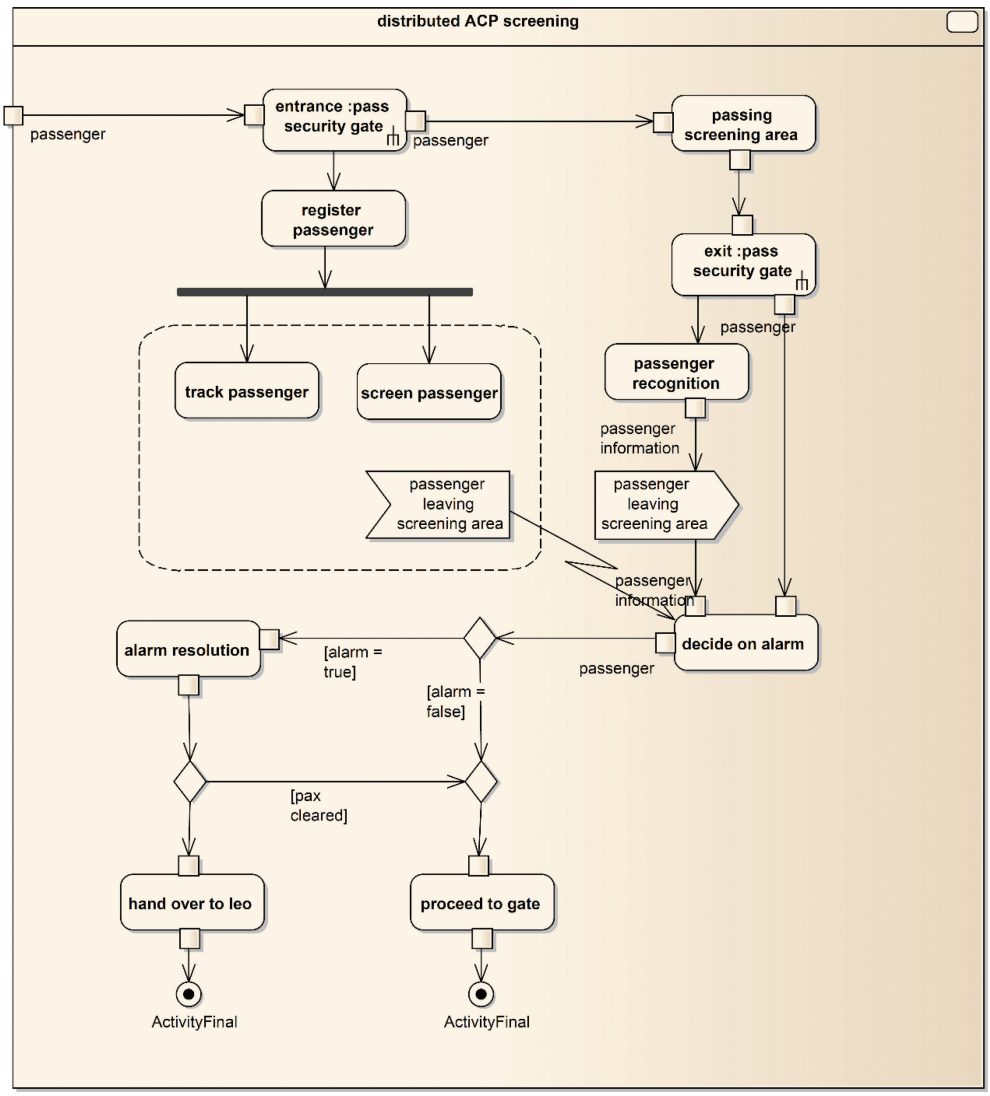

Figure 4. SysML activity diagram showing the passenger handling in a distributed ACP.

the action "decide on alarm resolution" to be executed.

Furthermore the concept of a Call Behavior Action, indicated by the little fork under the action name is used for the activity entering the control gate. This activity consists again of various actions modeled in a separate activity diagram. This is quite useful when modelling reoccurring sets of activities in a condensed way in the context of the overall process.

4.2.4 *State machine diagram to determine passengers' screening status*

One of the security concepts of an airport checkpoint is that screened people are strictly separated from people that are not yet screened. This is an obvious way to exclude the exchange of prohibited items between passengers. In a distributed ACP it is the standard situation that at any time passengers with different screening status can meet each other and also can exchange items. This problem has to be solved by using a screening area with a relative low density of persons (e.g. multiple path-like geometries) and by continuously updating the state of the passengers.

Figure 5 shows a state machine diagram of a single passenger. The state machine diagram keeps track of the state of the passenger with respect to two different screening methods and the passenger tracking while moving around in the screening area.

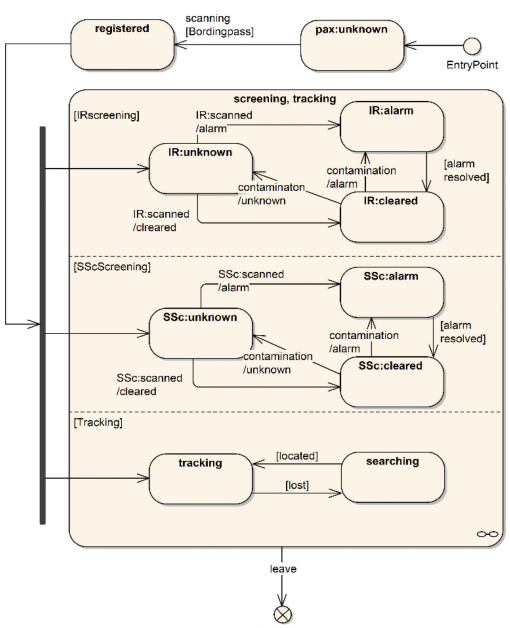

Figure 5. SysML state machine diagram for the passenger sta-tus, while being screened in a distributed ACP.

The logic displayed in the diagram is that if passengers come too close to one another, the passenger with the better screening status switches to the state of the person just met. The process of screening competes with this mechanism that people 'contaminate' each other. Every time a passenger passes by a detection device and nothing is found the passenger state improves again. So the concept of distributed checkpoint works only if people are faster cleared than they can contaminate each other. This could also mean to remove problematic passengers from the screening area.

A prerequisite to this kind of handling the passenger is that the system has to know the location of the passenger at all times. The passenger screening state switches back to unknown if the tacking system has lost the passenger for a significant amount of time.

5 CONCLUSION AND OUTLOOK

The paper gave an overview of modeling and simulation efforts in the domain of airport checkpoints and an overview of SysML modeling in domains close to the airport operation and security.

We focused on the static SysML modeling of a classical airport checkpoint and the dynamic modeling of more modern airport checkpoint designs. In particular, we showed how to model dynamic screening sensor data fusion using SysML sequence diagrams. We used SysML activity and state machine diagrams to model the behavior of a distributed airport checkpoint.

We will elsewhere give further SysML diagrams relevant for the checkpoint of the future and distributed checkpoints. We showed how information for typical current security and performance modeling approaches can be extracted from the presented SysML models. To this end, we are planning to employ the SysML models in future work.

The overall goal is that various performance areas can be assessed and optimized against each other with the help of underlying SysML models.

Achieving safe designs through evaluation of options at the conceptual level of safety system design

E. Alijagic & V.N. Dang
Paul Scherrer Institute, Villigen, Switzerland

ABSTRACT: When designing a safety system according to IEC61508/61511, after the risk/hazard analysis step that produces a set of Safety Functions (SFs), the designer is obligated to execute a number of additional steps. Some of these steps are:

– Allocating the target Safety Integrated Level (SIL) (or Risk Reduction Factor RRF) for each SF,
– Developing the Safety Requirement Specification (SRS),
– Developing safety system concept design and
– Verifying that the concept design meets the target SIL.

Given the set of SFs, the designer typically generates a number of options in the concept phase. These options are clearly constrained by the way both SFs and their RRFs are specified. This has consequences for the subsequent lifecycle's steps too. When considering protection against a single consequence of different severities by multiple SFs, it may be beneficial for generating the concept design proposals to allow for variations in the RRFs while keeping the overall risk reduction below a tolerable level. Allowing variations in the RRFs could help to achieve cost savings in the associated design proposal. These savings can then be reinvested to achieve additional tightening of the SFs within this new design option.

The aim of this paper is hence twofold: (1) to show how variations in the RRFs affect the design options, and (2) to introduce a rough cost model to discriminate between the options on cost basis. We demonstrate the method using a case study.

1 INTRODUCTION

A safety system is needed for the purpose of mitigating a risk or bringing the process to a safe state if a dangerous process failure occurs. The system provides the protection through a number of safety functions. The Risk Reduction Factor (RRF) and Probability of Failure on Demand (PFD) are the primary variables used to specify the safety robustness of such a function. These factors, once fixed, affect the designer's decisions in subsequent design steps regarding the architectural constraints (IEC61508, IEC62061, ANSI/ISAS84.01) as well as corresponding testing/maintenance procedures. Except for trivially simple safety system architectures, the factors alone are generally not sufficient to realistically address the implementation, maintenance, and testing costs for additional design options made through the lifecycle.

It is widely accepted (Sallak et al. 2007) that optimization methods are necessary to determine attributes such as redundancy and reliability parameters in order to maximize the safety.

When generating cost-effective design options (Amari 2006), the designer typically poses questions such as which vendor to choose, how to keep the overall availability of safety functions at maximum, and how to keep overall design costs at minimum. In this respect, the designer would like to have a methodology that effectively controls the costs in the early design phases. Although he follows rigid guidance from the standards' lifecycles when designing the system, there are still opportunities where decision making may have different cost impacts without jeopardizing safety.

When assessing the risk R^{EUC} for the baseline system, the designer is tasked to address each hazard category separately and systematically (IEC60812, IEC61508). Per category, he first determines the tolerable risk level R^{tol}. Then moves to identifying and quantifying the risk contributors (hazardous situations). After deciding how to provide the necessary protection by safety functions, RRF and PFD targets are allocated.

The process of RRF allocation necessitates (IEC61508) quantification of the failures in the underlying process in the first place. Subsequently, the designer continues with selection of the physical components for the safety functions.

The method proposed in this paper refers to a safety system implemented by a single layer of protection. The purpose is to give a methodology

that helps the designer with selection of RRF and PFD targets that minimize the design cost without jeopardizing the required safety level target.

It is also presumed that the redundancy of components within a safety function is:

- realized by components with same PFD meaning that the same PFD is allocated to all components within a component system.
- implemented independently. As common cause failures are major problems for high-reliability safety systems that depend on redundancy, an insufficiently independent implementation of such components can severely reduce the overall availability of the safety function. Where necessary, the redundant components are diversified to combat the system's vulnerability on common mode and common cause factors.

Given a cost profile for a component from a system, the methodology for the designing a safety function is established through the following steps:

1. Obtaining RRFs for the safety functions and transferring them to their components (S, LS, A) PFD targets,
2. Translation of the safety functions' PFD targets to the components' PFD targets,
3. Calculation of the components' redundancies that respects adopted cost profile.

The method is validated using a case study introduced in the last chapter of this paper.

2 COMPUTATIONAL FRAMEWORK

2.1 *Mathematical preliminaries*

The improvement in safety provided by the to-be–designed safety system, can be formulated as an improvement in the reliability of the safety system components. This reliability can be improved (Kuo & Wan 2007) either by incremental improvements in component reliability or by provision of redundant components in parallel. As emphasized in (Kuo et al. 2001) it then may be advantageous to preventively increase the component reliability to some level and provide redundancy at that level. Unfortunately, increasing the targets to anticipate for uncertainties in the subsequent design phases may push the designer against the limits of the technology where some components become extremely costly to manufacture and/or test. On another side, more channels clearly introduce more costs per channel but since each component in a redundant setting needs a lower RRF target allocated, the component's cost could be much lower than a single component's one to which a large RRF is imposed. Hence, depending on adopted components cost profiles, there is a room for trading-off between costs and redundancy without jeopardizing safety.

Presuming that individual risks R_i, $i = 1, ..., N$ associated to the consolidated hazardous situations are known, the overall baseline risk is simply

$$R^{EUC} = \sum_{i=1}^{N} R_i \tag{1}$$

where it is assumed that the independent and uncorrelated risk sources are obtained after the grouping. Since the risk of the unprotected system is the product of the Frequency (F) of the failures and the Loss (L) of the consequence i.e.

$$R_i = F_i L_i,\ i = 1, ..., N$$

the practitioner may choose to reduce each individual risk through the frequency or the loss.

By deciding to target the frequencies of the failures, the designer produces PFD targets for the safety functions associated to the individual risks. The risk reduction equation under consideration when reducing risks is

$$\frac{R^{EUC}}{\alpha} = \sum_{i=1}^{N} \frac{F_i L_i}{\alpha_i}, \quad \alpha := \frac{R^{EUC}}{R^{tol}}\ . \tag{2}$$

where (α_i, $i = 1, ..., N$) are the risk reduction factors related to the elemental risks. This problem does not have a unique solution and, hence optimization may help to find factors that are in some sense more preferable than others.

For example, optimization can be used to find the RRF such that

$$\frac{R^{EUC}}{\alpha} = \sum_{i=1}^{N} \frac{F_i L_i}{\alpha_i}, \quad \min_{\alpha_i} \left\{ \sum_{i=1}^{N} \alpha_i \right\}.$$

This optimization problem has the following solution

$$\alpha_i = \alpha \frac{\sqrt{F_i L_i}}{R^{EUC}} \sum_{i=1}^{N} \sqrt{R_i},\ \ i = 1, ..., N \tag{3}$$

Since the designer chooses to reduce the elemental risks by changing their frequency only, it can be easily seen that α_i, $i = 1, ..., N$ are of no use unless all losses are the same. The formula (3) fails to produce different targets for the same individual risks whose frequencies differ. Rescaling the factors from the optimization problem then may come into rescue. We reformulate the optimization problem as:

$$\frac{R^{EUC}}{\alpha}=\sum_{i=1}^{N}\frac{L_i}{\alpha_i/F_i},\quad \min_{\alpha_i}\left\{\sum_{i=1}^{N}\frac{\alpha_i}{F_i}\right\} \tag{4}$$

where, instead of R_i, $i=1, ..., N$, losses L_i, $i=1, ..., N$ are used. Then, the formula (3) becomes

$$\alpha_i=\alpha\frac{F_i\sqrt{L_i}}{R^{EUC}}\sum_{i=1}^{N}\sqrt{L_i},\quad i=1, ..., N \tag{5}$$

such that we may define:

$$PFD(SF_i)=\frac{1}{\alpha_i},\quad i=1, ..., N. \tag{6}$$

We take a short aside from the mainline to demonstrate that α_i, $i=1, ..., N$ are not necessarily equal when the individual risks are equal. For simplicity, assume the case $N=2$ and $R_1=R_2$. Then:

$$\alpha_1=\frac{\alpha}{R^{EUC}}(R_1+F_1\sqrt{L_1L_2}),$$

$$\alpha_2=\frac{\alpha}{R^{EUC}}(R_2+F_2\sqrt{L_1L_2}).$$

The calculated factors demonstrate that, under condition $R_1=R_2$, it follows that $\alpha_1=\alpha_2$ if and only if $F_1=F_2$. Also, by comparing these RRFs one concludes that $F_1>F_2$ implies $\alpha_1>\alpha_2$. Or, when translated to the PFD terms, $F_1>F_2$ implies $PFD(SF_1)<PFD(SF_2)$.

The objective function from the latter optimization problem then becomes:

$$\frac{R^{EUC}}{\alpha}=\sum_{i=1}^{N}F_iL_iPFD(SF_i).$$

Since each safety function is implemented by sensor, logic solver and actuator components, the designer must allocate PFD targets to them as well. These PFD are related via the so-called inclusion—exclusion formula

$$PFD(SF_i)=PFD(S_i)+PFD(LS_i)+PFD(A_i),\quad i=1, ..., N \tag{7}$$

where the terms associated to the cut-sets of the components' failure spaces are excluded as postulated in the introduction.

When allocating the PFD targets to the components the designer should also be concerned about the design costs. Each component has its own cost profile that depends on its PFD. It could then be beneficial to choose a design option that minimizes the costs without affecting required safety targets.

The search for a more cost-effective design for a set of safety functions can be formulated as an optimization task. That is, the PFD targets as well as the components' redundancies can be obtained by solving a multi-optimization task:

$$\frac{R^{EUC}}{\alpha}=\sum_{i=1}^{N}F_iL_i\left\{PFD(S_i)+PFD(LS_i)+PFD(A_i)\right\},$$

$$\min_{\substack{PFD(S_i)\\+PFD(LS_i)\\+PFD(A_i)}}\left\{\sum_{i=1}^{N}\frac{1}{F_i\left\{\begin{array}{l}PFD(S_i)\\+PFD(LS_i)\\+PFD(A_i)\end{array}\right\}}\right\},$$

$$\min_{\substack{PFD(S_i),\\PFD(LS_i),\\PFD(A_i),\\N_{S_i},N_{LS_i},N_{A_i}}}\left\{\begin{array}{l}\displaystyle\sum_{i=1}^{N}N_{S_i}C_{S_i}\left(\frac{1}{\sqrt[N_{S_i}]{PFD(S_i)}}\right)\\ \quad+N_{LS_i}C_{LS_i}\left(\frac{1}{\sqrt[N_{LS_i}]{PFD(LS_i)}}\right)\\ \quad+N_{A_i}C_{A_i}\left(\frac{1}{\sqrt[N_{A_i}]{PFD(A_i)}}\right)\end{array}\right\} \tag{8}$$

where parameters $C_{S_i}, C_{LS_i}, C_{A_i}, i=1, ..., N$ are uniformly increasing component cost functions on the RRF factors associated to sensors, logic solvers, actuators from SF_i, $i=1, ..., N$ and $N_{S_i}, N_{LS_i}, N_{A_i}$, $i=1, ..., N$ are the redundancies of the components.

Obviously, the solution of problem (8) depends on the choice of the component cost functions. Typical cases assume exponential cost functions. Such an assumption makes obtaining closed forms for the parameters difficult due to the transcendent functional dependencies between the variables. For this reason the designer is forced to look for other possibly suboptimal but more practical methods.

One should notice that the candidates for the components' PFD targets from the objective function are related exclusively to a single component. Hence multiplicity of components plays no role when determining the PFD targets for safety functions. This observation makes possible to split the optimization (8) into two subsequent optimizations:

$$\frac{R^{EUC}}{\alpha}=\sum_{i=1}^{N}F_iL_iPFD(SF_i),$$

$$\min_{PFD(SF_i)}\left\{\sum_{i=1}^{N}\frac{1}{F_iPFD(SF_i)}\right\},$$

and then to find PFD for the components and their redundancies such that the cost

$$\sum_{i=1}^{N} N_{S_i} C_{S_i}\left(\frac{1}{\sqrt[N_{S_i}]{PFD(S_i)}}\right) + N_{LS_i} C_{LS_i}\left(\frac{1}{\sqrt[N_{LS_i}]{PFD(LS_i)}}\right) + N_{A_i} C_{A_i}\left(\frac{1}{\sqrt[N_{A_i}]{PFD(A_i)}}\right) \tag{9}$$

of the overall design is minimized. To obtain a suboptimal solution to the second minimization we adopt the following assumption which is a frequently used 'rule-of-thumb':

(AS) More expensive components get larger PFDs

By allowing assumption **(AS)**, one may take

$$\begin{aligned} PFD(S_i) &:= k_{S_i} PFD(SF_i), \\ PFD(LS_i) &:= k_{LS_i} PFD(SF_i), \\ PFD(A_i) &:= k_{A_i} PFD(SF_i) \end{aligned} \tag{10}$$

where the factors k_{S_i}, k_{LS_i} and k_{A_i} are defined as:

$$k_{S_i} := \frac{C_{S_i}\left(\frac{1}{PFD(SF_i)}\right)}{C_{SF_i}\left(\frac{1}{PFD(SF_i)}\right)}, \quad k_{LS_i} := \frac{C_{LS_i}\left(\frac{1}{PFD(SF_i)}\right)}{C_{SF_i}\left(\frac{1}{PFD(SF_i)}\right)},$$

$$k_{A_i} := \frac{C_{A_i}\left(\frac{1}{PFD(SF_i)}\right)}{C_{SF_i}\left(\frac{1}{PFD(SF_i)}\right)}$$

and

$$C_{SF_i}\left(\frac{1}{PFD(SF_i)}\right): = C_{S_i}\left(\frac{1}{PFD(SF_i)}\right) + C_{LS_i}\left(\frac{1}{PFD(SF_i)}\right) + C_{A_i}\left(\frac{1}{PFD(SF_i)}\right), \quad i = 1, \ldots, N.$$

Straightforward substitution of these PFDs into (7) shows that they are admissible candidates as, by construction

$$k_{S_i} + k_{LS_i} + k_{A_i} = 1, \quad i = 1, \ldots, N.$$

Since the design targets are now created for the components from each safety function, minimization of cost functional (9) now reduces to minimizations per each component. That is, the required minimal redundancies follow from:

$$\begin{aligned} &\min_{N_{S_i}}\left\{N_{S_i} C_{S_i}\left(\frac{1}{\sqrt[N_{S_i}]{k_{S_i} PFD(SF_i)}}\right)\right\}, \\ &\min_{N_{LS_i}}\left\{N_{LS_i} C_{LS_i}\left(\frac{1}{\sqrt[N_{LS_i}]{k_{LS_i} PFD(SF_i)}}\right)\right\}, \\ &\min_{N_{A_i}}\left\{N_{A_i} C_{A_i}\left(\frac{1}{\sqrt[N_{A_i}]{k_{A_i} PFD(SF_i)}}\right)\right\}, \\ &i = 1, \ldots, N. \end{aligned} \tag{11}$$

Further cost reductions are usually made in the post optimization step of the design where it is decided what to share among the actual components. Generally, a single logic solver is shared amongst the safety functions. Sharing sensors or actuators is strongly problem-dependent and depends on the choice taken for safety functions.

2.2 *Sensitivity of the components PFDs on changes in $PFD(SF_i)$ around the given initial $PFD(SF_i)$*

When attempting to gain additional costs savings, the operator typically decides to slightly change the PFD targets for safety functions. By varying these targets he hopes to come out with a less costly design. We show that, in fact, this will not introduce additional cost savings under Assumption **(AS)**. To demonstrate this, it is sufficient to take any PFD from (10) and evaluate its relative sensitivity to changes in $PFD(SF_i)$ around the initial $PFD(SF_i)$. We perform this on RRF terms α_i and obtain:

$$\frac{\partial k_{S_i}}{\partial PFD(SF_i)} \times \frac{k_{S_i}}{PFD(SF_i)} = \frac{\partial\left(\frac{C_{SF_i}(\alpha_i)}{C_{S_i}(\alpha_i)} - 1\right)^{-1}}{\partial \alpha_i} \times \frac{C_{S_i}(\alpha_i)\left(C_{SF_i}(\alpha_i) - C_{S_i}(\alpha_i)\right)^2}{\alpha_i\left(C_{SF_i}(\alpha_i)\right)^3}$$

where the first term is infinitesimally small since it is a derivation of a slowly varying function at initial α_i and the second term is bounded. Hence,

$$\frac{\partial PFD(S_i)}{\partial PFD(SF_i)} \times \frac{PFD(S_i)}{PFD(SF_i)} \approx 1.$$

Therefore we state the following conclusion that requires further elaboration:

(C) Factors k_{S_i}, k_{LS_i} and k_{A_i} can be regarded as constants around the initial $PFD(SF_i)$. Hence, $PFD(S_i)$, $PFD(LS_i)$ and $PFD(A_i)$ are approximately linear functions of $PFD(SF_i)$.

Conclusion **(C)** is true if the adopted components' cost models are all continuous functions on the range of variations around the initial $PFD(SF_i)$ for all components from the safety function. Consequently, **(C)** is always true when the cost models accommodate the continuous cost profiles. Typically, the component price within more realistic cost profiles changes in jumps as the component's performance changes. The locations of the jumps may differ among components as well. As a result, deciding to significantly increase the initial PFD of one of the safety functions causing abrupt cost reductions for other components is compensated with a decrease in the initial PFD for the other safety functions. When a discrete cost profile is shared amongst the components of the same type (a very good approximation used in process industry), then this decrease leads to a disproportionate increase of the component costs for the other safety functions that ultimately outweighs the cost savings realized for the first safety function. Obviously, conclusion **(C)** is not necessarily true when all components accommodate different cost profiles.

Accordingly, the designer's attempt to increase the PFD of some safety functions and decrease those of the others can not lead to lower costs then those associated to the initial $PFD(SF_i)$ calculated by (5) and (6) unless all components accommodate different cost profiles. This is due to the adopted cost functional from (4) that gives minimal RRF factors optimally adjusted to the risk frequencies of the individual risks.

We close this chapter by introducing a generic component cost model used in the examples throughout the rest of this paper.

2.3 *Component costs model and the cost of redundant implementation*

A cost model; $C_x(\alpha)$, depending on a risk reduction factor α for a (generic) component $x \in \{S, LS, A\}$ is introduced according to the following specification:

– When no risk reduction is required then $\alpha = 1$ and $C_x(\alpha = 1) = 0$.
– For a small α (but larger than 1) there will be some initial component cost; $C_x(\alpha = 1+) = C_x^{start}$
– When the redundancy of a component is fixed, then an increase in α always implies an increase in $C_x(\alpha)$.

This specification for the cost function describes typical situations that occur in practice. Although it is generally accepted (Rao et al. 1999) in most research that a component's cost function follows an exponential closed model, we adopt a more realistic, rough model that features piecewise constant cost functions over the RRF's intervals.

On the top of Figure 1 the dependency of a cost on RRF factor is shown for the following specification

$$C_x(\alpha) = \left\{ \begin{array}{c} 200,\ 1 < \alpha \le 80, \\ 350,\ 80 < \alpha \le 150, \\ 500,\ 150 < \alpha \le 1200, \\ 5000,\ 1200 < \alpha \le 10000, \\ 15000,\ 10000 < \alpha \end{array} \right\}. \tag{12}$$

Such cost profiles are typical in practice, where the price of a product is kept constant for a large range of selected performance.

When the protection is redundantly implemented with N_x identical components, then $N_x\sqrt{\alpha}$ is the minimal required robustness for each component in the redundant setting to guarantee the same level of safety.

Thereby:

$$C_{x,N} := N_x C_x\left(\sqrt[N_x]{\alpha}\right) \tag{13}$$

is the cost of this redundant configuration. On the bottom of Figure 1, cost (13) of redundant setting is shown on basis of cost model (12).

It is worth of mentioning that $C_{x,N}$ does not necessarily have a global minimum. This is due to

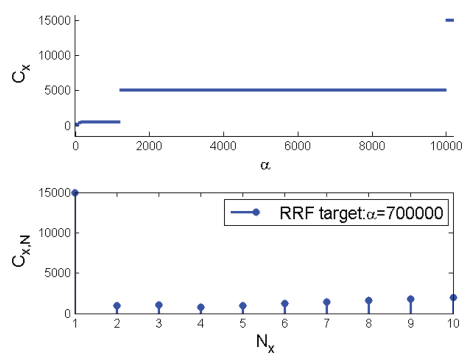

Figure 1. A component cost function (top) and the costs of its redundant setting (bottom) for RRF target set to 700000.

discontinuities in the cost function where, for some target RRFs, successively calculating roots causes the discrete jumps into other RRF regions that may be much more cost beneficial even for a larger number of components. No matter what cost function is given, for sufficiently large redundancy, the component cost will start to increase. It is therefore important to consider a sufficiently large range of N_x before concluding which value leads to a minimal component costs. To determine a sufficiently large search space for such N_x, it suffices to take N such that $\sqrt[N]{\alpha}$ belongs to the first cost level of the cost function. Any further increase of N leads to uniform cost increase since $\sqrt[N]{\alpha}$ can not escape the first cost level.

In the case of cost function $C_x(\alpha)$, the minimum costs for the target α=700000 are achieved for $N_x = 4$ with the resulting cost $C_{x,N=4} = 800$.

3 METHODOLOGY STEPS APPLIED ON A CASE

3.1 *Description of the case*

In this case we presume that three safety functions are needed to provide the risk reduction from $R^{EUC} = 9502000$ of the base-line system to the tolerable risk level $R^{tol} = 13.5743$. The RRF factor that corresponds to this reduction is $\alpha = 700000$. The individual risk levels and their associated frequencies are assumed as in Table 1.

Generally, the component cost profiles differ for each component. We restrict ourselves to the cases where each component group have approximately the same costs for their required performance level. This assumption somewhat simplifies the problem but does not narrow the scope of application.

We adopt the following cost profiles for each component:

– Sensor;

$$C_S(\alpha) = C_x(\alpha), \tag{14}$$

– Logic solver;

$$C_{LS}(\alpha) = \begin{cases} 100, 1 < \alpha \le 10 \\ 5000, 10 < \alpha \le 1000 \\ 50000, 1000 < \alpha \le 10000 \\ 70000, 10000 < \alpha \le 100000 \\ 100000, 100000 < \alpha \end{cases} \tag{15}$$

Table 1. The individual risk data assumed for the case.

R1, F1	R2, F2	R3, F3
500000, 30000	2000, 40000	9000000, 100000

– Actuator;

$$C_A(\alpha) = \begin{cases} 1000, 1 < \alpha \le 500, \\ 3500, 500 < \alpha \le 1500, \\ 25000, 1500 < \alpha \le 30000, \\ 30000, 30000 < \alpha \end{cases}. \tag{16}$$

3.2 *Step 1: obtaining PDF(SF_i), i = 1,2,3 targets for the safety functions*

A set of $PDF(SF_i)$, $i = 1,2,3$ for the set of the safety functions is obtained using formulae (5) and (6). We then, use

$$PDF(SF_i) = \left[\alpha \frac{F_i \sqrt{R_i / F_i}}{R^{EUC}} \sum_{i=1}^{N} \sqrt{R_i / F_i} \right]^{-1}, \quad i = 1,2,3 \tag{17}$$

and substitute the risk data introduced earlier. This calculations produce the targets found in Table 2.

3.3 *Step 2: translation of the safety function PFD target to the components' PFD targets*

The designer now proceeds with a determination of the PFD targets for the components from each safety function. As before, let $C_{S_i}(\alpha_i), C_{LS_i}(\alpha_i), C_{A_i}(\alpha_i)$ be the costs associated with the components from safety function SF_i to which RRF target $\alpha_i = \{PFD(SF_i)\}^{-1}$ is imposed.

The designer now uses (10) to calculate PFD targets for each component group. These targets are provided in Table 3.

These component PFD targets are then used to obtain minimal redundancies for each component from three safety functions.

Table 2. PFD targets for the three safety functions.

Logic solvers	5.5418E-06	6.8769E-05	7.1544E-07
Actuators	1.6625E-06	3.4385E-05	2.1463E-07

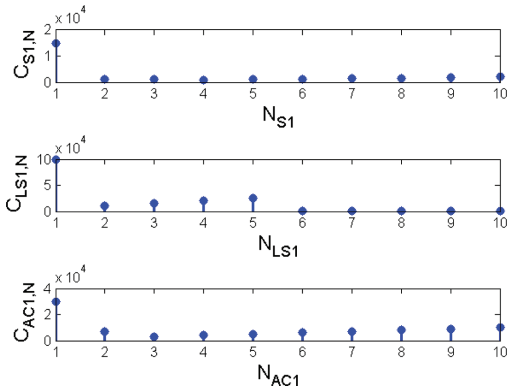

Figure 2. Minimal redundancies that determine the architecture for the first safety function.

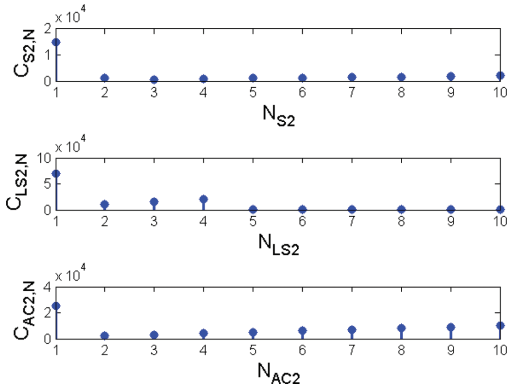

Figure 3. Minimal redundancies that determine the architecture for the second safety function.

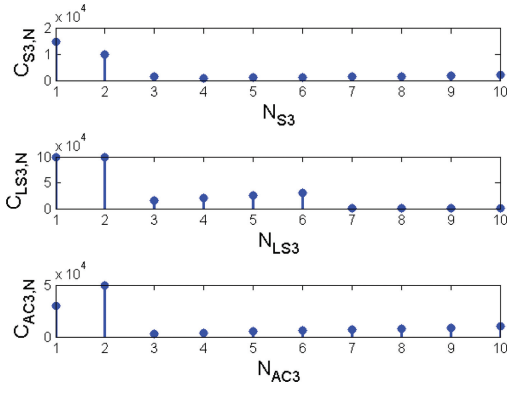

Figure 4. Minimal redundancies that determine the architecture for the third safety function.

3.4 *Step 3: calculation of the component redundancy that respects adopted component cost profiles*

We proceed with evaluation of minimal redundancies for each component group. By plotting the costs along with redundancy, one can determine which architecture has minimal costs.

Finally, component subsystem costs are listed in Table 4 along with the component redundancies within the subsystem. For the given data targets it follows that the design costs equal 12000.

The cost optimal architecture of the safety functions is shown in Figures 5, 6 and 7.

As the part of the post optimization procedure conducted on the current case to obtain additional

cost savings, the designer typically decides to share the logic solvers among the safety functions. This requires an additional robustness increase for the logic solvers to adequately combat the risk of multiple safety functions failure due to a single point of failure. This topic, however is beyond the scope of this paper.

4 CONCLUSIONS

Despite the rigid requirements imposed by the safety standards, the safety system designer still possesses some flexibility when selecting components for the safety functions as well as their PFDs. When in the process of generating and implementing design proposals, the budget limitations play a considerable role in component selection. In this respect however, the safety standard offers no guidance. When no proper measure for the effort is given, the designer is likely to strive to deliver the safe system against high costs. It was our intention to provide a methodology for a PFD allocation for safety functions and their components that can be used in conjunction with the standard's imperatives to produce a design proposal that respects the budget costs without jeopardizing safety.

In this paper we provide the designer with a three-step workflow on how to allocate PDFs to safety functions' components that respects the components' costs profiles in order to obtain a more cost-effective design. In the first step, we show how to avoid taking disproportionate decisions when allocating PFDs to the safety functions. In the second step, using the components' cost profiles we show how to translate the SFs' PFD targets to their respective component subsystems. The third step is concerned about finding cost-optimal redundancy for a component subsystems.

The cornerstone for this method is provided by the initial RRF/PFD allocation procedure used to correct the designer's decisions by obtaining a safe design with minimal performance requirements for the safety functions. By showing that components' PFD targets are weakly sensitive on changes in the PFD of their safety function around the initial PFD targets when Assumption **(AS)** is adopted, the designer's efforts to vary the initial PFDs for safety functions become obsolete. In other words, the initial PFD as obtained by (17) guarantee the minimal design costs.

The reach of the methodology is limited to the safety systems:

1. whose safety functions are independently implemented and
2. use single layer of protection to provide the required risk reduction.

A natural extension of the methodology should address the cost-optimal designer's decision making in case of multiple layers of protection as well as safety systems whose safety functions share components.

ABSTRACT: The implantation of simple engineering techniques in time-dependent survival probability predictions of structural and technical systems as stochastic systems of events is discussed. A possibility to avoid complicated multidimensional integrations in a probabilistic safety analysis of stochastic systems with perfectly ductile components is based on the approaches of Transformed Conditional Probabilities (TCP) and Conventional Correlation Vectors (CCV). Dynamic (time-dependent) autosystems of extreme events of particular single and mixed ductile elements are treated as correlated components of static stochastic systems with m random failure modes. The unsophisticated and fairly exact prediction of the probability-based reliability of stochastic systems of events is demonstrated by numerical examples and histograms of their reliability indices.

1 INTRODUCTION

The reliability of structural and technical systems should always be defined for some reference period. The failure of a series system (Fig. 1, a) is caused by the first brittle component fracture. Therefore, a series system with m elements is in failure state whenever any of its elements has failed. When components of this system are ductile, it can continue to operate at reduced reliability indices of components.

A parallel system (Fig. 1, b) consisting of perfectly ductile elements can fail only when all of its contributory units have reached their limit states. Therefore, the reliability of parallel systems can be increased significantly. It can be said that the strongest component m of a parallel ductile system must survive all extreme situations (Dey and Mahadevan, 2000). Components of multi-states series-parallel systems are composed of fixed numbers m_1 of individual elements and m_2 of parallel subsystems formed from ductile elements (Fig. 1, c).

For static series and parallel structural and technical systems as systems of events, the safety or failure regions are conditioned, respectively, by unions and intersections of survival or failure probabilities of ductile components the number of which m depends on a number of random discrete failure modes. Thus, the dynamic (time-dependent) probability-based reliability indices β_k of stochastic systems may be obtained by the complicated failure modelling of their stochastically dependent elements and subsystems.

Therefore, the exact probabilistic analysis of multidimensional integrals of traditional dynamic stochastic systems of events is very difficult and sometimes not feasible. Therefore, the computer programs adopting the bi-model bounds for system reliability were proposed (Estes and Frangopol 1998).

The total failure probabilities of parallel and series systems as the intersections and unions of these probabilities in m modes may be expressed, respectively, as:

$$P\left(\bigcup_{k=1}^{m} F_k\right)_{ss} = P\left[\bigcup_{k=1}^{m}\left(X_k \le -\beta_k\right)\right]_{ss} \approx 1-\Phi_m\left(-c,\rho\right) \quad (1)$$

$$P\left(\bigcap_{k=1}^{m} F_k\right)_{ps} = P\left[\bigcap_{k=1}^{m}\left(X_k \le \beta_k\right)\right]_{ps} \approx \Phi_m\left(c,\rho\right) \quad (2)$$

where X_k (k = 1, 2, …, m) and β_k are the jointly normal random variable and reliability index for k-th element of systems, $\boldsymbol{\rho}$ is a correlation matrix. The computation of system probability of failure by Eqs. (1) and (2) involves the integration of multivariate normal distributions.

Improved computational methods for probabilistic analysis of systems were proposed by Mori &

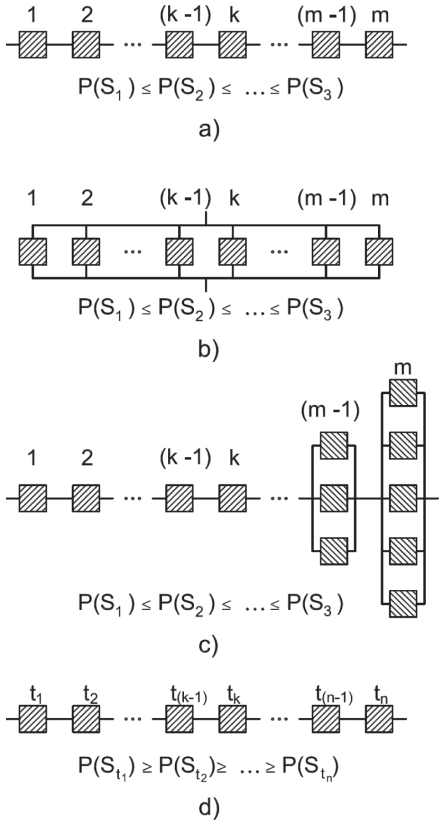

Figure 1. Schematic representations of static stochastic series (a), parallel (b) and series-parallel (c) general systems of events and dynamic autosystems (d).

Ellingwood (1993), Melchers (1994), Ditlevsen (1997), Mori & Kato (2003), Ahammed & Melcher (2005). These improvements are inconvenient for designers due to their mathematical complexity.

According to Pandey (1998 a, b), An & Pandey (2002), Pandey & Sarkar (2002) and Yuan & Pandey (2006), this computation can be simplified, when the multidimensional joint normal distribution is represented as a product of m conditional probabilities approximating by one-dimensional normal distribution. According to this method of the Product of Conditional Marginal (PCM), Eqs. (1) and (2) may be rewritten as:

$$P\left(\bigcup_{k=1}^{m} F_k\right)_{ss} \approx 1-\prod_{k=1}^{m}\Phi\left(c_{k|(k-1)}\right) \tag{3}$$

$$P\left(\bigcap_{k=1}^{m} F_k\right)_{ps} \approx \prod_{k=1}^{m}\Phi\left(c_{k|(k-1)}\right) \tag{4}$$

where $c_{k|(k-1)}$ represents a conditional normal fractile obtained by assuming that the conditional variable $X_{k|(k-1)} = X_k \left| \bigcap_{i=1}^{(k-1)} X_i \le c_i \right.$ is normally distributed. Thus, the Product of Conditional Marginal (PCM) method may be treated as a simplified computational method.

The probabilistic reliability systems of events are analysed by Žiba (2000). The analysis is based on the concepts of entropy as defined in information theory and applied to probability theory. The recommended approach allows concentrating the system analysis only on important failure modes and connects uncertainty, redundancy and robustness of systems of events. Despite this approach, the system analysis leads to complicated computations.

Kang *et al.* (2003) suggested the calculation of failure probabilities of complicated parallel and series systems, including a reliability analysis of offshore platforms, to base on the concept of Equivalent Linear Failure Modes (ELFM).

Levitin *et al.* (1998) and Levitin (2004) extends the Universal Generating Function (UGF) technique of the multistate system analysis to the format when the performance distributions of some elements depend on the states of other elements. This useful new heuristic methodology may be used by researchers and some designers.

The probability $P\left(R_S \ge E_l\right)$ means that total system capacity R_S is higher than extreme demand levels E_l. Thus, according to Ramirez-Marquez *et al.* (2004), the heuristic genetic algorithm and methodology of UGF for Multistate Series–Parallel Systems (MSPS) may be approximated and developed.

According to Li *et al.* (2007), it is possible to transform a computation of reliability parameters, using the joint probability density functions of safety margins of system components.

Song & Kang (2009), Kang & Song (2010) suggest to compute the failure probabilities of system of events by simplified matrix procedures, using the Matrix-based System Reliability (MSR) method. However, the presented analysis of large systems with different reliability and dependency of components is difficult. MSR, like the above-mentioned PCM, UGF and other methods, are hardly translated into everyday design reality and cannot be treated as universal design approximations.

According to available data of demonstrated methods, the exact and approximated reliability analysis of systems with correlated components requires multivariate integrations procedures and therefore is very difficult and sophisticated. The main task of this paper is to present for designers new unsophisticated concepts and uniform methodological analytical formats on probability-based

approaches for reliability predictions of structural and technical systems as systems of events.

2 SAFETY OF PERFECTLY DUCTILE SYSTEMS

2.1 *Ductile autosystems as components of general systems*

In the probability-based analysis of structural and technical systems, the simplified but exact applied predictions of dynamic reliability indices of particular elements are very relevant. An autosystem consisting of normal or oblique sections, connections and deflections as a dynamic (time-dependent) highly correlated decreasing series stochastic system (Fig. 1, d) belongs to a single element of a system of events and characterizes its changes in random durability (the ability to preserve its efficiency for a long period of time). Now, the values of deterministic parameters of a durability of elements due to their deteriorating and ageing are assessed and presented at design codes or standards by deterministic implicit recommendations and related with long-term experience of designers.

Any autosystem is a highly correlated series system of particular elements and their durability parameters are related to reliability indices. However, the values of safety and durability indices may be objectively defined only by fully probability-based concepts and models because probabilistic approaches allow us explicitly predict uncertainties of analysis parameters and design models.

The safety margin of time-dependent hierarchical stochastic performance processes of particular perfectly ductile elements (Fig. 1, d) may be expressed as:

$$Z_{tk} = g\left(\mathbf{X}_{tk}, \boldsymbol{\theta}\right) = g\left(\theta_R R_{tk} - \boldsymbol{\theta}_E \mathbf{E}_{tk}\right) \tag{5}$$

where $\mathbf{X}_{tk}$ and $\boldsymbol{\theta}$ are the vectors of basic and additional variables representing respectively random resistances R_{tk} (responses) and action effects $\mathbf{E}_{tk}$ (demands) of particular elements effected by extreme actions and design model uncertainties at cut t_k of finite decreasing sequence of survival probabilities $\mathrm{P}(S_{t1}) \geq \mathrm{P}(S_{t2}) \geq \ldots \geq \mathrm{P}(S_{tk}) \geq \ldots \geq \mathrm{P}(S_{tn})$. Thus, in an autosystem analysis, several dynamic safety margins are included. The vector $\mathbf{E}_{tk}$ depends also on redistributions of actions.

2.2 *Instantaneous and total survival probabilities of dynamic ductile autosystems*

According to the concept of Transformed Conditional Probabilities (TCP) (Kudzys *et al.* 2009, 2010, 2013), the instantaneous failure probability of a stochastic ductile autosystem at time t_k, assuming that analyzed element was safe at time less than t_k, may be written as follows:

$$P\left[Z_{tk} \leq 0\right] = P\left[F_{tk} \left| \bigcap_{ti=t1}^{t(k-1)} S_{ti} \right.\right] \approx 1 - P\left(S_{tk}\right) \times \left(1 + \rho_{k|f}^{x_k} \left[\frac{1}{P\left(S_{tk}\right)} - 1\right]\right) \tag{6}$$

where F_{tk} and S_{tk} denote the failure and survival probabilities of single particular elements at time t_k;

$$\rho_{k|f}^{x_k} = \left(\frac{1}{k-1}\sum_{i=1}^{(k-1)} \rho_{ki}\right)^{x_k} \tag{7}$$

is the bounded conventional correlation factor of a quadratic matrix between safety margins of autosystem elements as a member of conventional Correlation Vector (CCV) written in the form:

$$\boldsymbol{\rho} = \left[1, \rho_{2|1}^{x_2}, \ldots, \rho_{k|1\ldots(k-1)}^{x_k}\right] \tag{8}$$

when the vector $\boldsymbol{\rho} = 0$ or $\boldsymbol{\rho} = 1$, the proposed Eqs. (12), (14) and (15) give accurate solution.

Basic correlation coefficients between system elements may be calculated by the equation:

$$\rho_{ki} = \rho\left(Z_{tk}, Z_{ti}\right) = \frac{Cov\left(Z_{tk}, Z_{ti}\right)}{\boldsymbol{\sigma} Z_{tk} \times \boldsymbol{\sigma} Z_{ti}} \tag{9}$$

where σZ_{tk} and σZ_{ti} are the standard deviations of safety margins Z_{tk} and Z_{ti} calculated by Eq. (5). Their components $\rho(R_{tk}, R_{ti})$.

The bounded index of a conventional correlation factor may be expressed as:

$$x_k = P\left(S_{t1}\right) \times \left(\frac{4.5 - 4 \times \rho_{kf}}{1 - 0.98 \times \rho_{kf}}\right)^{\nu_k} \tag{10}$$

where its index

$$\nu_k = \frac{\sum_{ti=t2}^{tk} P\left(S_{tk}\right)}{\left(k-1\right) \times \left(k + 2\beta_k^2 - 15\beta_k + 30\right)^{1/2}} \tag{11}$$

helps us evaluate an effect of survival probabilities of system elements $P(S_{tk}) = \Phi(\beta_k)$ on the bounded index by Eq. (10) when a reliability index of k-th element is equal to β_k.

According to probabilistic format presented in Eq. (6), the total survival probability of particular

elements as dynamic ductile autosystems with n components may be presented as:

$$P_{as}(S) = P_{as}\left[\bigcap_{tk=t1}^{m} S_{tk}, \exists S_{tk} \le S_{t(k-1)},\ k \in [1,n]\right]$$

$$= 1 - \begin{bmatrix} P(F_{t1}) \bigcup P(F_{t2}|S_{t1}) \bigcup \dots \\ \dots \bigcup P\left(F_{tk}\left|\bigcap_{tk=t1}^{t(k-1)} S_{t(k-1)}\right.\right) \bigcup \dots \\ \dots \bigcup P\left(F_{tn}\left|\bigcap_{tn=t1}^{t(n-1)} S_{t(n-1)}\right.\right) \end{bmatrix}$$

$$\approx P(S_{t1}) \times P(S_{t2}) \times \left\{1 + \rho_{2|f}^{x_2}\left[\frac{1}{P(S_{t2})} - 1\right]\right\} \times \dots$$

$$\dots \times P(S_{tk}) \times \left\{1 + \rho_{k|f}^{x_k}\left[\frac{1}{P(S_{tk})} - 1\right]\right\} \times \dots$$

$$\dots \times P(S_{tn}) \times \left\{1 + \rho_{n|f}^{x_k}\left[\frac{1}{P(S_{tn})} - 1\right]\right\}$$

$$\approx P(S_{t1}) \times \prod_{k=2}^{n}\left(P(S_{tk}) \times \left\{1 + \rho_{k|f}^{x_k}\left[\frac{1}{P(S_{tk})} - 1\right]\right\}\right) \quad (12)$$

where the bounded conventional correlation factor, $\rho_{k|f}^{x_k}$, is expressed by Eq. (7) and n is the number of extreme events.

2.3 *Survival probabilities of static series and parallel ductile general systems*

The safety margins of performance functions of components of static general systems are:

$$Z_k = g(\mathbf{X}_k, \boldsymbol{\theta}) = g(\theta_R R_k - \boldsymbol{\theta}_E \mathbf{E}_k) \quad (13)$$

Analogically to Eq. (12) and following the same probabilistic approaches, the total survival probability of static series (Fig. 1, a) and series-parallel (Fig. 1, c) ductile general systems with m components (autosystems) may be defined as:

$$P_{ss}(S) = P_{ss}\left[\bigcap_{k=1}^{m} S_k, \exists P(S_k) \le P(S_{(k-1)}),\ k \in [1,m]\right]$$

$$= 1 - P_{ss}\left(\bigcup_{k=1}^{m} F_k\right)$$

$$\approx P(S_1) \times \prod_{k=2}^{m}\left(P(S_k) \times \left\{1 + \rho_{k|f}^{x_k}\left[\frac{1}{P(S_k)} - 1\right]\right\}\right) \quad (14)$$

where m is the number of random discrete failure modes or conventional autosystems as single elements and mixed components of systems; $\rho_{k|f}^{x_k}$ is the bounded conventional correlation factor assessed by Eq. (7).

The total survival probability of static parallel ductile general systems (Fig. 1, b) with m components may be presented as:

$$P_{ps}(S)$$

$$= 1 - P_{ps}\left[\bigcap_{k=1}^{m} F_k, \exists P(F_k) \le P(F_{(k-1)}),\ k \in [1,m]\right]$$

$$\approx 1 - P(F_1) \times \prod_{k=2}^{m}\left(P(F_k) \times \left\{1 + \rho_{k|f}^{x_k}\left[\frac{1}{P(F_k)} - 1\right]\right\}\right) \quad (15)$$

$P(S_k)$ from Eq. (14) and $P(F_k)$ from Eq. (15) denote the survival and failure probabilities of ductile autosystem $k = 1 \dots m$ at time t_k. For parallel general systems the demand vector $\theta_E \mathbf{E}_k$ corresponds to failure state after statical redistribution of actions.

The generalized reliability indices of series and parallel systems of events is presented as:

$$\beta_{ss} = \Phi^{-1}[P_{ss}(S)] \quad (16)$$

$$\beta_{ps} = \Phi^{-1}[P_{ps}(S)] \quad (17)$$

where $\Phi^{-1}[\bullet]$ is the inverse cumulative distribution function of the standard normal distribution of their survival probabilities $P_{ss}(S)$ by Eq. (14) and $P_{ps}(S)$ by Eq. (15).

The design documents recommended by the Joint Committee on Structural Safety (JCSS, 2000) are acknowledged as the progressive probabilistic model code in the design of structural members and their systems. According to these documents, the reliability index of structures is related to the consequences of failure classes when the target value is equal to β_t = 3.3–4.3 (EN 1990, 2002; ISO 2394, 1998). Particular elements and members of the structure may be designed on the same higher or lower reliability index as for the entire structure. However, there exist recommendations to use the so-called "thrifty and advanced" method in design practice. These recommendations are based on decreased target reliability index $\beta_{STR} = \beta_t \prod_{i=1}^{6} \gamma_i = 2 - 2.5$. They are included in the Lithuanian National Standard STR 2.05.03:2003. Therefore, the failure probabilities of structures of buildings and civil engineering works may increase inadmissibly by 100–500 times.

3 NUMERICAL EXAMPLES

3.1 *Series autosystem with 5 and 20 components*

Consider series autosystems with n equireliable and equicorrelated components (An & Pandey, 2002). At all failure modes cases the same reliability index $\beta_{tk} = 4.0$ and the same value 0.1 or 0.95 for correlation coefficients between the failure modes are assumed. Reliability indices of these series autosystems calculated by three methods are presented in Table 1 and Figure 2, when the number of their failure modes n is equal to 5 and 20.

Table 1. The values of reliability indices of series autosystems calculated by different methods.

The number of failure modes, n	ρ_{ki}	Design methods: TCP + CCV by Eq. (12)	Numerical integration (An & Pandey, 2002)	PCM by Eq. (4)
5	0.1	3.6031	3.6013	3.6013
	0.95	3.7922	3.7901	3.6036
20	0.1	3.2299	3.2238	3.2237
	0.95	3.2927	3.2540	3.2273

3.2 *Series systems with four reliability indices of components*

According to Zhao *et al.* (2007) consider a series system with four failure modes in which the first-order reliability indices have been obtained as $\beta_1 = 2.5$, $\beta_2 = 2.5$, $\beta_3 = 3.0$, $\beta_4 = 3.5$ and the correlation coefficient between every pair of failure modes is assumed to be $\rho = 0.86$. The results for the system reliability index are presented in Table 2. The reliability index of a series system calculated using

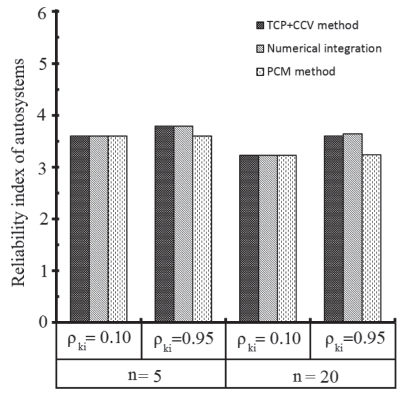

Figure 2. Comparison of reliability indices of series autosystems consisted of 5 and 20 components.

Table 2. Calculation results of series system reliability index, β_{ss}, by Eq. (16).

Bounds	Design methods: Zhao et al. (2002)	Feng's	Ditlevsen's	Numerical integration	TCP + CCV by Eq. (16)
Lower	2,333	2,331	2,351	2,330	2,327
Upper	2,317	2,311	2,273		

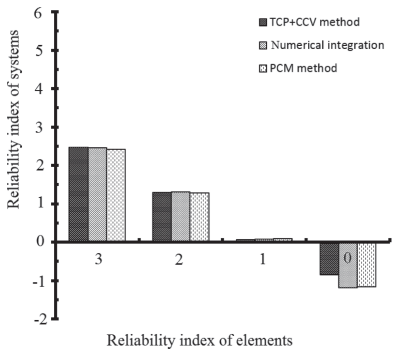

Figure 3. Reliability indices, β_{ss}, by Eq. (16) for series general systems.

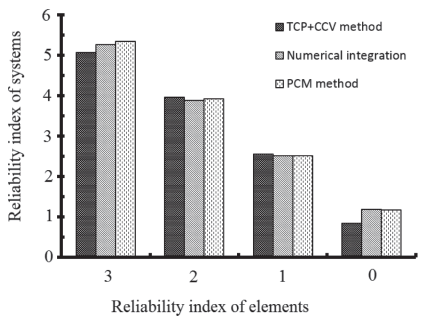

Figure 4. Reliability indices, β_{ps}, by Eq. (17) for parallel general systems.

the method TCP + CCV by Eq. (16) is close to the solution obtained through numerical integration.

3.3 *Series and parallel general systems with equireliable elements*

The analysis of reliability indices of series and parallel systems with 6 equireliable elements, the reliability index of which is $\beta = 0–3$ (Pandey 1998 a, b) are shown in Figure 3 and 4, respectively. The correlation coefficients are given in product form, i.e. $\rho_{ki} = \lambda_k \lambda_i$, $k \neq i$, and $\lambda_i = \sqrt{(13-2i)/12}$, $k,i = 1, 2, \ldots, 6$.

The conventional correlation factors of autosystems are: $\rho_{2|1} = 0.8292$, $\rho_{3|21} = 0.6963$, $\rho_{4|321} = 0.5567$, $\rho_{5|4321} = 0.4041$ and $\rho_{6|54321} = 0.2155$. They can be calculated using the matrix of basic correlation coefficients and Eq. (7).

The illustrative examples show that the results of system analysis obtained by the proposed TCP + CCV method are very close to the probabilistic data computed by exact but sophisticated numerical integration and PCM methods based on complicated integration formats.

4 CONCLUSIONS

The simplification of methodology of probability-based analysis and prediction of reliability indices of time-dependent structural and technical systems as systems of extreme events may be related to the autosystem concept. It is very useful and possible to separate the formats of probabilistic analysis of dynamic series autosystems with single and mixed particular elements (normal and oblique sections, connections, deflections) from static series, parallel and series-parallel systems consisting of autosystem components.

The proposed approaches allow us to simplify the mathematical format, if the prediction of survival probabilities and reliability indices of sustainable series, parallel and series-parallel systems are based on the additional concepts of Transformed Conditional Probabilities (TCP) and Conventional Correlation Vectors (CCV). They help us avoid of complicated multidimensional integrations both in a safety analysis of general systems and their autosystem components.

A separated reliability analysis of structural and technical systems into dynamic by Eq. (12) and static by Eq. (14) or (15) parts helps designers to simplify probabilistic calculations. The presented unsophisticated probability-based approaches, design models and calculation equations may be convenient for many practitioners and can stimulate designers to use the full probabilistic methods in their practice more actively and effectively.

ACKNOWLEDGMENT

The first author would like to express their gratitude to the Research Council of Lithuania for the Postdoctoral fellowship. Postdoctoral fellowship is being funded by the European Union Structural Funds project "Postdoctoral Fellowship Implementation in Lithuania".

Safety-based approach in multifunctional building design

A. Taraszkiewicz & M.K. Gerigk
Gdańsk University of Technology, Gdańsk, Poland

ABSTRACT: The modern trend in design of the public buildings is to create multifunctional environments in one building, hosting a variety of functions. Multifunctional buildings entertain large number of visitors. The complexity and vulnerability of this type of public space are the main reasons to use within their design process the performance based approach including the recognition of hazards. Safety and reliability approach is now used in structural design and assessment. The paper presents safety-based approach used in the architectural design on the example of multifunctional building. The holistic method of design proposed in the paper considering hazards scenarios and management is presented and compared with the traditional design process based on the civil engineering codes.

1 INTRODUCTION

1.1 *Tendencies*

Organization of contemporary city reveals a trend to build multifunctional structures. The aim of the article is to present the necessity to improve the safety based approach in multifunctional building design. In the time of rapid development of urban spaces it is significant that the use of the land is rather intensive. In consequence, new built architecture in cities is represented by multipurpose facilities. In recent years more and more demanding structures are designed, built and operated to satisfy the increasing needs of the society (Arangio 2012). The reason to provide more detailed safety in multipurpose systems is avoiding unpredictable to cause negative influence.

1.2 *The case context*

Multifunctional buildings created today are designed in a traditional way, which is based on master plans and building codes. It may not be sufficient in relation with safety performance for complex structural systems.

Current actions in built environment are focused around the sustainable development (World Commission on Environment and Development 1987). Actual project should take social, economical and environmental factors. Safety approach is an integral component of any field relative to actual standard of development.

2 GENERAL DEFINITIONS

2.1 *Multifunctional building*

Multifunctional building is a structure that contains at least two functions in the functional programme. Multipurpose buildings are typical for the metropolitan area usage. In general multifunctional building contains a large amount of functions, mixed-use spaces that create a complex system. Multifunctional building allows to use the urban space in more efficient and compact way. The priority objective for such type of building is conservation of the city area and improvement of the quality of urban space. Furthermore, complex functional system allows to provide more economic communication, cheaper technical infrastructure, easy accessibility of services and counteracting chaotic urban sprawl.

The goal for multifunctional building is to create a new model of environment and user friendly urbanization.

2.2 *Complex system*

From the architectural point of view the system represented by a building is defined by its functions. A multifunctional building is a complex structure internally. At the same time it is also a part of the wider system in relation to the external context.

The external context, the built environment, comprises the urban design, land use, transportation system, and encompasses patterns of human activity within the physical environment (Handy & Boarnet 2002).

2.3 *Safety-based approach*

Safety is complementary with the level of risk. The common definition of risk (associated with hazard) is a combination of the probability that hazard will occur and the (usually negative) consequences of that hazard. The consequences can be expressed

in material damage or in loss of human life (Suddle 2001). Safety-based approach is necessary to improve usefulness of built environment. Safety methods are successfully applied in many practical fields connected with architectural design like: complex systems (Zio 2009); logistics (Nowakowski & Werbińka 2009); transportation including maritime and multimodal transportation (Soares & Teixeira 2001) (Abramowicz-Gerigk 2006) (Abramowicz-Gerigk & Burciu 2008) (Abramowicz-Gerigk & Burciu 2013) (Gerigk 2004) (Gerigk 2005) (Gerigk 2006) (Gerigk 2008) (Gerigk 2012); where the influence of achieved research is present in practical project designs.

Risk assessment in civil engineering design is now considered as principal rule to evaluate the consequences of building projects. There is a crucial importance of placing safety at the earliest possible stage in the project planning (Visscher et al. 2006).

3 MULTIFUNCTIONAL SYSTEM SAFETY

3.1 *Design and assessment process*

Designing a multifunctional building is a complex process. There are many factors that have an impact in the planned structure. In the life cycle of a project design the following phases are to be considered:

– concept phase,
– design phase,
– construction phase,
– exploitation phase,
– disposal phase.

In each phase the safety assessment is required. Moreover, life cycle of the project is a dynamic process in its character, so the safety assessment needs to be updated when the new hazards can appear. As it is shown in Figure 1. hazardous situation can be revealed in each phase of a design process. Each hazardous situation has its priority and importance to be resolved. It is important to resolve any hazardous situation in time to avoid overlapping, what could cause unpredictable losses.

The following stakeholders participate in the design and assessment process, when the building's essential functions and the infrastructure are defined (Nilsson & Hees 2012):

– building owner,
– tenants,
– facility staff,
– occupants,
– neighbors,
– municipality,
– regulators,
– designer,
– risk manager,
– insurer,
– fire brigade.

The final structure of the design and assessment process depends on their decision and understanding.

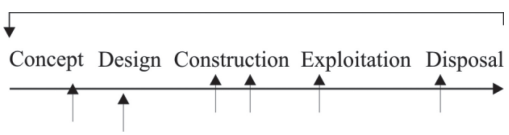

Figure 1. Multifunctional system life cycle scheme with emerging hazardous situations.

3.2 *Internal functional system*

Every function included in the structure plan must be located in the place, where it should work properly in the entire system. Recently the mixed-use buildings take the form of muli-level structures.

The base to define the outcome structure is the multifunctional building functional system. The income for determining the functional programme are the requirements defined by the developer as well as the location context. The example of the multifunctional program is presented in Table 1.

Multifunctional building design consists of a number of projects in various technical fields and a specification dependent on functional programme. The location of a function system helps to define the rest of the important subsystems. There are the following integrated subsystems:

– Construction system,
– Lighting control system,
– Electric power control system,
– HVAC (Heating, Ventilating and Air
– conditioning) system,
– Security and observation system,
– Access control system,
– Fire alarm system,

Table 1. Functional programme.

Level	Function
…	…
–2	Garage
–1	Garage, subway, logistics
0	Public communication, gastronomy, shopping
1	Fitness, art gallery, cinema
2	Offices, business
…	…

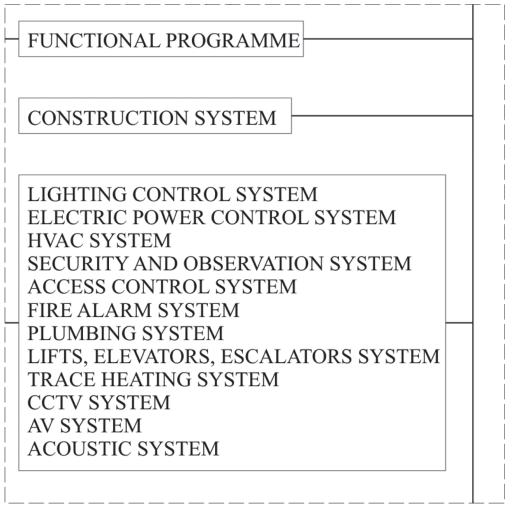

Figure 2. Internal functional system scheme.

– Plumbing system,
– Lifts, elevators, escalators system,
– Trace heating system,
– Closed-Circuit Television (CCTV),
– AV (audio-video) system,
– Acoustic system,
– Other engineering systems.

All the mentioned above systems (Doukas & Patlitzianas 2007) must be integrated with the basic architectural project.

The internal functional system of a multipurpose building can be defined as a compact structure formalized in horizontal and vertical directions.

3.3 *External functional system*

The internal functional system is dependent on the external system. The outside space of the building is the context, where multipurpose interior environment goes smoothly to exterior and is connected with different types of access. All the internal subsystems are supplied from the outside city supply systems.

Describing the external system it is necessary to mention the environmental conditions which in most cases have a significant and direct impact on the building performance. The external system components are as follows:

– Social infrastructure,
– Technical infrastructure,
– Transportation infrastructure,
– City logistics supply system,
– Waste disposal,
– Weather conditions.

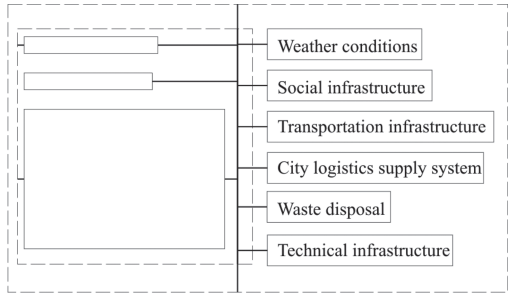

Figure 3. External functional system scheme.

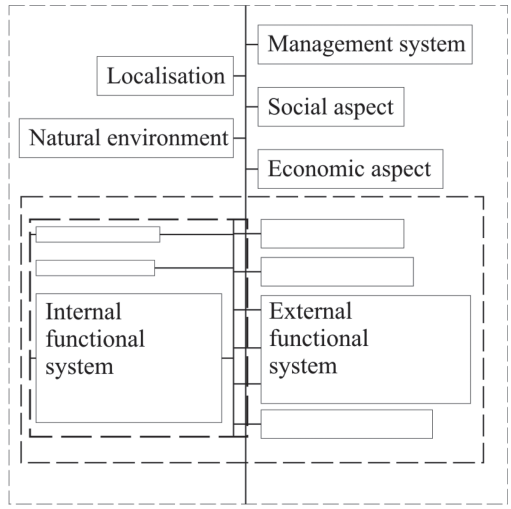

Figure 4. Environment system scheme.

3.4 *Environment*

Looking from the outside, it is easy to observe the integrity of the inside and outside. Creating a multifunctional safety-based system it is important to take into account elements related to each one of the subsystems. Environmental factors which have the influence on the building are as follows:

– Internal functional system,
– External functional system,
– Management system,
– Localization,
– Social aspect,
– Economic aspect,
– Natural environment.

3.5 *Safety approach in architectural design*

In the architectural design process the implementation of the safety criterion should be the priority.

Architectural design coordinates all factors which affect the structure of a multifunctional building. The success of the project depends on good coordination of the project as well as proper system management in each life cycle phase. Safety criteria for an architectural design are significant for the outcome of the process. The most important criteria are:

– Aesthetics,
– Functionality,
– Performance,
– Reliability,
– Design for minimum risk.

The safety-based approach in the design process refers to the elimination of the identified hazards or reduction of the associated risk through design. The risk should be evaluated with respect to people using the building, internal and external functional systems.

Greater complexity in the system increases the possibility that design faults will occur and emerge into the final product (Stephans 2012). According to (Stewart & Melchers 1997) the system failure of engineered structures may be defined as either structural collapse, functionality or serviceability failure. Moreover, it appears that human errors during the planning and design phases as well as construction phase are considered to be the most frequent. The DIN 1055 code declares, that human errors are not considered due to control processes and training. Human errors are not included in the design process. The systems view of human error regards errors and adverse events as a function of a system of interacting parts, any or all of which could present opportunities for preventing and correcting errors (Expert Working Group on Human Factors in Latent Print Analysis 2012).

4 HOLISTIC METHOD IN DESIGN

4.1 *Traditional design*

Traditional design is based on restricted requirements of building codes, law and local master plan. Taking into account only the measures listed above the project team can work out the new design. After the evaluation, when the design meets all the requirements it is ready to be realized. Developers usually should be aware of the design information and limits (Visscher et al. 2006).

In the traditional design the needs of a client or developer were the only sufficient factors for the design team to lead the project and the most important criteria were the investment cost and time.

This traditional approach never meets all the necessary requirements for example with respect to the emergence of the building. Disregard to the strategic criteria can have effect of reducing safety and reliability of the system.

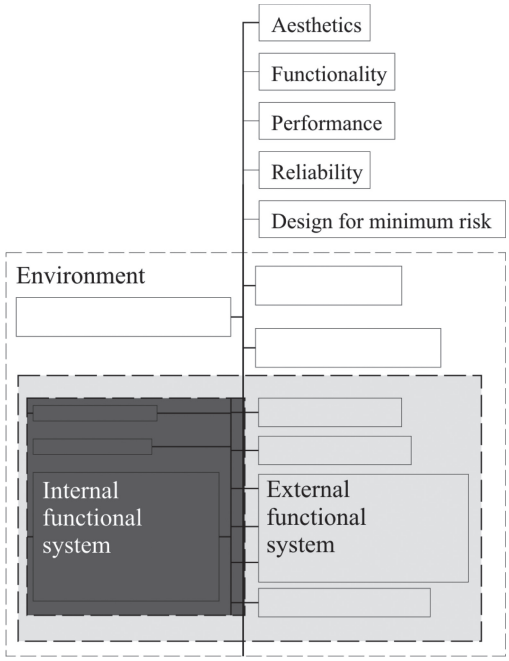

Figure 5. Multifunctional building design scheme.

Traditional approach is based on codes. Standardization and rules improve the design process, but it is not possible for them to manage the whole fluent processing.

4.2 *Multifunctional building design*

Multifunctional building design requires taking the safety-based approach into the design process with more attention. The fundamental quality of holistic method in the multifunctional building design is to reach the general system scope. The outcome of the process, that is multifunctional building design, should be fluently working system, where the functions do not interfere with respect to each other.

Defining the basic parameters of the multifunctional building design may result in its more efficient use. Optimizing durability should be the basis for each architectural project.

5 CONCLUSIONS

Traditional design is based on restricted requirements of building codes. The actual trend in public utility buildings indicates the necessity to improve the safety-based approach in their design.

The safety-based approach applied in architectural design of the multipurpose buildings puts more responsibility on the designer and allows him to use his creativity much more efficient avoiding hazardous solutions. The formal description of the architectural project is difficult in its aesthetic aspects, however the formal description of the functional aspects can have positive influence on the final result as we all appreciate and admire a beauty coming from orders, comfort and safety.

Management of controls of fire protection systems in Switzerland

E. Nachtigall & S. Metzger
Quantum Brandschutz GmbH, Basel, Switzerland

ABSTRACT: Fire protection systems play an increasingly important role in resolving fire safety challenges. Fire protection systems interact with each other and with other safety and security related systems in a huge network. Together with growing demands and continuous technical development this leads to a rising complexity of such systems. Controls of fire protection systems are predominantly of static nature and neither considers the dynamic nature of fire nor the interactions between systems. Thus, the potential of fire protection systems is not yet fully realized and utilized. Controls of fire protection systems are therefore often planned, implemented and modified in an inconsistent manner. This paper shows how the controls of fire protection systems can be planned, implemented and tested to respond adequately to fire safety aims and to meet the safety demands of society. For this purpose a comprehensive approach to manage the controls of fire protection systems concerning the life cycle phases of buildings based on current Swiss regulations has been developed. The main groups of stakeholders and their special roles and responsibilities in this process are shown. Clear identification of processes, best practice approaches and planning instruments to support the technical and management processes are presented.

1 INTRODUCTION

Nowadays, modern fire alarm systems are much more than devices for fire detection and alarming the fire brigade. In modern buildings these complex instruments of fire protection systems can have the following functions:

- Fire detection (automatic and manual)
- Control of fire protection and building service systems
- Interaction with building safety and security systems
- Alarm/Inform (local and fire brigade)
- Evacuation of people

Because of different functions a fire alarm system can have multiple dependencies to other technical systems. Some examples are shown in Figure 1.

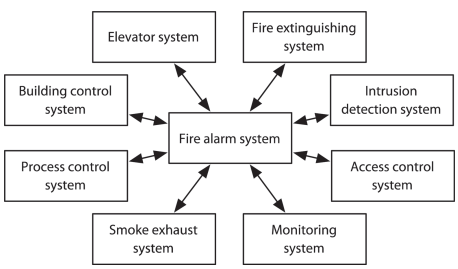

Figure 1. Examples of dependencies of technical systems to fire alarm system in buildings.

Usually a fire alarm system has numerous dependencies to other safety and security related systems (e.g. fire extinguishing, intrusion detection, access control and smoke exhaust systems). Due to safety and/or security reasons also non safety and security related systems (e.g. elevator, building control, process control and monitoring system) can be connected to a fire alarm system. This is based on the fact that many seemingly non safety and security related systems can become very relevant during complex emergency situations or scenarios (Nachtigall & Klingsch 2011).

2 CONTROLS OF FIRE PROTECTION SYSTEMS

Fire protection systems in buildings usually have many sensors, control units containing complex control logic and actuators. In most cases this complexity can be reduced to a simple control chain to demonstrate the interrelations (Burns 2001).

A usual control chain in fire protection systems containing a sensor, a control unit and an actuator is show in Figure 2.

In this example a sensor (e.g. an automatic fire detector) is activated by combustion products such as smoke, heat or combustion gases. After activating the control unit (e.g. a fire alarm or detection system), it initiates programmed Controls of Fire Protection Systems (CFPS) or activates other actuators in the building. An actuator is for example a

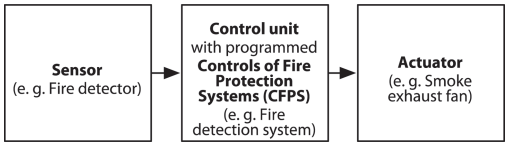

Figure 2. Control chain in fire protection system.

smoke exhaust system that ensures that the defined fire safety goals can be reached.

In modern large buildings usually a fire alarm system, sometimes with thousands of sensors and many different fire safety related and other building service systems are used. For mastering this complexity and also for planning and maintaining the CFPS in some countries (e.g. Switzerland) the following instruments are used:

- Report
- Matrix
- Plan/Visualisation
- The report usually includes the following contents:
- Introduction, description of the project and main boundary conditions
- Life and fire safety goals taken from the fire safety report
- Goals of CFPS to support life and fire safety goals
- Basics: Regulations and guidelines, plans and other documentation
- Basic and detailed description of CFPS
- Zoning of the building
- Detailed CFPS for all fire protection systems and other relevant safety and security related systems and non safety and security related systems
- Mode of alarm
- Conclusion

Another important tool to plan CFPS is the matrix or fire safety matrix. A matrix with only very few elements for an exemplary area or zone is shown in Figure 3.

A matrix represents logical connections between fire safety related sensors and actuators. In this context, the X in a cell of the matrix implies that the specific interaction described in the function cell occurs. For instance, upon activation of the sprinkler or an automatic fire alarm detector in the considered area the fire department is alerted and the smoke exhaust system is activated.

This simple matrix exemplifies the most important relationships in CFPS. More complex schemes can be necessary for large modern buildings, usually containing many different fire protection systems and other relevant safety and security related systems. In many cases CFPS are static and do not

Controls of Fire Protection Systems in area ... / Sensor/Switch ...	Actuator/System ...	Fire alarm system	Fire brigade alarm	Smoke exhaust system	Smoke exhaust fan	HVAC system	Venting system	Other systems

Figure 3. Matrix with CFPS for an exemplary area.

consider the time or dynamic interactions between systems (Jost 2005). To overcome those limitations, a model for the dynamic control of fire protection systems was developed (Nachtigall 2013c).

The final instruments of planning CFPS are special plans or visualizations. These instruments typically provide information for CFPS in floor plans. The plans can be used to visualize areas with common CFPS, as well as location of actuators and its activation function.

These three information instruments form the basis for a complete planning of the CFPS. To understand the planning process of CFPS first the life cycle of a building and the corresponding fire safety services have to be explained.

3 LIFE CYCLE OF A BUILDING AND FIRE SAFETY SERVICES

A basis for the provision of engineering services in civil engineering is in Switzerland the SIA 112 (Swiss Norm 508 112). This norm, developed by the Swiss Society of Engineers and Architects (SSEA) presents and explains performance phases for the life cycle of a building. The different main- and subphases of these performance phases are shown in Figure 4.

The SSEA main performance phases start with strategic planning (1) followed by preliminary studies (2). In this two main phases a wide range of fire safety consulting services are usually performed in subphases (11–22).

In project planning phase (3) fire safety planning in subphases (31–33) and fire safety engineering methods are performed. It bears repeating that the early involvement of the fire safety engineer is crucial for the success. In tender phase (4) tender monitoring (41) to optimize costs of all fire safety systems and services can be done.

Figure 4. Life cycle of a building, SSEA-performance phases and fire safety services.

The implementation phase (5) is crucial to costs and on time commissioning of technical building equipment and the whole building. In this phase such fire safety services as construction supervision, quality assurance (51–53) and fire safety engineering methods (52–62) can dramatically reduce construction costs, enables the flexible use of the building and ensure the realization of planed life and fire safety.

The switch from implementation phase (5) to management phase (6) is the most challenging part in the whole life cycle of a building. Therefore the put into the operation of fire protection systems and implementation of CFPS in subphases (52–53, 61–62) are very important (SSEA 2013). Well-known and best-executed processes of the commissioning and put into operation are crucial for success and cost certainty.

In management phase (6) also fire prevention (61) and support during renovation subphase (62) by experienced fire safety companies in those fields are important to support or improve a high level of fire safety (Hasofer & et al. 2007). Periodic checks, maintenance and adjustments of already implemented CFPS in subphases (61–62) help also to sustain the intended fire safety level.

4 CONTENT BASED PLANING PROCESS OF CONTROLS OF FIRE PROTECTION SYSTEMS

Based on the presented life cycle of a building following planning process for CFPS in different phases with corresponding subphases are necessary:

Phase 33: The process of creation of CFPS report usually contains the following steps:

- Analysis of CFPS from the fire safety report containing:
  Examination of available documents, and conduct a rough analysis
  - Identification of specific features of the building and its fire control systems
- Creation of CFPS report with focus on:
  - Setting the control policies with the principal
  - Create the building-specific concept CFPS (1st version of the CFPS report)

Phase 51: Creation of CFPS matrix containing:

- Create the CFPS matrix (1st version of the CFPS matrix) based on the CFPS report
- Examination of the draught fire case control by the principal

Phase 52: Updating of the CFPS documents:

- Adjusting the CFPS report (2nd version of the CFPS report)
- The CFPS report and matrix to be submitted to the authority and approved by the latter
- Customizing and finalizing the CFPS report (3rd version of the CFPS report)
- Customizing and finalizing the CFPS matrix (2nd and 3rd version of the CFPS matrix)
- The programming of the fire alarm system by the fire alarm systems suppliers as defined by CFPS report and matrix (both 3rd version)

Phase 53: Integral Tests: For the successful commissioning of the building facilities the following steps of the integrals tests (which include preparation, implementation and documentation) are necessary:

- Start meeting with the leaders of the principal, fire alarm systems suppliers and other stakeholders
- Create the test program
- Presentation and discharge of the test program by the authority
- Performing integral tests
- Documentation of the tests with protocols and fault lists
- Adaptation of the CFPS documents

5 STAKEHOLDERS AND THEIR ROLES FOR CONTROLS OF FIRE PROTECTION SYSTEMS

Besides the shown planning process of CFPS the information level and qualification level of stakeholders of the process are important for successful implementation of CFPS. Therefore a stakeholder-centered approach to planning of

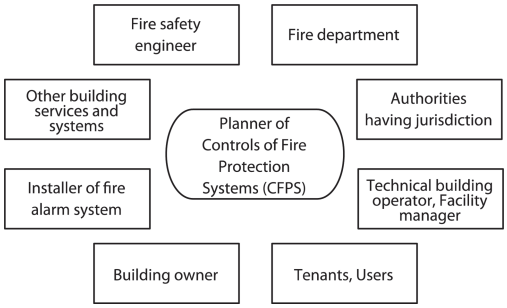

Figure 5. Different stakeholders of processes for CFPS.

CFPS is necessary. Such stakeholder-centered approach with its stakeholders to planning of CFPS is shown in Figure 5.

By far the most important role to plan and maintain CFPS is the planner of CFPS. He must communicate and get the necessary information from other technical designers and stakeholders.

At the beginning of the planning process the fire safety engineer or the author of the fire safety report must be consulted. For the best practice the fire safety engineer is the same person or at least a person in the same organization as the planner of CFPS. This is because CFPS are to support and to implement integrated fire protection systems and to reach the life and fire safety goals, which has, been carried out in fire safety report.

The needs of the fire department and authorities having jurisdiction are to be considered by the planer of CFPS. In most cases those two stakeholder groups controlling the whole process.

Consultations with planers and builders of building services and fire alarm system are also necessary. Other stakeholders such as tenants and users as well as the technical building operator or the facility manager have also to cooperate with. All important information must be communicated to those stakeholder groups.

6 MODULES FOR CONTROLS OF FIRE PROTECTION SYSTEMS

Besides the pervious considering of content based planning process of CFPS and description of stakeholders who are usually involved in the process, modules for CFPS are to develop. These modules oriented model can help to understand the process of planning of CFPS not only based on content or documents introduced before but also based on modules, which contain actions and documents. A modules oriented management system for processes to planning CFPS is shown in Figure 6.

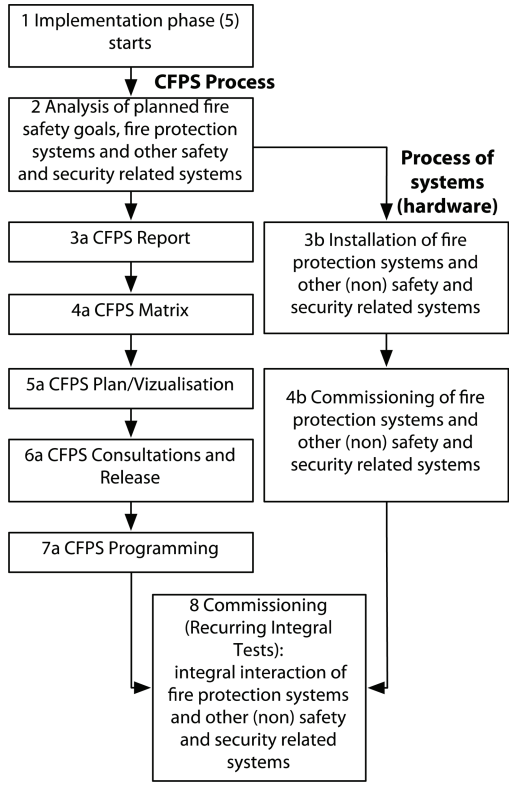

Figure 6. Management system modules of processes for CFPS.

At the beginning of the implementation phase an analysis of planned fire safety goals, fire protection systems and other (non) safety and security related systems is performed.

At this point two parallel processes start. The first process is the planning and implementation process of CFPS. The second process is the process for installation and commissioning of technical systems in the building.

The modules of CFPS process, which is in the focus of this paper, contain the following the steps:

- Creating the CFPS report (3a)
- Creating the CFPS matrix (4a)
- Creating CFPS plans or visualization (5a)

Then the process steps of consultations and release process (6a) followed by the process of programming (7a) CFPS are usually performed. After this in process step (8) both parallel processes are integrated again in integral test. Those important tests are necessary to show correct integral interactions of fire protection systems and other (non) safety and security related systems, which could be

relevant for life and fire safety. Needless to say that this process step must be repeated after changes of technical systems or after about two or three years to show the correct interactions of those systems which are crucial for life and fire safety.

The presented modules for CFPS are derived from regulations provided by the Swiss VKF (Association of Cantonal Fire Insurers; German: Vereinigung Kantonaler Feuerversicherungen) (VKF 2008), (VKF 2007).

In Switzerland at different companies, which provide services in fire, safety planning and engineering as well as in planning of CFPS the presented or similar processes are successfully developed and used.

7 FURTHER DEVELOPMENT OF CONTROLS OF FIRE PROTECTION SYSTEMS

The following key points are essential for the success in fire safety services and especially in CFPS services:

- Strategic focus on integral fire safety engineering
- Consistent operational excellence in fire safety engineering and CFPS
- Constant improvement
- High quality services on-time
- Customer centricity
- High employee engagement

These influencing factors are general in nature and meet many situations and service-oriented companies (Hess 2012). However, they are necessary for a sustainable development of companies in this field. The better the company in those key points is situated, the more likely it is possible to implement the presented management system of CFPS successfully.

Beside the implementing of the introduced management system the following points could became relevant in future for the processes interrelated with CFPS:

- Model the building and fire scenarios with the help of Computer Fluid Dynamics (CFD) including dynamic interactions of fire protection of systems (Mahdavi 1996)
- Development of software tools around the planning processes of CFPS to automate and improve the quality of processes (Männchen 2012), (Merz & et al. 2010), (Lieb & Gerhardt 2004)
- Implementation of functional safety methods in fire protection systems to achieve the life and fire safety goals quantitatively (Börcsök 2007), (IEC 2010), (Meyna & Pauli 2010), (Nachtigall 2013b)
- Development of systems approach or a special systems theory of fire safety (Ropohl 2012), (Nachtigall 2013a)
- Embedding the processes of fire safety in the overall risk management (ISO 2011)
- Further development of appropriate standards for CFPS and recurring integral tests (SSEA 2013), (VDI 2005), (GOST 2011), (Ernst & et al. 2014), (Lucka 2014)

8 CONCLUSIONS

First of all the paper introduces the concept of Controls of Fire Protection Systems (CFPS) used in Switzerland. Main documents for planning CFPS such as CFPS report, matrix and plans and their most important contents are presented.

Then the paper introduces and explains different fire safety services in the life cycle of a building. This life cycle is based on phases and subphases, which are used in Switzerland to structure the processes in civil engineering. According to the findings in the paper fire safety services should be offered during the whole life cycle to reach and optimize the intended level of life and fire safety.

After introducing the fire safety services approach based on the life cycle content based planning process of CFPS is presented. Also the main stakeholders and their roles for CFPS process are shown.

Furthermore management system modules of processes for CFPS derived from regulations in Switzerland are characterized and discussed.

Finally some indications for companies to succeed in fields of fire safety services as well as possible further developments of CFPS are given.

The paper presents processes for management of controls of fire protection systems, which are used in Switzerland. To handle the growing complexity in safety and security related systems in civil engineering and special in fire protection systems a comprehensive approach is identified. The discussed management system based on modules can also be implemented in other countries. Positive experiences of application of presented management system in modern and complex buildings are available and can be used for further development.

Electronic components with time-dependent failure rates—reasons, values and consequences

P. Zeiler, O. Koller & B. Bertsche
Institute of Machine Components, University of Stuttgart, Stuttgart, Germany

ABSTRACT: For reliability calculation of electronic components, handbooks are typically used. The calculation shows a high level of uncertainty and usually has no direct relationship to a physical damage mechanism. Moreover, the calculation procedure assumes constant failure rates. A power module (integrated in electric and hybrid vehicles) and an electrolytic capacitor were used to examine whether this assumption is universally valid. The physics of failure of both exemplary electronic components showed that the dominant failure mode had a significantly increasing failure rate. This demonstrates that the general assumption of constant failure rate for electronic components is not permissible. It has wide-ranging consequences for reliability and safety analysis of these components and their specification. The influences of an increasing failure rate on the proper specification of a component are shown. Furthermore, the influences on preventive maintenance, functional safety and availability are considered.

1 INTRODUCTION

The reliability calculation of electronic components is typically done based on handbooks. The handbooks calculate constant failure rates based on exponential distribution which are adjusted for the particular environmental conditions and individual loads.

Using the example of a power module (integrated in electric and hybrid vehicles) and an electrolytic capacitor, it will be examined whether this approach is universally valid. A Weibull analysis of test results for this component showed a significantly increasing failure rate due to mechanical stresses caused by thermal cyclical of the component during operation. The test analysis for aluminium electrolytic capacitors showed a similar result.

This demonstrates that the assumption of a constant failure rate is not permissible in general. The modelling of the failure behaviour by an exponential distribution is obviously not correct for components with increasing failure rate. The use of a time-dependent failure rate in the model, applying the Weibull distribution, has wide-ranging consequences for reliability and safety analysis of these components and their specification.

The commonly used specification parameters can lead to dramatically misleading component reliability and safety over the specified life time. This will be demonstrated by investigating the influence of different increasing failure rates on the reliability and safety characteristics and specification parameters. An adequate specification parameter for components with time-dependent failure rates will be defined. The effect of preventive maintenance to limit the failure rate will be illustrated. The influence on functional safety and the procedure to specify the availability will be noted.

This paper is organized as follows: In chapter 2 some basics and definitions are provided. Chapter 3 describes the commonly applied procedure to calculate the reliability of electronic components. Electronic components with time-dependent failure rate are presented in chapter 4, followed by the consequences in chapter 5.

2 BASICS & DEFINITIONS

In the following some definitions and basic explanations are summarized which are essential for the topic of the paper.

2.1 *Reliability*

The reliability $R(t)$ of a component is the probability that, when operating under stated environmental conditions, the component will perform its intended function adequately for a specified interval of time t (Bertsche 2008).

The mathematical description is based on the probability density function (pdf) $f(t)$, the failure probability $F(t)$ described a cumulative distribution function (cdf), with $f(t) = \mathrm{d}F(t)/\mathrm{d}t$, the reliability $R(t) = 1 - F(t)$ and the failure rate $\lambda(t) = f(t)/R(t)$.

The failure rate is a conditional probability, as it describes the probability to fail in an infinitesimal time interval dt at time t under the condition that the observed element has survived until time t.

The expected value of life time τ is defined as

$$MTTF = E(\tau) = \int_0^\infty t\, f(t)\,\mathrm{d}t = \int_0^\infty \big(1 - F(t)\big)\,\mathrm{d}t\,, \qquad (1)$$

which is the mean life time $MTTF$ (Mean Time To Failure).

A quantile is defined as the value which is undercut by a given probability α. The α-quantile Q_α of a cdf $F(\bullet)$ is defined as

$$Q_\alpha = F^{-1}(\alpha). \qquad (2)$$

2.2 *Exponential distribution*

Starting from an initial value the pdf of the exponential distribution decreases monotonic according to an inverse exponential function. The pdf is given by (Bertsche 2008)

$$f(t) = \lambda \cdot e^{-\lambda t}, \quad t \geq 0 \text{ and } \lambda > 0\,, \qquad (3)$$

with the constant failure rate λ as the only parameter, i.e. the probability of failing in an interval is independent of the time elapsed up to the beginning of the interval. This memory-less property makes the distribution mostly inapplicable to describe sufficiently the failure behaviour of mechanical components, like aging and wear-out.

The mean life time described by the exponential distribution is

$$MTTF = \frac{1}{\lambda}. \qquad (4)$$

2.3 *The Weibull distribution*

The usual description of the failure behaviour of mechanical or automotive components is provided by the three-parameter Weibull distribution (Bertsche 2008), with the pdf

$$f(t) = \frac{b}{(T - t_0)}\left(\frac{t - t_0}{T - t_0}\right)^{b-1} e^{-\left(\frac{t-t_0}{T-t_0}\right)^b}, \quad t \geq t_0 \geq 0 \qquad (5)$$

with shape parameter b, scale parameter T and failure-free time t_0. For $t_0 = 0$ one speaks of a two-parameter Weibull distribution. With $b = 1$ and $t_0 = 0$ the Weibull distribution is reduced to the exponential distribution with $\lambda = 1/T$.

It is obvious that the failure rate of a Weibull distribution is a function of time

$$\lambda(t) = \frac{f(t)}{R(t)} = \frac{b}{T - t_0}\left(\frac{t - t_0}{T - t_0}\right)^{b-1}, \qquad (6)$$

which could depict all three sections of the well-known bath tub curve depending only on the shape parameter.

2.4 *Bath tub curve*

The failure rate λ(t) will change over the component life time of a population as shown in Figure 1.

The bath tub curve generally emerges through superposition of three typical failure modes and is therefore subdivided into the following sections:

- Section I of a decreasing failure rate ($b < 1$) represents early failures due to material or manufacturing defects. Quality control and initial component testing usually help to avoid this kind of failures. Actuarial statisticians call this section of the curve "infant mortality".
- Section II of a constant failure rate ($b \cong 1$) represents random failures caused by sudden stresses, extreme conditions e.g. like over-voltage regarding electronic components, handling errors, etc. In actuarial terms this could be equated to the accidents encountered by a population of individuals on a day-to-day basis. This section of the bath tub curve is usually assumed in the reliability calculation of electronic components, see chapter 3.
- Section III of an increasing failure rate ($b > 1$) represents wear-out or aging failures. Here the failure rate increases as equipment deteriorates. For mechanical components like bearings, gearwheels or shafts there is knowledge about the Weibull parameters in this section (Bertsche 2008). With this, the curve progression in this section of the bath tub curve is well-known.

During component development, one tries to increase the reliability of the component systematically, i.e. to avoid early failures (pre-aging) and delay the beginning of wear-out and aging failures as far as possible.

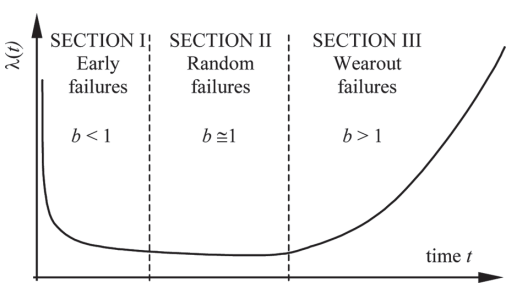

Figure 1. Failure rate λ (t) over component life time.

2.5 *Availability*

For a component which is repaired after failure or maintained the availability is used as parameter. The availability $A(t)$ is defined as the probability that a component is operating satisfactorily at time t (Bertsche 2008).

3 RELIABILITY CALCULATION OF ELECTRONIC COMPONENTS

According to IEEE (2003) component reliability is determined from field or test data, from physical failure modelling (physics of failure), or using so-called handbooks.

For reliability calculation of electronic components, handbooks are typically used (Koller et al. 2011). The handbooks calculate constant failure rates based on exponential distribution. The exponential distribution corresponds to a Weibull distribution with shape parameter $b = 1$. Therefore only random failures are described in section II of the bath tub curve, which are characterized by a constant failure rate.

Handbooks for predicting reliability list basic or fundamental failure rates for electronic components that have been obtained from empirical field or test data evaluations. The basic or fundamental failure rates are adjusted for the particular environmental conditions and individual loads on components using multiplicative or additive factors (Koller et al. 2011).

The first handbook for predicting reliability, now in widespread use, is the MIL-HDBK-217 standard (MIL-HDBK-217F Notice2 1991). It also uses field data to determine empirical failure rates and a multiplicative model for adjusting basic and fundamental failure rates to individual component loads. The model in the MIL-HDBK-217 standard assumes a linear relationship

$$\lambda_p = f(\lambda_b, \pi_1, \pi_2, \ldots, \pi_n) = \lambda_b \cdot \pi_1 \cdot \pi_2 \cdot \cdots \cdot \pi_n . \quad (7)$$

Here λ_p describes the predicted failure rate of the element, based on the individual load, λ_b describes the basic failure rate, and π_i describes the adjustment factors for the given boundary conditions. The adjustment factors take environmental factors such as the temperature and humidity into consideration. The individual loads, such as current flow or operating voltage, are also incorporated in the adjustment factors. In some cases, variables that describe load strength, such as component quality, are also included when setting the adjustment factors.

The adjustment factors for the active load are typically physically motivated and depend on just a single variable. To describe the temperature dependency of the failure rate, for example, the Arrhenius equation is used, see Equation 8 (MIL-HDBK-217F Notice2 1991). According to Arrhenius, this equation from physical chemistry describes the dependency of reaction speed on the temperature

$$k = A \cdot \exp\left(\frac{-E_A}{R\vartheta}\right). \quad (8)$$

The reaction speed constant k is calculated using the following parameters: A is a pre-exponential adjustment factor, E_A is the activation energy, R stands for the general gas constant, and ϑ is the absolute (thermodynamic) temperature. This Arrhenius equation is then used to define the adjustment factor that describes the temperature dependency of the failure rate. The adjustment factor (MIL-HDBK-217F Notice2 1991) from Equation 9 thus includes the failure rate acceleration factor between an increase in temperature ϑ and the failure rate λ

$$\pi_\vartheta(\vartheta) = \exp\left(-\frac{E_A}{R}\left(\frac{1}{\vartheta[°C] + 273.15K} - \frac{1}{298K}\right)\right). \quad (9)$$

The activation energy E_A is parameterized using field failure data. As can be seen in Equation 9, the temperature adjustment factor takes on the value 1 for a temperature of $T = 298$ K. This corresponds to the temperature at which the basic failure rate was determined.

When using handbooks for reliability analysis, a common criticism is that the calculation has a high level of uncertainty. An investigation in (Jensen 1995) of the calculation of the failure rate for a 64 K memory module showed that failure rates calculated using 5 different handbooks varied by a factor of 6.

Failure rates in the handbooks typically have no direct relationship to a physical damage mechanism. As a rule, several damage mechanisms may actually be summarized in one failure rate (Poech 2010). For this reason, a reliability calculation based on handbooks cannot provide any deeper understanding of the damage mechanisms in the product, and it is difficult to derive any potential optimizations in the development process. Rather, this reliability calculation is based on purely empirical relationships.

4 ELECTRONIC COMPONENTS WITH TIME-DEPENDENT FAILURE RATE

Chapter 3 showed that reliability analyses of electronic components typically use handbooks.

They assume constant failure rates. Using the example of a physically motivated approach for determining the reliability of a power module and an electrolytic capacitor, it will be examined whether this approach is universally valid.

4.1 *Power modules*

Power modules are integrated in electric and hybrid vehicles, for example, in order to connect the transistors of the power electronics to the heat sinks. The use of power modules is typical for power levels above one kilowatt (Hensler 2012). Power modules have electrical, mechanical, and thermal functions. The silicon chip, the bonds, and the copper layer form the electrical circuit. This electrical circuit is insulated from the rest of the module by means of an electrical insulator (typically ceramic). The insulation is applied to a heat spreader that ensures that heat is distributed uniformly within the module and that the heat is thus dissipated away from the chip. The heat spreader is typically made of copper and also provides mechanical stabilization. It is connected to the heat sink by a so-called thermal grease, and the heat sink in turn is cooled by means of a cooling medium (air or liquid).

The principle configuration of a power module is shown in Figure 2.

4.1.1 *Physics of failure*

Because the power modules contain materials with different thermal expansion coefficients, cyclical warming and cooling of the component during operation causes mechanical stresses induced by thermal strain in and between the individual connection layers. For the example of an application in electric and hybrid vehicles, the temperature cycles arise due to brief, intense currents in the power modules, such as during the recuperation processes, when vehicle braking energy is converted to supply to the vehicle electrical system. Figure 3 shows an example of the temperature increases of a hybrid vehicle in the New European Driving Cycle (NEDC).

Because of this cyclical thermal load, the solder layers can be considered as critical layers, because they are typically located between two materials with different thermal expansion coefficients and have to compensate for the stresses that arise. Because these stresses that occur will inevitably lead to crack formation and ultimately to failure over the life of the component, the fatigue strength and thus the reliability of the power module plays a decisive role.

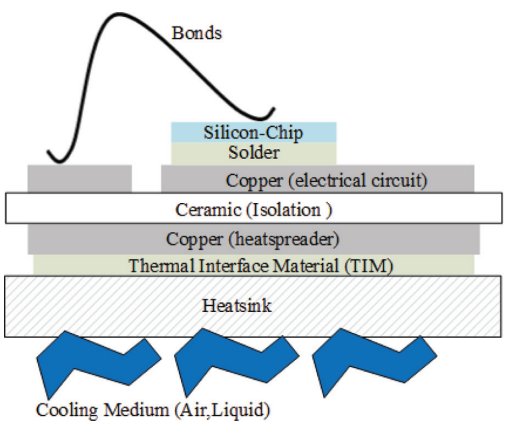

Figure 2. Configuration of a power module.

4.1.2 *Exemplary results*

In (Lutz et al. 2011), tests of the reliability of these power modules were performed and published. Five repeat tests were performed for a load level at a defined temperature rise. The failure data from this test were used to perform a Weibull analysis of the failure data. The result of the Weibull analysis is shown in Figure 4.

When evaluating the failure data shown in Figure 4, the resulting shape parameter is between

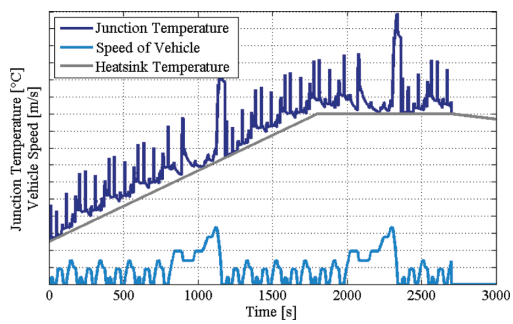

Figure 3. Junction temperature curve for a hybrid vehicle.

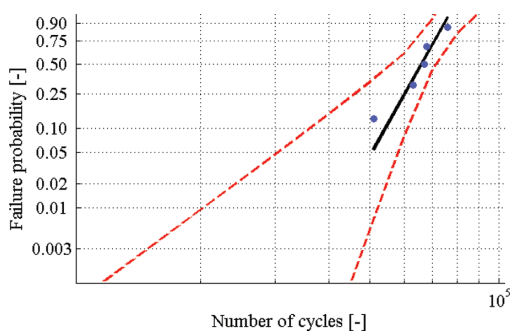

Figure 4. Failure data of a transistor on a power module.

$b = 4.49$ and $b = 10.49$ using a confidence interval of 90%. For a confidence level of 50% a shape parameter of $b = 6.86$ was determined. The shape parameter is significantly greater than the shape parameter of $b = 1$ used in the handbooks.

4.2 *Electrolytic capacitors*

Other experiments on the physical failure behaviour of electronic components have had similar results regarding their failure behaviour (Gerling 2011).

In (Perisse et al. 2004) the failure behaviour of aluminium electrolytic capacitors was investigated. The results showed, that the reliability calculation by using the exponential distribution subject to major inaccuracies. The use of the Weibull distribution with a shape parameter greater than 1 provides significantly better results.

The physics of failure is related to the time-dependent evaporation of the electrolyte. This evaporation process depends on several parameters like voltage, current and temperature (Perisse et al. 2004).

The result of the regression using the Weibull distribution is shown in Figure 5. The resulting shape parameter is between $b = 2.06$ and $b = 4.32$ using a confidence interval of 90%. For a confidence level of 50% a shape parameter of $b = 2.98$ was determined.

4.3 *Concluding remarks*

The physics of failure of both exemplary electronic components showed that the dominant failure mode had a significantly increasing failure rate. The root cause of such a failure mode can be either caused by cyclic thermal load or by forces based on electromagnetic or electrostatic phenomena. The root cause leads to cyclic stresses in the material or to micro movements e.g. micro bending. A cyclic bending leads to stresses in the material as well.

A similar situation can be observed for the packaging. Here e.g. mechanical vibrations of the application can lead to movements of the circuit board or of individual components. Mechanical stresses are consequently induced in the materials of the packaging. Sensitive elements are the bonding wires and the solder connections.

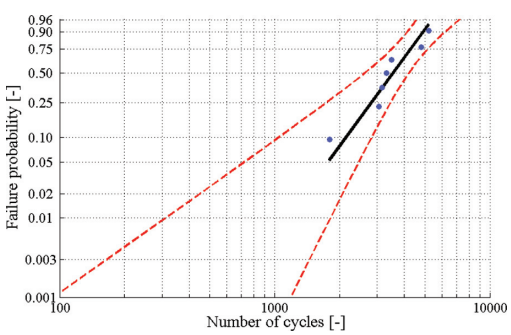

Figure 5. Failure data of an electrolytic capacitor.

These cyclic mechanical stresses lead to fatigue or ageing of the concerned materials. Crack formation or wear-out is a typical failure mode that can be observed. These failure modes are common if mechanical components are considered. This does not surprise as the principle failure mechanism is purely on the material mechanical side.

This demonstrates that the assumption of an exponential failure behaviour is permissible only for a small section of the component life which is characterized by a constant failure rate, the so-called 'useful life' (Denson 2006). In no way can the general assumption be made that the failure behaviour of electronic components can principally be modelled by a constant failure rate.

Rather, for reliability analysis of electronic components all significant failure modes need to be considered. On the one hand there are the failure modes based on electrical overstress which normally indeed show a constant failure rate. But on the other hand there are mechanical failure modes of parts inside the electronic component or its packaging which exhibit an increasing failure rate, i.e. a time-dependent failure rate.

5 CONSEQUENCES

The use of a time-dependent failure rate instead of using a constant failure rate has wide-ranging consequences. Subsequently, several topics are given to illustrate the influence of the time-dependent failure rate. It is assumed that the failure behaviour with time dependent failure rate is described by a Weibull distribution (see section 2.3). In the following sections the situation with constant failure rate is given first. Then the situation with time-dependent failure rate is described. The principal effects are illustrated by varying the shape parameter from $b = 1$ (i.e. constant failure rate) as a reference over $b = 2$, 3, 4 up to 5 (i.e. increasing time-dependent failure rates).

5.1 *Influence on specification*

For a constant failure rate, the specification can be done by two parameters:

- expected value *MTTF or*
- constant failure rate λ

Both parameters are equivalent as there is a fix relation between them, as described by Equation 4.

For a time-dependent failure rate, the specification is quite different. Subsequently, two principal situations are explained.

5.1.1 *Identical MTTF*

Given that the same expected value *MTTF* shall be specified for a component with time-dependent failure rate this would lead to the following consequences, as shown in Figure 6 for an exemplary *MTTF* of 50,000 h. As a reference the dotted line for $b = 1$ shows the corresponding constant failure rate of $2 \cdot 10^{-5}$ 1/h. For values of $b > 1$, the increasing failure rate can be observed. Compared to the constant case, for small life times the failure rate is below the reference value. But for life times at around *MTTF* or higher, the failure rate can be significantly higher. At *MTTF* for $b = 5$ the resulting failure rate is approximately 3 times higher compared to the reference rate. This can be potentially critical.

5.1.2 *Maximum failure rate*

The specification parameter *MTTF* is only useful for constant failure rates as the risk of failure is constant as well. With an increasing failure rate *MTTF* only describes the expected value, but not the distribution of the risk of failure. Therefore, it can be necessary to specify a maximum risk of failure, as shown in Figure 7.

Given that the same maximum failure rate shall be kept until time 50,000 h, in this example the value of $\lambda = 2 \cdot 10^{-5}$ 1/h, it will lead to different scale parameters T for the Weibull distribution and different expected values *MTTF* as well.

Figure 8 shows that for the given assumption, the *MTTF* of the Weibull distributions with $b = 2$ and higher are considerably higher than the *MTTF* for the constant failure rate. That means for the same maximum failure rate a more demanding *MTTF* would need to be specified.

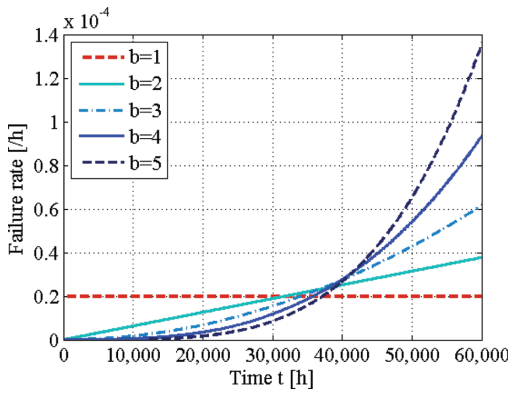

Figure 6. Failure rates for different shape parameters (with identical *MTTF* = 50,000 h).

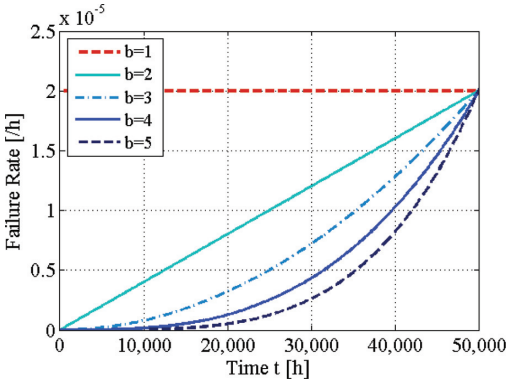

Figure 7. Different failure rate progressions (with identical maximum failure rate at 50,000 h).

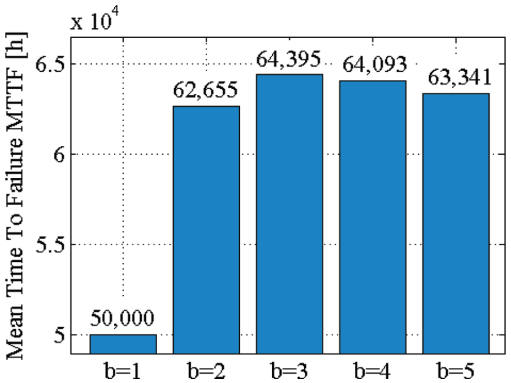

Figure 8. *MTTF* for different shape parameters (with identical maximum failure rate at 50,000 h).

5.1.3 *Influence on B_x life time*

The failure probability at the life time specified with the parameter *MTTF* is 63.2% for a constant failure rate (i.e. Weibull shape parameter $b = 1$) or approximately 50% for an increasing failure rate (e.g. Weibull shape parameter $b = 3.5$). That means, at this time half (or even more than the half) of the component's population are expected to be failed. Because of this, the *MTTF* as a specification parameter is often criticized.

Therefore, the B_x life time is applied as appropriate specification parameter, which defines the time at which a failure probability of x % is reached. Depending on the application a specification of a B_1, B_5 or B_{10} value is common. It is assumed that the same failure probability of 63.2% shall be reached at time 50,000 h. Figure 9 shows the corresponding failure probability distributions $F(t)$ for shape parameter b = 1, 2, 3, 4 and 5. It can be seen that the failure probability of 10% is

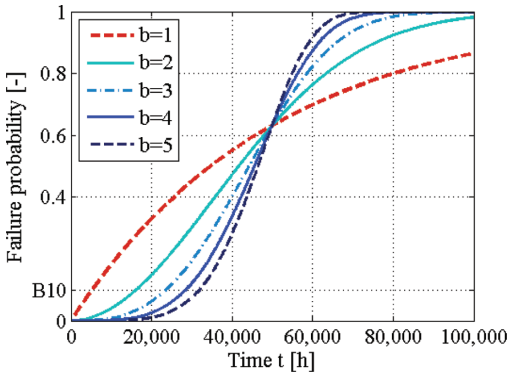

Figure 9. Influence of shape parameter b on B_{10} life time.

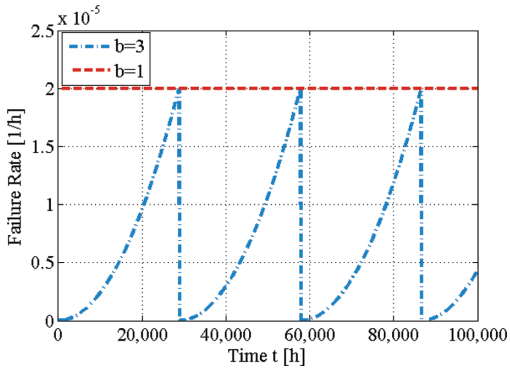

Figure 10. Limiting the failure rate by preventive maintenance.

reached at different life times depending on the shape parameter.

For $b = 1$ the B_{10} life time of 5,268 h is relatively low. In comparison the B_{10} life time of 31,879 h for $b = 5$ is high. It can be seen that the spread of the B_{10} life times is significantly high. That means, for increasing b the B_{10} life time specification is higher under these conditions.

5.2 *Influence on preventive maintenance*

For components with constant failure rate there is no benefit by performing preventive maintenance actions, if the maintenance action is the replacement of an old by a new component. As a new component has the same failure rate as a component which is operated for many hours, the risk to fail in a specific time interval stays the same.

For components with increasing failure rates, the situation is quite different. Here, replacing a component by a new one has an influence on the failure rate. Two principal situations are possible.

5.2.1 *Limiting the failure rate*

The replacement interval can be determined in order to keep the time-dependent failure rate within a specific limit. This strategy is shown in Figure 10 for a component with a Weibull distributed failure behaviour with shape parameter $b = 3$ and scale parameter $T = 50{,}000$ h. Here, a replacement interval of $T_{PM} = 29{,}000$ h is limiting the failure rate up to $2 \cdot 10^{-5}$ 1/h.

5.2.2 *Limiting the failure probability*

The replacement interval can be determined in order to keep the failure probability within a specific limit. This strategy is shown in Figure 11 for a component with a Weibull distributed failure behaviour with shape parameter $b = 3$ and scale parameter $T = 50{,}000$ h. Here, a replacement interval of $T_{PM} = 16{,}667$ h is limiting the failure probability to 20% within the intended operation time of 100,000 h.

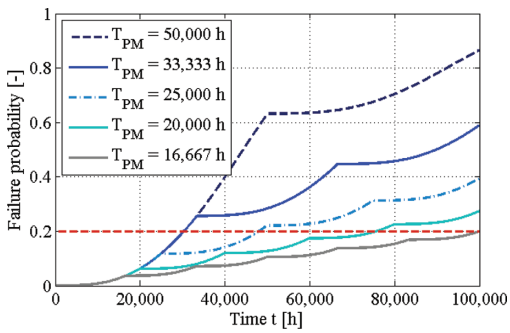

Figure 11. Limiting the failure probability by preventive maintenance.

5.3 *Influence on functional safety*

The standards for functional safety (e.g. ISO 26262 2011) define a maximum level of unsafety, so-called Safety Integrity Levels (SIL), which is tolerated for a specific level of danger. As the malfunction of electronic components can also contribute to the level of unsafety, an increasing failure rate would lead to an exceeding of the SIL over life time. This situation is illustrated in Figure 12. A component with constant failure rate is constantly within the SIL, whereas the increasing failure rate leads to an exceeding of this limit.

Here, two countermeasures should be considered in the specification. The specification of a maximum component failure rate (according to section 5.1.2) in order to fulfil the SIL within the intended product life time might be necessary.

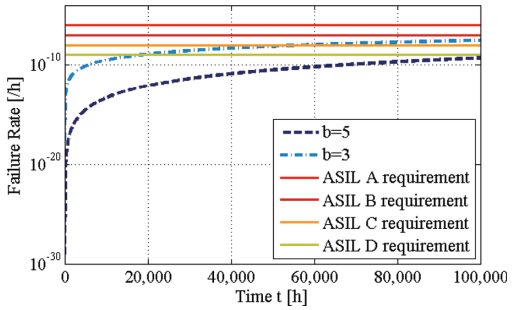

Figure 12. Influence of shape parameter b on functional safety (T = 1,000,000 h); Requirements from ISO 26262.

Alternatively, the specification of preventive maintenance in order to keep the failure rate within the necessary level might be considered (according to section 5.2.1).

5.4 *Influence on procedure to calculate the component availability*

Taking reparable systems into account, where a failed component is repaired and then set into operation again, the availability is used as the relevant parameter.

Assuming constant rates for failure and repair behaviour, the availability can be specified based on the Markov process. Often the calculation is based on an analytical solution.

If time-dependent failure and repair rates need to be considered, the Markov process is no longer applicable. Then, other methods like renewal process (Fritz et al. 2000) or even Petri nets (Zeiler & Bertsche 2013) need to be used. These methods are typically analysed by numerical or simulation based procedures.

6 CONCLUSIONS

For reliability calculation of electronic components, handbooks are typically used. The calculation shows a high level of uncertainty and usually has no direct relationship to a physical damage mechanism. Moreover, the calculation procedure assumes constant failure rates.

A power module (integrated in electric and hybrid vehicles) and an electrolytic capacitor were used to examine whether this assumption is universally valid. The physics of failure of both exemplary electronic components showed that the dominant failure mode had a significantly increasing failure rate. Even though these are electronic components it was explained that finally cyclic mechanical stresses prevail which lead to fatigue or ageing of the component material or the packaging. Crack formation or wear-out is then the typical failure mode which can be observed.

This demonstrates that the general assumption of constant failure rate for electronic components is not permissible. Moreover, beside the failure modes based on electronic physics of failure the failure modes based on mechanical physics of failure needs to be considered.

Several consequences of a time-dependent failure rate were presented. The commonly used specification parameters for electronic components—the failure rate or the *MTTF* value—are no longer applicable or provide dramatically misleading specifications. This was shown by investigating the influence of different increasing failure rates on the reliability and safety characteristics. A more appropriate specification parameter for components with time-dependent failure rates was defined. Specifying preventive maintenance is able to limit the increasing failure rate or to guarantee a maximum failure probability. For functional safety, an increasing failure rate can lead to an exceeding of the safety integrity level. This can be avoided by either appropriate component specification or by applying preventive maintenance. The specification of the component availability requires different methods compared to them applicable for constant failure rates. Based on these specifications a correct and safe application of electronic components can be ensured.

Availability and reliability evaluation of systems periodically maintained

N. Hu, J. Huang, Ch. Yang, Y. Zheng & O. Dong
China Electronic Product Reliability and Environmental Testing Research Institute, Guangzhou, China

ABSTRACT: Availability and reliability evaluation of redundant systems under periodic maintenance is one of the difficulties in the field of reliability engineering. In order to overcome the disadvantages of existing evaluation methods, an instantaneous availability analytic approach for such systems is deduced, considering fault detection rate, fault isolation rate and repair rate. Limitations of this approach are discussed. Furthermore, a simulation model is devised to accomplish the evaluation of instantaneous availability and MTBCF. The validity of this simulation method is proved. And a simulation tool for availability and reliability evaluation of redundant systems periodically maintained is developed with MATLAB. At last, a case is studied.

1 INTRODUCTION

Redundancy design is an effective method to improve system availability and reliability, which is always used in the design of large and complex equipment. Redundancy is designed to enhance systems' ability to complete required functions, and to satisfy the demands of availability and mission reliability. However, maintenance is an important and essential guarantee for the long-running operation of redundant systems. As time goes by, the full potential on availability and reliability of such systems can only be reached through multiple maintenance and repair. Otherwise, the availability and reliability will both degrade ceaselessly; afterwards the systems will develop into non-redundancy, and finally breakdown.

For some large and redundant systems, such as space stations and unattended radars on islands, the most popular and appropriate maintenance policy is periodic maintenance. For the demonstration and design of these systems, availability and reliability evaluation under periodic maintenance needs to be solved first.

So far, studies related to availability and reliability evaluation of redundant systems with repairs are mostly aimed at on-condition maintenance (RADC-TR-77-287 1977, Chen 2007, Liu & Song 2010, and some of the references therein). In especial, Markov chains (Liang & Zhang 2011), Petri nets (Yuan 2011) and their extended models are widely used. Semi-Markov chains (Li 2013) and DSPNs (Deterministic and Stochastic Petri Nets, Yuan 2011) provide feasible ideas for the modeling of systems periodically maintained. But there are still some problems remain to be solved when evaluating system availability and reliability with them, for examples, the mathematical description of waiting time form failure occurrence to the next maintenance, and the algorithms for instantaneous availability and system MTBCF (mean time between critical failures).

Concerning the evaluation of systems periodically maintained there are only a few papers. Chen (1997) built the evaluation model for both availability and MTBCF of systems under periodic maintenance. Zhao et al. (2004) studied the approximation algorithm for MTBCF, based on the assumption that reliability function of systems periodically maintained could be regarded as exponential distribution with constant failure rate and reasonable error. Nicholls (2005) deduced the accurate algorithm for MTBCF of systems periodically maintained. However, these studies are all based on the assumption that all faults could be repaired successfully within a period of time. The fact is that any fault in complex systems needs to be detected, isolated, and then fixed. Each of the three steps is with a probability of success rather than inevitable event. The probabilities, namely FDR (Fault Detection Rate), FIR (fault isolation rate) and RR (repair rate), are all between 0 and 1 in engineering practice. In this case the above research findings will be not applicable any more.

The propose of this paper is to build the availability and reliability evaluation model of systems periodically maintained, concerning FDR, FIR and RR. The limitations of analytical algorithm are discussed, and a simulation model is devised to accomplish the availability and reliability evaluation of redundant systems under periodic maintenance. The validity of this simulation method is proved. Then, a simulation tool for the evaluation is developed with MATLAB.

2 AVAILABILITY MODELING OF SYSTEMS PERIODICALLY MAINTAINED

2.1 *System model and assumptions*

Systems definition: It is supposed that a redundant system contains n units. The instantaneous availability of which are independent but follow the same exponential distribution ($A(t) = e^{-\lambda t}$, where t = the failure rate of each unit. Note that the probability that a unit or system without maintenance is able to perform its mission at time t equals to the probability that it is able to perform its mission for a stated period of time [0, t]—that is the instantaneous availability equals to the reliability). The system is workable when at least k units are in operation without failures. Maintenance interval is constant T_0. And fault detection rate is supposed to be *FDR*; fault isolation rate equals *FIR*; repair rate equals *RR*. Maintenance time is negligible.

Without regard to maintenance, the instantaneous availability model of redundant systems could be easily obtained according to system reliability algorithm. For example, the instantaneous availability function of k/n(G) voting systems composed of n same units is

$$A_S(t) = \sum_{i=k}^{n} C_n^i (A(t))^i (1 - A(t))^{n-i} \quad (1)$$

where $A(t)$ = instantaneous availability of a unit; and $A_S(t)$ = instantaneous availability of the system.

In accordance with equation (1), if we can get the instantaneous availability $A^*(t)$ of a unit periodically maintained, then instantaneous availability of the system $A_S^*(t)$ could also be calculated.

2.2 *Availability modeling of units under periodic maintenance*

Under the condition of periodic maintenance, the states of a unit may develop as Figure 1. The availability of a unit in each maintenance period could be calculated according to the developing path.

Maintenance is generally divided into three steps: fault detection, fault isolation and repair. In order to simplify the calculation, the probability of a unit to be repaired well could be expressed as the product of the probabilities of success of each step:

$$P = FDR * FIR * RR \quad (2)$$

In the first maintenance period, $t \in [0, T_0)$; maintenance is not yet involved, and the instantaneous availability of the unit equals to

$$A^*(t) = e^{-\lambda t} \quad (3)$$

In the second maintenance period, $t \in [T_0, 2T_0)$; there are two available paths leading the unit state to be workable: (1) the unit worked until time t without failures; (2) the unit failed in the first maintenance period, and repaired (at T_0) to work

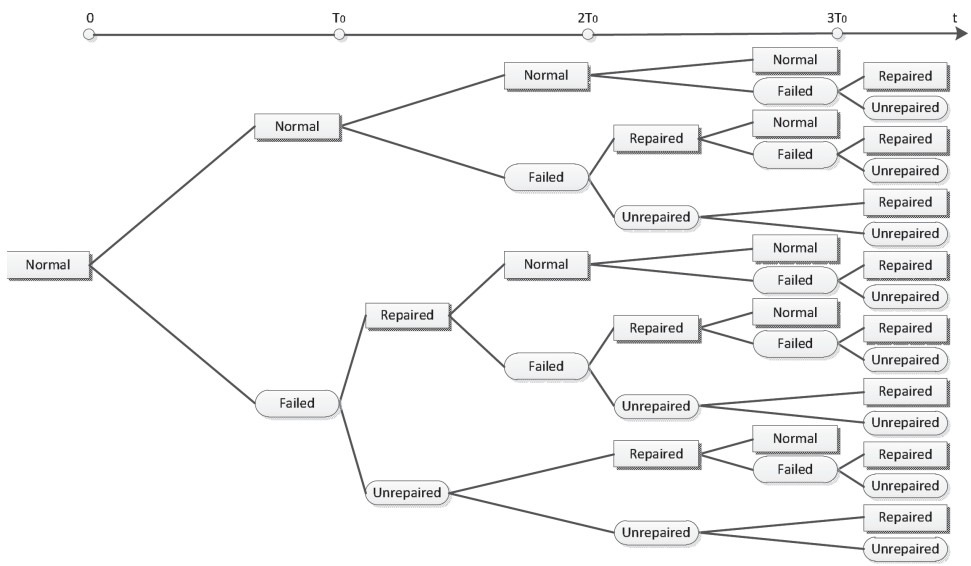

Figure 1. States developing paths of a unit under periodic maintenance.

until time t. So the instantaneous availability of the unit equals to

$$A^*(t) = e^{-\lambda t} + (1 - e^{-\lambda T_0}) * P * e^{-\lambda(t-T_0)} = e^{-\lambda t}[1 + P(e^{\lambda T_0} - 1)] \quad (4)$$

In the third maintenance period, $t \in [2T_0, 3T_0)$; there are five available paths leading the unit state to be workable: (1) the unit worked until time t without failures; (2) the unit failed in the second maintenance period, and repaired (at $2T_0$) to work until time t; (3) the unit failed in the first maintenance period, and repaired (at T_0) to work until time t; (4) the unit failed in the first maintenance period, and repaired (at T_0) to fail in the second maintenance period, and repaired (at $2T_0$) to work until time t; (5) the unit failed in the first maintenance period, but repaired in the second maintenance period (at $2T_0$), and worked until time t. So the instantaneous availability of the unit equals to

$$A^*(t) = e^{-\lambda t}\{[1 + P(e^{\lambda T_0} - 1)]^2 + P(1-P)e^{\lambda T_0}(e^{\lambda T_0} - 1)\} \quad (5)$$

Analogously, in the fourth maintenance period, $t \in [3T_0, 4T_0)$; there are thirteen available paths leading the unit state to be workable. And the instantaneous availability of the unit equals to

$$A^*(t) = e^{-\lambda t}\{[1 + P(e^{\lambda T_0} - 1)]^3 + P(1-P)e^{\lambda T_0}(e^{\lambda T_0} - 1)(1 - P + 2e^{\lambda T_0})\} \quad (6)$$

This can be proved that the number of workable states of a unit under periodic maintenance will increase following exponential distribution with time, and the instantaneous availability of a unit approximately appears as periodic changes. As a result, it is not practical to calculate the instantaneous availability of a unit in each maintenance period, but when $t \in [4T_0, +\infty)$, the instantaneous availability of a unit in each maintenance period could be regard approximately as the same distribution within the maintenance period $t \in [3T_0, 4T_0)$.

2.3 *Availability modeling of systems periodically maintained and its limitations*

The unit states developing paths under periodic maintenance have been described in the above chapter, and the piecewise function of instantaneous availability of a unit has been built. Combine the piecewise function with equation (1), the instantaneous availability of redundant systems could be obtained as follows:

$$A_S^*(t) = \sum_{i=k}^{n} C_n^i (A^*(t))^i (1 - A^*(t))^{n-i} \quad (7)$$

However, besides the deviation introduced by approximate treatment, the above calculating method also bears the following weaknesses:

1. The calculating method could only calculate instantaneous availability of the system, but not MTBCF.
2. When the number of redundant units is too large, the combinatorial number in equation (7) could easily become too large to calculate. For example, a phased array radar may contains tens of thousands of components, and less than 10% of component failures are permitted for the radar working state. Using MATLAB (R2012a), we can obtain that $C_{10000}^{9866} \approx 2.0501 \times 10^{307}$, but larger combinatorial number would become incomputable.

Calculating methods has been greatly limited in practical applications because of its weaknesses analyzed above. A simulation method will be devised to accomplish the availability and reliability evaluation of redundant systems periodically maintained.

3 AVAILABILITY AND RELIABILITY SIMULATIONS OF SYSTEMS PERIODICALLY MAINTAINED

3.1 *Simulation inputs*

The inputs of this simulation model contain information on three aspects:

1. System information: *n* represents the number of units; *MTBF* (mean time between failures) represents the mean lifetime of units; *k* represents the number of essential working units for the redundant system.
2. Maintenance policy: T_0 represents repair interval; *FDR* represents fault detection rate; *FIR* represents fault isolation rate; *RR* represents repair rate.
3. Simulation set-up: *TT* represents task time; *m* represents the number of simulation.

3.2 *Simulation outputs*

The outputs of this simulation model mainly contain instantaneous availability of the system and MTBCF, which are defined as follows:

1. Instantaneous availability of the system $A_S^*(t)$: the probability that redundant system is in workable state at time *TT*, namely the probability that the number of workable units is not smaller than *k* at time *TT*.
2. MTBCF: the mean task time between critical failures (the number of workable units is smaller than *k*) of the redundant system.

3.3 *Simulation process*

A simulation method will be introduced in this passage to generate the state sequence of the redundant system in the mission time. In the sequence, 1 represents that redundant system is in workable state; 0 represents that system is in failed state. The time intervals among system failures could be obtained through the state sequence, and the mean of such time intervals could be regarded as MTBCF if the sequence is long enough. Through large amount of simulations, the frequency ratio of the redundant system in workable state at each moment could be regard as instantaneous availability of the system. The simulation process is depicted in Figure 2, and the main procedures are as follows:

1. Generate a random number according to exponential distribution the mean of which is MTBF as a lifetime of the unit.
2. Remark the unit state as 1 within the life cycle; remark the unit state as 0 till the next repair cycle.
3. At the beginning of the next repair period, generate a random number between 0 and 1, remarked as pp.
4. If pp ≤ P (P = FDR * FIR * RR), the unit is successfully repaired, and return to (1).
5. If pp > P, the unit is not successfully repaired this time. Remark the unit state as 0 till the next repair cycle, and return to (3) until the full state sequence of the unit in mission time has been generated.
6. Repeat (1)~(5) until the state sequence of n units have all been generated.
7. According to k and the state sequences of n units, generate the state sequence of redundant system; calculate MTBCF.
8. Repeat (1)~(7) until m groups of simulations have been done. Calculate instantaneous availability of the system according to the frequency ratio of the redundant system in workable state at each moment.

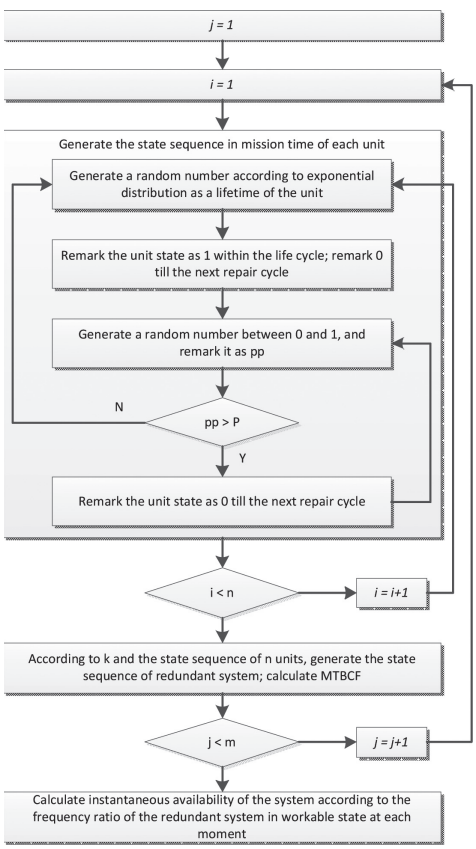

Figure 2. Availability and reliability simulation process of systems periodically maintained.

3.4 *Proving of simulation model*

As for small-scale redundant systems, the instantaneous availability under periodic maintenance could be obtained by calculating method introduced before. An 11/12(G) voting system is to be discussed. Through comparing simulation results with computing results, the validity of this simulation method could be proved.

Model parameters are set up as follows:

$n = 12$, $MTBF = 80{,}000$ h,
$k = 11$, $T_T = 20{,}000$ h,
$T_0 = 2160$ h, $FDR = 0.98$,
$FIR = 1$, $RR = 0.97$,
$m = 10{,}000$.

The results of system reliability obtained from the two methods are depicted in Figure 3. The red curve repeats system reliability using the calculating method introduced before, and the blue one repeats system reliability obtained from simulation method. These two curves basically coincide

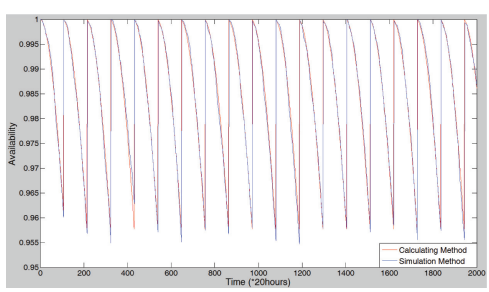

Figure 3. Instantaneous availability of a system obtained from calculating and simulation methods.

with each other. This illustrates the consistency of the two methods. Through further analysis, the maximum relative error between the results is calculated to be 1.6055%. Thus, the simulation model is proved to be correct and applicative.

4 CASE STUDY

Towed array sonar is a system of hydrophones towed behind a submarine or a surface ship on a cable. It mainly consists of a source array and a receiver array. In order to ensure its detection range and positioning accuracy, the source array is always hundreds of meters long and contains thousands of similar components.

Supposing that a source array of sonar contains 1000 components, and 10% component failures are allowable. The lifetime of each component follows a same exponential distribution, the mean of which is 20,000 hours. The source array works 24 hours a day without closing down. MTBCF of the source array is demanded to be 35,000 hours in the contract. If maintenance personnel repair the source array every three months; *FDR*, *FIR* and *RR* are all supposed to be 0.98, does the source array satisfy its demand on MTBCF?

Applying the availability and reliability simulation approach for redundant systems periodically maintained, a simulation tool is developed, the interface of which is depicted in Figure 4. Set 1000 times of simulation, the instantaneous availability distribution of the source array is obtained, as shown in Figure 5, and the MTBCF equals to

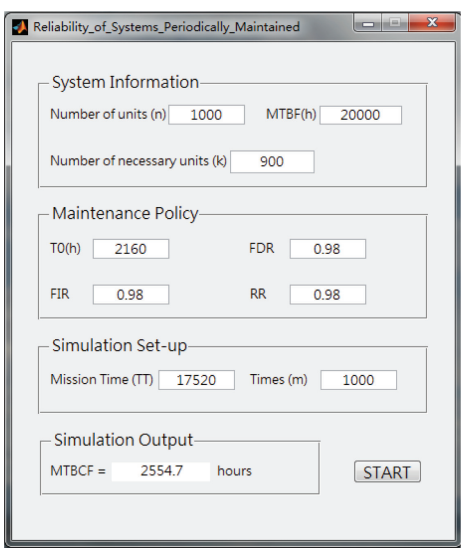

Figure 4. Simulation interface.

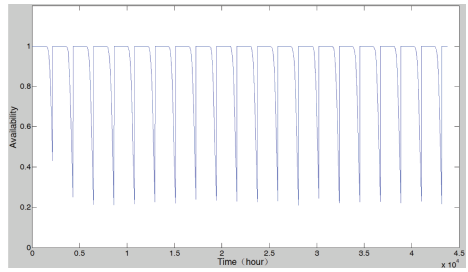

Figure 5. The instantaneous availability distribution of the source array in the first five years.

Table 1. MTBCF of the source array with different periodic maintenance interval (T_0).

Periodic maintenance interval (day)	MTBCF (hour)
90	2554.7
85	3388.6
80	5573
75	12,289
70	39,105
65	181,580

2554.7 hours. Apparently, this does not satisfy the demand of design.

In order to increase MTBCF of the source array to satisfy its designing demand, system design and/or maintenance policy need to be modified. Generally there are four doable solutions: (1) design or purchase components with higher reliability (to get larger unit *MTBF*); (2) increase the number of redundant components (to get larger n); (3) improve maintenance level (to get larger *FDR*, *FIR* and/or *RR*); (4) shorten periodic maintenance interval (to get smaller T_0).

At a later developmental stage, changing system design is always difficult and costly; the aim of specified MTBCF could be achieved through shortening periodic maintenance interval without any other changes. Using the simulation tool (Fig. 4) MTBCF of the source array with different periodic maintenance interval (T_0) could be easily obtained, as depicted in Table 1.

As shown in Table 1, it could be concluded that when the repair cycle is short than 70 days, the MTBCF of the source array will be larger than 35,000 hours, and there are still a tolerance of 11.73%. In this way, the designing demand will be satisfied properly.

$$\frac{39{,}105-35{,}000}{35{,}000}\times 100\% \approx 11.73 \tag{8}$$

5 CONCLUSION

An analytic and a simulation approaches are presented in this paper. Both of the approaches are aimed at solving the problem of availability and reliability evaluation of redundant systems under periodic maintenance, considering fault detection rate, fault isolation rate and repair rate. Using the simulation tool we have developed, instantaneous availability and MTBCF of the system could be easily obtained, which are of great significance for designers to make and optimize the maintenance policy. The simulation efficiency would be raised in further application to shorten the simulation time.

Reliability and safety based design of lifesaving appliances systems

Z. Burciu
Gdynia Maritime University, Poland

ABSTRACT: Life boats and liferafts are the lifesaving appliances used on all types of vessels. Liferafts are the most popular due to their low weight and low space demands. However they are used for the dozens of years their operational characteristics did not change a lot. The main improvements are the lighter materials and better constructions of boarding platform for easier entry of survivors from the water. The paper presents a new approach to design of the elements of liferaft system based on the liferaft reliability and safety functions developed on the basis of model and real scale investigations.

1 INTRODUCTION

1.1 *Backgound*

The liferafts are the most popular lifesaving appliances used on board all types of floating units—from the largest offshore installations and merchant vessels to the sport yachts and leisure boats. They are used in advanced Maritime Evacuation Systems on passenger ships with thousands people on board.

The serious accidents at sea are always related to the necessity of making decision to abandon ship, taking into consideration the real chances of survivors (Burciu, 2011; Gerigk, 2004; Gerigk, 2005; Gerigk, 2006; Gerigk, 2008; Gerigk 2012). Even in calm weather and in coastal or harbour waters the accidents can happen (Abramowicz-Gerigk, 2005; Abramowicz-Gerigk, 2006; Abramowicz-Gerigk, 2008; Abramowicz-Gerigk & Burciu, 2013), in case of extensive fire or hull damage due to collision the people on board have to leave the vessel.

In cases of sudden disasters, when there is no time to launch any lifesaving appliances the only available means of protection for the survivors are the liferafts, which can be launched automatically from 4–8 m depth, by the hydrostatic release system.

There are several problems with liferafts operation, which can be solved changing the recently used traditional approach to the design into the reliability and safety based approach (Abramowicz-Gerigk & Burciu, 2012).

1.2 *General requirements*

The liferafts are used for the dozens of years however their operational characteristics did not change a lot. The main improvements allowed decreasing their weight and increasing insulation to give better thermal protection of the survivors on board.

This situation is mainly caused by the general assumption that liferaft should be not expensive and commonly available, meeting the rules of the International Life Saving Appliances Code (LSA), Convention for Safety of Life at Sea (SOLAS, 2008; IMO Resolution MSC. 48(66), 1996) and European Union standards (EU Directive of Marine Equipment 96/98/EC, 1996).

The practical result is that the survivors in real sea conditions have serious problems to get into the liferaft from the water, liferafts lose their stability in wind and waves (Hervey & Jordan, 1990, www.surviteczodiak, 2013; Standards for Life Rafts and Inflatable Rescue Platforms, 1992) and it is not possible to predict their leeway due to their shape and flexible construction of the canopy.

The general requirements for liferafts comprise:

– design and construction of buoyancy part,
– canopy,
– canopy supports,
– capacity and mass.

All materials and components used in the construction and repair of liferafts shall be weather resistant. A liferaft shall withstanding exposure for 30 days afloat in all sea conditions and shall be able to withstand 15 months on board ship with a minimum of protection. It should withstand dropping into the water from a height of 18 m. A floating liferaft shall be capable of withstanding jumps onto it from a height of at least 4 m above its floor and towing at a speed of 3 knots in calm water when is fully loaded.

Every liferaft shall have a canopy. The canopy should be automatically set in place when the liferaft is launched. The canopy shall provide:

– insulation against heat and cold;

– one entrance for a liferafts designed to accommodate eight or less persons and two diametrically opposed entrances for the others;
– entrance shall be clearly indicated and be provided with a closing arrangement;
– sufficient ventilation inside;
– viewing port;
– means for collecting rain water;
– headroom under all parts of the canopy for occupants to sit comfortably upright on the floor.

Canopies should have supports; they are mainly the inflatable arches. Capacity and mass of an approved liferaft shall have a carrying capacity of six or more persons but no more than fifty persons, except in special cases.

The total mass of a liferaft, not designed to be launched, its container and its equipment shall not be greater than 185 kg.

There are no remarks with respect to the stability and motion characteristics, which have the biggest influence on the success of Search and Rescue Action at sea.

2 PERFORMANCE OF LIFESAVING APPLIANCES DURING SEARCH AND RESCUE ACTION AT SEA

2.1 *Reliability of liferaft*

The success of search and rescue action at sea is dependent on the time to rescue the survivors and on the type and condition of lifesaving appliances available to be used by survivors.

Search and rescue action at sea can be carried out during the day and at night. Time of search action is the basic reliability parameter, describing possibility to rescue survivors.

The reliability of *SAR* system is defined as follows:

$$R_{SAR} = P\left(S_p \geq T_D\right) \tag{1}$$

where R_{SAR} = reliability of *SAR* system; T_D = time of rescue action; and S_p = time to survive for the search object.

With respect to the International Life-Saving Appliances Code, Chapter IV (SOLAS, 1980) every liferaft should be constructed in the way it can withstand 30 days in all sea conditions.

$$R_{tr}(30) = P\left(t_p \geq 30\right) \tag{2}$$

where $R_{tr}(30)$ = reliability of liferaft; t_p = time of operation without failure.

The operational reliability of a liferaft can be defined as a characteristic informing whether it fulfils live saving functions in the given hydrometeorological conditions.

To define the reliability function for the liferaft a random variable Z denoting limit wind velocity for the liferaft have been introduced (Burciu & Grabski, 2011). The value of the liferaft reliability function for wind speed x is given by the formula:

$$R(x) = P\left(Z > x\right) \tag{3}$$

where $R(x)$ = is the liferaft reliability; Z = is the maximum wind velocity with respect to liferaft safety, x = is the wind velocity.

Applying the relation of functions gamma and beta we can obtain:

$$f_Z(x) = \frac{\lambda_1^{\alpha_1}\lambda_2^{\alpha_2}}{3^{\alpha_1}2^{\alpha_2}B(\alpha_1,\alpha_2)} \frac{x^{\alpha_2-1}}{\left(\frac{\lambda_1}{3}+\frac{\lambda_2}{2}x\right)^{\alpha_1+\alpha_2}}, \quad x>0 \tag{4}$$

Density of distribution of the random variable Z, which can be interpreted as 'limiting safe' wind velocity for the liferaft can be formulated. Function $R(x)$:

$$R(x) = P\left(Z > x\right) = 1 - \int_0^x f_z(z)dz$$
$$= 1 - \frac{\lambda_1^{\alpha_1}\lambda_2^{\alpha_2}}{3^{\alpha_1}2^{\alpha_2}B(\alpha_1,\alpha_2)} \int_0^x \frac{z^{\alpha_2-1}}{\left(\frac{\lambda_1}{3}+\frac{\lambda_2}{2}z\right)^{\alpha_1+\alpha_2}}dz \quad z>0$$

is the reliability function of the liferaft.

Values of reliability function for 6, 10 and 20 person's liferafts without sea anchor (drogue) (Burciu & Grabski, 2011, Burciu Z. 2012) are presented in Table 1.

2.2 *Design parameters and elements influencing liferaft safety and reliability*

The basic elements influencing liferaft reliability and safety of the survivors on board are:

– construction parameters: size—dimension and capacity, shape of underwater part and canopy, ballast system, shape and position of canopy supports,
– operational parameters:
  • trim of the liferaft,
  • non-linearity of the wind coefficients,
  • air pressure in buoyancy chambers,
  • number and position of the occupants.

The lack of the significant changes in the construction of liferafts is mainly caused by the limited

Figure 1. Trials of the liferaft leeway conduced in real working conditions.

requirements and satisfactory results of the trials performed only in calm sea conditions.

Figure 1 presents the field investigations on the liferaft leeway—trials carried out in real sea conditions.

The results of the field experiments carried out at Gdynia Maritime University in real sea conditions showed that search and detection of liferafts are very difficult. The reasons of the obstructions are liferaft construction, shape, construction materials, equipment and colour of the canopy.

A. Construction characteristics

All the currently produced and purchased liferafts are diverse with respect to their size, shape, construction solutions, including:

– entrance openings,
– landing platforms,
– ladders,
– ballast systems—ballast chambers or pockets.

The basic elements of a liferaft are presented in Figure 2.

The elements of a liferaft influencing leeway and reliability of a liferaft are presented in Figure 3.

B. Material characteristics

The traditional liferaft is made of rubber and impregnated fabric, which are very good dielectrics. This is the reason they are almost invisible on the screen of the navigational radar.

There are several types of passive radars reflectors used to increase the reflective characteristics of a liferaft. The folded reflectors can be unfolded automatically or manually (Polish liferafts) and installed on the canopy, after the liferaft is launched.

This means that the possibility of liferaft detection is dependent mainly on the applied or not radar reflector, its technical parameters—mainly the effective reflection area and its proper installation on the liferaft canopy.

Figure 2. A liferaft with a canopy, drogue and ballast system.

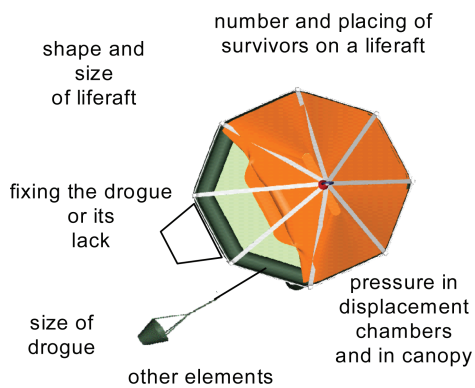

Figure 3. Elements influencing leeway/reliability of a liferaft.

The liferaft echo and disturbances from waves visible in the navigational radar display, on board a ship is presented in Figure 4.

The maximum range of liferaft detection very seldom exceeds the distance of 0.5 ÷ 0.6 Nm (Nautical mile). At the sea state 8 due to the intensive disturbances from the waves they are not visible.

The diagram in Figure 5 presents the trim of 6 persons liferaft with 10% of occupants.

Trim of the liferaft is defined as the list angle measured between the liferaft axis on the direction of liferaft motion and line perpendicular to the water surface.

The lack of the stiffened floor, drop of the pressure inside the liferaft causes the change of liferaft floor shape, trim to the leeward side and in case the liferaft sea anchor is not deployed or has broken off—loss of stability and keel of.

The shape and size of liferaft are the reasons of non-linearity of aerodynamic coefficients, causing the unpredictable leeway divergent from wind direction.

The non-linear aerodynamic coefficients in the stream layout, influencing the errors of leeway direction determined in wind tunnel for 6—persons liferaft at wind speed 10 m/s (20 knots) is presented in Figure 6.

The flexible inflatable liferaft construction and material characteristics are the main reasons of serious difficulties in liferaft operation by survivors. The operational obstructions for the survivors can be classified as follows:

– constructional: difficulties to get into the liferaft from the water, insufficient thermal protection, difficulties with bailing out the water from the liferaft,
– applied materials: difficult or even impossible radar detection,
– outfitting in radar reflector: the existed radar reflectors have to small effective reflecting surface, decreasing the probability of search object detection.

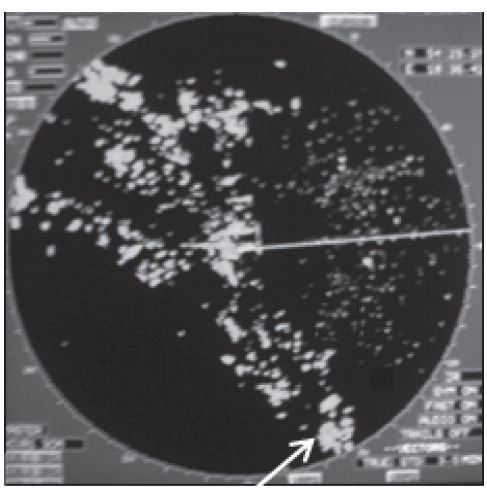

Figure 4. Radiolocation signal—radar echo of a liferaft and disturbances from waves presented in the navigational radar display on board ship.

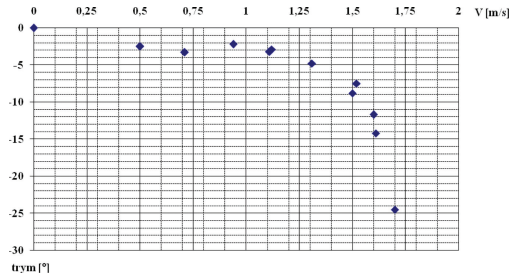

Figure 5. Trim of 6—persons liferaft with 10% occupancy.

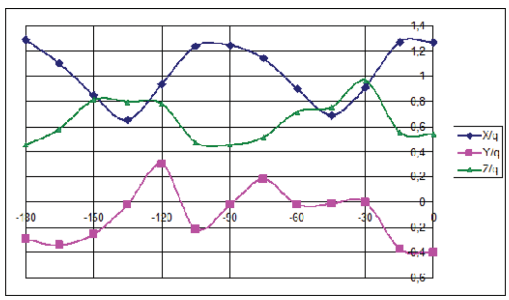

Figure 6. Diagram of non-linear aerodynamic coefficients in the stream layout, influencing the errors of leeway direction determined in wind tunnel for 6—persons liferaft at wind speed 10 m/s (20 knots).

The described elements and characteristics of the liferaft decrease the reliability function of the liferaft. Safety and reliability enhancement should be obtained using safety and reliability based approach in liferaft design.

3 DESIGN SOLUTIONS INCREASING SAFETY AND RELIABILITY OF LIFERAFT

The proposed design solutions increasing liferaft detection and operational standards are as follows:

– equipment increasing liferaft signature in all ranges of detection: NIR, VIS, LIR and radar, with use of the most advanced materials and technologies,

– application of coatings with high reflection characteristics influencing visual detection,
– elimination of disturbances in the wind leeway by the new design of liferaft shape, decreasing the aerodynamic resistance,
– drainage system allowing to keep dry floor inside the liferaft,
– entrance lock,
– efficient ballast system,
– new solution of marine anchor—construction and fastening to the liferaft,
– new solution of non flexible liferaft floor for better stability and thermal protection of survivors.

4 CONCLUSIONS

The results of the research conducted are as follows:

– lack of the canopy and not full (not sufficient) internal pressure result in an increase of trim of the liferaft in the downwind direction,
– flooding of the liferaft occurs at a 6 person liferaft occupied by 3 up to 6 persons, when the pressure is lower than the operational value,
– the liferaft trim increases with an increase of the number of persons onboard the liferaft,
– low pressure in the liferaft floor increases the angle of flooding of the liferaft.

The proposed solutions will increase the safety of survivors using the liferaft and increase liferaft reliability:

– decrease of hydrodynamic resistance,
– reduction of non-linearity of aero dynamical coefficient in stream layout influencing the errors of leeway direction,
– easier entrance to the liferaft—elastic lock,
– decrease of survivor contact with water and influence of low temperature—inflatable floor,
– increase of range of detection with different types of detectors:
  • radiolocation means,
  • infra-red cameras,
  • optical day light cameras.

Nuclear power plant safety improvement with new system for safety injection

B. Gjorgiev & A. Volkanovski
Reactor Engineering Division, Jožef Stefan Institute, Ljubljana, Slovenia

ABSTRACT: Nuclear power plant safety depends on the actions taken to prevent nuclear and radiation accidents or to limit their consequences. This paper proposes improvements of nuclear power plants safety with consideration of a new system for safety injection. The system consists of water source, pipes, valves and portable fossil-fuel driven pump. Similar mitigation concept is the diverse and flexible coping capability strategy, or shortly known as FLEX, proposed by the US industry. The paper investigates the system capability to cope with the station blackout event and the large loss of coolant accident. Analyses are done with probabilistic safety assessment. The reference probabilistic safety assessment model of a nuclear power plant is modified in order to take into account additional system. The core damage frequency of the nuclear power plant probabilistic safety model is used as a risk measure. The new system is modelled using the fault tree approach with a top event defined as a possible failure to deliver water to the nuclear power plant. The obtained results show decrease of core damage frequency with the introduction of the proposed system. This finding indicates improvement of nuclear power plant safety.

1 INTRODUCTION

Nuclear Power Plant (NPP) safety depends on the actions taken to prevent nuclear and radiation accidents or to limit their consequences. The Probabilistic Safety Assessment (PSA) results show that the Station Blackout (SBO) event, implicated by complete loss of Alternate Current (AC) power in the NPP, is important for NPP safety (Volkanovski and Prošek, 2013). When SBO occurs one of the main challenges is to maintain effective decay heat removal. Another important safety event is the large loss of coolant accident (Large LOCA). The pressure and water in the primary loop are lost in few seconds in case of Large LOCA event. If no coolant is injected in the reactor core and no decay heat removal is established core damage is eminent.

A connection between NPP and different types of hydro power plant is proposed for NPP safety improvements (Gjorgiev et al., 2012, Gjorgiev et al., 2014). The hydro power plants are used as alternative AC power sources. The main objective of such source is the SBO event mitigation, i.e. provide cooling of the reactor core using electrical energy from alternative power supply. The results show significant decrease of the station blackout core damage frequency and significant decrease in total core damage frequency. For the performed analyses (Gjorgiev et al., 2012, Gjorgiev et al., 2014) the standard PSA methodology was used on systems which are non-safety classified and not located at the NPP site.

The US Nuclear Regulatory Commission (NRC) issued order EA-12-049 (U.S.NRC, 2012a) requiring nuclear power plants to develop mitigation strategies for beyond-design-basis external events, shortly known as FLEX. The nuclear industry in US, through the Nuclear Energy Institute (NEI), developed a generic framework for response to this order that is documented in the NEI FLEX Implementation Guide (NEI 12-06) (NEI, 2012). The FLEX represents an approach to develop flexible and diverse strategies for increased defense-in-depth by providing multiple, diverse methods to supply power and water to support key safety functions.

A new system for nuclear power plant safety improvement which consists of water source (off-site or on-site) and components for establishing connection with a nuclear power plant is proposed in this paper. For the connection a pipe under pressure is considered. To establish the required pressure both a portable gas-fired motor driven pump and gravity are used. Water reservoir or the nearest river can be considered as a source of water. In this paper for demonstrative purposes a water reservoir was selected as a source of water. The reservoir may be placed on-site or offsite as a part of on-river accumulation, i.e. hydro power plant reservoir or any other natural or manmade accumulation. Since the system has passive component

for water injection, it can be considered as partially passive system for injection of water in the primary or secondary reactor coolant side. The system is utilized in at least two scenarios. One is the loss of all offsite and onsite alternating current power supply, which is known as station blackout event. The other is the large loss of coolant accident (Large LOCA).

The main objective of this paper is to investigate the safety implications of the proposed system on a NPP. Probabilistic Safety Assessment (PSA) is used as tool for risk assessment. A PSA model of generation two NPP is used as a case study. The reference PSA model is modified in order to consider the proposed system. The change in core damage frequency is used as risk measure. The proposed system is modelled using the fault tree approach with a top event defined as a possible failure to deliver water to the nuclear power plant.

The changes of the NPP core damage frequency and the shares of the SBO and Large LOCA events are quantified. The effects of the proposed system on NPP safety are analyzed and discussed. The results show that the introduction of the new system in the NPP-PSA model improves NPP safety.

2 DESCRIPTION OF THE PROPOSED SYSTEM

2.1 *System configuration*

The proposed system for water injection in both the primary and secondary loop is presented with the schematic shown on Figure 1. The system as shown on Figure 1 is consisting of water source, pipes, portable fossil-fuel powered pump and valves. In order to satisfy the required conditions for work additional elements are considered as well. In this study water reservoir is considered as a source of water. The valves 1, 2, 3, 4 and 5 are identical. Valve 1 is continuously open, valves 2 and 3 are opened when the pump is used for water injection in the Steam Generators (SG), and valves 4 and 5 are opened when the water has to be injected in the primary coolant loop. The basic principle of the system shown in Figure 1 is that both, pump or gravity can be used as necessary force that drives the water from the reservoir towards nuclear power plant cooling systems. It is assumed that the portable pump is protected from the severe internal external events.

In this study the application of the proposed system for mitigation of two initiating events, SBO and Large LOCA, is analyzed. Figure 1 shows that two connections to the NPP systems are provided. Line 1 is used for the SBO event mitigation, while Line 2 is used for the Large LOCA mitigation.

When SBO occurs the cooling of the reactor core must continue in order to remove the decay heat. The proposed system is connected to the secondary loop, i.e. the steam generators through the same connection used by the Auxiliary Feedwater (AFW) system. After SBO occurs, valves that provide the connection with the secondary loop and the proposed system are opened. The system delivers cold water to the secondary side of the steam generators, this way allowing heat to be dissipated through the secondary side safety valves. In this scenario a certain pressure in the range of 80 bars (Volkanovski and Prošek, 2013) is required. This is the main reason for the application of the portable pump shown on Figure 1.

For Large LOCA mitigation, the proposed system is connected to the primary loop through the same connection used by the low pressure injection system. Water is directly injected in the primary coolant loop vessel by gravity.

2.2 *Potential issues and solutions*

During Large LOCA fresh non-borated water can cause increased reactivity when injected in

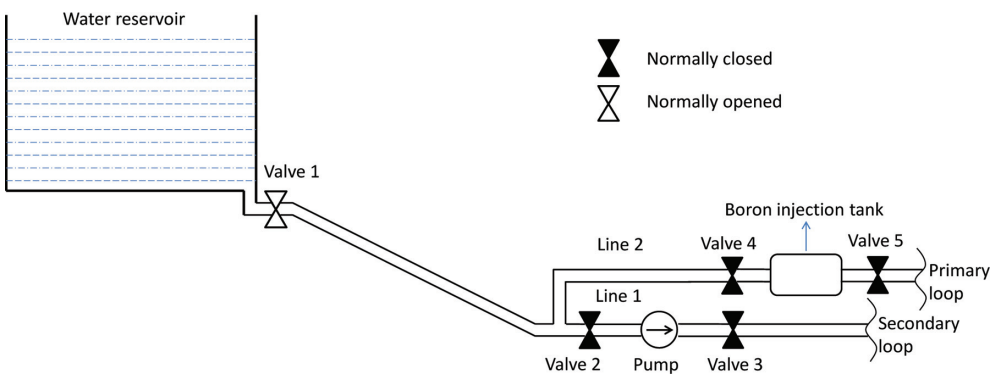

Figure 1. Schematic of the passive system and NPP connection.

the reactor core (U.S.NRC, 2012b). Therefore, the water from the system is borated before it is injected in the primary loop. One way to provide boron in the water is using tank as shown on Figure 1. The boron is directly diluted, i.e. carried by the water when it passes through the tank. This tank can be positioned near the joint were the connection between the proposed system and the installation of the low pressure injection system is established. It is assumed that the water temperature never falls beneath the minimal allowed temperature according to technical specifications (U.S.NRC, 2012b).

The uncontrolled water injection during SBO in a steam generator may result with overfill, which in turn may result in jeopardizing of steam generator integrity (U.S.NRC, 2012b). This issue also applies to any other system (e.g. FLEX) that can be used for residual heat removal through the steam generators when no power is available to monitor their water level. In this study is assumed that the amount of water and the time intervals in which the water is injected in the steam generators is known.

3 PROBABILISTIC SAFETY ASSESSMENT MODEL

PSA is a standard method for assessing, maintaining, assuring and improving the nuclear power plant safety (U.S.NRC, 1982, Roberts et al., 1981). It is generally used to find the weak points of a plant and to make recommendations for possible changes in design (Čepin, 2002). The traditional application of PSA for NPP safety evaluation in general considers only safety related systems which are located at the NPP site. In this paper The PSA model takes into consideration systems that are classified as non-safety systems. This modification allows PSA evaluation of changes in core damage frequency of an NPP when new systems that can be used in emergency scenarios such as SBO and Large LOCA are introduced.

3.1 *Reference nuclear power plant model*

The PSA model of a generation 2 Pressurized Water Reactors (PWR) was used in the analyses (Bertucio et al., 1990). The NPP model has two emergency diesel generators. The model considers only the internal initiating events. Figure 2 shows the share of the most dominant initiating events in the total CDF.

The first ten basic events identified with largest Fussell–Vesely (FV) importance measure in the reference PSA model are given in Table 1. The second column in Table 1 contains basic events with description given in third, unavailability in fourth column and FV importance measure given in fifth column.

Table 1 shows that the basic events FE-NRAC-HALFHR and FE-NRAC-7HR, both related to AC power restoration, are dominant contributors in the reference PSA model.

3.1.1 *Station blackout event tree*

The station blackout event tree is given on Figure 3. The SBO event tree contains all functional events of a representative SBO event tree for Westinghouse pressurized water reactors (Volkanovski and Prošek, 2013, Bertucio et al., 1990, U.S.NRC, 2005). Due to the phenomenology and possible special events that can occur, the station blackout is evaluated in separate event tree. Those special events include preservation of coolant inventory, controlled supply of feed water to

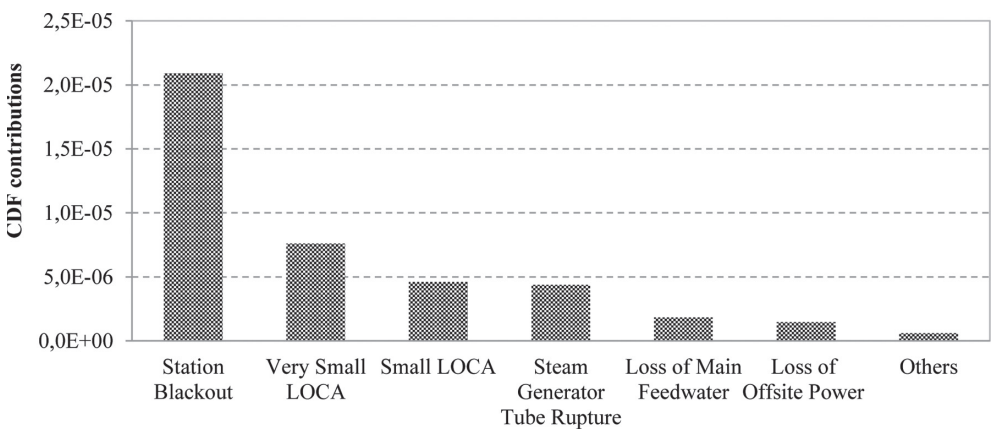

Figure 2. Schematic of the proposed system for safety injection.

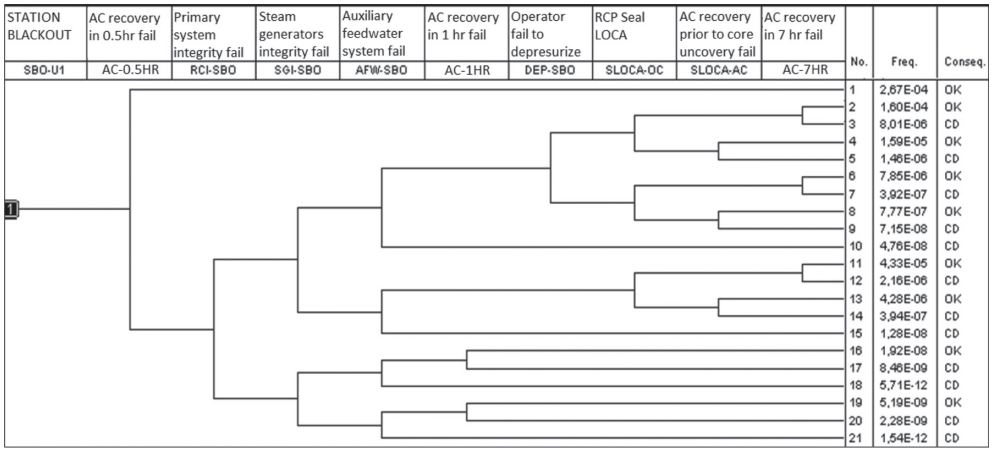

Figure 3. The SBO event tree for the reference PSA model.

the steam generators and extension of battery life (Volkanovski and Prošek, 2013, Bertucio et al., 1990). Successful reactor scram is being presumed when entering into the SBO event tree. Additionally, separate event tree considers the anticipated transients without scram.

The second functional event AC-0.5HR in the station blackout event tree is related to the restoration of electrical power to the plant safety buses before the dryout of the coolant on the secondary side of the steam generator, assessed from the wide range level, and start of the core heat up. Period of 30 min is assumed to be available for restoration of power in the PSA model for this functional event (Volkanovski and Prošek, 2013, Bertucio et al., 1990). The successful mitigation of the transient is related with power restoration within first 30 min results in successful mitigation of the transient, regardless of other failures, except criticality, in that time period.

The preservation of the reactor coolant system inventory until power is restored is related with the third functional event RCI-SBO. Loss Of Coolant Accident (LOCA) is being implicated by the failure to reclose the power operated relief valves. The importance of this functional demand is related with the failure probability of the power operated relief valves during SBO.

The fourth functional event SGI-SBO represents the secondary side integrity functional event. The reference PSA model (Bertucio et al., 1990) assumes inoperability of the atmospheric relief valves during station blackout due to the unavailability of control power. It is assumed that the safety valves will conduct the steam relief. Uncontrolled depressurization is implicated by the safety valves failure to reclose. This jeopardizes the steam generators integrity.

The probability of the auxiliary feedwater system failure during SBO, calculated with a

corresponding fault tree, is related with the fifth functional event AFW-SBO. The auxiliary feedwater fault tree comprises multiple failures of the auxiliary feedwater system during SBO including turbine-driven pump failure to start and operate, check valves failures, air operated valves failures and undetected leakage. The fault tree does not consider the motor operated pumps and their equipment since these pumps are not available during SBO.

The sixth functional event AC-1HR corresponds to the restoration of power to the plant safety busses and isolation by the pressurizer block valve before core uncover starts. In the reference PSA model, period of 1 h is taken (Volkanovski and Prošek, 2013, Bertucio et al., 1990) as an available time for power restoration.

The cooling and depressurization of the reactor coolant system during a long term station blackout is represented with the seventh functional event DEP-SBO. The goal of the depressurization is to reduce pressure and consequential reactor coolant system leak rate, in case any leak develops. Reactor coolant system pressure reduction as well as Seal LOCA risk decrease is achieved by depressurization. However, this reduction of Seal LOCA risk is not considered in the model.

The eighth functional event SLOCA-OC corresponds to the reactor coolant pumps Seal LOCA. While the ninth functional event, SLOCA-AC, corresponds to the Seal LOCA with failure to recover electrical power prior to core uncover.

The tenth functional events AC-7HR is related to the power restoration to the plant safety busses before core damage starts. In the reference PSA model, a period of 7 h is taken (Volkanovski and Prošek, 2013, Bertucio et al., 1990) as an available time for power restoration before core damage starts.

3.1.2 *Large LOCA event tree*

The Large LOCA event tree is given on Figure 4. The Large LOCA contains all functional events of a representative Large LOCA event tree for Westinghouse pressurized water reactors (Bertucio et al., 1990).

The second functional event D5 in the Large LOCA event tree is related to the injection of water from the accumulators in the primary loop. The water is injected immediately as the pressure in the reactor coolant system drops as a result of the large brake in the cooling system pressure boundary.

The third functional event D6 in the Large LOCA event tree is related to the capability of the Emergency Core Cooling Systems (ECCS) to respond early after the Large LOCA event occur, thus providing high volume, low pressure injection flow needed to cool the reactor core (Bertucio et al., 1990).

The forth functional event CS corresponds to the containment integrity, i.e. capability of the containment heat removal system to successfully maintain containment pressure and temperature at acceptable levels. While the fifth functional FE-CV event is related to the functionality of the emergency core cooling systems due to containment failure.

The sixth functional event H1-LH is related to the low pressure recalculation cooling. This system has to provide the volume of flow needed under large LOCA condition.

3.2 *PSA model with the proposed system*

As shown on Figure 1, there are two modes for operation of the proposed system. First mode is when the system is used for SBO mitigation. Second mode is when the system is used for Large LOCA mitigation. Two fault threes were created for modeling of the system failure in each mode of operation.

3.3 *Proposed system—NPP connection modelling*

3.3.1 *The SBO event tree modification*

The SBO event tree from Figure 3 was modified in order to consider the proposed system. The functional event ADD-SYS.SG was added between AFW-SBO and AC-1HR functional events as shown in Figure 5. The ADD-SYS.SG functional event corresponds to the delivery of water by the proposed system to at least one of the three steam generator during SBO.

The system is considered to be capable to deliver water to at least one steam generator for 72 hours. A new functional event AC-72 HR which corresponds to recovery of AC power in 72 hours is added as the last functional event in the SBO event tree. The failure of both, the AFW and the proposed system, results with core damage.

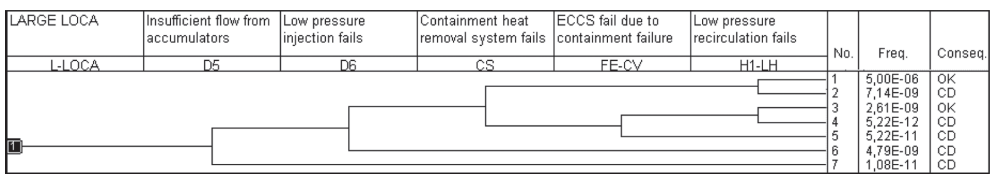

Figure 4. The Large LOCA event tree for the reference PSA model.

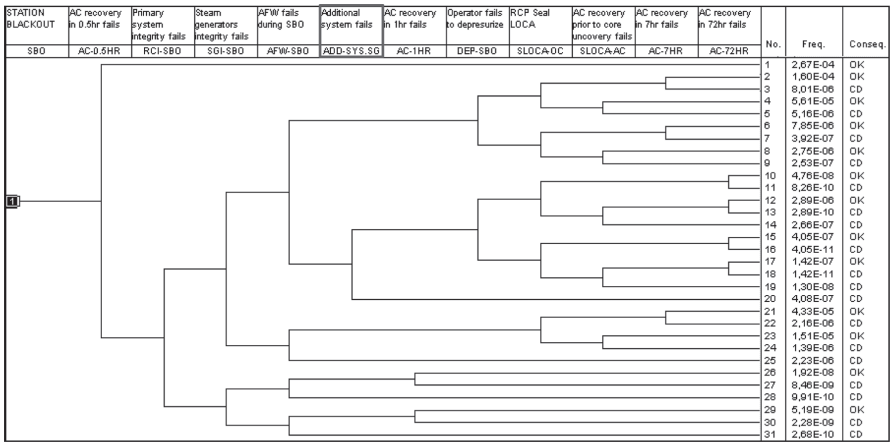

Figure 5. The SBO event tree, comprising the proposed system.

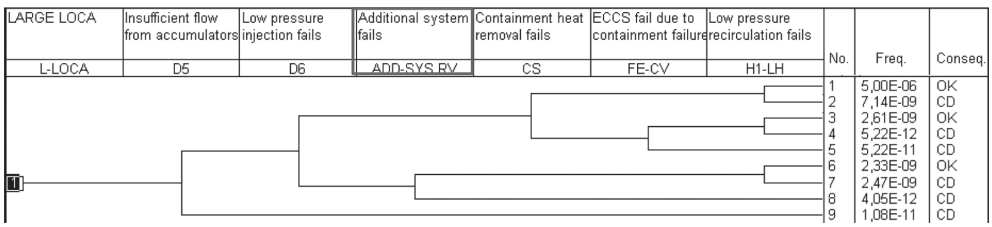

Figure 6. The Large LOCA event tree, comprising the proposed system.

Table 2. Reliability parameters of components used in the fault tree analysis.

Component failure mode	Unavailability [/]	Source
Pump failure to start	4.82E-2	(IAEA, 1988)
Pump failure to run	3.00E-5	(IAEA, 1988)
Pump operator failure	1.00E-3	(Bertucio et al., 1990)
Valve failure to stay open	6.18E-5	(IEEE, 1983)
Valve failure to close	4.24E-6	(IEEE, 1983)
Boron tank failure	6.43E-4	(IAEA, 1988)
Reservoir failure	1.00E-5	(Yan and Lan, 2013)
Pipe failure	1.00E-4	(Fleming and Lydell, 2004)

3.3.2 *The Large LOCA event tree modification*
The Large LOCA event tree (Fig. 4) was modified with the introduction of the ADD-SYS.RV functional event. As shown on Figure 6 the ADD-SYS. RV functional event was positioned between the D6 and CS functional events. The ADD-SYS.RV functional event corresponds to the delivery of water by the proposed system to the primary coolant system.

3.3.3 *Proposed system input data*
For the unavailability of the components of the proposed system two failure modes were considered: failure to remain in position and failure to change position. For the failure to remain in position mode the repairable parametric reliability model was used. For the failure to change position mode the per-demand reliability model was used. The reliability parameters are presented in Table 2.

4 ANALYSIS AND RESULTS

The results from the proposed system fault tree quantification analysis are shown in Table 3, where $Q_{ADS\text{-}SG}$ denotes the unavailability of the system used for SBO mitigation, while $Q_{ADS\text{-}RV}$ denotes the unavailability of the system used for Large LOCA mitigation.

The results from the CDF quantification are shown in Table 4. Table 4 shows that the Total CDF

9	FE-QS-SBO	Failure of SG safety relive valves to reseat during SBO transient	2.70E-01	6.26E-02
10	AFW-TDP-FR-2P6HR	AFW turbine-driven pump fails to run for 6 hr	3.00E-02	5.91E-02

is reduced for 13% compared to the base model. Table 3 also shows that both the CDF (SBO) and CDF (Large LOCA) are reduced for 26% and 23% respectively with the introduction of the proposed system.

The identified first ten basic events with largest FV importance measure in the modified PSA model with the proposed system considered is given in Table 5.

Table 5 shows that the basic events FE-NRAC-HALFHR and FE-NRAC-7HR, both related to AC power restoration, remain dominant when the proposed system is introduced in the reference PSA model. The basic event FE-SLOCA-NRACSL-LT, related to core uncover during SBO due to seal LOCA, is becoming the third most dominant basic event according to FV importance measure as shown in Table 5. This event is not among the ten most important basic events in the reference PSA model as shown in Table 1. Table 5 shows the basic event AFW-TDP-FR-2P6HR, related to the AFW turbine-driven pump capability to run for 6 hr, has decreased importance when the new system is considered for coolant injection.

5 DISCUSSION

As observed from the obtained results when the new system for water injection is introduced in the PSA model of an NPP, the shares of the SBO and Large LOCA events in CDF are significantly reduced. The introduction of this system can be especially beneficial for NPPs that have large share of these two events in the total CDF.

6 CONCLUSIONS

New system for nuclear power plant safety improvement has been proposed. The system is consisted of water reservoir, pipes, portable fossil-fuel powered

pump and valves. It uses both, pump and gravity to inject the water in the nuclear power plant cooling systems.

The proposed system is connected with the primary coolant loop through the connection for low pressure injection systems and with the steam generator through the connection for the auxiliary feedwater system. In this study the proposed system is used for mitigation of SBO and Large LOCA initiating events. The core damage frequency of a nuclear power plant is used as a risk measure.

Probabilistic safety assessment model of a nuclear power plant was used for the analyses. The model is limited to the internal initiating events only. Fault tree models of the proposed system are made. The SBO and the Large LOCA event trees in the reference nuclear power plant model are modified with the introduction of the new system.

The results show decrease of the SBO and Large LOCA core damage frequencies. Subsequently this resulted with reduction of the total core damage frequency. The results show that the introduction of the new system contributes to improvement of nuclear power plant safety.

A systematic approach for defense against transient failures

H. Schäbe
TÜV Rheinland InterTraffic, Cologne, Germany

I. Shubinski
IBTrans., Moscow, Russia

ABSTRACT: Transient failures become more and more important because computer systems become smaller and it can be expected that a growing number of charged electric particles are able to penetrate Earth's weakening magnetic field. Charged particles cause transient failures in computer systems. A transient failure does not persist in the hardware but, however, can influence data and program flow. We describe the mechanisms that lead to transient failures. There exist many measures to protect safe computers from these influences. We provide a systematic method of defense against transient failures. The method is based on the idea to express the computing system as a Markov automate. Then, the method consists of two steps. In the first step, the system is expressed as a Markov automate and a method is applied to ensure that the present state cannot be changed by transient failures. For this purpose, checksums, self-correcting codes or saving redundant copies of the data can be used. In the second step, the transition between states is secured against transient failures. For this sake, repeated computing and protection of the software executing code against transient failures is applied. We demonstrate the approach with the help of an example. The approach helps to give a systematic approach to construct a system that is stable against transient failures. It needs to be noted, that the methods applied do not fully protect against systematic or persisting faults.

1 INTRODUCTION

Usually in the theory of reliability and safety of a lot of attention is dedicated to failures, especially to dangerous ones. However, apart from them, there are other events that seem to be much less important at first sight. These are transient failures (faults), see Shubinski (2012), Qi et al. (2008) and the references cited in Shubinski (2012). Transient failures are defined as follows. A functional transient failure is an event consisting of a unique distortion of information that is either processed or stored in an information processing and transmitting system under the influence of interior or exterior destabilizing influences (e.g. noise) Shubinski (2012).

Current standards on railway safety as EN 50128 or IEEE 1483 name them or require some countermeasures which do not necessarily cover transient failures completely. ISO 26262-109 names transient faults and describes, how they should be accounted for in reliability and safety calculations. But the standards do not give a systematic approach against transient failures or provide a deeper discussion on the causes and nature of transient faults.

Research has been carried out on many specific problems connected with transient faults. We cite here only the dissertations by Xiaobin (2005) and Gfeller (2009). These studies are focused on specific problems as e.g. transient faults in networks or specific processors.

The subject has become relevant for two reasons. Firstly, the miniaturization of computer technology leads to increasing sensitivity of hardware to exterior influences. Secondly, the weakening of the magnetic field of the earth is accompanied with an increasing number of charged cosmic particles arriving at the earth's surface. As a result, occurrence rate of transient failures can be greater than the failure rate of hardware failures by three or more orders of magnitude Shubinski (2012).

This paper presents a systematic method of developing a system that is stable with respect to transient failures.

In the second chapter, it is discussed how transient failures arise and to which consequences they lead. The third chapter is devoted to methods of detection of transient failures. The fourth chapter is dedicated to protection methods against transient failures gives a systematic approach for protection against transient failures. Principle is explained, which basic properties a system must have to be stable against transient failures. In the

fifth chapter an example is given. The conclusion is contained in the last chapter.

2 TRANSIENT FAILURES

In Information Systems (IS), transient failures and intermittent failures have no significant effect on the reliability of the IS. This is explained by the following reasons:

- Many ISs are classified as mission-critical systems. Therefore, when designing the information system special measures to stabilize the system are taken regarding acceptable limits of temperature and humidity, climatization, careful design of electrical schemes, excluding events as races between and competing signals etc.
- Many information systems work in real time. They perform well-defined informational tasks according to a given schedule. For these systems, transient failures mainly influence the function of these system. These are such failures that, under certain circumstances, can lead to control failures under certain conditions and have serious consequences for the entire system, and even for the environment.
- Transient failures exist only for very short time. They occur in hardware and are vanishing themselves, i.e. the hardware returns to its original physical condition, but not necessarily to the original functional state.

Hardware failures can be caused by:

2.1 *Noise acting on inputs and power supply*

The actual transfer function of a circuit can be approximated by a piecewise linear function. Figure 1 provides an example of the transfer function. It is characterized by the parameters a_i ($i = 1,0$)—the output voltage level of a logic one or zero, b_i—input level for a switching from $1 \rightarrow 0$ ($i = 1$) or from $0 \rightarrow I$ ($i = 0$). The switching band is given by $\Delta b = |b_1 - b_0|$. For a typical transfer characteristic, there are three areas, corresponding to the different states of the circuit. Area I—closed contacts, area III—open contacts, and an intermediate area II—switching between the states. Under the influence of influences the system can move from area I to area III, i.e. a malicious output code "I" is produced instead of the "0" (transient failure $1 \rightarrow 0$). Under the influence of interference also a failure with a $0 \rightarrow 1$ transition can occur.

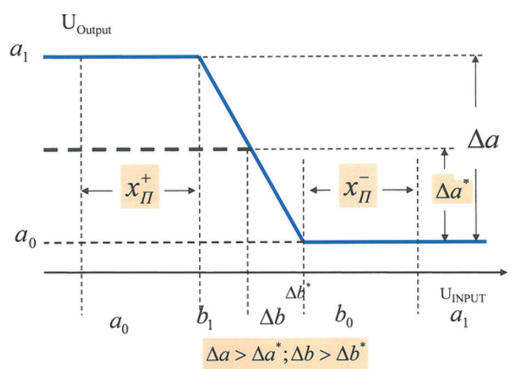

Figure 1. Typical transfer characteristics of a digital integrated circuit.

From Figure 1 its can be seen that for a given threshold Δa, a larger differences between b_0 and b_1 leads to smaller admissible amplitudes of input noises x_π^+ and x_π^-. This causes a reduction of the stability of the system with respect to noise. An analogous result is caused by a reduction of the difference of logical levels Δa. Note that, Δa is especially small for fast integrated circuits, since a reduction of the switching time Δb^* requires a reduction of Δa^*.

Systematic experimental data on transient failures of integrated circuits are not available. In order to derive the characteristics of transient failures it is convenient to use experimental data on the input signal and noise and the transmission characteristics in the amplitude-frequency range of the integrated circuits and to apply computational models. By this approach, first a range of possible probabilities of transient failures of trigger components at the inputs are obtained. From them, the characteristics of transient failures of the integrated circuit are derived.

2.2 *Electromagnetic interference*

If the noise can affect the system through inputs, power and weight, then the system can also be exposed to electromagnetic radiation. Consequently, a current can be induced, an interference occurs which impacts the components. This signal acts in the same method on the contacts of IP as an obstacle to coming right contacts and wires and as described top.

2.3 *Influence of radioactive particles*

The third mechanism is the impact of radioactive particles. Usually, in a first step gamma quants pass close to the IC. This can likely be radiation produced as a result of radioactive decay. Gamma radiation has the property that it passes through the material quite well and it is difficult to protect against it. A Gamma quantum can yield emission

of an alpha particle by an excited nucleus. An alpha particle is a charged particle that can affect the inputs and outputs of the integrated circuits or the registers and the memory. Due to this impact, a bit might switch.

The consequences of transient failure can be the following:

- Distortion of stored data
  In this case, the system continues to function on the basis of incorrect information. Then, even correctly executed functions provide a false result. If the data are no corrected this process continues. In particular, a transient failure can influence the output of the integrated circuit and cause a dangerous command.
- Changing the program sequence
  This means that the system does not perform a function at all, performs another function instead, performs the function early, late or in a wrong order, which can lead to a dangerous system failure.

3 DETECTION OF TRANSIENT FAILURES AND PROTECTION FROM THEIR DANGEROUS CONSEQUENCES

There are a number of well-known methods of protection from the effects of transient failures [1]. First of all, methods for the detection of transient failures are needed. The following well-known methods of detection exist:

- Cross comparison in multi-channeled systems
  In this approach, the results of two or more channels of a system are compared. If they results differ, a failure or a transient failure is assumed.
- Use of checksums
  Besides the data themselves, checksum is saved. Changes of the data changes will lead to a situation, where the checksum and the data do not match any more. By this means, many faults can be detected, but not all.
- Algorithms
  Algorithms are used for calculation or for the determination of the reaction system that are tolerant with regard to transient failures.
- Multi-version programming
  Two or more versions of the software are created, which are based on the same algorithm. The results are compared. Since the impact of a transient failure is supposed to be different on both versions of the software, faults would be detected by comparison.

These are the well-known, classic methods of protection, which are suitable for a wide class of faults and failures.

After having detected a transient failure, a reaction of the system is required, which should be implemented in another part of the system than that one, in which the fault has occurred. However, also the equipment used for fault detection and reaction is susceptible to transient failures and, therefore, also these devices must be protected against transient failures.

4 A SYSTEMATIC APPROACH

In this section we construct a systematic method for protection from transient failures.

A system failure caused by a transient failure arises due to a deviation, which is kept in the system either directly or indirectly. Indirectly saving to memory a transient fault is more dangerous, as it is more difficult to detect.

An example of a direct saving to memory incorrect data is the distortion of saved data, such as system parameters. Indirect saving to memory occurs, for example, if the system performs an incorrect operation that will lead to distortion of data, which are then saved to the memory.

Software can be imagined as a finite automate. The status of the automate is the entirety of all of the data recorded in the memory and that either came from the outside (sensor data, the status of external devices etc.) or that were derived as a result of the software processes themselves (calculation results, commands that were derived by the software and have been directed to external devices, the point at which the software has arrived in the program sequence). All information is discrete and depends only on the entire history of the system, but not on its future.

Now, the software will be expressed as a Markov system (described by a Markov chain or a Markov process, see Feller (1968)): That means, the next step depends only on the current state, but not on the history.

This is described in the sequel. The state of the system at a given moment in time is described as vector in the state space of the system, which contains all necessary information for an unambiguous description of all data, code, registers, etc. This state vector can have a very large size, but it is finite. Then the software and the computing system a digital system can be represented as a Markov chain.

The task of protection from transient failures is thus reduced to two sub-problems:

1. Protection of the system state as stored in the memory from distortion by transient failures,
2. Protecting of the transition to the next state (i.e. computing) from distortion caused by transient faults.

In order to solve both these subtasks, for each of these tasks the following measures can e applied:

1. Use of checksums, redundant storage
   With these methods it is possible to detect corruption of data characterizing the system state. If the method of information storage includes redundant information, it is even possible to recover distorted information. This might happen if one uses error-correcting codes, as e.g. applied on CDs, or the information is stored twice with separate checksums for each version.
   In order to have a safe working system, one can introduce a state machine, which reflects all important aspects of the information processing process, especially the distinction between hazardous and safe conditions. It is important to a state machine, which is as simple as possible.
   In the standard EN 50128 (2011), Annex D.24 Finite State Machines are required as a possible measure. This measure is just motivated by protection against transient faults.
2 Multi-version programming
   If the software is programmed in various versions carrying out calculations using different methods, transient failures cannot distort the data processing in both versions of the software in such a manner, that the results are the same. It is also possible to apply the same code on different computers with different compilers so that different executable software results.

If a state machine is used, before a state transition is initiated the conditions and the next state can be obtained using different algorithms.

5 EXAMPLE

This section an example of a system is described that uses a systematic approach for protection against transient faults presented above. For the example we assume that a safe computer is required for calculations. In addition, these computations have to be carried out cyclically. For example, the braking distance is computed every 100 milliseconds in order to verify that the train will be able to stop before the next red sign.

In the first step those data set needs to be determined, which clearly describes the state of the system. In this example, these are the position, the speed, the deceleration and the braking curve, which describes the braking ability of the train. Further, the actual time is important, alternatively the cycle number. Obviously, these data should be written into memory together with a checksum. Then it is possible to detect data corruption caused by malfunctioning. If, however, it is important not only to detect but also restore the correct data, i.e. restoring the correct state, it is necessary to either store data redundant or to use error-correcting codes. In the first case, the data is stored twice with a hash code. Then it is easy to determine which version of the data has been damaged. In the second case, one needs to pay attention to the fact that with a large number of transient failures a recovery of a wrong state would become probable.

Anyway, calculations need to prove that the measures implemented against transient failures detect errors with sufficiently high probability, so that the probability of undetected distortions is sufficiently low.

In the second step, the system needs to be protected from the consequences of transient failures when transition from one state to another occurs. The easiest option is the determination of the next state several times. Calculations are carried out twice, so that possible errors can be detected. If in case of failure, the calculation is repeated for the third time, so the error can be corrected by switching to that state, which has been determined by the majority of calculations.

In this example, same calculations are repeated on the same processor and with the same software version. This is possible because the transient failure does not lead to a permanent fault. It should be noted that the described measures do not protect from permanent or systematic failures.

In connection with the transition of the system to the next state, however, one needs to consider the software module that carries out the calculations to determine the subsequent state. If a transient failure distorts the software, then the software remains in a distorted form in the memory, although the memory would store the software correctly at the next occasion of software upload to the system. Therefore, the software must be written into memory together with a checksum. Moreover, for each application of this software, i.e. also when recomputing the transition to the next system state it is necessary to check the integrity of the software (or portions thereof) with the checksum.

6 CONCLUSION

In this paper, we studied transient failures. We have described the causes of transient failures and protection methods against them. The description given in chapter 2 can be seen as an illustration, where transient failure come from. Also, the description of detection mechanisms in chapter 3 is a list of known mechanisms. In the fourth section we have derived a systematic approach, which consists in two steps. At the first step, the system is represented as a Markov automate, the state of which is stored using protection methods, for

example using a checksum. In the second step, a reliable method of transition between states is constructed, e.g. using redundant calculations. The systematic approach has not been derived using cause and effect analysis by just combining causes of transient failures with detection mechanisms, because both lists can be incomplete. Instead, we consider the system as a system with discrete and countable system states with the Markov property. Such an approach is new. From this model, the two step approach is derived.

The approach is illustrated by an example.

Reliability allocation for a system with complex redundancy

Z. Vintr & T. Vintr
University of Defence, Brno, Czech Republic

ABSTRACT: The paper deals with the possibilities of allocating reliability requirements for a system using complex redundancy. It means system consists of a few identical subsystems and for its common function it is quite enough if only certain part of these subsystems operates. The subsystems not operating at a certain moment serve as redundancy in case that the subsystems which are operating fail. All the system, however, is not a trivial parallel structure, because if the system is to work properly, always more than one subsystem should operate and the subsystems can operate only in configurations set in advance. Practical application of the suggested method of reliability allocation is demonstrated for a pantograph system of a high-speed train. In order to provide the proper function of the system, the minimum number of operating pantographs in pre-set configurations providing safe current collection has to be always available. Using some pantograph configurations (e.g. two pantographs being one after another very closely) is in fact not possible for safety reasons. The article presents the procedure of reliability allocation for this specific system. Suggested method is based on a truth table and Boolean algebra application.

1 INTRODUCTION

At present it is common that when placing an order for developing and designing complex technical systems, it is essential to include both quantitative and qualitative reliability requirements for a specific system (IEC 2007).

Quantitative requirements are usually put in the form of the numerical values of selected reliability measures which are supposed to be met by a suggested system as a whole. It is then necessary to divide these global requirements properly into single parts of a system. This process is called the allocation of reliability requirements.

The aim of the process is to determine the reliability requirements of single parts of the system so that the system as a whole could satisfy the set requirement while meeting the partial ones. This process should be understood at the same time as essential part of the allocation of requirements for other system properties related to its dependability (Bartak et al. 2006).

It is always necessary to consider the fact that the decisions made in terms of reliability requirements allocation affect significantly system life cycle cost (Balik at al. 2005). In technical literature we can find a great deal of different procedures and methods of allocating reliability requirements (Kuo & Zhu 2012, Stapelberg 2009, Wessels 2010). They are, however, mostly restricted only to the systems of simple series or a parallel structure, or the system having simple ways of redundancy.

If the system structure is more complex, all the allocation process will be a lot more complicated and it is necessary then to combine single procedures and methods, or find new ones (Vintr & Vintr 2012, Vintr & Holub 2001, Wang et al. 2001, Furch 2012, Valis 2014, Maga 2006).

In the article we have introduced a possible procedure for allocating system reliability requirements. The system consists of a few identical subsystems and for its common function it is quite enough if only certain part of these subsystems operates. The subsystems not operating at a certain moment serve as redundancy in case that the subsystems which are operating fail.

All the system, however, is not a trivial parallel structure, because if the system is to work properly, always more than one subsystem should operate and the subsystems can operate only in configurations set in advance.

A high-speed train pantograph system which is introduced in this article can serve as an example of such system. When allocating reliability requirements for this system, a method using a truth table and Boolean algebra has been used.

2 RELIABILITY ALLOCATION PRINCIPLES

When considering complex technical systems, usually it is not possible to quantify reliability requirements for single items directly, but it is necessary to perform the gradual decomposition of the

requirements depending on the complexity and functional structure of the system. The starting point is to define single levels of system complexity characterized by items which are considered to be inseparable at a certain level. The example of such system division is shown in Figure 1.

The allocation of reliability requirements is then performed gradually following single selected levels of system complexity. Requirements for all the system are first redistributed throughout single subsystems, afterwards, when made for single subsystems, the requirements are distributed to subsystem assemblies, and the process will continue throughout all selected levels of system complexity up to individual components.

The process should be performed so that the set requirements for individual elements reliability would provide that the requirements for the system as a whole will be satisfied (Birolini 2004). Then it should be provided that:

$$R_S \geq R_S^*, \tag{1}$$

where: R_S-system reliability given by the reliability of single system items specified during allocation along with considering the system structure, R_S^*-required system reliability.

Allocation process can be relatively simple if the system has no redundancy. Should the system contain redundancy, allocation of reliability goals for individual components is more difficult.

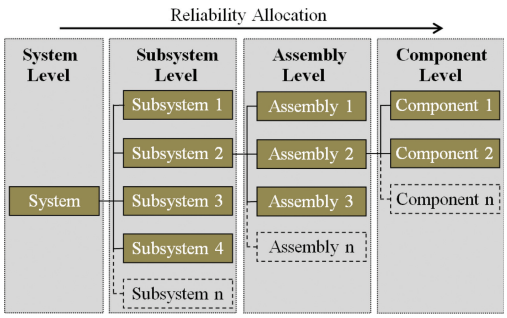

Figure 1. Reliability allocation concept.

In addition to above, complexity of individual components, costs, technology risks and failure effects should also be considered. In other words the allocation must be done in such a way that other design constrains are not violate. A case-by-case optimization is often possible (Birolini 2006).

3 TRAIN PANTOGRAPH SYSTEM

The suggested method, dealing with the allocation of reliability requirements, will be shown with the example of the pantograph system of a high-speed train with two engines placed at the beginning and at the end of the train (see Fig. 2). Either of these engines is equipped with pantographs designed the same way, but only one pantograph can operate on each engine. In order to assure right in-service operation, it is necessary to keep a certain minimum distance between single pantographs which operate (collect power) simultaneously. This is provided only in certain operating pantograph configurations shown in Table 1 (a cross in the table represents pantograph in operation).

When pantographs move along the overhead line, the line starts vibrating and if the specified minimum distance between pantographs were not kept, it could result in damaging the pantographs or the overhead line. Moreover, the train is required to be constantly powered by both engines. The train operator is permitted to use during the operation any of the allowed pantograph configurations.

The technical specification states that the reliability of a pantograph system as a whole cannot be lower than a required value R_S^*, and then the requirement expressed by the Equation 1 should be met. The aim of the allocation in this case is to determine the requirement for single pantograph reliability.

Further solution is based on a simplified assumption that a train set moves in one direction during all its life time. It is also presumed that all pantographs are designed identically and are of the same reliability. Basically, it is about a uniform distribution of reliability requirements.

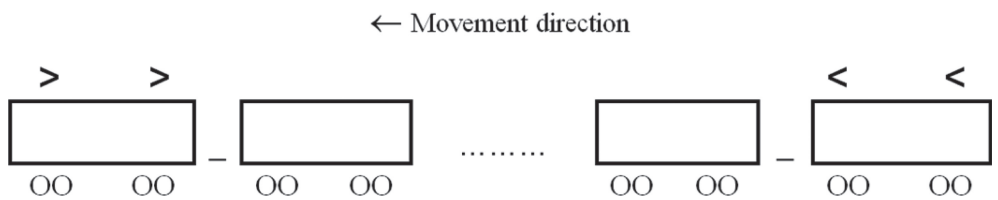

Figure 2. Pantograph system configuration.

Table 1. Allowed operational configuration of the pantograph system.

Allowed operational configuration	Ordinal number of pantograph (from the front of the train set)			
	1	2	3	4
I	X		X	
II	X			X
III		X		X

4 PROCESS OF RELIABILITY ALLOCATION USING THE TRUTH TABLE

The indicated task may be solved in different manners, but in view of its character applying a truth table seems to be the most convenient (IEC 2006). All possible combinations of faults and up states of single pantographs are going to be put in the table and each combination will be matched with all the system state with respect to allowed pantograph operational configurations.

Possible system states are put in Table 2 where value "0" means fault, whereas value "1" means up state. In the last column of the table there is for each combination an expression showing the probability that the combination will occur.

The symbols used in the Table 2 have the following meaning R_i—up state probability of *i*-th pantograph and Q_i—fault probability of *i*-th pantograph. Mutual relationship of these quantities can be expressed by the following formula:

$$Q_i = 1 - R_i \tag{2}$$

The probability that during assumed operating time all system will be in the up state might be, when applying the truth table, set as the sum of probabilities put in these lines which express some of the system up states:

$$\begin{aligned} R_S = {} & R_1R_2R_3R_4 + R_1R_2R_3Q_4 + R_1R_2Q_3R_4 \\ & + R_1Q_2R_3R_4 + Q_1R_2R_3R_4 + R_1Q_2Q_3R_4 \\ & + R_1Q_2R_3Q_4 + Q_1R_2Q_3R_4 \end{aligned} \tag{3}$$

Further solution is based on the assumption that the reliability level of all used pantographs is the same and the following equations apply:

$$\begin{aligned} R_1 = R_2 = R_3 = R_4 = R_p \\ Q_1 = Q_2 = Q_3 = Q_4 = Q_p \end{aligned} \tag{4}$$

Then, the Equation 3 might be put in the form below:

$$R_S = R_p^4 + 4R_p^3Q_p + 3R_p^2Q_p^2 \tag{5}$$

Table 2. Possible states of the pantograph system.

No.	Ordinal number of pantograph: 1	2	3	4	System state	Probability of relevant state occurrence
	State of pantographs					
1	1	1	1	1	1	$R_1R_2R_3R_4$
2	1	1	1	0	1	$R_1R_2R_3Q_4$
3	1	1	0	1	1	$R_1R_2Q_3R_4$
4	1	0	1	1	1	$R_1Q_2R_3R_4$
5	0	1	1	1	1	$Q_1R_2R_3R_4$
6	1	1	0	0	0	$R_1R_2Q_3Q_4$
7	1	0	0	1	1	$R_1Q_2Q_3R_4$
8	0	0	1	1	0	$Q_1Q_2R_3R_4$
9	0	1	1	0	0	$Q_1R_2R_3Q_4$
10	1	0	1	0	1	$R_1Q_2R_3Q_4$
11	0	1	0	1	1	$Q_1R_2Q_3R_4$
12	1	0	0	0	0	$R_1Q_2Q_3Q_4$
13	0	1	0	0	0	$Q_1R_2Q_3Q_4$
14	0	0	1	0	0	$Q_1Q_2R_3Q_4$
15	0	0	0	1	0	$Q_1Q_2Q_3R_4$
16	0	0	0	0	0	$Q_1Q_2Q_3Q_4$

and after replacing Q_p according to the Equation 2 and proper modifications we get the following equation:

$$R_S = 3R_p^2 - 2R_p^3 \tag{6}$$

After solving this equation, we get the requirement for pantograph up state probability.

5 PROCESS OF RELIABILITY ALLOCATION USING THE BOOLEAN ALGEBRA

Application of Boolean algebra is the second way haw to solve the presented problem. According to Table 1 the conditions for the pantograph system up state can be described by the following equation:

$$S = (S_1 \cap S_3) \cup (S_1 \cap S_4) \cup (S_2 \cap S_4) \tag{7}$$

where: S = the symbol indicates that the pantograph system is in up state, S_i = the symbol indicates that the *i*-th pantograph is in up state.

However, the Boolean terms S_1, S_2, S_3, and S_4 cannot be directly replaced by the corresponding probabilities in order to obtain a value for system reliability. This is because Equation 7 is in effect a set of "overlapping" (not "disjoint") terms. For these reason Equation 7 should by modified to non-overlapping terms using the methods for disjointing Boolean expressions (IEC 2006).

Application of these methods the following equation can be received:

$$S = (S_1 \cap S_3) \cup (\bar{S}_1 \cap S_2 \cap S_4) \cup (S_1 \cap \bar{S}_3 \cap S_4) \quad (8)$$

where: $\bar{S}_i$—the symbol indicates that the *i*-th pantograph is in down state.

In purely Boolean terms, Equation 7 and Equation 8 are equivalent. In Equation 9 each literal can be replaced by the corresponding probability:

$$P(S) = P(S_1)P(S_3) + P(\bar{S}_1)P(S_2)P(S_4) + P(S_1)P(\bar{S}_3)P(S_4) \quad (9)$$

where $P(S) = R_s$ = probability of the pantograph system up state (pantograph system reliability), $P(S_i) = R_i$ = probability of the *i*-th pantograph up state (*i*-th pantograph reliability), $P(\bar{S}_i) = Q_i$ = probability of the *i*-th pantograph down state (*i*-th pantograph unreliability).

After replacing individual probabilities corresponding reliability/unreliability term the following equation can be received:

$$R_S = R_1R_3 + Q_1R_2R_4 + R_1Q_3R_4 \quad (10)$$

Further solution is based on the assumption that the reliability level of all used pantographs is the same (see Equation 4):

$$R_S = R_p^2 + 2Q_pR_p^2 \quad (11)$$

After replacing Q_p according to the Equation 2 and proper modifications we can get the same formula as it has been already presented (see Equation 6). A practical solution of the Equation 6 is not presented there, since it is not the area of our interest in the article and it is purely mathematical.

6 CONCLUSION

The article introduces a possible procedure for allocating reliability requirements for a system consisting of a few identical subsystems. For a common system operation it is quite sufficient if only a certain part of these subsystems works. It applies that these systems can operate only in the configurations set in advance. A possible representative of a system of this kind is the pantograph system of a high speed train.

While allocating reliability requirements for this system, it is impossible to use standard methods and allocation procedures. That is the reason why we introduced a relatively simple procedure using a truth table which solves the problem effectively. The truth table can be used also for other types of systems where conventional methods of reliability requirements fail.

ABSTRACT: There are many network systems in the world, for example, Internet, electricity network and traffic network, etc. In this study, we consider two-objective network design problem with all-terminal reliability and construction cost. In the general, it is a rare case that a solution makes both of all-terminal reliability and construction cost optimum simultaneously. Therefore we consider an algorithm for obtaining Pareto solutions. However, existing algorithms for Pareto solutions are inefficient as we must calculate all-terminal reliabilities of all sub-networks. So, it takes much time to obtain Pareto solutions when the number of nodes and edges is large. For an efficient algorithm, we research the difference between the Pareto solutions and the other networks. By using such properties, we constitute the searching space in which sub-networks take close values to Pareto solutions, and propose new algorithm for obtaining Pareto solutions. Finally, we evaluate our proposed algorithm by numerical experiments.

1 INTRODUCTION

There are many network systems in the world, for example, Internet, electricity network and traffic network, etc. These systems forms basis of society, so stabilizing operation of systems and designing systems to operate effectively are important problems. The evaluation of network systems considers various measures, for example, reliability, distances, flow and time. To optimize these measures, the problems are formulated as shortest path problem, maximum flow problem and so on.

Making a decision reasonably needs to consider plural measures when we evaluate these network systems. In our study, we consider all-terminal reliability and construction cost for network as important measures for evaluation. However, there exists a trade-off between reliability and construction cost, so it is a rare case that a solution (network system) makes all-terminal reliability and construction cost optimum simultaneously. Therefore we consider an algorithm for obtaining Pareto solutions of a two-objective network with all-terminal reliability and construction cost. The reliability and cost problems for the network systems have been studied in a long period. Specially calculating reliability is known to be more difficult than other measures, and the numerous papers have been published. As to calculation of reliability, many papers have appeared over the years dealing with the network reliability theory. These studies were reported by Boesch et al. (1988, 2009). Koide (2002) proposed efficient algorithm for calculating reliabilities of all sub-network. Akiba et al. (2007) improved Koide's algorithm and applied its improved algorithm to obtaining Pareto solutions with all-terminal reliability and construction cost. Though, this algorithm also needs to calculate all-terminal reliabilities and costs for all sub-networks. So, taking much time to obtain Pareto solutions is problem, as the number of nodes and edges in the all-terminal network is large.

In order to construct an efficient algorithm, we researched differences between the optimum networks, which become Pareto solutions, and the other networks. Based on these obtained properties, we reduce the number of networks whose reliability and cost must be calculated, and propose a new algorithm for obtaining the subset of Pareto solutions. And we evaluate the efficiency and accuracy of a proposed algorithm by numerical experiments.

2 DEFINITION OF PROBLEM

2.1 *Network model*

In this study, we consider networks with undirected edges, that is, networks have not directed flow for constructing networks. Let $g = (V, E)$ be a given network with the set $V = \{v_1, v_2, \ldots, v_n\}$ of nodes and the set $E = \{e_1, \ldots, e_m\}$ of edges. $X_g = (x_1, x_2, \ldots, x_m)$ also signifies a given network g, where x_i is a binary variable which takes 1 if edge e_i exists or else takes 0. Furthermore, we define some notations as follows.

n, m: The number of nodes and edges in V and E, respectively
G_n: The set of network with all n nodes connected.
For $i = 1, 2, \ldots, m$,
e_i: i-th edge
p_i, c_i: Reliability and construction cost of edge e_i, respectively
$R(g)$, $C(g)$: All-terminal reliability and total cost for network g, respectively.

The following assumptions are considered throughout this paper.

A. All terminal nodes do not fail.
B. Connections for all edges are mutually statistically independent.
C. All edges have reliability and construction cost.

2.2 *Definition of problem*

In this study, we consider network design problem with all-terminal reliability and construction cost. The problem can be expressed as follows.

$$R(g) \rightarrow \max$$

$$C(g) \rightarrow \min$$

$$s.t.\ g \in G_n$$

It is a rare case that a network makes all-terminal reliability and construction cost optimal simultaneously. For solving this problem, we search for Pareto solutions. Let G be the set of feasible solutions. For g, $g' \in G$, g becomes Pareto solutions if there are no other feasible solution g' which satisfies either 3 conditions as follows:

1. $R(g) < R(g')$ and $C(g) > C(g')$
2. $R(g) = R(g')$ and $C(g) > C(g')$
3. $R(g) < R(g')$ and $C(g) = C(g')$

That is, our considered optimal network design problem means obtaining Pareto solutions from all the sub-networks g', where $g' = (V, E')$ is all the sub-networks of g for $g = (V, E)$, $E' \subseteq E$.

2.3 *Existing algorithm*

We introduce existing algorithm by Koide (2002), which calculate all-terminal reliabilities for all sub-networks of complete graph. This algorithm divides edge sates into two conditions as follows.

a. "Deleting" means an operation of removing edge e_i from the network g, that is, edge e_i fails.
b. "Contracting" means an operation of unification for both end nodes of edge e_i, that is, edge e_i works completely.

Let $g - e_i$ be the network g with edge e_i deleted, and g/e_i represent the network g with edge e_i contracted, respectively. Then, all-terminal reliability $R(g)$ can be expressed as the following equation.

$$R(g) = (1 - p_i)R(g - e_i) + p_i R(g / e_i) \quad (1)$$

When equation (1) is applied to all sub-networks of complete graph, same form sub-networks appear plural times in recursive process. Koide (2002) proposed the efficient algorithm in which calculated reliabilities were memorized and referred. He called it "factmem method".

Furthermore, Akiba et al. expanded "factmem method" and proposed advanced algorithm, "improved factmem method" (Akiba et al. 2007). The following properties are considered in Akiba et al.'s algorithm.

1. If sub-network with n nodes and less than $n - 1$ edges is conducted by factmem method, it is not necessary to calculate its all reliability.
2. If the number of nodes comes to one in contracting process, it is not necessary to operate anymore for its network.

Moreover, Akiba et al. apply "improved factmem method" to two-objective network design problem with all-terminal reliability and construction cost.

3 PROPERTIES OF NETWORKS

3.1 *Outline of our proposed algorithm*

We consider network design problem with all-terminal reliability and construction cost. For this problem, proposed algorithm by Akiba et al. (2007) can reduce computing time for all-terminal reliability. However, their algorithm doesn't consider the relation between reliability and cost, and must calculate reliabilities and costs for all sub-networks. This process expands search space for Pareto solutions and makes computing time increase.

This section describes outline of our proposed algorithm. For explanation, the following nota-

tions are defined. For $k = n - 1, n, \ldots, n(n-1)/2$, let us define notations blow.

g_k: The network with n nodes connected by k edges
G_n^k: The set of g_k
$pareto(G)$: The set of network $g \in G$ which satisfies the definition of Pareto solutions.
gp_k: The network which satisfies definition of Pareto solutions in G_n^k
GP_n^k: The set of g_k. That is, $GP_n^k = pareto(G_n^k)$.

Figure 1 shows the outline of algorithm. Our proposed algorithm does not consider all sub-networks. We assume networks G_n^k are constructed. When $k = n - 1$, the set G_n^k has all networks which connect all nodes. Among G_n^k, a part of networks are selected as the candidate networks for construction of network set G_n^{k+1}. And an element of G_n^{k+1} is constructed by adding one edge to selected networks from G_n^k. For G_n^{k+1}, a part of G_n^{k+1} are selected, and an edge is added. This operation is repeated until $k = n(n-1)/2$.

The following sections explain the range of selected networks and criteria for added edge.

3.2 *Range for considered networks*

3.2.1 *Classifying Pareto solutions*

We consider selecting networks for adding edges. We divided G_n^k into the following two kinds of networks. One is $gp_k (\in GP_n^k)$ obtained as Pareto solutions and the other is $g_k (\in G_n^k \backslash GP_n^k)$. We researched which of the following two cases was efficient. One is the case that an edge is added to gp_k and $g_{k+1} (\in G_n^{k+1})$ are constructed. Another is the case that an edge is added to g_k. When g_k has much lower reliability and higher cost than gp_k, g_{k+1} constructed from g_k can hardly become Pareto solutions GP_n^{k+1}. Based on the above property, we define rank of Pareto solution and suppose the following property in order to select networks to add an edge.

Definition 1: Let $GP_n^{k,j}$ be Pareto solutions in rank j ($j = 1, 2, \ldots, R$), and defined as following formula.

$$GP_n^{k,j} = pareto(G_n^k \backslash \bigcup_{i=1}^{j-1} GP_n^{k,i}) \quad (2)$$

where $GP_n^{k,1}$ is the same as GP_n^k.

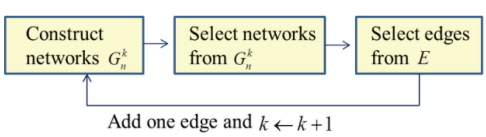

Figure 1. The outline of our algorithm.

Property 1: g_{k+1} constructed from $gp_k (\in \cup_{i=1}^{R} GP_n^{k,i})$ is likely to be Pareto solutions GP_n^{k+1}.

Property 1 means networks close to each Pareto solutions $GP_n^{k,1}$ are likely to be candidate networks for construction of G_n^{k+1}. R is lower boundary of considered rank as candidate. In an experiment with networks of 5 nodes, all Pareto solutions GP_n^{k+1} could be constructed by $gp_k \in GP_n^{k,1}$, $GP_n^{k,2}$.

3.2.2 *The slope of Pareto solutions*

Next, we take notice of the shape of Pareto front and propose restricting the range by the slope of Pareto solutions. This restriction adopts the straight line connecting origin point and one of Pareto solutions. Two properties are assumed below.

Property 2–1: For $gp_{k-1}^* = \arg \max_{gp_{k-1} \in GP_n^{k-1}} R(gp_{k-1})$, g_k which satisfies $R(gp_{k-1}^*) < R(g_k)$ can construct $gp_{k+1} \in GP_n^{k+1}$ by adding an edge.

Property 2–2: For $gp_k'' = \arg \min_{gp_k \in GP_n^k} (R(gp_k)/C(gp_k))$, g_k which satisfies $R(gp_k'')/C(gp_k'') < R(g_k)/C(g_k)$ can construct $gp_{k+1} \in GP_n^{k+1}$ by adding an edge.

By the above two properties, we consider two lines as shown in Figure 2. First line is L_1 which is parallel to abscissa axis and passes through gp_{k-1}^*. Property 2–1 means the region above L_1. Second line L_2 is connecting gp_k'' and origin point. Property 2–2 signifies the region above L_2. In Figure 2, the region surrounded by two lines, L_1 and L_2, is made the range of network selection.

3.2.3 *Network topology*

We consider characteristic of network topology. For network with all nodes included cycle structure, its all-terminal reliability is known to be higher than other topologies' all-terminal reliabilities (Jan 1993). Comparing networks (a) and (b) in

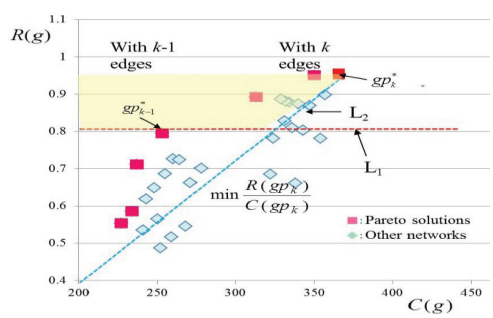

Figure 2. The image of restricted space by two straight lines.

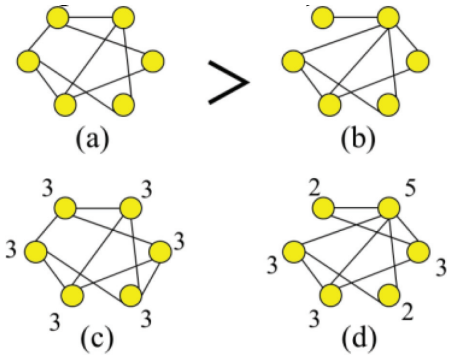

Figure 3. The influence of network topologies.

Figure 3, all-terminal reliability of network (a) is superior to that of network (b).

In addition, we researched Pareto solutions in terms of the degree of node. Networks like (c) in Figure 3 were more found in Pareto solutions as compared with networks like (d). Networks (c) and (d) are different in the number of edges connected to some node. The number of edges is called the degree of node. In network (c), degree of each node takes similar value. On the other hands, network (d)'s degrees vary widely. Using binary variable x_i which takes 1 if edge e_i exists or else takes 0, we assume the property about the degree of node below.

For node v_j, let d_j be the degree of node v_j as follows.

$$d_j = \sum_{i=1}^{n} x_i \tag{3}$$

where x_i are summed up on i such as $s(e_i) = v_j$ or $e(e_i) = v_j$, and $s(e_i)$ and $e(e_i)$ are nodes at both ends of edge e_i.

Property 3: Pareto solutions include networks as the degree of node satisfies following equation.

$$\left| D_1 + D_2 \right| = n \tag{4}$$

where $D_1 = \{d_j \mid 1 \le j \le n, d_j$ is the sum of 1 and quotient of 2 $k/n\}$, and $D_2 = \{d_j \mid 1 \le j \le n, d_j$ is equal to the quotient of $2k/n\}$.

3.3 *Criteria for adding edges*

3.3.1 *Efficiency of edges*

Next, we consider adding edge to selected networks. Pareto solutions depend on two objective functions, reliability and cost of each edge. Therefore this section mentions how two values of edge give influence on Pareto solutions. For e_i, we define following index.

Definition 2: $f_i = p_i/c_i$ denotes efficiency of edge e_i.

Figure 4 shows the following two cases. One is the case of adding the edge e_1 with minimum f_i. Another is the case of adding the edge e_2 with maximum f_i. In both cases, e_1 or e_2 is added to the network g_k. In light of this result, we assume the property as follows.

Property 4: If f_i is larger than other edge's, network $g_{k+1} = (V, E' \cup \{e_i\})$ is likely to be Pareto solution $gp_{k+1} \in GP_n^{k+1}$, where $g_k = (V, E')$.

3.3.2 *Validity of edge*

Next, our study focuses on the number of times that each edge is contained in Pareto solutions. To look for influences other than the value of reliability and cost, we researched Pareto solutions with small number of edges. The edges included in many Pareto solutions GP_n^k were also included considerably in Pareto solutions with more than k+1 edges. In addition, the many included edges don't necessarily match edges with high efficiency f_i. Whether a network becomes Pareto solution will depend on the way of edge link in addition to the value of reliability and cost on edge. Therefore, considering the number of times allows us to construct dominant networks effectively.

For obtained Pareto solutions GP_n^k, we sum up included times for each edge and this measure is applied to select edge. Using binary variable x_i which takes 1 if edge e_i exists or else takes 0, we define the following index.

Definition 3: Total value as satisfying following equation (5) is defined as validity x_i^k of edge e_i.

$$x_i^k = \sum_{\{gp_r \in GP_n^r\}} x_i \tag{5}$$

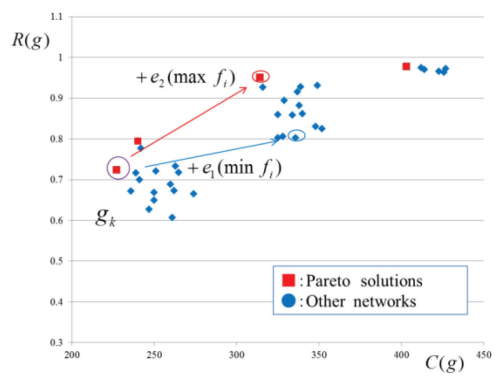

Figure 4. The influence of efficiency of edges for networks.

4 PROPOSED ALGORITHM

Combining the above-mentioned criteria of edge and range of considered networks, we construct algorithms which reduce the number of considered networks. However, reduction of considered networks influences obtaining Pareto solutions, and causes us subset of Pareto solutions. Computing time and accuracy of search vary according to considered lower boundary rank R and the number of edges ec added to candidate networks.

Numerical experiments were given by using a network with 6 nodes and 15 edges. Cost c_i and reliability p_i of each edge were prepared in a following pattern. p_i was given by random number uniformly between 0.50 and 0.99. c_i was set for $c_i = 100 * p_i + a$, where a was given by random number uniformly between 5 and 10. Calculating reliabilities and costs for all sub-networks took around 10 seconds.

Table 1 shows some algorithms which are different in combination of range for considered networks and criteria of edge. For example, $AL_{SD,V}$ adopts the slope of Pareto solutions and the degree of nodes as range for considered networks, and adds edges according to validity of edge. The following sections compare these algorithms.

4.1 *Comparison of ranges of considered networks*

In the following explanation, we describe $AL_{SD,V}$ of Table 1. ${G_{n,1}}^k$ and ${GP_{n,1}}^k$ signify considered networks by the slope of Pareto solutions, and ${G_{n,2}}^k$ and ${GP_{n,2}}^k$ by the degree of nodes. Among ${G_{n,1}}^k$, networks which satisfy the range for considered networks are set in ${GP_{n,1}}^{k,2}$, where $pareto({G_{n,s}}^k)$ is set in ${GP_{n,1}}^{k,1}$.

[Algorithm $AL_{SD,V}$]

STEP 1: Set lower boundary rank R and ec.
$k \leftarrow n-1$, $r \leftarrow 1$ and $s \leftarrow 1$.

Table 1. Combination of ideas in evaluated algorithms.

	Range of networks			Criteria of edge	
	Rank	Slope	Degree	Efficiency	Validity
$AL_{SD,V}$		Used	Used		Used
$AL_{S,V}$		Used			Used
$AL_{RD,V}$	Used		Used		Used
$AL_{R,V}$	Used				Used
$AL_{RSD,V}$	Used ($k \geq K1$)	Used ($k < K1$)	Used		Used
$AL_{RSD,E}$	Used ($k \geq K1$)	Used ($k < K1$)	Used	Used	

STEP 2:
STEP 2–1: If $s = 2$, for all $g_k \in {G_{n,s}}^k$ calculate d_j ($j = 1, 2, \ldots, n$).
If $|D_1 + D_2| \neq n$, ${G_{n,s}}^k \leftarrow {G_{n,s}}^k \backslash \{g_k\}$.
STEP 2–2: For all $g_k \in {G_{n,s}}^k$, calculate $R(g)$ and $C(g)$.

STEP 3:
STEP 3–1: If $s = 2$ and $k = n(n+1)/2$, calculate $pareto\{\cup_{i=n-1}^{k}({G_{n,1}}^i + {G_{n,2}}^i)\}$ and end algorithm. Else go to STEP 3–2.
STEP 3–2: For $gp_{k-1}^* = \arg \max_{gp_{k-1} \in GP_{n,s}^{k-1}} R(gp_{k-1})$,
if any $g_k \in {G_{n,s}}^k$ satisfies $R(gp_{k-1}^*) > R(g_k)$, ${G_{n,s}}^k \leftarrow {G_{n,s}}^k \backslash \{g_k\}$.
STEP 3–3: ${GP_{n,s}}^{k,1} \leftarrow pareto({G_{n,s}}^k)$.
For $gp_k'' = \arg \min_{gp_k \in GP_{n,s}^k} (R(gp_k)/C(gp_k))$,
if any $g_k \in ({G_{n,s}}^k \backslash {GP_{n,s}}^{k,1})$ satisfies $R(gp_k'')/C(gp_k'') < R(g_k)/C(g_k)$, ${GP_{n,s}}^{k,2} \leftarrow {GP_{n,s}}^{k,2} \backslash \{g_k\}$.

STEP 4:
STEP 4–1: If $k = n-1$ or n, $x_i^k \leftarrow f_i$. Else if $k = n+1$, calculate x_i^k and $x_i^k \leftarrow f_i + x_i^k$.
STEP 4–2: Select $gp_k \in (\cup_{r=1}^{R} {GP_{n,s}}^{k,r})$.
$l \leftarrow ec$.
STEP 4–3: Select $e_i \in (E \backslash E')$ which satisfies max x_i^k, and construct g_{k+1} and ${G_n}^{k+1} \leftarrow {G_n}^{k+1} \cup \{g_{k+1}\}$. $E' \leftarrow E' \cup \{e_i\}$, $l \leftarrow l-1$. Repeat up to $l = 0$.
STEP 4–4: If select all $gp_k \in (\cup_{r=1}^{R} {GP_{n,s}}^{k,r})$, go to STEP 4–5. Else go to STEP 4–2.
STEP 4–5: If $k = n-1$, construct sub-networks GC with cycle topology independently from x_i^k, and ${G_n}^{k+1} \leftarrow {G_n}^{k+1} \cup GC$.
STEP 4–6: $k \leftarrow k+1$, $r \leftarrow 1$ and go to STEP 2–2.
STEP 4–7: $k \leftarrow n$, $s \leftarrow 2$ and ${G_{n,s}}^k \leftarrow GC$. Go to STEP 2.

Moreover, changing combination of network properties constructs three other algorithms which are $AL_{S,V}$, $AL_{RD,V}$ and $AL_{R,V}$ of Table 1. $AL_{S,V}$ (Takahashi et al. 2013) excludes STEPs on the node degree from $AL_{SD,V}$. $AL_{RD,V}$ and $AL_{R,V}$ substitute rank of Pareto solution for STEPs on slope of Pareto solution of $AL_{SD,V}$ and $AL_{S,V}$, respectively. Varying parameters R and ec as shown in Table 2, numerical experiments are conducted. For example, $AL_{RD,V}$ takes values of 3 patterns on R and 10 patterns on ec, so 30 experiment patterns are conducted. Table 1 also indicates where the result

Table 2. Parameters on each algorithm.

	$AL_{SD,V}$	$AL_{RD,V}$	$AL_{S,V}$	$AL_{R,V}$
R		1 to 3		1 to 3
ec	1 to 10	1 to 10	1 to 10	1 to 10
Result	Figure 4	Figure 4	Figure 5	Figure 5

of each algorithm is shown. Figure 4 and Figure 5 compare the above four algorithm on influence by R and ec. Figures 4 and 5 show change of obtained rate and computing time in each algorithm. Obtained rate means the percentage of obtained Pareto solutions by our algorithm to real Pareto solutions. In Figure 4, items of "rank1, rank2 and rank3" are results of $AL_{RD,V}$, and "slope" corresponds to $AL_{SD,V}$. Similarly, items of "rank1, rank2 and rank3" and "slope" are results of $AL_{R,V}$ and $AL_{S,V}$, respectively in Figure 5.

Comparing both figures, using the slope of Pareto solutions is efficient. Although more computing time is taken, using the rank of Pareto solutions can obtain real Pareto solutions more. In terms of node degree, the pattern number that obtained rate is over 90% is 7 in Figure 5. In Figure 4 this number is 13. However increasing computing time is problem.

4.2 *Combination of ranges for considered networks*

Next, we construct algorithm $AL_{RSD,V}$ of Table 1, which changes the range for considered networks at some number of edges. K_1 is the parameter.

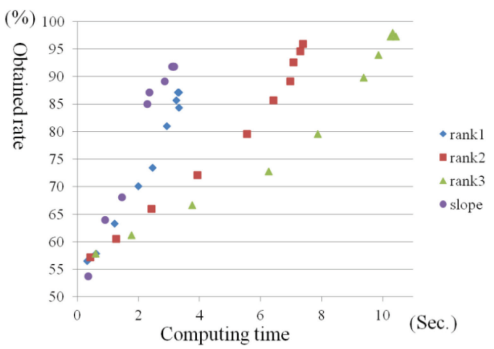

Figure 4. The comparison of $AL_{SD,V}$ and $AL_{RD,V}$.

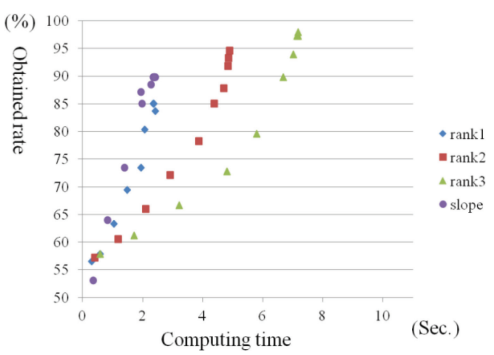

Figure 5. The comparison of $AL_{S,V}$ and $AL_{R,V}$.

[Algorithm $AL_{RSD,V}$]

Substitute following STEP 3 for STEP 3 of $AL_{SD,V}$.

STEP 3:

STEP 3–0: If $k < K_1$, Go to STEP 3–1–1. Else go to STEP 3–2–1.

STEP 3–1–1: For $gp_{k-1}^{*} = \arg \max_{gp_{k-1} \in GP_{n,s}^{k-1}} R(gp_{k-1})$, if any $g_k \in G_{n,s}^{k}$ satisfies $R(gp_{k-1}^{*}) > R(g_k)$, $G_{n,s}^{k} \leftarrow G_{n,s}^{k} \backslash \{g_k\}$.

STEP 3–1–2: $GP_{n,s}^{k,1} \leftarrow pareto(G_{n,s}^{k})$. For $gp_k'' = \arg \min_{gp_k \in GP_{n,s}^{k}} (R(gp_k)/C(gp_k))$, if any $g_k \in (G_{n,s}^{k} \backslash GP_{n,s}^{k,1})$ satisfies $R(gp_k'')/C(gp_k'') < R(g_k)/C(g_k)$, $GP_{n,s}^{k,2} \leftarrow GP_{n,s}^{k,2} \backslash \{g_k\}$. Go to STEP 4–1.

STEP 3–2–1: If $k = n(n+1)/2$, obtain $pareto\{\cup_{i=n-1}^{k} G_{n,1}^{i}\}$ and end of algorithm. Else, $GP_{n,s}^{k,r} \leftarrow pareto(G_n^{k} \backslash \cup_{j=1}^{r-1} GP_{n,1}^{k,j})$.

STEP 3–2–2: If $r = R$, go to STEP 4–1. Else, $r \leftarrow r+1$ and go to STEP 3–2–1.

In $AL_{RSD,V}$, slope of Pareto solutions is used as the range for considered networks when $k < K_1$. In the case of $k \geq K_1$, rank of Pareto solutions is applied to the range for considered networks.

Setting patterns of parameters R, ec and K_1 as shown in Table 3, numerical experiments are conducted. Figure 6 shows comparison of $AL_{RSD,V}$ and $AL_{SD,V}$. In this figure, the items of "rank1, rank2 and rank3" mean results of $AL_{RSD,V}$. The item of "slope" is the same as "slope" of $AL_{SD,V}$ in Figure 5, where Figure 6 is different in the scale of abscissa axis. From this result, using rank of Pareto solutions becomes more efficient in some patterns than using the slope of Pareto solutions. In addition, from an accurate point of view, the number of patterns that obtained rate is over 90% is 18 in Figure 6.

4.3 *Comparison of criteria of edge*

In order to research the influence of efficiency and validity of edges, we describe $AL_{RSD,E}$ and compare $AL_{RSD,E}$ with $AL_{RSD,V}$ of Table 1.

[Algorithm $AL_{RSD,E}$]

Substitute following STEP 4 for STEP 4 of $AL_{RSD,V}$.

Table 3. Parameters on $AL_{SD,V}$ and $AL_{RSD,V}$.

	$AL_{SD,V}$	$AL_{RSD,V}$
$R(k \geq K_1)$		1 to 3
ec	1 to 10	1 to 10
K_1		9

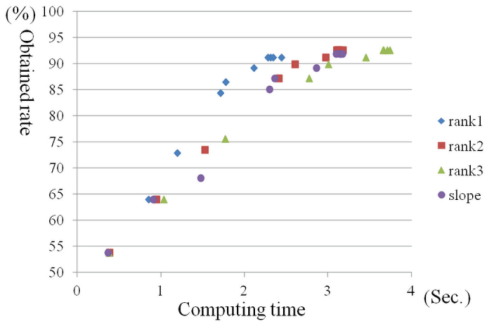

Figure 6. The comparison of $AL_{SD,V}$ and $AL_{RSD,V}$.

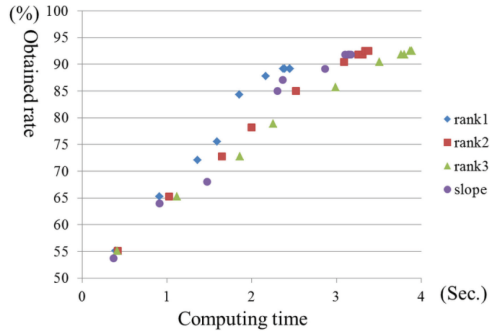

Figure 7. The comparison of $AL_{RSD,V}$ and $AL_{RSD,E}$.

Table 4. Parameters on $AL_{RSD,V}$ and $AL_{RSD,E}$.

	$AL_{RSD,V}$	$AL_{RSD,E}$
$R(k \geq K_1)$	1 to 3	1 to 3
ec	1 to 10	1 to 10
K_1	9	9
Result	Figure 6 & Figure 8	Figure 7 & Figure 9

STEP 4:

STEP 4–1: If $k = n - 1$, calculate f_i.

STEP 4–2: Select $gp_k \in (\cup_{r=1}{}^{R} GP^{k,r}{}_{n,s})$. $l \leftarrow ec$.

STEP 4–3: Select $e_i \in (E \backslash E')$ which satisfies max f_i, and construct g_{k+1} and $G_n{}^{k+1} \leftarrow G_n{}^{k+1} \cup \{g_{k+1}\}$. $E' \leftarrow E' \leftarrow \{e_i\}$, $l \leftarrow l - 1$. Repeat up to $l = 0$.

STEP 4–4: If select all $gp_k \in (\cup_{r=1}{}^{R} GP_{n,s}{}^{k,r})$, go to STEP 4–5. Else go to STEP 4–2.

STEP 4–5: If $k = n - 1$, construct sub-networks GC with cycle topology independently from f_i and $G_n{}^{k+1} \leftarrow G_n{}^{k+1} \cup GC$.

STEP 4–6: $k \leftarrow k + 1$, $r \leftarrow 1$ and go to STEP 2–2.

STEP 4–7: $k \leftarrow n$, $s \leftarrow 2$ and $G_{n,s}{}^{k} \leftarrow GC$. Go to STEP 2.

Setting patterns of parameters R, ec and K_1 as shown in Table 4, numerical experiments are conducted. In Figure 7, the items of "rank1, rank2 and rank3" show results of $AL_{RSD,E}$. The item of "slope" is the same as "slope" of $AL_{SD,V}$ in Figure 6. "Slope" is plotted as a measure for comparison with $AL_{RSD,V}$ of Figure 6. As the result, $AL_{RSD,E}$, which used efficiency as criteria of edge, made efficiency of search decrease a little.

We take notice of error rate of both algorithms. Our algorithms output some non-Pareto solutions as optimum solutions. Error rate means the percentage of these non-Pareto solutions by our algorithm to real Pareto solutions. Figure 8 and Figure 9 compared error rate when ec varied as shown in Table 4. Comparing two figures, $AL_{RSD,E}$ is likely to obtain non-Pareto solutions. When $ec = 2,3,4$, the error rate increased.

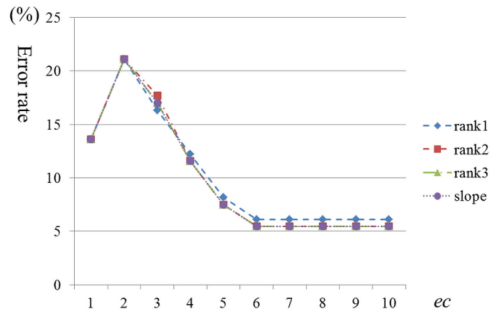

Figure 8. The influence of validity of edges for networks.

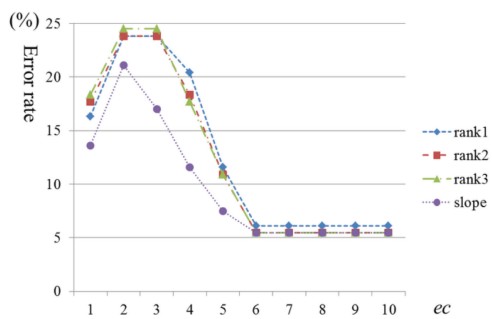

Figure 9. The influence of efficiency of edges for networks.

5 CONCLUSION

In our study, we focused on optimum network design problem with two-objective network with

all-terminal reliability and construction cost. Our study introduces criteria for added edges and range of considered networks. Combining these properties, we proposed the algorithm restricting the number of networks that must be calculated. With regard to the range for considered networks, numerical experiment suggested combining slope and rank of Pareto solutions was effective. As criterion of edge, using validity of edge wasn't greatly different from using edge efficiency in obtained rate, but validity was superior in error rate. Therefore $AL_{RSD,V}$ could obtain the subset of Pareto solutions more accurately and efficiently among algorithms which we constructed in this study. The future work is to consider combination of network properties which we haven't used, and to adapt these network properties to algorithm process effectively.

SYMBAD—Artificial Neural Networks in furtherance of managing aircraft testing

W. Kosiński, J. Wójcik & M. Zieja
Air Force Institute of Technology, Warsaw, Poland

ABSTRACT: SYMBAD is the structure of Artificial Neural Network (ANN) developed on the basis of experimentally gained data from the military aircraft testing. These tests were done in Air Force Institute of Technology for many years and for the different types of aircraft. Potential usage of this programme for the managing of aircraft prototypes testing has been formulated as well. This case is presented in this article. The presented program will be improved based on the knowledge of researchers.

The SYMBAD program has been developed under the Borland C++ Builder programming environment. It uses an innovative approach to any issues of the aeronautical testing.

The SYMBAD's structure can be easily adjusted depending on the type of test equipment, eg. for unmanned air systems, helicopters and combat aircrafts. Moreover, programme modification can include type of research being conducted: for a new-designed and -developed aircraft as well as for an upgraded one, for those in production, and for the aircraft equipment/systems built in the aircraft.

Input programme data take into consideration requirements listed in technical specifications, rules and regulations of aircraft building, standards, and Customer's requirements.

Paper presented programme uses neutral network to optimize the flight test programme as well, according to the Customer's requirements, at a proposed cost, with safety of both the staff and the aircraft provided.

1 INTRODUCTION

In-flight aircraft testing is conducted according to Flight Test (FT) programme which is already prepared and approved (MoD 2010). Creating FT Programme requires enormous experience of researchers as well as knowledge of requirements listed in technical specifications, rules and regulations on aircraft building, standards, and Customer's requirements. The FT schedule which is a plan of flight trials execution over a specific period of time is an integral part of the FT programme. Account is taken of the availability of labour and resources, climatic conditions and other factors that may affect the execution of the trials, such as predispositions of flight test team members, their proficiency, etc., with flight test safety taken into consideration.

Taking into consideration all conditions mentioned above, which FT programme should fulfill, a tool, which allows to streamline FT programme development basing on AFIT experience, was presented.

Neural networks (Tadeusiewicz R. 1993, Rutkowski L. 2005), were used ex. for optimization of municipal transport vehicles usage (Świderski A, 2006) or for risk areas determination in aircraft renovation conduction (Jasińska J, 2010).

Presented programme has to be adjusted to match specified time and expenses. Tool used for FT programme time optimization is SYMBAD, software developed by Air Force Institute of Technology (AFIT).

2 FLIGHT TEST TIME SIMULATION SOFTWARE SYMBAD 2012/2013

The SYMBAD 2012/2013 software has been developed under the Borland C++ Builder programming environment. It uses an innovative approach to any issues of the aeronautical testing. The software can be used to estimate time consumed by specified tests on particular date and in particular place. Software uses following information as input data:

- reliability of individual aircraft tests,
- flyable days in particular months,
- flyable hours in particular months
- availability of the pilots
- the pilot data,

The software may also deliver a printout with the set of tests and predictions on time needed to accomplish them.

Interface of SYMBAD software and its modules have been expanded on in articles (Wójcik, J, & Zieja, M. 2012, Wójcik, J, & Kosiński, W. & Zieja, M. 2013).

Below, as a remainder, two example software windows are presented. (Fig. 1 and Fig. 2).

When analysing aircraft testing data, firstly, identification of threats that can influence programme is done and risk of occurrence of such events is estimated. Secondly, results of these analysis are imported directly to SYMBAD software.

An example of flyable hours in function of test conducting date analysis is presented below Depending on date specified by costumer, amount of flyable hours in the day varies (Fig. 3).

Another analytical example is the dependence of the number of days suitable for aircraft flight testing on the Customer-indicated test site (Fig. 4).

Data presented above is obtained from annual analysis performed during flight tests. The problem of analysis conduction and identification of threats has been expanded on in article (Hass A.M.J.: 2003, Jasińska, J. & Wójcik, J. & Kosiński, & W. Krupnik, D, 2011, Jasińska, J. & Wójcik, J. & Kosiński, W. 2012, Kosiński, W. & Pokora, W. 2012, Kosiński, W. & Wójcik, J, & Warchulski, J. & Zieja, M. 2012).

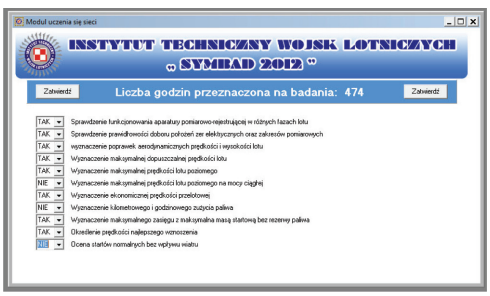

Figure 1. Network learning module in SYMBAD software.

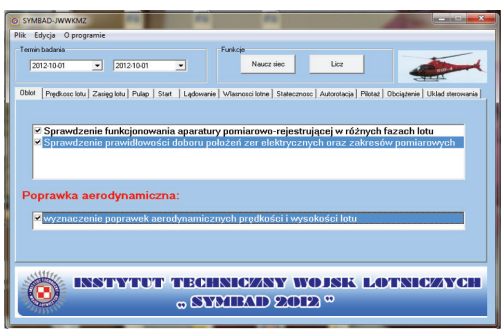

Figure 2. SYMBAD software interface.

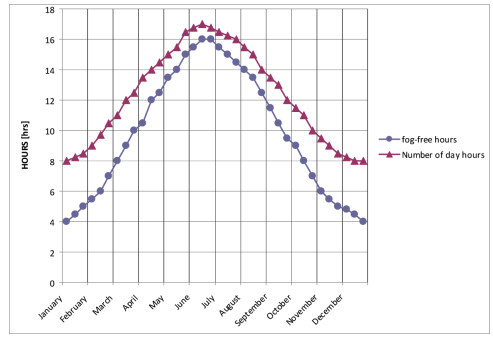

Figure 3. Distribution of flying hours in the daytime in particular months.

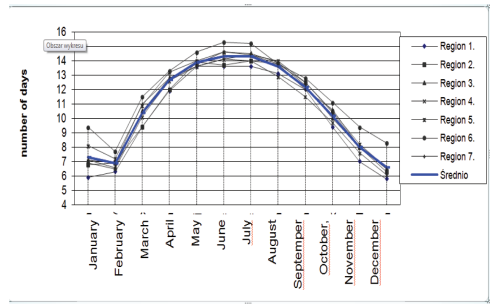

Figure 4. The average number of days with the following weather conditions: cloud cover ≤ 6/10; visibility ≥ 6 km on military airfields in various regions of Poland.

2.1 *Formal structure of aircraft testing model implemented in SYMBAD software*

For the need of flight tests optimization, flight test programme model (MBL) has been defined as ordered three:

$$MBL = < S_o, S_t, S_i > \quad (1)$$

where: S_o—organization structure of flight test programme, S_t—technical structure of flight test programme, S_i—information structure of flight test programme.

2.1.1 *Organization structure of flight test programme*

Within the concept of organization FT programme the following ordered pair is defined:

$$S_o = <B, R_o> \quad (2)$$

where: B—set of tests, R_o—relation defining organization of FT programme.

The initial assumption is $B \neq \phi$, which means that set of flight tests cannot be empty because:

$$B = \left\{ b_i; i = \overline{1,I} \right\} \neq \phi$$

where: b_i—pointer (np. number) of flight test, I—cardinality of set B.

Reliances and dependencies direction between two flight tests in given FT programme are described by relations. Hence, relation R_o takes the following form:

$$R_0 \subseteq B \times B = \left\{ < b_i, b_j >; i \neq j; ij = \overline{1,I} \right\} \quad (3)$$

Relation R_o, which is transformation of flight test research set B into itself, defines organizational-dependency reliances between each flight test in FT programme. Mainly they are limited to Figure 5.

$$R_0 = \left\{ R_0^1, R_0^2, R_0^3 \right\}$$

where: R_0^1—relation of organizational dependency (test subordination), R_0^2—relation of organizational priority (prioritized test), R_0^3—relation of organizational equivalence (independent tests).

Formally, dependency (or priority) can be specified by order relations ($\prec$) described on two elements b_i,b_j

$$< b_i, b_j > \in R_0^1 \Rightarrow b_i \prec b_j \quad (4)$$

Relation (4) describes organizational dependency between test, that is, if test b_j is to be done, test b_i has to be completed prior to it. This means that test b_j cannot be carried out without completing test b_i, while equivalence relation (R_0^3) marks possibility of simultaneous test conduction.

2.1.2 *Technical structure of flight test programme*

Concept of technical flight test structure S_t is referred to total personnel and aircraft readiness concerning specified flight test $b_i \in B$.

Formally, technical flight test structure S_t is defined in the form of ordered three:

$$S_t = <P, SP, R_t> \quad (5)$$

where: $P = \{pk; k = \overline{1,K}\}$—personel set, $SP = \{sp_l; l = \overline{1,L}\}$—aircraft set, R_t—relations of aircraft personnel assigning them to specified aircrafts and FT programmes.

Set of personnel P and aircraft set SP is synonymous with sets of technical readiness $\{dgt\}$ which are describing readiness to carry out given test set, that is:

$$P \equiv \left\{ dgt_i; i = \overline{1,I} \right\} \wedge SP \equiv \left\{ dgt_j; j = \overline{1,J} \right\} \quad (6)$$

By the relation R_t elements of personnel set P and aircraft set SP are assigned to specified flight tests (or FT sets) $b_i \in B$, that is:

$$R_t = \subseteq B \times P \times SP = \left\{ < b_i, p_{ik}, sp_{il} >; i = \overline{1,I}, k = \overline{1,K}, l = \overline{1,L} \right\} \quad (7)$$

Ordered threes $<b_i, p_{ik}, sp_{il}>$ defined in that way consist of personnel and aircraft readiness to carry out any given FT sets. Hence, relation R_t defines subsets of personel and aircraft for each and every fight test:

$$R : B \times P \times SP \rightarrow \left\{ DGT_i; i = \overline{1,I} \right\} = \left\{ P_i \subseteq P; SP_i \subseteq SP; i = \overline{1,I} \right\} \quad (8)$$

where: DGT_i—set of personnel and aircraft assigned to specified flight test set.

2.1.3 *Information structure of flight test programme*

Within the concept of informational structure S_i of MBL model, data analysis and threats identification system is defined. Mainly it consist of:

$$S_i = <A, O> \quad (9)$$

where: A—data analysis and threats identification system, O—planned optimization and applied prevention system.

Main task of data analysis and threats identification system A is determining:

- faulty elements of FT system,
- flyable days in particular months,
- flyable hours in particular month days,
- the necessity to repeat the test because of either weather conditions or a failure to carry out the test,
- unreliability of measuring equipment,
- susceptibility of the aircraft to failure, necessity of fault clearing,
- unforeseen events,

In turn, tasks of planned optimization and applied prevention system include:

- determining time of carrying out single flight test, $b_i \in B$,
- introducing correspondent prevention $\beta_i \in \beta$,
- determining personnel work time,
- determining aircraft work time.

Information structure S_i supplies SYMBAD software with relevant input data, that is, having

specified time period $T_i \in T$ available (counted in days N, where $i = \overline{1,N}$) which is spent on carrying out FT, calculating pointer of FT intensification α is possible. Thanks to this pointer, real time of carrying out the FT (αt), measured in hours, can be estimated.

Hence

$$\alpha t = \sum_{i=1}^{i=N} \alpha_i t_i, \tag{10}$$

where: $t_i = t_m^d$—flyable days in particular day (d—day, m—month), $\alpha_i = k_i l_i$—k_i marks number of personnel (crew) while l_i is the pointer of flyable hours t_i usage.

For the need of article case with using one aircraft in FT was considered. If more aircraft is available for FT, their readiness and amount has to be included in calculations, which makes problem more complicated.

3 ADAPTATION OF ANN ALGORITHM IN MBL STRUCTURE OF SYMBAD SOFTWARE

According to the article (Wójcik, J, Kosiński, W. Zieja, M. 2013) expected value of uncompleted FT in amount of time takes the following form:

$$B(t) = \frac{\lambda}{\beta} \ln(1 + \beta\alpha t) \quad for\ \beta \geq 1, \tag{11}$$

where: α—flight tests (flights) intensity, t—time planned for competing the tests, λ—pointer of uncompleted tests, β—pointer of learning, effectiveness of prevention applied during tests.

In turn, general model of artificial neuron network takes Figure 5.

Problem of ANN neuron network functioning and creating as well as activation function alone has been covered in article (Wójcik, J, & Zieja, M. 2012, Kosiński, W. Wójcik, J, Warchulski, J. Zieja, M. 2012).

It is worth to remark that information structure S_i of model MBL determines time of FT $T_i \in T$ while organization structure S_o as well as technical structure S_t is responsible for pointer of FT completion failure and activation function. In addition, organization structure determines way of neuron construction in ANN. In turn, pointer $\beta_i \in \beta$ is determined in process of network learning.

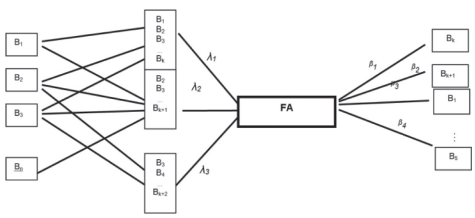

Figure 5. ANN Model.

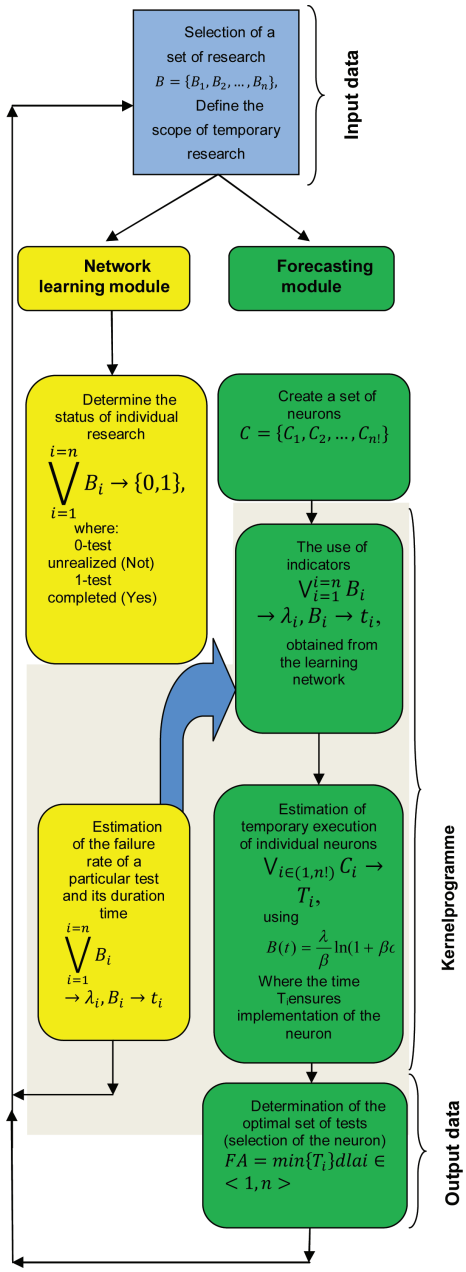

Figure 6. SYMBAD software algorithm.

4 GRAPHICAL INTERPRETATION OF THE MODEL

At the end, an example of MBL model usage for graphical imagining of processes occurring in SYMBAD software is presented. Algorithm presented below is described with details in article (Wójcik, J, Kosiński, W. Zieja, M. 2013).

5 CONCLUSION

Analysis of developed tests programmes and FT carried out according to them shows, that not always FT programme is completed totally according to assumptions. FT specification, complexity of test subject, participation of many teams, great variability of logistic insurance concepts and third conditions cause that big experience of project manager and collaborating teams as well as ability to foresee and estimate possible threats is required to estimate FT programme completion times.

Therefore, risk management in FT planning relies in great part on FT completion experience database. To meet requirements listed above, FT model (MBL) which corresponds with risk management in FT planning was presented in this article. MBL model enables to:

- identificate threats (S_i),
- estimate FT programme failure rate (S_l),
- develop FT programme (S_o),
- propose action that influence FT reliability (S_t),
- estimate time of FT programme completion (S_t,S_o),
- estimate place and year season influence on FT completion time (S_i).

As the next step ANN algorithm was adapted to MBL model (chapter 4,5). That enabled to extract in most transparent way each and every step of network's actions. Only ANN defined in that way was implemented in SYMBAD software. ANN is computing kernel of the software. Thanks to usage of MBL model and ANN, SYMBAD software has become tool that enforce FT developing.

Considering complexity of FT development and conduction process it is correct to make a statement that SYMBAD software alone will not exchange project manager (his rational way of thinking), however, it can be valuable assistance for him, foreseeing and estimating relevant pointers.

Model approach to problem of FT, adapted by MBL, enabled additional systemizing of FT completion experience database.

Further work on usage of ANN in MBL model will concentrate on detailed analysis of activation function which will be presented in next articles.

Developed programme is transparent and functional. It can be supporting tool not only for aircraft test planning but also for various technical objects tests planning, based on test conduction experience database.

Accelerated Life Test method for satellite electronic instrument

D. Shu, Z. Liang, Z. Zhiteng & M. Haibo
China Academy of Aerospace Standardization and Product Assurance, Beijing, China

ABSTRACT: This paper described the general process of Accelerated Life Test and its limits in use of satellite electronic instrument briefly; analysis several accelerated life test methods based on failure rate, empirical formula, accelerated degradation and transformation; proposes accelerated life test method based on activation energy estimate forecast, provided a new way for ALT of satellite electronic Instrument, and validated its applicability. Subject results promote the use of other satellite electronic instrument.

1 INTRODUCTION

For a spacecraft with high reliability and long life, electronic products reliability directly determines the life and reliability of the system. As the increase of satellite life and reliability index, higher requirements of life and reliability of satellite electronic products on project is also put forward. So how to evaluate and verify the life and reliability index is a problem that must be solved, and Accelerated Life Test (ALT) method can well solve the problem. The ALT method and assessment theory for electronic products on parts and subassembly level are relatively mature now and widely applied in engineering. But for an electronic unit, the ALT method and evaluation theory are not yet mature due to its complex in structure, diversity of failure mechanism and failure mode. Generally, only 1:1 life validation test or baseline test under accelerated stress is carried out. The role of accelerated life test on single devices cannot be replaced by the test on parts and subassembly, which is a new research direction of the accelerated life test technology. The study and application of the technology will be able to save a lot of research time, funds, manpower and material resources, having important engineering significance.

2 TRADITIONAL PROCESS OF ALT DESIGN AND EVALUATION AND ITS LIMITATIONS

2.1 *Traditional process of ALT design and evaluation*

According to the traditional design and evaluation process of ALT, the stress that affects the trial product most should be selected as accelerated stress. Then the acceleration model, product life distribution on this stress level, the accelerated stress level and distribution of tested samples can be determined and the test can be carried out. So product life data can be evaluated and product life can be obtained eventually. The details of traditional design and evaluation process of ALT are described in the following sections.

2.2 *The limitations of traditional methods in ALT design assessment of satellite unit*

The ALT experimental design mentioned in section 2.1 of traditional process is not applicable to satellite unit due to its characteristics which mainly include the following aspects:

1. The sample size is small
   The manufacturing process is complex and the cost is higher for satellite products, so the life test sample size is unlikely to be too large, especially for satellite unit. Sometimes only one product can be used for the life test. So it's hard to get the acceleration coefficient of products by the method of assessment.
2. Failure modes are diverse and failure mechanisms are complex
   The structure satellite unit is complex and its failure modes are diverse, and the corresponding failure reason is more complex. One of the premises of ALT is to ensure that the failure mechanism doesn't change and the accelerating model used for extrapolation is established based on the failure mechanism analysis. So the complexity of failure mechanism limits the application of ALT on satellite unit.
3. Failure data is difficult to obtain
   With continuous increase of satellite life, the designed life of the satellite products is also greatly increased. The time and money required to obtain failure data are very high, sometimes it is very difficult to accept even on the project. In traditional method, there must be sufficient

failure data for statistical analysis. So the obstacle for obtaining failure data is also one of the difficult points of ALT for satellite unit.

3 THE IDEA FOR ALT OF SATELLITE UNIT

There are several ideas in the study of ALT of satellite unit. The ideas are introduced here and their advantages and disadvantages are briefly analyzed.

3.1 *Failure rate ratio method*

According to GJB/Z299c-2006 "Electronic Equipment Reliability Prediction Handbook" and MIL-HDBK-217-F "Electronic Equipment Reliability Prediction", it can be seen that failure rate of components under different temperature is different. Through statistical calculations of all components failure rate, we can get product failure rate λ under different temperature T, also known as reliability prediction with stress method. With the increase of temperature, the product failure rate also will increase. As for the electronic products obeying index distribution, life characteristic (the reciprocal of failure rate, also known as average life) will be reduced accordingly.

The assumption is that the expected value of instrument failure rate is λ_0 under the using stress S_0 and the expected value of instrument failure rate is λ_i under the accelerated stress S_i. According to the characteristics of exponential distribution, the acceleration coefficient can be defined as:

$$A_i = \frac{L_0}{L_i} = \frac{\lambda_i}{\lambda_0} \tag{1}$$

where A_i is the acceleration coefficient, L_i the life characteristic under accelerated temperature stress, L_0 is the life characteristic under normal temperature stress, λ_i is the working failure rate under accelerated temperature stress; λ_0 is the working failure rate under normal temperature stress.

According to the above method, we can estimate the acceleration coefficient and carry out experiment design and evaluation. We should note that this method is based on the stress reliability prediction method. If the expected value cannot fully reflect the accelerated stress, the use of this method is restricted, such as multiple stress accelerated life test, etc. And for satellite unit, due to the complexity of its failure mechanism, failure rate ratio can only be as a reliability characterization of the product in different conditions but not as an accurate measure of life characteristic value, and there is no accurate theoretical basis.

3.2 *Empirical formula method*

This method is based on the empirical formula for the research of electronic products in USA. Namely the temperature raises every 10 °C, the double failure rate rises:

$$A_i = \frac{\lambda_i}{\lambda_0} = 2^{\left(\frac{T_i - T_0}{10}\right)} \tag{2}$$

where A_0 is the acceleration coefficient, T_i the acceleration temperature, T_0 is the normal temperature, λ_i is the working failure rate under accelerated temperature stress, λ_0 is the working failure rate under normal temperature stress.

This method can be used to estimate the acceleration coefficient and carry out experiment design and evaluation. Similar with failure rate ratio method, the theory of this method is not accurate, only as an experimental design reference value of the acceleration coefficient, and can only be used when the temperature is a single accelerated stress.

3.3 *Degradation fitting method*

For space instruments, the accelerated degradation test method is good ways to solve the difficulty of obtain the failure data. There are many literatures about accelerated degradation test and there are two problems we should pay attention to:

1. The degradation trends must be accurately obtained. This method can be only used for space instrument that its key performance parameters is obtained conveniently and has obvious degradation trends. The performance degradation of life for the instruments commonly used on the satellite at present, such as interfering closed loop fiber optic gyro, secondary power, PVC and PCU, cannot be measured generally because of closed loop feedback. So degradation test method is not suitable for these products.
2. The performance degradation component caused by accelerated stress must be decoupled from the measured data. The key performance parameters of instrument are often affected by many factors because of the complexity of its failure mechanism. How to decouple and fit the performance degradation caused by accelerated stress is one of the guarantees for implementing accelerated degradation test successfully.

3.4 *Transformation method*

The basic idea of transformation method is according to the principle of bucket. The life of any kind of product depends on the life of its component that easily becomes invalid. No matter how

superior the performance of important parts and design on the product is, if the failure of any spare parts or components that affect product performance occurs, the product's life comes to an end. So the product life depends on the reliable life of its weak parts. Therefore, the ALT of the product is converted into ALT of its parts or components after the weak points are found out.

Usually, the methods to find out the weak points of the instrument are as follows:

- Similar products analysis
- Statistical analysis to determine weak points from the using information
- Pareto diagram method
- Failure tree analysis method
- Failure Mode, Effects and Criticality Analysis (FMECA) method.

It is worth to notice that the weakness of satellite unit is often affected by the complex natural and induced environment. Because of the complexity of electrical and thermal stress, it's a large risk to replace the unit's ALT with weak components' ALT.

3.5 *Summary*

Four kinds of ALT methods of instrument are introduced in this section and have their own advantages and disadvantages. A new ALT design method based on reverse deduction of activation energy will be put forward in the following representation. Then combined with a certain type satellite control system PVC, the design and evaluation methods are introduced.

4 ALT DESIGN AND EVALUATION METHODS BASED ON THE ESTIMATION OF ACTIVATION ENERGY

The core of ALT is to find the life characteristic relationship of products between normal and accelerated stress. That is to describe the relationship between the two life characteristics with acceleration model and obtain the estimating parameters of the model through the evaluation data. In this chapter, the acceleration coefficient under different stress is got through analysis of product weaknesses and estimation of activation energy, as the basis of experiment design and data extrapolation.

4.1 *Establishment of model*

According to different stress, the acceleration model should be different. For electronic products, generally high temperature is chosen as the accelerated stress and Arrhenius model is selected as the acceleration model. Arrhenius model expression as follows:

$$L(T) = Be^{\frac{E_a}{KT}} \tag{3}$$

where L is the life characteristics, T is the absolute temperature; K is the Boltzmann constant, E_a is the activation energy, B is the undetermined coefficient.

Then the acceleration coefficient under the using temperature T_i as opposed to temperature T_0 is:

$$A_i = e^{\frac{E_a}{K}\left[\frac{1}{T_0}-\frac{1}{T_i}\right]} \tag{4}$$

where T_0 is the using environment temperature, T_i is the acceleration temperature, A_i is the acceleration coefficient.

4.2 *Activation energy determination of key components*

The unknown parameter E_a in formula 4.1 is activation energy that an atom on the crystal lattice to move to another lattice or clearance position need. For products, there is barrier in the process of transformation from normal state to failure state. The barrier is just the activation energy. The smaller the activation energy is, the easier the physical failure process becomes. If the activation energy is large, the acceleration coefficient becomes larger, then the failure speed is accelerated and failure happens. For certain types of products, activation energy is the physical significance of a fixed value. The activation reference value of main failure mechanism for some components is given by standard of the USA and Europe Aviation Bureau, and listed in Table 1.

Table 1. The typical activation energy given by ECS-Q-30-1 (2002).

Products	Type	Activation energy (eV)
Semiconductor	Gallium arsenide	1.4
	Silicon	1.1
Resistance	Metal film resistor	1.35
	Carbon resistor	1
	Winding resistor	1
Capacitor	Ceramic capacitor	1.67
	Glass film, mica capacitor	1.1
	Plastic film capacitor	3.4
	Tantalum capacitor	0.34

*In addition to the above table, activation energy of failure mechanism for silicon semiconductor is given by MIL-HDBK-338.

The activation energy in the table above is obtained from statistical analysis of test data after a large number of samples. But for aerospace electronic products, because of the lack of history test information, the unknown parameters in the acceleration model is often difficult to obtain by assessment especially for the lack of 1:1 life test failure data, making it difficult to obtain aerospace electronics acceleration life. The following methods can solve this problem to some extent.

4.3 *Solving the acceleration coefficient*

When estimating acceleration coefficient, failure rate ratio method tends to be more conservative and the computing process is also more complex because of the inclusion of all components' failure rate. According to formula (4), acceleration factor can be determined if the acceleration energy of the product is known. In the case of difficult to get the activation energy of the product, the activation energy of key or weak components can be used to replace it. The experimental design can be done after the calculation of acceleration coefficient. Then combined with the test results, the test can be evaluated and the effectiveness of the test can be verified.

The selection of activation energy should be determined comprehensively by FMEA, thermal analysis and reliability prediction of the product. Generally the largest inherent failure rate activation energy of the component is the priority. And the activation energy of key or weak components can be used to replace the product activation energy according to the engineering experience.

4.4 *Reverse deduction of test time*

To meet the needs of product reliability test, the accumulative test time which is used to check the reliability index R_L can be deduced:

$$R_L = \exp\left\{-\frac{t\chi_\gamma^2(2r+2)}{2T^*}\right\} \tag{5}$$

where R_L is the reliability lower limit, the equivalent accumulative test time, r is the correlation failure number, γ is the confidence, according to the requirement of the reliability of the product, t is the life index requirements.

If the T^* is got, then the experimental time can be deduced under the accelerated stress through the acceleration factor obtained above, and the test should be designed.

$$T^* = \sum_i t_i n_i A_i + \sum_j t_j n_j k_j \tag{6}$$

where T^* is the accumulative test time, t_i is the accelerated life test time, n_i is the sample size of accelerated life test, A_i is the acceleration coefficient, t_j is the on-orbit and history test time, n_j is the sample size of on-orbit and history test, k_j is the environmental factors.

4.5 *ALT of a certain electronic satellite unit*

PVC product is a voltage conversion component specially developed for control and propulsion system. It supplies power for the control and propulsion systems, such as the central control unite, gyro, momentum wheel, SADA, earth sensor, sun sensor, promoting power amplifier, etc. It is a certain type of key instrument directly related to the normal working of a certain satellite platform. Because of its high life and reliability requirement, the conventional test methods are not suitable for it. ALT of the PVC mainly including the following several aspects:

(1) Determine key and weak points of the product and estimate the activation energy of the machine, according to which to conclude the acceleration coefficient under different stress; (2) Estimate the test time required for verifying the life and reliability index. Then through analysis with the conventional life test and on-orbit data, the validity of the test and the correctness of the method can be verified; (3) Through estimated test time and combined with the engineering practice, the stress level and the cut-off time of the experiment can be finally determined; (4) Implement the test. Then process the test data to judge whether there are degradation trends and combine with other data to do the assessment; (5) Determine the activation energy by the test results, and the validity of the test results can be verified by the reverse deduction of the activation energy.

The life index of the product is verified by experiment. Reliability index under different working mode is presented by assessment, providing the basis for subsequent products. The good results are recognized by the product development personnel and experts in the industry.

5 CONCLUSIONS

The conclusions of this paper are as follows:

1. When the sample size, test time and many other conditions are limited, using the activation energy of key components to replace the one of electronic instruments to design and evaluate the test is feasible.
2. Because the determination of experimental time is very sensitive to the choosing of activation energy in the design of experiment, how to reasonably determine the activation energy

is the key part in the process of experimental design.

3. In this paper, the ALT methods of instruments satisfy the long life and high reliability requirement of aerospace electronic product assessment project in a certain extent, and can be applied in other aerospace electronic, electromechanical and photoelectric products.

At present, the above method has been applied to a variety of accelerated life tests on electronic product design, implementation and data assessment, having excellent application prospect.

ACKNOWLEDGMENT

The research described in this paper was carried out by the China Academy of Aerospace Standardization and Product Assurance.

What is need to be emphasized is that the accelerated life test method discussed in this paper has got good achievement in a certain type of satellite device developed by China Academy of Space Technology. For security reasons, public discussion of test data is prohibited here.

Reliability of the airlines operations system

A. Słodownik & J. Żurek
Air Force Institute of Technology, OH, USA

ABSTRACT: Liberalization of European air transportation market resulted in more competitive airlines business environment and intensified airlines efforts to improve effectiveness of schedule performance. The problem of effectiveness of flights schedule performance has become more important in light of introduction of limits on free of charge aviation emissions and announced introduction of airlines financial responsibility to passengers for flights delays.

Airlines perform flights within the frame of their operational systems in close cooperation with air traffic management system. The key factor influencing effectiveness of performing flights is access to air space in accordance with offered schedule timing and possibility of flights realization at minimum fuel cost. In real conditions of constrained capacity and disturbed air space it is not possible to provide optimum access to air space for all space users what results in flights delays and higher fuel consumption, what in turn negatively impacts airlines profitability. In order to objectively assess the quality of access to air space one should compare total costs of flight realization incurred by airlines against optimum flight realization cost. This kind of analysis lays the ground for valuation of air traffic management system performance. In general the value of air traffic management system performance is manifested in its relationship to the airlines main product—the flight schedule. Measuring the value of air traffic management system performance should therefore be related to how the air traffic management system impacts the airlines' ability to plan and operate their schedules. This is the issue of reliability cost of the airlines operational system. To be competitive the airlines should maintain equilibrium of operational reliability and cost. In general airlines calculate their flight operations cost as a sum of direct operation cost and cost of delays. Direct operating cost is the sum of fuel cost and time related cost and is dependent on quality of access to air space managed by air traffic management system. Delay cost in turn is the sum of additional direct operation cost and market cost calculated as potentially lost revenue. The analysis of potentially lost revenue can be based on the models of decision choice, where schedule unreliability is modeled as a loss of utility of the airlines product. For the purpose of airlines schedule reliability cost analysis the problem should be analyzed as total cost of access to air space including additional costs of adjustment of the flight timing imposed by air traffic control. Currently applied measures are based on high level Key Performance Indicators (KPI) and their application for more detailed analysis is limited. In this paper authors propose more specific category of schedule reliability cost measure based on the concept of division of reliability states space into four categories of states depending on cost effectiveness of punctual (against flight plan) flight realization. The measure of cost effectiveness of reliable flight realization is based on the known concept of cost index but interpreted as a function of marginal cost of aircraft ground speed. Proposed measure of reliability cost is also the measure of such categories of flight operations reliability measures like equity of airlines access to the air space and effectiveness of flight planning.

1 CURRENT STATE OF TAXONOMY OF FLIGHT OPERATIONS PERFORMANCE METRICS

Under general concept of System Effectiveness (SE), the System Effectiveness is defined as:

$$\mathrm{SE} = O_R * R_M * D_A \tag{1}$$

In equation (1) operational readiness, O_R is the probability that the system is either available at beginning of the mission or can be brought to an operationally ready state by the beginning of the mission within a prescribed period of time. The probability that having started the mission successfully, system will complete the mission without failure is mission reliability, R_M. The probability that having completed the mission the system has performed successfully all of its required mission objectives and required end results is design adequacy, D_A. Following definition of System Effectiveness (SE), the effectiveness of flight realization can be modeled as a realization of transportation cycles. Operational readiness O_R of the

transportation cycle is the probability of the completion of the aircraft ground service cycle until scheduled time of departure. Mission reliability is the probability of punctual realization of scheduled flight, but design adequacy is the probability of the assignment of the aircraft of sufficient capacity (sufficient number of passenger seats) to accommodate demand for the flight.

Under current taxonomy of reliability of flight operations metrics, the following basic measures are in use by airlines: distribution of arrival delays, distribution of departure delays, distribution of block times (from departure from airport departure gate to time of arrival at arrival airport gate), distribution of load factors (percentage of used passenger seats). Airports monitor following productivity measures: departing and arriving passenger and cargo traffic by time of the day, day of the week, months and calendar year, departing and arriving aircraft by aircraft type and time of operations (departure, arrival, ramp handling timing). With known distribution of the flight operations times, the reliability of realization of transportation cycle can be modeled as a consecutive realization of basic transportation cycles composed of two phases of the cycle, the ground service phase followed by flight realization phase. Reliability of realization of the phase of transportation cycle is defined as:

$$R = P[X'' \le t'' \mid X' \le t'] \tag{2}$$

$$R = \frac{1}{H(t)} \int_{-\infty}^{t''} F(t'' - s, s) * \quad h(s) ds \tag{3}$$

where: X''—random moment of the completion of realization of the phase; t''—scheduled time of the completion of realization of the phase; X'—random moment of the beginning of realization of the phase; t'—scheduled time of the beginning of realization of the phase; $H(t)$ id the CDF of the random moment of beginning of the phase; $h(s)$ is the PDF of random moment of beginning of the phase; $F(\cdot)$ is the CDF of the time of realization of the phase. The model of airline operation cycle is being applied for stochastic optimization of time buffers in airline schedules for improvement of robustness of planned schedules. Reliability of realization of transportation tasks can be analyzed from different perspectives, the airlines perspective, the Air Traffic Control (ATC) system perspective, the airports perspective and passengers and air cargo markets perspectives.

Taking into consideration the dependence of airline flight operation on air traffic management system the Air Traffic Services Performance Focus Group of FAA identified the following attributes of flight operations performance: Capacity—potential throughput that can be achieved under a given set of conditions; Delay—difference between actual flight time and baselined optimum times; Access—users ability to utilize system resources and services; Predictability—ability to forecast system behavior and to meet a commitment; Flexibility—ability of the system to permit users to adapt their operations to changing conditions; Efficiency—a percent measure of how close an operational parameter is close to a given "optimal" value (System Efficiency, User Efficiency, Resource Efficiency). With reference to given attributes of system performance, several detailed measures have been identified: Capacity—System Level Capacity, Airport Level Capacity, Airspace Volume Capacity, Diversions by Course; Delay—Delay by Phase of Flight, General Delay, Delay by Course; Access—Approvals, % of requests approved for user preferred flight plan by Communication, Navigation, Surveillance Services; Predictability—Variability of delay (for delays by phase of flight), Standard Deviation of absolute difference between forecast and actual delay; Flexibility—Alternatives—an average number of alternative flight plans offered in response to flight plan request; Approvals for deviations (% of approvals related to flight plan changes; max. allowable deviation from approved flight plan); total number of restrictions in route, altitude, speed, heading per volume of aerospace); Efficiency—Time (% of departure within x minutes of standard departure time); Altitude (% of difference between user requested (optimal) and system imposed changes); Speed (% of difference between user requested (optimal) and system imposed changes); Distance (% of difference between user requested (optimal) and system imposed changes.

According to Eurocontrol rules, the performance of European air traffic control system is monitored by following performance/safety categories: Traffic, Safety, Capacity, Environment and Cost. The key performance indicators per performance category are defined as following: Traffic: Number of IFR flights in European airspace per year; Safety: Number of accidence including accidences with Air Navigation System (ANS) contribution; Capacity: Average en-route Air Traffic Flow Management (ATFM) delays per flight; Environment: Horizontal en-route flight efficiency measured by percentage of trajectories flown not in conformance with planned trajectories;

From system effectiveness perspective, the reliability of the timely schedule realization represents only one dimension of the system effectiveness. The second dimension is economy of realization of air transportation tasks. Both dimensions are interdependent. Currently, the flight operation costs are measured at high level of aggregation. Air Traffic

Management System costs are measured as an en-route real cost per Service Unit (SU*); Service unit is related to Maximum Take-Off Weight of the aircraft (MTOW) and is defined as:

$$\text{Weight Coefficient} = (\text{MTOW})^{0,7} \tag{4}$$

$$\text{TSU} = \sum_{\text{Number of flights}} (\text{Weight Coefficient}) \tag{5}$$

where TSU is total service units. Current system of charges for ATC services in based on the concept of service units SU (charges for overflying of the airspace) and terminal service units TSU for services provided in the terminal airspace.

Airlines calculate aggregated direct operation cost per unit of aircraft productivity (one passenger seat flown per distance of 1 mile (or 1 kilometer). For each flight airlines forecast direct operating cost based on statistic weather forecast data and related statistic optimum flight levels (tables of statistic of available loads).

In general, the contemporary level of measurement of flight operation performance can be described as a statistical description of the air traffic and timing of flights realizations. There are no in-depth absolute measures of flight operations reliability costs. The problem lies in high level of complex interactions between all factors involved in flights realizations and random nature of operations environment. Therefore in search for industry accepted metrics of flight reliability and related costs, the contemporary research is oriented on comparative analysis of performance trends. Based on such analysis the industry is developing methods of compensation for air traffic management system related inefficiencies. It seems to be the only way to improve the methodology of calculation of charges for air space usage based on real airlines flight operations costs.

2 PROPOSED APPROACH TO RELIABILITY COSTS

In the controlled airspace, aircraft perform flights on the basis of optimal flight plans filled before the flight and corrected according to changes in the air traffic. Flights are performed along available optimum trajectories and at the speed resulting from the timing of flight realization imposed by air traffic control. At every moment of cruising phase, the state of the flight is defined as a vector $s(t)$:

$$\overline{s(t)} = \left\{ \begin{matrix} GW(t), \overline{k(t)}, P(t), H(t), T(t), \\ M(t), W_f(t), \overline{V_{GR}}(t) \end{matrix} \right\} \tag{6}$$

where: $GW(t)$—aircraft weight; $\overline{k(t)}$—coordinates of the aircraft position; $H(t)$—altitude; $T(t)$—air temperature; $M(t)$—Mach number; W_f—fuel flow; $\overline{V_{GR}}$—ground speed. For each aircraft type and each state of the flight the corresponding fuel efficiency performance of the aircraft is defined as a specific range S_R defined as a distance flown by the aircraft from one unit of consumed (burned) fuel:

$$S_{R(CORR)} = \frac{V_{GR}}{W_f} \tag{7}$$

where $S_{R(CORR)}$ is specific range corrected for wind (in still air $S_{R(CORR)} = S_R$). Given the term (definition) of the scheduled flight time cost (c_t), the direct operating cost of the scheduled flight (sdoc) of the flight lasted T time units is defined as:

$$\text{sdoc} = c_t * T + c_f * F \tag{8}$$

where: c_t—cost of the unit of the flight time; c_f—cost of the unit of the fuel; T—flight time; F—total fuel used.

$$\text{sdoc} = c_t * T + c_f * F = c_t * \left(\frac{R}{V_{gr}} \right) + c_f * \left(\frac{R}{S_{R(CORR)}} \right) = c_t * \left(\frac{R}{a \times M + V_w} \right) + c_f * \left(\frac{R}{S_{R(CORR)}} \right) \tag{9}$$

where: R—range (distance flown); a—speed of sound; M—Mach number; V_w—wind speed. Given the definition of the Operation Reliability Cost Function (ORCF) as a direct operating cost (doc) of scheduled (punctual) realization of the flight per unit of distance flown and definition of the Reliability Cost Index (RCI) as a ratio of the time cost (c_t) to fuel cost (c_f), the RCI and ORCFCF are defined as:

$$\text{RCI} = \frac{c_t}{c_f} \tag{10}$$

$$\text{ORCF} = \frac{doc}{R} = c_t \left(\text{RCI} \frac{1}{a \times M + V_w} \right) + c_f \left(\frac{1}{S_{R(CORR)}} \right) \tag{11}$$

For the given state of the flight realization $s(t)$, parameterized by gross weight of the aircraft, altitude and atmospheric conditions there is Mach number corresponding to maximum range of aircraft—the maximum distance flown from the unit of fuel. This Mach number is defined as M_{LRC} and corresponds to long range cruise state of the flight. From perspective of flight economy, the realization of the flight at the M_{LRC} Mach number,

is the most fuel cost effective (fuel efficient) flight realization. However the possibility of the flight realization at M_{LRC} is dependent on approval by Air Traffic Control (ATC) of the availability of optimal access to airspace at the flight timing corresponding to flying at M_{LRC} Mach number. In general the ATC system imposed speed (and resulting flight timing) is the result of the analysis of availability of the airspace capacity at forecasted time of arrival at arrival airport terminal zone. The cost of fuel required to increase speed from maximum range cruise Mach number (M_{LRC}) to ATC system imposed speed is equal to the cost of flight time reduction resulting from increasing speed from maximum range cruise speed to required speed. This cost can be interpreted as a marginal cost of the cruising speed (MC) and are defined as:

$$\mathrm{MC} = \frac{\partial ORCF}{\partial M} \tag{12}$$

The minimum of the Operation Reliability Cost Function (ORCF) and related Mach number can be computed from the following equation:

$$\frac{\partial ORCF}{\partial M} = 0 \tag{13}$$

The Operation Reliability Cost Function (ORCF) is the sum of flight time cost and fuel cost. Based on definition of Reliability Cost Index, the flight time cost can be interpreted as additional fuel cost to complete the cruising phase of the flight within time T. If the flight realization at M_{LRC} Mach number corresponds to ATC approved flight timing, the time cost and RCI are equal to zero. Therefore the time cost can be interpreted as an additional cost expressed in cost of the additional fuel required to complete the flight in conformance with the ATC requested flight timing. So the RCI is the indicator of the marginal cost of the cruise speed. For each moment of the realization of the flight at system's imposed speed and for the known cost of the fuel there is corresponding Reliability Cost Index RCI (t) which can be interpreted as an indicator of current reliability cost of flight realization. The indicator of reliability cost of the whole flight, the Flight Reliability Cost Index (FRCI) is defined as:

$$\mathrm{FRCI} = \frac{1}{t''_{crs} - t'_{crs}} \int_{t'_{crs}}^{t''_{crs}} \mathrm{RCI}(t)dt \tag{14}$$

where t'_{crs}—moment of the beginning of the cruise phase of the flight; t''_{crs}—moment of the completion of the cruise phase of the flight. Based on the definition of FRCI, one can propose the measure of effectiveness of the ATC system as two parametric Key Performance Indicator (KPI) of the effectiveness of flight realization. Let's define two random variables X and Y corresponding to different categories of the effectiveness of flight realization as following:

$$X = \begin{cases} 1 & \text{for } FRCI_R \le FRCI_P \\ 0 & \text{for } FRCI_R > FRCI_P \end{cases}$$
$$Y = \begin{cases} 1 & \text{for } T'' \le t'' \\ 0 & \text{for } T'' > t'' \end{cases} \tag{15}$$

where: T''—actual time of arrival; t''—planned time of arrival. Let's define four sets of states S_{11}, S_{10}, S_{01}, S_{00} corresponding to different categories of effectiveness of flight realization:

$$\begin{aligned} &S_{11}\text{—}\textit{Set of Intentional Stated};\ P_{11} = P\{X = 1, Y = 1\} \\ &S_{10}\text{—}\textit{Set of Disturbed States};\ P_{10} = P\{X = 1, Y = 0\} \\ &S_{01}\text{—}\textit{Set of Disturbed States};\ P_{01} = P\{X = 0, Y = 1\} \\ &S_{00}\text{—}\textit{Set of Disturbed States};\ P_{00} = P\{X = 0, Y = 0\} \end{aligned} \tag{16}$$

where, P_{11}, P_{10}, P_{01}, P_{00} are probabilities of the defined states. State S_{11} is intentional state or state of intentional flight realization. State S_{10} is the state of delayed flight realization but without additional fuel cost. State S_{01} is the state of punctual flight realization (against flight plan timing) but at additional fuel cost. State S_{00} is the state of total inefficiency characterized by delayed flight realization and higher (against flight plan) fuel consumption at cruising phase of the flight. Probabilities of defined states are proposed Key Performance Indicators of the effectiveness of airline's realization of the scheduled flights in controlled airspace. They are also measures of the quality of the information provided by Air Traffic Control system (ATC). The advantage of the proposed methodology of measurement of airlines operation reliability over current statistical measures is in assumption of the aircraft performance characteristic as a reference base for assessment of quality of flight planning and air traffic management services manifested in adjustment of flight plan during the flight realization according to current flights movements in controlled airspace. Under this methodology one can take into account fuel cost used for adjustment of aircraft movement to ATC system's requirements. This assumption allows for better assessment of the results of the complex interdependencies of the airline, Air Traffic Control (ATC) system and airports (as points in the process of schedule realization).

Quantitative evaluation on storage reliability of pyrotechnics based on thermodynamic characteristic of dynamite and performance degradation data

Zhao Wan, Wu Hang & Cheng Hai Long
China Academy of Aerospace Standardization and Product Assurance, Beijing, China

ABSTRACT: Aiming at the deficiency of the traditional storage reliability evaluation method in dealing with zero-failure data, a method was proposed based on the performance degradation data. By analyzing the thermodynamic characteristic of dynamite and the failure physical model of pyrotechnics, the relationship of reliability and the performance degradation quantity was established, and then the storage reliability evaluation for pyrotechnics could be evaluated. An example was given about how to practice finally. The validity and applicability was validated. This method puts forward a new idea for storage reliability evaluation of pyrotechnics and other analogous products.

1 INTRODUCTION

Pyrotechnics is widely used in kinds of spacecraft, and it is a kind of high reliability and long storage life of one-shot product. It is difficult to obtain the storage failure data in a short term, traditional method based on failure data can't meet the requirements of its storage reliability evaluation.

The storage failure of pyrotechnics is often caused by several kinds of failure mechanisms, and multiple degradation processes occurs at the same time. The degradation reaction rate depends on the fastest process. Generally speaking, Storage reliability of pyrotechnics depends on three aspects:

1. The storage properties of pyrotechnics, such as thermal stability, hygroscopicity;
2. The structure of pyrotechnics, such as airproof quality;
3. The external environment, such as temperature, humidity conditions.

It has been shown that among the above three aspects, the thermodynamic characteristics of pyrotechnics is the immanent cause that determines the storage reliability, and environmental temperature and humidity are important external factors influencing storage reliability. At present, humidity is controlled strictly during the design, production, storage period, and the structure has a good airproof performance. In this case, the change of environmental temperature is the main factor which can cause the gradual degradation of thermodynamic characteristic of dynamite. Final failure occurs when the degradation develops to a certain extent.

According to the engineering experience, the sensitive parameters of pyrotechnics are the most critical parameters which can reflects its performance change. The poor sensitive parameter expresses the poor performance of pyrotechnics. Therefore, the relationship between reliability and storage time can be established through the analysis of the trend of sensitive parameters change. Accelerated storage life test is a way to get storage performance degradation data. This paper presents a method to establish the quantitative relationship between reliability and storage time by analyzing the temperature stress accelerated storage life test data for example. This method puts forward a new idea for storage reliability evaluation of pyrotechnics and other analogous products.

2 CHOOSING THE SENSITIVE PARAMETERS OF PYROTECHNICS

In order to determine the failure degradation of pyrotechnics in the storage process, the sensitive parameters is chosen as degradation parameters. A certain pyrotechnics has two sensitive parameters at most, usually one. When the sensitive parameters can't meet the design requirement, the degradation failure occurs. Thus the sensitive parameters must have following properties:

1. They can be precisely defined and monitored;
2. They have significant time-degradation trend in long-time work or test.

For example, the average ignition sensitivity, reaction time of electric detonator, the ignition

pressure of igniter and the separation impulse of explosive bolt.

These parameters objectively reflect the working status of pyrotechnics.

3 DEMONSTRATION OF QUANTITATIVE EVALUATION METHOD

Assuming that a certain explosive bolts conducted accelerated storage life test under three temperature stress as 60°C, 71°C, 80°C, and Arrhenius model was chosen as the accelerated model. Samples and detecting time in the test process was shown in Table 1.

Assuming that its reliability requirements was $R_L = 0.99$ ($r = 0.95$), and its sensitive parameter was separation impulse ($m_L v$, the impulse generated by bolt body when separated). Zero-failure data was achieved in three stress level. It was difficult to solve the storage reliability evaluation problem by traditional method based on failure data analysis. If the separation impulse test data appeared obvious degradation trend along with prolonged test time, then it was able to assess the storage reliability by analysis on the degradation trend of its separation impulse.

3.1 *Reliability model*

Explosive bolt achieves the separation function mainly by using the force of the explosion which can make the bolt body to break off. When the explosion pressure is increased to certain strength, explosive bolt is divided into two bodies. Assumed that the explosion force of dynamite and bearing capacity of structure are two random variables, the product separation reliability can be expressed as the probability of explosion force exceeds bearing capacity of structure, and the expression is:

$$R = P(E_{explosion} > E_{bearing}) \tag{1}$$

Reference to the stress-strength model in mechanical field, the reliability model of explosive bolt can be established as follows:

$$R = \Phi\left(\frac{K-1}{\sqrt{C_{VL}^2 \cdot K^2 + C_{VS}^2}}\right) \tag{2}$$

where:

C_{VL}—variation coefficient of explosion force;
C_{VS}—variation coefficient of bearing capacity;
K—Margin, $K=E_{\text{explosion}}/E_{\text{bearing}}$

Table 1. Sample size and time for explosive blot accelerated storage life test.

T/°C	No. of explosive bolts	Group	No. of experiment	Detecting time/d
60	30	1	10	36
		2	10	57
		3	10	71
		4	8	85
71	30	1	10	14
		2	10	22
		3	10	28
		4	8	35
80	24	1	10	13
		2	10	15
		3	10	20

3.2 *Determination of the model parameters*

3.2.1 *Determination of K*

Assumed that the dynamite combustion product obey the ideal gas equation:

$$pV = m_D f \tag{3}$$

where:

p—Pressure generated by combustion or explosion of dynamite, $N \cdot m^{-2}$
V—capacity of vessel, m^3
m_D—main charge mass of explosive bolts, mg
f—dynamite characteristics, energy produced by per unit mass of dynamite, $N \cdot m \cdot kg^{-1}$

When the structure design is finalized and the dynamite is selected, the explosion force is proportional to the dynamite mass. As the working time is nearly instantaneous, this research ignored the heat loss and the tiny change of the chamber volume as working, which means that the explosion energy has been used in two aspects; one is to separate the bolt body, the other is to produce kinetic energy when bolt body flies out.

Assuming that

- m_M is the critical dynamite charge mass, mg, the charge mass which just makes the explosive bolt to separate;
- m_L is the mass of the bolt head, mg
- v is the average speed of the bolt head flying out when the explosive bolt separates, m/s

Then, according to the working principle of the explosive bolt, its output energy meets the relationship below:

$$m_D RT = E_{explosion} = \frac{1}{2} m_L v^2 + E_{bearing} = \frac{1}{2} m_L v^2 + m_M RT \tag{4}$$

That is:

$$K = \frac{E_{explosion}}{E_{bearing}} = \frac{m_D f}{m_M f} = \frac{m_D}{m_M} = \frac{\frac{1}{2} m_L v^2}{E_{bearing}} + 1 \qquad (5)$$

After storage, the dynamite characteristics f changed, then induced the explosive force changed. According to the formula (7), as the bearing capacity unchanged, the dynamite characteristics change inevitably caused the speed change of the bolt head flying out. That's to say, the separation impulse changed. Kinetic energy 1/2 $m_L v^2$ can be calculated by detect the separation impulse $m_L v$. Then the margin K can be achieved.

3.2.2 *Determination of variation coefficient*

According to the above analysis, variation coefficient of explosion force C_{VL} can be expressed by the variation coefficient of Kinetic energy. The tensile strength of the material and the section diameter of the bolt body are the main factors which can influence the bearing capacity. But the design of these factors is aiming to meet the connection function, and it has been determined before the separation reliability design, and these factors change so little in the process of storage that can be neglected. Then the variation coefficient of bearing capacity C_{VS} can be considered constant and it can be calculated by the acceptance test data.

3.3 *Reliability calculation based on performance degradation data*

Assuming that $f = 11.63 \times 10^5 N \cdot m/kg$, $m_D = 480$ mg, m_M = 255 mg, then margin before storage is K = 1.8824 and the variation coefficient C_{VS} = 0.1149. According to calculation method above C_{VL}, K and R before and after storage can be calculated under the triple temperature levels.

According to the design requirements of this explosive bolt reliability and the above calculated results, the time when the reliability down to less than 0.999 marked the failure time under each temperature level with the analysis tool MATLAB. The results are as follows:

$T_1 = 60°C$, $t_{failure} = 80d$;
$T_1 = 71°C$, $t_{failure} = 31d$;
$T_1 = 80°C$, $t_{failure} = 15d$;

According to the acceleration model, it can be obtained:

$E_a = 81.77124\ kj \cdot mol^{-1}$
$t = 4013.804\ d \approx 10$a

The explosive bolt approximately has 10 years storage life in which it can meet the reliability requirement of 0.999. According to Table 2 and computing results above, two parameter exponential fitting curve (R^2 = 0.9708) of relationship between the reliability and storage time at normal temperature can be achieved as shown in Figure 1.

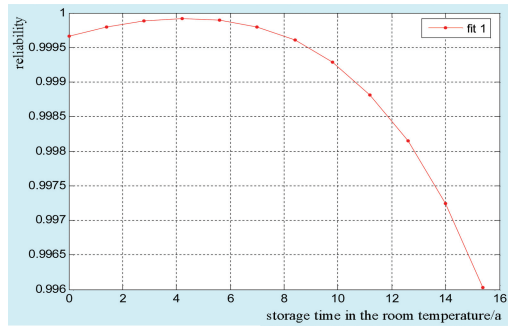

Figure 1. Reliability curve of explosive blot at normal temperature.

4 ANALYSIS AND CONCLUSIONS

Through the above research and analysis, this paper draws the following conclusions and suggestions:

1. As for the pyrotechnics sensitive to temperature, the quantitative relationship between reliability and storage life can be established. This paper presented the method and demonstrated it by a specific example.
2. The earlier storage period is a gradual mixing, homogeneous process for dynamite, and its performances won't appear obvious degradation within a short period of time (such as less than 4 years) usually but a certain improvement. However, with increasing of storage temperature and prolonged storage time, the molecules number and its vibration amplitude and frequency continually increase, which can increase the fracture probability of the weakest pharmaceutical molecules, then the dynamite chemical decomposition gradually accelerate which can cause the obvious degradation of sensitive parameters.
3. The more samples and detection points, the higher credible degrees of the calculation results. All the dear readers are advised to perform further application verification and improvement to this method in the follow-up test and study.

Telematics used in the campaigns machinery safety management systems

J. Napiórkowski, P. Szczyglak & K. Kołakowski
University of Warmia and Mazury, Olsztyn, Poland

ABSTRACT: The manuscript used in the campaigns machines management supporting systems analyzed. The types of demonstrated systems in the direction of productivity and quality of worker process growth, and service maintenance supporting are developed. Despite the many advantages they support user safety in a small extent. For this reason, the authors, four concepts of existing supervising work processes extensions present. These include: the concept of the machine exploitation permissions and the operator daily work time supervising system, the field emergency call system, the agricultural machinery rotating components limited access, and field collision courses correction system.

1 INTRODUCTION

The main technical objects used in the campaigns are the agricultural machineries. The reliability and safety of these machines evolution takes place at the all stages of its existence, instead especially during their exploitation. This type of machines are characterized by a short period of use in relation to the storage period, and the work processes execution under varying field and weather conditions, biological materials with variable, dependent from time, physical and chemical properties, and persons do not have a proper general education accessibility. Therefore, they have to fuel feel the strict of realized quality and safety process requirements.

There are many emergency in the agricultural sector every year. In Poland, only in 2013, the number of 23 374 emergency to the Regional Offices and Local Insurance Institutions were reported. 11.8% of all cases were accidents which by the hit or grab by the moving machinery elements occurred. In Poland, in 2013, the number of 77 fatal accidents were reported (OPR. 2013). In many cases, in addition to bodily injury or death during an accident, related to the machinery and the plantation destruction considerable material losses occurs. The main reasons of the accidents with the agricultural machines are: the inadequate machine technical condition, not in accordance with applicable regulations maintenance performing, unauthorized and noncompliance with the operator work time. For this reasons it is very important to emergency risk and its effects minimizing technologies develop. The main objective of machinery safety models developing is to identify the potential hazards, and terms of the reliability and safety critical machines elements, and the intended emergency due to the function implementation analysis, and operators injury risk (Wenlong & Wentao 2012, Griepentrog, Andersen, Andersen, Blanke, Heinemann, Madsen, Nielsen, Pedersen, Ravn & Wulfsohn 2009).

Mostly, the machinery safety analysis is carried out using models:

- cause-and-effect relationships—emergency effects in terms of their appearance reasons analysis;
- sequential—chains of emergency analysis, the tree of fault and accidents method;
- biotechnical—the human-machine relations disturbance analysis;
- energy transfer—the destructive energy transfer analysis;
- deviations analysis—the deviations from the normal, containing human, techniques and the environment influence identification;
- holistic—takes into account the organizational, environmental, technical and technological functions.

For campaigns machinery use, the holistic models are of particular significance. The appearance of the accident which can be regarded as a systemic approach is a dynamic change of energy, matter, and information. Each process of this machines can be in the system terms described, which take into account:

- organizational functions—safety, training, and control procedures; personnel education and training; management procedures, unauthorized persons access; work procedures; process implementation parameters.

– environmental functions—formation, soil type and moisture, machinery movement system, weather conditions, working elements physicochemical characteristics and parameters variability, communication system.
– technical and technological functions—safety provide technical systems, functional process solutions, machine constructional parameters, the process realization ergonomics, machine preparation for the campaign,the machine maintainability.

Safety system modeling can be carried out using two research methods:

– constructional and functional structure of the machine in terms of the relevant legislation requirements analysis;
– constructional and functional solutions adaptation in the risk analysis aspect.

The crisis situations dynamic, the need of fast analysis and interactive decisions makes implies. It can occur that the incoming information analysis exceeds the capabilities of the operator. At this point the specialized decision support systems lend a hand.

The aim of this paper is to develop the original solutions for decision in crisis situations in the operating, multi-functional, telematics, used in the campaigns, agricultural machinery systems supporting.

2 AGRICULTURAL MACHINERY MANAGEMENT SYSTEMS ANALYSIS

The dynamic growth of digital technology characterized past years. It has been a significant development of the agricultural machinery used in the campaigns management supporting systems. They mainly focused on an efficiency and quality of work improvement and service performed operations supporting. For these type of agriculture telematics, based on GPS technology systems belongs:

– John Deere FarmSight (John Deere 2014).
– Efficient Agriculture Systems (Claas 2014).
– Advanced Farming System (Case IH 2014).
– The Precision Land Management (New Holland in 2014).
– Agrosky + iMonitor (Same 2014, Deutz-Fahr 2014 Lamborghini 2014).
– Fendt Variotronic (Fendt 2014).

These systems have a similar functional structure and allow for (Doruchowski 2009, DomiScore 2010, John Deere 2014, Claas 2014):

– Stress-free operator's work, supported by precision GPS positioning system with an accuracy at the operating time to a few centimeters.
– Field machine automatic steering.
– The fuel costs, work time, pesticides, fertilizers, seeds grains, etc., by the working width utilization factor and the effective efficiency improving reduction.
– Work at night in limited visibility conditions, while maintaining the highest quality of working process.
– The functioning machinery and transport objects automatic synchronization.
– Work time control (operating time, stop time, transport time).
– The machine position localization using the Google Earth (the ability to machine during the night parking monitoring, in this time when machine will change its position, the system generates an unauthorized use alarm signal).
– Selected machine settings from the stationary fleet management equipment supervision.
– Remote data acquisition in order to use them to the worker process functional optimization.
– Remote diagnostics and maintenance scheduling with the immediate service notification possibility.

Despite of many advantages of applied, agricultural machinery used in the campaigns management supports systems, they slightly enhance the safety of their use and mainly limited to:

– The cutting Header disconnection after the harvester operator seat will be left for longer than 5 seconds,
– The cutting Header disconnection and the grain harvester on a circular trajectory set, after the 20 minutes of steering wheel extortion disappearance.
– Stop the engine in case of the ladder for access to engine compartment lowering.
– Prevent to control the position of a sloped conveyor in transport mode.
– Field mode restriction of maximum speed 19 km/h.
– Blockage the harvester engine start in the case of the threshing, header or the harvest drive is switched on.

In terms of the safety of use the agriculture machinery in campaign conditions, there is no operator daily work time permissions supervising systems. There are also no field emergency call rapid solutions. Another solution that should be used is to supervise the machinery rotating components access, as well as the other machines online positioning data exchange to correct field collision courses.

3 THE CONCEPT OF THE MACHINE EXPLOITATION PERMISSIONS AND THE OPERATOR DAILY WORK TIME SUPERVISING SYSTEM

The agricultural machines unauthorized exploitation belong to a frequent abuses. The accidents perpetrators are people do often not have the relevant qualifications. In this group there are persons which do not have an authorized permissions from the producer to operate and service the machine. Unfortunately, many of these people are irresponsible parents and permitted to operate the machines by children. To prevent this type of incidents, the operate permissions verification, machine producer supervised system is proposed. The necessary thing in the system is to online permissions verification, divided to utilities (working process control) and maintenance permissions (service and re abbreviated pair operations). For this reason, the producer, after having been conducting appropriate training, should give registered, individual, personal chip cards. Their task is to limit the access to the machines exploitation of unauthorized persons. Each mobile machine should be equipped with card reader. Starting the machine requires activation using the chip card. After reading the data from the card, the onboard mounted GSM/GPRS module will transmit to the machine producer monitoring server the identification data. Identification data will be compared with a stored on the server database. In case of identified data with stored in the server data compatibility, the machine will sent an information to deactivate the security system. After the verification, the user will be able to start the machine. While machine is running (only in the field), the permissions will be checked at the defined time interval. This solution will allow to stop the machine in case of the chip card from the reader in order to use it to activate other machines removal. In the case of assemblage of machines, composed of tractor and accompanying machine, the system will gave the possibility to the producer and type of accompanying machine by ISOBUS module check. In this case, the system may generate for both, the tractor and the accompanying machine the independent activation messages. Starting the assemblage of machines will be possible in the case of more than one producer permissions authorization. In the assumption of personal card is to give the possibility to store the necessary information, to run a group of machines that are in a one farm and which were manufactured by different producers. In the system, as was earlier mentioned, will functioning cards with a different permissions range. The user card will have permissions to the machine work process. This will be the basic functional range. The service card provides access to, related to the exploitation, more than standard options (e.g. the service technician will have permission to start machine working components while the rotating elements cover panel is removed, in order to carry out the measurements of vibration and rotation speed).

In such a way functioning system will allow to monitoring the operator daily work time. At the time the user logs in the system, (insert personal chip card) at the card will be the activation recorded. From this moment, the units of time, from the daily work time resource, until they are run out, the system will be subtracted. Additionally, after the allowable time, the operator, to complete the technological process, will be able to extend the work time of a maximum 30 minutes. After this time, the

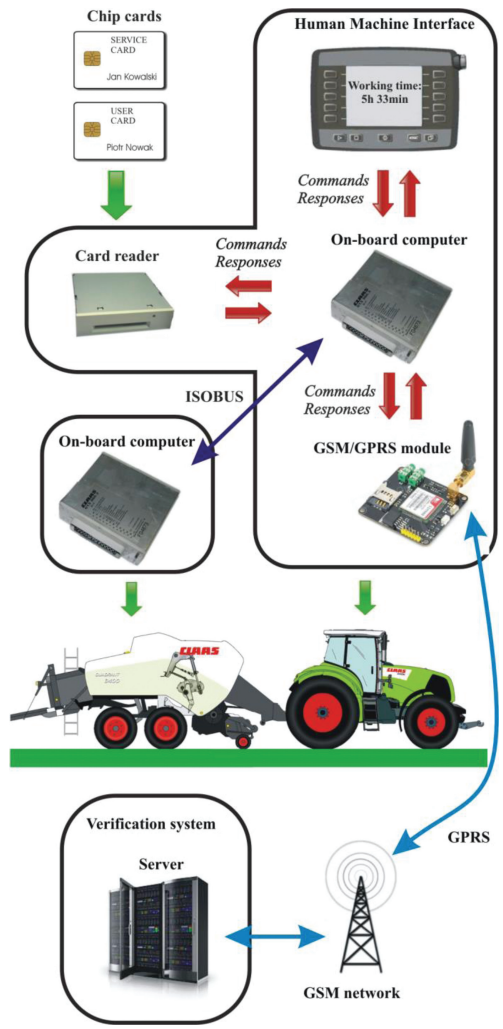

Figure 1. Structural diagram of the machines exploitation and operators daily work time permissions supervision system.

engine stop and the machine will start only in the transport mode. Thanks to the possibility of stored on the card daily work resource time, the proposed monitoring subsystem, after the time limit is run out, prevent to continue the work with this card at the other machines. The time limit will be renewed every 24 hours by the system. Operator during operation of the machine will be able to, using the display board system, the available daily work time control. Figure 1 shows a structural diagram of the machines exploitation and operators daily work time permissions supervision system. The presented system implementation standardization of the shared by the various machines producers chip card recording data requires. Operator monitoring time will be only in the field mode by the onboard machine control system realized. Stopping the machine in the transport mode caused by work time resource exhaustion could have finish in collision.

4 THE CONCEPT OF THE FIELD EMERGENCY CALL SYSTEM

The accidents during agricultural machinery exploitation occur frequently. The major safety approach objective is to prevent them. In the case of an accident, through the systemic solutions, the associated with its losses should be minimize. This type of systems are being developed in a many research centers in the world. The most advanced, that automatically call emergency services in the case of an road accident is eCall system (Emergency Call). It is under the European program in the field of road safety implemented. The studies, conducted using eCall has shown that its use can response time from the emergency calls by 40–50% reduce and the accident losses reduce by 15%. According to the EU directive, the all new vehicles sold in the EU after 1 October 2015 should be provided with an IVS (In Vehicle System). In option for an additional charge, this type of devices, by producers of vehicles are already offered (Friday 2009, Bronk, Lipka, Low & Zurek 2011).

From the information transfer aspect, the eCall is an extension of the functioning 112 emergency call system number, of the E112 position location. In this system the telecommunication operators commit themselves to the vehicle location to the PSAP rescue center (Public Safety Answering Point) by MNO (Mobile Network Operator) free information transfer. In the case of an accident, the vehicle sensors (e.g. temperature, acceleration, airbags initiation) generate signals that will be by the IVS module analyzed. This module receives information about the current position of the vehicle from the GPS. In the next step, the IVS, in the form of a data block MSD (Minimum Set of Data) normalized message generate. This is the minimum set of data that is necessary to locate the vehicle. The MSD data structure describes the European EN15722 standard. MSD dataset contains information about: signal control (if the IVS system generated the MSD automatically or was by the driver initiated), the Vehicle Identification Number (VIN according to ISO 3779), UTC timestamp, location data (geographic longitude and latitude, travel direction), the energy carrier placed in the vehicle characterization (e.g. petrol, diesel, CNG, LPG, hydrogen) and other data from the IVS module board. In addition to the MSD messages, simultaneously in the eCall system, using the in-band techniques, the transmission of the voice is realized. Voice transmission allow to complete the transferring information to the PSAP in the case of the accident victims the consciousness keeping

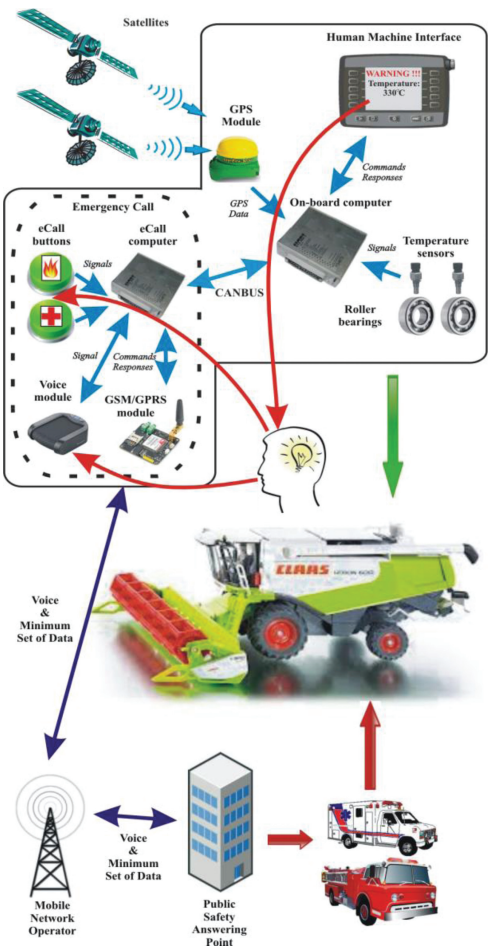

Figure 2. Structural diagram of modeled on the eCall, original field emergency call system.

(Bronk, Lipka, Low & Zurek 2011, Nowacki & Kaminski 2011, Botezatu & Barca 2008, Żardecki & Pijanowski 2012). Figure 2 shows a structural diagram of the proposed, modeled on the eCall, original field emergency call system.

To the necessary changes, aiming at the adaptation to agricultural machineries the eCall system are:

- Resignation of MSD automatic message transmission. MSD message should be initialized only by the operator. During the agricultural machinery work, there are big vibrations and dust, which the correct work of the standard diagnostic sensors disabling (such as acceleration sensors). This could bring the fake alarms.
- The operator should has a possibility to the MSD message with the needed assistance type data generate (in the case of fire—the fire department, in the case of injury—the ambulance service is called). For this reason it is necessary to respectively a MSD message sending buttons secured and tagged. The message after several seconds of delay time should be sent. At the time, when only one button is pressed, the MSD sent message contains information about the need for intervention only one of the emergency services (fire department or ambulance). However, if two buttons at the delay time will be pressed, the message will contain MSD about the need for the intervention of two emergency services. This solution will reduce the number of generated MSD messages and will eliminate the useless emergency call. It should be noted that the system in this form will be used for emergency calls that have also with other, combined machines occurred.
- On-board information systems, in which modern agriculture machinery are equipped, should be with a selected working groups temperature monitoring subsystem, with an alerts generating possibility equipped. This subsystem will the operator in the early detection of the fire risk support. Machines used in the harvest season are to the invitation of fire particularly hard working environment exposed (dust, low humidity and flammability of material). Machines elements of that the greatest risk generate are the engine and high loaded bearings that require the grease with abnormal characteristic use (e.g. the straw chopper bearing mounted in the grain harvester). In the case of fatigue wear of this bearings, they produce large amounts of energy. Their temperature monitoring could the occurrence of fire eliminate and in the case of fire, the time to call the appropriate emergency services through the field emergency call system shorten. The selected working groups temperature monitoring subsystem would the improper grease for high loaded bearings use make difficult. The agricultural machinery users, often to minimizing the cost of exploitation, the cheap substitutes of recommended grease use. In the case of high loaded bearings, cause they fast fatigue wear and as a consequence of this it may bring out the fire. In the case of permanently ignoring of selected working groups too high temperature alerts, subsystem will stop the machine (only in the field mode). Reactivation of the machine would need the service intervention. This solution allowed to reduce the risk of the fire.

5 THE CONCEPT OF THE AGRICULTURAL MACHINERY ROTATING COMPONENTS LIMITED ACCESS SYSTEM

In the case of agricultural machinery technical unfitness, the unauthorized persons (not having theoretical and practical knowledge) attempt to repair the damaged components and the current procedures are breaking. During this type of repairs, often comes to emergency, of which the clothes grab by rotating parts mostly occur. The consequence of this are extensive injuries, bones fractures and even death. Agricultural machinery producers warns the users against the cover panel during the components work opening by appropriate signs at the machine placing.

In order to limiting the access to the working, rotating machine components, the modification of the on-board information system to control possibility of the cover opening is need. While running the engine, the locks that allow to open the machine covers must be locked by the driver. Locking should be initiated by a sent from the machine driver via CANBUS module the coded signal. In the case of using the analog signal lock control (voltage application) machine users could bypass the security by get the voltage from an external source. This system would prevent also the start of the engine when the cover opening was diagnosed. During the machine qualified service technician repair, there is a need to perform confirmatory tests. These include for example the acceptable level of vibrations measurements. This required to run the machine while the covers are open. To verify the permissions of the service technician, the chip card reader can be used. After a chip card in the on-board information system chip card reader is placed, the service employees would obtain the special access to more than standard permissions, that allow the machine with open covers start. Figure 3 shows a structural diagram of the proposed, agricultural machinery rotating components limited access system.

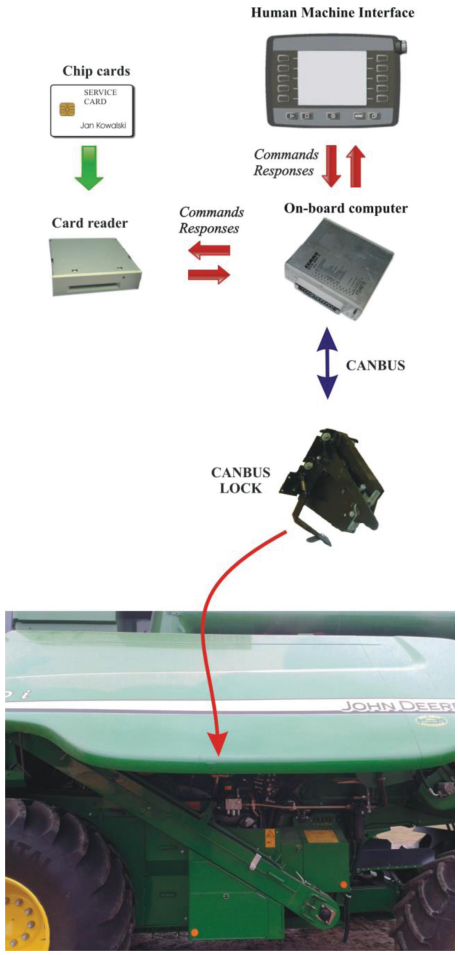

Figure 3. Structural diagram of the proposed, agricultural machinery rotating components limited access system.

6 THE CONCEPT OF THE FIELD COLLISION COURSES CORRECTION SYSTEM

In order to reduce the field collision probability, it is desirable to collision courses monitoring. The system concept is on the V2V (Vehicle to Vehicle) technology modeled. From the second half of 2012 in Ann Arbor, Michigan, USA, the researches with the participation of 3000 vehicles of V2V system were conducted. V2V system assumes the traffic movement vehicles data exchange. Each of the equipped with V2V driver vehicles, exchange data (vehicle location, speed, etc.) with other vehicles by radio. The frequency of data exchange is set at 10 Hz. The V2V functioning systems assumes: fuel consumption and exhaust emissions, and the number of accidents and unwanted crashes reduction (e.g. reckless driving), and the traffic movement improve (Siva & Narla 2013).

The concept of the proposed field collision courses correction system is on machines necessary information radio transfer to enable their position prognoses focused (location coordinates, direction and speed of the movement). In the case of two machines movement trajectory intersection, the system prevent the collision by immobilized them. Once they stop, it will be necessary to switch the machines in safe mode and maintaining, with extreme caution, move the machine to a safe distance. Then the operator will be able to restart the system. The machines used in the campaign season conditions (vibrations and huge dust) making impossible the distance ultrasonic sensors use (a solution for many years in the cars to supporting the driver during parking used). For this reason, mutual positioning and track prediction, only on the basis of onboard GPS module data, in which modern precision agricultural machines are equipped as standard, will be performed. Another problem to be solved is to determine the position of the cooperating machines (e.g. tractor and trailer). In this case, two solutions are proposed. The first one is dedicated to modern machines with on-board controller equipped. The memory controller will the necessary parameters needed to determine their location saved (dimensions and turning radius). After connected the machine to the tractor, the data will be to the mounted on the tractor controller via ISOBUS sent. During the location data analysis, the controller will determine the whole machine movement trajectories. Another solution would through the operator panel to the mounted on the tractor memory controller, the relevant data of connected machine introducing. The data will be entered once, and on further machine uses it will be from the controller memory loaded. This solution is dedicated for machines that are not in the board driver equipped. In addition, the system will be able to field obstacles data (e.g. trees, energy poles) and the machines operation field range enter. This information will, to the system from the stationary, equipped with a specially software, computer management position introduced. After draw up the machine areas maps range, with added obstacles, these data via a telematics system will be to the on-board machine controller transferred. It is very important in the case of operator unconsciousness, when the machine try to leave the defined area of its operation, the system will disable the engine itself and switch off its working components (optional dedicated to grain harvesters). It should be noted that each machine in the system will be able to the system deactivation.

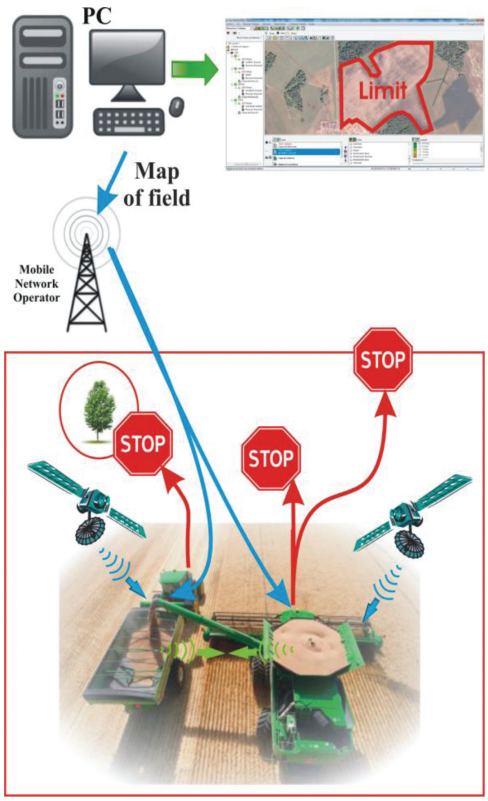

Figure 4. Structural diagram of the proposed field collision courses correction system.

Figure 4 shows a structural diagram of the proposed field collision courses correction system.

7 SUMMARY

Many agricultural machinery producers the management process support systems for used in campaigns agricultural machinery offer. They are mainly targeted to the performance and quality of working process and service maintenance supporting improve. Despite many advantages, unfortunately, they support their use and service safety to a small extent. Presented concepts of extension of existing machines working processes supervising systems can reduce the risk of: field conditions collision, the unauthorized persons exploitation and emergency occurrence at the maintenance and repair time access. In case of field emergency call system, there is a possibility of the emergency services arrival time by 40–50%, and emergency losses by 15% reducing. The system checked solutions, upon the agreed in the EU eCall system that will be in new cars sold from the October 1, 2015 installed is using. This will the conceptual field call system implementation process shorten and also will on its reliability and functionality affect.

Collection and analysis of failure data for pressure equipment

P.A. Bragatto, S. Ansaldi, C. Delle Site & P. Agnello
Inail Settore Ricerca Certificazione e Verifica, Rome, Italy

ABSTRACT: Failure rates of pressure equipment are essential for plant operators to plan risk based inspection as well as for Authorities to make decisions on land use planning. Detailed failure records have been gathered for a decade in a couple of industrial districts, with a significant number of installed equipment. Documents have been analyzed by means classical statistical method to get failure rates and compared with the values used in European countries for decision making. In order to understand how failure modes are affected by the types of equipment, construction material, industry and management model gathered documents have been organized by means of advanced semantic methods. A number of "frequent accident" has been singled out, to be proposed to inspectors and industrial practitioners.

1 INTRODUCTION

Pressure equipment is essential in many industries, including oil, chemical, textile food, waste and healthcare industry. In high risk industries, furthermore, pressure systems are critical also for major accident prevention. Thus in all involved industries, it is essential to assure pressure equipment reliability and safety. In this framework the knowledge about the pressure equipment failures is essential to drive inspection and maintenance activities. In particular the failure rates FR and failure mode FM, associate with a type of equipment, are the basic parameters. FRs, in particular, are essential for the risk assessment and FMs for the risk management.

In the Seventies huge efforts have been made to provide the nuclear and chemical engineers with a credible set of data on pressure vessels failure frequencies and modes. In an article by Bush (1988), the historical studies, conducted in previous decades at three major industrial countries, USA, UK and Germany, are reviewed and compared in a critical way. In the review eight national studies on pressure vessels are reported in detail. In each study, 10.000 to 100.000 pieces of equipment were observed for ten years and more. Those studies consider, as a whole, 3 million years-vessel (both fired and unfired) with some 8.600 minor faults and 155 major events. In following decades the world of pressure equipment changed dramatically, because the new steels alloys introduced in the years, the new certification rules introduced by the PED Directive in 1998, the new design and production techniques, the new inspection and maintenance methods; but, at now, the study of the Seventies are still unparalleled.

2 FAILURE RATE AND RISK MANAGEMENT

The importance of FM and FR for risk management are briefly discussed, as well as the information sources available in the public domain and the research needs.

2.1 *Failure rates and modes for risk based inspection and maintenance*

The pressure equipment risk management is aimed to control uncertainties that could jeopardize in the objectives of these systems, which are basically a profitable and safe production and a continuous and regular service. Equipment failure is still a major uncertainty in a process plant and consequently efforts to develop knowledge about the frequency and the mode of failures are worthwhile indeed. For that reason a credible set of general failure rates is essential to promote an efficient management of hazardous equipment. A particular application of risk management is the Risk Based Inspection RBI program, which optimizes inspection at process plants and other facilities. In RBI, times and types of inspection are driven, inter alia, by FMs and by FRs. American Petroleum Institute provides, in the recourses basis for RBI implementation, general failure rates and modes for many type of systems, including pressurized ones (API 2008). RBI details, benefits and compatibility with European and national

legislations on pressure equipment verification has been discussed by Bragatto & al. (2012) and by Pittiglio & al. (2014).

2.2 *Process equipment failure rates for risk based decisions in land use planning*

FRs affect also a few essential decisions by competent Authorities in the framework of the "Seveso" Directive. According to the art. 10 of the Directive 2012/18/EU Seveso III (replacing art. 9 in Seveso II Directive), establishments' operators must provide the authority with a detailed "Safety Report", which must include a probabilistic evaluation of the accident scenarios connected to the top events, as derived by hazard identification. The event probabilities are, in turn, derived from the FRs of the preventive and protective systems, by means of Fault Tree and Event Tree Analysis. The FRs of pressure equipment contribute to the computation with other mechanical, hydraulic, electrical, electronic and possibly human and organizational systems. The probabilistic evaluations coupled with consequence modeling and potential impact area computation are essential for Authorities to make vital decisions about new plants approval, emergency planning and land use planning LUP. Even decision making models for LUP are very different in different countries, FRs play always an essential role, as discussed by Bragatto & al. (2013).

2.3 *Trustable sources for pressure equipment failure rates*

The scientific weakness of the generic failure frequencies have been discussed by a historical review of Fragola (1996). Authorities must anyway accept a trade-off to make standardized and uniform decisions. An inadequate value of a single FR value in a fault tree is able to affect vital decisions. For that reason, in order to harmonize LUP decisions in the framework of Seveso Legislation, in a few countries set of "official" FRs was published by competent authorities. The main sources are the following:

i. PURPLE BOOK (1997) is a study of the TNO for the Dutch Competent Authority.
ii. FRED (2012) is managed by the British Competent Authority, HSE.
iii. AMINAL (2009) is the study of the Flanders Regional Authority in Belgium.

FRED is more conservative than PURPLE BOOK and AMINAL, but the approach is basically the same: data are derived from scientific literature and processed considering the advices of a number of experts (Pasman 2011). Thus for pressure equipment the historical studies of the Seventies, even though in new guise, are still alive. The criticality of the general frequency of has been recognized by British and Dutch Authorities, which has promoted, in the framework of "Seveso" activities. a feasibility study to improve the level of trust of FRs, gathering new data on the "field". In this study (Bellamy & al. 2012) accident national and European databases have been exploited. According to Manuel & al. (2012), the two found limits are: i) it is difficult evaluate the actual reference equipment population, because there are no data on the total number of pipes and pressure vessels at the Seveso establishments; ii) failures without severe consequences for humans or environment are not reported in the open sources.

Multinational chemical and oil corporations, which control directly hundreds of plants, are able to gather detailed and complete information on both equipment failures (even without consequences) and equipment population, but results, as proprietary, cannot be found in the public domain and, consequently, they cannot be accessed neither by Authorities or minor companies.

2.4 *Knowledge management techniques*

Even more important than establishing shared FRs is to understand of the types of failure depend on the type of equipment, as well as on the operating condition and on the industrial sector. The collection of data on failures should serve primarily to develop and share this knowledge. The information, however, is fragmentary and not homogeneous at all, thus it is important to have appropriate tools peer knowledge management.

In order to extract knowledge from heterogeneous sources and to support semantic search "ontology" has been widely used for a decade. It is, basically, a way to put together concurrent taxonomies, adding a number of relationships. It has been demonstrated adequate to support pressure equipment certification by Camossi & al. (2008) and Ansaldi & al. (2006).

3 OBJECTIVES

The present study focuses just the pressure equipment, for which data in the public domain are quite older, even though essential in many industries. As in a few countries, including Italy, all phases of pressure systems life-cycle are driven by national regulations a valuable source of knowledge could be provided by the competent authorities. The control bodies' experience has been exploited both to update pressure equipment FRs and to improve and share knowledge about the types and causes of the failures in pressure equipment.

3.1 *Update failure rates*

The first objective is to have updated pressure equipment FRs, suitable for risk management in Italian industries, as well as to make equitable decisions on Seveso plants and LUP. For those purposes it is necessary to gather data on pressure equipment failures in a few sample area, where equipment population is known, to derive failure rates and to compare them with the values adopted by other competent authorities in Europe.

3.2 *Improve knowledge about failure mode*

The second and more important objective is to provide the Italian industries with a trustable basis of knowledge on pressure equipment FMs. The types of failure are expected to depend on the types of industry, of equipment, of management system and of material. Furthermore types of inspection and repair may be suggested, based on the collected experience. The knowledge must be accessible and usable for all industries.

4 MATERIAL AND METHODS

4.1 *Pressure equipment verification*

In Italy the mandatory periodical verifications on pressure equipment, are in charge of the local control agencies (ASL), whilst INAIL is in charge of the first verifications. Thus the two bodies, working together, may have a clear picture of pressure equipment on the territory and gather detailed information on incidents and failures that occur in their territory. Together with the ASL of Varese, a systematic information collection about pressure equipment failures was experimented. Varese province is featuring a large number of small and medium sized manufacturers, in particular in textile and allied industries. The observation time was 11 years, until 2013. The equipment population is 6000 items in service, including some 400 steam generators. This data has been assumed almost constant in the observation time. In the observation period there are 53 recorded event. The recorded events include both major failures with severe consequences (e.g. loss of the equipment, injuries or death, environmental damage) and minor fixable failures. For each event has been produced a detailed sheet, describing type of failure, type of equipment, type of material, type of consequences, type of causes, type of certifications and lifetime. Further details and photographs, as relevant, have been enclose too. The industries are classified according to the NACE scheme.

For the purpose of comparison was analyzed also a collection of recorded faults present in the public domain (Frabetti & al. 2006). It contains 53 events collected in 7 years (1995–2001) in a highly industrialized Italian area (Emilia-Romagna), with a population of about 46,000 in equipment pressure. The study did not provide frequencies.

In Emilia data collection, steam generators were considered separately, as failures of boilers were recognized much more frequent and less severe than other type of equipment. To keep consistency with Emilia data, also in our study steam generators has been definitely discriminated from other type of equipment.

A number of failures, recorded by others regions, have been included into the study. Namely there are 5 records coming from other districts and 4 documents on failure much more detailed, coming from testing laboratories. Furthermore a dozen of accident records, coming from national and international databases have been included as relevant to the pressure equipment. They have not been useful for the FRs as data on the reference population are lacking, but they have been valuable for investigating the FMs.

4.2 *Statistical analysis*

The FR calculation needs just the number of occurrences and the number of items in the reference population. The number of events is relatively low, but the information collected for each event is very detailed. As a large diversity of equipment is involved, with many types of fault; the statistical analysis of the documents had to balance two conflicting needs: the different classes of membership (e.g. types of activities, types of equipment, types of damage, class of age) should be discriminated to have interesting and detailed results; but the sample cannot be fragmented too much, to avoid a loss of statistical significance. For this reason, before numerical processing, has been investigated the different taxonomies to be used to organize the study. A too articulate taxonomy cannot lead to significant statistical results, but a flat classification leads just to generic results. The strategy then is to obtain classifications with two or a maximum three levels.

The first level of the taxonomies will drive the numerical calculations, to have failure rates, while the second level, not suitable to produce "numbers", will be used to synthesize the documents in order to facilitate the search for recurring events. In Table 1 the list of the used taxonomies are shown.

4.3 *Frequent accident*

Starting from the taxonomies mentioned in § 4.1 a complete "ontology" of the matter "pressure equipment failure" have been built. To have the ontology of the pressure equipment failure a number of relationships between concurrent classification have been added.

Table 1. The basic taxonomies used to organize the matter. Just the very first level is shown.

Equipment	Steam generator, sterilizer, LPG tank, vessel, piping, heat exchangers, chemical oven, cylinders, tanks
Consequences	Production, asset, workers, environment
Part	Shells, ends, openings, nozzles, manifolds, supports, valves, tube plate, tube, furnace
Industry	According to NACE code
Fluid	Liquid, gas vapour; non hazardous, hazardous, corrosive
Repair	Restoration, replacement, surface treatment, non repairable
Failure/defect	Crack, crack through/hole, surface deterioration, deformation, occlusion, explosion/fire, rupture
Cause	Welding, human factor, maintenance, process, fatigue/corrosion, age

For instance a few parts are present just in a few types of equipment; a few type of equipment are present just in a few industry, a few damage occur just in a few types of equipment; a few types of repair are just for a type of failure and so on. The resulting ontology has been used to drive both basic failure statistics and knowledge organization. By exploiting the developed ontology, it is possible to have a sort of "intelligent search". Instead of looking for a string as in usual search engine, it is possible to look for a complete sentence that must put together a few types or "categories" present in the taxonomies included in the ontology. For instance it is possible to find in the stored documents a sentence where a particular type of damage occurs in a certain type of equipment in a certain type of industry. A free text search is even possible, as the pre-defined taxonomies cannot cover such a complex matter. The search is highly facilitate by the use of IBM® OmniFind™, a special engine, which recognize synonyms, even in different languages. The engine is also able to summarize automatically the resulting document, according to the key words used in the free text input and the categories as defined in the taxonomies. As the search is based on both the taxonomies and free text, the "logical proximity" definition adopted to find out "similar" events, combines both hierarchical distances coming from taxonomies and distance coming from text comparison according to MinHash algoritm:

$$P_{a-b} = \frac{\left(\Sigma_i^N \left(1 - \frac{h_i^{a-b}}{R_i} \right) + \frac{K^a \cap K^b}{K^a \cup K^b} \right)}{N+1}. \quad (1)$$

where p_{a-b} = proximity of event records a and b; h_i^{a-b} = hierarchical distance of event records a and b, according to the ith taxonomy; r_i = rank of ith taxonomy; N = number of taxonomies; K^a and K^b sentences singled out respectively in the event records a and b by the free search.

The index p^{a-b} ranges from 0 to 1. By means of the proximity metrics it is possible to build a set of similar events, which may be considered "frequent failures". Two event records have been considered "similar" if proximity $p^{a-b} \geq 0{,}67$. Similar events have been clustered in order to have a "frequent failure". A cluster of failures has been eligible as "frequent failure" if the number of events is ≥3 and all proximity are above "similarity" condition.

5 RESULTS

5.1 *Failure rates*

FRs have been derived separately for the new data of Varese and for the older data from Emilia. Steam generators have been discriminated. Resulting failure rates have been compared with the value suggested by the National Competent Authorities and by API. Furthermore the failure rate derived from Bush's review has been included. Table 2 summarizes the results.

The rate of failure for steam is very high, even though there are no major failures. It has to be stressed that, a number of major defects, resulting after periodical inspections have been accounted as "failures", because the significant consequences on repair costs or plant availability. As in other studies "major defects" are not included, the rate is not so worrying. Furthermore the age of failed equipment end the type of industry are essential for understanding the data.

As shown in Table 3 the steam boilers in Varese are quite older and, obviously, that affects the failure rates. The types of industry are shown in Figure 1.

Table 2. Comparison of failure rates.

	Minor/ repairable	Non repairable	Major
Bush 1970*	3.9E-04	1.3E-04	2.6E-05
TNO 1999	9.6E-06	9.6E-07	5.0E-07
API 2008	1.0E-04	1.0E-05	6.0E-06
AMINAL 2009	1.2E-05	2.2E-06	3.2E-07
HSE 2012	4.0E-05	1.0E-05	6.0E-06
Other Emilia*	6.6E-05	3.8E-05	6.9E-06
Steam Emilia*	4.7E-04	2.5E-04	3.1E-05
Other Varese**	8.9E-05	5.4E-05	1.8E-05
Steam Varese**	9.0E-03	1.3E-03	–

*Reworked from literature data; **Original data.

Table 3. Age and failure.

	Steam Varese	Other Varese	Steam Emilia	Other Emilia
Average	23.4	14.5	14.2	15.0
Max	54.0	36.0	37.0	41.0
75° percentile	31.0	19.0	20.0	22.0

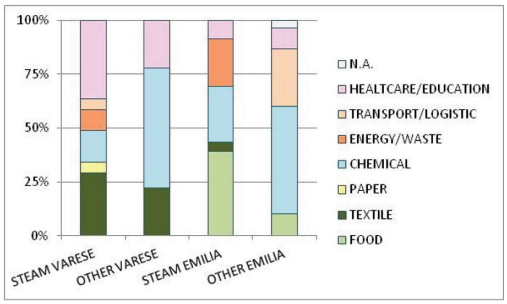

Figure 1. Failures and type of industry.

For Varese, there is a predominance of failures in textile and healthcare, whilst in Emilia food industry is peculiar. For the other equipment (non steam boiler), results for Varese are not so far from FRED (2012) and API (2008) suggestions, and lower than historical rates by Bush (1988). In the rates derived from the literature rates, healthcare facilities are not included, whilst are present in Emilia and in Varese studies and, contribute to increase the rates.

5.2 *Failure types*

As shown in Figure 2 failures have been classified as blast, fire, deformation, total and partial ruptures, as well as a number of degradation (peeling, occlusion, fouling, extended surface corrosion, multiple cracks, hole and crack through).

The assumed causes range from environment, inadequate repair or maintenance, inadequate design, process, human error, inadequate welding, stress and chemical corrosion, obsolescence (Fig. 3).

As shown in Figure 4, repairs after failure techniques include surface treatment, NDC programs, equipment modification, restoration (filling and grinding), and replacement of the damaged part.

The types of failure, the damaged part and the types of repair depend on the process and on the fluid, which in turn depend on type of industry. A more depth statistical study could need a fragmentation of the sample with loss of significance. Thus the further investigation are to find "frequent failures", as discussed in § 4.3.

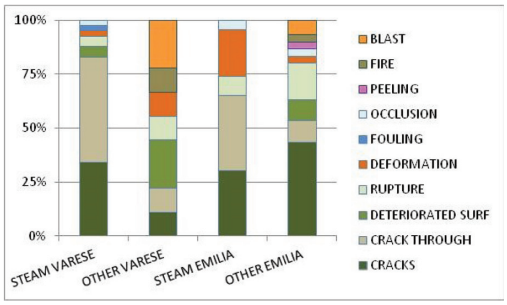

Figure 2. Failures and types of damage.

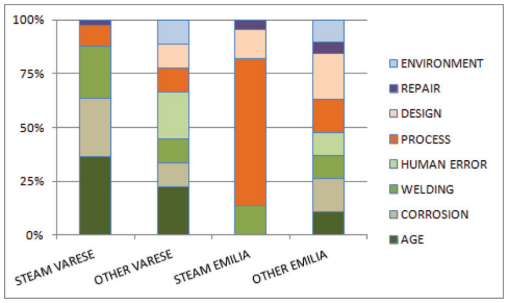

Figure 3. The types of assumed cause.

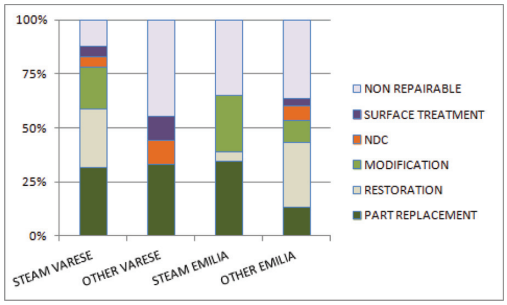

Figure 4. The types of repair.

5.3 *Frequent failures*

Table 4 show an example of the identification of a "frequent failure".

It is known that the chemical characteristics of the water supply is a source of troubles for thermal systems, including steam generators, health exchanger and sterilizer autoclaves. The problem is recorded in 6 documents, as shown in Table 4. Items matched in the defined categories are highlighted in different colour and searched free text is underlined. The first two records are very close indeed and the four following ones are less and less

Table 4. A set of "similar" incidents. The keywords, as given to the search engine are highlighted.

1	**Steam Generators** cracks in the weld between the tube shell and tube plate caused by corrosion due to incorrect treatment of water. Demolition
2	**Steam Generators** cracks in the weld between the tube shell and tube plate caused by corrosion and caustic fragility due to incorrect treatment of water Demolition
3	**Steam Generator** Following internal visit is detected widespread fouling of all parts side H_2O. Causes: the water supply to the **Steam Generator** without or insufficient treatment of water due to the softener device out of order. Repair: Chemical washing
4	**Heat Exchanger** corrosion of all parts on the water side Cause the sulfite concentration was less than that recommended by the manufacturer. This have resulted in the presence of a non-negligible amount of dissolved O_2 in water that has given rise to the widespread pitting. Repair: Chemical washing
5	**Autoclave Sterilizer** Steam formed by water from the ion exchange resin softener. Safety valve abnormality blocked by fouling. Absence of the condensate drain hole and the use of water with features not appropriate are the causes. Repair: Valve replacement and modification of the vent line.
6	**Autoclave Sterilizer** tearing of the shell due to a weakening of the intergranular material stainless steel triggered by chlorinated compounds as was used sea water. Demolition

Table 5. A further set of "similar" incidents. The keywords, are highlighted.

1	Food industry **Steam Generator** deformation in the central area of the rear tube plate deformation caused by pressure of the furnace probably due to stress … resulting in **excessive heat load** on the furnace …
2	Food Industry **Steam generator** some deformation of the tubes of the combustion chamber … with bulges result in **overheating** bubble
3	Food industry **Steam Generator** … ***Intermittent operation with alternating cycles very frequent***. three crack though in the back of the shell … It is assumed that the **continuous thermal stress** and the resulting deformation of the tube plate has caused the cracks …
4	Textile Industry **Steam Generator** plastic deformation due to the operation of the furnace in the **absence of water supply** as shown in photographic surveys the fault was caused by the **failure of the supply of water** to the generator for about 3 hours

"similar", according to the adopted metric. In the set the average mutual proximity is 0.73, with a standard deviation 0.08.

A further example of frequent failure identification is in Table 5. The problem is the thermal stress and the consequent deformation of some parts. The four case are pretty close each other. The average mutual proximity is 0.91 with a standard deviation 0.04.

Two further significant clusters have been found:

– reactors in chemical industry with corrosion phenomena due to aggressive compounds, such as chlorides (3 records; 0.8 average proximity);
– boilers switching from oil-fired to natural gas-fired, with consequent thermal stress, due to the higher calorific value of the natural gas (3 records; 0.75 average proximity).

A few documents contain also photos and evidences from metallurgical studies. Thus, for described "frequent failures" it is possible to add also imagine, in order to have more effective alert sheets for the industrial practitioners.

6 CONCLUSIONS

General pressure equipment failure frequencies, as proposed by FRED or API are basically confirmed by the filed experience of the Italian control bodies; but for steam boilers, which should be considered apart.

Types of equipment, damage mechanisms, materials, industries, processes are very different and available data are few. For this reason, the "frequent failures" found by means of the semantic search, are more interesting. In the future the metric will be improved, in order to include the experts' judgment and have more focused sets. Also taxonomies need to be improved, in order to include the user experience. A further develop line is to extend the document collection, including also national and international open data and proprietary sources.

ACKNOWLEDGEMENTS

The authors are particularly in debt to Mr. Sergio Barassi of ASL/Varese, for his valuable contribution to the present research.

Reliability analysis of prototypes based on small and heterogeneous test data volumes. Case study: Organic fibre prototype analysis

A. Lücker, M. Hinz & S. Bracke
University of Wuppertal, Germany

G. Knübel
Henkel, Germany

ABSTRACT: The analysis of failure behaviour and reliability parameters concerning the product's life cycle is fundamental within the early product development phases. Initial measurements regarding the product reliability analysis are based on prototypes. Especially in chemical process engineering, which deals with organic materials (e.g. fibre technologies), the scattering of the product characteristics (e.g. fibre strength or geometry), treatments and load profiles is significant. The challenge regarding the further processing during the prospective product life cycle is the quantitative, statistical risk and reliability estimation, which is primarily caused by the small prototype test data in combination with heterogeneous distributions of fibre characteristics. In this paper, an approach for the analysis procedure of prototype test results, based on heterogeneous prototype characteristics and small data volumes (e.g. sample size 15–25), is shown. The approach is explained within a case study out of the chemical process industry with the focus on the analysis of reliability parameters of fibre samples.

1 INTRODUCTION

The analysis of product failure behaviour and reliability parameters concerning the products life cycle is fundamental within the early product development phases. Initial measurements regarding the analysis of product reliability characteristics are based on prototypes. The challenge is the comprehensive analysis regarding the detection and mapping of expected failure modes and failure behaviour. Based on this analysis, product and manufacturing process optimisation is feasible.

Especially in the chemical process engineering, which deals with organic materials (e.g. fibre technologies), the scattering of the product characteristics (e.g. fibre strength or fibre geometry) is significant. Furthermore, the influences of product treatment (e.g. stress, side load, chemical treatment) have to be analysed. In this paper, the statistically reliability and risk analysis of organic fibre material within in the early phase of the product development is shown.

The challenge regarding the further processing and the usage during the prospective product life cycle is the quantitative risk and reliability estimation, which is primarily caused by the small prototype test data in combination with the heterogeneous distributions of the fibre and treatment characteristics.

From a statistical point of view, the validity of the test results based on a low test data volume and the distribution heterogeneities is considerable. For example parametrical distribution models are unverifiable; therefore parametric significance tests are not applicable.

This paper shows results of research collaboration between University of Wuppertal and Henkel, Düsseldorf, with regard to the development of an approach for the analysis procedure of prototype test results, based on heterogeneous prototype characteristics and small data volumes.

2 GOALS OF RESEARCH WORK

The goals of the development of an approach for the analysis procedure of organic fibre test results, based on heterogeneous prototype characteristics and small data volumes, are as follows:

1. Detection of significant impacts with regard to fibre strength and fibre geometry,
2. Analysis of significant impacts of the stress, side load and chemical treatment regarding the test cycle,
3. Determination of reliability characteristics of organic fibre materials based on heterogeneous prototypes,

4. Determination of facility adjustment for the maximal differentiability based on an analysis of variance and optimisation of accelerating testing method for further prototype tests (e.g. pre-damaged organic fibres).

The approach is explained with the help of a case study "Organic fibre prototype analysis" out of the chemical process industry with the focus on the analysis of reliability parameters of fibre samples. With the use of nonparametric as well as parametric statistical methods, fibre characteristics (e.g. centre, dispersion, trends) and interdependences are analysed with regard to material, geometry and origin aspects.

3 3 BACKGROUND: PROTOTYPE TESTING STRATEGIES

This chapter focuses on theoretical principals and application areas of accelerated testing procedures. Based on these theoretical aspects the analysis of the main characteristics regarding the test cycle within the case study "Organic fibre prototype analysis" is performed (Hinz 2014).

According to (Escobar 2006), "Accelerated Tests" (ATs) is a term used for two completely different kinds of tests with different purposes, "qualitative ATs" and "quantitative ATs". The key differences are presented briefly in Figure 1.

Qualitative ATs are used to identify product weaknesses caused by flaws in the product's design or manufacturing process. This is done by gradually increasing stresses until the product fails. The aim is to improve the product reliability in a very short period of time, usually hours or days. Common names for this type of tests are HALT (Highly Accelerated Life Test), STRIFE (Stress-Life) and EST (Environmental Stress Testing) (Chan 2001). Tests of this type do not involve any statistical or mathematical methods. The only target of these methods is the increase of the robustness of the product. The knowledge about the product lifetime or the degradation process over time is not in demand.

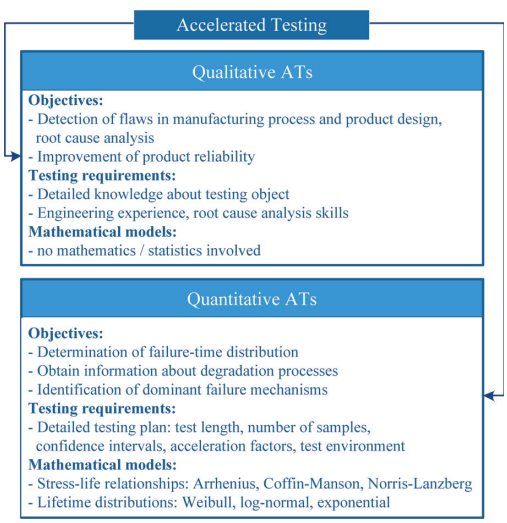

Figure 1. Test strategies of accelerated testing.

Quantitative ATs are used to obtain information about the failure-time distribution and degradation in a relatively short period of time (usually weeks or months) by accelerating the use environment. In most cases a model to describe the relationship between failure mechanism and accelerating variables already exists. They are also well-suited for finding dominant failure mechanisms and are usually performed on individual assemblies rather than full systems. In order to set up a quantitative AT, several different parameters must be known, for example test length, number of samples, desired confidence intervals, field and test environment, stress-life relationship and distribution model.

3.1 *Acceleration models*

One key factor is to determine the acceleration factor. It can be obtained by two different methods, either by using existing physical/chemical acceleration models or by determining empirical acceleration models by experimentation.

Various physical/chemical models for well-understood failure mechanisms are already available. They describe the failure-causing process and allow extrapolation to use conditions for specific environment variables.

If there are no chemical/physical models to describe the failure-causing processes adequately it may be necessary to develop an own empirical model by experimentation. An empirical model usually provides an excellent fit to the available data, but still can provide false extrapolations for working conditions.

3.2 *Acceleration methods*

Products, which are not in continuous use, can be accelerated by the increase of the usage rate. This means that the time between the load phases is reduced. It has to be considered whether the increased use rate changes the cycles to failure distribution. A toaster for example could heat up increasingly cycle after cycle until it reaches temperatures which would not appear under normal use conditions. A case study for this purpose was performed by (Guangbin 2006).

By increasing experimental variables like temperature, humidity or radiation, chemical processes that lead to certain failure modes can be accelerated (e.g. the chemical degradation of a photovoltaic module can be accelerated by inducing an electric potential).

If the environmental stress exceeds the strength of the testing object, the unit (prototype) will fail. This means that a unit operating at higher stress levels will generally fail after a shorter period of time than a unit at lower stress levels (e.g. amplitude in temperature cycling, voltage, or pressure).

The test strategy used in the case study "organic fibre prototype analysis" is a quantitative accelerated test with the need of the development of own empirical model by experiments. Though, the usage rate of the fibres is increased. The response type of the test used in the case study relates to the accelerated life test which is neither right nor interval censored.

Detailed information about response types of accelerated tests can be found in (Escobar 2006), (Nelson 1990), (Escobar 2003) and (Hinz 2014).

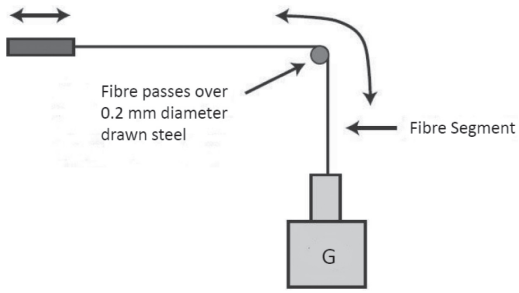

Figure 2. Schematic visualisation of test facility (Swift 2001).

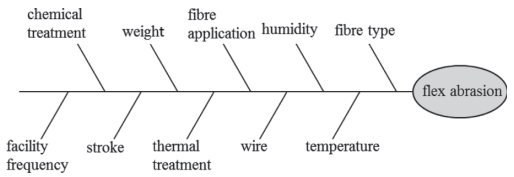

Figure 3. Main influence variables regarding the test procedure of flex abrasion.

4 ORGANIC FIBRE PROTOTYPE ANALYSIS

In this chapter, organic fibre prototype analysis including test facility is discussed. Subsequently, organic fibre data such as thickness or heterogeneity is explained. Furthermore the main influences on the fibres and the test plan is presented. However, various works on flex abrasion resistance investigations with the focus on chemical treatments of organic fibres were performed by (Yang 2001), (Yang 2003), (Dusenbury 1954), (Choi 1992) and (Pyket 1998).

The prototype analysis is the base of operations for present and future work on reliability analysis of organic fibre prototypes after chemical or thermal treatment.

4.1 *Test facility*

Reliability of organic fibres, such as cotton, depends on various influences, e.g. mechanical stress, different types and applications, external treatments or environmental conditions. Main influence variables regarding the test procedure are shown in the Figure 3. In order to simulate the most important impacts, a flex abrasion test facility, shown in Figure 2, was used. Detailed information about the testing machine can be found in (Swift 2001).

Fibres are placed in a plastic tab on the one side over 0.2 mm diameter steel wire and a weight on the other side. The plastic tab is connected to a drive unit, which induces a constant, linear, reciprocating motion. The flex abrasion machine provides the opportunity of variation of three parameters: stroke and frequency of the motion as well as the weight placed at the end of the fibre. Every measurement consists of 24 fibres.

Measured reliability information is the number of cycles of passes of the fibre, whereby back and forth motion is counted as one cycle.

Every parameter of the machine can be varied discretely within given ranges.

In order to avoid a high number of experiments, the number of every parameter will be limited to two adjustments:

- stroke—4 and 10 millimetre
- frequency—1 and 2 Hertz
- weight—10 and 20 gram

4.2 *Organic fibre*

Different types of organic fibres can be found in many branches of the industry (chemical, textile, cosmetics) and products (also of everyday use, like clothes, ropes, bags).

High number of applications corresponds to the number of fibre types. Within the case study "Organic fibre prototype analysis" three different types of fibres have been tested. For the sake of convenience they are renamed to type A, type B and type C and are representative for a wide range of products.

Heterogeneity of organic fibres plays a certain role due to the variance of material properties and

Table 1. Excerpt of the test plan.

No.	Fibre type	Stroke [mm]	Frequency [Hz]	Weight [g]
1	Fibre type A	10	2	20
…	…	…	…	…

7	Fibre type A	10	2	10
8	Fibre type A	10	2	20
9	Fibre type A	4	1	10
10	Fibre type A	4	1	20
11	Fibre type A	4	2	10
12	Fibre type A	4	2	20
…	…	…	…	…
19	Fibre type B	4	2	10
20	Fibre type B	4	2	20
…	…	…	…	…
28	Fibre type C	4	2	20

physical dimensions. Previous to the flex abrasion tests, the thickness in form of the cross section of the fibres has been measured and varies between 1695 μm^2 and 7016 μm^2 with the mean value of 3446 μm^2.

4.3 *Test plan*

A two-stage test plan for the flex abrasion experiments of the organic fibres was developed. The first stage investigates the influence of mechanical parameters and heterogeneity of organic fibres. Second stage deals with thermal and chemical treatment, which is not part of the current case study, and is planned to be examined in the further research work.

An excerpt of the first stage of the test plan is shown in the Table 1. The first four measurements (no. 1–no. 4) are of the same type of fibres and have the same adjustment of the parameters. The aim of these measures was the determination of the homogeneity of the samples. The next measurements contain all possible permutations of three fibre types, two strokes, two frequencies and two weights. This leads to eight (number of permutations for stroke, weight and frequency) measurements for every fibre type and 28 measurements (24 with parameter variation and four for the homogeneity of the samples) all in all.

5 STATISTICAL ANALYSIS AND RESULTS

The applied parametric and nonparametric statistical methods with their advantages and disadvantages shall be discussed in this chapter.

In the first instance, goodness of fit test will be performed in order to choose the proper statistical methods in the subsequent steps. Afterwards, the correlation analysis shall be undertaken in order to detect the linear dependencies between the single samples as well as between the number of cycles and the diameter of the fibres within every single sample. The homogeneity of the fibres is to be investigated with the help of significance tests with regard to the focus and the variances of the samples.

Lastly, the results of the measurements in form of plotted cumulative probabilities will be discussed.

5.1 *Goodness of fit tests*

In order to choose the eligible strategy for the correlation analysis as well as significance tests, the distribution of all samples has to be examined. Therefore, the goodness of fit tests with the null (and alternative) hypothesis:

$$H_0 : F = F_0 \text{ (and } H_1 : F \neq F_0) \quad (1)$$

that the sample data is distributed in a certain way (either normally or Weibull) has to be proven. Thus, for the normal distribution Kolmogorov-Smirnov and Shapiro-Wilk (Sachs 2009) tests are available. Accordingly Anderson-Darling, Kolmogorov-Smirnov and Chi-squared (Sachs 2009) tests can be applied for the Weibull distribution (Table 2).

In case of both distributions the applied Kolmogorov-Smirnov test doesn't provide results for all samples (sample size to small). Therefore, the results of this test will not be analysed.

The hypothesis that the sample data are Weibull distributed by a significance level of $\alpha = 5\%$ can't be rejected in case of 79% (for Anderson-Darling) and 93% (for Chi-squared) of the samples. Nevertheless it's important to note, that the amount of data within a sample stays at a low level. An example of Weibull distributed fibres (Table 1, fibre no. 1) is shown in Figure 4.

The hypothesis that the sample data are normally distributed by the same significance level as

Table 2. Goodness of fit tests—results.

	Normal distribution	Weibull distribution
Anderson-Darling	–	79%
Kolmogorov-Smirnov	No results	No results
Pearson χ^2	–	93%
Shapiro-Wilk	50%	–

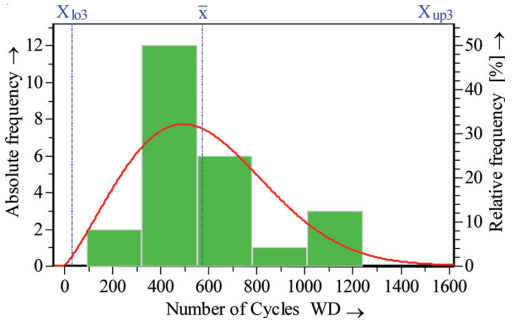

Figure 4. Density function of fibre no. 1 (Table 1).

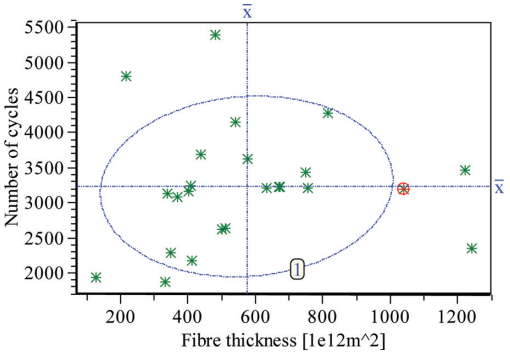

Figure 5. Scatter plot of fibre no. 1.

in case of Weibull distribution can't be rejected in case of 50% of the samples by an application of the Shapiro-Wilk test.

For the reason, that the null hypothesis of normally distributed samples can't be rejected only by the half of the measurements, the use of parametric tests is not possible. Therefore, nonparametric tests such as Mann-Whitney U or Levene's (Hartung 1998) for the comparison of the samples shall be applied. Also the Pearson product-moment correlation assumes the normal distribution of the samples. Hence, the use of Spearman's rank correlation, which is independent on the distribution model, is more adequate.

5.2 *Correlation analysis*

This part of the research work focuses on the impact of the fibre thickness on the durability of the fibres. Durability is represented quantitatively by the number of cycles of the flex abrasion test. The impact is presented in form of the Spearman's rank correlation coefficient. The correlation coefficient gives a value between –1 and 1 inclusively, where –1 is total negative, 1 is total positive and 0 is no correlation. Spearman's rank correlation is a nonparametric tool which describes the linear dependency between two variables, and can be defined as:

$$r_S = \frac{\sum_{i=1}^{n}(R(x_i)-\overline{R(x)})(R(y_i)-\overline{R(y)})}{\sqrt{\sum_{i=1}^{n}(R(x_i)-\overline{R(x)})^2 \sum_{i=1}^{n}(R(y_i)-\overline{R(y)})^2}} \quad (2)$$

where r_s is the rank correlation coefficient; $R(x_i)$, $R(y_i)$ are the ranked variables and, $\overline{R(x)}$, $\overline{R(y)}$ are the ranked arithmetic means.

A representative example of a distribution of the measured quantities in form of a scatter plot of fibre no. 1 is shown in the Figure 5. In this case the rank correlation coefficient equals $r_s = 0.31$.

The correlation analysis has been performed in case of all samples. Therefore, 28 coefficients are available. The mean value of the coefficients is $\overline{r_{mean}} = 0.23$, whereupon the maximum value equals to $r_{max} = 0.58$. This result provides very weak linear dependency of fibre thickness on the fibre durability. This means, that the fibre durability is independent of the fibre thickness.

5.3 *Significance tests*

For the comparison of samples, various significance tests according to different applications are available. Nonparametric significance tests do not require dependences on specific distributions. In comparison to similar application cases of parametric significance tests, further application cases and benefits such as simple calculation and detection of randomness of failure data are available.

The main focus of these tests is the comparison of the first four samples (fibre no. 1—no. 4) in order to prove their homogeneity. For this purpose two nonparametric statistical tests were performed.

Mann-Whitney U test with the null (and alternative) hypothesis:

$$H_0 : F(z) = G(z) \text{ (and } H_1 : F(z) \neq G(z-\Theta)) \quad (3)$$

that the samples have the same focus, and

Levene's test with the null (and alternative) hypothesis:

$$H_0 : F(z) = G(z) \text{ (and } H_1 : F(z) \neq G(\Theta z)) \quad (4)$$

that the variances of the samples are equal.

A visual example of the comparison of fibre no. 1 and no. 2 in form of a boxplot is shown in Figure 6. It can be observed, that no significant difference with regard to the focus (horizontal, black line in the middle of coloured rectangles) as well as variances (bold, vertical, black lines) between both samples occurs. This qualitative analysis can be

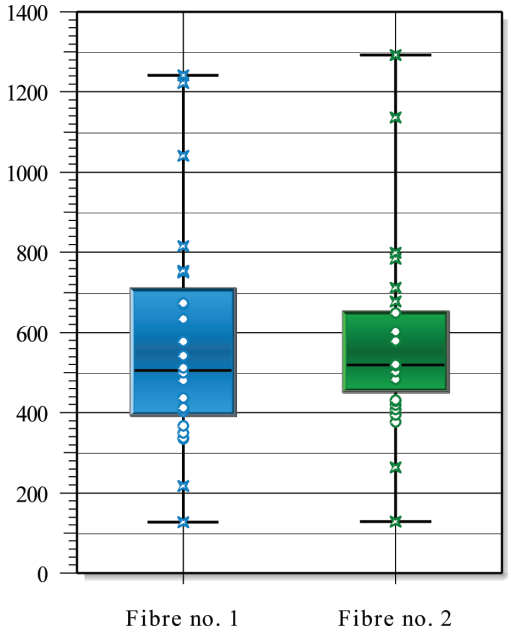

Figure 6. Boxplot—comparison of the samples.

confirmed by the quantitative study of all samples. Null hypothesis of both tests couldn't be rejected in all cases (comparison of every single sample with all the others). This means, that the samples (not the single fibres!) are homogeneous. Therefore, every single measured sample is representative for the rest of the result analysis.

5.4 *Discussion of test results*

In this chapter, results of the measurements of flex abrasion test procedure shall be discussed. The results in form of plots of cumulative probability are shown in Figures 7–9. All three figures are build-up in the same way: Number of cycles is plotted on the abscissa and cumulative probability on the ordinate. The scaling of the abscissa varies in different figures.

In Figure 7 measurements (no. 5–no. 12) of fibre type A are presented in order to discuss the influence of all parameters of the tests.

At first, the influence of the frequency shall be discussed. For this purpose, four pairs of measurements with constant stroke and weight and varying frequency, are available in Figure 7. The red and blue curve (fibre no. 5 & 7) or the dashed green and dashed black curve (fibre no. 10 & 12) serve as an example for the characteristics of the frequency influence of all measurements. It can be observed that the variation of the frequency between one and two Hertz has no influence on the trend of

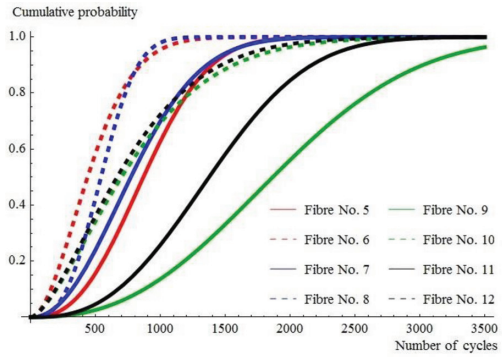

Figure 7. Results of flex abrasion test of all measurements of fibre type A.

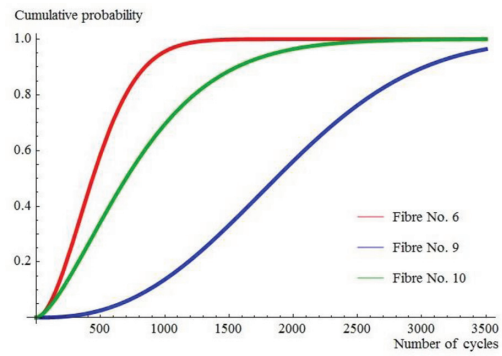

Figure 8. Influence of the weight and stroke on the measurements.

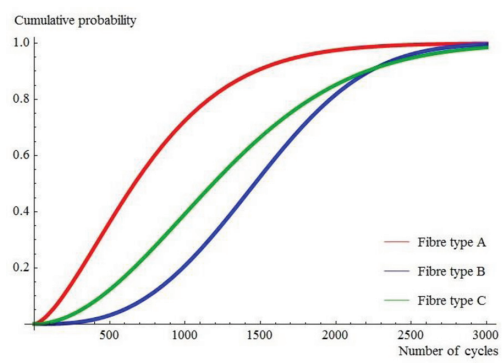

Figure 9. Influence of different types of fibres.

the curves (curve pairs mentioned above are nearly congruent). To confirm this statement, an analytical calculation with assumption of linearity of the movement acceleration has been performed. The result was considered in form of rate of the origin

Table 2. Impact of weight and stroke—setup and results.

No.	Stroke [mm]	Weight [g]	x_{min}	x_{av}	x_{max}	s_{min}	s_{av}	s_{max}
6	10	20	355	474	593	219	281	395
9	4	10	1553	1909	2266	657	845	1185
10	4	20	559	803	1046	447	576	808

force acting on the fibre by a weight of 20 grams to the force caused by the acceleration. The increase of the frequency from one to two Hertz causes a force change of about 2%.

For a remarkable difference of the results, the frequency would have to be increased into a level which is already out of the specification range of the test facility.

Figure 8 shows the impact of the stroke and the weight on the reliability of the fibres. For the comparison of the parameters adjustment and results Table 2. The presented results are in form of the arithmetic mean (x_{av}) with its confidence interval consisting of lower and upper confidence bounds (x_{min} & x_{max}) as well as the variance (s_{av}) with the confidence interval (s_{min} & s_{max}).

By the systematic analysis of the curves in Figure 8 and numerical results in Table 2, it can be observed that fibre no. 6 reached the lowest and fibre no. 10 the highest number of cycles. Therefore, the corresponding weight and stroke setup of fibre no. 6 causes the highest loss of reliability. Furthermore, the increase of the weight causes remarkable higher difference in the results than the increase of the stroke. In spite of the increase of the stroke, the upper bound of the confidence interval of fibre no. 6 is still higher than the lower bound of fibre no. 10. As a consequence, the visualisation of the distribution models is different, but statistically not significant. The influence of the fibre type on the reliability is shown in the Figure 9. It can be noticed that the fibre type A reaches the lowest and the fibre type C the highest number of cycles. All the fibres were tested by the same setup of the testing parameters.

6 SUMMARY AND OUTLOOK

This paper shows results of a research work with regard to an approach for the analysis procedure of prototype test results, based on heterogeneous prototype characteristics and small data volumes within the early phase of product development. The research activities were applied within a case study "Organic fibre prototype analysis" out of the chemical process industry. The goal is the analysis of reliability parameters of heterogeneous fibre samples. The analysis of fibre characteristics (e.g. centre, dispersion, trends) and interdependences were done with the use of nonparametric as well as parametric statistical methods. Main results are:

1. 93% of the fibre samples can be fitted by using Weibull distribution models in a sound way.
2. Thickness of fibres has no impact regarding to the reliability parameters within the analysed range of number of load cycles.
3. Variation of frequency within the range of 1 Hz–2 Hz has no impact regarding the reliability parameters.
4. The length of stroke has a significant impact in comparison to the weight load.
5. The arithmetical differentiation of reliability parameters between fibre types A to C is feasible in spite of small sample sizes and heterogeneous data.
6. The facility adjustment for the maximal differentiability for further prototype tests.

The used approach shows that the structured combined application of nonparametric as well as parametric statistical methods is successful. The transfer of the approach to similar technical problems is feasible. Next steps of research work will be the analysis of chemical treatment and their impact on fibre reliability parameters.

ACKNOWLEDGEMENTS

The author thanks Doris Oberkobusch, Detlef Fischer and Andreas Kirch (all Henkel AG & Co. KGaA) for their support with regard to fibre information and support of test procedure as a basis for our research work.

How to present and understand uncertainty of production assurance analyses with respect to data quality

C. Persskog-Lundtofte, S. Isaksen & L.M. Pedersen
Safetec Nordic AS, Oslo, Norway

ABSTRACT: Production assurance analyses of production systems include reliability data such as failure rates and repair data. Often the available data from reliability data sources are poor with respect to population or not existing when searching for reliability data of a specific component of the production system. As a consequence, a more generic data set is applied, which might not be relevant for the component since the data set might contain data from components that are constructed differently or operate differently. These two issues are typically conflicting and the challenge is to find a proper balance. Results commonly produced from Production assurance analyses, like system production availability and component criticality, depend heavily on the reliability data which have been used as input. Reliability data used in such studies are typically listed in a report, but without further discussion or evaluation of data quality. This paper proposes a simple and practical method of understanding and presenting the uncertainty related to these quality aspects, which involves evaluating and ranking components with respect to data quality. This paper also discusses how to analyse the effect of reliability data quality on the production assurance analysis results.

1 INTRODUCTION

In production assurance analyses, also called Reliability, Availability and Maintainability (RAM) analyses, the performance of a production system can be measured and form a basis for decisions that can increase profit through reduced downtime and reduced operations and maintenance cost.

Typically, a flow network as a representation of the production system and its components combined with Monte Carlo simulation utilizing the discrete event simulation technique is used to generate the results of a RAM analysis.

These analyses have been performed for production systems in the oil and gas sector for about 30 years and an industry standard, ISO 20815, describing the methodology has been established. Even though this standard gives the industry the clarity and precision required to be able to carry out high quality analyses, some have pointed out (e.g. Aven & Pedersen (2014)) that there still is confusion in the industry concerning how to represent and treat uncertainties with respect to production assurance analyses. Aven & Pedersen further present a framework on how to understand and present these uncertainties in practical production assurance analyses.

This paper follows the lead of this framework but focuses in detail on uncertainty factors related to quality in reliability data. Results commonly produced from production assurance analyses, like system production availability and component criticality, depend heavily on the reliability data which have been used as input. Reliability data used in such studies are typically listed in a report, but without further discussion or evaluation of data quality. The purpose of this paper is to propose a simple and practical method of understanding, presenting and treating the uncertainty related to quality of reliability data.

Section 2 presents and discusses quality aspects of reliability data. Section 3 discusses the effect of data quality on the results of a production assurance analysis. In Section 4, a case study is introduced which presents an example of how to understand and present the uncertainty related to data quality aspects in a simple and practical way.

2 DATA QUALITY

2.1 *Definition of high-quality data*

In ISO 14224 high-quality data are defined to be characterized by the following:

1. Completeness of data in relation to specification;
2. Compliance with definitions of reliability parameters, data types and formats;
3. Accurate input, transfer, handling and storage of data (manually or electronic);
4. Sufficient population and adequate surveillance period to give statistical confidence;
5. Relevance to the data user's need.

In ISO 20815 it is stated that selection of data should be based on the following principles:

1. Data should originate from the same type of equipment and, if possible, originate from identical equipment models.
2. Data should originate from equipment using similar technology.
3. Data should originate from periods of stable operation, although early-life or start-up problems should be given due consideration.
4. Data should, if possible, originate from equipment that has been exposed to comparable operating and maintenance conditions.
5. The basis for the data used should be sufficiently extensive.
6. The amount of inventories and failure events used to estimate or predict reliability parameters should be sufficiently large to avoid bias resulting from "outliers".
7. The repair and downtime data should reflect site specific conditions.
8. The equipment boundary for the originating data source and analysis element should match as far as possible (study assumptions should otherwise be given).
9. Population data (e.g. operating time, observation period) should be indicated to reflect the statistical significance (uncertainty related to estimates and predictions) and the "technology window".
10. Data sources should be quoted.

Based on these definitions of high-quality data and statements of what principles selection of data should be based on, the need for a practical method to evaluate quality of reliability data has been identified.

2.2 *Data quality aspects*

When choosing reliability data for a component one often needs to compromise between two aspects of data quality; relevance and population, see Point 4) and 5) of the ISO 14224 definition of high-quality data. A more generic data set has a larger population but is less specific and the data set might contain data from components that are constructed differently or operate differently and therefore are less representative.

The authors of this paper are not aware of any standard which classifies relevance and population of reliability data. There may be many opinions about e.g. which factors are important when defining relevance of data and what a large data set is. The examples in the next subsections are merely suggestions.

2.2.1 *Relevance*

One can set up a scale of relevance with grades of Low, Medium and High with respect to the principles from ISO 20815 stated in chapter 2.1. This classification of relevance is a difficult exercise and must be done by people who understand both the equipment in the system to be analyzed and the equipment from which historical data is obtained. It is not feasible to come up with general criteria for classification into e.g. High, Medium and Low relevance of reliability data which is valid for all industries and equipment. For instance, the first principle for selection of data in ISO 20815 is about the "same" type of equipment, but this is not clearly defined. In ISO 14224, "equipment type" is defined for many equipment classes, but it is difficult to generally classify data from the same equipment type with certain relevance. For instance, pump types include centrifugal, reciprocating and rotary. But one can still argue that data for small centrifugal pumps in a chemical injection system are not very representative for large crude oil export centrifugal pumps.

There are other factors than the general design which should determine if equipment is of the same 'type' or not. Which factors are the most relevant may vary from one equipment class and industry to another. Manufacturer, size, design power, design pressure, design temperature, etc may have different significance and uniqueness in different cases and it is up to experts to use their knowledge of these factors to classify the relevance of the available data.

Other criteria related to relevance like operating and maintenance conditions must also be taken into account. The first principle of data selection in ISO20815 also mentions identical equipment models. If this is the case and operating and maintenance conditions also are the same, the relevance is obviously high. However, usually the data source contains a mix of many different equipment manufacturers and models which are unknown. It is rather the exception that the analyst has access to much data for the one particular equipment model of interest. If this condition is not fulfilled, it can be argued that relevance may still be high if equipment can be defined as similar based on other factors.

When only low relevance data (or no data) are available, it is recommended to perform an Failure Mode, Effect and Criticality Analysis (FMECA) to identify possible failure modes and have experts giving their views on the likelihood of these failures occurring.

2.2.2 *Population*

In order to calculate the reliability of equipment, information regarding the number of failures, the surveillance (or operational) time and the age of the equipment at the time of failure is required. The latter is only relevant if another lifetime model than the exponential is used. In order to have a solid basis for calculating the failure rate, there

should be a lot of failures. This is the paradox of reliability data; the analyst wants failures whereas the operator does not.

There may be large differences in the failure rate for different equipment classes. If a certain number of failures is required before the data quality in terms of population can be graded with 'high', the surveillance time of reliable equipment must generally be longer than the surveillance time of unreliable equipment. Perhaps data collection on non-pressurized tanks would require thousands of equipment years in surveillance to give an amount of failures to establish high quality data, while data collected for only one large compressor over a few years would give the same quality.

For the non-pressurized tank, the total surveillance time would be a better indicator of data quality. If this is large and the failures few, it only means that reliability is high. For the compressor, failures are more frequent, and a sufficiently high amount may be reached long before surveillance time equals that of the tanks. 'Sufficient' in this case expresses the amount which gives the analyst confidence that the lifetime distribution derived from the data is suitable and accurate for predicting the reliability of similar equipment. Hence, depending on the equipment class, there should be a balance between total surveillance time and amount of failures.

In case of no observed failures there are several Bayesian methods to estimate the failure rate, for instance using a non-informative prior.

Grading into e.g. high, medium and low may in this case be purely quantitative. The following scale is suggested:

- High quality: Total surveillance time > 100 years OR Total number of failures > 20
- Medium quality: Total surveillance time > 30 years OR Number of failures > 6
- Low quality: None of the conditions above are met.

Dependent and cascading failures should not be counted when comparing the amount with the criteria.

It should be noted that the classification above is merely a suggestion. When grading reliability data from high to low quality with respect to population, it is suggested to apply a scale which is relative to the amount of data that is generally available in the industry. This scale is suggested based on experience and available data in the Norwegian oil and gas industry.

When speaking about data population, one would perhaps think of the amount of components, rather than the amount of failures or surveillance time. The total surveillance time is calculated as the number of equipment units multiplied by their average surveillance time. So when the criterion for high quality is more than 100 years, it refers to so-called equipment-years. The amount of equipment units is not included in the suggested grading, since the difference in quality of data based on e.g. 10 equipment units observed for 10 years each or 50 equipment units observed for 2 years each depends on the context.

When the purpose is to undertake lifetime analyses, a longer surveillance time per equipment unit may be preferred. In other circumstances, a higher amount of equipment units may be preferred. For instance with a dataset containing little information, it is not known to what degree it is homogeneous. In that case, as many different equipment units as possible may be preferred to cover the variety and not have biases in one direction or the other. If a non-homogeneous data set is the only data available, the variance in the empirical data is used in the predictions to express uncertainty of the time to failure due to low quality data as described in Section 3.3.

2.2.3 *Availability of information*

Point 1), 2) and 3) of the ISO 14224 definition of high-quality data relates mainly to quality properties to be ensured in the data collection process, rather than relevance or population. Even though ISO 14224 is a standard which is written to ensure these properties when followed, mistakes can be made during the data collection process. It can therefore be beneficial for data quality improvement to assess the basis of the reliability data at hand, such as the registered failure events and make adjustments if needed.

Another aspect is the availability of this information regarding boundaries, definitions of failure, etc. Many data collection projects do not follow ISO 14224. They may or may not make accurate definitions and guidelines for data collectors to follow and if they do, these may not be transparent in a data handbook with "processed" reliability data in the form of e.g. failure rates.

If failure rates on e.g. gas turbines are used as input in a study, are the definitions associated with the data source clear? What are the defined boundaries of the gas turbine? Are failures on the Waste Heat Recovery Unit (WHRU) included in the failure rate? Are trips due to excess of specified operational parameters defined as gas turbine failures and included? Obviously, the answers to these questions influence the failure rate. Unfortunately, several data sources are not clear on these points and rely on the analysts to define gas turbines and gas turbine failures the same way as the data collectors.

The result of lack of information of this kind does not reduce the relevance of data, but the *uncertainty* about the relevance of data. Hence, the amount of information regarding definitions associated with the data becomes an important quality

aspect as well. Again it may be difficult to establish general criteria to classify the amount of information as high, medium or low. However, relevance of data cannot be classified as high, if there are large uncertainties about the data set, and many of the factors defining high relevance are unknown.

The whole process of data collection involves several steps, where each can lead to loss of information. This is illustrated in Figure 1. The information loss can be due to limitations in information systems or wrong interpretations, errors when recording information, etc. Normally the information about equipment attributes or failure events is not recorded for the purpose of reliability analyses in the first place. People recording this information do not have that objective in mind and often little knowledge about reliability data and analyses in general. This will often result in manual work by the data collector to covert information into a reliability data format like e.g. ISO 14224. Spelling mistakes and similar can always be identified and corrected with proper quality assurance at several stages in the process, but established formats is more difficult to change.

Also, it is quite common that the interpretation and analysis of raw data is not done by the person applying the data for a reliability study. In many cases, access to the database itself is restricted, and analysis, handling and organising of data are done for publishing in a reliability data handbook, which is the only access the analyst has. Such a handbook of processed data will typically lack a lot of the information available in the raw data.

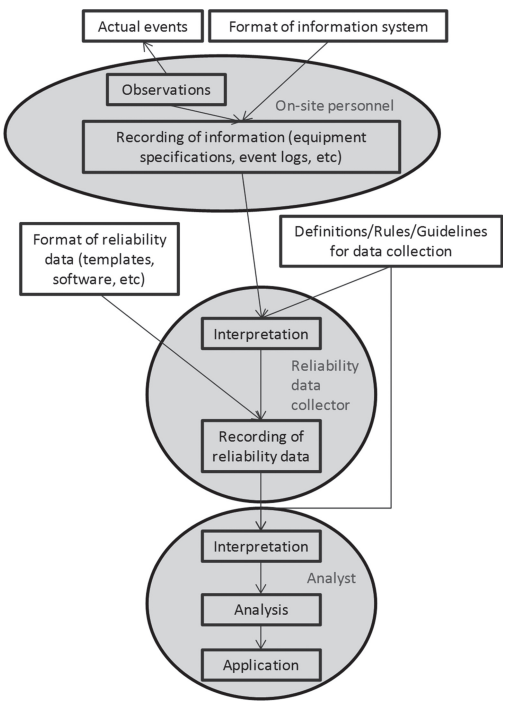

Figure 1. Illustration of data collection process.

2.2.4 *Maintenance data*

As reliability data is discussed and evaluated in terms of quality, it is important not to forget maintenance data, since availability depends on both. Maintenance data or downtimes tend to get less attention because it is often excluded from reliability data handbooks or other sources. This exclusion is justified by the argument that generic data are not useful since the downtimes are plant-specific and dependent on different maintenance strategies, as stated in data quality principle 7 in ISO 20815.

The quality of these data, however, is just as important. To evaluate the quality, however, may be more difficult since they are often given as expert judgment. Also, the downtimes may consist of several factors such as run-down, diagnosing, mobilization, active repair and ramp-up. Each of these factors may be of various quality even though they are given by the same expert, since some downtime-related activity may be harder to predict than others.

3 EFFECT OF DATA QUALITY ON RESULTS

In almost every reliability analysis, the reliability data are one of the main uncertainty factors due to lack of quality. This results in a certain lack of confidence in the prediction which has been made. This section discusses how to possibly manage such uncertainties. There are different topics to discuss as there is not one solution. In general, the best way to handle uncertainties related to lack of quality reliability data depends on the purpose of the analysis. When the goal is to prove that the production availability reaches a certain target, it may be useful to reverse the traditional analysis and investigate what reliability parameter values are required to reach it. Then, by comparing those with the actual data at hand, one may evaluate the degree of confidence in those values representing good predictions.

If the purpose is to compare different designs solutions, perhaps the main focus should be on the components which are different from one design to another, and especially those with low quality reliability data. By e.g. sensitivity analyses as described later in this Section, the influence of different parameter values can be evaluated and compared for different concepts.

Knowing that the results are heavily influenced by the reliability data which are used in the study, it

would be useful to obtain more detailed knowledge about this effect. New and improved information about reliability would change the results, but the question is if that change can be quantified. If so, it would help the analyst to know which data are more crucial to improve.

In any case it is important to address and not avoid the problem. It may be tempting to leave the result without highlighting the data quality issues. It is better, however, to evaluate the effect of low quality data on the results and identify the components where data quality improvement is the most crucial.

3.1 *Importance measures*

Component importance measures are commonly used to quantify the impact of one component on the system availability. Applying importance measures would thus seem the appropriate solution to the problem of evaluating the impact of low quality data on the results. Unfortunately, things are a bit more complicated than that. There are many component importance measures, but they are all functions of both the component's structural position in the system and its availability. When there is large uncertainty associated with the component's availability due to low quality data, there will also be large uncertainties in the component importance results. In other words, when the availability changes, the importance of the component also changes.

A possibility could be to temporarily ignore the availability and only consider the criticality given the structural position in the system. This can be found by e.g. assigning equal availabilities to all components and then apply an importance measure. No component can be more critical than the ones which are in series with the rest of the system. These are often present in production systems and will thus always end up with the highest criticality when differences in availability are ignored. In that case it is easy to determine which components should be prioritized when it comes to obtaining improved reliability data.

There are several challenges still. Sometimes, the only way to obtain better data is to start a new data collection campaign. This may take time, and perhaps decisions which the analysis influences need to be taken quickly. Also, by ignoring the availability to obtain component importance results one may get a wrong impression of the priorities. Even though there is uncertainty about the lifetime distribution of a component, one would usually have an idea about which components are more reliable and which are less reliable. For instance, one may have a system with a storage tank in series with the system and connected with two redundant offloading pumps, all with low quality reliability data. When availability is not considered, the tank is much more critical for production, but even with low quality data, most analysts would agree that it also is much more reliable than the pumps. So it cannot easily be concluded that obtaining high quality data for the tank is more crucial. Hence, applying importance measures for this purpose should always be accompanied by sound judgment.

3.2 *Sensitivity analysis*

Sensitivity analyses can be performed on parameters in a lifetime distribution, and will in that case be related to the component importance measures as they in essence evaluate the effect of changes in the component availability. The advantage of sensitivity analyses is that they provide more flexibility where the analyst can experiment with different specific parameter values. These may for instance represent failure rates from different data sources. Or one may define a range covering what is perceived as the most realistic values and plot a graph showing the system availability as a function of component availability within that range.

Sensitivity analyses are very simple. As long as a model is established, the calculations or simulations are just repeated over again for different parameter values. As new results are produced, one can observe the effect of the change in the parameter value. Whenever Monte Carlo simulation is used as the calculation method, a possible disadvantage with sensitivity analysis is the additional simulation time. Depending on the duration of the initial base case simulation, the extra time required for sensitivity analyses may be an issue, because one parameter change requires one additional full simulation.

3.3 *Lifetime distributions*

There are many methods to fit empirical failure data to a probability distribution function. That distribution is typically also used in the predictions, i.e. the variation in empirical data represents the uncertainty in the prediction. However, with little data, the exercise of fitting them to a distribution is difficult. With e.g. only two failure records at times t_1 and t_2, there can be no good fit. For equipment in the oil and gas industry with regular preventive maintenance, it is common to assume that the time until a failure follows the simple one-parameter exponential distribution. That way, all which is needed is finding the λ parameter by dividing the number of failures by total surveillance time.

If data quality is low, one may want to reflect the high uncertainty in the predictions with high variance. For a given mean, the variance in the exponential distribution is also given. Hence, another distribution with higher variance might be appropriate. However, sometimes the analyst

may be convinced that the exponential model is suitable without having good quality reliability data, just because e.g. similar type equipment with more data shows this trend. The dilemma is then what failure rate, λ to use. If the data consist of only one component observed for 5 years with two failures, the assumption of an exponential distribution yields $\lambda = (5/2 = 2.5)$. A confidence interval for λ is given by the Chi square distribution (See Ross 2009). A 90% confidence interval gives $[1.1 < 1/\lambda = MTTF < 14.1]$.

There is obviously a very large difference between a failure every year and every 14 years. The large spread in the confidence interval makes it difficult to be confident about 2.5 being a good predictor for the future failure rate, when only based on these data. One possibility is to perform sensitivity analyses as discussed, where a best case and worst case is calculated in addition to the base case, and where certain percentiles of λ are used. But if there are many components with low quality data, there may be too many sensitivities to keep the overview of all the results.

Another possibility is to express the parameter(s) with a distribution function. In the exponential case, the λ can first be generated from a Chi square distribution and then the failure time generated from the exponential distribution based on this λ. This is a quite common approach but one needs to be careful with the interpretation as it is important to understand the difference between the history (empirical data) and the future (predictions). The traditional interpretation of this distribution is that it represents the uncertainty of λ, as if there were a true or correct value. Aven (2009), however, emphasises the subjective nature of predictions and advocates the interpretation of λ as the analyst's degree of confidence in λ being a good predictor for the failure time. The outcome of this model is therefore nothing but a representation of the analyst's uncertainty regarding the time of failure due to low quality in historical data.

4 A CASE STUDY

4.1 *General information*

The case study is based on a production assurance analysis of an offshore oil production system in the Norwegian oil industry. The production system is considered to be representative for a typical topside oil production system with regards to design, production critical subsystems and components. One of the objectives and focus in this case is to provide decision support for several power generation/supply alternatives:

1. Two turbine driven generators
2. One larger turbine driven generator
3. As case 2 but with additional combustion chamber, HRSG and steam turbine
4. Power from shore.

A number of components modeled in the analysis have been selected to be assessed with regards to the quality of their reliability data as described in section 2 of this paper.

4.2 *Reliability data*

Part of the data dossier of the components in the study is presented in Table 1. The data in the case study are comparable with data from typical reliability data sources in the oil and gas industry which follows ISO 14224 during the data collection process.

4.3 *Data quality assessment*

A data quality assessment was carried out and each component's data source was graded with High (H), Medium (M) or Low (L) with respect to relevance and population. The result of the data quality assessment is presented in Table 2.

The scale presented in Section 2.2.2 has been used to score the data sources with respect to population. Relevance has been scored with respect to the author's knowledge of the data sources and the analyst's knowledge of the components in the system which has been communicated to the analyst through meetings and technical documentation.

A more graphical representation of the data quality result, which shows the distribution between population and relevance with reference to the component IDs is presented in Table 3.

Table 3 shows that the most critical components with respect to data quality are components with ID: 3, 4, 5, 7 and 10.

As shown, a large generic data set of centrifugal pumps has been chosen to represent specific groups of components due to lack of more relevant data.

Further, a more specific data set with low population has been chosen for the heating medium circulation pumps.

There were no specific Waste Heat Recovery Unit (WHRU) data found, only Heat Recovery Steam Generator (HRSG) which is a type of WHRU generating steam and is present for one of the power alternatives. However, two of the other alternatives include one or two WHRUs which are made for water heating and therefore a different type. Hence WHRU data have low relevance.

The submarine power cable data (12) are highly relevant as the source contains the exact same cable type and the population is barely on the "medium" level. Normally, the argument would be that there is enough evidence of a high reliability with only two failures in 35 years. However, since the downtime is expected to be very high compared to other equipment on the platform, a change in the data may have

Table 1. Case study reliability data.

Component	Nr. of failures	Surv. time (years)	Data source categorisation
Inlet heater	12	111,5	Heat exchangers—shell and tube
1st stage separator	59	535,8	Vessels—separator
Gas injection discharge cooler	11	55,1	Heat exchangers—plate conventional
Heating medium circulation pumps	1	12,0	Pumps—centrifugal—cooling systems
Produced water recycle pump	210	370,0	Pumps—centrifugal
Foam inhibitor pump motor	2	50,0	Electric equipment—electric motors—pump-chemical injection
Seawater lift pump	210	370,0	Pumps—centrifugal
Gas turbine	175	43	Gas turbines—10–50 MW
Electric generator	12	34	Electric generator—turbine driven
Waste Heat Recovery Unit (WHRU)	287	784	HRSG—combined cycle plants
Heat Recovery Steam Generator (HRSG)	287	784	HRSG—combined cycle plants
Submarine power cable	2	35	Submarine power cables-AC—XLPE type—60–219 kV

Table 2. Result of data quality assessment.

		Data quality	
ID	Component	Relevance	Population
1	Inlet heater	M	H
2	1st stage separator	M	H
3	Gas injection discharge cooler	L	M
4	Heating medium circulation pumps	M	L
5	Produced water recycle pump	L	H
6	Foam inhibitor pump motor	H	M
7	Seawater lift pump	L	H
8	Gas turbine	M	H
9	Electric generator	M	H
10	WHRU	L	H
11	HRSG	M	H
12	Submarine power cable	H	M

Table 3. Graphical representation of data quality assessment.

	Relevance		
Population	Low	Medium	High
High	**5, 7, 10**	1, 2, 8, 9, 11	
Medium	**3**		6, 12
Low		**4**	

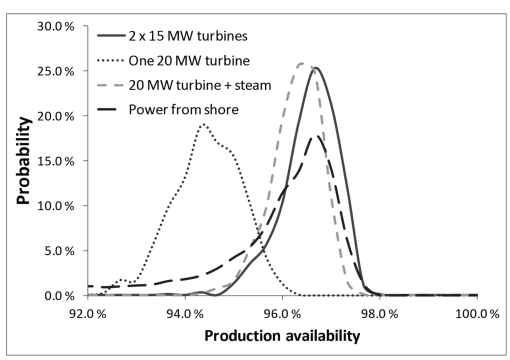

Figure 2. Production availability results.

high impact on the results. Because of this expected high sensitivity and the fact that the population is close to fall in the "low" category, the power cable should be subject to extra attention as well.

If it is desired to improve the data quality of the data dossier of this production assurance analysis, one should focus on these components and data sources.

4.4 *Effect of data quality on results*

The production availability results for the four power alternatives are given in Figure 2. Since we know that these results in part are based on low quality reliability data, it seems appropriate to evaluate the effects of this uncertainty factor.

Many of the components in Table 3 with low relevance or population are common for all 4 power alternative cases. Instead, the study focused on the components with low quality data which were not common for all 4 cases, namely the Waste Heat Recovery Unit (WHRU) and the submarine power cable. The power cable is only included in Case 4 and the WHRU in Cases 1 and 2 as listed in Section 4.1.

Component importance results were already present as part of the output from the initial calculations. The submarine power cable was the most important of all components in the system, according to the applied measure. The WHRU had little importance in Case 1 (2×15 MW turbines) due to redundancy but somewhat higher importance in Case 2 (single 20 MW turbine). It was then decided to run sensitivities on WHRUs as well as submarine power cables to evaluate the effect of different parameter values for the time to failure.

Experts were brought in who agreed that the WHRU generally should be more reliable than the HRSG. Hence, the data assigned to the WHRU could be regarded as "worst case". Improving WHRU reliability could only benefit Case 2, but running sensitivities for higher WHRU Mean Time To Failure (MTTF) values only yields a very marginal improvement.

It was more difficult for experts to agree on the reliability for submarine power cables. Hence it was decided to look at chi square quantiles as discussed in Section 3.3. Instead of generating chi square distributed lambdas in the simulation, sensitivities were run for different quantiles, where the lowest and highest values used were the 5% and 95% quantiles, respectively.

Figure 3 plots the mean system availability as a function of submarine power cable MTTF.

It seems from the graph that the system is quite sensitive to changes in the submarine power cable MTTF. Using the base case value for MTTF of power cable, Case 4 results are quite similar to Case 1 and Case 3 in terms of mean system availability. But varying the power cable MTTF, Case 4 may also be significantly better or worse. Due to this and the already existing heavy left tail seen in Figure 2 due to the long downtime, Case 4 (power from shore) represents a more risky alternative for better or for worse. This is important information for a stakeholder and would not have been highlighted in a more traditional approach without data quality assessments and sensitivity analyses.

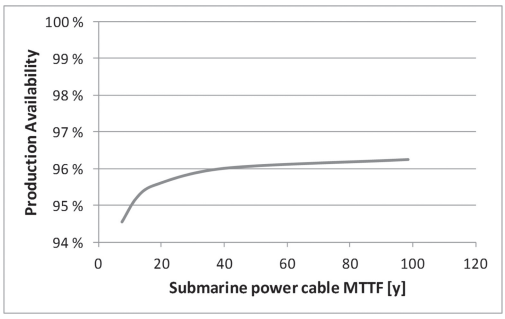

Figure 3. Case 4: System availability as a function of submarine power cable MTTF.

5 CONCLUSION

Results commonly produced from Production assurance analyses, like system production availability and component criticality, depend heavily on the reliability data which have been used as input. Reliability data used in such studies are typically listed in a report, but without further discussion or evaluation of data quality. This paper has proposed a simple and practical method of understanding and presenting the uncertainty related to data quality aspects, which involves evaluating and ranking components with respect to the population and relevance of their data source. This paper has also discussed how to analyze the effect of reliability data quality on the production assurance analysis results.

The case study has demonstrated how evaluating quality and performing additional analyses give a broader picture of the expected system performance. It is by no means giving definite or simple answers which give the stakeholders obvious choices as this is impossible with low quality data. Hence, presenting results as one correct answer obscures inevitable uncertainties and may lead to bad decisions because they are based on less information than they could have been. By evaluating the quality of the data and the impact on the results, uncertainties, which should be an important part of the decision making, become more visible.

Universal method of battery life prediction

Y. Hanyu, T. Yamamoto, T. Ezawa & A. Itakura
Systems Engineering Laboratory, Toshiba Research and Development Center, Japan

ABSTRACT: Grid-connected Lithium-ion Battery based Energy Storage Systems (LiB-ESS's) must maintain strict safety and reliability standards for more than 15 years. However, predicting the lifespan of LiB-ESS's has been a difficult task, since the cells inside usually contain battery cells supplied by third-party manufacturers. Especially, the lack of detailed information on chemical composition and aging behavior of such battery cells pose a problem in quantifying reliability and establishing maintenance schemes. Therefore, a universally applicable cell diagnostic and life prediction method is highly desirable.

1 INTRODUCTION

The utility-scale Energy Storage Systems (ESS's) market is set to expand to more than 6 GW in 2017 to accommodate more intermittent power sources such as wind and solar. Among such ESS's, on lithium-ion secondary battery (LiB) based systems are expected to play a key role. This is because high capacity and voltage (hence, high energy density) and versatility in scales and layouts makes LiB-ESS's an attractive option for integration in existing facilities. In the meantime, the system requirements span safety, reliability, long mean-time-before-failure and system life for building-integrated systems. For the system life, technical recommendations issued by Electric Power Research Institute gives a typical figure of 10 years or longer (Rastler 2010).

To date, correctly predicting the lifespan of LiB-ESS's, or even estimating the remaining battery lifetime has been a formidable task, since the component cells often come from third party sources and information on chemical composition and aging behavior is not always available. This is because such data is often directly linked to manufacturer's market competitiveness, but at the same time, the unavailability of data would pose a problem in quantifying reliability, predicting battery life and establishing maintenance schemes. Ideally, we must have a universal method that does not rely on classified information. Therefore, we have developed a universal method of LiB life prediction based on differential capacity versus potential (dQdV) profiles that are obtainable from routine charging. Since the method does not use any classified information, it can be applied to any LiB-ESS systems.

The peaks on dQdV profiles are usually associated with certain chemical or physical processes. These peaks are known to exhibit high sensitivity toward slightest changes in the chemical state of battery electrodes, and any associated changes to the internal resistance upon aging (Wang 2010). The dQdV profiles are effective for fingerprinting batteries, but the same methodology can be applied to identify battery aging. In essence, our "universal method of battery life prediction" is fingerprinting of battery aging.

The method has three stages: initial battery aging experiment on the specimen cells to construct a database, then formulation of aging behavior, and then the actual evaluation and life prediction. Once the battery database is built by the end of second stage, the target battery model of any conditions—new or used, can be evaluated at will in the third stage, possibly as a commercial service.

2 METHOD

The charge-discharge (C/D) experiments were conducted in a MP-01 programmable temperature-controlled galvanostat/potentiostat (Fujitsu Telecom Network). Data analysis was conducted by Matlab software. Eight 30 Ah electric vehicle battery specimen cells were used for the experiment. 2 cells were tested for long-term storage test under increased temperatures. 6 cells were tested for continuous C/D cycling under different temperatures and current rates. The temperature levels were 35 degrees and 45 degrees, the C/D cycling depths were 50–90 and 10–90, and the electric current levels were 30 A and 90 A. The combination of these levels generated 8 combinations, but cycling experiment for SoC 10–90% at 30 A current was omitted due to logistical constraints. The experimental conditions are summarized on Figure 1 (Left). The current, voltage, temperature and cumulative charge in Ah were recorded at 1 s interval, which typically gave a potential profile consisting of ~3600 data points

Ch.	Temp.	Current	SoC Range
1	35°C	0 A	100%
2	45°C	0 A	100%
3	35°C	90 A	10-90%
4	45°C	90 A	10-90%
5	35°C	30 A	50-90%
6	45°C	30 A	50-90%
7	35°C	90 A	50-90%
8	45°C	90 A	50-90%

for one charge or discharge. The potential profiles were smoothed by taking a simple moving average over 20 points and dQdV profiles were derived. The dQdV parameters were found by fitting 5th-order polynomials to segments of dQdV profiles. Once the peaks were identified, other parameters such as peak height ratio, peak width, peak area and inflection points were calculated.

3 RESULTS AND DISCUSSION

Battery aging is a complex phenomenon with numerous inputs and outputs. However, there are essentially only two key performance indexes—capacity and power. Our method aims to predict the two key performance indexes.

The method starts with prior construction of a database for target battery model. The database contains a list of selected dQdV parameters sorted according to aging time and conditions. This puts a limitation that only commercially available mass-produced cells on the market can be evaluated by this method. On the contrary, the method is not limited to certain battery types or brands. Although the method's primary target is LiB's, it is potentially applicable to other batteries including Ni-H_2 and Na/NiCl.

3.1 *Parameterization of differential potential (dQdV) profiles*

In the first stage, a cell's aging behavior is parameterized by obtaining the time series of a changing dQdV parameter. This is achieved by subjecting multiple specimen cells to different aging conditions and periodically measuring the potential profile at different stages of aging. In our experiment, 2 cells were tested for long-term storage at 35 and 45 degrees. 6 other cells were tested for continuous charge-discharge (C/D) cycles under different controlled conditions. The variables were temperature, current rate, and the state of charge (SoC). Each had two variations as shown on Figure 1.

The collected potential profiles were re-drawn into dQdV profiles by plotting $(Q_n - Q_{n-1})/(V_n - V_{n-1})$ against V (Fig. 2). In general, dQdV profiles are highly sensitive. For example, any small changes to the voltage plateau in charge profiles appear as noticeable peak shift in the corresponding dQdV profiles.

On this plot, the highest peak near 4.13 V and peaks between 3.80 V and 4.05 V are thought to have their origins in Lithium Manganese Oxide (LMO) and Nickel-Cobalt-Aluminium oxide (NCA) cathode materials, which were also confirmed by spectroscopic methods (X-ray photoelectron spectroscopy and energy dispersive x-ray spectroscopy). The LMO peak near 4.13 V was virtually constant regardless of the state of aging, but the NCA peaks between 3.80~4.05 V exhibited a rapid decay over time. The assignment of peaks was confirmed by measuring the dQdV profiles of pure LMO-based cells and NCA-based cells.

In addition to peak heights and positions, inflection point, area, width and depth were parameterized, too. The inflection point $V_{MAX/5}$ was approximated as the point where the profile rises above 1/5 of the LMO peak height. In our specimen cells, the inflection point near 3.8 V ($V_{MAX/5}$) shifted to higher voltage in pace with aging. In addition, while the area (Q_{LMO}) on the right of LMO peak remained constant, area on the left (Q_{NCA}) has decreased (Fig. 2).

The fact that LMO is unmoving implied that V_{LMO} can be used as a point of reference. By taking the distance between peaks and features, one may take potential biases and electrical resistance out of the equation. In our example, this was achieved by measuring V_{rel} ($V_{LMO} - V_{MAX/5}$) instead of V_{LMO} and $V_{MAX/5}$. Another possible use of V_{LMO} is to determine if the cell is not fatally damaged. If V_{LMO} is found outside certain "normal" range (in this case, 4.11 V ~ 4.16 V), one may detect an abnormality for the cell and may halt its use for safety reasons.

Another notable finding was that changes in dQdV parameters often preceded capacity loss.

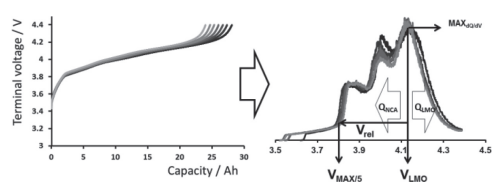

Figure 2. Conversion of charge profiles (left) into dQdV profiles obtained by plotting $(Q_n - Q_{n-1})/V_n - V_{n-1}$ against V. The peak heights, peak area and such are extracted as dQdV parameters (right).

A common practice is monitoring of battery capacity alone, but this may overlook the preliminary signs appearing in dQdV profiles regarding future capacity loss.

Many more parameters can be extracted from a dQdV profile, but choosing parameters showing good correlation to battery performance is crucially important. In our example, V_{rel} and Q_{NCA} were found to have strong correlation to capacity and internal resistance respectively (Fig. 3C and D). Polynomial fitting can be performed to parameters other than what is shown on Figure 3, but the criteria and methods for choosing the correct dQdV parameters is an ongoing work.

To establish a quantitative relation between dQdV parameters and battery performance, polynomials were fitted to the correlations. These polynomials have dQdV parameters as the input, and battery performance as the output. Once the polynomials are in place, it sometimes becomes possible to find the parameters from mere segments of a dQdV profile. For example, charging from SoC = 0% 15% would probably be enough to deduce V_{rel}, from which the cell capacity can be estimated.

It is a typical occurrence that two cells with the same charging capacity age at different rates in the future. Such difference is caused by difference in the battery's internal state, but they are not detectable by conventional method that measures capacity alone. For example, if two cells have 96% retention of the original capacity, but one cell's V_{rel} is found 10% lower than the other, we can conclude that the cell is about to start losing its capacity very soon. This has been otherwise indistinguishable.

3.2 *Formulation of battery aging in terms of dQdV parameters*

The second stage focuses on establishing an equation that has aging conditions and time as the input, and dQdV parameters as the output. Battery aging is a complex phenomenon involving electrolyte decomposition, formation of solid electrolyte interface, degradation of cathode materials and many other causes. Nevertheless, the complex phenomenon roughly divided into two large categories: aging due to time and aging due to current load. We hypothesized changes in dQdV parameters also consist of time contribution and load contribution. (Fig. 4) The aging conditions investigated in this study included temperature, State of Charge (SoC) and current rate, as their link to battery aging has been discussed many times in literature.

We have assumed a model shown on Figure 4A to describe the changes in dQdV parameters. The equation calculates the change for certain duration of time, and by recursively solving the equation and summing all results, the total change over a prolonged period of time can be found. The change due to time was labelled "CAL" and the change due to load was labelled "CYC". In this scheme, battery aging occurring under long-term storage condition would consist of only CAL element, and a under load would have both CAL and CYC element.

In our model, the CAL element consists of two functions, $F_{cal}(SoC_i)$ and $\exp(\alpha/T_i)$. The former depends on the SoC, and the latter depends on the temperature. The CYC element consists of three parts: The SoC-dependent $F_{cyc}(SoC_i)$, the temperature dependent $\exp(\beta/T_i)$, and the current-

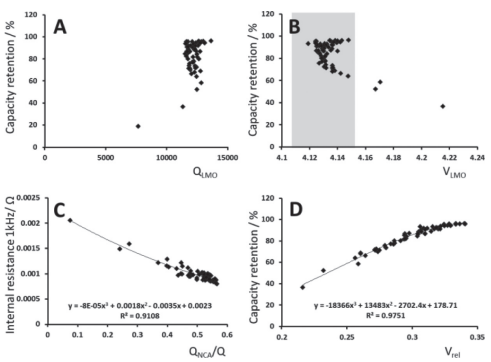

Figure 3. Correlation of dQdV parameters to battery performance—(A) The correlation between Q_{LMO} and capacity, (B) V_{LMO} (LMO peak position) as a diagnostic tool, with the green band showing the "healthy" or "safe" zone. (C) The correlation between Q_{NCA}/Q vs. internal resistance and (D) the correlation between V_{rel} and capacity.

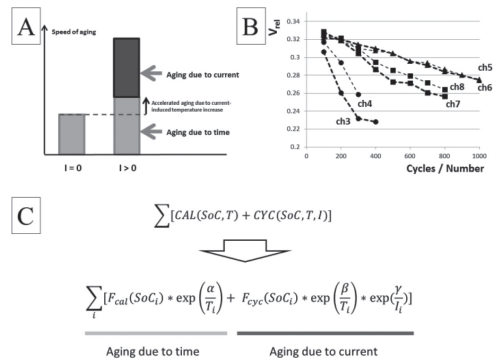

Figure 4. (A) The aging behavior of cells in ch 3–8, (B) the aging phenomenon divided into CAL and CYC, each corresponding to "Aging due to time" and "aging due to current". Each has different input variables. (C) The overall equation that estimates the progress of aging over a certain interval. In our case, the interval was set as 1 min.

dependent exp(γ/I_i). We have applied this model to explain two selected dQdV parameters—Q_{NCA} and V_{rel}, and found all coefficients by comparing the slopes between channels shown on Figure 4B.

The coefficients of CAL were found by first comparing ch-1 and ch-2, which had CYC = 0, for having zero applied current. First, coefficient α was found by dividing CAL of ch-1 by CAL of ch-2. Subsequently, the value of $F_{cal}(SoC_i)$ was found. The CAL contributions were calculated for ch3~8 and subtracted to single out CYC contributions for these channels. The CAL element found from this experiment appeared rather large, or in other words, aging due to time is grossly overestimated. This is an ongoing work.

First, the calculated CAL elements were subtracted from the graphs of ch3~ch8 of Figure 4(B) to highlight the CYC element and generate calibrated graphs for ch3~ch8. Then, γ was found first by dividing the calibrated slope of ch-7 by ch-5. Likewise, β was found from ch-7 and ch-8. Finally, $F_{cyc}(SoC_i)$ was found by dividing ch-3 with ch-7. Here, γ < 0, and Ii = "very small" when there was no current, so that CYC tended to zero when there was no current. Conversely, rapid aging was expected if I was large. The worked coefficients are shown on Figure 5. The equations deduced here are used in the third stage to predict Q_{NCA} and V_{rel}, and further, the battery performance.

Due to limited number of experiments, $F_{cal}(SoC_i)$ and $F_{cyc}(SoC_i)$ were assumed as stepped functions, but in reality, they are probably curved functions. More accurate functions can be found by performing aging experiments with a higher resolution of SoC, i.e., conducting long-term storage experiment at SoC = 10, SoC = 20, SoC = 30 and so on.

3.3 *Estimation of expected battery life*

The third stage is the operational phase. In this stage, cells of unknown state, whether new or old, are evaluated. The equations deduced in the first and second stages are used and future battery performance is predicted for evaluation. However, assumption of future battery usage and settings of the threshold of decision is at operator's discretion.

Figure 6 (left) represents one possible implementation format. In this implementation, the axes of this XY plane are capacity and internal resistance. The error margin is represented in terms of data point dispersion, and we can see that the result becomes less certain toward "2nd year." When a cell's capacity drops or internal resistance increases to a certain level, one may declare that the cell must be renewed. A typical threshold is 70% for electric vehicle batteries. In this example, we have assumed a typical commuter use of an EV—one round of charging and discharging every day.

Figure 6 (right) is the second form of implementation. This time, the axes are capacity and power. The "Power" here is defined as the cell capacity measured at high current rate. In this example, a cell enters the "red zone" (end of life or unsafe for use) if either the capacity drops below 10 Ah, or fast discharge capacity drops to below 10 Ah. Either case, one may decide to renew the cell.

The procedure for the third stage starts with acquiring the dQdV profile for the target cell. Then, the dQdV parameters are extracted and compared against the database. In our example, if V_{LMO} lay outside 4.11~4.15 V range, we can conclude that either the cell is unusable, or the measurement is incorrectly set up (Fig. 3). If the latter is unlikely, we can reject the cell as "not safe for use" or "end of battery life reached".

By setting the future battery usage conditions such as temperature of operation and charge-discharge patterns, the equations obtained in the second stage can be used to approximate how current dQdV parameters change into the future. Once the future parameters are estimated, the polynomials from the first stage (Fig. 3) are used to deduce the future cell performance.

In the first form of implementation, we made an assumption that probability distribution of battery performance expands according to a "Brownian motion". This expansion can be refined by increasing the number of experiments

$$\sum_i [F_{cal}(SoC_i) * \exp\left(\frac{\alpha}{T_i}\right) + F_{cyc}(SoC_i) * \exp\left(\frac{\beta}{T_i}\right) * \exp(\frac{\gamma}{I_i})]$$

Q_{NCA}		V_{rel}	
α	-4675.43	α	-5582.55
β	2009.426034	β	808.2075908
γ	-3.199074273	γ	-3.449673721
F_{cal}(SoC=90)	3.433095	F_{cal}(SoC=90)	17.00965
F_{cyc}(SoC=70)	2.32044E-07	F_{cyc}(SoC=70)	1.6305E-06
F_{cyc}(SoC=30)	9.4E-07	F_{cyc}(SoC=30)	4.5E-06

in the first stage to some statistically reliable number. Having more experimental samples in the first stage may also solve the problem of overestimated CAL element, which predicts excessively rapid aging in Figure 6 (Left).

In the second form of implementation, predicted battery performance is more expressly shown. The method was verified by comparing predicted battery performance before load, and the actual measured value obtained after the load. The battery used in this experiment was a "used cell", which underwent charging and discharging under the SoC range of 50–90 at 1 C (30 Ah) current rate for 500 times under 35 degrees environment. At this point, the cell's capacity was 25.959 Ah, and the predicted cell capacity by the 1000th cycle was 21.65 Ah. The cell was then cycled for additional 500 cycles. The cell capacity decreased to 21.002 Ah, which was a 3.1% less than the predicted value. At this point, the scheme of cell capacity prediction using dQdV profiles remains at the level of demonstration, and a statistical assessment of reliability is an ongoing work.

4 CONCLUSION

We have developed a universally applicable method of battery life prediction, which takes advantage of the high sensitivity of dQdV profiles to battery aging. The method quantifies dQdV profile shapes as parameters, and changes to the parameters are used to predict the future battery performance. The method predicts battery aging more accurately since dQdV profile analysis yields more information than simple tracking of capacity over time, which is a current common method. The predicted result can be used to draw a Ragone plot, or to optimize the maintenance scheme.

Reliability prediction of electronic boards by analyzing field return data

ABSTRACT: In this study, we perform field return data analysis of electronic boards. We cooperate with one of the Europe's largest manufacturers and use their well-maintained data with over 1000 electronic board failures. We follow two steps that are filtering the return data and modeling the filtered data with probabilistic distribution functions. In the first step of filtering we propose a new technique to eliminate improper data, correlated to incomplete and poorly collected data, from the whole field return data. In the second step of modeling, we use the filtered data to develop our reliability model. Rather than conventionally using a single distribution for all service times that does not accurately model the substantial changes of the electronic boards reliability performance over time, we use different distributions for different service time intervals. In order to determine the distributions we propose a technique that deals with forward and backward time analysis of the data.

1 INTRODUCTION

The rapid developments in electronics, especially in the last decade, have initiated the inception of electronics reliability (O'Connor & Kleyner, 2011). Conventionally used accelerated reliability tests have lost their significance; time consuming and expensive feature of these tests is against the demands of today's very *rapid electronic product cycles* (Pecht, 2010). This underlines the importance of using the product's field return data for reliability analysis that is relatively cheap and time saving (Kleyner & Sandborn, 2004; Wu, 2012). In this study, we propose a complete reliability methodology exploiting field return data of electronic boards.

Field return data can be used for variety of purposes that include the prediction of future claims, the estimation of field reliability, and the identification of opportunities for quality and reliability improvement. (O'Connor & Kleyner, 2011). If one assumes that the return data is error free then it is not difficult to claim that it is the most trustworthy data in analyzing reliability of a product compared to accelerated test or simulation based data. However, in reality field return data contains errors corresponding to improper, correlated, incomplete, and poorly collected data that result in misleading reliability predictions. In this study, we first deal with this problem. We propose a systematic approach to eliminate errors from field return data. We call this process of elimination as "filtering".

In the filtering process, we classify errors into two categories: obvious and hidden errors. Obvious errors are the errors that can be easily determined with applying one-by-one data check. Changing data orderings make this process even faster. Examples for such errors are unknown assembly dates, invalid time-to-failure values, and quality related errors. In contrary to the obvious errors, hidden errors and their probable sources cannot be directly determined from the data. Examples for hidden errors are significant changes in product manufacturing process, data loss, and inappropriate data recording in services. Hidden errors are fatal and overwhelm obvious errors in terms the number of occurrences. This obligates us to eliminate hidden errors before starting statistical analysis. In this work, we propose a new systematic approach to determine and eliminate both obvious and hidden errors. After eliminating the errors, now we have "filtered data" that is accurate and ready to be used in our statistical modeling.

In statistical modeling, the hazard rate of an industrial product is an important parameter especially for companies which have high volume products in the field. Additionally, hazard rate functions can directly be used for warranty forecasting. In this study, we mainly construct our model on hazard rate functions. In the literature it is well accepted to assume that the hazard

rate function of a product shows a bathtub characteristic. In general hazard rate models depict an entire bathtub curve as a combine of two Weibull distributions for early failure and wear out periods (Dhillon, 1999; Kececioglu, 2002). This is illustrated in Figure 1. Although the models using all regions of the bathtub curve are theoretically correct, they are not practically applicable to some industrial product groups with relatively long lives (Kleyner & Sandborn, 2004). Electronic boards, studied in this work, fall into these product groups. Electronic boards are expected to work at least 10–15 years with a warranty period of at most 5 years. This is illustrated in Figure 1.

In this study, we propose a model regarding early failure and useful life periods of electronic boards. Our model is based on Exponential and Weibull distributions among many other distribution options regarding the optimum curve fitting. Rather than conventionally using a single distribution for all time-to-failures that does not accurately model the substantial changes of the board's reliability performance over time, we use different distributions for different service time intervals. For this purpose we propose a new technique that deals with forward and backward time analysis of the data. In the fitting process we use "rank regression" and "maximum likelihood" methods.

The data used in this study (filtering and modeling analysis) contains assembly and return dates for each warranty call. Warranty period of the board is three years. The maintenance policy for electronic boards under this study is to replace the board with a new one in any suspected case such as stopping from time to time or breaking down entirely in the field. Therefore the analyzed data has no record of repaired boards. Throughout our analysis we benefit from Weibull++ by ReliaSoft Corporation.

The structure of this paper is as follows. In Section 2-Filtering, we describe the filtering procedure of field return data. In Section 3-Modeling, we work with the filtered data to develop our statistical model. Finally, Section 4 reports the conclusion of the work.

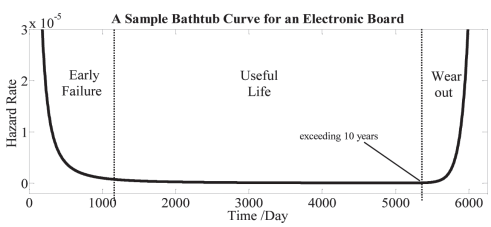

Figure 1. A bathtub curve—hazard rate function over time.

2 FILTERING

In order to guarantee accuracy of the analysis and eliminate errors, field return data must be filtered. For this purpose, we use a step by step procedure. In the first step, we filter obvious errors from the whole data. We filter data having unknown assembly date, data with quality failure records that result in zero time to failure (TTF), and data with negative TTF or unreasonable TTF.

In the second step which is the main target of this section we are dedicated to find and eliminate hidden errors. As it is mentioned before, obvious errors can be easily found by applying one-by-one data check. But, we cannot find hidden errors as direct as we find obvious errors. Here, a systematic approach is needed. By using Weibull++ ReliaSoft Corporation software we survey the consistency of the data and systematically investigate if there are hidden errors or not. We use 2 parameter Weibull distribution for our analysis because of being mathematically more tractable than other distributions (Reliasoft, 2014; Babington et al., 2007). Also using Weibull distribution to model reliability has long been approved in the literature. Maximum likelihood method (MLE) is selected for parameter estimation since regression methods generally work best for large data sets (O'Connor & Kleyner, 2011). In analysis, we deal with six month assembly time intervals. Selecting 6 month intervals is quite reasonable because we have 54 month return data.

The proposed methodology targeting hidden errors is as follows. We first perform forward analysis for 1–6, 1–12, 1–18, 1–24, 1–30, 1–36, 1–42, 1–48 and 1–54 month time intervals. This is illustrated in Figure 2. For example, 1–6 time interval represents products assembled in the first six months. Similarly, 1–42 time interval represents the whole data excluding the ones assembled in the last six months. In forward analysis we expand time window from left to right where the left edge is fixed. We then perform backward analysis for time intervals of 48–54, 42–54, 36–54,…,12–54, and 1–54. This is illustrated in Figure 3. Here, we expand time window from right to left where the right edge is fixed. Finally we perform analysis for seperate 6 month time intervals of 1–6, 7–12, 13–18, 19–24, 25–30, 31–36, 37–42, 43–48, 49–54. This is illustrated in Figure 4. Note that X-axes in figures represent assembly times (not TTF). As a result, using parameters of Weibull distributions of these three analysis, we filter improper time intervals corresponding to hidden errors.

We develop our filtering systematic mainly on a Weibull parameter β that explains the hazard rate function's behavior. If $\beta < 1$, it indicates a decreasing hazard rate and is usually associated with the early failure region. If $\beta \approx 1$, it means a constant

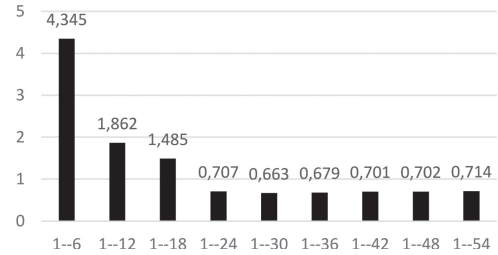

Figure 2. Beta (β) values for forward analysis.

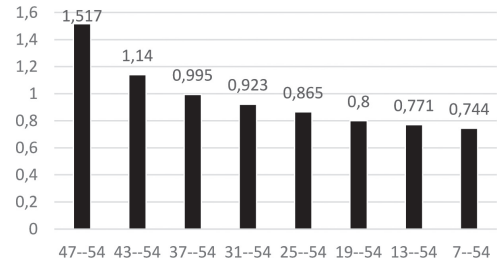

Figure 3. Beta (β) values for backward analysis.

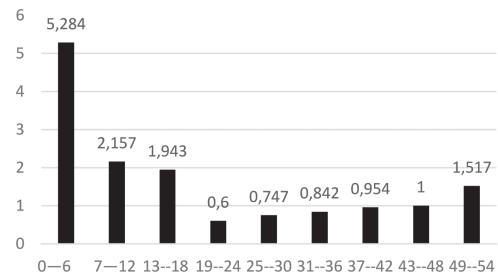

Figure 4. Beta (β) values for analysis of 6-month periods starting from the beginning.

hazard rate and is usually associated with the useful life region. If $\beta > 1$, it indicates an increasing hazard rate and is usually associated with the wear out region, corresponding to the end life of the product. As a reminder, the early failure, useful life, and wear out regions are illustrated n Figure 1. As follows we investigate Figure 2, Figure 3, and Figure 4 in details regarding β values.

Figure 2 shows β parameters of Weibull distributions for the forward analysis. Looking at β values we can derive that there are problems in the first 3 intervals 1–6, 1–12, and 1–18. These β values are greater than one, meaning that we are in the wear out region. This is impossible; the first 18 months of the field return data are suspected. Figure 3 shows β parameters of Weibull distributions for the backward analysis. Again, by looking at the β values we see that the last 6 months have $\beta > 1$. Here, we cannot come to a conclusion since we have insufficient data (sample size of 10) for the products assembled in the last six months. This low amount of sample size is not enough to perform accurate statistical analysis. Finally, Figure 4 shows β parameters of Weibull distributions for 6 month periods. If we look at β values we can derive that the first 3 intervals 1–6, 7–12, and 13–18 having $\beta > 1$ are suspected.

In conclusion, we should filter the first 18 months of the field return data corresponding to hidden errors. In other words, the products assembled in the first 18 months have insufficient field return data with hidden errors. Note that if we just performed backward analysis, we would not find any hidden errors. This could also happen for only performing forward or 6-month analysis for a different case. However, with performing backward, forward, and 6-month analysis together, as suggested in this study, we consider all aspects of hidden errors. We have now 36 month field data to be safely used in statistical reliability modeling.

3 MODELING

As we discussed in introduction, the field return data can not be used for analysis of the wear out region since electronic boards get into this region long after their warranties expire. Therefore, we only deal with early failure and useful time periods. We develop our hazard rate function with phases having "Decreasing Failure/Hazard Rate (DFR)" and "Constant Failure Rate (CFR)" like those proposed by Yuan et al. (2010) and Chen et al. (1999). Here, DFR and CFR correspond to early failure and useful life regions, respectively. The proposed overall hazard rate function $h_0(t)$ is presented in Equation 1 where $h_1(t)$ = hazard rate function in early failure period, $h_2(t)$ = hazard rate function in useful-life period, t = time (TTF), and τ = change point from DFR to CFR.

$$h_0(t) = \begin{cases} h_1, & t < \tau \\ h_2, & t \geq \tau \end{cases} \quad (1)$$

Using a piecewise hazard rate function for reliability modeling, as we suggest, is a well-studied subject in the reliability and statistics literature. This includes the determination of τ often called as change point problem. In some sources τ is even called as burn-in time. Studies on parametric change point analysis of nonmonotonic hazard rate functions consider the change point as a parameter and propose statistical estimation methods like MLE and least squares (Yuan & Kuo, 2010;

Blischke 2011). Also nonparametric methods were studied widely. Bayesian estimation method with prior distribution belief about change point was discussed using test data in Yuan & Kuo, (2010). A confidence interval for parametric estimation of change point in two phase hazard model was given by Chen et al. (2001). In this study, we propose a novel change point detection method with determination of the separate hazard rate functions $h_1(t)$ and $h_2(t)$ via parametric analysis and processing the data with graphical inferences.

The data that we use, have TTF values between 1 and 36 months, since the product has 3 year warranty period. In our model, we do analysis for forward and backward time windows. While forward analysis is a widely used method in warranty analysis, investigating TTF values from backward is a new method that we introduce for accurate determination of the change point τ and the hazard functions $h_1(t)$ and $h_2(t)$. In our method, M_f and M_b are used as the number of months that constitute the boundaries of time windows. In Figure 5, an explicit demonstration of the time windows are shown.

The forward analysis is conducted by using the filtered data with TTF values less than or equal to M_f. For example, if $M_f = 3$, the data to be analyzed will contain TTF values of 1, 2 or 3 months. After starting with $M_f = 1$, M_f is increased by adding months one-by-one (M_f = 2, 3, 4,…,36). In other words, the forward time window is gradually expanding to the end of the TTF line as seen in the upper part of Figure 5. In forward time window analysis, we see that 2 parameter Weibull distribution is a good fit for almost all different M_f values. Although in some cases the best fitting is achieved with Lognormal or Gamma distribution, these distributions show almost the same DFR pattern as that from Weibull distribution in our analysis. Therefore we determine Weibull distribution for $h_1(t)$. Note that in forward analysis we do not see a change point for M_f from which the DFR pattern changes significantly.

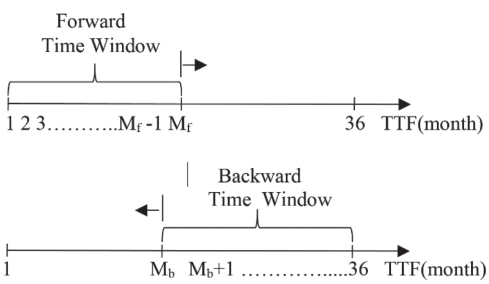

Figure 5. Demonstration of forward and backward time windows.

The backward analysis is conducted by using the filtered data with TTF values between M_b and 36 months (1–36, 2–36 …30–36…). In other words, one end of the backward time window is fixed at 36-month and the other is gradually expanding to the beginning of the TTF line as seen in the lower part of Figure 5. In the backward time window analysis, we always achieve the best fitting with Lognormal or Gamma distribution for $M_b < 14$ (months) and Exponential distribution for $M_b \geq 14$ (months). Therefore there is a change point approximately in the 14th month and we determine Exponential distribution for $h_2(t)$. The change point $\tau = 14$ (months) also results in $M_f = 14$ for $h_1(t)$ and $M_b = 14$ for $h_2(t)$ that are shown in Figure 6 and Figure 7, respectively.

Note that in this study we determine the change point from the backward analysis, but this is not a necessary and sufficient condition. For different field data, corresponding to different products, we could have had multiple change points or a single change point derived from the forward analysis. These cases are beyond the scope of this paper and considered as future work.

After determination of the change point, two phase hazard rate function, consisting of Weibull and Exponential distributions, can be constructed directly. In this case, there is a discontinuity problem at the change point; overall hazard rate function is not continuous. In order to solve this problem, we

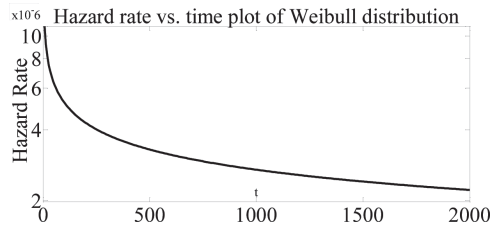

Figure 6. Hazard rate function h_1 (t) of forward analysis with Weibull distribution for Mf = 14 months. Beta: 0,715 Eta (Day): 2.44E + 6.

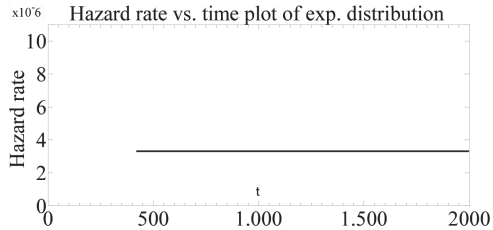

Figure 7. Hazard rate function h_2 (t) of backward analysis with Exponential distribution for Mb = 14 months. Mean time (Day): 303179.252, Gamma (Day): 382.086.

propose a smoothing and fitting method similar to the method suggested by Selmic & Levis (2002) for neural networks.

We achieve smoothing with a sigmoid function as a smooth step function approximation. Sigmoid function is given as follows.

$$s(t,\tau)=\frac{1}{1+e^{-b(t-\tau)}} \tag{2}$$

In Equation 2, τ is the change point in a unit of day. In our case its value is 14×30 days. Sharpness parameter b of the sigmoid function, can be calculated empirically. As a result, overall hazard rate function is given as:

$$h_0=\big(1-s(t,420)\big)\times h_1+s(t,420)\times h_2 \tag{3}$$

$$h_0=\left(1-\frac{1}{1+e^{-b(t-420)}}\right)\frac{\beta t^{\beta-1}}{\eta^{\beta}}+\frac{1}{1+e^{-b(t-420)}}\lambda \tag{4}$$

where β and η are the shape and scale parameters of the Weibull distribution $h_1(t)$, respectively. Additionally, λ is the hazard rate of the Exponential distribution $h_2(t)$. A plot of $h_0(t)$, $h_1(t)$ and $h_2(t)$ are shown in Figure 8 that clearly shows the idea under our smoothing operation.

A small distortion and error around the change point is an expected situation with this kind of smoothing. In our smoothing process, there is a slight difference between the overall hazard function $h_0(t)$ and $h_1(t)$ just before the change point at the 14th month (420th day). This can be seen in Figure 8. Fortunately, hazard rate values of $h_1(t)$ and $h_2(t)$ near the change point are very close to each other's because of neutrality of the data that results in very low error values.

It should be noted that there may be seen different distributions in the forward and backward analysis. The distributions do not have to be only Weibull and Exponential. We already know that distributions like Gamma, Lognormal, etc. can give all phases of bathtub curves with DFR, CFR and IFR tendencies according to values of the distribution parameters. Therefore, the proposed method of having continuous hazard rate functions can be directly applicable to different distributions.

4 CONCLUSION

In this study, we propose a methodology to process field return data and model the hazard rate function of electronic boards. We cooperate with one of the Europe's largest manufacturers and use their well-maintained data with over 1000 electronic board failures. The main goal of our study is developing a precise reliability model for electronic boards including warranty forecasting. To reach our goal, we follow two steps that are filtering and modeling.

In the filtering step, we propose a new systematic approach to determine and eliminate both obvious and hidden errors. Our method separately investigates the data in six-month time intervals, and shows us the problematic time spans corresponding to incomplete data that need to be excluded. In the modeling step, we use the filtered data to develop our reliability model. Our model is achieved by performing forward and backward time analysis of the data, and eventually finding the best fitting distributions for different time-to-failure intervals. In the fitting process we use "rank regression" and "maximum likelihood" methods. Throughout our analysis we benefit from Weibull++ by ReliaSoft Corporation.

The proposed methodology, targeting a specific electronic board, can also be applied to the return data of other electronic boards. We apply it and the results, not to be disclosed here, show us clear evidence of our methodology's success.

ACKNOWLEDGEMENTS

We would like to thank Dr. Aydogan Ozdemir from Electrical and Electronics Faculty of Istanbul Technical University for his comments and suggestions regarding this work. We are also grateful to Tunay Çakar and Hasan Avcı for their helps.

ABSTRACT: This paper describes a Monte Carlo (MC) based approach for reconstructing missing information in a Part Life DataBase (PLDB) used by General Electric (GE) for reliability analysis in support to the optimization of scheduled maintenance strategies. The PLDB contains quantitative and qualitative data coming from field observations at inspection of GE turbines. The approach is based on the Maximum Likelihood Estimation (MLE) technique to identify the parameters of the GE turbine binary degradation model, on the Fisher Information Matrix to estimate the confidence intervals on the estimated parameters, on a double-loop MC approach to propagate these confidence intervals onto the probabilities of occupying one of the degradation states over time, and, thus, estimate the missing equivalent starts (i.e., the up-time) to be associated to the recorded inspection observations (i.e., the degradation state) within the incomplete PLDB. Results of the application of the novel approach to a real industrial PLDB are discussed.

1 INTRODUCTION

General Electric (GE) offers to its customers a maintenance service on a set of components, such as the nozzles of the turbines, which is based on the subsequent steps:

I. The customer sends GE the component removed from the system upon a maintenance inspection. GE experts check the component and qualitatively classify its health state into 'Good', 'Light', 'Medium' and 'Heavy' (see Fig. 1).
II. The component ID, the information about its working time and the result of the inspection are stored in a Part Life Data Base (PLDB) for reliability life data analysis. This can be used to infer the component future failure behavior and identify the corresponding optimal maintenance decision that minimizes a cost objective function. Moreover, PLDB can be used to produce the cost estimate of maintenance service contracts to be signed with customers.
III. Components that can be fixed (with different repair procedures according to the entity of the damage) are sent back to the costumer in an As Good As New (AGAN) state.

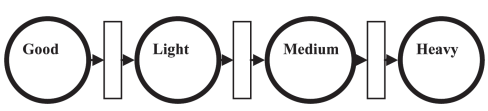

Figure 1. Scheme of the degradation mechanism.

With regards to step II, currently GE carries out the reliability life data analysis by modeling the component behavior as binary, i.e., there are only two possible component states: 'working' and 'failed'. This is done by treating 'Good' as 'working' state and combining 'Light'', 'Medium', 'Heavy' into a single 'failed' state (Fig. 2). In this work, we also adopt this latter simplified binary

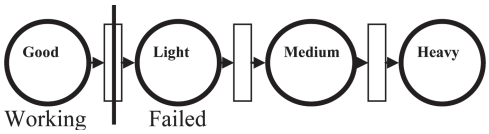

Figure 2. Simplified scheme of the binary degradation mechanism.

degradation model to describe the evolution of the erosion mechanism affecting the nozzle system of the turbines. The statistical evidence gathered by GE is exploited to improve their reliability prediction.

2 AVAILABLE DATA

The available dataset, i.e., the PLDB, consists of a set $N = 30$ records regarding field observations of the nozzle system of turbines operated by GE. Each record contains:

1. The machine (i.e., turbine) ID;
2. The inspection time (i.e., equivalent starts);
3. The degradation state of the component. This field may have four possible ordinal entries: 'Good', 'Light', 'Medium', 'Heavy';
4. The time at which the observation started, to give due account to the left censored data;
5. The value of the main covariate of the degradation process (e.g., temperature);
6. The machine total working time; this constitutes an upper bound for the missing time instants (to be estimated) at which the inspections have been performed.

When the i-th machine with $n = 22$ nozzles is inspected, a number n_s^i and n_f^i of nozzles can be found in 'working' and 'failed' states, respectively. In the latter case, records are referred to as interval censored records, whereas in the former case, records are right censored.

Beside the $N = 30$ complete data, another dataset is available containing the data of $M = 32$ additional machine inspections with unknown equivalent starts, i.e., the degradation state of every nozzle in the turbine is known, but the inspection time at which this situation has been encountered is missing.

In this context, the goal is to:

– Develop a method based on the Maximum Likelihood Estimation (MLE) technique to estimate the parameters of the binary degradation model, based on quantitative and qualitative data coming from field observations at inspection;

  Implement a technique based on the Fisher Information Matrix to estimate the confidence intervals on the estimated parameters;

Table 1. Example of data in PLDB.

	# Components safe	# Components failed
27.2 [units of time]	18	4
Missing	13	9
…	…	…

– Develop and implement a technique for propagating the estimated uncertainties (confidence intervals) onto the probabilities of occupying the degradation states over time;
– Develop a technique to estimate the missing equivalent starts to be associated to the recorded inspection outcomes.

Notice that the data considered in this paper and the corresponding results shown are different from the real ones from GE field experience, in respect of GE policy on confidential information.

3 ESTIMATION OF THE MODEL PARAMETERS

The aim of the first task of the work is to exploit the evidence contained in the available dataset with $N = 30$ complete data to estimate the values of the parameters of the stochastic model describing the degradation mechanism under study. The assumption is that the transition from 'working' to 'failed' state obeys a two-parameter $\underline{\theta} = \{\beta, \eta\}$ Weibull distribution, where β is the shape factor and η the scale factor. This latter represents the number of equivalent starts before which 63% of turbine nozzles fail.

Resorting to the Maximum Likelihood Estimation (MLE) technique (Kendall & Stuart 1979), the LogLikelihood function L can be written as:

$$L(\beta,\eta) \propto \log\left(\prod_{i=1}^{N} F\left(t_i|\beta,\eta\right)^{n_f^i} R\left(t_i|\beta,\eta\right)^{n_s^i}\right) \qquad (1)$$

where $R\left(t|\beta,\eta\right) = e^{-(t/\eta)^{\beta}}$ is the reliability of the n_s^i nozzles of the i-th machine which is found in 'working' state upon inspection, whereas $F\left(t|\beta,\eta\right) = 1 - e^{-(t/\eta)^{\beta}}$ is the unreliability of the n_f^i nozzles that are found in 'fault' state. In this respect, notice that the available dataset contains right-censored data in case of survived components, and interval censored data (where the intervals in which the failures occurred start at time $t = 0$) in case of failed components (Zio 2007).

Figure 3 shows the shape of the Log-Likelihood function L relevant to the $N = 30$ data contained in the PLDB dataset, whereas

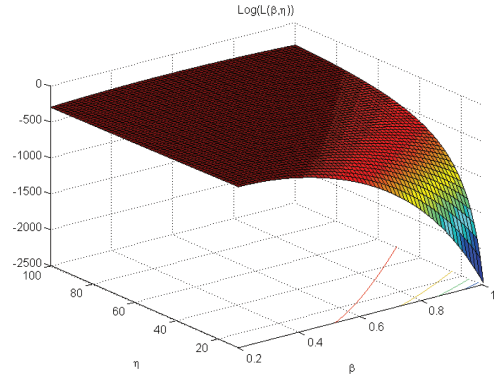

Figure 3. Log-likelihood function L.

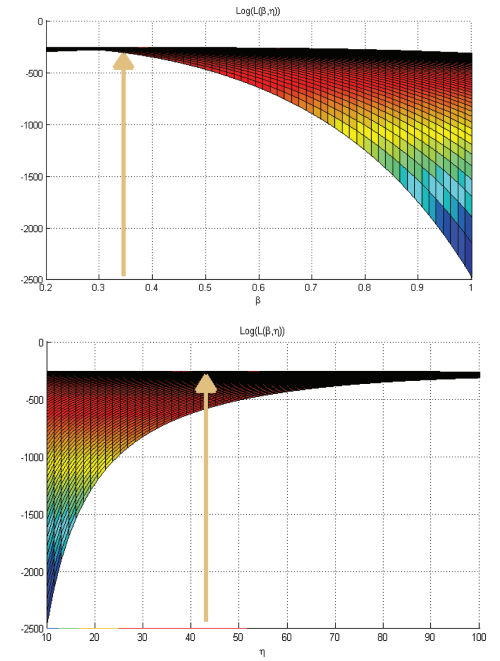

Figure 4. Log-likelihood function L, projected on the β and η axes.

Figure 4 shows that its maximum value is located in $\underline{\hat{\theta}} = \{\hat{\beta}, \hat{\eta}, \} = \{0.36, 45.23\}$.

Figure 5 shows, in log-log scale, the Cumulative distribution Function (cdf) of the Weibull distribution corresponding to the MLE values of its parameters $\underline{\hat{\theta}}$.

3.1 *Uncertainty of the model parameters*

An estimation of the confidence intervals on the parameters of a stochastic 2-parameter model can

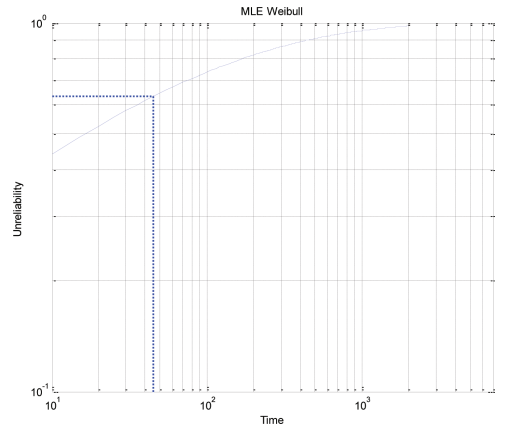

Figure 5. Point estimate of the unreliability plot.

be obtained by exploiting the asymptotic properties of the ML estimator $\underline{\hat{\theta}} = \{\hat{\beta}, \hat{\eta}, \}$. In fact, if $\underline{\hat{\theta}}$ is a unique solution to the maximization problem of $L(\beta, \eta)$, then (Papoulis & Pillai 2002, Kendall & Stuart 1979):

$$\text{i. } E(\hat{\theta}) \to \theta \tag{2}$$

$$\text{ii. } (\hat{\sigma}_\beta, \hat{\sigma}_\eta) \to (\sigma_\beta, \sigma_\eta)_{CR} \tag{3}$$

where $(\sigma_\beta, \sigma_\eta)_{CR}$ are the Cramer-Rao lower bounds (Papoulis & Pillai 2002) of the standard deviations of any unbiased estimator of $\underline{\theta} = \{\beta, \eta\}$. That is, any choice of an unbiased estimator of $\underline{\theta}$ brings a variability in the ML estimate which is necessarily larger than $(\sigma_\beta, \sigma_\eta)_{CR}$.

$$\hat{\theta} \text{ is asymptotically normal.} \tag{4}$$

With respect to ii), the approximated values of the variances $\underline{\hat{\sigma}} = (\hat{\sigma}_\beta, \hat{\sigma}_\eta)$ of the parameters $\underline{\hat{\theta}} = \{\hat{\beta}, \hat{\eta}, \}$ are provided by the main diagonal of their covariance matrix (Kendall & Stuart 1979). This can be computed as the inverse $J(\underline{\theta})^{-1}$ of the expected Fisher information matrix $J(\underline{\theta})$ whose generic (i, j) entry, $i, j = 1,2$ is (Kendall & Stuart 1979):

$$J_{ij} = E\left(\frac{\partial \log L(\underline{\theta})}{\partial \theta_i} \cdot \frac{\partial \log L(\underline{\theta})}{\partial \theta_j} \right) \tag{5}$$

where $L(\underline{\theta}) = L(\beta, \eta)$ is the likelihood function, and $\theta_1 = \eta$, $\theta_2 = \beta$.

In the reference case study, the estimated standard deviations $\underline{\hat{\sigma}} = (\hat{\sigma}_\beta, \hat{\sigma}_\eta)$ of $\underline{\hat{\theta}} = \{\hat{\beta}, \hat{\eta}, \}$ are given

by the entries (1,1) and (2,2) of the matrix $J(\underline{\theta})^{-1}$, respectively:

$$\begin{bmatrix} E\left(\left[\frac{\partial \log L(\beta,\eta)}{\partial \beta}\right]^2\right) & E\left(\frac{\partial \log L(\beta,\eta)}{\partial \beta}\cdot\frac{\partial \log L(\beta,\eta)}{\partial \eta}\right) \\ E\left(\frac{\partial \log L(\beta,\eta)}{\partial \eta}\cdot\frac{\partial \log L(\beta,\eta)}{\partial \beta}\right) & E\left(\left[\frac{\partial \log L(\beta,\eta)}{\partial \eta}\right]^2\right) \end{bmatrix}^{-1} \tag{6}$$

It is worth noticing that under mild regularity conditions, the matrix in Eq. (6) is equal to:

$$\begin{bmatrix} -E\left(\frac{\partial^2 \log L(\beta,\eta)}{\partial \beta^2}\right) & -E\left(\frac{\partial^2 \log L(\beta,\eta)}{\partial \beta \partial \eta}\right) \\ -E\left(\frac{\partial^2 \log L(\beta,\eta)}{\partial \beta \partial \eta}\right) & -E\left(\frac{\partial^2 \log L(\beta,\eta)}{\partial \eta^2}\right) \end{bmatrix}^{-1} \tag{7}$$

This allows us giving a rough, informal interpretation of Fisher information. In fact, notice that in general:

$$\frac{\partial^2 \log L(\underline{\theta})}{\partial \theta_i^2} = \frac{L'(\underline{\theta})}{L(\underline{\theta})} \tag{8}$$

Then, this second derivative can be interpreted as a measure of how quickly the probability distribution function (pdf) changes when we change the parameter in the proximity of the MLE estimation. The expectation of the square of this value gives us a more robust version of this measure: if Fisher information is large, then the distribution quickly changes when we move from the MLE value of the parameter (i.e., the distribution with parameter $\underline{\hat{\theta}}$ is different from the distributions with parameters close to $\underline{\hat{\theta}}$); on the other hand, if Fisher information is small, this means that the distribution corresponding to $\underline{\theta} = \underline{\hat{\theta}}$ is 'very similar' to distributions with values of the parameter not so close to $\underline{\hat{\theta}}$. In the former case, we should be able to robustly estimate $\underline{\hat{\theta}}$ based on the data, whereas in the latter case the robustness of the estimation is worse.

3.2 *Confidence intervals on the probability plot*

In this case study, the values of $\underline{\hat{\sigma}} = (\hat{\sigma}_\beta, \hat{\sigma}_\eta)$ are $\underline{\hat{\sigma}} = (0.17, 28.1)$. Figure 6 shows the distribution of $\hat{\beta}$ and $\hat{\eta}$ (top and bottom, respectively). Derivatives of $L(\beta,\eta)$ are computed resorting to the MATLAB symbolic toolbox.

Figure 7 shows the cdf of the unreliability and its pointwise double-sided 90% confidence interval. The width W_η of the double-sided 90% confidence intervals for η is equal to $W_\eta = 70 - 17 = 53$,

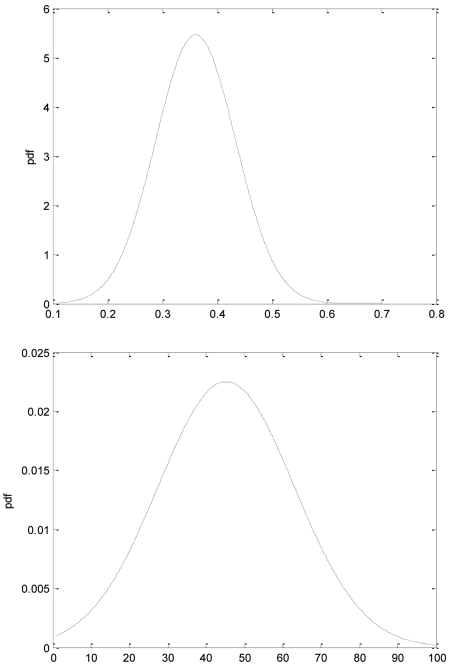

Figure 6. Distributions of $\hat{\beta}$ (top) and $\hat{\eta}$ (bottom).

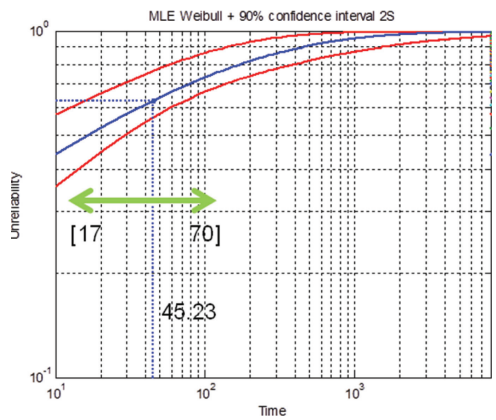

Figure 7. Unreliability and confidence intervals.

whereas the width W_U of the double-sided 90% confidence intervals for the unreliability at $t = \hat{\eta}$ is equal to $W_U = 0.78 - 0.56 = 0.22$.

In particular, the upper and lower bounds are found resorting to a MC sampling method implemented by the following procedure (Zio, 2013):

i. Partition the time axis into C small channels of length Δt.
ii. Sample β from $N(\hat{\beta}, \hat{\sigma}_\beta)$;
iii. Sample η from $N(\hat{\eta}, \hat{\sigma}_\eta)$;

iv. For each channel i of the time axis, compute $R(t_i|\beta,\eta)$, where $t_i = i \cdot \Delta t$, $i = 1, \ldots, C$.
v. Repeat steps ii–iv a large number of times (e.g., 500 in this work).
vi. For each time channel i, find the 5th and 95th percentiles of the gathered statistics, i.e., the pointwise double-sided 90% confidence interval.

4 ESTIMATION OF THE EQUIVALENT STARTS

The aim of this Section is to propose a procedure to infer such equivalent starts, on the basis of the statistical evidence made up of the N complete data. Two different approaches to the missing data problem are typically proposed. The first approach consists in developing models to reconstruct the missing data based on Artificial Neural Networks (AANN) (Hines, 1996), Principal Component Analysis (PCA) (Luh, 2011), Auto-Associative Kernel Regression Methods (AAKR) (Baraldi, 2012), Fuzzy Similarity methods (Baraldi, 2013) and similarity measures computed taking the correlation (Kim et al., 2005) and entropy (Brock et al., 2008) of information. The second approach consists in substituting the missing data by statistical values, e.g., the mean value of the available data (Schafer, 2002). However, the performance of especially the latter approach tends to decrease when applied to datasets containing few complete data. In our approach, we make use of a MC based approach for reconstructing missing information in the PLDB: as anticipated above, a number M of additional turbine inspection outcomes have been collected by GE, which report the degradation state at inspection of each of the $n = n_f^i + n_s^i$ components of the i-th machine, but not the time (expressed in equivalent turbine starts) at which that inspection has been performed.

From the statistical standpoint, every machine inspection can be regarded as the result of n repeated trials, each one consisting in testing the health state of the nozzle after it has been working for a time interval [0, t]. For each trial, two mutually exclusive events can occur: 'nozzle is in failed state', and 'nozzle is in working state'. For the sake of simplicity, we assume that the n trials are independent on each other. From the practical point of view, this means that the evolution of the degradation mechanism affecting any nozzle does not influence the evolution of any other degradation process relevant to any other nozzle of the turbine.

The probability of having a failed nozzle in a single trial reads:

$$p = F(t|\beta,\eta) = 1 - e^{-\left(\frac{t}{\eta}\right)^{\beta}} \tag{9}$$

Simple analytical manipulations of Eq. (9) yield:

$$t = \eta \sqrt[\beta]{-\log(1-p)} \tag{10}$$

Eq. (10) allows us relating t with the degradation states recorded on the i-th machine at time t. Data in the original database allows us to calculate the ML estimators $\underline{\hat{\theta}} = \{\hat{\beta},\hat{\eta},\}$ of $\underline{\theta} = \{\beta,\eta,\}$: these are normally distributed random variables with $N(\hat{\beta},\hat{\sigma}_\beta)$ and $N(\hat{\eta},\hat{\sigma}_\eta)$, respectively, as shown in Section 3. It is important to notice that also p is a random variable, as it depends on the inspection outcome n_f^i of the i-th machine at time t, as shown in the following. Therefore, t turns out to be a random variable, that is a function of the random variables β, η and p.

Our objective is to find the ML estimate $\hat{p}^i$ of the probability p^i of having at inspection of the i-th turbine, $i = 1, \ldots, N$, a given value n_f^i of failed components and, thus, $n_s^i = n - n_f^i$ of safe components.

To do this, first notice that the number of failed components N_f^i is a binomially distributed random variable. Therefore,

$$P(N_f^i = n_f^i) = \binom{n}{n_f^i} p^{i\,n_f^i} (1-p^i)^{n-n_f^i} \tag{11}$$

Then, given the outcome n_f^i of N_f^i, the ML estimate of the probability p^i is given by the value $\hat{p}^i$ that maximizes the likelihood function $L(n_f^i \mid p)$:

$$L(n_f^i \mid p) = \binom{n}{n_f^i} p^{i\,n_f^i} (1-p^i)^{n-n_f^i} \tag{12}$$

from which we get that the maximum likelihood estimate $\hat{p}^i = n_f^i/n$ (Papoulis & Pillai 2002).

The second step of the proposed procedure aims at describing the uncertainty in the ML estimator $\hat{p}^i$, which is a random variable with its own distribution. In this respect, notice that the probability of having a number N_f^i of observations of 'failed' components not larger than n_f^i is:

$$P(0 \le N_f^i \le n_f^i) = \sum_{k=0}^{n_f^i} \binom{n}{k} p^{i\,k} (1-p^i)^{n-k} \tag{13}$$

with $0 \le n_f^i \le n$. Being p a random variable, the probability that $\hat{p}^i \ge p_u^i$ is given by (Birolini, 2004):

$$P\left(\hat{p}^i \ge p_u^i\right) = \sum_{k=0}^{n_f^i} \binom{n}{k} p_u^{i\,k} (1-p_u^i)^{n-k} \tag{14}$$

Eq. (14) defines the incomplete Beta function $I_{1-p}(n-n_f^i, n_f^i+1)$ (Kendall & Stuart 1979), which is the distribution of $\hat{p}^i$. We can sample a possible realization of p for a given n_f^i from this distribution.

On the basis of the considerations above, for any outcome n_f^i we can exploit Eq. (10) to estimate its missing equivalent inspection time t, by sampling α, β and p from the respective distributions.

For example, if $n_f^i = 16$, then $\hat{p}^i = n_f^i/n = 0.727$. The probability, e.g., 0.95, that $\hat{p}^i$ is larger than a given value p_u^i, e.g., 0.848, is given by the probability of having at most $n_f^i = 16$ outcomes out of n, when the probability of finding a fault component in a single trial is p_u^i. That is, larger values of $\hat{p}^i$ are more 'compatible' with experimental results accounting for larger values of n_f^i. In other words, there is a small probability, e.g., 0.05, of having the evidence n_f^i out of n with values of p larger than p_u^i. For clarity sake, the CDF of $I_{1-p}(6,17)$ is shown in Figure 8.

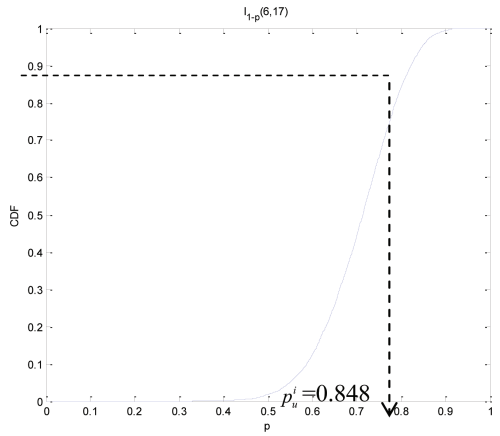

Figure 8. CDF of the incomplete beta function for $n_f^i = 16$ and $n = 22$.

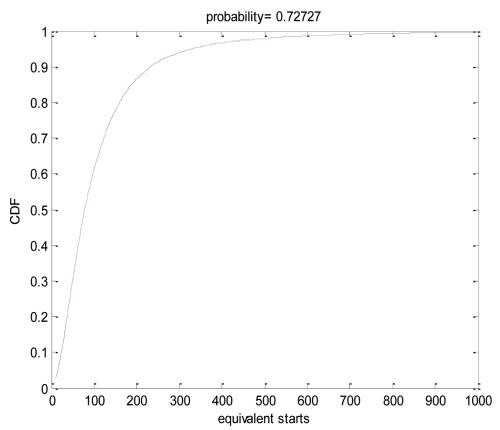

Figure 9. Distribution of t for $n_f^i = 16$ and $n = 22$.

The following MC sampling procedure is implemented to find a possible realization of the missing equivalent starts t for an inspection on the i-th turbine with $n_f^i = 16$:

i. Sample β from $N(\hat{\beta}, \hat{\sigma}_\beta)$;
ii. Sample η from $N(\hat{\eta}, \hat{\sigma}_\eta)$;
iii. Sample p from $I_{1-p}(n-n_f^i, n_f^i+1)$;
iv. Compute t with Eq. (10).

The MC procedure from i) to iv) is repeated a large number of times (i.e., 10^4); this allows building the probability distribution of t (Fig. 9) and to calculate its percentiles (e.g., 50th percentile), to be assumed as reconstructed missing equivalent starts.

5 ESTIMATION OF THE PARAMETERS ON THE MERGED DATASET

Hereafter, the merged dataset containing $N+M$ turbine inspections is considered, where the

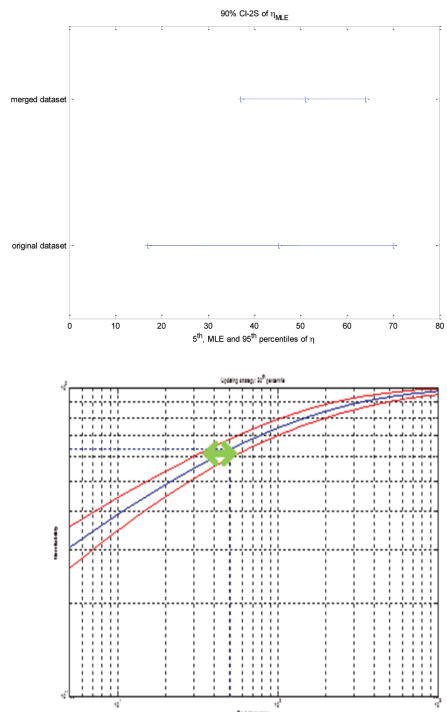

Figure 10. Uncertainty reduction in the estimation of η (top) and unreliability and confidence intervals (down).

equivalent starts t corresponding to the M turbine inspections are taken from the corresponding distribution estimated as in Section 4. In this case, the Log-Likelihood function L can be written as:

$$L(\beta,\eta) \propto \log\left(\prod_{i=1}^{N+M} F\left(t_i|\beta,\eta\right)^{n_f^i} R\left(t_i|\beta,\eta\right)^{n_s^i} \right) \quad (15)$$

where $R\left(t|\beta,\eta\right) = e^{-(t/\eta)^{\beta}}$ is the reliability of the n_s^i nozzles of the i-th machine which are found in 'working' state upon inspection, whereas $F\left(t|\beta,\eta\right) = 1 - e^{-(t/\eta)^{\beta}}$ is the unreliability of the n_f^i nozzles that are found in 'fault' state. If $i \le N$, then t_i is the equivalent starts value reported in the original complete dataset, otherwise, t_i is the 50th percentile of the distribution of t corresponding to n_f^i.

Parameters $\hat{\beta}$ and $\hat{\eta}$ can be calculated following the procedure detailed in Section 3, on the merged original and reconstructed datasets (N+M machine inspections). Figure 10 shows the reduced $\hat{\sigma}_{\eta}$ when the merged dataset is used,

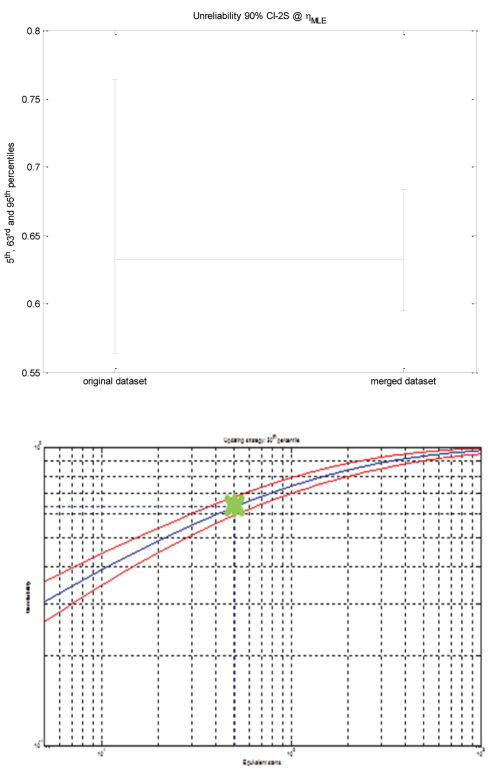

Figure 11. Uncertainty reduction in the estimation of the unreliability at t = $\hat{\eta}$ (top) and unreliability and confidence intervals (down).

with respect to the original dataset (N machine inspections, as shown in Fig. 7). In particular, on the left, the pointwise double-sided 90% confidence intervals for η are plotted for these two cases. Similarly, Figure 11, shows the contribution of the additional M outcomes in reducing the uncertainty of the estimation of the unreliability at $t = \hat{\eta}$.

6 CONCLUSIONS

In this work, a procedure has been presented to complete the data collected at field inspections of components and, thus, exploit all available data gathered. The procedure has been illustrated with reference to nozzle system of turbines operated by GE. It has been shown that such procedure is capable of:

- Estimating the parameters of a Weibull distribution as well as the related uncertainties;
- Reconstructing missing equivalent starts to reduce the uncertainty on the estimation, relying on an enlarged database that contains original (complete) data and additional (reconstructed) data.

In this respect, it has been shown that the reduction of the uncertainty in the estimates depends on the number of records collected in the field inspections, and that, in some particular cases, the proposed procedure conservatively leads to estimations of the scale factor of the Weibull distribution heavily shifted towards zero. Future work will be focused on solutions to avoid such anomalous situations.

Using field experience in the treatment of Common Cause Failures in reliability assessment

S. Hauge & S. Håbrekke
SINTEF Technology and Society, Safety Research, Trondheim, Norway

M.A. Lundteigen
The Norwegian University of Science and Technology (NTNU), Norway

ABSTRACT: The reliability of Safety Instrumented Systems (SISs) that employ redundancy is highly influenced by Common Cause Failures (CCFs). A widely used CCF model is the beta factor model, but a general challenge is lack of data to support the model parameters. Few initiatives have been taken to collect operating experience, except for the nuclear industry whose results are not directly applicable to other sectors. Use of checklists represents an alternative approach, but their underlying assumptions are not always well documented. Their applicability for the large variety of safety-critical equipment has also been criticized. This paper presents recent experience with CCFs and systematic failures (which are closely interrelated) along with new CCF checklists, based on an ongoing research project financed by the Research Council of Norway and the PDS forum members (www.sintef.no/pds).

1 INTRODUCTION

Safety Instrumented Systems (SISs), i.e. safety-critical systems that are based on electrical/electronic or programmable electronic technology, often employ redundancy to enhance their performance. The intended reliability effects of redundancy may however, be reduced if the system components are exposed to similar environmental exposures, design errors, and errors made during operation and maintenance. When multiple failures are attributed to a shared cause, they are often referred to as Common Cause Failures (CCFs). Standards that frame the development of SIS, such as IEC 61508 (2010), IEC 62061 (IEC 62061, 2005) and IEC 61511 (IEC 61511, 2003), require that measures are implemented to avoid CCFs and that the remaining effects of CCFs are included in reliability analyses.

Models for including CCFs in reliability analyses of SISs have evolved since the 1970s, and several models have been proposed for this purpose (Rausand and Hokstad, 2008). Excluding this failure category would lead to a significant underestimation of the calculated reliability (Rausand and Høyland, 2004), and most reliability experts would question analyses that would do so. The most common CCF model adapted by the process industry is the standard beta factor model (IEC 61511, 2003, ISA TR 84.00.02, 2002, SINTEF, 2013b). The PDS method (SINTEF, 2013b) has been developed with basis in this model and an extension of this, the multiple beta factor model (Hokstad and Corneliussen, 2004).

A common challenge for all CCF models is the lack of suitable data to support the model parameters. The nuclear industry has given CCFs considerable attention and carried out several CCF data collection projects to build generic data bases on CCFs (NEA, 2004, NEA, 2014, SKI, 1998). The process industry and the petroleum industry have not run similar projects, not as part of large data collection projects, like e.g. OREDA (OREDA, 2009) nor through other known initiatives. Hauge et al. (2006) investigated how the industry control CCF, but the study was of a qualitative nature. The PDS data handbook (SINTEF, 2013a) is one of few data sources that propose values of beta for commonly used components, but these are mainly established on the basis of expert judgments, comparison with other data sources and some results from operational reviews. The value of having generic data bases for CCFs may also be questioned. As discussed by Rausand (2012), the contribution from CCFs is strongly influenced by local, plant-specific conditions. This is also supported by results from operational failure reviews as discussed later in this paper.

Expert judgment is therefore often used in the process of determining the CCF model parameters, and checklists are used as a means of structuring such input. Two widely accepted examples

are found in IEC 61508 (2010) and IEC 62061 (2005), but even for these the foundation has been questioned: First, the same checklist questions are suggested for a wide range of component types with very diverse properties and failure modes. Second, the selection of checklist questions is not well explained, and rationales for weight and scores in relation to the checklist questions are not presented. Third, several of the checklist questions tend to be very general and "high level", and users of the checklists may interpret the meaning quite differently. A better approach may therefore be to develop equipment-specific CCF checklists, preferably with a content and structure that build on operating experience taking into account facility specific conditions.

The main purpose of this paper is to discuss the extent of CCFs and to suggest CCF component specific checklists, with basis in an extensive review of failures recorded for SISs in the oil and gas industry.

The content of this paper is based on an ongoing research project funded by the Norwegian Research Council and the member of the PDS forum.[1] Failures reported for a large variety of SIS components at offshore and onshore oil and gas facilities in Norway have been included in the review (totaling up to more than 10000 maintenance notifications). Based on this, the most typical CCF causes and their relative importance are being presented and discussed. The new knowledge has been used as basis for developing component specific checklists, targeted to address the most important CCFs for each of these.

Operational failure reviews have been carried out at six facilities, allowing the results to be considered as rather general for both onshore and offshore facilities, in particular for facilities located in environments similar to those in Norway and on the Norwegian Continental Shelf.

2 RESEARCH APPROACH (PDS PROJECT)

The main approach in this research project has been as follows:

Step 1: Carry out a literature review and a workshop on the treatment of CCFs in PDS forum. The results were used as input to steps 2–4. **Step 2:** Review of reported failures (maintenance notifications). The operational reviews were facilitated by SINTEF, but involved key discipline personnel (automation, mechanical, process) from the specific facility and company in question. Each notification was reviewed with the purpose of classifying failures according to IEC 61508 (2010). **Step 3**: Analysis of results. The results from all six facilities were reviewed, and the failures associated with the same type of components with shared causes were—given a set of associated criteria—classified as complete CCFs or failures that could have caused a CCF. Some of the results are given in Section 5 of this paper. **Step 4:** Development of component-specific CCF checklists based on the results in Step 3. Two examples of preliminary checklists are given in Section 6.

2.1 *Literature review*

The main purpose of the literature review was to investigate the state of the art for methods for determining model parameters of CCF models. Very comprehensive approaches like what is used in the nuclear power industry to support multiple-Greek letter CCF models, see e.g., NUREG/CR-5485 (1998) and NUREG/CR-6268 (2007), have not been studied in detail in this paper. Instead, the focus has been on identifying methods available for determining the β in the beta factor model, and on the definitions of CCF that may be useful as assistance in the analysis and classification of failures reported for safety-critical components. Literature referenced in a study by Rausand and Hokstad (2008) has been key for the review.

3 CCF DEFINITIONS AND APPLICATION

3.1 *CCF attributes*

CCF definitions have been proposed and refined over several decades. Smith and Watson (1980) did a detailed review of definitions available as early as in 1980. They concluded that a set of multiple failures could be defined as a CCF if *all* the following conditions are met: (1) The components affected are unable to perform as required, (2) multiple failures exist within (but are not limited to) redundant configurations, (3) The failures are "first in line" type of failures and not the result of cascading failures (i.e. where a failure of one component has triggered the failure of another component), (4) the failures occur within a defined critical time period (e.g., the time a plane is in the air during a flight or the time between two test intervals), (5) the failures are due to a single underlying defect or a physical phenomenon (the common cause of failures), and (6) the effect of failures must lead to some major disabling of the system's ability to perform as required.

In this paper, the term *complete CCF* is used to denote multiple events that fulfill all six criteria, with an extension of criterion 2. Multiple failures

[1] www.sintef.no/pds.

are considered for the whole category of similar components, and not only for similar components within the same safety function.

Regarding criterion six, it may be open to interpretation what to define as a major disabling. For example NEA (2004) defines a complete CCF as the event where *all* components in a population of interest have failed due to a common cause. In this paper, we include more events in the definition of complete CCFs. For example, in a 1oo3 configuration, the NEA definition requires failure of all three components to define it as a complete CCF, whereas in this paper a simultaneous failure of two components is considered sufficient. Actually, in the failure reviews, any simultaneous failures of two (or more) components due to a shared cause, is defined as a CCF event, although the components do not necessarily belong to the same safety function. This is further discussed in section 5.

The identification of CCFs among reported failures would overlook many possible causes of CCFs if focusing on complete CCFs alone. Systematic failures, i.e., failures that are due to errors made in specification, design, installation, or operation and maintenance, and which are not due to natural degradation of the component state, may be replicated for several components. When a systematic failure is found, it is important to also ask if other components may have been affected. Therefore, in the failure reviews, it has, for each systematic failure, been questioned whether the failure could have resulted in multiple failures within a relatively short time window. If yes, the failure has been defined as a potential CCF.

The term *potential* CCFs is thus used to capture a broader category of CCFs, and includes all foreseeable causes that may result in a CCF based on a review of recorded failures. This term is also mentioned in the ICDE guideline, but not formally defined. In practice we see that a potential CCF very much resembles a systematic failure. The two are however not identical; A failure may be systematic without necessarily having the potential to create a CCF (under given conditions and configurations). On the other hand, a potential CCF will always have the properties of a systematic failure.

The two categories complete and potential CCFs have been introduced to serve two different purposes. Complete CCFs may, when counted up, be used to estimate how often CCFs have occurred. The main problem is that a plant specific CCF failure rate will have a high level of uncertainty, due to limited amount of samples. Potential CCFs cannot be included, at least with the same weight as complete CCFs, in the estimation of CCF failure rates. However, potential CCFs are important for identifying potential failure causes as well as vulnerabilities in design or its operating environment that, if prevented or modified, could reduce the future occurrence of CCFs.

3.2 *Root cause, coupling factors and defenses*

Parry (1991) and Paula et al. (1991) split CCF causes into root causes and coupling factors, and this concept has been adapted in many types of CCF analyses (NUREG/CR-5485, 1998, NUREG/CR-6268, 2007, Lundteigen and Rausand, 2007).

A **root cause** is the most basic reason or reasons for the component failure, which if corrected, would prevent recurrence (NUREG/CR-5485, 1998). Examples of root causes are high or low temperature, excessive sand production, large vibrations, earthquake, fire, sudden changes in loads, high or low pressures, moisture or high humidity, heat radiation, electrical failure, lack of procedures, failure to follow repair or test procedure, systematic calibration failures, design failure, inadequate testing/inspection/follow-up etc.

All too often, the description of a failure is limited to the most obvious cause or a simple statement that "the component has failed". Without a proper identification of the root cause, it is difficult to select the most efficient defense measure. For example, in the review of reported failures, we see that failed detectors are often just replaced by a similar type without further analysis. We also see that valves being stuck during a functional test may be lubricated and then operated successfully. Lubrication has a short term effect on the valve performance, and actual root cause is seldom revealed. Such strategies are often insufficient for the purpose of selecting the most effective defense measures.

A **coupling factor** is a characteristic of a group of components or parts that identifies them as susceptible to the same causal mechanisms of failure (NUREG/CR-5485, 1998). Such characteristics may be related to the use of common procedures, common design principles, the same environmental exposure and/or operating environment, and the same personnel involved in design, installation, operation, or maintenance. Some examples of coupling factors may be that the same operator calibrates all level transmitters mounted on the same vessel. Another example is that a whole set of flame detectors are located in an area exposed to sea water spraying. A coupling does not trigger any failure by itself, but its presence may replicate or allow the replication of the same failure onto several components.

3.3 *Defense strategies*

It may be argued that the occurrence of root causes mainly impacts the total (i.e. independent

and dependent) failure rate, whereas a change in coupling impacts the beta factor in the beta factor model. Defenses against CCFs may therefore aim for both of these tactics (Lundteigen and Rausand, 2007). In practice, there may be operational constraints that limit the freedom in available defense measures. For example, root causes that are external, such as snow, sea spray, low or high ambient temperatures, or process parameters such as acidity and sand content in fluid, cannot always be modified, and their effects must be catered for when selecting defense measures.

Development of component-specific checklists for CCFs should therefore ideally capture the relevant coupling factors as well as typical failure causes associated with a component group, and these may be identified by review and analysis of reported failures.

4 DETERMINING THE BETA FACTOR

Several authors have suggested ways (checklists, influence diagrams) for determining beta values (Humphreys, 1987, Brand, 1996, Johnston, 1987, Zitrou and Bedford, 2003, Zitrou et al., 2003, IEC 61508, 2010, IEC 62061, 2005). An overview of these approaches is provided in Rausand and Hokstad (2008). The first approaches, such as Humphreys (1987) and Brand (1996) were developed with basis in the Nuclear industry, and build on insight and experience from this sector. Zitrou and Bedford (2003) and Zitrou et al. (2003) have extended the approach by Brand (1996) to include site-specific factors into influence diagrams. Insight to these methods has to some extent been used as inspiration for the checklists proposed in Section 6.

5 OPERATIONAL REVIEWS

In general, limited attention is given to CCFs during daily plant operation and during failure registration and follow-up in particular. This impression was also supported by the operational reviews which looked into various component groups of safety critical equipment on six facilities. Many multiple failures revealed in these reviews were not identified or registered as CCFs, even if the same type of failure had been notified by alarms or observed in many subsequent tests. This can be explained by inadequate investigation of the failure cause in the first place, inadequate overview of the failure history and last but not least a limited focus on CCFs in general.

In this paper we look into some results for three equipment groups; Shutdown valves, point gas detectors and level transmitters. Selected summary figures are given in Table 1.

The table lists the number of observed DU-failures, the number of registered CCF events among these DU failures, the number of DU-failures that are part of these CCF events (in brackets), and the aggregated operational time of the population. Note that a CCF can comprise from two to several DU-failures. At most 19 DU-failures have been registered for one CCF. Also note that potential CCFs are not included in the tables. More details for each of the three component groups are given below.

5.1 *Shutdown valves*

The shutdown valves shall close upon a demand. Several of them also have requirements with respect to closing time and some of them to maximum leakage rate in closed position. In total, 221 DU failures were observed for the shutdown valves from the six operational reviews. The DU failures mainly include the three failure modes fail to close on demand, leakage in closed position and delayed operation. The 11 CCF events registered involved the following failures:

- 19 DU failures (delayed operation) were due to poor design of hydraulic connections resulting in too long closing times.
- 11 other DU failures (fail to close) were due to incorrect valve type for the specific application (fail-open valves installed in fail-close application).
- Additional six DU failures (fail to close) of another type of valve were due to poor design (these were not designed for the intended use and degraded immediately). All these valves had to be replaced.
- Six DU failures (delayed operation) were due to changing hydraulic oil viscosity (caused by temperature variations).
- Four DU failures (fail to close) were due to actuator capacity. The operation of these valves is normally assisted by pipeline pressure, but when testing with no (delta) pressure over the valve they were unable to close.
- Three DU failures (fail to close) were due to damaged gaskets combined with dirt from operation.

Table 1. Results from operational reviews.

Component group	DU	CCF	Operational time
Shutdown valves	221	11 (59)	37 000 000 hrs
Point gas detectors	36	2 (14)	49 000 000 hrs
Level transmitters	52	2 (11)	12 000 000 hrs

– Three DU failures (leakage in closed position) were due to a leakage problem with a group of valves of similar type. No root cause of this problem was revealed.
– Two DU failures (fail to close?) were caused by wrong mounting of solenoid valves made while modifying the control of these valves.
– Two DU failures (failure to close) on similar types of valves were detected simultaneously (unknown cause).
– Two DU failures (fail to close) were caused by corrosion on the actuator stem due to wrong material selection.

An additional (unknown) number of DU failures (delayed operation) were due to inadequate bleed-off (wrong tuning of bleed-off valve).

In addition, several systematic failures were observed with a potential of causing CCF events. Examples are valves that did function due to low temperatures and ice/freezing, stuck hand wheel due to rust, insufficient lubrication and cleaning of valves, nitrogen leakage from valve accumulators and incorrect adjustment of valve during previous maintenance.

5.2 *Point gas detectors*

Gas detectors shall detect the presence of gas and initiate an alarm at specified concentration(s). Besides hydrocarbon gas, some H_2S, CO_2 and O_2 detectors are also included in the sample. In total, 36 failures were defined as DU failures for point gas detectors from the six operational reviews. The failure modes included e.g. no measurement ("dead"), unsteady measurement and wrong measurement. The two CCFs registered involved the following failures:

– Ten DU failures (incorrect measurement) were due to poor design of a detector type, such that all the detectors had to be replaced.
– Four DU failures (incorrect measurement) were all detected at the same time by random observations (no alarm). The four detectors had frozen measurement and had to be replaced.

Potential CCFs included detectors that did not function due to environmental influences causing dirty lenses, dense filter due to inadequate maintenance procedures, poor design of the detector mirror, and erroneous calibration.

5.3 *Level transmitters*

Level transmitters shall measure correct level in a tank or vessel and initiate alarm(s) at specified level(s). In total, 52 failures were defined as DU failures for level transmitters from the six operational reviews. These include failure modes such as wrong measurement, unsteady measurement and frozen measurement. The two registered CCFs involved:

– Nine DU failures (incorrect measurement) were due to wrong measuring principle for the specific application, resulting in wrong level measurements (revealed randomly or on tests). It should be noted that many vessels have very challenging measurement conditions, and a suitable level measurement principle hardly exist for all operational situations.
– Two DU failures (incorrect measurement) due to wrong data values in their data sheet.

Systematic failures that could potentially have resulted in CCFs included transmitters exposed to cold temperatures resulting in icing/hydrate formation in impulse lines, incorrect mounting of transmitter, and a transmitter exposed to an electrical failure.

5.4 *Estimation of beta*

Estimation of beta based on the results from Table 1 can be performed using various estimators. The well recognized estimator is (NUREG/CR-4780, 1989):

$$\hat{\beta}_1 = \frac{N_{\mathrm{DU,CCF}}}{N_{DU}} \tag{1}$$

Here $N_{DU,CCF}$ is the number of DU failures included in a CCF event (e.g. 59 for shutdown valves, ref. Table 1) and N_{DU} is the total number of DU failures experienced for the population. As discussed in section 3.1, in the failure reviews simultaneous failures of two (or more) components have been classified as CCF events, although the components do not necessarily go into the same safety function. Therefore, the above estimator will be rather conservative when estimating betas in general. A more appropriate estimate for the beta value may be (NUREG/CR-4780, 1989):

$$\hat{\beta}_2 = \frac{2 \cdot N_{CCF}}{N_{DU,I} + 2 \cdot N_{CCF}} \tag{2}$$

Here, N_{CCF} is the number of actual CCF events, e.g., two for level transmitters, and $N_{DU,I}$ are those DU-failures that are not affected by any CCF, e.g., 41 for level transmitters. This estimate assumes that each CCF event results in failures of two components. In reliability calculations CCF is mainly considered for two (or three) redundant components. Also in the PDS method, beta is defined as the fraction of failures of a single component that causes both components of a redundant pair to fail due to a CCF. In addition,

Table 2. Estimated beta values.

Component group	$\hat{\beta}_1$	$\hat{\beta}_2$
Shutdown valves	27%	12%
Point gas detectors	39%	15%
Level transmitters	21%	9%

modification factors are introduced to cater for different voting configurations (SINTEF, 2013b). Estimated beta values for each of our three component groups are shown in Table 2.

From the results we see that shutdown valves and gas detectors seem to have a somewhat higher estimated beta value than level transmitters. Also, the estimated beta indicates that beta values around 10% (and even more for valves and detectors) seem realistic. However, it should be noted that these estimates are based on a rather limited number of CCF events, although the accumulated operational period is rather extensive.

Most of the CCFs are facility specific and the same type of CCF may not necessarily appear on more than one facility. E.g. for point gas detectors and level transmitters, no complete CCF events have been observed on several facilities. On the other hand the data collected from the operational reviews are "the best available" and will together with expert judgments and component specific checklists hopefully result in an improvement in the estimation of CCFs taking facility specific conditions into considerations.

6 NEW EQUIPMENT SPECIFIC CHECKLISTS

As discussed above, the fraction of CCFs will vary significantly between installations and equipment types. Therefore, development of equipment specific checklists is a main activity in the ongoing research project. The purpose of developing such checklists is not necessarily limited to only estimating a value for beta after having judged a specific design in light of control questions. A checklist may also be used to point at possible defense tactics that, if implemented, will result in a reduction of the beta-factor. It may for example be of interest to reassess the value of beta in operation, and it is therefore relevant to document what kind of defenses that are assumed implemented and how these are followed-up in actual operation. Table 3 and Table 4 show some preliminary examples of checklists.

The structure of the suggested checklist is based on the following assumptions: (i) Component specific CCF vulnerabilities can be listed with basis in the review of reported failures: These are specific conditions known to affect the vulnerability to CCFs (e.g. sand in the production flow, presence of ice and snow, same operators calibrating several transmitters, etc.). These conditions are assumed to affect the beta-value regardless of defenses in place. (ii) Defenses may be introduced to reduce the impact of CCF vulnerabilities, but not to a zero level. For example, sand detectors, heat tracing of impulse lines, 3rd part control of work, etc.).

The columns of the table include: **Category:** A categorization of CCF vulnerabilities. These may be underlying (coupling) factors and causes that may increase the likelihood of experiencing a CCF. **Weight:** The assessed weight of the associated cause/factor based on results from the operational reviews. **Relevance:** Whether the specific cause/factor is relevant for the application under consideration. **Defenses:** Measures or strategies that may prevent or reduce the likelihood of the associated cause or coupling to come into force. A division between procedural/training/documentation meas-ures and physical measures has been made. **Efficiency (Eff):** A scaling comparable to the scaling used for potential CCFs in (NUREG/CR-6268, 2007), with one added level. The following scaling factors are suggested:

2.0: No measure is implemented resulting in a "penalty" of a factor 2. **1.0:** The measure is judged to have a *low* efficiency and does not go beyond what is considered "state of the art" in protection. **0.5:** Measures have been taken, but the effect of the measure is considered *medium*/limited or it has not been documented that the foreseen effects have been achieved. **0.1**: Measures have been taken, and it has been documented that the measures have a *high*/significant (and positive) effect on the issue in question.

Modification factor (Mod Factor): The product of efficiency factors assigned to each defense. The factor is used to update the weight of beta for this particular category.

When establishing the checklists, six main categories of underlying causes and coupling factors (threats) that may increase the likelihood of experiencing a CCF have been defined:

Design properties: Covering aspects related to redundancy, diversity and functionality of the specific equipment (see example in Table 3). *Special considerations*: Aspects related to previous experience with/maturity of the equipment, complexity of the design, possible weak points in the design, etc.

Human machine interface: Aspects related to accessibility to and maintainability of the equipment, including planned level of human interaction in

Table 3. Example checklist—environmental control category.

Category	Weight	Relevance	Procedure, training and documentation defenses		Technical/physical/separation defenses		Mod Factor
Design properties	30%	Y/N	Defenses/evaluation	Eff.	Defenses/evaluation	Eff.	
Are redundant valves of the same type (make, manufacturer, material selection, etc.)?	5%	Y	Has the design been reviewed with the purpose of revealing common vulnerabilities, associated with sizing, material selection and so on	2.0 (no)	Have measures identified in the design review been implemented to reduce the identified negative impacts of similar valve types?	0.5 (M)	1.0
Have max and/or min closing time been defined for the redundant valves in question	20%	Y	Have design reviews been carried out with the purpose of identifying possible design constraints in view of response time requirements?	1.0 (L)	Has it been confirmed that utility systems have sufficient capacity, as well as the individual valve actuators?	0.5 (M)	0.5
Is leak tightness an issue for the redundant valves in question	5%		Have max leakage rates been uniquely defined, i.e. consistency between all documentation specifying maximum internal leakage rates are ensured?	1.0 (L)	Has it been confirmed that the valves are suited for keeping fully tight in closed position? May the operating condition alter this capability?	2.0 (No)	2.0
Environmental control	15%	Y/N	Defenses/evaluation	Eff.	Defenses/evaluation	Eff.	
Are valves exposed to an internal environment such as dirt, sand, hydrate formation, etc. possibly affecting valve performance?	6%	Y	Has specific procedures for control of sand, dirt, hydrate formation, etc. been implemented, including procedures for cleaning and lubrication of valves?	1.0 (L)	Have physical measures for control of internal environmental influences such as sand traps, inhibitors, etc. been implemented?	0.5 (M)	0.5
Must the valve function under a large variety of pressure and flow conditions?	3%	Y	Have the valves, actuators and hydraulic blocks been verified and tested for all relevant pressure, temperature and flow conditions?	1.0 (L)	Has extra sizing/dimensioning of actuator, etc. been implemented to ensure that the valve will function under all foreseeable process conditions?	0.5 (M)	0.5
Are the valves exposed to snow, temperature changes, icing conditions, sea spray, etc., possibly affecting valve performance?	6%	Y	Are procedures for removing ice, build-up of snow, etc. during periods with cold temperatures in place and implemented (including procedures to check that e.g. heat tracing is functioning/is on)?	0.5 (M)	Are valves exposed to snow, ice, sea spray, cold temperatures equipped with separate weather protection/ isolation/heat tracing?	0.5 (M)	0.25

operation and maintenance. *Environmental control*: Covering aspects related to suitability of the equipment versus the design envelope (fit for purpose), and the level of alternating environmental conditions (see example in Table 3). *Operation & Maintenance*: Covering the operational personnel's proneness to perform errors and failures as well as the organization's readiness to prevent such failures. Aspects related to procedures, competency and training are included here. *Operational follow-up and management of change:* Aspects related to how experienced failures are treated and followed-up, alignment of test intervals in light of experienced failure history, root cause analysis incl. identification of systematic and common/shared failure causes, implantation of failure reducing measures as well as handling of changes and modifications affecting the particular equipment.

Each of these six categories have, based on experiences from the operational reviews, been assigned a generic weight (e.g. 30% of the CCFs can be explained by design related properties). It should be remarked that the weights at this stage are preliminary. For each category a number of checklist questions have been suggested, each with a weight summing up to the total weight of the associated category. For example, from Table 3 it can be seen that the closing time question is given a weight of 20%, since much problems have been experienced related to this issue. If a generic beta of 10% is assumed for shutdown valves, then, in effect, 2% of this beta can be related to closing time problems.

Based on an evaluation of the defenses related to each particular threat, this contribution can increase (no defenses implemented), remain unchanged (only "state of the art" defenses implemented) or decrease (additional defenses implemented). For example, for the referred closing time question, the resulting modification factor is 0.5, meaning that the beta contribution is reduced from 2% to 1%. Following this procedure for all questions will then yield an updated beta factor for shutdown valves based on plant specific conditions.

Defenses are per today predefined in the checklists. As part of the ongoing work it is being considered whether the checklists should have an added flexibility of the users being able to add their own defenses.

7 CONCLUSIONS AND FURTHER WORK

This paper has proposed a new type of CCF checklist, with basis in experience collected for the oil and gas industry. The approach, i.e. the definition of CCF categories and defenses, is as such generic, and may be applied also to other industry sectors. The weighting and detailed formulation of underlying information in the checklist should, however, be updated to reflect the industry sector experience in question.

Further work is needed to finalize the checklists. The next step is to present the checklist the PDS members and include their input and feedback in the final stage of the checklist development. Additional data may be gathered if needed from future operational reviews. The authors would like to present a more complete checklist proposal in a new and more extended publication, covering not only the shutdown valves but also detectors and transmitters.

The overall aim is to provide a more comprehensive framework for the treatment of CCFs in reliability assessments that may be applied in the design phase and updated to monitor status of CCFs at regular stages in the operational phase

ACKNOWLEDGEMENT

The present work has been carried out as part of the research project "*Tools and guidelines for overall barrier management and reduction of major accident risk in the petroleum industry*", a project that has been sponsored by the Research Council of Norway and the PDS participants (www.sintef.no/pds).

A geometric test for the analysis of contingency tables

J. Quigley & K.J. Wilson
Department of Management Science, University of Strathclyde, Glasgow, UK

ABSTRACT: The Chi-squared test for contingency tables has good performance when sample sizes are sufficiently large but is not appropriate with small samples. This is particularly relevant to reliability analysis where some failure types will occur infrequently. When this condition is violated, Fisher's exact test is often used as it is valid for all sample sizes. However, Fisher's test has been criticised for being overly conservative. Alternatives have been proposed but typically involve more complex computations. In this paper we propose an alternative test based on a geometric projection of the multinomial distribution onto the n-sphere. Each multinomial observation is represented by a single point on this sphere. The angle between two points representing two different multinomial observations can then be compared to the distribution of the angle under the assumption that the realisations come from the same underlying distribution. The null hypothesis distribution is simulated and easy to compute. This new test is compared to the Chi-Squared test and Fisher's Test in terms of both Type I and Type II errors and its potential use in reliability modelling is indicated using a real case study concerned with a manufacturer assessing different patterns of failures of machines across different regions.

1 INTRODUCTION

Contingency tables are used in the areas of safety and reliability modelling when there are several machines, systems or failure types which are possibly spread over different locations. That is, whenever data are in form of frequency of events for categorical variables. Typically we wish to know whether there are differences between the probability of failure between the different states of two of the different factors such as failure type and location. Examples include (Conte,Rubio, Garcia, & Cano 2011, Maiti & Khanzode 2009, Colombo & Ihm 1988, Schneidewind 1992).

Conte et al. (Conte, Rubio, Garcia, & Cano 2011) considered a 19×19 risk-injury contingency table of the accident rates in Spanish companies over an 11 year period to identify separate risk and injury groups. Maiti and Khanzode (Maiti & Khanzode 2009) investigated a relative risk model using a two way contingency table for fatal roof and side fall accidents at coal mines in India.

In Colombo and Ihm (Colombo & Ihm 1988) failure rates at nuclear power plants were considered. The failure rates of components were broken down by plant location and reactor system. This led to a contingency table for the numbers of failures which was further complicated by the different exposures at each of the plants. Schneidewind (Schneidewind 1992) was interested in the validation of software metrics. His proposed methodology used contingency tables as an important part of this validation process, counting up the numbers of correct and incorrect classifications of each type.

An example of a contingency table, based on the two factors in Colombo and Ihm (Colombo & Ihm 1988), is given in Table 1.

In such a contingency table we would typically be interested in whether there were differences in the probabilities or rates of failures which result in the observed numbers of failures $n_{i,j}, i, j = 1,2,3$ between the different locations or systems. Thereare two main statistical tests which could be used to do this; the Chi-Squared Test and Fisher's Exact Test (Pearson 1900, Fisher 1922).

In the Chi-Squared test expected frequencies are calculated for each of the cells in the contingency table $e_{i,j}$ and these are then compared to the observed frequencies to form the Chi-Squared test statistic

$$\chi^2 = \sum_{i=1}^{I} \sum_{j=1}^{J} \frac{(n_{i,j} - e_{i,j})^2}{e_{i,j}^2},$$

Table 1. An example contingency table with factors location and system.

	Location		
System type 1	$n_{1,1}$	$n_{1,2}$	$n_{1,3}$
System type 2	$n_{2,1}$	$n_{2,2}$	$n_{2,3}$
System type 3	$n_{3,1}$	$n_{3,2}$	$n_{3,3}$

which is compared to the χ^2 distribution on $(I-1)(J-1)$ degrees of freedom. The Chi-Squared Test is useful when all of the observed frequencies are equal to at least 5 but performance becomes poor when at least one of the frequencies is smaller than this (Cochran 1954). It cannot be carried out with multiple observed frequencies of 0.

Variants to the Chi-Squared Test have been proposed for small sample sizes. Two of the most prominent are the Yates correction and Fisher's Test. In Fisher's Test an exact p-value is calculated based on the assumption that the row and column totals are fixed. While the Fisher Test is exact and so is suitable for small sample sizes it has been criticised for being overly conservative (Liddell 1976). This conservatism stems from the discrete nature of the test statistic and the assumption of fixed marginals. Several other variants have been proposed in the literature but many of these rely on intensive numerical methods and are therefore, for practitioners wishing to test for differences quickly and simply, not always suitable or appropriate.

(Olbrich 1965) proposed a geometric projection of the multinomial distribution onto the n-sphere. Each multinomial observation was represented by a single point on this sphere and the difference between two multinomial realisations of the same degree was represented by the angle between the two points on the sphere. This representation had the nice property that it was variance stabilising. The representation was not commutative, however; if the order of the categories were switched in the multinomial distributions then the points on the sphere and the angle between the points did not remain the same.

In this paper we propose a commutative version of the (Olbrich 1965) representation. We then use this version to define a hypothesis test to test for differences in contingency tables. The test statistic is the angle between the two multinomial realisations. We use the variance stabilising property of the transformation in order to approximate the distribution under the null hypothesis that the two realisations come from the same underlying probability vector. The test does not require intensive numerical methods.

The remainder of the paper is structured as follows. In Section 2 we review the method of (Olbrich 1965), give our proposed commutative adaption and outline the geometric hypothesis test. In Section 3 we investigate the properties of the proposed transformation and in Section 4 we conduct a simulation study to assess the performance of the Geometric Test against the Chi-Squared Test and Fisher's Test for both Type I and Type II errors. Finally, in Section 5 we give an illustrative example of the method and we conclude the paper in Section 6.

2 GEOMETRIC TRANSFORMATION OF MULTINOMIALS

2.1 *The Olbrich transformation*

Consider two realisations from a multinomial distribution in n dimensions, $(x_1, \ldots, x_n)$ and $(y_1, \ldots, y_n)$. Let

$$x_T = \sum_{i=1}^{n} x_i,\ y_T = \sum_{i=1}^{n} y_i,$$

be the total number of observations from each of these multinomials. Then the proportions of the observations in each of the categories are

$$p_i = \frac{x_i}{x_T},\ q_i = \frac{y_i}{y_T}.$$

Olbrich proposed representing the multinomials in spherical co-ordinates as points on an n-shphere using these proportions. Denote these points by $\underline{\theta}, \underline{\phi}$ respectively. Then

$$\underline{\theta} = \left(\cos^{-1}\left(\sqrt{p_1}\right), \ldots, \cos^{-1}\left(\sqrt{p_n}\right)\right),$$
$$\underline{\phi} = \left(\cos^{-1}\left(\sqrt{q_1}\right), \ldots, \cos^{-1}\left(\sqrt{q_n}\right)\right).$$

We can use such a transformation to calculate the angle between any two multinomial realisations on the n-sphere. This is given in the below result.

Theorem 1. *The angle A_O between two multinomial realisations $(x_1, \ldots, x_n)$ and $(y_1, \ldots, y_n)$ with proportions of observations in each category $p_i = x_i/x_T, q_i = y_i/y_T$ is given by*

$$A_O = \cos^{-1}\left\{\sum_{i=1}^{n+1}\sqrt{p_i q_i\left[\prod_{j=0}^{i-1}(1-p_j)(1-q_j)\right]}\right\},$$

where $p_0 = q_0 = 0$, and $p_1 = q_1 = 1$.

Proof. We can represent these points in Cartesian co-ordinates in $(n+1)$ dimensions. That is,

$$\begin{aligned}
c_1 &= r\cos(\cos^{-1}(\sqrt{p_1})),\\
c_2 &= r\cos(\cos^{-1}(\sqrt{p_2}))\sin(\cos^{-1}(\sqrt{p_1})),\\
&\vdots\\
c_n &= r\cos(\cos^{-1}(\sqrt{p_n}))\prod_{i=1}^{n-1}\sin(\cos^{-1}(\sqrt{p_i})),\\
c_{n+1} &= r\prod_{i=1}^{n}\sin(\cos^{-1}(\sqrt{p_i})).
\end{aligned}$$

The radius is $r = \sqrt{\sum_{i=1}^{n+1} c_i^2}$. This representation can be tidied up, using the fact that $\sin(\cos^{-1}(z)) = \sqrt{1-z^2}$, to

$$
\begin{aligned}
c_1 &= r\sqrt{p_1}, \\
c_2 &= r\sqrt{p_2(1-p_1)}, \\
&\vdots \\
c_n &= r\sqrt{p_n\prod_{i=1}^{n-1}(1-p_i)}, \\
c_{n+1} &= r\sqrt{\prod_{i=1}^{n}(1-p_i)}.
\end{aligned}
$$

We denote the Euclidian co-ordinates for $\underline{\theta}$ as $(c_1(\underline{\theta}), \ldots, c_{n+1}(\underline{\theta}))$ and for $\underline{\phi}$ as $(c_1(\underline{\phi}), \ldots, c_{n+1}(\underline{\phi}))$. Then the angle between these two points is

$$
A_O = \cos^{-1}\left(\frac{\sum_{i=1}^{n+1} c_i(\underline{\theta})c_i(\underline{\phi})}{\sqrt{\sum_{i=1}^{n+1} c_i(\underline{\theta})^2 \sum_{i=1}^{n+1} c_i(\underline{\phi})^2}}\right).
$$

This reduces to the result given.

The angle has the nice property that it tends to zero for two multinomial realisations from the same underlying distribution as the sample sizes go to infinity. To see this, consider

$$
\begin{aligned}
\lim_{x_T, y_T \to \infty} A &= \cos^{-1}\left(1-\rho_n + \sum_{i=1}^{n}\sqrt{\rho_i^2\prod_{j=1}^{i-1}(1-\rho_j)^2}\right) \\
&= \cos^{-1}\left(1-\rho_n + \sum_{i=1}^{n}\rho_i\prod_{j=1}^{i-1}(1-\rho_j)\right) \\
&= \cos^{-1}(1) \\
&= 0.
\end{aligned}
$$

2.2 *The commutative property*

Upon inspection of the angle, A_O, in Theorem 1, it is apparent that the choice of label, i.e., i, which a category is assigned will influence the resulting value of the angle. That is, if the categories of the multinomial variables are re-ordered, then the angle between them using the Olbrich transformation will be different.

Consider a simple 2×2 table with the two categories being "blue" and "not blue". Here the test statistic reduces to one of the two following test statistics depending on which category is assigned to be the first category.

$$
\begin{aligned}
a_O &= \cos^{-1}\left(\sqrt{p_{blue}q_{blue}} + (1-p_{blue})(1-q_{blue})\right) \\
&\neq \cos^{-1}\left(\sqrt{(1-p_{blue})(1-q_{blue})} + p_{blue}q_{blue}\right).
\end{aligned}
$$

This non-commutative property is a result of the dependence structure in the probabilities which ensures that they sum to 1 over all categories. As such, if we re-define the probabilities used within the test such that they are conditionally independent then we will have a commutative representation of the angle between two multinomial realisations.

As such, by using probabilities conditionally independent on categories with a lower index value and following the same geometric transformation as in Olbrich's work we can obtain a commutative formula for the angle. This is given in the following theorem. The proof follows the same form as that for Theorem 1. It is left to the reader.

Theorem 2. *The angle A_G between two multinomial realisations $(x_1, \ldots, x_n)$ and $(y_1, \ldots, y_n)$ with conditional proportions of observations in each category given that they weren't in any previous categories $\gamma_i = x_i/x_{T_i}$, $\beta_i = y_i/y_{T_i}$, where $X_{T_i} = \sum_{j=i}^{n} x_j, Y_{T_i} = \sum_{j=i}^{n} y_j$, is given by*

$$
\begin{aligned}
A_G &= \cos^{-1}\left(\sum_{i=1}^{n+1}\sqrt{\gamma_i\beta_i\left[\prod_{j=1}^{i-1}(1-\gamma_i)(1-\beta_i)\right]}\right) \\
&= \cos^{-1}\left(\sum_{i=1}^{n}\sqrt{p_iq_i}\right),
\end{aligned}
$$

where $p_0 = q_0 = 0$, and $p_1 = q_1 = 1$.

2.3 *Geometric hypothesis test*

Suppose we have two multinomial realisations $\underline{x}$ and $\underline{y}$ with underlying probability vectors $\underline{p}$ and $\underline{q}$ respectively. We wish to test whether the two vectors come from the same underlying multinomial distribution. The hypothesis test will take the form

$$
\begin{aligned}
H_0 &: \underline{p} = \underline{q}, \\
H_1 &: \underline{p} \neq \underline{q}.
\end{aligned}
$$

The test statistic is

$$
A_G = \cos^{-1}\left(\sqrt{\sum_{i=1}^{n}\hat{p}_i\hat{q}_i}\right),
$$

for observed $\hat{p}_i = x_i/x_T, \hat{q}_i = y_i/y_T$. The p-value is then

$$
\Pr(a \geq A_G) \approx \frac{1}{N}\sum_{i=1}^{N} I(a_i \geq A_G),
$$

where N is a large number of simulated values of A_G under the assumption that H_0 is true. To calculate $a_1, \ldots, a_N$ we need to estimate the probability vector under the null hypothesis, $\underline{p}_0$. This is

$$
\underline{\hat{p}}_0 = \frac{1}{2} \times (\underline{\hat{p}}_1 + \underline{\hat{p}}_2).
$$

Thus we see that to perform the test we carry out a parametric bootstrap (Efron & Tibshirani 1993) on $\underline{p_0}$.

3 PROPERTIES OF THE TRANSFORMATION

We have evaluated the mean and standard deviation of the angle A_G resulting from the transformation of one multinomial variable compared with its mean. The aim is to develop some intuition concerning the behaviour of this transformation. We have considered the mean and standard deviation with respect to the underlying probabilities and sample size.

Specifically, we have used Maple 17 software to calculate the mean and standard deviation exactly for multinomial distributions with 3 to 10 categories. In varying the underlying probabilities we used the standard deviation of the probabilities, as this is related to the Euclidean distance of the vector of probabilities from the vector of equal probabilities. Our standard deviations range from 0 to 0.5. We give two figures below to illustrate the analysis. The overall conclusions made are based on the more comprehensive investigation.

In Figure 1 we see the change in the mean and standard deviation of A_G for a 3-dimensional multinomial distribution over different sample sizes. In the left hand plot the standard deviation is 0 and in the right hand plot it is 0.29. In Figure 2 we see the same two plots for a 10 dimensional multinomial distribution.

An interesting pattern in the mean of angle from the transformation is that it monotonically decreases as sample size increases. Our study considered 99 different combinations of probabilities, number of categories and sample sizes, from which we are ableto fit a curve to the relationship between the mean angle, the standard deviation of the probabilities and the number of samples. That is,

$$\overline{x}_A = 1.356 - 2.8 \times s_p + (0.8 \times s_p - 0.34)\log(n),$$

where $\overline{x}_A$ is the mean of A_G and s_p is the standard deviation of the probabilities. This excludes the cases with equal probability. The fit of the curve was very good with $R^2 = 87.8\%$, and it shows that the mean decreases at a rate $o(\log(n))$ and is not affected by the number of categories m. The standard deviation of the probabilities influences the mean in two ways; it decreases the mode and increases the rate of decay with respect to sample size.

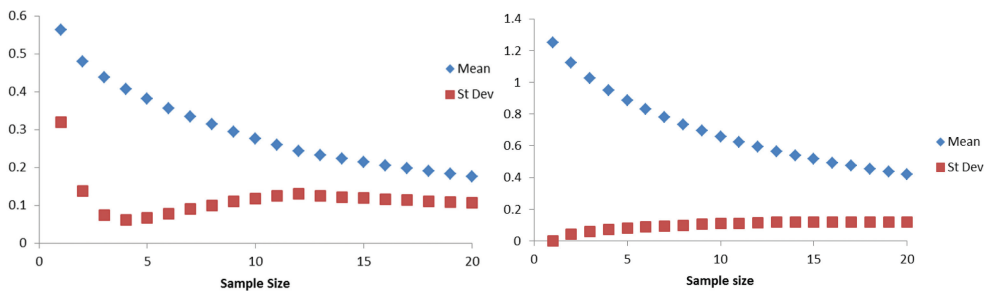

Figure 1. Mean and standard deviation of A_G for $m = 3$ with standard deviations of 0 (left) and 0.29 (right).

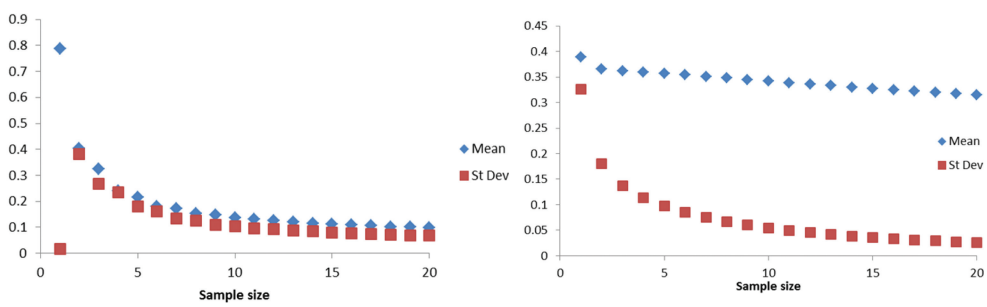

Figure 2. Mean and standard deviation of A_G for $m = 10$ with standard deviations of 0 (left) and 0.29 (right).

4 SIMULATION STUDY

4.1 *The distribution of A_G*

We wish to compare two multinomial realisations to test if they come from the same underlying distribution, i.e., if the have the same probability vector.

In Figure 3 we give histograms of the angle A_G for the trinomial distribution simulated with the same underlying probabilities for a range of different parameter vectors. In each case 10,000 pairs of points are simulated and there are 50 observations for each simulated point.

We see that in all cases the distribution of A_G has a mode which is close to zero and is right skewed. Of course, if the two realisations are the same then the angle between them will be 0.

We can carry out a similar simulation exercise for trinomial realisations which come from distributions with different underlying probability vectors. The resulting histograms are given in Figure 4. Again, each graph is the result of 10,000 simulations.

This time we see that the distributions of A_G are generally much more symmetric and have modes which are typically larger than in Figure 3. This suggests that A_G may be a useful statistic within the hypothesis test we have outlined in Section 2.3.

4.2 *Type I and Type II errors*

We will investigate the properties of the test with respect to Type I and Type II errors. All results are based on 1000 samples. The Type I error probabilities are given in Table 3 in the Appendix for two different probability vectors and different sample sizes. The probabilities from the Pearson Chi-squared test are also given.

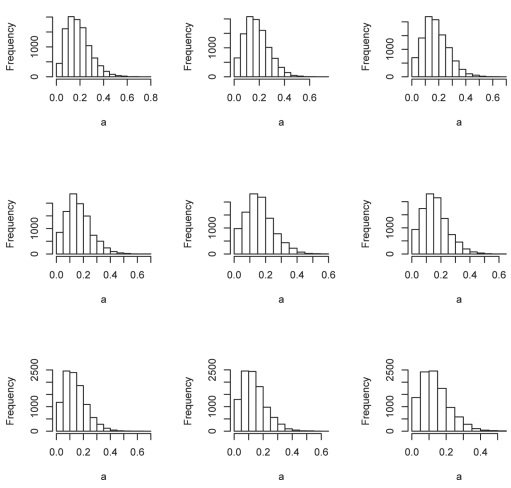

Figure 3. The distribution of A_G for 10,000 simulated pairs from the trinomial distribution with the same probability vector.

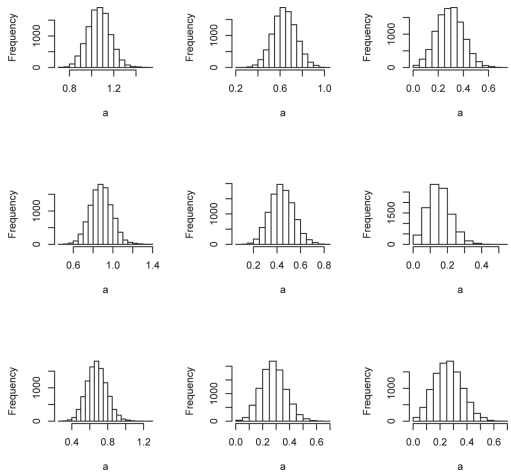

Figure 4. The distribution of A_G for 10,000 simulated pairs from the trinomial distribution with different probability vectors.

We see that, for $\underline{p}_1$ and $\underline{p}_2$ all three tests are performing fairly well, with the proportions of Type I errors being close to 0.05 for all tests over almost all sample sizes. This indicates that, for trinomials in which all of the categories have reasonably large probabilities, all of the tests perform satisfactorally with respect to Type I errors. However, for $\underline{p}_3$ in which there are small probabilities of being in some of the categories and hence small numbers of observations in those categories, all three tests have proportions of Type I errors well below 0.05 for a sample size of 5. The geometric test then performs well from a sample size of 10 whereas the other two tests are still making too few Type I errors up to a sample size of approximately 30.

The Type II errors are given in Table 4 in the Appendix. In Table 4 probabilities are $\underline{p}_1 = (1/3, 1/3, 1/3)$, $\underline{p}_2 = (1/2, 1/4, 1/4)$ and $\underline{p}_3 = (8/10, 1/10, 1/10)$. We see that the Geometric Test outperforms the other two tests for all combinations of probability vectors for sample sizes of 5 and 10. Beyond a sample size of 10 the Fisher Test, in particular, typically out-performs the Geometric Test. However, in this paper we are interested in situations where we have small probabilities and possibly few data and the in this case the Geometric Test give an improvement, albeit small, over the other two tests. When combined with its superior Type I error probabilities for the trinomial distribution with low probability events and this new Geomet-

ric Test looks to have some strengths over the two traditional tests.

5 ILLUSTRATIVE EXAMPLE

The illustrative example in this section is based on a desensitised version of real data. The numbers used are typical rather than specific values.

A company manufactures machinery which is then sold to operators in the power sector. As part of the contracts for the machinery the manufacturer guarantees specific levels of performance including reliability levels. There are different possible failure types of the machines which at a high level can be classified as Design, Installation, Maintenance and No Fault Found.

The reliability of the machinery depends on how it is operated and how it is maintained. This is not in the control of the manufacturer. It is suspected that there could be systematic differences between different regions as to the reliability of the sameequipment as a result of different operating procedures and different operating and maintenance capabilities.

Data have been collected on the numbers of failures by failure type and region and are given in Table 2.

We wish to test whether there are differences in the failure patterns across the different regions. The expected numbers of failures in each of the cells conditional on fixing the totals across rows and columns are given in brackets in Table 2.

Suppose we ask the question: is there a difference in the pattern of failures between Europe and North America? For the Pearson Test $p = 0.074$, for Fisher's Test $p = 0.090$ and so you cannot reject the null hypothesis that there is no difference in the pattern of failures between the two areas.

If we use the Geometric Test, however, we get a Test Statistic $A_G = 0.465$ which corresponds to a p-value of $p = 0.049$. Thus we see that the Geometric Test detects the difference between the two areas in this case when the Fisher and Pearson tests do not. This would make a difference to automatic identification of associations between factors that might provide insights into reliability behaviours.

Table 2. Contingency table of the number of failures of specific failure types across different regions.

Type/region	Europe	N America	Africa	Asia
Design	2 (5)	12 (12)	7 (6)	6 (4)

6 CONCLUSIONS

In this paper we have considered the analysis on contingency tables for numbers of failures in a reliability context. There will typically be some failure types with low probability and as such small numbers of realised failures in some of the cells in the contingency table. This means that the traditional Chi-Squared Test will be unsuitable and the most common alternative, Fisher's Test, is conservative meaning that statistically significant differences will be missed.

We have considered an alternative to these tests, which we have named the Geometric Test, which represents multinomial observations as points on the n-sphere. The test statistic is then the angle between the points and the p-value is approximated by sampling from the distribution under the null hypothesis. This new test out-performed the other two tests with respect to the Type I errors when some categories of the multinomial variable had small probability and with respect to Type II errors for small sample sizes.

There is much work still to be done for this method from both theoretical and applied perspectives. The test needs to be validated on a much larger simulation study and an investigation could be carried out into the theoretical properties of both the teststatistic and the test. There is also work to be done in evaluating the performance of the test in more than 3 dimensions and extending the test to more than two simultaneous miultinomial variables. It would also be interesting to benchmark the commutative test against the non-commutative transformation of Olbrich.

From an applied perspective, in order for the method to be useable for reliability practitioners it will be needed to be automated so that large numbers of simulations do not have to be run every time the test is performed.

Assessment of a remaining working life of energetic devices using service data

M. Sykora, M. Holicky & J. Marková
Klokner Institute, Czech Technical University in Prague, Prague, Czech Republic

K. Presl
ČEZ, a.s., Prague, Czech Republic

ABSTRACT: Numerous fossil power stations in the Czech Republic and their key devices are reaching their design working life. The data from measurements and statistical methods may be applied with advantage for estimating a remaining working life. The paper discusses statistical methods appropriate for such analyses and provides suggestions for practical applications. Important steps of the analysis include selection of a suitable regression model and estimation of probability of exceeding a limiting value. Inherent randomness and trend of the observed parameter as well as statistical uncertainty due to a limited amount of the data should be taken into account. Aleatory uncertainties due to randomness and actual trend of the observed parameter as well as epistemic uncertainty due to lack of data and imprecision of a test method should be taken into account. Implementation of the theoretical procedures for the prediction of a remaining working life of important energetic devices is illustrated considering service data of the capacity of a generator and creep of steam piping.

1 INTRODUCTION

Numerous fossil power stations in the Czech Republic and their key devices are reaching their design working life. Effective maintenance plans, including time schedules, repair strategies and extent of repairs, should be based on credible estimates of the remaining working life of key energetic devices. That is why the monitoring systems are installed to provide operators with information concerning performance of energetic devices of production units of power stations.

Statistical analysis of monitoring data and outcomes of inspections may significantly improve estimates of the remaining working life of energetic devices. That is why the paper discusses statistical methods appropriate for such analyses. Basic tools, ready for daily use in the engineering practice, are recommended for major steps of the statistical analysis and suggestions for practical applications are provided.

2 BASIC STEPS OF STATISTICAL ANALYSIS

An operator of a power station commonly records an immense amount of measurements of technical parameters. Examples of the technical parameters (hereafter 'parameters') include:

- Parameters describing the creep of steam piping,
- Capacity of a generator,
- Outcomes of dissolved gas analysis, oil physical/chemical tests or tests of insulation of a transformer,
- Carbonation depths of concrete and corrosion rate of reinforcement in cooling towers etc.

Monitoring data can be used to predict a remaining working life of energetic devices (hereafter 'remaining life'). Statistical analysis of such data should include the following basic steps:

1. On the basis of expert judgements, parameters that may be used for prediction of a remaining life are identified and their measurements are collected. It is important to realise that different parameters may be selected for different production units.
2. The selected parameters are assigned by limiting values. When a limiting (critical) value is exceeded, a decision should be taken and device should be repaired or replaced.
3. Each statistical sample (set of measurements of a parameter) should be tested for outliers (minimum or maximum values). It is recommended to combine appropriate

graphical illustration of the data (e.g. by means of histograms) with statistical tests (for instance Grubbs' or Dixon's tests). Significance level (the probability that an extreme measurement is incorrectly detected as an outlier) is commonly selected as 0.05 or 0.01, Holicky (2013). When a cause of an outlying observation is identified (e.g. deviations from standard test conditions, human errors affecting measurements or incorrect records of data), the outlier is removed from the sample.

4. In case of the doubts about statistical dependence of parameters a correlation coefficient (Holicky (2013)) is determined. For a high degree of statistical dependence it may suffice to monitor one parameter only.
5. In the case of insufficient experimental data, Bayesian updating (JCSS (2001)) may be applied to combine information from different sources (few test results e.g. with measurements from different locations or devices with similar operating conditions, with results of theoretical models or with expert judgements). As an example, complex assessments of a steam turbine may be conducted in periods of about ten years and experience gained from other turbines can be then useful.

   Note that Bayesian updating allows updating estimates of remaining working life when new monitoring data become available.
6. To predict the trend of a parameter an appropriate regression model is selected on the basis of technical experience and its fit to the empirical data is verified.
7. When the parameter is proved to be dependent on a considered factor (device age, in-service time, number of starts etc.), boundaries of the regression curve and probabilities of exceeding limiting values are estimated.

Steps 6 and 7 concerning the prediction of parameters are described in detail in the following section.

3 PREDICTION OF PARAMETERS

Prediction aims to describe a principal trend of the parameter X with a considered time factor t. It may be important to take into account (or filter out) regular fluctuations around the regression curve caused by seasonal factors (such as increased power production in winter periods) and/or by long-term effects (resulting e.g. from a management plan of the power station).

In addition the parameter X is often fluctuating around the trend in a purely random manner. Such a random effect is normally time-independent and is caused by minor factors that are often difficult to identify. Examples of such factors may include unspecified deviations from 'standard' test conditions or measurement uncertainty (more specifically random component related to an individual measurement) due imprecision of a test method, testing device or minor human errors. Description of this random effect should be based on probabilistic methods and is an important part of the analysis.

Details of the regression analysis are provided in many publications, see e.g. Ang & Tang (2007) or Ryan (2008). In most cases linear, parabolic or exponential functions are used to describe the trend of X with t. An important assumption is that the operating conditions are same for a period covered by measurements and for a period of prediction.

The statistical prediction should consist of the following steps:

1. Considering technical experience with the parameter X, an appropriate regression model is selected. In common cases a linear model is appropriate:

$$X = \beta_0 + \beta_1 t + \varepsilon \tag{1}$$

   where β_0 and β_1 = regression coefficients; and ε = random error of the model.

   For some parameters physical evidence suggests a non-linear trend (e.g. exponential for parameters describing the creep of steam piping). If possible a non-linear relationship between X and t is then linearized by a suitable transform.
2. On the basis of a residual scatter (Ryan (2008)) a fit of a regression model and experimental data is assessed; normally the regression model is deemed appropriate for relatively high residual scatters, say over 0.6.
3. Dependence of X on t is verified by the test of a statistical hypothesis $\beta_1 = 0$ (commonly at a significance level of 0.05 or 0.01). If the hypothesis is rejected, the parameter X is assumed to be dependent on t. Otherwise the prediction hardly makes sense.
4. Prediction intervals of X are determined for a selected confidence level—probability that the parameter will be covered by the interval. A common confidence level is 0.95; however lower values (e.g. 0.75) may be accepted particularly in case of small sample sizes.
5. Probability P_{lim} of exceeding a limiting value is estimated for a selected value of t. Note that an acceptable value of P_{lim} should be established considering consequences associated with exceeding the limiting value. The consequences may considerably differ for various parameters—ranging from a requirement on the planned repair of a device to the need of

an immediate intervention causing unplanned outage of a production unit. That is why associated risks should be considered rather than probabilities, Sykora et al. (2013).

Relationships for prediction intervals and probability P_{lim} as well as more details on the prediction can be found in literature; Ang & Tang (2007), Holicky (2013) and Ryan (2008).

4 CASE STUDIES

4.1 *Capacity of generator*

The capacity of rod winding is considered as an important parameter for prediction of the remaining working life of a generator. Measurements of the capacity of a selected phase of the generator, taken at 100% of nominal voltage each about three years, are shown in Figure 1. No measurement is identified as an outlier. It appears that the capacity is significantly dependent on time (residual scatter is 0.63).

Figure 2 indicates variation of the probability P_{lim} of exceeding the limiting value with time. It follows that the probability is relatively high; for instance $P_{lim} = 0.15$ is predicted for year 2016.

It is important to realise that the width of the prediction interval (Fig. 1) and estimated probability P_{lim} (Fig. 2) are affected by different uncertainties:

- Aleatory uncertainties due to inherent variability of the observed parameter affected by properties of rod winding and service conditions,
- Epistemic uncertainties caused by lack of statistical data and imprecision of a test procedure (measurement uncertainty).

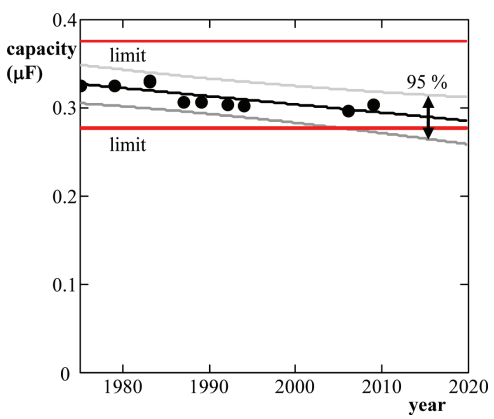

Figure 1. Variability of the capacity of a generator with time.

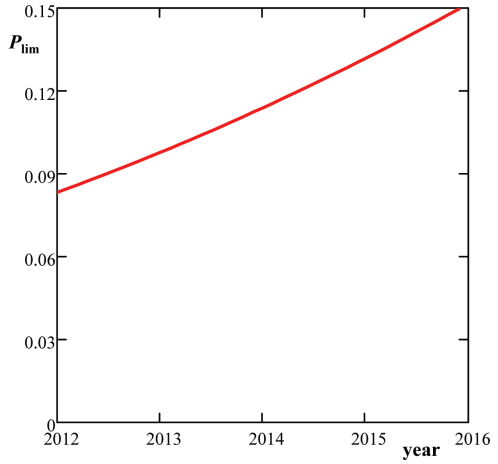

Figure 2. Variation of the probability P_{lim} of the capacity of a generator with time.

The former type of uncertainties is indeed a reason for regular monitoring. The latter uncertainties can be apparently reduced either by increased frequency of measurements or by the application of a more advanced test method.

In an illustrative example assume that a test method cannot be readily improved. The number of measurements n is then optimised to reduce the statistical uncertainty and minimise expected total costs C_{tot} related to a specified reference period. The optimum number of measurements can be assessed as:

$$\text{minimum}_n\ C_{tot}(n) = n \times C_1 + C_f \times P_{lim}(n) \qquad (2)$$

or, equivalently, using the standardised total costs:

$$\text{minimum}_n\ c_{tot}(n) = n + C_f / C_1 \times P_{lim}(n) \qquad (3)$$

where C_1 = all costs related to a single measurement; C_f = all costs related to exceeding the limiting value; and c_{tot} = total costs standardised by C_1.

The so-called pre-posterior analysis (JCSS (2008)) can be conducted to optimise decisions in regard to acquisition of new data. Consider that the total cost is optimised for a period from 2014 to 2020 and a decision can be to conduct zero to four measurements during this period (from 2014 each two years). In the pre-posterior analysis it is assumed that the future measurements will follow the trend indicated Figure 1. Note that in a more advanced analysis the assumption could be relaxed and e.g. influence of measurement uncertainty could be modelled.

The standardised total costs given in Equation (3) are optimised with respect to the

decision parameter n. Figure 3 shows the variation of the total costs c_{tot} and of the probability P_{lim} with the number of measurements n for two representative values of the cost ratio $C_f/C_1 = 10$ and 40. It can be concluded from Figure 3 that:

– For $C_f/C_1 = 10$: no measurement is taken since the total costs are affected more significantly by the cost of measurement than by the cost related to exceeding the limiting value,
– For $C_f/C_1 = 40$: one measurement is optimal.

Note that the optimum number of measurements may be significantly affected by a minimum period between the measurements. This period normally follows from a management plan, depending particularly on planned outages of a power plant.

In principle the result of a new measurement may affect an outcome of the prediction and thus a number of measurements should be re-optimised after each measurement.

4.2 *Creep of high-pressure steam piping*

The remaining working life of a high-pressure steam piping made of steel 15 128.5 is predicted. The piping has been in service for 22 years (absolute operating temperature 528 °C and pressure 9.6 MPa). The remaining working life is estimated using the Larson–Miller Parameter (LMP).

Values of LMP given by Rund et al. (2013) are based on results of creep tests that include stresses σ and time to rupture t provided by Kuboň (2011). Variation of σ with LMP is indicated in Figure 4. No measurement is identified as an outlier. Exponential relationship between LMP and σ is considered:

$$\sigma = \beta_0 - \exp \beta_1 t + \varepsilon \tag{4}$$

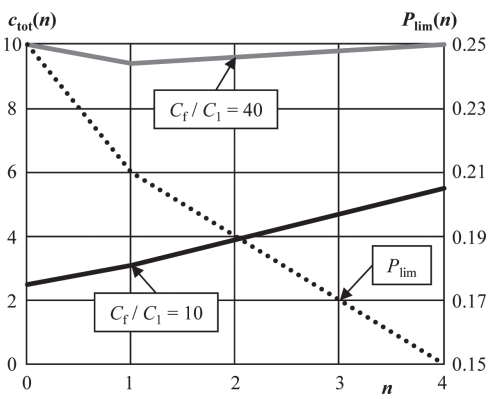

Figure 3. Variation of c_{tot} and P_{lim} with n for $C_f/C_1 = 10$ and 40 (example of the capacity of a generator).

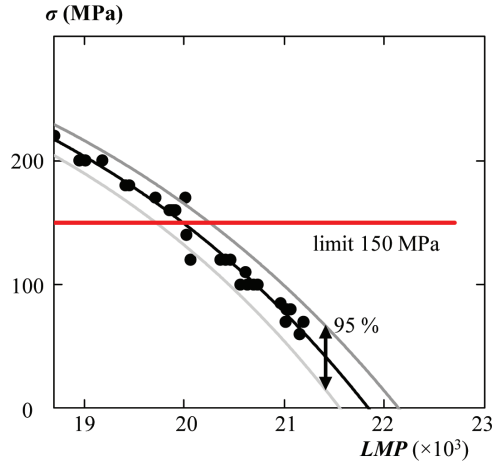

Figure 4. Variation of σ with parameter LMP (example of the creep of steam piping).

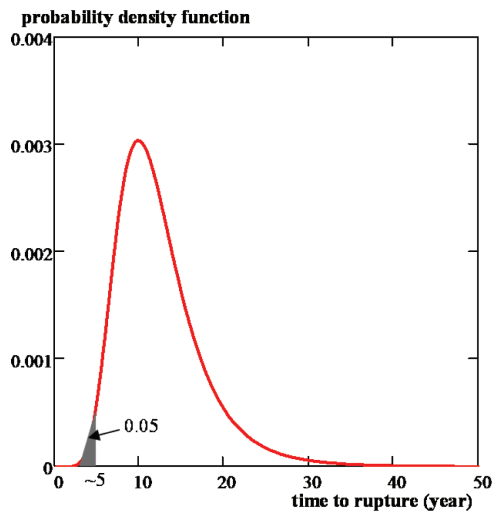

Figure 5. Probability density function of the time to exceeding the limiting value (example of the creep of steam piping).

The following transform enables to apply a linear regression:

$$\sigma' = \ln(\beta_0 - \sigma) \tag{5}$$

The following regression coefficients are obtained; $\beta_0 = 376$; and $\beta_1 = 2.71 \times 10^{-4}$. Prediction intervals and a limiting value are indicated in Figure 4.

It is assumed that the end of a working life of the piping is reached when the stress drops below 150 MPa. Probability density function of the time

to exceeding the limiting value (time to rupture) in shown in Figure 5.

The acceptable value of P_{lim}, needed to estimate a remaining working life, could be established on the basis of risk-informed decision making similarly as for the capacity of a generator. For illustrative purposes a value of 0.05 is considered and remaining working life is then estimated as about five years (Fig. 5).

5 DISCUSSION

The present contribution proposes a procedure for the prediction of a remaining life of energetic devices using monitoring data. The procedure is intentionally simplified for daily use in the engineering practice. It is recommended to supplement such an analysis by more advanced theoretical procedures whenever validity of the accepted assumptions is doubtful or significant deterioration mechanism (for instance with rapid progress) is detected. Examples of more advanced procedures were presented e.g. by Hammer et al. (2012), Wang et al. (2011), Wei et al. (2013) or in documents of the Electric Power Research Institute EPRI.

In particular due attention should be paid to effects of spatial variability of investigated technical parameters that may play an important role in the prediction. These effects should be taken into account when assessing large surfaces exposed to unfavourable environment such as for steam piping or cooling towers. Numerous models for spatial variability are available, see e.g. Allaix et al. (2009) or Sykora & Holicky (2013).

6 CONCLUSIONS

Methods of mathematical statistics provide efficient tools for the analysis of monitoring data concerning energetic devices. Important steps of the analysis include selection of a suitable regression model and estimation of probability of exceeding a limiting value. Aleatory uncertainties due to randomness and trend of the observed parameter as well as epistemic uncertainties due to lack of data and imprecision of a test method should be taken into account.

ACKNOWLEDGEMENTS

This study has been conducted at the Czech Technical University in Prague, Klokner Institute, within the research project TACR TE01020068 Centre of research and experimental development of reliable energy production supported by the Technology Agency of the Czech Republic.

Model for Information Quality determination of teleinformation systems of transport

M. Stawowy
Faculty of Transport, Warsaw University of Technology, Warsaw, Poland

ABSTRACT: This paper discusses a model for determining Information Quality (IQ) of teleinformation systems based on modeling the Certainty Factor (CF). This modeling practice is usually used for expert or artificial intelligence systems. Here, however, discussed are computer systems using data of teleinformation systems. Modeling CF is one of method, which can get information about properties of system when we have not full data to have it. Model was developed by Buchanan, Shortliffe for the rule system MYCIN at 1975 on Stanford University. I will try use this method to receive factor that will tell me "how good is this system which I analyzing". At the end I will show computer program to simulate different value to receive different result.

1 INTRODUCTION

In data communication systems intended for transport Information Quality (IQ) has a strong effect on traffic safety of vehicles. Particularly with regard to data communication information related to supervision over traffic received from different detectors. Data transmission and all measurements performed using those detectors can be burdened with various errors, which will introduce some scope of information uncertainty. The uncertainty may indicate the quality of information. The lower the uncertainty the higher the information quality.

Information quality is caused by many factors. As presented on Figure 1 information quality includes:

1. **relativity**—information meets the recipient's needs and is of essential importance for him/her,
2. **accuracy**—information is relevant to the level of knowledge represented by the recipient, defines the subject precisely,
3. **relevance**—information is never out-of-date, its updating cycle is consistent with its content,
4. **completeness**—information contains an optimal number of data, which is sufficient to process the information into specific knowledge, the level of detail depends on the recipient's needs,
5. **consistency**—particular elements and data correspond with each other, the form corresponds to the content, data updates are consistent with the objectives,
6. **suitability**—suitable presentation of information as well as description associated with the presentation ensuring correct interpretation,
7. **availability**—information is available when it is needed by competent recipients,
8. **credibility**—information confirms the authenticity of the data, contains elements ensuring the reliability of the message,
9. **congruence**—the information is consistent with different information, interpreted in the proper context.

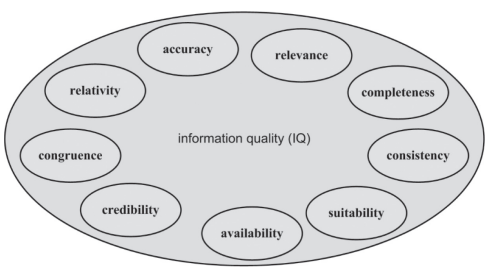

Figure 1. Components of information quality in technical terms. Prepared by the author based on Olaisen 1990 and Encyklopedia zarządzania and MITIQ.

In order to estimate the information quality of a selected system you should model the uncertainty the reverse of which could indicate IQ. Uncertainty can be modelled by using, among others, Bayesian networks. However, in this case, the data come from various sources and to simplify the modelling, and thereby calculation, could be used the theory mathematical evidence created by Dempster and Shafer. However, since we assess information from computer systems (modern detectors and

data transmission systems are controlled using microcontrollers), and the analysis they perform is a string of decisions (algorithms executed by the controllers), could be model the certainty factor of a hypothesis (CF Certainty Factor) (Shortliffe & Buchanan 1984, Heckerman 1992, Stawowy 2013) used in expert and artificial intelligence systems. Here it is necessary to make an assumption that the CF designated for a suggested model will be the sought IQ.

Usually, known publications talking about statistical models like Vinay & Khelil & Suri 2010 or Weng & Vespa 2011. Uncertainty models usually are used in management or logistic like in Rodrigues, Stantchev, Potter, Naim, & Whiteing, A. 2008. Presented work by Raghunathan 1999 was similar but not used presented in this article.

2 MODELLING THE CERTAINTY FACTOR OF A HYPOTHESIS FOR A DATA COMMUNICATION SYSTEM

The first part of this chapter specifies the dependencies used to calculate the values of the CF. It results from the variable directions of development of this method.

2.1 *Modelling the certainty factor of a hypothesis*

The formal simplified description of the certainty factor is as follows:

$$CF_{(s)} = MB_{(s)} - MD_{(s)} \tag{1}$$

where: *CF*—certainty factor, *MB*—reflection of knowledge, that is measure of belief, *MD*—reflection of ignorance, that is measure of disbelief, *s*—hypothesis based on some information.

It is important to remember that:

$$MB \to [0,1]; MD \to [0,1] \text{ that } CF \in [-1,1] \tag{2}$$

So, as it results from formula 2 the result of the calculations should fit within the range from –1 to 1. The value of 1 will indicate the highest IQ.

A model using the CF can be presented in the form of a graph where the nodes are the observations and the hypotheses. The branches are the certainty factors of the hypotheses. A simple models has been presented on Figure 2a and 2b.

The whole begins from observation nodes (e1, e2). The following dependence has been used for calculation of parallel CFs (Heckerman 1992):

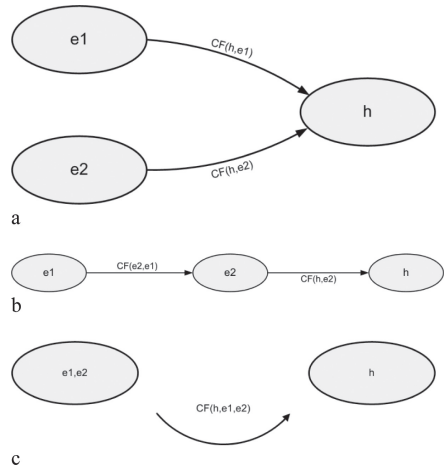

Figure 2. Sample CF models: a) parallel, b) serial, c) folded down. Prepared by the author.

$$CF_{(h,e1,e2)} = \begin{cases} CF_{(h,e1)} + CF_{(h,e2)} - CF_{(h,e1)} \cdot CF_{(h,e2)}, & CF_{(h,e1)} \text{ and } CF_{(h,e2)} \geq 0 \\ \dfrac{CF_{(h,e1)} + CF_{(h,e2)}}{1 - \min(|CF_{(h,e1)}|; |CF_{(h,e2)}|)}, & CF_{(h,e1)} \cdot CF_{(h,e2)} < 0 \\ CF_{(h,e1)} + CF_{(h,e2)} + CF_{(h,e1)} \cdot CF_{(h,e2)}, & CF_{(h,e1)} \text{ and } CF_{(h,e2)} < 0 \end{cases} \tag{3}$$

The following dependence has been used for calculation of serial CFs (Heckerman 1992):

$$CF_{(h,e1,e2)} = \begin{cases} CF_{(e2,e1)} \cdot CF_{(h,e2)}, & CF_{(e2,e1)} > 0 \\ 0, & CF_{(e2,e1)} \leq 0 \end{cases} \tag{4}$$

Using formulas 3 and 4 and the graphs (Fig. 2a and 2b) can folded down to a single branch with two nodes and the CF of this branch will be the sought value of the certainty factor of a hypothesis like on Figure 2c.

2.2 *Certainty factor model for a data communication system in transport*

A data communication system is a constituent part of a larger thematic system. For this reason, the telematic system has been described along with modelling in order to show the degree of influence on information quality held by the data communication part. A telematics system (e.g.: motorway) consists of many elements, such as: traffic supervision and measurement, monitoring, toll collection, meteo, display of information for drivers, signs with variable content, alert and service communication, data transmission, radio road information and integrated

control (Wawrzyński 2003). Each of these elements has specific requirements with regard to the quality and credibility of information. There is plenty of those characteristics and due to the limited volume of this study the modelling has been limited to one of the elements of motorway telematics. Traffic supervision and measurement has been chosen as this demonstratory element.

Traffic supervision and measurement usually include:

1. Proximity sensors such as inductive loops or detectors using infrared radiation.
2. Video detectors measuring the occupancy or speed of vehicles live and in the mean measurement value mode as well as identifying and counting the vehicles.
3. Data transmission routes.
4. Data interpretation tools.

Only one of the aforementioned components will be used for further modelling. Namely the video detector will be used to measure the speed of vehicles live (Jelušić, Anžek & Ivanković 2010, Stawowy 2013).

2.3 *Principle of measurement of the speed of vehicles using a video detector*

The sequence of images is transferred for analysis via cameras. The analyser detects the location of vehicles on subsequent frames of the image sequence. Displacement is then measured. After considering the time of the displacement one can determine the speed of those vehicles. Figure 3 presents the window of the speed measurement program using virtual vehicle displacement detectors (Stawowy 1997, Kędzierska, M. & Jasionek 2004).

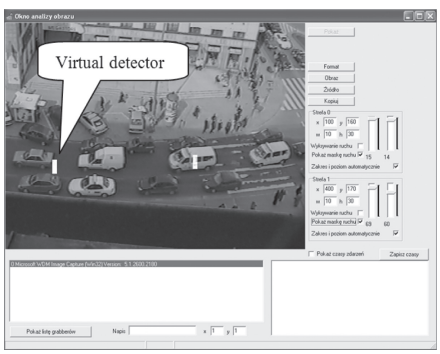

Figure 3. Window of the speed measurement program using virtual vehicle displacement detectors. Prepared by the author. The program has been written by the author of this article.

2.3.1 *Modelling the certainty factor of a hypothesis*

The first stage of analysis in such a measurement speed system is movement detection. The usual in this kind of video data analysis systems problem is interference (unwanted information). Especially in systems based on differential image analysis. Also the first stage of a decision will be whether we are dealing with motion of an object or noises or some other phenomena causing similar changes in the image as a moving vehicle. Therefore, it can be identified that we are dealing with two states of observation:

1. Movement occurred,
2. detection error.

A detection error can be broken down into different causes, which may be subsequent states of observation:

1. scene interference,
2. software failure,
3. data sent incorrectly.

So ultimately there may be more states of observation:

e1.1. movement occurred.
e1.2. scene image interference,
e1.3. software failure,
e1.4. data sent incorrectly.

At a further stage in order to measure the speed you should be certain that you have detected the locations of the same object of in two different places. Using the method of location of vehicles using virtual detectors you can distinguish such states of observation as:

e2.1. Moving object detected,
e2.2. software failure,
e2.3. data sent incorrectly.

The next node will have such states of observation as:

e3.1. Moving object detected by subsequent virtual detector,
e3.2. moving object not detected by subsequent virtual detector,
e3.3. detected object is not the same object as the one detected by the previous virtual detector,
e3.4. software failure,
e3.5. data sent incorrectly.

The last step is determination of the speed. The following states of observation will be present at this stage:

e4.1. speed determined,
e4.2. incorrect time measurement,
e4.3. software failure,
e4.4. computer system breakdown.

The graph for such a model is quite complicated, since we have transitions made of several layers. Intermediate hypotheses have been inserted to simplify the model. This is made possible by dependencies 3 and 4 described in the previous sub-chapter. Intermediate hypotheses can be subsequently determined in such a way:

h1. Movement detected,
h2. moving object detected,
h3. moving object detected by subsequent video detector,
h4. speed measured.

Figure 4 presents parallel graph of the model including all assumptions. Figure 5 presents serial graph of the model in second stage, after folded down parallel calculation. Graph is serial because

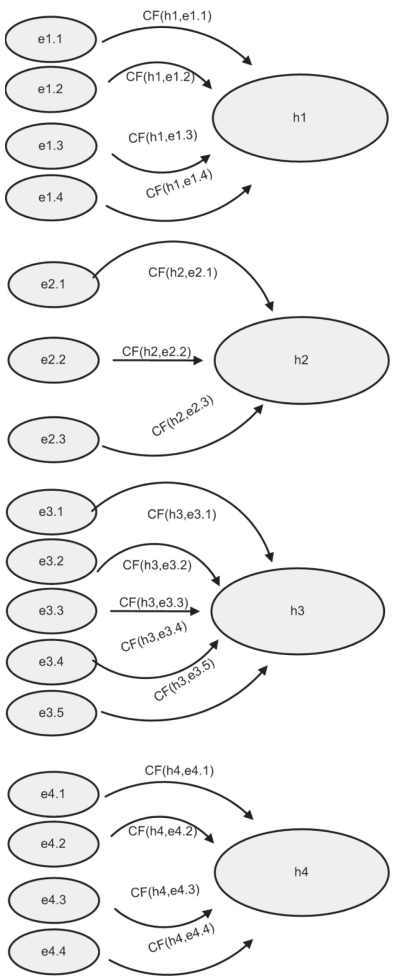

Figure 4. CF parallel model graphs. Prepared by the author.

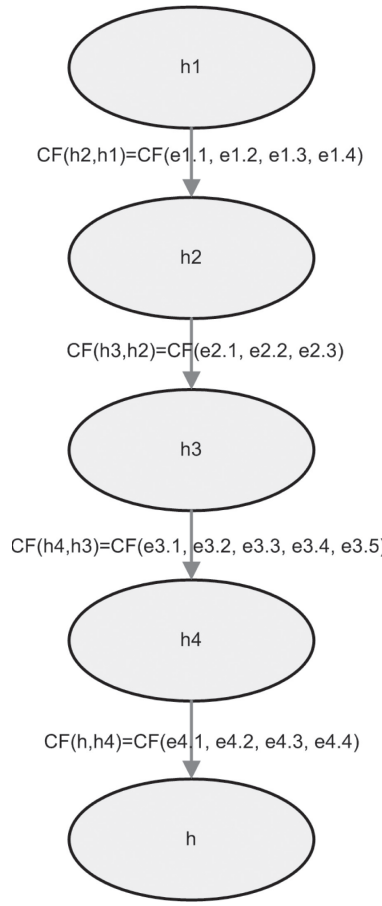

Figure 5. CF serial model graphs. Prepared by the author.

hypotheses are dependent on. It is mean that next hypotheses may not be met without previous. (Heckerman 1992, Stawowy 2013).

3 SAMPLE CALCULATION

The first calculation involves simplification aimed at determination of certainty factors of the intermediate hypotheses which will consist of subsequent CF calculations on the basis of formulas 3 and 4.

Subsequent values of certainty factors of the hypotheses are presented in Table 2. These values are not real but near to reals. Used only for demonstration methods possibilities.

According to the assumptions from chapter one the IQ of the modelled system is 0.5504. IQ was calculated by program special written for it.

4 SIMULATION OF EXAMPLE

A special program has been written in order to conduct the simulation. This program uses normal distributions with a standard deviation of 10% of the mean value. The distributions have been limited with a range of values that may be accepted by the CF according to formula 2. The values of subsequent CFs from Table 1 have been substituted as mean values. The number of repetitions of the simulation amounted to 10000. The result of the simulation is presented in Figure 6 (Meeker 1998). There is a density function of CF.

Comparing values $CF_{(h1, e1.1)}$ as well as $CF_{(h2, e2.1)}$ it would seem that $CF_{(e1.1, e1.2, e1.3, e1.4)}$ should be higher than $CF_{(e2.1, e2.2, e2.3)}$. However, this is not so due to the high impact of parameter $CF_{(h1, e1.2)}$. The courses also show which of the hypotheses affects the IQ the most negatively. In this case this was hypothesis h1 described as *movement detected* in chapter 2.3.1.

The next stage dealt with simulation of determination of hypothesis h1 using the same principles and values as in the IQ simulation. Figure 6 presents such a simulation. The courses of the distributions of parameters $CF_{(h1, e1.3)}$ and $CF_{(h1, e1.4)}$ overlap through a separated resolution of the simulation.

Figure 8 presents the simulation of hypothesis h1 with parameter $CF_{(h1, e1.2)}$ changed from –0.1 to –0.02. As a result, this significantly influenced the location of the values of hypothesis h1 during the simulation.

5 SUMMARY

This paper presents the method of determination of Information Quality (IQ) of a data communication system as a subsystem of motorway telematics with the use of modelling of the certainty factor of a hypothesis. After applying this type modelling gives

Table 1. Assignment of particular CF values. Prepared by the author.

h1	h2	h3	h4
CF(h1, e1.1) = 0.9	CF(h2, e2.1) = 0.8	CF(h3, e3.1) = 0.99	CF (h4, e4.1) = 0.99999
CF(h1, e1.2) = –0.1	CF(h2, e2.2) = –0.1 * 10^{-3}	CF(h3, e3.2) = –0.001	CF (h4, e4.2) = –0.1 * 10^{-3}
CF(h1, e1.3) = –0.1 * 10^{-3}	CF(h2, e2.3) = –0.3 * 10^{-4}	CF(h3, e3.3) = –0.1 * 10^{-3}	CF (h4, e4.3) = –0.3 * 10^{-4}
CF(h1, e1.4) = –0.5 * 10^{-6}		CF(h3, e3.4) = –0.3 * 10^{-4}	CF(h4, e4.4) = –0.3 * 10^{-4}
		CF(h3, e3.5) = –0.25 * 10^{-4}	

Table 2. Subsequent values of CF and value of IQ. Prepared by the author.

CF	Value
CF(e1.1, e1.2, e1.3, e1.4)	0,7098
CF(e2.1, e2.2, e2.3)	0,7998
CF(e3.1, e3.2, e3.3, e3.4, e3.5)	0,9698
CF(e4.1, e4.2, e4.3, e4.4)	0,9997
IQ	0,5504

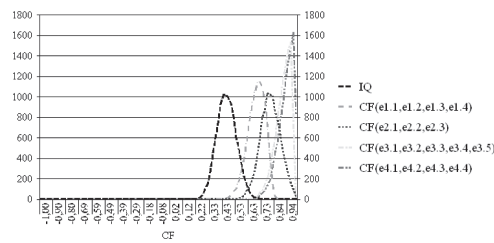

Figure 6. Result of simulation made for the examined example. Prepared by program written by the author.

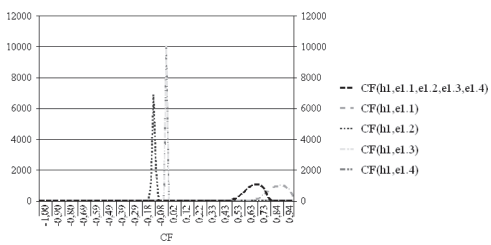

Figure 7. Result of simulation made for hypothesis h1 and unchanged CF parameters. Prepared by program written by the author.

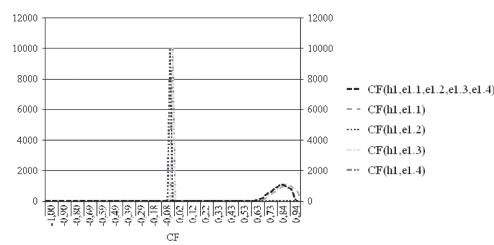

Figure 8. Result of simulation made for hypothesis h1 for $CF_{(h1, e1.2)}$ = –0.02. Prepared by program written by the author.

the possibility to connect many various properties of the examined analysis process such as: reliability of system elements, quality of the selected measuring method, quality of the data warehouse as well as safety resulting from the certainty of data.

It should be noted that subsequent stages of calculations are quite replicable and thereby easy to implement as a computer program or a computer simulation.

It also presents sample calculations for a real live speed measurement system. Used more and more for supervision of public road traffic.

Also a simulation of the example has been made using normal distributions of CF observations. The simulation demonstrated the possibility to identify the weakest link of the system. The simulation has also demonstrated the impact of the weakest link on the final result.

The results are intuitively correct, however, at the next stage this examination they should be compared with other methods of determining of information quality. One should also consider more measurement errors, which have not been considered in this model.

A framework proposal to analyse the performance of assets under complex system

T. Grubessich, E. Johns, P. Viveros, R. Stegmaier & F. Kristjanpoller
Department of Industrial Engineering, Universidad Técnica Federico Santa María, Valparaíso, Chile

ABSTRACT: The historical analysis of the information is fundamental to support studies based on indicators of performance of a process and to feed representative models of the real system. Both studies are very im-portant for management and control of the processes as well as for the decision making of the enterprises. It is very important that this analysis represent effectively the system, since every deviation produced can lead to mistaken decisions. In this paper a methodological proposal is set up that incorporates additional activities to the traditional approach of the analysis and through which we can obtain results according to the reality of the system. The difference between both methodologies, is that in the methodological proposal is analysed the impact of the detentions of one equipment in the rest of the equipments, analyzing the consequences of the detention of the equipment of the system. The same effect is analysed when the detention in the system is produced by other reasons to the equipments. The differences between the results of both methodologies are appreciated to an equipment level, since to system level the indicators of performance are the same. However, the differences to an equipment level can be relevant, determining indicators significantly different and be-havior representations very different, being this last one of large importance at the moment of creating models to the system.

1 INTRODUCTION AND PROBLEM STATEMENT

The historical analysis of the information is fundamental for the realization of studies in varied areas within the organizations. The main benefit of this type of analysis is to increase the comprehension grade the system possesses, and taking this basis, varied possibilities are open to deepen the knowledge so much to support the management of the system as to support the process of the associated decision making.

Within the most concrete applications that can be done about the historical analysis of the information, is the definition of the actual and past state of the process through the indicators of performance. Some of the indicators considered are related to with reliability, maintenance, availability and utilization, among others (Ahmada & Dhafrb, 2002; Calixto, 2013; Muchiri et al, 2013, Van Horenbeek & Pintelon, 2014), in order to describe the functioning as much of the equipments, as of the system in a global manner. This analysis helps the detection of opportunities of improvement and the information here obtained is fundamental for a in a second analysis will be defined a behavior of the equipments according to the different perspectives that will be of interest (Sharma & Kumar, 2008; Viveros et al, 2012). Some of these perspectives of study are the time between failures, repairing time, production rates, among others.

In addition, when to this information we incorporate the logic of the functioning of the system (Distefano & Puliafito, 2009; Jau-Chuan & Yunn-Kuang, 2007; Singh & Goel, 1995; Zio et al, 2006) is possible to build a representation of the system that allows to carry out deeper and powerful studies from varied points of view and interests, such as impact of new investments in equipments in equipments, possible adjustments in the maintenance policies, changes in the design of the process, etc.

To carry out the above mentioned, appear diverse types of models that set up methodologies to represent the system (Bause & Kritzinger, 2002; Buzacott & Shanthikumar, 1993; Fuqua, 2003; Schryver et al, 2012; Zio & Pedroni, 2010). Some of these models are: mathematical models, stochastic models, deterministic models, simulation models for discrete events, Markov chains, among others. Each of these models, achieve different representation grades of the system, so its correct selection is relevant to accomplish with the desired objectives. On the other hand, each model possesses different requirements of information and development times, since many times is not possible to apply any model to a specific system.

Nevertheless, in order the model represent correctly the real system without matter of the type used, is fundamental that the behavior of the equipments and of the system will be well defined, and this will be closely related with the study of the historical information to be carried out. Any deficiency in this study directly rebounds in the model with such an impact that could invalidate the conclusions obtained. Is here where takes root the importance of the study of the historical information carried out.

Having in consideration the above mentioned, we present this document, which aims to propose a methodology for the historical information analysis of the assets in a complex process, in order to assure the correct presentation of the interactions between the equipments of the system.

With respect to the study of the historical information, where there have been detected in varied experiences in the national industry such as mining, cellulose, water treatment, present bankrupts that can engage the analysis validity, so it is considered that one methodology that guide the way to carry out the study of the historical information, is relevant and necessary.

As mentioned before, when there is a mistake, the main impact in the study of the historical information, are bankrupts in the definition of the behavior of the involved equipments and its aftermath in the system. These bankrupts lead to deviations between the generated model and the real system. The origins of these bankrupts are factors that aren't full analyze. Two of these factors are considered relevant due to the impact and the frequency they have are the way in which are analyzed the operational detentions. Will define what is understood for both factors as follows:

– The state change propagation consists of failures or detentions of individual equipments that induces an effect of total or partial functioning of the system.
– On the other hand, the operational detentions are produced by forced detentions, product of external phenomenon to the system by proper conditions of the process and that affect to the system in its grouping. Some examples of this type of detention are: supply failures, social problems, environmental, internal of the productive process (material lack to produce, accidents, etc.) design problems of the process that lead to detentions, among others.

When these effects are not considered in all its dimensions, is used to finish describing the behavior of the equipments with deviations to the reality, which generates mistakes at the moment to represent to the system through a model that incorporate those equipments. The impact of this deviation is difficult to quantify since it depends on the features of the system, however it is noticed that even can incite the model to miss its validity.

From the described situation, it is necessary to generate a methodology that supports the phase of the analysis of the historical information of the equipments of the process of the system and of the external factors that affect the system, in order to describe correctly the behavior of the system and its parts.

In order to ensure a correct description methodology proposal, this paper contains the following sections: a description of the proposed methodology and the traditional method, a numerical example where the proposed methodology is applied and compared with the traditional method and the conclusions of the study.

2 METHODOLOGY PROPOSAL

In order to explain the proposed methodology for the study of the historical information of a determined process, first it will be explained, in general, how to treat the historical information. As of this information, it will be shown how to work with it until reach the required information with an adequate format using the traditional focus. Then, will be shown how the methodology proposal functions from the same historical information and the differences with the present way of work.

2.1 *General scheme of analysis*

To start with the explanation, is necessary to understand what is the basis information needed, how and when is generated. For this, first is presented the following scheme that shows the main phases that lead, generally, to the study of the historical information (Fig. 1).

As we appreciate in the scheme, there exist activities that must be performed before applying the methodology of the historical information as with the traditional approach or the methodology proposal. These activities correspond to: to obtain the data base that contains the relevant information, the uprising of the logical configurations of the system failure and from the two formers, to create the unified data base with all the relevant information and in an adequate format. To understand a little more about these activities, will give a short description of each of them as following.

Data base of varied sources: the data required are those concerning to the events of failure and the repair of the equipments related to the system. These data generally come from operations and maintenance area of the organization (Bunea et al, 2008; Caldeira et al, 2013; Kans). Each organiza-

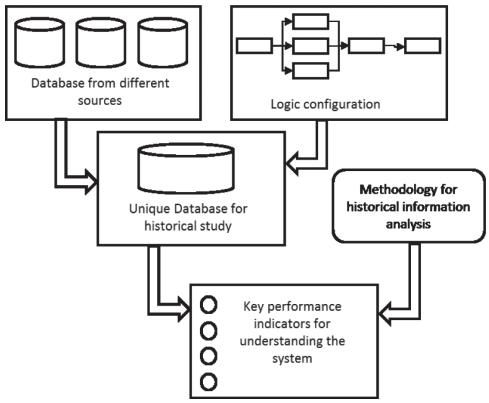

Figure 1. Scheme for historical analysis.

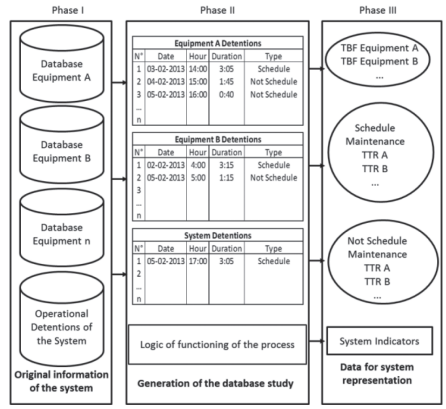

Figure 2. Traditional methodology for analysis.

tion defines the fields registered in each event, so they generally vary from organization to organization. Nevertheless, there are key fields that are required and which are the basis for a large number of studies. These fields correspond to: identify code of the equipment in which carry out a task, date and time of the activity starting, its duration and the work type performed (e.g. preventive, corrective, operational detention). As mentioned before, is probable that in order to get this information we have to use the database of different areas, as operations and maintenance. With this information, there are generated database for each equipment. In the type of events it must differentiate if they are scheduled or not still even they can specify other types.

Logical Configuration: It must be determined the logical configuration of the system, so for realize the functional dependencies in the equipments, subsystems and system respectively.

Data base unified for the historical study: Considering the data base related to the failure events and with failure logic of the system, it is generated a unique database withal this information and in which will be applied the methodology of historical analysis.

The final result of the analysis is the obtaining of required indicators such as the time between failures, repair times, availability, utilization, etc. All these seen for each equipment in separate form and for the general system.

2.2 *Traditional approach of analysis*

The following scheme introduces the traditional approach of analysis of the historical information with a more detailed description of the form in which it proceeds (include all the activities of the previous scheme). This scheme draws through phases, the activities of the former scheme. Next, is shown a diagram that will give an explanation of each one of these phases.

Phase I: Original information of the system: In this phase, the data are dispersed in different database of the organization, so there must be gathered the fields defined as necessary for the study. It must be verified the coherence of the information, since working with different database can produce incongruences due to the way the information is entered. Also in this phase the operational detentions are identified in the system.

Phase II: Generation of the database study: Once captured the required data they must be arranged giving a framework that allows to understand the relevant events that occurred in the system and its important features. On the other hand, it must be defined the logic of functioning of the process. In this step also are identified the operational detentions in the system.

Phase III: *Data for system representation*: To achieve a correct representation of the system, is commendable to set up the interesting events from which to characterize to the system. In this case, the events of interest can correspond to the changes in the states of the equipments and of the system. Already defined the equipments and system events, it can be possible to proceed to bunch the events by its type, taking into account the study approach. In this case, the events are bunched generating the periods between detentions, the periods of the detentions (Scheduled or not) and the key indicators of the system.

2.3 *New methodological proposal of analysis*

The proposed methodology is based on the traditional approach, but it incorporates an additional activity called Interaction of the system with equipments and other factors). To understand which is

the effect that is desired to reflect in the analysis, the following explicative schemes are shown.

To start, it is considered a system composed by a series of equipments with a determined logical configuration (Fig. 3).

Then, when some event occurs in one of the equipments or out of them, but affecting to system, it is registered a detention in the system, which is shown in the following scheme (Fig. 4).

The arrows towards the system reflect these possible events and the lozenge in one side of the system reflects the detention. This last is detected and measured in the traditional approach of the analysis and also in the methodology proposal. However, this detention has effects in the rest of the equipments expressed in the following scheme (Fig. 5).

This effect is not considered with the traditional approach and it is incorporated with the proposed methodology.

With the additional activity of the proposed methodology, it is possible in an integral way all the effect of the detentions in each one of the equipments, generating more representative information

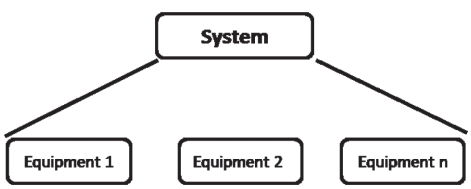

Figure 3. Scheme of a general system.

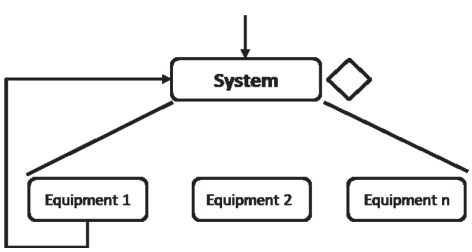

Figure 4. Scheme of a system with a detention.

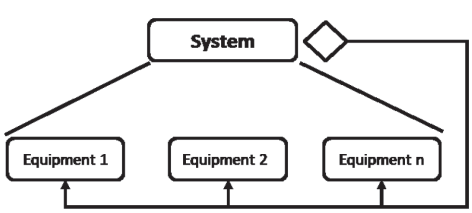

Figure 5. Effect of the detention on the equipments.

of each one of them. Is like that from the methodology with traditional approach, is incorporated the mentioned activity, achieving the following work scheme for the proposed methodology:

With respect to the interactions desired to be worked, is important to emphasize that they point to the same effect, but its causes are different. In respect to the effect, which must be in mind is that at the moment a detention occurs in the system (without matter the cause), this one generates that the hour meter of all the equipments stop, so the time lapse in the system is detained. Therefore, this time must be discounted from the time of the failures of all the equipments of the process.

Let's suppose a composed system by various components, among which are the equipments A and B that are in a parallel configuration. Let's suppose also that from step 2 of the scheme, the following information is obtained of the historical behavior of the system between the periods t_1 and t_2.

By the side of the system, it detained in the interval t_8 and t_7. The detentions of the equipments A and B do not affect the system due to the configuration of the existing failure. If we follow the traditional way of the analysis of the performance of the equipments in the step 3, the time of good functioning for the equipment A is $T_3 - t_4$, meanwhile for the equipment B is $t_5 - t_6$. However, it is not like that, since these two did not function between t_7 and t_8. In this way, the new methodology considers the impact of the detentions of the system, transmitting these times to each one of the equipments that compose it, achieving the following effect:

As of, in this example, the time of good functioning between failures of the equipment A would be: $t_3 - t_4 - (t_8 - t_7)$ and for equipment B: $t_6 - t_5 - (t_8 - t_7)$. It is necessary emphasize that the difference between both methodologies, may cause large variations in the results at the moment of measuring the time of good functioning of the equipments. However, calculating the indicators of performance of the system, the results must be the same with both methodologies.

With respect to the causes that lead to the detention of the system, are taken as focus the two more relevant. The external factors to the system and the design of him, related to the operational detentions and the equipment detentions that may cause detentions in the system or subsystem conditioned by the configuration in which the equipments are found. This last cause will be defined as state change propagation detention. It is necessary to have in mind that both methodologies include these detentions, but the traditional focus does not include the effect of these detentions in the rest of the equipments, generating differences in the result of the methodologies.

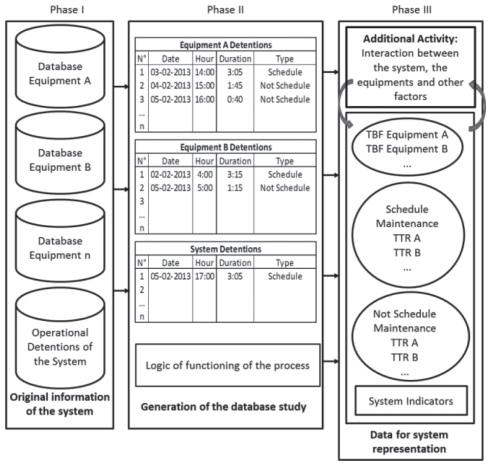

Figure 6. Proposal methodology for analysis.

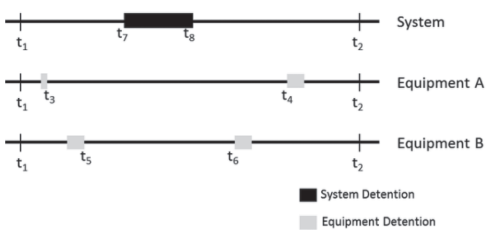

Figure 7. Sample of detentions on a system.

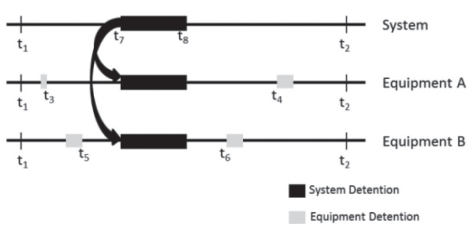

Figure 8. Detentions on a system an effect on equipments.

To deeper understand the application of this methodological proposal, next will show an application which will introduce both methodologies, its differences and the results as following.

3 NUMERICAL EXAMPLE

In order to understand how is executed the methodological proposal set up and the impact this have in the results, next will be shown an example in which will be used as much the traditional focus of analysis as the proposed methodology. In this way will appreciate the differences in the application of both analyses and in the results that are generated. Both methodologies will start from the same basis information that proceed from steps 1 and 2 of the Figures 2 and 6 already described, so the comparison will be totally valid. The case established, consist of a system composed by six equipments in a serial configuration. All of them begin to function at the same time and are considered new. After 1.040 chronological hours we have the following detentions data:

We must indicate that all the detentions of the equipment correspond to the not scheduled type, that is to say failures that are not expected by the equipment. On the other hand, exists the record of an operational detention of the system with duration of forty hours. These detentions are given by foreign factors to the system equipments, but it generates a detention in the same one.

The next step to be performed correspond to phase 3 represented in the Figures 2 and 6 where are differences between both methodologies. To follow with the analysis, will be indicated the steps that continue with the traditional focus, then will be performed with the proposed methodology and finally will be analysed the differences between results of the methodologies.

3.1 *Analysis with traditional approach*

3.1.1 *Application of the methodology in TBF*

Among the relevant indicators mentioned (such as TBF and TTR by equipment) will focus in the TBF that are produced by each equipment. To begin, will show Table 2 with the detentions of

Table 1. Detentions data of the example.

	Detentions		
Equipment	Time [hh:mm]	Duration [hh:mm]	Type
3	63:42	33:54	Not schedule
2	155:23	32:35	Not schedule
4	376:29	31:52	Not schedule
System	500:00	40:00	Operational detention
5	550:56	34:27	Not schedule
6	618:24	35:33	Not schedule
1	680:53	33:15	Not schedule
3	724:38	34:33	Not schedule
2	783:57	32:40	Not schedule
1	869:48	33:27	Not schedule
2	1001:09	35:15	Not schedule

each equipment, specifying the number of failures, the chronological hour in which the event was produced and the duration of it.

Using the traditional methodology to calculate the respective TBF, simply are taken the periods at the moment the equipment is available (from the moment zero or finishing its repair) and the nearest failure of the same equipment. Once this is applied, we conclude the following TBF in Table 3.

3.1.2 *Analysis of the % of utilization*

In order to calculate of the indicator of utilization, will be considered the next expression:

$$Utilization = \left(\frac{UPT}{UPT + DWT + OPT} \right)$$

where the UPT correspond to the time the equipment was functioning, el DWT correspond to the time the equipment was being repaired and ODT are the operational detentions that affect to all the system and whose causes are foreign to the equipments. Nevertheless with this analysis approach, the UPT is calculated as the total period it is evaluated, less the periods associated to the DWT and the OPT.

In this way, we obtain the following results in Table 4.

Table 2. Time of detention and duration per equipment.

Equipment	N° detentions	Hour of detention [hh:mm]	Duration [hh:mm]
1	2	680:53	33:15
		869:48	33:27
		155:23	32:35
2	3	783:57	32:40
		1001:09	35:15
3	2	63:42	33:54
		724:38	34:33

3.1.3 *Analysis of the TBF*

As third point of comparison, the first 15 TBF of each equipment are analysed with the aim to appreciate the differences produced between both methodologies. Table 5 shows this information for the traditional approach:

3.2 *Analysis with the proposed methodology*

3.2.1 *Application of the methodology of the TBF*

Beginning with the calculation of the TBF, applying the proposed methodology, we must consider the impact of each failure in the system and in the rest of the equipments. In this way, if we take as an example the first TBF of the equipment 1 the failure is produced at 668 hours and 53 minutes. However, in all this time failures were produced in the equipments 2, 3, 4, 5 and 6, each one with certain duration.

When analyzing the impact of those failures in the first TBF of the equipment 1, is determined that, given the configuration of the system, the hour meter of the equipment is stopped, so the total hours must be discounted, all the detention hours that generated the repair of the rest of the equipments. Applying this method in this case, we determine to the following results in Table 6.

3.2.2 *Analysis of the % of utilization*

With the proposed methodology in the calculation of the% of utilization for equipment, it is considered the propagated detentions of the equipments within the system, which leads to indicators up time fewer than those calculated with the traditional focus. To show this effect, Table 7 displays the up time of each equipment without consider-

Table 3. TBF with the traditional methodology.

Equipment	TBF equipment i	Hour of detention [hh:mm]	Duration [hh:mm]	TBF traditional methodology

System	1	500:00	40:00	

Table 7. % of utilization with proposal methodology.

Equipment	Up time [HH]	Down time [HH]	Propagation [HH]	Detention [HH]	Utilization (%)
1	662,41	66,72	270,87	40,00	90,85%
2	662,41	100,52	237,07	40,00	86,82%
3	662,41	68,47	269,12	40,00	90,63%
4	662,41	31,87	305,72	40,00	95,41%
5	662,41	34,45	303,14	40,00	95,06%
6	662,41	35,56	302,03	40,00	94,91%

ing the propagated detentions and its respective percentage of utilization.

The expression that is used to calculate the indicator of utilization correspond to:

$$Utilization = \left(\frac{UPT}{UPT + DWT + PRT + OPT} \right)$$

where the period PRT is incorporated, associated to the propagated detentions, the UPT of the equipments is different to the previous methodology since the RPT periods are discounted, obtaining the real times of utilization.

3.2.3 *Analysis of the TBF*

Applying the proposed methodology to the same initial data, we can get the following TBF for each one of the six serial equipments in Table 8.

3.3 *Difference in the application and results of the methodology*

3.3.1 *Application of the methodology in the TBF*

In respect to the differences that arise from the generation of the TBF, Table 9 displays the results got through the distinct methodologies and its respective differences.

As we can appreciate, the differences between both methodologies are relevant, so that is imperative to define which is the most assertive to represent the behavior of the system. For this it will be analysed from two perspectives. The first one is to construct the representative models of the system and the second one the construction of key indicators of the performance, specifically, the utilization of the equipments.

With regard to the first point, at the moment of modeling the system behavior, the main thing is to represent correctly the behavior of each equipment and the relations between them that the system establishes. Then, in order to represent the random in the failure event of each equipment, it is used historical information of performance. This information must contain only periods of good functioning between failures, that is to say the times registered by hour meter. In the case the detentions will be foreign factors to the equipment, the hour meter must stop.

In the case of the traditional methodology, these detentions of hour meters are not considered so the period of good functioning is overestimated, while the proposed methodology is in charge of this issue, leaving the data clean in order to be used again.

On the other hand, and in order to assure a representative model of the system, they must consider the functional logic of the system, so in this way the model can stop the hour meters represented meanwhile the detentions of the system are produced.

With respect to the second point related to the indicators, will see the differences produced at moment of calculating the indicator of utilization of the equipments.

3.3.2 *Analysis of the % of utilization*

In order to begin, Table 10 shows the differences between the UPT and the% of utilization with each one of the methodologies.

As we can appreciate, exists a notorious difference in the value of the indicators of utilization with each methodology. It can be of importance that with the second methodology, the UPT of all the equipments is the same one, which is directly connected with equipments that posses a serial configuration, so the period in which each one works is exactly the same one at the rest. This reflects exactly what happens in the real system.

Table 8. First 15 TBF using the proposal methodology.

difference	–237,07	–257,41	–146,27	–260,23	–152,70	–296,54

3.3.3 *Analysis of the TBF*

From the obtained information with each one of the methodologies, it is calculated the mean time between failures proving the following differences in Table 11.

This demonstrates that at the moment to make a curve fit to each one of the equipments it becomes to behaviors substantially different with each way of work. As appreciated, with the traditional approach the mean time between failures is much greater, since if not identifying the propagated detentions of the equipments, the periods of good functioning are overestimated in a greater size.

Having in mind these differences, it is assumed that the proposed methodology is substantially better than the traditional approach, since it represents the system in a better way, as from the perspective of the indicators as the representation of the behavior of the equipments of the system (being this crucial point for the creation of representative models of the system).

It is important to indicate that the differences between the results utilizing one or other methodology varies in accordance with the impact that have the propagated and operational detentions and these at the same time depend on the configuration of the system and of the foreign factors to the equipments.

4 CONCLUSIONS

In the present paper, it has been analysed the way in which usually has been made the analysis of the historical information of the system related to the indi-

cators of utilization and periods of good functioning. It has been explained how, generally, is made this type of analysis and the defects that it brings when not considering the interactions of the equipments with the system and the detentions that bear the system by the external factors. These two phenomenons are expressed through the propagated detentions and the operational detentions, which are considered at the moment of making the analysis of the complete system, but many times are not taken into account at the moment of making the analysis by equipment.

In order to incorporate these factors to the analysis by equipment and produce more representative results of the system, a methodological proposal is introduced, that mainly add activities to the traditional approach, which capture and identify clearly the phenomenon of interest and incorporate them to the analysis for equipment. In this way, we obtain real periods of good functioning, also the times of propagated detentions and operational detentions. The great impact obtained with this modification in the analysis, are more representative indicators of the equipment and real times of good functioning between failures.

Counting with this more purified information, is possible to get key indicators according with reality and also the basic information is got to make curve fit that represent the behavior of the equipments.

Together with describing the proposed methodology, it was developed a numerical example in which are detailed the differences utilizing one or other methodology and in the obtained results. The breach between the results proves that are not fewer. However, is necessary to emphasize that the differences are not easy to quantify from the first in any case, since they depends the most of the configuration of the system, behaviours of the equipments, present external factors, among other factors.

Certainly this document and the proposed methodology approached on indicators related to the management of the assets, the main contribution of the methodology take roots in the outlining that in the historical analysis of the system, we must take into account not only the impact of the events occurred in the equipments and that affect to the system, but also we must pay attention to the effect that these events have in the system and how they affect to the involved equipments. These events in the system can be caused by the same equipments or by foreign factors to them.

ABSTRACT: Since the standard EN ISO 13849-1 became effective in December 2012, manufacturers in the area of the machine tool industry have to assess the functional safety of the safety-related functions in a probabilistic quantitative way. Due to the specifications of the standard in combination with little experience and few existing quantitative data in the machine tool industry, manufacturers have huge problems by adapting the new requirements. The presented research project tries to develop an alternative and practicable procedure which shall allow the manufacturers to fulfil the normative requirements with a proven in use approach. Therefore, as shown in the ESREL-paper 2013, a first data analysis of real field data was performed to proof if the available field data in the machine tool industry is useful to develop a proven in use approach. Further the standard includes assumptions concerning the failure behaviour of the components, which were also checked with the first field data analysis. The first examination included the reliability of the analysed systems. To realise an approach for the Functional Safety of safety-related functions it is necessary to analyse these functions separately on the basis of field data. The aim and content of the presented paper is to extract the safety-relevant information out of the checked reliability field data. Afterwards, the safety-related field data has to be further analysed to identify those data that are responsible for one exemplified single safety-related function. Consequently, the received quantitative results can be compared with the requirements of the EN ISO 13849-1.

1 INTRODUCTION

The requirements on the safety and reliability of machine tools become more and more important. The manufacturers of machines have to fulfil several different guidelines and standards according to the Functional Safety and reliability before the machines were placed on the market.

The importance of the Functional Safety was underlined with the safety standard IEC 61508 which deals with Functional Safety of electrical/electronic/programmable electronic safety-related systems (IEC 2011). The innovation of this fundamental standard consists of the probabilistic examination of the Functional Safety with quantitative parameters. It is a universal standard, which is applicable in every industry sector. One aim of the IEC 61508 is that the standard should facilitate the development of application sector standards. Until today several derivates have been developed and transferred to different industry sectors.

In the area of machine tools there are two main standards that deal with the quantitative Functional Safety. The standard IEC 62061 "Safety of machinery—Functional Safety of safety-related electrical, electronic and programmable electronic control systems" is a derivate of the IEC 61508. It has been developed for machinery, which contains the examined machine tools as a subset. However, it deals exclusively with electrical/electronical control chains.

Because of the high amount of mechatronical systems in many types of machinery (e.g. machine tools), an additional standard for the mechatronical control chains of machinery has been prepared in parallel, the EN ISO 13849 "Safety of machinery—Safety-related parts of control systems" (ISO 2008). The standard consists of the two parts "General principles for design" and "Validation", but only the first part is relevant for this paper. The EN ISO 13849-1 replaced the former standard EN 954-1, which handled the

Functional Safety of machines in a descriptive and deterministic way. Consequently, a considerable paradigm change took place to a probabilistic point of view that causes many new demands for the manufacturers of any kind of machinery and consequently for the machine tool industry.

With the introduction of the EN ISO 13849-1 and the end of the transition period of EN 954-1 in December 2011, manufacturers in the machine tool industry are obliged to perform quantitative safety evaluations of their machines.

The new standard claims the quantitative evaluation of safety-related functions of a machine over an expected operation time of 20 years. This can only be realised by a probabilistic assessment of the Functional Safety of the relevant functions. The quantitative safety which is required by the EN ISO 13849-1 is specified by different "Performance Level" (PL). The PL is defined as an average probability of a dangerous failure per hour and is classified in different groups. An illustration of these different groups and the procedure to select a Performance Level for a safety-related function with the so called "Risk Graph" of the EN ISO 13849-1 was illustrated in the ESREL-paper 2013 "EN ISO 13849-1—New quantitative requirements for Functional Safety in the machine tool industry" (Günnel et al. 2013).

2 CONSEQUENCES OF EN ISO 13849-1

According to the EN ISO 13849-1, the appointment of a Performance Level represents the capability of a safety-related component to perform a safety-function. To determine the PL of a safety-function, the standard advises to use different aspects that contribute to the failure prevention of the safety-related function. One aspect is the $MTTF_D$-value (mean time to dangerous failure) of the single considered components which is the inverse failure rate of the exponential failure distribution.

The consequence of using the $MTTF_D$-value for calculation of the PL is that the standard assumes a constant failure rate (exponential distribution) for the failure behaviour of the components (Meyna & Pauli 2010). The problem with constant failure rates and the exponential failure behaviour is that components and systems with this behaviour are considered to have no ageing process. This assumption of the EN ISO 13849-1 is arguable, because machine tools that are used in real production environment are clearly subject to ageing processes.

The new probabilistic requirements of the EN ISO 13849-1 cause tough challenges for the manufacturers and huge uncertainty by the developers of machine tools, because they have no experience with this way of assessing their machines. The manufacturers have no or very insufficient documented quantitative data about the safety of the machines that can be used for a quantitative evaluation. Consequently, a few general quantitative parameters were developed that can be used by every company for the assessment.

A consequence of the general available parameters is that the existing machine tool concepts, which were built according to type C product standards for more than 10 years and which have a real and high Functional Safety in the field, appear not to be adequate to reach the required Performance Level at the first glance. Thus the machine tool manufacturers are exposed to new requirements to install additional safety equipment in their machines that causes extra costs and therewith an economical risk. The amount of maintenance can also increase when more components are assembled. This causes additional investments and costs for the user, too.

The assumption of the EN ISO 13849-1 and the existing general quantitative parameter leads to the theoretically wrong impression that the Functional Safety of some functions of the existing machine tools is not adequate.

3 APPROACH "PROVEN IN USE"

In order to correct this misleading conclusion, the VDW initiated the presented research project.

The aim of this project is to determine quantitative reliability parameters of existing machine tool concepts on the basis of real operational field data. Thus, it can be checked, whether the failure behaviour of the machines, functions and components is really exponential distributed or not. Additionally, it can be determined if the Functional Safety of the present machine tool concepts, which are well tried proven to be safe for many years, are practically sufficient according to the new requirements of the EN ISO 13849-1.

Furthermore, the research project shall proof the capability of a proven in use approach on the basis of the identified field data. Thus, a complementary procedure to the EN ISO 13849-1 could be developed, that is able to support the manufacturers of machine tools with a quantitative calculation of the Functional Safety that complies with the standard.

A first study, which was presented in the ESREL-paper 2013, should prove, if the existing operational field data in the machine tool industry is sufficient for a proven in use approach (Günnel et al. 2013).

Further quantitative reliability parameters of machine tools should be determined on the

basis of operational field data for the first time. Therewith, the assumption of the standard EN ISO 13849-1 should be proven, if exponential failure behaviour of the machines and components really exists.

In the context of the first study, the field data of the clamping function of a turning machine were selected to be analysed. The field data of two different companies that are involved in the life cycle of a turning machine were examined. The first company was a manufacturer of components and subsystems that are used in the clamping function of a turning machine. The data in this case were service data of one component and one subsystem of the clamping function, which consist of warranty-, goodwill- and bill-cases. The second company was an operator of turning machines, whose field data of three turning machines were malfunction messages that are automatically generated by the machines and send to a data base.

Both weekly documented field data could be screened after events that occur at the clamping function so that consequently the field data could be prepared and a very first reliability-related data analysis was executed. Thereby, the empirical failure probability was calculated and two theoretical reliability distributions (exponential and Weibull) were fitted.

The results of the analysis showed that the existing operational field data in the machine tool industry can generally be used for probabilistic reliability and safety assessments and consequently for a proven in use approach. The used field data included reliability events so that further researches were necessary to extract the subset of safety-relevant events.

The first outcomes of the data analysis clarified that the assumption of the EN ISO 13849-1 concerning the constant failure behaviour could not be confirmed. The empirical failure behaviour of the clamping function, the subsystem and the component could better be described with a Weibull distribution that is able to consider an ageing process of the systems. But there are additional analyses necessary to verify these first results. It is advisable to analyse different machine tools and different safety-related functions to find universal findings.

In summary the first study generated promising findings. It should be noted that the very first field data analysis just examined quantitatively the reliability of the whole clamping function. But for a proven in use approach it is essential to quantify the safety of the single safety-related functions.

Therefore, a second study was initiated that shall quantify the Functional Safety of safety-related functions for the first time. This study will be described in the content of this paper.

4 QUANTIFYING FUNCTIONAL SAFETY

As described before, the aim of the second VDW-study is to perform further field data analyses that quantify the Functional Safety of a safety-related function on the basis of real field data for the first time. This allows the possibility to demonstrate quantitatively the Functional Safety of existing safety-related functions that complies with the requirements of the EN ISO 13849-1.

The data base of the before mentioned operator of machine tools was used to generate and receive the field data for these analyses. To verify the findings of the first study a different machine tool was selected that has been analysed. After a first screening of the data base nine identical milling machines were identified that have a sufficient amount of data. The clamping function of the milling machines—comparable with the examined turning machines—is one of the most important functions. Consequently, one safety-related function of the clamping function was selected.

The safety function "prevention of unexpected start-up of a movement of a linear or rotational axis with an incorrectly clamped workpiece" of the standard prEN ISO 16090 (ISO 2013) was chosen to be analysed and quantified in order to keep the practical use of the researches.

The field data that has to be extracted from the data base of the operator could not be restricted to those data, which appear at the selected safety function. Thus, like in the first study, all field data must be collected that appear at the whole clamping function of the milling machine.

After the field data was determined, the manufacturer of the milling machines was contacted. As described before, the data consists of malfunction messages that are automatically sent to a data base. These messages are codes with a very short description of the malfunction. The meaning of the codes and the description is defined by the manufacturer so that only he knows which component or system is affected.

The entire field data of the data base represents the reliability of the whole clamping function. In cooperation with experts of the manufacturer of the milling machines it was possible to scan the detected malfunctions and to select those, who possibly can have an influence on the safety of the clamping function. The result of this procedure is that only the safety-relevant malfunctions remain in the data set. Therewith, it was possible to extract the subset of the safety-relevant events out of the complete reliability-relevant field data.

The reduced safety-relevant field data was checked again in cooperation with the experts of the milling machine manufacturer in the next step. Thereby, the malfunctions are identified that can

occur at the selected safety-related function. With this limitation the received reduced field data represent the safety-related malfunction messages which appear at the examined safety function.

Hence, it was possible with the support of expert judgments to constrict the reliability-related field data of the whole clamping function in two steps to the safety-related field data of one single safety function. Thereby, the allocation of the malfunction messages to the safety function is not definite, because the messages can also be relevant for further safety functions. Consequently, it is a worst case examination that needs to be stated more precisely in future researches.

Out of the determined field data the empirical failure probability is calculated. Afterwards, the theoretical failure probability of the exponential and Weibull distribution is determined on the basis of the empirical failure probability. To compare the goodness of fit of the probability distributions to the empirical distribution the respective coefficient of determination is calculated.

As shown in the ESREL-paper 2013 (Günnel et al. 2013), the exponential distribution cannot be used to describe the failure behaviour with an ageing process, as it is the case with machine tools. Thus, the following results contain the exponential distribution to verify the findings of the first study, but are not regarded further. The Weibull distribution in contrast can describe different ageing processes and is used in the following to describe the empirical failure behaviour.

The aim of the proven in use approach is a quantitative verification of the existing Functional Safety in the field, which can be compared with the quantitative requirements of the EN ISO 13849-1.

Therefore, it is necessary to determine a quantitative value out of the fitted Weibull distribution. The standard defines as quantitative value the Performance Level. The PL are shown in the following Table 1.

The definition of the PL is not explicit because there are several existing parameters that describe an average probability. However, a parameter is needed which is constant over the whole lifetime and represents an average probability.

Table 1. Classification of the Performance Level (ISO 2008).

Performance Level	Average probability of a dangerous failure per hour [1/h]
a	$\geq 10^{-5}$ to $<10^{-4}$
b	$\geq 3 \cdot 10^{-6}$ to $<10^{-5}$
c	$\geq 10^{-6}$ to $<3 \cdot 10^{-6}$
d	$\geq 10^{-7}$ to $<10^{-6}$
e	$\geq 10^{-8}$ to $<10^{-7}$

A very common value which is often used and also described in the EN ISO 13849-1 is the $MTTF_D$, which is the inverse failure rate of the exponential distribution. Next to the fact that the exponential distribution cannot be used for lifetime consideration, the failure rate does not agree with the definition of the Performance Level because the failure rate is not a probability value. Thus, a different value has to be selected.

The base standard of Functional Safety (IEC 61508) defines the PFH-value as the "average frequency of a dangerous failure per hour" as a comparable value in part four (IEC 61508-4). Under remark two to this definition the IEC 61508 states that the PFH is the mean value of the failure density function. This definition also fits to the definition of the EN ISO 13849-1, because the density function is a probability value. Consequently, the failure density is also useable to perform a proven in use approach.

But the mean value of the failure density function does not include the areas of high failure densities. In contrast the maximum of the failure density function as value includes all areas of the density function and consequently every existing failure density. This value is also consistent to the definition of the EN ISO 13849-1 and is therefore used for the presented proven in use approach.

5 RESULTS

As described before nine existing identical machines have been analysed. The results consist of the safety-related empirical and theoretical failure probability of the safety-related function. Further, the failure density function of the theoretical distribution function is calculated and illustrated to clarify how the maximum of the failure density function is obtained. The received maximum values can finally be compared with the quantitative requirements of the EN ISO 13849-1 and the Performance Level can be determined.

The results of the data analysis are shown in the following figures exemplarily for one milling machine. The reached PL of the safety-related functions of all nine machines are illustrated in Table 2.

In the following Figure 1 the results for the data analysis of the selected safety-related function of one milling machine are shown. The green dots represent the empirical failure probability, the blue line the fitted theoretical exponential failure probability and the green line the fitted theoretical Weibull failure probability. The operating time of

Table 2. Maximum value of the probability density function and achieved Performance Level of the selected safety-related function of the nine milling machines (* = not comparable).

Milling machine	Max. value [1/hour]	Achieved PL
A	$4{,}0690 \cdot 10^{-5}$	a
B*	–	–
C	$5{,}5897 \cdot 10^{-5}$	a
D	$5{,}3218 \cdot 10^{-5}$	a
E	$1{,}4594 \cdot 10^{-5}$	a
F	$1{,}6554 \cdot 10^{-5}$	a
G*	–	–
H	$9{,}2845 \cdot 10^{-6}$	b
I	$5{,}9164 \cdot 10^{-5}$	a

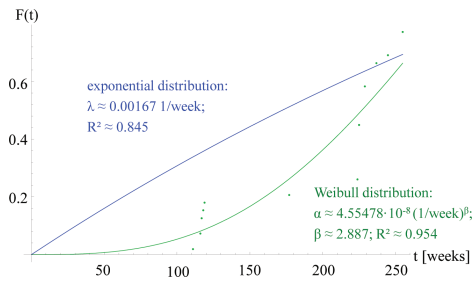

Figure 1. Empirical and theoretical failure probabilities of the selected safety-related function of a milling machine.

the milling machines was about five years at the time of data collection.

Figure 1 makes clear, that the empirical failure behaviour of the analysed safety-related function can approximately be illustrated with a Weibull distribution, because the theoretical failure probability of the Weibull distribution has a similar curve progression with the empirical failure probability. The coefficient of determination with $R^2 \approx 0.954$ is explicitly better than the coefficient of determination of the exponential distribution with $R^2 \approx 0.845$. The results of the other examined machines, which are not visualised here, also confirm the first outcomes of the first VDW-study that the exponential distribution in not adequate for field data analysis of systems with an ageing process.

With the determined Weibull distribution, which describes the empirical failure behaviour, it is now possible to calculate the failure density function that is used to determine the maximum value.

In the following Figure 2 the received failure density functions of both fitted distribution functions are visualised. Thereby, the same time period is shown like in Figure 1.

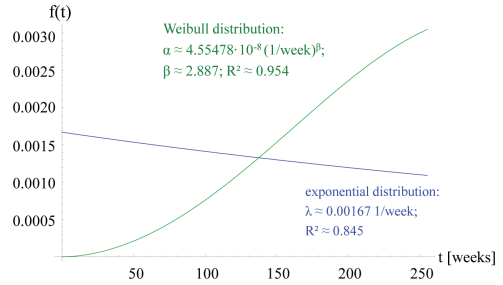

Figure 2. Theoretical failure density of the selected safety-related function of a milling machine.

With the density function of the Weibull distribution it is now possible to assess the maximum. As one can see in Figure 2, the displayed density function of the Weibull distribution does not have a maximum within the visualized time period. But the calculation of the peak value includes the entire progression of the density function.

As mentioned before and illustrated in Figure 1 and 2, the data analysis was performed on the basis of weekly documented field data so that the diagrams and distributions also have this time unit. In contrast the requirements of the EN ISO 13849-1 have the unit 1/hour. Thus, the determined nine maximum values of the machines have to be converted in this dimension.

Consequently, the obtained maximum values of all nine milling machines can be compared with the quantitative values of the Performance Level of the standard. The results of the comparison are displayed in the following Table 2.

As Table 2 makes clear, it is possible to demonstrate with the analysed field data for six safety-related functions a Performance Level a and for one also a PL b. Two regarded safety functions cannot be compared with the quantitative requirements because it was not possible to calculate a maximum of the failure density function. The reason for this is that the fitted Weibull distribution has a shape parameter λ of less than 1. The consequence is that the resulting density function has no explicit maximum. This failure behaviour is not usual for mechanical stressed systems like machine tools so that this has to be analysed more detailed in further researches.

In summary, the results of the second VDW-study make clear that it is possible to quantify existing safety-related functions of machine tools with a proven in use approach. The calculated maximum of the probability density function of the Weibull distribution is a useable value that can be compared with the quantitative requirements of the EN ISO 13849-1.

Furthermore, the findings of the first VDW-study concerning the incorrect assumed failure behaviour of the standard could be confirmed.

Nevertheless, there are further researches necessary to raise the accuracy of the proven in use approach. The mapping of the malfunction messages to the safety-related function, for example, could be more explicit so that the real amount of malfunction messages can be possibly reduced.

6 CONCLUSION

The introduction of the EN ISO 13849-1 requires a probabilistic quantitative assessment of the safety-related functions of machine tools and it causes huge uncertainty for many manufacturers and suppliers of machine tools, because there is only very little experiences with this kind of assessment among small and medium enterprises (i.e. machine tool builders). Furthermore, the released and existing quantitative data are universal and have no plausible connection to the single machine tool concepts and components of the manufacturers. With the use of these universal parameters many concepts of safety-related functions wrongly seem to be inadequate to achieve the new requirements, which cause extra costs for the manufacturers.

As the EN ISO 13849-1 requires the verification of average probabilities for the Functional Safety of safety-related functions over a lifetime of 20 years, which are called Performance Level, the assumed constant failure rate is problematic, because it considers no ageing of the machines.

The aim of this project is to detect and quantify the existing safety of the relevant functions of machine tools in the field. Thus, the assumption of the ISO EN 13849-1 and of the universal parameters can be checked. Afterwards, a proven in use approach shall be developed which complies with the requirements of the standard. The manufacturers can additionally calculate machine- or function-specific quantitative data.

In the lead VDW-founded study a first reliability-related data analysis was performed to survey, if the existing field data in the machine tool industry are useful to use them in a proven in use approach. Further, the assumed failure behaviour of the EN ISO 13849-1 was tested. The results of the analysis showed that the existing operational field data in the machine tool industry can generally be used for probabilistic reliability and safety assessments. The assumptions of the standard concerning the constant failure behaviour could not be confirmed.

Because of the positive results of the first study the second study was initiated to confirm the results of the first study and to quantify for the first time the safety of a safety-related function.

A different machine tool type was selected to be analysed for the confirmation of the results of the first study. The field data of the examined milling machines were collected at the same operator like in the first study. In cooperation with the manufacturer of the milling machines it was possible to extract the safety-relevant field data out of the entire reliability-related field data. With a second expert judgment of the manufacturer an allocation of the safety-relevant field data to a selected safety-relevant function was performed.

Further, a quantitative value was selected that can be determined out of a field data and afterwards be compared with the requirements of the EN ISO 13849-1.

The results of the field data analysis show that it is possible to quantify the Functional Safety of existing safety-relevant functions of machine tools with a proven in use approach. With the selected value it is possible to compare the determined quantitative safety with the specifications of the standard. Consequently, a quantitative proven in use approach of safety-relevant functions is possible that complies with the EN ISO 13849-1.

There are further researches necessary to raise the accuracy of the proven in use approach. It is advisable to quantify several safety-related functions of one subsystem and to analyse different machine tools.

Finally, the aim of this research project is to develop a general method to demonstrate the proven in use of the Functional Safety of existing and new safety-related functions of machine tools. This would help the manufacturers to perform a function—or machine-related verification that complies with the requirements of the standard EN ISO 13849-1. With this study a first quantification of existing safety-related functions with a proven in use approach has been realised.

The presented paper provides the findings of a VDW-funded study (VDW: German Machine Tool Builders Association, Frankfurt, Germany). This contribution made the researches possible so that the gratitude is aimed at the supporting people of the VDW.

ABSTRACT: The new control system standard ISO 13849-1 deals with the theoretical probabilities of hypothetical individual events; however, it avoids depicting them as relative frequencies. For the practical design engineers, a relative frequency approach is a more comprehensible form, because with the relative frequency a reconciliation with statistically acquired data is possible. This article closes some explanatory gaps caused by the one-sided emphasis on theoretical probability. In doing so, four contributions are provided in the context of field experience:

1. the concept of probability and the basic principles of distribution functions are elucidated using an "hourglass analogy",
2. fitting of an empirical Weibull distribution in order to evidence the theoretical requirements,
3. risk profiling method: plausibly stretched "risk snapshots" integrated to a "risk film" over the machine's lifetime,
4. proposals for a probabilistically founded dimensioning of enclosure.

This part 1 shall serve for a better understanding of the probabilistic concept, in particular for ongoing discussions of the merging of IEC 62061 & ISO 13849-1 into IEC/ISO 17305 in the Joint Working Group (JWG 1). Part 2 addresses more the practical design of machine tools and the corresponding standardization work of ISO/TC 39/SC 10 and before in CEN/TC 143. Together, part 1 and 2 are also intended to connect the world of International Standardization with the network of International Probabilistic Research, e.g. ESREL. For the sake of comparison with reality, a separate third paper of (Günnel et al., 2014) shows empiric findings of field data analyses.

1 INTRODUCTION

1.1 *Practical application problems*

The one-sided polarisation of ISO 13849-1 towards theoretical probabilities is a disadvantage, because the relative frequencies would enable the theory to be objectively verified. For the practical design engineer, a reconciliation with statistically acquired data or experimental results is necessary, as well as with subjective empirical values, e.g. by enumerating the relevant events (in the numerator) with regard to the total quantity of all events (in the denominator). This fraction is the original definition of a probability (see e.g., Montgomery), and it is a realistic introduction to probability theory, as also shown by the study of VDW (German Machine Tool Builder Builders Association) on operational dependability (Günnel et al., 2014). At the German Social Accident Insurance Scheme (BAuA 2010), the accident figures are recorded as frequencies, too, (with histograms), and they show two important results:

– a continuous improvement in safety due to decreased relative frequencies,
– an almost constant mutual relative percentage content of frequencies for individual degrees of seriousness (accident pyramids).

1.2 *Probability*

Mathematically viewed, probability has its unique definition within an axiomatic calculus. Yet, it is not at all clear what the term probability means, if it is applied to a non-mathematical situation (Main 2012).

As far as machine tools' safety is concerned, the terms "probability" or "likelihood" have not very often been used in developing the former product safety standards in CEN/TC 143. Their worldwide unique state of the art was established on a deterministic approach of the kind "identify hazard + compensate it with a bundle of safety measures = a safe machine" and is well-tried for more than a decade, now. Only when a second disconnecting channel in the control chains was discussed, the probability of a simultaneous failure of both channels was considered negligibly low. In contrast to this, since 2011 ISO 13849-1 made probability a key term in the standardization world. Most of the experts in the former deterministic approach are still in uncharted waters, when discussions circle around obviously different meanings of probability.

Here, in excerpted form only, the various manifestations of probability and certain fundamental relationships are explained: Probability as a theoretical value according to Laplace and Pascal is:

$$P(A) = \frac{number\ of\ events\ relevant\ for\ A}{number\ of\ all\ possible\ events} \tag{1}$$

e.g. rolling the dice

$$P(get\ a\ 6) = 1/6. \tag{2}$$

Probability as a relative frequency, e.g. of an experiment, according to von Mises:

$$F_{rel} = \frac{m(number\ of\ registered\ elements)}{n(number\ of\ all\ elements\ of\ a\ sample)} \tag{3}$$

Linking the two probability definitions with Bernoulli's Law of Large Numbers:

$$\lim_{n\to\infty} F_{rel} = P(A) \tag{4}$$

According to Bayes, probability can also mean a degree of personal belief, which however varies between different persons.

A well-defined mathematical fundament for calculating with probabilities was established by Kolmogorov. E.g. the first axiom postulated that every random event A has a probability $P(A)$, where:

$$0 \le P(A) \le 1 \tag{5}$$

Kolmogorov's Third Axiom on additivity, by the way, forms the basis for risk profiling, which is being proposed by the VDW for the superposition of individual "risk snapshots" to form a "risk film"; see below.

It needs no further explanation that the probability of mutual understanding can get very low, if students of Laplace and von Mises come across students of Bayes, even if they all apply the same mathematics of Kolmogorov.

For practical reliability engineering, the relationship between an experimentally determined histogram and an empirical density is very important and it has been compiled in very easily comprehensible form e.g. in Montgomery: several practical examples are adduced to explain how Bernoulli's Law of Large Numbers can be used to proceed from experimentally determined frequencies to theoretical probabilities and vice versa. In doing so, distribution functions can be derived, e.g. the normal distribution curve of Gauss.

ISO 13849-1 uses the Exponential distribution as a basis for describing the safety related reliability, without pointing it out. The probability of failure is then $F(t) = 1 - e^{(\lambda \cdot t)}$

In doing so, the failure rate λ plays an important role, several roles respectively, and it a priori assumes pure random failures. For the scope of the standard, which is "safety related parts of control systems", this is a very simple comparison standard. It fits quite well, if a constant failure rate λ can be suggested, e.g. for electronical products, which can be connected to the horizontal part of the "bathtub curve". In the VDW's study on operational dependability, by contrast, the Weibull distribution is used, because at machine tools the failures are not purely random, but the failure rate rises as the operating hours increase (as a consequence of wear and tear, ageing).

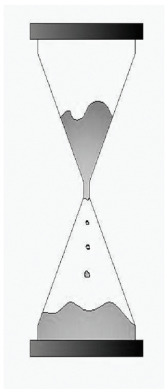
For the purpose of practical understanding, here the concept of probability and the basic principles of distribution functions are elucidated using an "hourglass analogy". This could help to improve the discussion about safety, in which the term "probability" still is mainly used in the sense "degree of belief" and not scientifically founded, but just subjectively emphasized.

1.3 *Hourglass analogy*

Detailed explanations of the basic probabilistic principles involved are provided e.g. in Montgomery. With a simplified model of an hourglass as an analogy, the basic concepts will be briefly outlined here; since with an hourglass the survival probability as "1 minus the probability of failure"

$$R(t) = 1 - F(t)$$

can be very vividly explained, because in the analogy it corresponds to the sand remaining in the glass. How are the various forms of a distribution function, namely:



– density function $f(t)$
– failure probability $F(t)$ or survival probability $R(t) = 1 - F(t)$
– failure rate $\lambda(t)$

depicted in the hourglass analogy?

Figure 1 illustrates how the "distribution function of an hourglass" is developed from the density function. The basic assumptions required here are that per time unit approximately n grains of sand trickle through and there are a total of N grains in the glass (for the precise functioning of an hourglass are reference is given below).

All formulae apply only for $0 < t \le N/n$, because at $t^* = N/n$ the hourglass has run empty.

The definition of the PFH_d (Probability of Failure per Hour) as the average of the (dangerous) density function over an interval T shows that it corresponds quite well to the hourglass analogy. Fig. 2 shows an illustrating graphic, comparing the

Formulae (6)

$$f(t) = \frac{n}{N}$$

Density function

$$F_d(t) = \int_0^t f(\tau) \cdot d\tau = \frac{n}{N} \cdot t$$

Probability of failure

$$R_d(t) = 1 - \frac{n}{N} \cdot t$$

Probability of survival

$$\lambda(t) = \frac{f(t)}{R_d(t)} = \frac{\frac{n}{N}}{1 - \frac{n}{N} \cdot t}$$

Failure rate

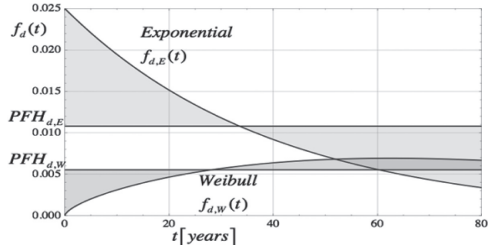

Figure 2. Comparison of PFH_d for Exponential and Weibull Distribution.

PFH_d-values of two different density functions, see also table 1 right column.

$$PFH_D = \frac{1}{T} \cdot \int_0^T \left(\frac{dF_d(t)}{dt} \right) \cdot dt = \bar{f}_d(t)$$
$$= \frac{1}{T} \cdot \int_0^T f_d(t) \cdot dt = \frac{F_d(t)}{T} \quad (7)$$

2 CRITICISM OF THE PERFORMANCE LEVEL

The PFH_d value is the crux of the matter in the studies of ISO 13849-1 and a "average variable in the kind of a frequency domain with the dimension [1/hour]". It is used not only for the quantifications, but also for the decision tree for determining target values as "performance level required" (PL_r, which is divided into PFH_d value ranges), see table 1. As explained above, an Exponential distribution is here assumed. For the example of "radioactive decay", it is true that in each second a fixed percentage of the atomic nuclei present in the substance will decay; the fewer nuclei are still present, the more slowly their number will decrease. This is not the case with the reliability of machine tools: the initial results from the VDW's studies on operational dependability show a significant deviation of the field data from an Exponential distribution (defining a temporally unchanging failure rate), because a time-dependence of the failure behaviour is clearly discernible. Against this background, during field data analysis criticism was voiced concerning the assumptions of a constant failure rate. As an improved model for the real failure behaviour, the Weibull distribution was chosen, which is able to factor in a failure rate rising to a maximum after a certain time period.

In the VDW's first study on the operational dependability of lathes, a Weibull distribution was approximated from field data for the clamping function of a lathe, with the following parameters: $\alpha = 0.000443$ and $\beta = 1.64$. For the empiric analysis, at the end of the available time series it was accumulated that $F(t) = 1$, which is an assumption on

Table 1. Classification of performance level (ISO 13849-1).

Performance level	Average probability of a dangerous failure per hour PFH_d [1/h]
a	$\ge 10^{-5}$ to 10^{-4}
b	$\ge 3 \cdot 10^{-6}$ to 10^{-5}
c	$\ge 10^{-6}$ to $3 \cdot 10^{-6}$
d	$\ge 10^{-7}$ to 10^{-6}
e	$\ge 10^{-8}$ to 10^{-7}

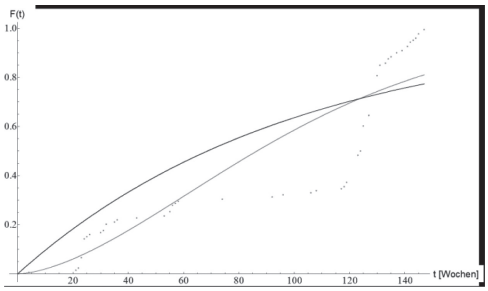

Figure 3. Empirical and theoretical failure probabilities for the clamping function of a lathe (Günnel et al., 2014).

the safe side. The curve for the empirical failure probability is shown separately in Fig. 3. It needs to be mentioned that all events influencing the reliability are incorporated in the empiric data, safety-related and non-safety-related events. How the separation of the safety-related share can be conducted by means of a fault tree, is explained in another ESREL 2014 paper of VDW (Günnel et al., 2014).

3 CRITICISM OF THE RISK MODEL AS SET OUT ON ISO 13849-1 AND CORRECTIONS

The phenomenon "risk" obeys a necessary causation. According to the ISO 12100 standard, which is meant to explain the Machinery Directive (MD) 2006/42/EG for the practical design, the risk assessment is the combination of risk analysis and risk evaluation. Risk analysis subsumes specifying the machine's limits (e.g., spatial and temporal limit), identifying the hazards involved, and estimating the extent of damage and the probability of its incidence. The risk $\mathfrak{R}$ is thus defined as a two-dimensional variable (damage severity S and expected frequency EF) which due to the EF element features a time-dependence:

$$\mathfrak{R} = S * EF \; where \; \mathfrak{R} = \mathfrak{R}(t) \tag{8}$$

Unfortunately, the risk increase due to time duration or number of repetitions of single hazards is not yet considered plausibly in ISO 12100.

Starting with the risk estimate, the risk assessment is used to decide whether, after executing the measures involved, the goals for risk reduction have been achieved.

For this purpose, the machine is divided into spatial and temporal limits, in accordance with 5.3.3./4 of the above-mentioned standard. In the risk assessments so far publicly available for machine tools, analysis concentrates on individual hazardous situations/events, typical for specific machines, in which the machines are being used (i.e., Man-Machine-Interaction, MMI). The modes of operation concept provide a standardized pattern for typical operator actions. From there, so called "stretched risk snapshots" can be derived as an abstracted MMI-model, which is needed as in input for the decision tree of ISO 13849-1. When this is done, the risk elements of ISO 12100 with regard to failure rates as "frequently based target values" are oddly compressed in ISO 13849-1, and the time slices of individual situations in relation to the machine's entire lifecycle is not plausibly recorded. For example, no distinction is drawn at all as to whether individual "risk snapshots" are frequently repeated or occur very rarely, although the risk content in the total risk for a particular machine is crucially determined thereby.

In order to cover the temporal limits appropriately in the risk assessment, in chapter 4 a VDW-proposal is explained for grouping together the individual "risk snapshots" in a holistic risk profile (the "risk film"). This proposal covers all relevant phases of the life-cycle (20 years in accordance with ISO 13849-1) of the machine tool involved together with their time slices t_j (as a weighting factor in the with $PFH_d \cdot t_j$ approximated exponential distribution). In doing so, realistic risk proportions are made available for risk assessment in accordance with ISO 12100. The aim of this "untangling" of the compressed risk elements in ISO 13849-1 is to enrich the current discussion in the standardisation working groups, in particular in sub group 5 of the "Joint Working Group" for the merging into IEC/ISO 17305.

A risk model that considers only PFH_d value ranges (without considering the time duration) is not plausibly congruent with the definition of risk in ISO 12100. This is because the relative frequency F_{rel} is closely dependent on the observation time t concerned, as can clearly be seen in Fig. 1 and Fig. 2; it is always the integral of the density function:

$$F_{rel}(t) = \int_0^t f(\tau) \cdot d(\tau) \tag{9}$$

This is a probability in the sense of a relative frequency.

In a recent publication (G. Gigerenzer), too, the misunderstandings and misdirections in risk estimation are vividly illustrated as "risk incompetence", which can be manifested even by high-ranking experts, if the risk is represented other than with relative frequencies in the Time Domain. Against this background, the risk definition provided in ISO 13849-1 can be seriously questioned

in regard to the PFH_d value ranges, because the time-dependence of the expected frequency of severity levels is not explicitly dealt with in the decision tree (called "risk graph") in Appendix A. Instead, the time-dependence is "accommodated" implausibly in risk parameter F, which is to be estimated out of the respective hazardous situation/event. Even recent discussions in the ISO working group in March 2014 for the ISO 13849-1 Amd 1 could not bring about a plausible definition of the parameter F, since it refers to the temporal ratio of hazardous exposure (which is plausible) *and in addition* to the frequency (*which is not plausible*). This risk model is therefore unsuitable for machine tools, because risk studies for machine tools must not simply ignore the temporally highly variable factor of man-machine interaction. It is precisely here that the greatest risk reductions can be achieved on the basis of defined access modalities within operating mode concepts, simply because the duration of the operator's exposure to hazard is minimised; temporally and spatially, e.g. with two-hand-control from a safely designed operator position. In the product standards for machine tools, there are detailed descriptions of how with the aid of fixed and movable guards the hazards resulting from random failures in the control chains can as far as possible be "kept away" from the operator. For risk assessment of machine tools, then one needs a "variable in the time domain", i.e. a reconciliation of:

– estimated expectable frequencies (EF) and corresponding severity levels (S) and
– tolerable limits for EF and S combinations.

From Meyna, the double-logarithmical Farmer diagram according to the Farmer graph (Farmer 1967) of Fig. 4 is explained in this context. A linear line represents a certain risk, comprising all possible combinations of EF and S of this risk. As regards machine tools, the S-axis could be normed to a maximum of one fatal accident, which can be considered—the very rarely occurring—worst case of injury. In the Farmer diagram, the individual steps for the risk reduction can be shown either as effect-related (reduced severity levels) or as cause-related (reduced frequencies) or as a mixture of the two; see Fig. 4 for the example of a flat-grinding machine with a primary wheel guard and an additional enclosure.

With the aid of the 3-step method of the Machinery Directive (or ISO 12100) in its specific implementation for machine tools, the effect of risk reduction can be illustrated as a vectorial variable, as described in VDMA Standard Sheet 34189; see the generalised principle in Fig. 4, starting with the "naked machine" by means of various measures:

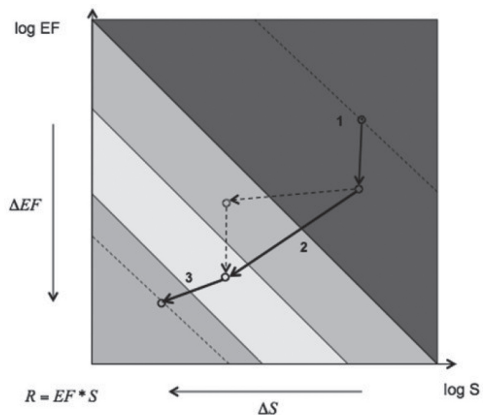

Figure 4. Theoretical risk reduction using the 3-step method acc. to ISO 16089 with primary wheel guard.

1. increase in inherent safety of the machine functions, in accordance with the technology-dependent state of the art
2. fixed or movable guard with interlocking and guard locking within an operating mode concept
3. instructive safety (operating instructions and training)

The functional safety plays a role only in the inherent safety of the machine functions and in the interlocking of the enclosure. With the third step a tolerable risk can be achieved, if the instructions for the intended application are followed by the user. Otherwise, only step 1 provides a risk reduction and an orange of even red risk range may put the operator in jeopardy, e.g. when defeating safeguards.

When applying ISO 13849-1, a case distinction drawn between a:

– Pure safety function pure (e.g., two-hand control with dependable stopping of the drives) and a
– technology-dependent machine function (e.g., tool clamping)

has so far not been defined.

The typical feature of a machine function is that the design engineer is in any case targeting a high level of reliability in order to optimise the machine's availability for the owner's benefit. The safety-related reliability (functional safety) is here always improved as well, because safety is a subset of the overall reliability/availability, since a failure of functional safety will be given full statistical weight in quantifying the dependability or availability of the machine concerned. A machine function can become a safety function if it has to be safely shut down when guard doors are opened, e.g. a gravity-loaded vertical axis. It is clear that in this context

time slices of the man-machine-interaction have to be factored in, because in the case of highly automated machines the transition to the safety function should have a far smaller time slice than the operation as a machine function. In fact, the trend to automation is going into this direction at least during the last decade.

Another unresolved discussion related to ISO 13849-1 is about the "overlapping of hazards". On the one hand side, safety functions are looked at very closely in order cope with every conceivable imponderability in the relevant control chain. On the other hand, these detailed dissections are not interpreted as regards the superposition of individual safety functions, i.e. a plausible composition that refers to the proportions of single effects is completely missing. This seems to be a considerable gap in the ISO 13849-1 on its way to probabilistic professionalism. As a consequence, the possible influence of an required increase of "Performance Level" on an improved operational safety is completely overestimated. This is at least true for machine tools, for which fixed and moveable guards within a safely defined modes of operations concept are the dominant risk reduction strategy. Uhlmann, Meister & Mödden are explaining the situation in detail (2012).

4 VDW'S PROPOSAL FOR RISK PROFILING

The overall machine risk is in the VDW's proposal totalled as a risk profile comprising the estimated individual contents of plausibly stretched "risk snapshots", as explained in VDMA Standard Sheet 34189, over:

- *all man-machine-activities and*
- *all hazards potentially caused by control system errors of*
- *all relevant machine components*
- *over all lifetime phases.*

In order to overcome the obstacles explained in chapter 4, VDW proposes an improved risk model in the Time Domain. Thereby, individual hazardous situations/events of man-machine interaction are modelled as (timely stretched) "risk snapshots" in order to follow ISO 12100, 5.5 (risk estimation), whereas the assumptions were made on the safe side for:

- the extent of damage in accordance with ISO 12100, 5.5.2.2 (Parameter *S* in accordance with accident statistics) and probability of occurrence of a damage in accordance with 5.5.2.3, with the influencing factors:

1. hazard exposure in accordance with 5.5.2.3.1 (Parameter F: activity-related),
2. probability of occurrence for the hazard in accordance with 5.5.2.3 (Parameter *O*: situation-related): the parameter *O* is in the risk profiles of the VDW mostly set to a value of 1, because the effects that reduce the probability of occurrence of damage are separately argued as a time share adducing a variable man-machine interaction. This is different from the utilization of parameter *O* in part 2 of this paper, because the "roof" of type A and B standards does not offer an explicit consideration of the time effect on the risk.
3. avoidability or controllability in accordance with 5.5.2.3.3 (Parameter *C*: operating-mode-dependent)

- and further relevant aspects in accordance with 5.5.3.

For a "risk snapshot", the connection between "cause" and "effect" can be depicted with the aid of the path diagram for mutually independent elements (*O*, *F*, and *C*) in Fig. 5:

1. The probability of a hazardous failure in all safety-relevant control chains $i = 1$ to m for the MMI activity $j = 1$ *to* n concerned $\sum_{i=1}^{m}\left(PFH_{d,i}\cdot t\right)$ as a possible "cause" and
2 The probability or relative frequency of an operator's injury with discrete severity levels Se 1 to Se 4 (in accordance with IEC 62061) as a possible "effect".

The result of the severity-level prognosis is directly dependent on risk parameters O_j, F_j and C_j. In order to arrive at the severity levels, the distribution of the severity levels Se 1 to Se 4 is connected with a histogram typical for machine tools (i.e., accident pyramids of the BAuA).

$$\mathfrak{R} = S_j \cdot F_j \cdot (1-C_j) \cdot O_j \cdot \left\lfloor \sum_{i=1}^{m} (-PFH_{d,i} \cdot t_j)_i \right\rfloor_j \quad (10)$$

Individual safety functions, with their expected frequencies are added together to form a superimposed failure probability $\sum_{i=1}^{m}(-PFH_{d,i}\cdot t_j)_i$, and multiplied by an occurrence probability O_j for the materialisation of a hazard.

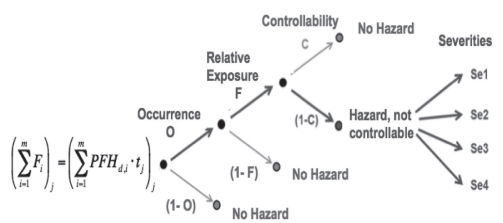

Figure 5. Risk path diagram, cause and effect relation.

The totalling function of the total risk $\mathfrak{R}(T)$ over all $j = 1$ to n risk snapshots during the time period $T = \sum_{j=1}^{n} \Delta T_j$ is obtained by totalling the snapshots with their temporal weighting in the approximated exponential function:

$$\mathfrak{R}(T) = \sum_{j=1}^{n} \mathfrak{R}_j(\Delta T_j) \tag{11}$$

$\mathfrak{R}(T)$

$$\sum_{j=1}^{n} \left[S_j \cdot F_j \cdot (1 - C_j) \cdot O_j \cdot \left(\sum_{i=1}^{m} PFH_{d,i} \cdot t_j \right) \right] \tag{12}$$

In this way, a plausible relationship is established between the multiplicity of causes (control system failures) and the bandwidth of possible effects (hazards and expectable severity levels) in the context of the highly time-variable man-machine interaction. The risk reductions can thus also be depicted in a time domain as an enclosure with interlock and locking in the context of an operating mode concept. This is what the product standards for machine tools are dealing with very successfully since more than a decade.

The risk profiling gives an interesting insight in the ongoing discussions about the "overlapping of hazards". The detailed dissections of single safety functions are dealt with in superposition (Kolmogorov's Third Axiom), and a plausible composition considering the proportions of single effects is introduced by this paper. This should not be neglected.

The risk profiling method is also intended to trigger a public discussion, particularly in the relevant standardisation bodies. For instance, in sub group 3 of the JWG 1 for the into IEC/ISO 17305, several machine examples have been discussed, for turning, grinding and milling machines, showing the significant risk reduction of guards, Fig. 8 to 12 are taken as examples from them. In addition, a presentation on this topic was given during the VDW's Technology Day at the METAV in March 2014. Furthermore, a comparison between different risk scoring systems (not yet compared e.g. in ISO/TR 14121–2) is feasible with the risk profiling, when a comparison object is selected, e.g. a machine as in fig. 8.

This risk snapshot, however, occurs more than once during a machine's service time (mission time), as a consequence a grouping of equivalent risk snapshots occurs. The factor with which the j-th snapshot has to be weighted over the exponential function as a group is reflected in the time slices; see Fig. 6, Fig. 7 and Fig. 9.

A practically useful risk model has to be able to depict the case that a reduction of activities with a comparatively increased risk of injury leads

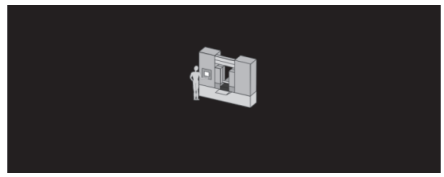

Figure 6. Individual risk snapshots within the service time (mission time).

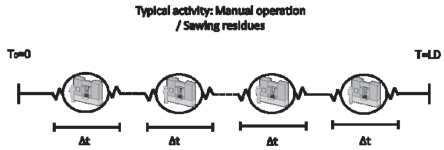

Figure 7. Repetition of risk snapshots and supsumption in a group as a a time share within the lifetime service time (mission time).

Figure 8. Example of a CNC milling machining center (5 axes).

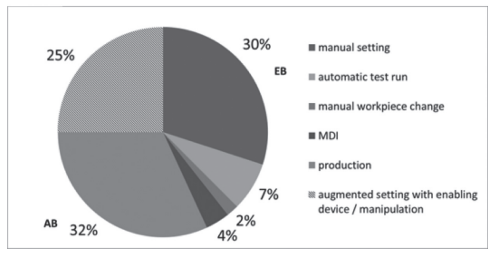

Figure 9. Time slices of different operating modes (AB = automatic mode, EB = setup mode, SBA = Special operating mode).

overall to a reduction in the total risk involved for the machine concerned. For example, for machine tools "offline setup" (instead of usual setup at the machine) is being developed using a 1-to-1 simulation model of the actual machine at a PC. This enables the risk to be significantly reduced by downsizing the amount of repeated activities during setup, see Fig. 10 with Operation Mode 2 (OM 2) as a significant risk share with 37,5%. This cannot, however, be argued with the risk model of ISO 13849-1, because it does not deal at all with a reduced repetition frequency of critical situations,

although this reduction (in the author's view) is the most important element in risk reduction for machine tools.

The result of the supsumption into groups of theequivalent risk snappshots of a time allocation over the service time (mission time) for the machine shown in Fig. 8 may resemble the diagram in Fig. 9.

The time shares of installation and troubleshooting are not listed, because these shares are relatively unimportant for the risk assumption caused by control failures on the other hand they represent accidents focuses caused by other reasons.

Furthermore, the cost-benefit ratio is for VDW companies an important issue in what is anyway a very predatory competition with low-price machines. This is another reason why a profiling method has been developed in the form of a Farmer Matrix and a two-dimensional Pareto diagram; see Figs. 10 and 11 below.

The risk presentation formats in Figs. 10 and 11 enable the design engineer to reduce the risk as best as possible, relating proposed additional

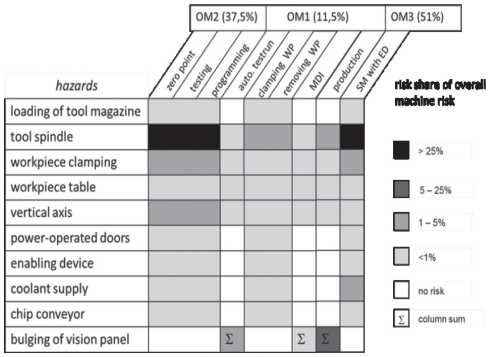

Figure 10. Two-dimensional Pareto diagram for the risk of a milling machine being used for its intended purpose, with a program test and enabling device in accordance with ISO 16090.

Expected frequency of a harm during a lifetime of the machine of 20 years acc. to PFH of PL of ISO 13849-1		Severity of a harm Acc. to IEC 62061 and 2010/16/EC

efforts to the benefits obtained. Parameter studies are possible, answering the question: Which efforts leads to the highest risk reduction? Or the question (see Fig. 12: Is the special operation mode really the "lesser evil" compared to defeated safeguards (manipulation)?

5 PROBABILISTICALLY FOUNDED GUARD DIMENSIONING

The safety of a machine tool depends very much on the impact resistance of fixed and moveable guards (enclosure with vision panels). In the current product standards a non-probabilistic approach is still the basis for empiric tests to determine the required guard thicknesses. However, in reality all design variables are random variables, which can be described with statistical methods. The deterministic approach does not consider very unlikely events, but, it is desirable to know, what the probability P for a perforation event is, when the dimensioning is in compliance with the standard requirements: Is the probability tolerable? The probabilistic requirements for the functional safety can be directly compared with the requirements for the guard dimensioning, because both serve the same goal: operator protection. As a first step, it could be evaluated, how the deterministically defined state of the art in product standards performs in the probabilistic domain, i.e. if the impact resistance and the impact energy are being considered random variables.

Out of the density functions for the impact resistance R and the impact energy E, the probability P of a perforation event can be calculated. If e.g. impact resistance and impact energy follow a standard distribution, the relevant mean values and standard deviations can be empirically derived. The difference of both density functions, the "limit state function" is again a standard

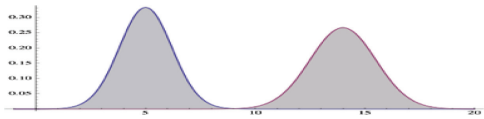

Figure 13. Intersection of two density functions.

distribution, of which the mean and standard deviation are functions of the input functions. The failure probability is the negative area element of the integrated limit state function. It is equivalent to the intersection area of the density functions of impact resistance and impact energy, see figure 13 and Montgomery. To start with, in Berlin and Tokio this approach is being studied for grinding machines, indicated in the CNC-Arena.

6 CONCLUSION

When comparing probabilistic theory and practice, the question arises, how the designer should consider a quantifiable tolerable risk in a responsible way. The deliberations above show that a quantitative risk assessment does not necessarily mean the numerical verification of the compliance with a tolerable limit. Due to the multi-dimensional variability of the man-machine-interaction as illustrated in the risk profiling in chapter 4, a precise proof is not feasible. However, showing the relative proportions of the risk reduction effects following the 3-step-method of ISO 12100 is much more important than giving an absolute value, which anyway depends on many subjective estimations. In doing so, estimates on the safe side that are summed up provide again a safe estimate. So, the essential effects become visible (see Fig. 10) and reproducible parameter studies can be conducted in a relatively objective manner (see Fig. 12). This enables the designer to justify that he derived a best possible design in the boundaries of technically available and economically acceptable means.

Depending on the specific aspects of a technology, numerically different tolerable risks develop as the significant differences in accident statistics of wood working and metal working machines clearly indicate, although the technologies are very similar except for the machined material (BAuA, 2010).

The best possible reference for a tolerable risk is the state of the art in well-tried product standards as ISO 16090 (before EN 12417). An increase of the requirements in the standard needs to be justified plausibly, and an appropriate consideration of the economic risk in Global competition is indispensable, not only in (small and medium) enterprises, but also from the Health and Safety experts.

Proving a tolerable risk can become a challenge, if product standards are not available. Then plausible probabilistic methods can be an useful argumentation platform, because the term "probability" in the law can be applied mathematically correct.

For the sake of comparison with reality, a separate third paper of Mödden & Günnel (ESREL, 2014) shows empiric findings of field data analyses.

Finally, a revealing oral statement on the quantitative consideration of safety, given by Dr. Heinrich Mushardt in 2013, an honoured VDW senior designer for machine tools, who retired recently, shall be quoted here:

"Under the obligation, to keep records of design analyses and to deal with potential hazards in a numerically plausible way, the designer can elude the allegation of culpable negligence. However, the completeness of analyses and the correctness of the decisions presumably can only be reviewed in case of damage. The numerically small values and the multitude of possible causes (for a hazardous effect) are located in the statistically limit range of small numbers. Statistically founded conclusions are not easy to obtain, when customers' requirements lead to a trend towards individual "one-off" designs. This causes scepticism whether the practical application of ISO 13849-1 can bring about significant improvements for the safety of machine tools. Risks due to foreseeable human behaviour shall be excluded, but there are also a not foreseeable misuse, technical failures and working errors. On this background, it should not be forgotten how rare severe injuries at machine tools occur altogether, and that if one severe accident happens, unforeseeable events or unforeseeable misuse of possibly criminal conduct play a major role but NOT primarily a lack of functional safety."

ABSTRACT: As stated in part 1 of the article, standard ISO 13849-1 deals with the theoretical probabilities of hypothetical individual events and the possibility of reconciliation of this theoretical approach with empiric field data is partly neglected.

In part 2 the problems arising during the real design of SRP/CS (Safety Related Part of a Control System) of machines are addressed on the background of relevant safety standards. Using the informative theoretical appendix A of ISO 13849-1 to determine the Performance Level required (PLr) may cause sometimes technically impracticable requirements, which are far beyond the state of the art in existing type C standards. For the sake of connection between theory and practice, the probability of occurrence of a hazardous situation must be taken into account in order to appropriately consider the required risk reduction of a SRP/CS in the context of the three-step-method of ISO 12100. For this purpose two practical solutions are provided:

– a methodology for PL_r definition for safety functions considering a realistic probability of occurrence of hazards, using a hybrid approach of ISO 13849-1 and IEC 62061,
– a "table based" methodology for the design of machine tool control system considering all the realistic "occurrences" as stated also in the "new" ISO/TR 14121-2. Those two contributions are extracted from the work during the ISO/TC 39/SC 10/WG4 meetings (ISO/CD 16090 for milling machines).

The selected safety function for 2.) is very similar to the safety function "prevention of unexpected start-up of a movement of a linear or rotational axis with an incorrectly clamped workpiece" of the standard ISO 16090-1. This safety function was chosen in another paper of Mödden, Günnel for ESREL 2014. Therein, the analysis of field data of real milling machines shows that a reliability between PL = a and PL = b is actually being achieved with state of the art design. This finding connects quite well theory and practice of state of the art milling machines.

1 INTRODUCTION

The design of Safety Related Parts of the Control System (SRP/CS) it is one of the emerging problems of the new standard requirements related to Machinery Directive (European Parliament and the Council of European Union, 2006).

The leading standards are ISO 13849-1:2008 and IEC 62061:2005 respectively from a "mechanical and electronic point of view".

If compared with the older "European standards" (EN 954-1:1996), the basic reliability concept of categories and design of systems with a given hardware fault tolerance has been rewritten in terms of reliability calculation.

Now the SRP/CS has to be designed using a validation procedure that requires a minimum reliability to be acquired in terms of Mean Time to Dangerous Failures ($MTTF_d$).

Also other very important concepts have been developed in the new standards mentioned above. Such as the requirement of a Diagnostic Coverage (DC) and the design of systems which considers the Common Cause Failures (CCF). Trying to

summarize with an understandable simplification, using the new standards a good architecture on the SRP/CS (for example doubled channels) is no longer sufficient to achieve the required minimum reliability.

The acronyms for the overall design safety concepts of the two standards are: PL (Performance Level, ISO 13849-1) and SIL (Safety Integrity Level, IEC 62061).

As it will be explained in detail in the next paragraphs those two different concepts, whose full calculation are performed in different ways, are comparable in terms of Average Probability of Dangerous Failure per Hour (PFH_D, expressed in terms of 1/h).

The main problem of those two "safety views", often sharing the same components on a real machine, is the results of risk assessment (see also Part 1 of this paper). The minimum PFH_D required for assuring a sufficient level of safety may be different if the calculation it is performed using the SIL or PL concept, because ISO 13849-1 is cutting at $MTTF_d$ at 100 year and IEC 62061 is doing it with 150 year.

And if some technologies are used for SRP/CS, e.g. pneumatic or hydraulic, only the PL concept according ISO 13849-1 is still valid for the full design process, but often both are valid.

The PL_r (required) needs to be derived from the risk assessment with the three-step-method of risk reduction according to ISO 12100:2010.

The Machine Directive only requires a risk assessment, but does not specify as it shall be done. Moreover also the ISO 12100, type A standard, specifies the principles of risk assessment and does not specify any method to do it.

In the following paragraphs some methods useful to calculate PL_r, in full accordance with the risk assessment principles of ISO 12100, will be presented. In the first paragraph, an hybrid method ISO 13849-1—IEC 62061 will be presented. In the second paragraph, a table method covering all the phase necessary to perform the risk estimation for a general safety function of a SRP/CS will be shown.

2 DEFINITION OF THE PL_r

Trying to merge the two different approaches of the two already mentioned standards, some preliminary consideration on the definition of a hazard occurrence probability in ISO 12100 has to be done.

2.1 *The "occurrence problem" on ISO 13849-1*

If somebody sees the element of risk of the Figure 1 ISO 12100, one can notice that the overall

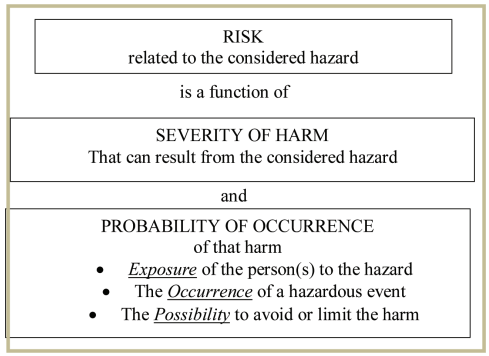

Figure 1. Elements of risk according to ISO 12100.

probability of occurrence of the harm depends on (see part 1 of the paper):

1. exposure,
2. occurrence of hazardous event,
3. possibility of avoiding or limiting the harm.

If one looks at the definition of Occurrence (point 5.5.2.3.2 of the ISO 12100), the relevant factors that influence the probability of occurrence of harm are:

1. reliability and other statistical data,
2. accident history,
3. history of damage to health,
4. comparison of risks.

The standard says clearly that *those factors shall be taken into account.*

Looking at informative Annex A of ISO 13849-1, concerned with the contribution to the reduction in risk made by the SRP/CS, amazingly, an explicit provision of the occurrence parameter is missing.

The method given here provides, as stated in ISO 13849-1: "only an estimation of risk reduction and is intended as guidance to the designer and standard maker in determining the PL_r for each necessary safety function to be carried out by an SRP/CS".

In our opinion this definition it is too conservative and some of the already mentioned relevant factors of ISO (e.g. real accident history) cannot be taken plausibly into consideration.

To give an example, we are looking at the Safety Function (SF) of limited speed monitoring—maximum spindle speed during some Modes of Safe Operation (MSO) for milling machines (ISO CD/16090, 2014, table J.2. paragraph 2). Among experts, there are no accidents known due to this risk. If the occurrence of a hazard is not taken into account, no risk reduction can be done. The same is true, if a real harm related with this risk

never occurs in the operational field. The point is that the machines are designed the last 10–15 years with high safety standards and the technology has been changed in the drive control system. Before this has been done, some accidents had occurred. This evidence/lack of injuries can be researched, for example, on national accident institution surveillance reports (e.g. INAIL 2013). From the "experience point of view" the theoretical severity of the harm is high, but in the "real world" we have no evidence of real accidents.

In the novel technical report ISO/TR 14121-2 (ISO 2012) the problem of *probability of occurrence of hazard* and its correlation with *probability of occurrence of harm* is clarified.

In point 5.4.3 of the ISO/TR it is clarified that occurrence of a real harm is a fundamental aspect to take into account and this occurrence is strictly connected not only with potential risk, but also with occurrence as stated in ISO 12100.

In all the risk estimation tools proposed in subsequent paragraph 6 of ISO/TR 14121-2 the occurrence is always taken into account.

For example if the risk graph method is used according to ISO 14121-2_2013, section 6.3.2, the occurrence is divided in three levels:

1. O1—low
2. O2—medium
3. O3—high.

In IEC 62061 there are even 5 levels as defined in table A.3.

In ISO 13849-1 one cannot find any definition or any variations or levels.

From statistical data on the market, usually we have data of occurrence of harm and not occurrence of hazard, which is different from a theoretical point of view. In other words, the SRP/CS designer has to be sure that there is no accident data recorded for a given SF, but this fact does not mean no occurrence of hazardous event. It only means that the designer managed to cope with the hazardous events by applying the right safety measures.

For instance usually we have designed and properly installed other protective measure (as guards) for a specific risk reductions (e.g. impact with moving parts) effecting also the SF risk estimation.

If the occurrence of hazard is low, the general hypothesis of reducing the risk index by one level appears to be a good compromise between the theoretical and the real application (see Fig. 2). This can be done, if you use the informative risk graph of ISO/TR 14121-2. On the other side, when the occurrence of hazard is high, the risk index is increased, if a possible severe injury is expected.

From the authors point of view, the entire machine tool is a very complex machine made of several hundreds or thousands of components and the correlation between different safety principles leading to a common risk reduction cannot be simply neglected, but needs to be considered properly (see chapter 4 of part 1 of the paper). If a very complex machine with several correlations between SF and other safety measures has to be taken into account, the designer has to take an overall view of the entire machine. The proposed risk estimation matrix method of ISO/TR 14121-2 (Table 1), taking into consideration directly the overall probability of harm it is a quite realistic approach.

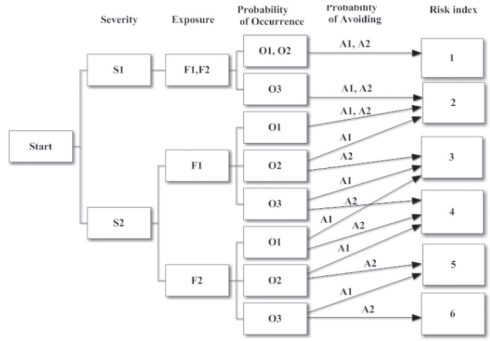

Figure 2. Risk graph from ISO/TR 14121-2.

Table 1. Risk estimation matrix from ISO/TR 14121-2.

Prob. of occurence of harm	Severity of harm			
	Catastrophic	Serious	Moderate	Minor
Very likely	High	High	High	Medium
Likely	High	High	Medium	Low
Unlikely	Medium	Medium	Low	Neglig.
Remote	Low	Low	Neglig.	Neglig.

2.2 *Element of risk in different standards and technical reports*

Before the merging project IEC/ISO 17305 is providing concrete results, we have at first to summarize the different meanings of risk element of ISO 13849-1 and IEC 62061.

2.2.1 *Severity (S or Se)*

In ISO 13849-1 only two severity levels are used, and they are called S1 and S2, where S2 is severe injuries. In contrast hereto, in IEC 62061 four severity levels are used, which largely correspond to the four severity levels of EU Decision on general safety of products (Decision 2010/15/EU, called RAPEX), see Table 2.

Table 2. SIL from IEC 62061.

Severity (Se)	Class (Cl)				
	3–4	5–7	8–10	11–13	14–15
4	SIL2	SIL2	SIL2	SIL3	SIL3
3		(OM)	SIL1	SIL2	SIL3
2			(OM)	SIL1	SIL2
1				(OM)	SIL1

Comparing the severity, bruises and/or cut wounds without complications are classified as S1 in ISO 13849-1 (Table A.1.), that corresponds only partially to the grouped severity levels Se1 and Se 2 of ISO 62061.

The severity levels Se 3 and Se 4 of ISO 62061 are, in accordance with Table A.1, largely congruent with severity level S2 of ISO 13849-1.

2.2.2 *Exposure (F or Fr)*

In ISO 13849-1 only two exposure levels are used, and they are called F1 and F2 (the F2 is frequent exposure, a very rough method which even tries to compress the duration of hazardous situations into a frequency, which is not plausible, as already stated in part 1 of the article).

In IEC 62061 five exposure (*Fr*) levels are used (Table A.2) with numerical values that can to be assigned.

2.2.3 *Possibility of avoiding the hazard—harm (P or Av)*

In ISO 13849-1 again only two probabilities of avoiding of hazard levels are used, and they are called P1 and P2 (the P2 is to be used, if there are no/little chances to avoid the hazardous situation).

In IEC 62061, we have a different theoretical contribution, here we have three levels of probability of avoiding or limiting *harm* (*Av*) not hazard (Table A.4) with three different numerical results possible from an overall estimation.

2.2.4 *Occurrence of hazard (Pr)*

In ISO 13849-1 is not possible to take an occurrence probability explicitly into account. Very different from this, in IEC 62061 we have five levels available. As regards automatically controlled machines, especially the risk of unexpected start-up of a movement has to be taken into consideration in the context of the three-step-method of risk reduction of ISO 12100. Only then it is possible to estimate the occurrence probability that will be caused, if the SRP/CS fails. The intended use needs to be taken into consideration e.g. as regards the modes of operation (e.g. setup, manual or automatic working, maintenance). On the background of a kind of "naked" machine (i.e. only step 2 of 3 steps of risk reduction is considered), the occurrence probability of a hazard due SF failure cannot reasonably estimated. But, ISO 13849-1 tries to do exactly this, not surprisingly concluding that the occurrence probability rather should be equals to 1.

2.3 *A practical "partial merging" method for type C standards*

The risk classification method in accordance with IEC 62061 is of general validity, and not only restricted to electrical control systems. Therefore, it can also be applied to mechatronic control chains as ISO 13849-1 regards them. The requirement for a SF made of mechatronic components can thus be defined either with the informative decision tree, (wrongly called "risk graph") of ISO 13849-1, or with a risk classification in accordance with IEC 62061. Other parts of IEC 62061 however, for example the beta factors estimation for common cause failures, are not useable, when hydraulic and pneumatic systems are used.

In IEC standard the results of risk estimation leads to a class of probability of harm (not hazard) CL:

$$CL = Fr + Pr + Av \tag{1}$$

In Table 2, the result of IEC 62061 is a SIL.

So a defined PFH_d value range dependent of a SIL is stated (see IEC 62061, Table 3).

The resulting PFH_d value range is likewise defined in ISO 13849-1 Table 3, Table 4.

From the Tables 3 and 4 we can conclude that because the value ranges of PFH_d are largely

Table 3. PFH_d and SIL.

SIL	Probability of dangerous failures per hour (PFH_d)
3	$\geq 10^{-8}$ to $< 10^{-7}$
2	$\geq 10^{-7}$ to $< 10^{-6}$
1	$\geq 10^{-6}$ to $< 10^{-5}$

Table 4. PL from IEC 13849-1.

PL	Average probability of dangerous failures per hour (1/h)
a	$\geq 10^{-5}$ to $<10^{-4}$
b	$\geq 3 \cdot 10^{-6}$ to $<10^{-5}$
c	$\geq 10^{-6}$ to $3 <10^{-6}$
d	$\geq 10^{-7}$ to $<10^{-6}$
e	$\geq 10^{-8}$ to $<10^{-7}$

congruent, the risk graph and the risk classification can be plausibly linked to each other. The PFH_d parameter is a common mathematical platform between ISO 13849-1 and IEC 62061 (assuming that also the IEC 62061 definition is an "average", as illustrated in part 1 of this paper).

The PL = a has no correspondence with SIL.

In Figure 3, the result of the decision tree of ISO 13849-1 is a PL_r.

A SIL 1 is equivalent to PL = b and PL = c. Only for injuries with a lower severity of S1, PL = b can be derived, since for a severity of S2 at least PL = c is demanded. SIL 1, however, subsumes the entire PFH_d value range of PL = b and PL = c.

SIL 2 is completely equivalent to PL = d and SIL 3 is fully equivalent to PL = e.

Furthermore, IEC 62061 provides, as we have already seen, more "levels" for each parameters and the overall CL, see equation 1 and Table 2 above. This enables a substantially more realistic and more accurate assessment of the risk reduction to be achieved by the SRP/CS than in ISO 13849-1.

The requirement for SIL 1 is, in accordance with Table 2 detailed for the following combinations and risk classes:

– severity level Se 3 with CL 8–10,
– severity level Se 2 with CL 11–13,
– severity level Se 1 and CL 14–15.

On the basis of these requirements of SIL 1, the following case differentiations are derived for the minimum PL_r:

Se 1 and CL = 14, SIL 1 → $PL_{r,min}$ = b
Se 1 and CL = 15, SIL 1 → $PL_{r,min}$ = c
Se 2 and CL = 11, SIL 1 → $PL_{r,min}$ = b
Se 2 and CL = 12 or 13, SIL 1 → $PL_{r,min}$ = c
Se 3 and CL = 8 or 9 or 10, SIL 1 → $PL_{r,min}$ = c

because injuries of Se 3 are irreversible and comparable to S2 in ISO 13849-1, and there PL = c (S2, F1, P1) is the lowest possible PL.

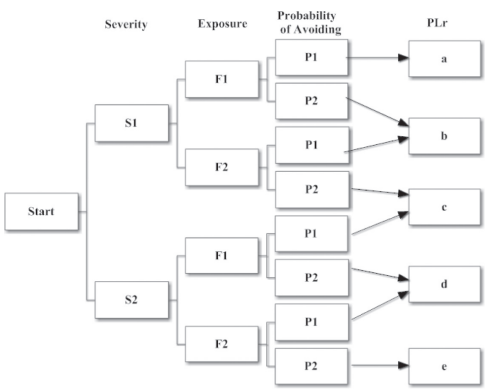

Figure 3. PL_r from IEC 13849-1.

In IEC 62061, below SIL 1 "other measures" must be provided at least (OM in Table 2). We have also a very important note to Table 3 point 5.2.4.2 in the IEC 62061. If we have less than SIL 1 from risk estimation, the minimum requirements are the ones of category B of ISO 13849-1.

The requirement of OM is, in accordance with Table 2, detailed for the following combinations and risk classes:

Se 1 and K = 11–13, AM → $PL_{r,min}$ = a
Se 2 and K = 8–10, AM → $PL_{r,min}$ = a
Se 3 and K = 5–7, AM → $PL_{r,min}$ = a

In addition to $PL_{r,min}$ = a, the wording "other measures" of IEC 62061 is used. Following this approach, the IEC 62061 OM + ISO 13849-1 PL = a become a kind of "safety integrity performance level" with the sum of the requirements of both.

In our opinion, this hybrid approach gives excellent results on removing the very rough risk estimation of ISO 13849-1 (see also Hedberg & others, 2011).

Example 1: the following example shows the difference that could be found using the direct approach of ISO 13849-1 instead of the hybrid one presented. The SF function being analysed here is *limited speed of spindle due to tool* being applied in different Modes of Safe Operation (MSO).

When exceeding the maximum processing speed of the tool, a controlled stopping of the tool spindle shall takes place according to IEC 60204-1: 2009, 9.2.2 depending on the technique applied.

Usually the maximum processing speed shall be provided in the tool parameters of the tool management (manual human data input).

The risk estimation of ISO 13849-1 leads for long stays during some operation to: S2-F2-P2 and then to PL = e. This is often far away from both, and from the state of the art of all the tooling machine technologies and from technical achievability.

If the risk estimation of IEC 62061 is used, we can find: CL = Fr + Pr + Av = 4 + 1 + 5 = 10 with a possible severity Se = 4 we have a SIL 2 and then with the partial merging approach PL = d. Then we have to define, if we have to use a category 2 or 3 system, because a PL = d can be designed in both ways. But when fixed or moveable guards are in operation (for example full enclosure with interlocked guards and guard locking during automatic machining), one can have longer stays according to IEC 62061, because the severity Se = 3 is sufficient.

The main difference between the two simplified risk estimation methods is that it is possible also to

take into consideration positive field experiences, e.g. that no accidents are known among experts for a certain machine type with a specific SF and so even Pr = 1 can be justified. The corresponding discussion is ongoing in the working groups of type C standards.

There are also some technical achievability problems with this SF, which will be considered in detail in the next paragraph.

3 A NOVEL TABLE METHOD FOR CONCISE RISK ESTIMATION OF A SAFETY FUNCTION OF A SRP/CS

From the machine builders point of view, a precise identification and explanation of all the SF's is needed in order to develop a model for both, the risk estimation and the quantification of the reliability (PL or SIL). However, in the current type C standards for machine tools, it is very difficult to find a precise identification and risk estimation for all the SF of a given machine.

Also some technical information of how to reach the required safety level is welcomed by machine designer (for example technical information based on state of the art of current machine on the market or technical achievability of a given PL).

A "technically design oriented" view leads to very detailed explanations of all the SF's, which could take several pages in the type C standard. The first ISO type C standard for machine tools with a small SF description is the ISO 23125:2010/Amd 1:2012—Safety of turning machines. In this standard the main SF are described in a single page (see point 5.11 b) trying to give the main information on PL_r regardless of the different requirements for similar SF in different zones of the machine. For example in this standard the enabling device SF has always a PL_r = d requirement, this is a very simplified approach.

It is clear that this simple table is not satisfactory at all, not even for a simple analysis: the PL_r of the SF depends on the kind of the control chain which builds the SF and it also depends on the risk reduction of an enabling device. So a realistic risk estimation has to consider all the factors of paragraph 2 of this paper for all the different risk reduction effects of an enabling device. Moreover this has to be done in all the specific applications, e.g. in every mode of operation there needs to be a specific requirement in a type C standard. Moreover an enabling device has always to fulfil at least two different safety functions: a "safe stop function", if it is released and "protection of unexpected movement", if the enabling device is not used.

Trying to summarise the main requirements for a methodology for SF requirement of a general type C standard, at least the following tasks have to be taken into consideration:

- identical SF in different zones of the machine (for example work zone, maintenance zone, tool magazine, tool changer) may lead to different required performance level depending on the individual risk estimations,
- identical SF used in different modes of operation may have different required performance level depending on the individual risk estimations. For example some "other protective measure" as partial guards or safe operator position may affect the risk estimation for the SF (se parameter P),
- detailed explanation of the risk reduction of a safety function and according additional normative requirements.
- remarks for details of SF which are not requirements, but can help the designer in defining a safe machine control system,
- classification with the parameter S, F, P, as explained above and with plausible description of why it was been chosen,
- additional explanations needed as stated in paragraph 1.1 of this paper. All those factors may affect the PL_r from a theoretical formulation to a realistic one as already explained.

It is also very important to give a clear definition of the main quantities to be used, especially when different definitions can be used. For example the definition of *short* and *long presence* differs from one standard to another, so a clear definition of what is a short stay and what is long stay is very important for exposure parameter (see paragraph 1.2.2).

The resulting concise table method comprises two different tables:

- ***SF_table 1***: list of SF with numbering, designation and cross reference to the occurrence probability of hazards that can be found later in the SF_Table 2 (see Table 5 below),
- ***SF_table 2***: table method for the concise risk estimation of every SF, see Table A.2, appendix A for the full table example.

Table 5. Example of SF_table1, numbering, designation and cross reference.

No. of SF	Designation	Cross-reference to SF_table 1
SF 01	Safety-related stop function	1.5, 1.9, 4.1, 5.3, 9.1, 10.1, …
SF 02	Manual reset function	
SF 03	Start/restart function	15.4, 20.4
SF 04	Local control function	1.7, 15.5

These two tables will be proposed as normative (mandatory) for the new type C standards of milling machines ISO 16090-1.

Going back to *example 1* of paragraph 2.3 the entire concise risk estimation in tabular method is presented in Table A.2 of appendix A.

The selected safety function is very similar to the safety function "prevention of unexpected start-up of a movement of a linear or rotational axis with an incorrectly clamped workpiece" of the standard prEN ISO 16090-1. This safety function was chosen in another paper of Mödden & Günnel for ESREL 2014. The analysis of field data of real milling machines shows that a reliability between PL = a and PL = b is actually being achieved with state of the art design.

3.1 *Typical demand rates of safety functions*

To perform the necessary $MTTF_d$ calculation and subsequent PL quantification according to ISO 13849-1, it is very important to give to the machine builder the *typical demand rates* of SF. This additional table will be informative, because different demand rates are possible for different machine types.

The demand rates are divided into groups of machine depending from the category defined in the standard. For the milling machine standard, it will define 4 different groups of machines: from the simple group 1 (manual machines) to the group 4 (complex transfer and special purpose machines). See Appendix A for the full table example of demand rates.

4 CONCLUSIONS

In this part 2 of the paper, the problems arising during the real design of SRP/CS using exclusively ISO 13849-1 are addressed. Using an ISO 13849-1/IEC 62061 "partial merging" approach based on the PFH_d, which is a common mathematical basis in both standards, proper risk reduction requirements for the SRP/CS or SF can be found both in terms of PL or SIL.

A novel "table based" methodology for concise risk estimation utilizable in type C standards is presented. The selected safety function is very similar to the safety function "prevention of unexpected start-up of a movement of a linear or rotational axis with an incorrectly clamped workpiece" of the standard ISO 16090-1. This safety function was chosen in another paper of Mödden & Günnel for ESREL 2014. The analysis of field data of real milling machines shows that a reliability between PL = a and PL = b is actually being achieved with state of the art design. This finding connects quite well theory and practice of state of the art milling machines.

Those two contributions are extracted from the work during the ISO/TC 39/SC 10/WG4 meetings (ISO/CD 16090-1 for milling machines).

Research on reliability qualification test design by considering inheritance factor

Yanlei Wang, Dinghai Xu & Longbo Liu
Naval Academy of Armament, Beijing, China

ABSTRACT: During the different development stages of the product, the approach that can design reliability qualification test plan scientifically, shorten testing time, improve test efficiency is needed. In order to use the test data from similar products in different development stages, the mixed Gamma distribution is used as prior distribution by considering product inheritance factor and correlation of testing data. After that a new reliability qualification test design method based on the Bayesian theory is established. Finally, the correctness and effectiveness of the proposed method is proved through examples.

1 INTRODUCTION

A large number of reliability tests must be carried out during the product development processes. But in different stages of development, the products are in different technology status. Generally speaking, the development process of product needs to go through virtual prototype, initial prototype and the formal prototype stages. Although the prototype states in different development stages are various, there has some continuity of inheritance. Therefore, the test data from the same kind of reliability test also has inheritance in different development stage. If the test information in different development stages can be combined properly (Wilson et al. 2006, Colombo 1990), the problems of the traditional reliability qualification test: the testing time is too long, lack of test samples and so on can be solved effectively.

Due to the test data in different development stages are not unified and from different populations, so it is difficult to solve the problem by only using the classical method based on large sample size (Ming 2009). While the Bayesian method (Huang et al. 2006, Gholizadeh et al. 2012) can make full use of priori information to make up the fact that the field test data is deficient, then the amount of field test can be effectively reduced in the premise of not reducing the degree of confidence.

In this paper, the inheritance factor is introduced to the development process of the product. This is better than the traditional Bayesian method to highlight the continuity of product technical states in different stages of development process, and also makes better use of reliability test data in different stages. Mixed Gamma prior distribution can be adopted to characterize differences of the product in different stages by using state inheritance factor. According to previous test data and the levels of risk of the producer and the user, the reliability qualification test program can be developed. The test program can not only make full use of the test information in each test phase, but also reasonably utilize different information from the whole development process and improvement process, and the guide line of the new method is presented for the reliability qualification test design.

2 MIXED PRIOR AND POSTERIOR DISTRIBUTION

Based on Bayesian method, it can significantly reduce the test sample size and shorten test time to make the product reliability qualification test plan by utilizing the priori information. How to use the priori information effectively and establish the prior distribution model is the key point to develop the Bayesian evaluation test programme.

2.1 *Determination of gamma prior distribution and posterior distribution*

The life of product is assumed to follow exponential distribution. The likelihood function of failure rate λ under fixed time censoring with replacement is given by

$$L(\lambda) = \frac{(T\lambda)^z}{z!}\exp(-\lambda T) \tag{1}$$

where T is the total test time, z is the number of failures.

For exponential distribution, the prior distribution of the failure rate λ is usually characterized by its conjugate distribution, Gamma distribution (Zhang & Jiang 2000, Wang 1993) whose probability density function is,

$$\pi(\lambda|a,b) = \frac{b^a}{\Gamma(a)} \lambda^{a-1} \exp(-b\lambda) \tag{2}$$

where, $\lambda > 0$, $a > 0$, $b > 0$, a and b is prior distribution parameters, it can be determined by the priori information (Coit & Jin 2000).

There are several kinds of methods to determine prior distribution parameters. The method using different quantiles of prior distribution proposed by Wang (1993) is adopted in this study. For different confidence levels, γ_1, γ_2, assuming the optimal precision confidence lower limit λ_1 and λ_2 of random failure rate of can be determined based on priori information of early prototypes. The quantiles of failure rate λ in the posterior distribution are λ_1 and λ_2, and the corresponding confidence levels are,

$$\begin{cases} \int_0^{\lambda_1} \pi(\lambda|a,b)\mathrm{d}\lambda = \gamma_1 \\ \int_0^{\lambda_2} \pi(\lambda|a,b)\mathrm{d}\lambda = \gamma_2 \end{cases} \tag{3}$$

From Equation (3), the parameters a and b can be solved based on the prior distribution.

According to Equation (1) and (2), the posterior distribution of the failure rate λ can be obtained based on Bayesian theorem,

$$\pi(\lambda|D) = \frac{(b+T)^{(a+z)}}{\Gamma(a+z)} \lambda^{a+z-1} e^{-\lambda(b+T)} \tag{4}$$

The upper confidence limit of failure rate, λ_U is given by

$$\int_0^{\lambda_U} \pi(\lambda|D)\mathrm{d}\lambda = \gamma \tag{5}$$

The lower confidence limit of reliability is given by

$$R_L = \exp(-\lambda_U T_0) \tag{6}$$

2.2 *The Gamma prior distribution with a mixed inheritance factor*

During the development process, the product would undergo testing, improvement and retesting. The product reliability is increasing in this process. Although conjugate distribution has strong adaptability and simple calculation, but it only considered the similarity and inheritance, and ignored the improvement and innovative uncertainty of the product. Hence, by combing the prior distribution with the test information before the initial prototype, it is necessary to introduce inheritance factor, namely the mixed Gamma distribution as advanced prior distribution. This is more reasonable, and the probability density function is expressed as follows,

$$\pi(\lambda|a,b) = \rho \frac{b^a}{\Gamma(a)} \lambda^{a-1} \exp(-b\lambda) + (1-\rho) \tag{7}$$

Assuming that the test data is D, based on the Bayesian formula, the posterior distribution can be obtained as

$$\begin{aligned} \Pi(\lambda \mid D) &= \frac{\pi(\lambda|a,b) \cdot L(\lambda)}{\int_0^{\infty} \pi(\lambda|a,b) L(\lambda)\mathrm{d}\lambda} \\ &= \frac{(1-\rho)\lambda^z e^{-\lambda T}\Gamma(a) + \rho b^a \lambda^{a+z-1} e^{-\lambda(b+T)}}{\dfrac{(1-\rho)\Gamma(z+1)\Gamma(a)}{T^{(z+1)}} + \dfrac{\rho b^a \Gamma(a+z)}{(b+T)^{(a+z)}}} \end{aligned} \tag{8}$$

where a and b are prior distribution parameters, determined in subsection 2.1; $0 \le \rho \le 1$ is called inheritance factor, reflecting the similarity between the initial prototype and the formal prototype in reliability point of view, describing degree of similarity and inheritance in function and structure of the product. Then $1 - \rho$ is the update factor, reflecting reliability uncertainty during improvement from the old product to the new one. When $\rho = 1$, the two populations are the same, mixed prior Gamma distribution is a generalized conjugate Gamma distribution. When $\rho = 0$, the two populations are completely different, there is no information useful for the prior distribution under the Bayesian assumption. Therefore, mixed Gamma prior distribution is based on prior information and prior distribution. Mixed distribution is used to describe the product reliability and uncertainty, and fully embodies the dialectical relationship of inheritance and development.

The parameter ρ reflects the degree of new product inherited from the original one. If the formal prototype compared to the initial one has made lots of changes, ρ is small, and conversely the value is large. Therefore, determining the value of ρ needs to consider the specific product in different development stages, it can give by experts based on the degree of the product's changes.

The upper confidence limit of failure rate, λ_U is

$$\int_0^{\lambda'_U} \Pi(\lambda|D)\mathrm{d}\lambda = \gamma \tag{9}$$

The lower confidence limit of reliability, R_L is,

$$R_L = \exp(-\lambda'_U T_0) \tag{10}$$

2.3 *Inheritance factor calculation*

In order to determine the degree of similarity between two products quantitatively, taking full account of the number of similar elements on the basis of similarity analysis should be carried out. First, define the number of similar elements between two systems is ρ_n; second, the similarity determined by each element is ρ_u; finally, the system similarity calculation formula is given by (Zhou 2004),

$$\rho_n = \frac{N}{K + L - N} \tag{11}$$

$$\rho_u = \sum_{i=1}^{N} \beta_i q(u_i) \tag{12}$$

$$\rho = \rho_n \bullet \rho_u = \frac{N}{K + L - N} \sum_{i=1}^{N} \beta_i q(u_i) \tag{13}$$

where, K, L, N stand for the numbers of elements for product A, B and their similar sections in one level respectively. $q(u_i)$ indicates the value of the similarity unit built by the similar feature in common of the similar products. And β_i is the weight coefficient of the similarity unit considered in $q(u_i)$. Equation (13) shows the similarity degree of two products accurately. From Equation (11)–(13), we can figure out that the similarity degree of the products is the quantized value acquired by comparing all information of two products actually.

In reliability engineering, while studying the similarity of different products, the differences between structure, function, design principle, working principle, material composition and working environment are mainly considered. Thus, in order to determining the similarity degree between the modified product and the original one, we only need to consider the six factors: structure, function, design principle, working principle, material composition and working environment of the product. Since new product is modified based on old one, the six factors considered usually refer to the similar elements, then we can consider as $K = L = N = 6$, that is $\rho_n = 1$. Thus, detailed values of weight coefficient and the inheritance factor of similar units could be determined by engineering information and expert experiences. This method directly uses the test data and has reduced the subjectivity. The format of the test data is time and number of failures.

3 RELIABILITY QUALIFICATION TEST PLAN BASED ON MIXED GAMMA DISTRIBUTION

On the base of posterior distribution from Equation (8), a reliability qualification test method can be developed. The basic idea is: first, use the formulae of both sides risk based on the posterior distribution to establish equations; second, solve the equations and obtain the qualification test plan (T, c), which must satisfy the producer's risk α_0, user's risk β_0 and distinguishing ratio D. For c must be an integer, the equations are always be solved by trial and error method (He & Dai 1995), but frequently the result is not objective.

By introducing optimization method, the solution procedure of the reliability qualification test plan would be divided into two sections, one section is to solve the equations with continuous variable; the second section is to obtain the final test plan by optimization process. Finally, an objective and steady plan can be obtained.

3.1 *Establishment of preliminary qualification test plan*

The concept of risk of the Bayesian theory based reliability qualification test plan is different from that of the classical qualification test plan. According to the posterior distribution, the producer's risk and user's risk are called posterior risk. (Ming 2009, Jiang & Zhang 2000, Chen et al. 2002). The reliability qualification test plan based on posterior risk often makes the user bear too much risk.

Suppose that the specified value and maximum acceptable value of the failure rate are λ_0 and λ_1, respectively. The test result of the fixed time censoring test is (T, z), and the following inequations will hold,

$$P(\lambda > \lambda_1 \mid z = x) > P(\lambda > \lambda_1 \mid z = x - 1) \tag{14}$$

$$P(\lambda < \lambda_0 \mid z = x) < P(\lambda < \lambda_0 \mid z = x - 1) \tag{15}$$

with

$$\begin{cases} P(\lambda > \lambda_1 \mid z = x) = \int_{\lambda_1}^{\infty} \Pi(\lambda \mid D, z = x) \mathrm{d}\lambda \\ P(\lambda < \lambda_0 \mid z = x) = \int_{0}^{\lambda_0} \Pi(\lambda \mid D, z = x) \mathrm{d}\lambda \end{cases} \tag{16}$$

Equation (14) and (15) are obviously in physical meaning: Equation (14) indicates the fact that for the same test time T, when the number of failure is z, the failure rate is greater than that when the number of failure is z–1. The physical meaning of Equation (15) is similar to Equation (14).

Let A_c denotes the maximum permitted failure number from the test samples for declaring the fact the product can pass the reliability qualification test; and R_e denotes the minimum number for refusing the fact that the reliability of the product can pass the test. Assuming the test plan is (T, c), then the maximum user's risk in the qualification test (the probability of which the product's real failure rate is larger than the maximum acceptable value but the product has passed the qualification test) is,

$$\max_{z\le c} P(\lambda > \lambda_1 \mid A_c) = P(\lambda > \lambda_1 \mid z = c) \tag{17}$$

The maximum producer's risk in the test (the probability of which the product's real failure rate is smaller than the specified value but the product has failed to pass the qualification test) is,

$$\max_{z\ge c} P(\lambda < \lambda_0 \mid R_e) = P(\lambda < \lambda_0 \mid z = c) \tag{18}$$

It should be noticed in Equation (18) that the range of rejection is $z \ge c$, not $z \ge c+1$. That's because when solving the test plan, T and c were assumed as continuous variables.

Plan (T,c) should satisfy

$$\begin{cases} P(\lambda < \lambda_0 \mid z = c) = \alpha \\ P(\lambda < \lambda_1 \mid z = c) = 1-\beta \end{cases} \tag{19}$$

By solving Equation (19), we can get a preliminary test plan (T', c') which satisfy the requirement of producer's risk α, user's risk β and the distinguishing ratio D.

3.2 *Establishing final test plan by optimization method*

For engineering practice, c must be an integer, researchers used to solve Equation (19) by tentative numerical method. But for different test plans, the prior information and inheritance factors are diverse, so it is not convenient to solve all of them by the tentative numerical method. Furthermore, the tentative numerical method will introduce too many subjective factors; and its repeatability is not good. Thus, the tentative numerical method cannot confirm that the derived results is the optimal one.

In subsection 3.1, we assume that c' is the judging failure number of preliminary test plan. Now we define that c denotes the judging failure number of the final test plan after rounded off. Let T be the decision variable, then set up optimization model as follows,

$$\begin{aligned} &\min \quad (\alpha-\alpha_0)^2 + (\beta-\beta_0)^2 \\ &\text{s.t} \\ &\begin{cases} \alpha = P(\lambda < \lambda_0 \mid z = c) \\ \beta = 1 - P(\lambda < \lambda_1 \mid z = c) \\ T > 0 \end{cases} \end{aligned} \tag{20}$$

The optimization objective function is the sum of the square of the risk values of the producer and the user. According to the solution of the proposed optimization model, parameter T can be obtained, thus final qualification test plan (T,c) can be obtained. For c must be an integer, after rounded off, the actual risk values α' and β' will deviate from the initial values slightly.

4 EXAMPLE

In this example, the development cycle of the product is assumed to be one year, and contains development processes of principle prototype A, B, early prototype A, B, and final prototype A, B. The reliability qualification test data in different stages are listed in Table 1.

According to engineering information and the experts' evaluated conclusion, the similarity degrees between product A and product B in the aspects of structure, function, design principle, working principle and material composition are 80%, 85%, 80%, 85% and 90%, respectively. As their work environment is different, we can set the similarity is 75% based on previous experience. According to Equation (13),

$$\rho = \rho_n \bullet \rho_u = \frac{N}{K+L-N}\sum_{i=1}^{N}\beta_i q(u_i) = 0.825 \tag{21}$$

In the same way, the inheritance factor of early prototype is 0.875.

Substitute test data of all process into Equations (3), (7) and (8) to obtain prior hyper-parameters $a = 0.4045$, $b = 1974.5$, then combine all the information above to derive inheritance factor. By calculating Equations (9) and (10), we can get the conclusion that the reliability of the product do not satisfy the requirement; it is needed to continue the reliability qualification test.

Normally, user's risk should not be higher than 0.2 in product qualification test.

By calculation of prior information of the principle prototype and the early prototype, when the confidence level of product failure rate is 0.8 and 0.9, the optimal confidence limit randomization is 1.246 and 1.536. That means the hyper-parameters can be obtained. After determining inheritance factor, test plan can be obtained by solution of Equations (19) and (20). In the case of that the failure number is 0, the total test time T is 0.6175 times of MTBF, in the case of that the failure number is 1, the total test time T is 1.932 times of MTBF.

Table 1. Reliability qualification test data of prototype A and prototype B in different stages.

Test stage	Accumulated time (h)	Failure number
Principle prototype A	2680	0
Principle prototype B	2400	1
Early prototype A	1600	1
Early prototype B	4248	0
Final prototype A	1840	0
Final prototype B	1720	0

5 CONCLUSIONS

The reliability qualification test plan established based on the proposed method both agrees well with classical qualification test plan based on large sample size, which makes it easy to be accepted in practical engineering; also it reflects the inheritance and development of the dialectical relations. Theoretically, it is more reasonable than traditional Bayesian plan of the reliability qualification test. An optimization model is purposely developed to solve the reliability qualification test plan. This model can make the test decision scientific and quantitative, and it has good robustness. Examples show that the proposed method can utilize test data fully and reasonably of all stages under the less sample condition. It can save test cost and time efficiently.

Optimal design on Accelerated Degradation Testing with Gamma process for reliability demonstration

C. Zhang, X. Lu, X. Chen & Y. Wang
Science and Technology on Integrated Logistics Support Laboratory, National University of Defense Technology, Changsha, Hunan, P.R. China

ABSTRACT: For products with high reliability and long lifetime, Accelerated Degradation Testing (ADT) may be adopted during product development phase to verify whether its reliability satisfies the predetermined level within feasible test duration. The optimal design of accelerated degradation testing for efficient reliability demonstration becomes a research focus to increase demonstration accuracy and to reduce test cost. The actual degradation from engineering is usually a strict monotonic process, such as fatigue crack growth, wear, and erosion. However, the method for reliability demonstration by ADT with monotonic degradation process hasn't been investigated so far. This paper proposes an optimal reliability demonstration method by ADT for this kind of products. We first apply Gamma process to describe the monotonic degradation. Next, we convert the required reliability into allowable cumulative degradation in ADT, and demonstrate the reliability by comparing the actual accumulative degradation with the allowable level. Further, we suggest an optimal ADT design for efficient reliability demonstration by minimizing the asymptotic variance of decision variable under the constraints of sample size, test duration, and test cost. The method is validated and illustrated with example on reliability demonstration of alloy product in the end.

1 INTRODUCTION

Reliability demonstration test is commonly adopted in product development phase to validate whether its reliability meets the specified requirement. Accelerated Life Test (ALT) could reduce test duration and has been applied in reliability demonstration for highly reliable products with long lifetime (Bris 2000, Krasich 2003).

For engineering circumstances, the reliability of highly reliable product is usually dominated by its performance degradation. Accelerated Degradation Test (ADT) is consequently promoted as feasible solution to reliability demonstration of this kind of products, for it reduces test duration further by comparison with ALT. Yang (Yang 2009) presented a reliability demonstration method based on degradation test under normal stress level using linear degradation model, and Huang (Huang 2012) proposed an optimal ADT plan for reliability demonstration based on linear degradation model.

Compared with linear degradation model, stochastic process model can reasonably identify the random variation in degradation process. Baussaron (Baussaron 2011) proposed a reliability demonstration method based on ADT using Wiener process model. Generally speaking, the performance degradation of product is usually a monotonic process, such as fatigue crack growth, wear, and erosion. Gamma process model is a strict monotonic process model, and it is more reasonable for these occasions than Wiener process model (Park 2005). Unfortunately, few literatures can be identified to deal with reliability demonstration by ADT using Gamma process model.

This paper proposes a reliability demonstration method by ADT for products with Gamma process. The rest of this paper is organized as follows. Section 2 gives a motivating example. Section 3 delivers the models for the problem. Section 4 suggests a reliability demonstration method by judging the cumulative degradation in ADT. Section 5 presents an optimal ADT plan for efficient reliability demonstration. Section 6 offers the results that apply the proposed method to the motivating example. Section 7 concludes the paper.

2 MOTIVATING EXAMPLE

The metal component subject to cyclic load could rupture when the length of fatigue crack reaches the threshold, which accounts for a majority of failure for metal component. Meeker and Escobar (Meeker 1998) described such a problem. Fatigue crack development process of a kind of alloy product is a strict monotonic process as shown

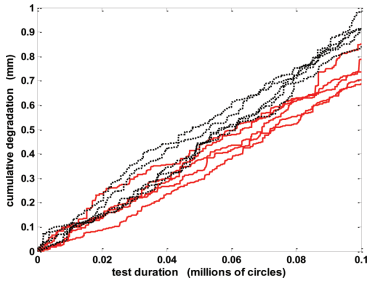

Figure 1. Typical fatigue crack development process of an alloy product from CSADT. (The red lines denote the degradation of 5 products under an elevated stress level, and the black lines denote a higher stress level.).

in Fig. 1, and should be described properly by Gamma process.

Suppose that the reliability of the alloy product required by consumer is $R_\beta = 0.9016$ with risk $\beta = 0.10$ at $t_0 = 0.1286$ millions of circles, and that the acceptable reliability for producer is required to be $R_\alpha = 0.9832$ with risk $\alpha = 0.30$ at the same time. If such a high reliability with long service duration is demonstrated by traditional fatigue life test, it will be unfeasible for the too lengthy test duration. So the reliability demonstration method by ADT for such kind of products with Gamma process should be investigated.

For this problem, there exist some issues worthy of further consideration.

1. If ADT is employed, how can we judge whether the reliability satisfies the requirement according to the degradation data acquired in ADT?
2. Can we possibly optimize the test plan for efficient reliability demonstration, which means better demonstration confidence with the constraints on sample size, test duration, and test cost?

3 MODELS

3.1 *Degradation model*

Let $\{X(t), t \geq 0\}$ represent Gamma process with shape parameter v and scale parameter u, $X(t) \sim Ga(vt, u)$, and its basic properties are as follows.

1. $P\{X(0) = 0\} = 1$.
2. $E(X(t)) = uvt$, $Var(X(t)) = u^2 vt$.
3. $X(t_j) - X(t_i)$ is s-independent from $X(t_k) - X(t_j)$ for $0 < t_i < t_j < t_k$.
4. $\Delta X(t) = X(t + \Delta t) - X(t)$, $\Delta X(t) \sim Ga(v\Delta t, u)$, $\Delta t > 0$, and its probability density function is defined as

$$f(\Delta x) = \frac{1}{\Gamma(v\Delta t)u^{v\Delta t}} \Delta x^{v\Delta t - 1} e^{-\frac{\Delta x}{u}}, \Delta x > 0 \qquad (1)$$

where, $\Gamma(v) = \int_0^\infty x^{v-1} e^{-x} dx$.

Gamma process is a strictly monotonic process with s-independent and non-negative increments. Suppose a failure occurs when the degradation reaches the specified threshold ω, then failure time T can be defined as the time when the degradation path cross ω, and the reliability at t can be expressed as

$$R(t) = P(T > t) = P(X(t) < \omega) = Ga(\omega \mid vt, u) \qquad (2)$$

The probability density function of T at t could be obtained from (2), but the formulation is too complex to be used in practice. Fortunately, the cumulative distribution of T could approximate to Birnbaum-Saunders distribution (Bris 2000, Padgett 2004).

$$F(t) = P(T < t) = P(X(t) > \omega) = \Phi(\sqrt{vt} - \sqrt{\frac{\omega^2}{u^2 vt}}) \qquad (3)$$

where, $\Phi(\bullet)$ is standard s-normal cumulative distribution function, u and ω are s-independent from stress levels. Refer to (3), the reliability for a given Gamma degradation process with u and ω is determined by vt.

3.2 *Acceleration model*

In an ADT for products with Gamma degradation process, the shape parameter v reflects the effect of stress level S_k on the performance. Acceleration model can be denoted as

$$\ln v_k = a + b\varphi(S_k) \qquad (4)$$

where, a and b are unknown coefficients of acceleration model, and $\varphi(S_k)$ is a known function of S_k. If $\varphi(S_k) = \ln S_k$, acceleration model is Inverse Power Law. If $\varphi(S_k) = 1/S_k$, it is Arrhenius equation.

The scale parameter u of Gamma degradation process reflects the random variation of the performance, and it is s-independent from stress levels.

4 RELIABILITY DEMONSTRATION BY ADT

Let R_β denote limit quality from consumer under use condition S_0 at time t_0 with corresponding consumer's risk β, and R_α denote acceptable quality

from producer under use condition S_0 at the same time with corresponding producer's risk α. Generally, $R_\beta < R_\alpha$.

4.1 *MLE for the models*

Suppose a constant stress ADT with N stress levels, n_k samples are tested under the stress level S_k, and the performance of the samples under S_k is measured as Δx_{kij} for m_k times with identical measuring interval Δt, $k = 1,2,...,N$, $i = 1,2,...,n_k$, $j = 1,2,...,m_k$.

According to (1), the likelihood function of such an ADT is

$$L(a,b,u) = \prod_{k=1}^{N}\prod_{i=1}^{n_k}\prod_{j=1}^{m_k}\left[\frac{1}{\Gamma(v_k\Delta t)u^{v_k\Delta t}}\Delta x_{kij}^{\,v_k\Delta t-1}e^{-\frac{\Delta x_{kij}}{u}}\right] \quad (5)$$

where, v_k can be expressed as (4).

Further, the log-likelihood function from (5) is

$$\ln L(a,b,u) = \sum_{k=1}^{N}\sum_{i=1}^{n_k}\sum_{j=1}^{m_k}[-\ln\Gamma(v_k\Delta t) - v_k\Delta t\ln u + (v_k\Delta t - 1)\ln\Delta x_{kij} - \frac{\Delta x_{kij}}{u}] \quad (6)$$

MLE of parameters $(\hat{a},\hat{b},\hat{u})$ can be solved from (6).

4.2 *Reliability demonstration method*

Similar to Cumulative Exposure Model (Nelson 1980), the remaining life of a degradation process also depends only on the current cumulative degradation and current stress regardless how the degradation accumulated. This is to say if the reliability of a degradation process at time t_0 under use condition S_0 is $R_0(t_0)$, and its reliability at time τ_k under elevated stress level S_k is $R_k(\tau_k)$, $R_0(t_0) = R_k(\tau_k)$, when and only when

$$E\left(X_0(t_0)\right) = E\left(X_k(\tau_k)\right) \quad (7)$$

where, $E\left(X_0(t_0)\right)$ is the performance degradation expectation at t_0 subject to use condition S_0, and $E\left(X_k(\tau_k)\right)$ is the performance degradation expectation at τ_k subject to elevated stress level S_k. From (7), we can obtain

$$\mu v_k\tau_k = \mu v_0 t_0 \quad (8)$$

$$\tau_k = \frac{v_0 t_0}{v_k} \quad (9)$$

where, $k = 1,2,...,N$.

From (3), we can denote the required reliability under the elevated stress level as

$$1 - \Phi(\sqrt{v_k\tau_k} - \sqrt{\frac{\omega^2}{u_\beta^{\,2}v_k\tau_k}}) = R_\beta \quad (10)$$

$$1 - \Phi(\sqrt{v_k\tau_k} - \sqrt{\frac{\omega^2}{u_\alpha^{\,2}v_k\tau_k}}) = R_\alpha \quad (11)$$

where, u_β and u_α are scale parameters corresponding to R_β and R_α respectively subject to S_k. Further,

$$u_\beta = \frac{\omega}{v_k\tau_k - \gamma_{1-R_\beta}\sqrt{v_k\tau_k}} \quad (12)$$

$$u_\alpha = \frac{\omega}{v_k\tau_k - \gamma_{1-R_\alpha}\sqrt{v_k\tau_k}} \quad (13)$$

where, γ_p is the 100 *pth* percentile from $\Phi(\bullet)$. we use (9), (12) and (13) to convert the required reliability $R_\beta(t_0)$ and $R_\alpha(t_0)$ under use condition S_0 into the equivalent reliability requirement $R_\beta(\tau_k)$ and $R_\alpha(\tau_k)$ under elevated stress level S_k.

After n_k products are tested under S_k, the cumulative degradation of n_k samples under S_k at time t_k

$$CD(t_k) = \sum_{i=1}^{n_k} X_i(t_k) \sim Ga(nv_k t_k, u) \quad (14)$$

where, $X_i(t_k)$ is the measured degradation under S_k, and $t_k = m_k\Delta t$. The observed reliability under S_k is exclusively determined by the cumulative degradation, so we can demonstrate the reliability by judging whether $CD(t_k)$ reaches the allowable level. In the rest of this section, we derive the allowable level.

Let Ac denote the allowable cumulative degradation level of n_k samples corresponding to the required reliability. If $CD(t_k) \le Ac$, the reliability will be accepted, otherwise the reliability will be rejected. So the customer's risk and the producer's risk associated with the demonstration above are as follows.

$$\beta = Ga(Ac \mid nv_k t_k, u_\beta) \quad (15)$$

$$\alpha = 1 - Ga(Ac \mid nv_k t_k, u_\alpha) \quad (16)$$

According to (3),

$$\beta = 1 - \Phi(\sqrt{n_k v_k t_k} - \sqrt{\frac{Ac^2}{u_\beta^2 n_k v_k t_k}}) \quad (17)$$

$$\alpha = \Phi(\sqrt{n_k v_k t_k} - \sqrt{\frac{Ac^2}{u_\alpha^2 n_k v_k t_k}}) \tag{18}$$

So Ac can be expressed as

$$Ac = \mu_\beta(n_k v_k t_k - \gamma_{1-\beta}\sqrt{n_k v_k t_k}) \tag{19}$$

or,

$$Ac = \mu_\alpha(n_k v_k t_k - \gamma_\alpha \sqrt{n_k v_k t_k}) \tag{20}$$

where, γ_p denotes the $100pth$ percentile from $\Phi(\bullet)$.

5 OPTIMAL ADT PLAN FOR RELIABILITY DEMONSTRATION

Demonstrating reliability by ADT on sampled specimens from a lot causes the type I and type II risk. The actual risk varies with the test plan, and it consequently has an influence on the sample size, test duration and test cost demanded for the ADT. This section investigates the optimal ADT plan for efficient reliability demonstration.

5.1 *Objective function*

From the reliability demonstration procedure in section 4, we find that the value of Ac determines the type I and type II risks. The larger asymptotic variance of $\hat{A}c$ is, the greater deviation of actual risks will be. Thus, we set the asymptotic variance of $\hat{A}c$ as objective function.

$$\min \hat{AV}ar(\hat{Ac} \mid n_k, m_k, \Delta t) \tag{21}$$

The asymptotic variance of $\hat{Ac}$ can be expressed as

$$\hat{AVar}(\hat{Ac}) = \left[\left(\frac{\partial \hat{Ac}}{\partial \hat{a}}\right), \left(\frac{\partial \hat{Ac}}{\partial \hat{b}}\right), 0\right] F^{-1} \left[\left(\frac{\partial \hat{Ac}}{\partial \hat{a}}\right), \left(\frac{\partial \hat{Ac}}{\partial \hat{b}}\right), 0\right]' \tag{22}$$

where, F denotes the Fisher information matrix. The detailed expressions for calculating $\hat{AVar}(\hat{Ac})$ are listed in the Appendix.

5.2 *Constraints*

The constraints in reliability demonstration by ADT usually include (Park):

1. The test time t_k under S_k should not exceed the specified test duration t_{Mk}.
2. The sample size should not exceed the number of the test units available.
3. The risks should not exceed the pre-determined level.
4. The total test cost Tc should not exceed the budget C_b.

Further, the total cost of conducting a reliability demonstration by constant stress ADT is given by

$$Tc(n_k, m_k, \Delta t) = C_{op}\Delta t \sum_{k=1}^{N} m_k + C_{mea} \sum_{k=1}^{N} n_k m_k + C_{it} \sum_{k=1}^{N} n_k \tag{23}$$

where, C_{op} denotes the unit cost for each operation, C_{mea} denotes the unit cost for each measurement, C_{it} denotes the unit cost for each test unit.

According to the above analysis, the optimization problem can be formulated as

$$\min \hat{AV}ar(\hat{Ac} \mid n_k, m_k, \Delta t) \quad s.t. \begin{cases} Tc(n_k, m_k, \Delta t) \le C_b \\ m_k \Delta t \le t_{Mk} \\ \sum_{k=1}^{N} n_k \le n_M \\ \alpha = \alpha_1 \end{cases} \tag{24}$$

where, $n_k, m_k \in \{1,2,3,...\}$, $\Delta t > 0$, $t_{Mk} \le \tau_k$. We adopt (19) to obtain $\hat{Ac}$, so the objective function contains the constraint on consumer's risk β.

5.3 *Solving optimal test plan*

We suggest the following procedure to solve the optimal ADT plan.

Step 1. Conduct the preliminary test to acquire the prior degradation data of products, and calculate the prior estimation of (a,b,u) by MLE.

Step 2. Deduce the objective function and constraints using the prior estimator $(\hat{a},\hat{b},\hat{u})$, and search optimal solution $(n_k^*, m_k^*, \Delta t^*)$ with nonlinear optimization method.

(Due to the complex objective function, the closed expression does not exist for $(n_k^*, m_k^*, \Delta t^*)$, but the optimal solution can be solved by nonlinear optimization method.)

Step 3. Conduct the reliability demonstration test according to the optimal test plan, and demonstrate the reliability by cumulative degradation in ADT, usually together with the degradation in the preliminary test.

(After acquiring new degradation data, MLE of (a,b,u) and Ac are renewed, and the decision of acceptance or rejection can be made accordingly.)

6 SOLUTION TO MOTIVATING EXAMPLE

In this section, we illustrate the proposed method with the motivating example by MC simulation.

We suppose $C_{op}=0.6$, $C_{mea}=1.3$, $C_{it}=55$ (Laiao 2006), and $(a,b,u)=(6.4906,1.8,0.009297)$, $\omega=0.9$ inch.

6.1 *Preliminary test*

Let $S_0=1$ and the relationship between v_k and S_k be Inverse Power Law. A preliminary test is simulated with two elevated constant stress levels $S_1=1.15$ and $S_2=1.25$. The number of test unit and measurement for S_1 and S_2 are $n_1=5$, $m_1=900$, $n_2=5$, $m_2=900$ respectively. The measurement interval is $\Delta t=0.0001$ millions of circles.

According to the true value of (a,b,u), a set of simulated degradation for preliminary test is shown as Fig. 1. Refer to (6), MLE of the parameters is $(\hat{a},\hat{b},\hat{u})=(6.4982,1.7288,0.009451)$.

6.2 *Optimal test plan*

Given the constraints configuration (C_b,t_{M1},t_{M2},n_M), the optimal test plan can be derived by the method in section 5. Let $(C_b,t_{M1},t_{M2},n_M)=(3000,0.1010,0.0874,30)$, the process for solving the optimal test plan is shown as follows. In this example, the cumulative degradation under S_1 is selected as decision variable, so the optimization model should be

$$\min A\hat{V}ar(\hat{A}c\,|\,n_1,n_2,m_1,m_2,\Delta t)$$
$$s.t.\begin{cases}0.6(m_1+m_2)\Delta t+1.3(n_1m_1+n_2m_2)+55(n_1+n_2)\le 3000\\ m_1\Delta t\le 0.1010\\ m_2\Delta t\le 0.0874\\ n_1+n_2\le 30\\ \alpha=30\%\end{cases} \tag{25}$$

where,

$$Ac=\frac{\omega(d-\lambda_{0.9}\sqrt{d})}{0.1286e^{6.4982}-\lambda_{0.0984}\sqrt{0.1286e^{6.4982}}} \tag{26}$$

$$\alpha=\Phi\left(d-\frac{(d-\lambda_{0.9})(\sqrt{0.1286e^{6.4982}}-\lambda_{0.0984})}{\sqrt{0.1286e^{6.4982}-\lambda_{0.0168}}}\right) \tag{27}$$

$$d=n_1m_1\Delta t\exp(6.4982+1.7288\times\ln 1.15) \tag{28}$$

$$A\hat{V}ar(\hat{A}c)=\left(\frac{\partial\hat{A}c}{\partial\hat{a}}\right)^2\hat{V}ar(\hat{a})+\left(\frac{\partial\hat{A}c}{\partial\hat{b}}\right)^2\hat{V}ar(\hat{b})+2\left(\frac{\partial\hat{A}c}{\partial\hat{a}}\right)\left(\frac{\partial\hat{A}c}{\partial\hat{b}}\right)\hat{C}ov(\hat{a},\hat{b}) \tag{29}$$

Using the constrained nonlinear optimization method, the optimal test plan is

$$(\Delta t^*,n_1^*,n_2^*,m_1^*,m_2^*,Ac)=(0.0011,7,11,91,79,5.1903) \tag{30}$$

So the optimal test is to measure 7 and 11 units under S_1 and S_2 respectively, the corresponding measurement number are 91 and 79, and the measurement interval is 0.0011 millions of circles. If the actual cumulative degradation under S_1 $CD>5.1903$ inch during the test, the reliability will be rejected; otherwise the reliability will be accepted.

The optimal test plans with different budget C_b, test time constraint t_{Mk} and specimen constraint n_M are as shown in Table 1, 2 and 3 respectively, and some conclusions can be drawn by comparison as follows by comparison.

1. C_b, t_{Mk}, and n_M have definite influence on the optimal test plan. More test budget, longer test duration and more specimens will be beneficial to objective function, and will help us achieve better reliability demonstration confidence.

Table 1. Optimal test plans under different budget C_b.

C_b, t_{M1}, t_{M2}, n_M	Δt^*	n_1^*	n_2^*	m_1^*	m_2^*	Ac	$AVar(Ac)$
2000,0.1010,0.0874,30	0.0053	7	19	19	16	5.2223	0.0826
2500,0.1010,0.0874,30	0.0017	7	13	58	50	5.1104	0.0724
3000,0.1010,0.0874,30	0.0011	7	11	91	79	5.1903	0.0661

Table 2. Optimal test plans under different time constraint t_{Mk}.

C_b, t_{M1}, t_{M2}, n_M	Δt^*	n_1^*	n_2^*	m_1^*	m_2^*	Ac	$AVar(Ac)$
3000,**0.0202,0.0175**,30	-	-	-	-	-	-	-
3000,**0.0505,0.0437**,30	0.0014	14	16	36	31	5.2276	0.0862
3000,**0.1010,0.0874**,30	0.0011	7	11	91	79	5.1903	0.0661

The optimal test plan in the first row cannot be constructed for the too short test duration.

2. If C_b, t_{Mk}, and n_M are too small, the asymptotic variance will not converge, and the optimal test plan may not exist.
3. t_{Mk} has greater influence on asymptotic variance than C_b and n_M, so longer test duration as possible is recommended.

6.3 *Sensitivity analysis for optimal test plan*

The optimal test plan depends on the prior information about a, b, and u. Usually the prior information may deviate from the actual value. Next, we evaluate how the deviation affects the optimal test plan in terms of the relative error $RB(\hat{AVar}(\hat{Ac}))$.

Let ε_1, ε_2 and ε_3 denote the error for a, b and u respectively, and the prior estimator deviates ±10% from the true value. $\varepsilon_1 = \varepsilon_2 = \varepsilon_3 = \{-10\%, 0, 10\%\}$. The error of a, b, and u are combined to display the sensitivity of the optimal test plan under same C_b, t_{Mk}, and n_M configuration. The results are shown in Table 4. Some conclusions about sensitivity of the optimal test plan can be drawn.

1. The deviation of u has no obvious influence on optimal test plan.
2. The deviation of b has perceptible influence on optimal test plan, but the optimal test plan is reasonably robust against the deviation of b.
3. The deviation of a has major influence on optimal test plan. In order to get a reasonable optimal test plan, it is recommended that the prior estimation of a be paid more attention.

6.4 *Validation for optimal test plan*

Next, we investigate the validity of the optimal test plan of (30) by MC simulation. Set $(n_1^*, n_2^*) = (7,11)$, 1000 sets of degradation data were generated by MC simulation with different combinations of $(\Delta t, m_1, m_2)$, and the corresponding Mean Squared Error (MSE) of Ac is investigated.

$$\hat{MSE}(Ac) = \frac{1}{N_{MC}} \sum_{w=1}^{N_{MC}} (\hat{Ac}_w - Ac)^2 \tag{31}$$

where, N_{MC} is the number of MC simulations for each test plan, $\hat{Ac}_w$ is the estimated Ac in the wth simulation for the test plan, Ac is the true value of decision variable corresponding to the actual value.

The results are shown in Table 5. It shows that the proposed optimal test plan yields the smallest

Table 3. Optimal test plans under different specimen constraint n_M.

C_b, t_{M1}, t_{M2}, n_M	Δt^*	n_1^*	n_2^*	m_1^*	m_2^*	Ac	$AVar(Ac)$

7 CONCLUSIONS

This paper discussed the reliability demonstration by ADT for highly-reliable products with Gamma degradation process. We proposed a reliability demonstration method by judging the cumulative degradation in ADT with the allowable level, and also presented an optimal test plan design for reliability demonstration with ADT by minimizing asymptotic variance of decision variable to increase demonstration accuracy under the constraints on available test samples, test duration, and test cost. The method was illustrated by the motivating example.

8 APPENDIX

The expression of Fisher information matrix is

$$F=\begin{bmatrix} E\left(-\frac{\partial^2 \ln L}{\partial a^2}\right) & E\left(-\frac{\partial^2 \ln L}{\partial a\partial b}\right) & E\left(-\frac{\partial^2 \ln L}{\partial a\partial u}\right) \\ E\left(-\frac{\partial^2 \ln L}{\partial b\partial a}\right) & E\left(-\frac{\partial^2 \ln L}{\partial b^2}\right) & E\left(-\frac{\partial^2 \ln L}{\partial b\partial u}\right) \\ E\left(-\frac{\partial^2 \ln L}{\partial u\partial a}\right) & E\left(-\frac{\partial^2 \ln L}{\partial u\partial b}\right) & E\left(-\frac{\partial^2 \ln L}{\partial u^2}\right) \end{bmatrix}$$

where,

$$E\left(-\frac{\partial^2 \ln L}{\partial a^2}\right)=\sum_{k=1}^{N}\sum_{i=1}^{n_k}\sum_{j=1}^{m_k}\psi_1(v_k\Delta t)(v_k\Delta t)^2 =\sum_{k=1}^{N}\psi_1(v_k\Delta t)(v_k\Delta t)^2 n_k m_k$$

$$E\left(-\frac{\partial^2 \ln L}{\partial a\partial b}\right)=E\left(-\frac{\partial^2 \ln L}{\partial b\partial a}\right)=\sum_{k=1}^{N}\sum_{i=1}^{n_k}\sum_{j=1}^{m_k}\psi_1(v_k\Delta t)(v_k\Delta t)^2\varphi(S_k) =\sum_{k=1}^{N}\psi_1(v_k\Delta t)(v_k\Delta t)^2 n_k m_k\varphi(S_k)$$

$$E\left(-\frac{\partial^2 \ln L}{\partial a\partial u}\right)=E\left(-\frac{\partial^2 \ln L}{\partial u\partial a}\right)=\sum_{k=1}^{N}\sum_{i=1}^{n_k}\sum_{j=1}^{m_k}\frac{v_k\Delta t}{u}=\frac{\Delta t}{u}\sum_{k=1}^{N}v_k n_k m_k$$

$$E\left(-\frac{\partial^2 \ln L}{\partial b^2}\right)=\sum_{k=1}^{N}\sum_{i=1}^{n_k}\sum_{j=1}^{m_k}\psi_1(v_k\Delta t)(v_k\Delta t)^2\varphi^2(S_k) =\sum_{k=1}^{N}\psi_1(v_k\Delta t)(v_k\Delta t)^2 n_k m_k\varphi^2(S_k)$$

$$E\left(-\frac{\partial^2 \ln L}{\partial b\partial u}\right)=E\left(-\frac{\partial^2 \ln L}{\partial u\partial b}\right)=\sum_{k=1}^{N}\sum_{i=1}^{n_k}\sum_{j=1}^{m_k}\frac{v_k\Delta t\varphi(S_k)}{u} =\frac{\Delta t}{u}\sum_{k=1}^{N}v_k n_k m_k\varphi(S_k)$$

$$E\left(-\frac{\partial^2 \ln L}{\partial u^2}\right)=\sum_{k=1}^{N}\sum_{i=1}^{n_k}\sum_{j=1}^{m_k}\frac{v_k\Delta t}{u^2}=\frac{\Delta t}{u^2}\sum_{k=1}^{N}v_k n_k m_k$$

and,

$\psi_1(z)=\dfrac{d\ln^2\Gamma(z)}{dz^2}$ is trigamma function.

The expression of asymptotic variance-covariance matrix is

$$V=F^{-1}=\begin{bmatrix} Var(a) & Cov(a,b) & Cov(a,u) \\ Cov(b,a) & Var(b) & Cov(b,u) \\ Cov(u,a) & Cov(u,b) & Var(u) \end{bmatrix}$$

By δ method, the asymptotic variance of $\hat{A}c$ can be calculated by using the following formulation

$$A\hat{V}ar(\hat{A}c)=\left[\left(\frac{\partial\hat{A}c}{\partial\hat{a}}\right),\left(\frac{\partial\hat{A}c}{\partial\hat{b}}\right),0\right]F^{-1}\left[\left(\frac{\partial\hat{A}c}{\partial\hat{a}}\right),\left(\frac{\partial\hat{A}c}{\partial\hat{b}}\right),0\right]'$$

where,

$$\frac{\partial\hat{A}c}{\partial\hat{a}}=\frac{\omega(2n_k e^{\hat{a}+\hat{b}\varphi(S_k)}t_k-\gamma_{1-\beta}\sqrt{n_k t_k e^{\hat{a}+\hat{b}\varphi(S_k)}})}{2(e^{\hat{a}+\hat{b}\varphi(S_0)}t_0-\gamma_{1-R_\beta}\sqrt{e^{\hat{a}+\hat{b}\varphi(S_0)}t_0})}- \frac{\omega(n_k e^{\hat{a}+\hat{b}\varphi(S_k)}t_k-\gamma_{1-\beta}\sqrt{n_k e^{\hat{a}+\hat{b}\varphi(S_k)}t_k})(2e^{\hat{a}+\hat{b}\varphi(S_0)}t_0-\gamma_{1-R_\beta}\sqrt{e^{\hat{a}+\hat{b}\varphi(S_0)}t_0})}{2(e^{\hat{a}+\hat{b}\varphi(S_0)}t_0-\gamma_{1-R_\beta}\sqrt{e^{\hat{a}+\hat{b}\varphi(S_0)}t_0})^2} =\frac{\omega\sqrt{n_k t_k e^{2\hat{a}+\hat{b}\varphi(S_0)+\hat{b}\varphi(S_k)}t_0}(\gamma_{1-\beta}\sqrt{e^{\hat{a}+\hat{b}\varphi(S_0)}t_0}-\gamma_{1-R_\beta}\sqrt{n_k t_k e^{\hat{a}+\hat{b}\varphi(S_k)}})}{2(e^{\hat{a}+\hat{b}\varphi(S_0)}t_0-\gamma_{1-R_\beta}\sqrt{e^{\hat{a}+\hat{b}\varphi(S_0)}t_0})^2}$$

$$\frac{\partial\hat{A}c}{\partial\hat{b}}=\frac{\omega(2n_k e^{\hat{a}+\hat{b}\varphi(S_k)}t_k\varphi(S_k)-\gamma_{1-\beta}\varphi(S_k)\sqrt{n_k t_k e^{\hat{a}+\hat{b}\varphi(S_k)}})}{2(e^{\hat{a}+\hat{b}\varphi(S_0)}t_0-\gamma_{1-R_\beta}\sqrt{e^{\hat{a}+\hat{b}\varphi(S_0)}t_0})}- \frac{\omega(n_k e^{\hat{a}+\hat{b}\varphi(S_k)}t_k-\gamma_{1-\beta}\sqrt{n_k e^{\hat{a}+\hat{b}\varphi(S_k)}t_k})}{2(e^{\hat{a}+\hat{b}\varphi(S_0)}t_0-\sqrt{e^{\hat{a}+\hat{b}\varphi(S_0)}t_0}\gamma_{1-R_\beta})^2} \cdot(2e^{\hat{a}+\hat{b}\varphi(S_0)}t_0\varphi(S_0)-\sqrt{e^{\hat{a}+\hat{b}\varphi(S_0)}t_0}\varphi(S_0)\gamma_{1-R_\beta})$$

One producer, two brands: A comparison of car operating conditions

M. Jadwinska, T. Siekierka & M. Zając
Wroclaw University of Technology, Poland

ABSTRACT: Currently, car companies are the owners of several brands. It is associated with the marketing policy of companies (Min Han 1990). Some brands under one company to be sporty, other family or luxury—in line with the image of the brand. Regardless of the image—sharing cars within a group often use the same components. As a result, companies can save time on designing cars, and money—thanks to the production of the same item for several brands. Since the current vehicles of different brands are built from the same components leaving the factory, they should have a similar operational and reliability parameters. The aim of the article is to compare the number of vehicles manufactured by the same company: one of them is the average vehicle, while the other should be in your group to premium. Paper presents the results of their observations and analysis of the results.

1 INTRODUCTION

Today, maintaining the brand is basically the same as customer retention, and is to provide more and better products for a good price (Raff 1991). The market is global and ruled by globalized consumer, whose needs are diverse. In addition, the modern consumer freed almost entirely from unnecessary sentiments of loyalty anachronistic and actively looking for information about the products and the opportunity to buy them as cheaply as possible. The same applies to cars. Created divisions have their foundation in the techniques associated with marketing. For example, in the area of family vehicles distinguishes the following classes (Vinson & Scott & Lawrence 1977): safe family car, the car for a family with a child, a comfortable family car, roomy family car, family car trouble-free, economical family car, family car environmentally friendly, best family car, etc.

Regardless of the distribution of representatives of each class can have many features in common, not limited only to the functional features. They are simply made from the same components, elements, systems, for example, may be driven by the same engine. There are some engines passing into legend, and installed in many vehicles. There is no more popular diesel engines than 1.9 TDI Volkswagen Group produced and constantly modernized in the years 1991–2011. He has performed in over 40 different versions with different inter alia, torque, power, injection system, the assembly. He was installed in many cars of Volkswagen Group: from Skoda Fabia and VW Polo to Sharan and Ford Galaxy. Production finished with the introduction of EURO 5 standard, which was not able to fulfill, even by useing DPF.

Lowering the cost of production means that car companies use the same elements or components in different models. Since it uses the same elements and can therefore be concluded that cars today are characterized by similar operating costs and reliability.

The purpose of this article is to demonstrate differences in the operation of vehicles within the same group of different brands. The collected data come from an authorized service network, have been collected in the second quarter of 2014.

Maintenance strategies represent one of the many areas of maintenance research theory. Among the many listed models fulfill an important role in the maintenance system strategy is based on the control of main parameters of the model—the so-called strategies to control the state of the system (called inspection maintenance, inspection and replacement models). Computational problem in this type of strategies is the selection of optimal moments inspecting the object that operating costs were minimal (Koucky & Valis 2011). Overview of system status control models can be found, inter alia, in (Nowakowski & Werbinska-Wojciechowska 2012).

At the same time, it is worth emphasizing that in the available literature can find a number of works that address the problem (Werbinska 2008):

the impact of the changing environment on the functioning of the technical system,

the impact of technological progress on serviced component and system

as well as appear in works that compare, under certain assumptions, different operating strategies.

In the area of modeling maintenance of technical facilities used mathematical methods involving, among others. probability theory, renewal theory, or the theory of Markov processes. However, there are a number of issues, the complexity of which can't be described using analytical functions (Valis & Pokora 2014). Therefore, there are a number of studies involving the implementation of linear and nonlinear programming, dynamic programming, simulation methods or heuristic methods that have been mentioned only in developed literature review; preventive maintenance strategies, in its classical form, are hardly used in practice—there have been many modifications thereof which allow a more accurate reflection of the actual functioning of the technical process (Valis & Zak 2014).

In a situation where the system components are not dependent or relationship can't be properly defined, maintenance problems are solved by using the models to maintain a dedicated technical objects. In this case, two basic policy of maintaining technical facilities are used—Strategy Exchange BRP blocks (Block Replacement Policy) and the Strategy Exchange According to Age ARP (Age Replacement Policy). The first method is the most commonly used by car manufacturers as a recommendation for vehicle users. Nevertheless, there is often the need to implement corrective support. In time of increasing the competence and diagnostic systems inside a vehicles, successive producers decide to change their approach to cases of vehicle maintenance by the user and showing maximum period between every service preventive indicate the information from the system informing the user of the need to make the necessary adjustments (Loska 2011).

2 THE CASE

The data presented in this chapter come from two authorized Vehicle Service Station (VSS) in Poland. Both brands belong to the same group, one of them belongs to the premium class, the second class of vehicles popular.

During the study observed number of cars admitted to the (VSS) for repair or maintenance works. Were counted separately damage to individual components and the time of repair. The object of the study was the number of people visiting customer service. During the study reported more visits in the premium segment because of the greater amount of vehicles. As a subjective observation can be treated better assessment of clients of premium warranty terms in the premium segment, the overall culture of service and maintenance.

Figure 1 shows a graph of the typical numbers of visits to the service station in 2014. The direct

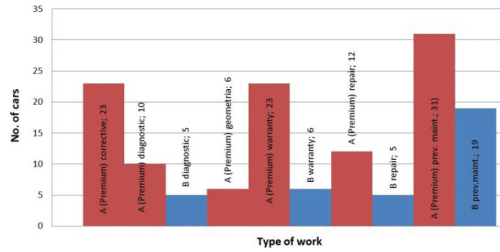

Figure 1. Graph of the numbers typical visits to the service station 2014.

relationship were presented two brand vehicles, one of which represents a group of cars in the premium segment. The first column of the chart shows the number of shares of default arising from various types of faults, especially new models introduced on the market.

These faults are often caused by flaws in the component reliability testing or are the result of errors in the manufacturing process. It is not possible to check all the parts and components of a new product in every possible way. In today's era of technology and the growing amount of electronic systems (eg., traction control) for vehicles more common are errors on the background of software drivers and modules of the car. Unfortunately, this type of defect also require manual servicing a car in order to update the software. There is no information about the vehicles not belonging to the premium brands. It may be caused by more complex systems installed in the premium brands, so default action to remove those defects than in the remaining brands.

The second group shown in Figure 1 is a comparison of the number of visits by the need to carry out a diagnosis of the vehicle. The procedure aims to establish and verify a fault in the vehicle. Here should not be surprising that a greater number of visits of vehicles in the premium segment is caused by greater complexity of the product, both the hardware and software. Each following group, which can be found in chart shows a comparison is visits to the site due to components or services covered by the warranty. There used to guarantee the distribution that is obtained when purchasing a new vehicle called. As it can be seen there were reported 23 visits vehicles of brand A (Premium), while in brand B only 6. The reason of this situation may be less extensive warranty of car brands B segment, as well as the general conviction customers a premium for better quality services in the authorized repairer (VSS). Direct comparison with the previous statement is related to repairs of both brands. Therefore, the argument is redundant results. Cars representing the brand A (Premium)

were on VSS 12 times, while Brand B vehicles only 5 repairs related to the scope of work not covered by the warranty.

Most owners owning Brands A (Premium) go to service vehicles to an authorized (here 31 times) than car owners Brands B (19 visits). Often this involves in Poland with a sense of the value of the product, but also, unfortunately, owner's wealth, which is the main reason the results presented.

In case of replacement it was compared to replacement of individual components of the vehicle. Here both Brand A and B, which can boast of nine visits to the service. It is possible to deliver the customer's own part, purchased privately. Service is obliged to request the customer's responsibility to replace the defective part on privately purchased replacement. The customer pays only for the service exchange.

When it comes to seasonal wheel exchange in the car, especially with winter tires to summer and vice versa, there is 31 visits reported for brand A (Premium), while brand B can score the result of 13 visits. When changing wheels often include a wheel alignment, which was mentioned above. Vehicle geometry on the example of Brand A (Premium), which is nothing else like setting toe in the car rarely be recorded in the site itself, however, is often typed as one of the steps to replace wheels.

The results of changing the oil in the cars of both brands are very similar. The exchange is based mainly on the exchange of the oil filter, oil and oil drainage. Therefore, the service rates depend largely on the capacity of the engine, and thus the amount of oil that is needed to be replaced. Nowadays, the boundaries between oil change intervals in gasoline and diesel, which are usually around 30k. miles.

Figure 2 shows the number of visits to the VSS premium brand vehicles and traditional to a specific service.

3 CONCLUSIONS

The selection of an appropriate strategy for maintaining complex systems requires the determination of policy for handling the group of elements, and not for each item separately working. The complexity of such a task is growing, especially when working elements are not identical, eg in the area of reliability whether there is between them, depending, for example in terms of economic or structural.

Preventive maintenance strategies, in its classical form, are hardly used in practice—there have been many modifications thereof which allow a more accurate reflection of the actual functioning of the technical process.

In the case of passenger cars, in an era of increasing the competence of information systems and diagnostic manufacturers are increasingly turning to the change in approach to terms of vehicle maintenance by the user.

The study indicates that the need to select an appropriate maintenance policy exists within a single company producing vehicles part of the same elements. Number of visits is higher in vehicles representing the premium class. This may seem surprising, but it should be noted that these vehicles are usually much better equipped, hence the number of possible points of damage or lack of functionality is greater. Hence the cost of vehicle maintenance premium compared to conventional vehicles is higher. As it comes from the research rule is repeated in different vehicle segments.

ABSTRACT: To ensure the navigation safety of ships, the characteristics of ships that go through the bridge waterway of Wuhan Yangtze River Bridge need to be studied. Ships' AIS information was used as a data source to analyze the distributions of the ship speed when ships navigating into and out of the bridge waterway downstream, as well as when passing by the buoys and the navigable hole. Then the shortest distance between the ships and their nearest buoys, the ships and the bridge piers were all calculated, the relationship between the distribution of the shortest distance and the corresponding ship speed was studied. Statistic analysis and K-S testing prove that, the ship speed of the downstream ships that navigate into and out of the bridge waterway, pass by the buoys and the navigable hole, obeys positive skew distribution respectively. The shortest distance between ships and the bridge pier obeys negative skew distribution, the shortest distance between ships and the navigation buoy is almost normal distributed. There is no linear relationship between the ship speed and the shortest distance.

1 INTRODUCTION

The ship traffic of the Wuhan Yangtze River Bridge Waterway is intensive, whilst the navigable hole of this bridge is narrow (128 metres), accidents occur in this waterway area frequently every year, so it is necessary and of significance study on the voyage characteristics of ships in this waterway area, which is important for the supervisor to ensure the safety of ships. Automatic Identification System (AIS) information can be obtained by parsing the AIS messages which are received through Vertical Horizontal Filter (VHF) by AIS base station. AIS information mainly includes the static, dynamic, and navigation information of the ship. Accident statistics, ship collision avoidance (Weng et al., 2012, Mou et al., 2010), statistics or modeling and simulation of traffic flow (Yan et al., 2010, Jin et al., 2012, Goerlandt et al., 2011), etc. can be researched by using the ship AIS information as a data source. At the same time, further study on the voyage behavior characteristics of ships can be carried out through the statistical analysis of AIS information. The voyage behavior characteristics of ships voyaging in the harbor waterway area and sea area are studied both domestically and overseas (De 2010, Gunnar et al., 2009, Zhu et al., 2012). Voyage behavior characteristics of ships, traffic flow (Mou et al., 2010), navigation ability (Zhou et al., 2013, Hu et al., 2013, Ai et al., 2013), ship speed and safe distance (Hou et al., 2010), etc. in the bridge waterway of the Yangtze River were studied by the domestic scholars. The linear regression model of the length, ship speed, ship course and the closest point of approach (CPA) was came up (LLOYD 2004), and the safe waterway space (MEINE et al., 2004) was studied by some scholars overseas. To sum up, study of the voyage characteristics of ships in the process of navigating into to navigating out of the bridge waterway of the Wuhan Yangtze River Bridge is relatively rare.

The ships' AIS information is used as a data source, the distributions of the ship speed when the ships navigating into and out of the bridge waterway, passing by the buoys and the navigable hole downstream are analyzed in this paper. Then the shortest distance between ships and their nearest buoys, ships and the bridge piers when ships passing by are calculated. The relationship between the distribution of the shortest distance

and the corresponding ship speed are studied. The model of the distribution function is built and then hypothesis testing is completed.

2 DATA PROCESSING

The AIS base station, which built in the Wuhan segment of the Yangtze River waterway can receive AIS messages broadly, all the information about the ships upstream and downstream in the bridge waterway of this segment can be received. As the distribution of the buoy start to become intensive about one nautical mile from the upstream of the Wuhan Yangtze River Bridge, the area between one nautical mile from the upstream and one nautical mile downstream of the bridge was chosen as the target bridge waterway. The AIS information of all the downstream ships whose ship speed were higher than 2 knots from January 7 to 16 in 2014 was chosen as preprocessing data, this preprocessing data includes 20275 pieces of information. Considering the loss of information in the process of receiving AIS messages, the preprocessing data are in discontinuous time.

This paper mainly studies the distribution law of the ship speed of the downstream ships from navigating into to leaving out of the bridge waterway, as well as the law of the shortest distance, and the relationship between the shortest distance and the corresponding ship speed. Therefore, the ship speed of the ships should be statistically analyzed, and the shortest distance should be calculated.

2.1 *Selection of ship speed*

In order to get the data of ship speed needed for the study, the moment when a ship arrives the place where is one mile away upstream from the Wuhan Yangtze River Bridge and the same distance downstream from the bridge, and this two moment are chosen as the time the ship navigates into or navigates out of the bridge waterway. The moment when a ship is closest to a buoy or the bridge pier is chosen as the time the ship voyages by them, the ship speed correspondingly is the average ship speed of that in two positions, where is the closest AIS information point to the buoy or the bridge pier.

To get the ship speed data for ships navigate into and out of the bridge waterway, the range of longitude and latitude of the axis, which parallel to and is one mile away from the Wuhan Yangtze River Bridge was used as the limited parameters to select ships' AIS information, 4566 pieces of information are obtained as the ship navigate into the bridge waterway, 1322 pieces of information are obtained as the ship navigate out of the bridge waterway. To get the ship speed information when the ship navigates by the buoy and the bridge pier, the information about the ship whose distance is farther than 500 metres from the buoy, or is farther than 200 metres from the bridge pier, is excluded, AIS information of 936 ships which navigate by the navigation, 506 ships which go through the navigable hole is finally obtained.

2.2 *The calculation of shortest distance*

In order to calculate the shortest distance between the ship and the buoy in the bridge waterway, as well as the shortest distance between the ship and the bridge pier, the position where AIS device is fixed for sending the ship AIS messages is regarded as the AIS information point, the buoy or bridge pier is regarded as the target object, the longitude and latitude of the buoy or bridge pier is set as target point. It is also assumed that the ship navigates in line between two AIS information points. The algorithm for calculating the shortest distance is shown in Figure 1.

1. Select the AIS information points which are at a certain distance from the target point. The data in this algorithm are the same as the former data of ship voyaging by the buoy and going through the bridge, the selection criteria is that the distance from these AIS information points to the

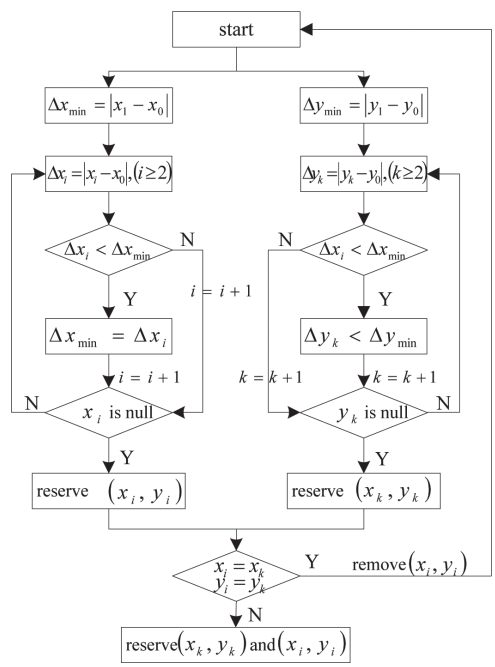

Figure 1. The algorithm of the shortest distance.

buoy is about 500 m, and to the bridge pier is about 200 metres.

2. All of the AIS information for one ship can be obtained in one day, according to the MMSI information in the received AIS messages, for a ship has a fixed MMSI number. All of these AIS information points are then listed in time sequence, and then subtract the longitude and latitude of ships with that of the target object (bridge pier or buoy) respectively. The obtained absolute value of the difference is then recurrently compared; the minimum absolute values of the longitude difference Δx_{min} and latitude difference Δy_{min} are kept, as well as the corresponding longitude and latitude value of the ship, (x_i,y_i), (x_k,y_k). If and $x_i = x_k$, the AIS information that has an inferior absolute value of the longitude difference and latitude difference is kept. Therefore, two or three AIS information points can be obtained where the absolute values of the longitude difference and latitude difference are minimum, and these AIS information points are called reserved points. The process of this step is shown in Figure 2.
3. As is discussed above, it is assumed that the ship navigates in line between two AIS information points. If there are two reserved points, the distance from the target point to the line formed by these two points is calculated and kept; if there are three reserved points, mark them by A, B, C in turn. The distances from the target point to the line formed by A, B and line formed by B, C are calculated respectively, compare these two distances and then keep the smaller one. On this basis, the minimum distance from the ship to the target object can be obtained, and that is the shortest distance.

The geographic location of the target buoy used in this paper is 114.283833° east longitude and 30.54833° north latitude. The two bridge piers of the downstream navigable opening (#7) of the Wuhan Yangtze River bridge are the target bridge pier. Actually, the calculated shortest distance is the distance from the point where AIS device is fixed for sending the messages to the middle point of the buoy and bridge pier.

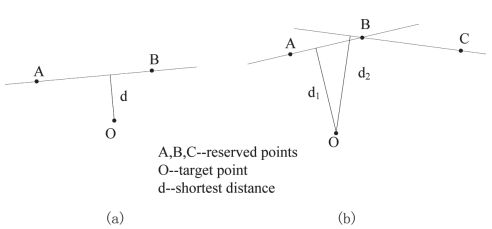

Figure 2. Step 2 of the shortest distance algorithm.

After the above calculation of the distance, 445 shortest distances from ships to the buoy are gained; the maximum value among the shortest distances is about 102 metres. 246 shortest distances from ships to the bridge pier are gained; the maximum value among these shortest distances is about 68.5 metres.

3 THE DISTRIBUTION LAW

3.1 *The distribution law of ship speed in the bridge waterway*

By selecting and counting the ship speed information of ships in the bridge waterway of the Wuhan Yangtze River Bridge, statistical analysis of 4 ship speed characteristics of the ships are carried out, the frequency histogram of the ship speed is drawn.

The distribution of the ship speed when ships navigate into the bridge waterway is shown in Figure 3. The unit of the speed is knot (kn) in the figure, the same as in the following figures.

The information indicates that, the ratio of the ships whose ship speed between 4 knots and 10 knots accounts for about 96.1%, whose ship speed between 5 knots and 7 knots accounts for about 58.56%, whose ship speed above 10 knots accounts for less than 2%.

Then use the testing of Kolmogorov-Smirnov (hereinafter referred to as K-S test) to test the speed distribution of ships when entering the bridge area. Let X be the sequence of speed value for the ship entering the Bridge area, let the significance level be 5%. Then put the vector X into the function H = kstest (X), consequently the value of H can be calculated out with the help of Matlab, that is H = 1. According to the principle of the K-S test, X is originally assumed to obey the

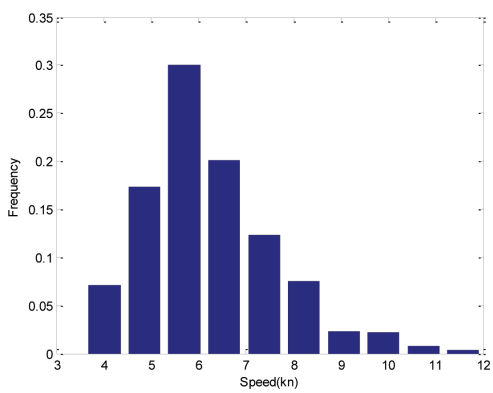

Figure 3. The ship speed distribution when ships navigate into the bridge waterway.

standard normal distribution, if H = 0, the original hypothesis cannot be rejected, if H = 1, the hypothesis is rejected. In summary, the speed of the ship entering the bridge area does not obey the normal distribution.

Skewness function is further applied to analyze the skewness of the speed distribution. As is known, skewness can be used as a statistic parameter to weigh the direction and degree of the distribution deflection. If the value of skewness *SK* is 0, it means that the distribution obeys a normal distribution. When *SK* is over 0, the distribution obeys positive skew distribution; while it is under 0, it obeys negative skew distribution. The *SK* can be calculated as:

$$SK = \frac{n\Sigma(x_i - \overline{x})^3}{(n-1)(n-2)sd^3} \quad (1)$$

Where n is the size of the speed sequence X, x_i is the i-th number, *sd* is the standard deviation of X, $\overline{\chi}$ is the mean of X. The skewness *SK* of the speed distribution which can be calculated out using Matlab is 0.8433 when ship entering the bridge area, obeying a positive skewness.

The distribution of the ship speed when ships navigate by a navigation buoy is shown in Figure 4.

The information indicates that, the ratio of the ships whose ship speed between 4 knots and 9 knots accounts for about 92.1%, whose ship speed between 6 knots and 8 knots accounts for about 54%, whose ship speed above 9 knots accounts for less than 8.3%.

Similarily, the value of the H can be calculated as 1 under this circumstance, the value of the skewness is 0.7563, the ship speed obeys positive skew distribution.

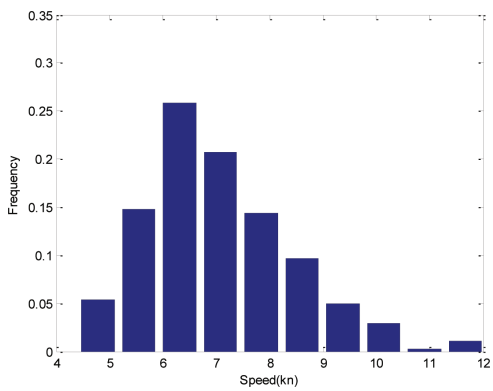

Figure 4. The ship speed distribution when ships navigate by the buoy.

The distribution of the ship speed when ships navigate by the bridge pier is shown in Figure 5.

The information indicates that, the ratio of the ships whose ship speed between 4 knots and 9 knots accounts for about 93.5%, whose ship speed between 6 knots and 8 knots accounts for about 54.9%, whose ship speed above 9 knots accounts for less than 7.3%.

The value of H equals 1 under this circumstance and the value of the skewness is 0.5813, the ship speed also obeys positive skew distribution.

The distribution of the ship speed when ships navigate out of the bridge waterway area is shown in Figure 6.

The information indicates that, the ratio of the ships whose ship speed between 5 knots and 13 knots accounts for about 91.1%, whose ship speed between 5 knots and 8 knots accounts for about 57.8%, whose ship speed above 10 knots accounts for less than 16.2%.

The value of H equals 1 under this circumstance and the value of the skewness is 0.8374, the ship speed obeys positive skew distribution.

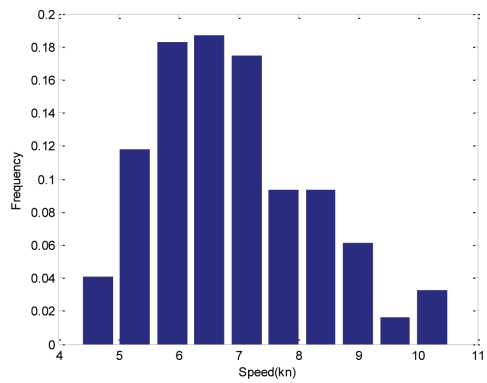

Figure 5. The ship speed distribution when ships navigate by the bridge pier.

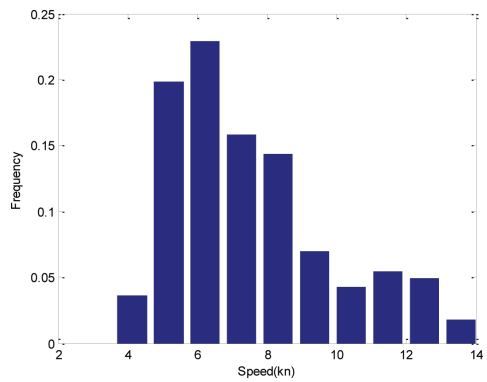

Figure 6. The ship speed distribution when ships navigate out of the bridge waterway.

3.2 *The distributive law of the shortest distance*

Through calculating and statistically analyzing the shortest distance, the frequency histogram of the shortest distance is drawn, and the hypothesis testing is completed.

The distribution of the shortest distance when ships passing by the buoy is shown in Figure 7. The unit of the distance is metre (m) in the figure, the same as in the following figures.

The information indicates that, the ratio of the ships whose distance from the navigation buoy is above 60 m accounts for about 91.93%.

The value of H equals 1 and the value of the skewness is 0.0053, which is much near zero, therefore the shortest distance under this circumstance is almost normal distributed.

The distribution of the shortest distance when ships navigating by the bridge pier is shown in Figure 8.

The information indicates that, the ratio of the ships whose distance from the navigation buoy is between 35 m and 65 m accounts for about 94.3%.

The value of H equals 1 and the value of the skewness is –0.5755, therefore the shortest distance under this circumstance obeys negative skew distribution.

At last, the distribution of the ship speed and shortest distance under different voyage circumstance (shown in figure 3 to figure 8) can be concluded, as shown in the table 1.

It can be seen that the ship speed of ships navigating in the bridge waterway obey positive skew distribution, which means that the low ship speed account for the majority, ships are more likely to choose a low speed when navigating in this special waterway. The shortest distance between ships and the bridge pier obeys negative skew distribution, which means that the bigger value of the shortest distance is dominated. The shortest distance between ships and the navigation buoy is almost normal distributed. In conclusion, when ships navigate in the bridge area waterway, a more conservative navigation method is usually adopted, that is low speed or far away from the buildings.

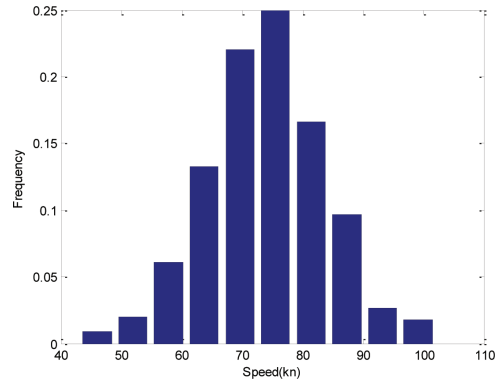

Figure 7. The shortest distance distribution when ships passing by the buoy.

(a)

(b)

Figure 9. The relationship between the ship speed and the shortest distance.

3.3 *The relationship between the ship speed and the shortest distance*

In order to study the relationship between the ship speed and the shortest distance, the ship speed is chosen as the horizontal axis, the shortest distance as the vertical axis, the relationship between them is shown in Figure 9.

As is shown in the Figure 9, there is no specific functional relationship between them, what can be observed is, most of the minimum shortest distance between the ships and the buoy are around 60 metres, there is little shorter than 60 metres (figure (a)); most of the minimum shortest distance between the ships and the bridge pier are between 40 metres and 65 metres, there is little shorter than 40 metres or farther than 65 metres (figure (b)).

4 CONCLUSION

According to the processing of the ships' AIS information which is received by the AIS base stations, the ship speed information related to ships which navigate downstream in the Wuhan Yangtze River bridge area at the following moment was selected out and analyzed statistically, that is when ships navigating in and out of the bridge area, passing by the buoys and the bridge piers. Then the shortest distance was calculated out using the former selected ship speed information between the downstream ships and their nearest buoys, between the ships and the bridges. The relationship between the distribution of shortest distance and the corresponding ship speed was also analyzed. Finally, Hypothesis testing was carried out aiming at the shortest distance and the ship speed.

The result shows that the ship speed is a positive skew distribution whenever the ship is navigating into the bridge area, voyaging by the navigation buoy, going through the bridge or navigating out the bridge area. Ships when navigating out the bridge area will normally ship speed up comparing with which when navigating in. The range of the ship speed is familiar when the ship voyage by the navigation buoy and the bridge pier. As for the shortest distance, it is negative skew distribution when the ship goes through the bridge, while it is almost normal distributed when the ship voyage by the navigation buoy and. However, the formerly noted ship speed does not have a linear relationship with the shortest distance. This result reflects that a certain rule exists in the distribution of ship speed and the shortest distance when ships navigate through the bridge area. It can provide a basis for the next research on the relationship between the ship types and the ship voyage behaviors in the bridge area, as well as the research on the behavior characteristics and rules for ships navigating in the continuous bridge area.

Fleet-level reliability estimation of repairable units

Amir H.S. Garmabaki, Alireza Ahmadi & Jan Block
Division of Operation and Maintenance Engineering, Luleå University of Technology, Luleå, Sweden

ABSTRACT: This paper investigates reliability analysis of a repairable unit at fleet level. In fleet, multiple similar systems are running in different operating environments. In fact, due to the highly censored data as well as high variations in failure rate within the fleet, merging the datasets becomes a challenge. The non-parametric analysis is used to capture the failure trend of repairable units at fleet level. Consequently, fleet data have been aggregated and the actual number of failure has been compared with the expected total number of failures. In addition, parametric models are used to model the reliability trend obtained through a non-parametric approach to identify the reliability parameters at fleet level. Real data are used to demonstrate the applicability and validity of the proposed method. Results shows the accuracy of log-linear process is reasonably acceptable.

1 INTRODUCTION

Repairable systems are those systems that can be restored to fully satisfactory performance by a method other than replacement of the entire system (Ascher and Feingold, 1984). Reliability analysis of repairable units can be classified into parametric and non-parametric methods.

The parametric method entails stochastic point processes, including the Homogeneous Poisson Process (HPP), the Renewal Process (RP), the Non-Homogeneous Poisson Process (NHPP), and the Generalized Renewal Process (GRP). For further discussion, see e.g., (Kijima and Sumita, 1986), (Rigdon and Basu, 2000), (Rausand and Høyland, 2004), (Ebeling, 2010), and (Kumar and Klefsjo, 1992). Application of parametric methods require a lot of statistical assumptions and analytical skills for implementation, which make these methods inapplicable for some real-world cases. The application of these methods for a single system/unit is fairly straightforward. However, in practice, the analyst is often dealing with multiple similar systems that are installed in different equipment/plants, that are running in different operating environments and with varying influencing factors.

The application of parametric reliability analysis methods at fleet level, even if very limited in scope, is quite complex and time-consuming for a variety of reasons. For instance, failure analysis is made more difficult by the highly multi-censored nature of the reliability data belonging to different failure modes (Block et al., 2013a). The analysis of time-censored and failure-censored data need different treatment and application of different methods. Moreover, drawing conclusions at fleet level from these individual analyses requires statistical assumptions that, in practice, entail a degree of uncertainty.

The non-parametric method provides a graphical estimate of the number of recurrences (repairs/failures) per unit and per the whole population, versus utilization/age. The method is non-parametric in the sense that it does not use a parametric model for the population. This estimation involves no assumptions about the form of the mean function or the process generating the system histories.

Within available non-parametric methods, Mean Cumulative Function (MCF) was introduced to estimate the expected average number of failures per unit within population of a fleet, see (Nelson, 2003). In this process, the number of systems at risk at each failure node is the basis of computation. MCF results, in combination with total utilization at fleet level, can be used to estimate the total expected number of failures at fleet level.

In addition, Ebeling (2010) used a method to aggregate data at failure nodes in order to calculate the cumulative number of failures for a whole fleet of jet engines. That methodology considers the cumulative operation time of all other engines at any failure nodes/dates and considers that the failure nodes are not chronologically ordered. This requires complete information on the status of all systems at all failure nodes. However, in some cases; specifically for the case of this study, such complete information is not available due to the variety of operational bases and operators.

Recently, Block et al. (2013b) discussed the reliability behavior of repairable units at fleet level. They performed a case study and evaluated the goodness of fit of the estimated linear curves

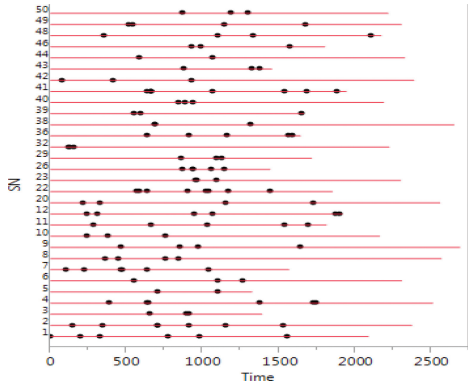

Figure 1. Event plot of units' failures.

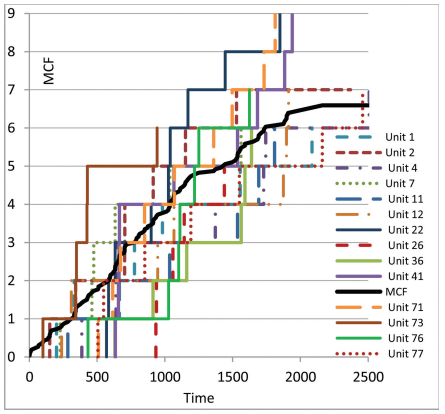

Figure 2. Cumulative failure events for 14 units.

against the actual MCF. In addition, Block et al. (2013a) used the power law process to calculate the expected number of failures at fleet level.

In this study, we have introduced an approach to compute the cumulative number of failures at fleet level, in which the recurrent failure events of units within the fleet are chronologically ordered (see Fig. 1).

In addition, we have used the power law as well as the log-linear and homogeneous poisson processes to fit a curve on the MCF, and to the variation of estimation by different models.

The rest of this paper is designed as follows: In Section 2, MCF is introduced; Section 3 reviews some parametric models. The proposed non-parametric model is discussed in Section 4. Aircraft Radar Transmitter Unit (Case Study) is studied by parametric and non-parametric methods in Section 5. Finally, conclusions and discussions are given in Section 6.

2 MEAN CUMULATIVE FUNCTION (MCF)

Here, we discuss a simple and informative plot for analyzing recurrent repair data. The plotting method provides a non-parametric graphical estimate of the number/cost of repairs per unit versus age. This estimate can be used to evaluate the repair rate of the population with respect to age and predict future number/cost of repairs. The MCF plot reveals most of the information that we are searching for in recurrent data (Nelson, 2003). A key advantage of the MCF plot is that it provides a single summary plot for a group of units, which is easily compared with other MCF plots of different populations. The MCF plot is the population of staircase functions for all the studied units. This staircase is a consequence of the non-parametric estimation. Non-parametric MCF estimation methods have been described by (Nelson, 2003, Block et al., 2013b, Meeker and Escobar, 1998). The mathematical formulation of MCF is discussed as follows, see (Nelson, 2003).

Let n denote the number of observed units, and let m denote the number of unique failure times. Also, let $t_1, \ldots, t_m$ be the unique failure times. Then the non-parametric estimator of the MCF is

$$\hat{\mu}_{NP}(\mathrm{t_j}) = \sum_{k=1}^{j}\left[\frac{\sum_{i=1}^{n}\delta_i(t_k)\times d_i(t_k)}{\sum_{i=1}^{n}\delta_i(t_k)}\right] = \sum_{k=1}^{j}\left[\frac{\sum_{i=1}^{n} d\cdot(t_k)}{\sum_{i=1}^{n}\delta\cdot(t_k)}\right], \quad j=1,\ldots,m \tag{1}$$

where $d_i(t_k)$ is the number of failures recorded at time t_k for unit i, and

$$\delta_i(t_k) = \begin{cases} 1 & \text{if unit } i \text{ is still functioning} \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

Also, the total number of failures reported at time t_k is given by

$$d.(t_k) = \sum_{i=1}^{n}\delta\cdot(t_k)\times d_i(t_k) \tag{3}$$

And $\delta\cdot(t_k) = \sum_{i=1}^{n}\delta_i(t_k)$ is the number of systems at risk for failure. Figure 2 depicts the MCF of 13 transmitter unit failures which are plotted by JMP/SAS software.

3 PARAMETRIC MODELS

In practice, one may want to know in what cases the parametric or non-parametric model are suitable. However, one should always do a MCF plot, as it

reveals information that parametric model fitting does not, see (Nelson, 2003). However, information given by non-parametric approaches are valid for the associated set of data and utilization, and failure prediction during the future operations is not possible. Hence the application of parametric approaches arises. Here we discuss fitting different models to the MCF data regarding our case study. We attempt to fit the power law process, log-linear process, and homogeneous poisson process to the MCF curve.

3.1 *Power law model*

The power law model is part of parametric NHPP models when the ROCOF of the NHPP is considered as

$$w(t) = \frac{\beta}{\theta}\left(\frac{t}{\theta}\right)^{\beta-1}, \ \theta > 0, \beta > 0, t \geq 0 \tag{4}$$

where $W(t) = \int_0^t w(s)\, ds$ and θ, β are scale and shape parameters, respectively, see (Ascher and Feingold, 1984).

3.2 *Log-linear model*

The log-linear form of intensity function also allows for increasing and decreasing the rate of occurrence. This model was proposed by (Cox and Lewis, 1966). The ROCOF of an NHPP is defined by

$$w(t) = e^{\alpha+\beta t} \ ; -\infty < \alpha, \beta < \infty \tag{5}$$

Where $W(t) = \int_0^t w(s)\, ds$ and α, β are scale and shape parameters, respectively.

3.3 *HPP model*

The HPP is the simplest statistical model for repairable systems. The HPP is a poisson process with a constant intensity function. In this process, the system does not wear out during the time between failures. The HPP cannot be used to model systems that are improving or deteriorating. Hence, it should be applied with caution. It is worth noting that the PLP and log-linear model reduce to the HPP model when $\beta = 0$. Here, we consider that

$$w(t) = e^{\alpha} = \lambda \text{ and } W(t) = \lambda t \tag{6}$$

4 PROPOSED NON-PARAMETRIC MODEL

Here, we discuss how to calculate and plot the Actual Total Number of Failures (ATNF) with/without censoring age at the fleet level. Let us consider a fleet consisting of k units/components and assume that the i:th unit, $i = 1, ..., k.$, is observed during the period $[0, T_i]$, which experienced N_i failures in their time horizon, $i = 1, ..., k$. Let T_i be the total operation time of the i:th component. And let t_{ri} be the age of the i:th component at the r:th occurrence of failure, $r = 1, ..., N_i$; $i = 1, ..., k$. Also, $m = \sum_{i=1}^{k} N_i + k$, $m' = \sum_{i=1}^{k} N_i$ and order all t_{ri} from smallest to largest. Let $S_c^{'}$ *and* S_w' where $c = 1 ... m$ and $w = 1 ... m'$, be the chronologically merged data: $S_1 \leq S_2 \leq ... \leq S_m$ and $S_1' \leq S_2' \leq ... \leq S_{m'}'$ for data with/without censored, respectivily. Then the actual failure time is given by:

$$\text{Actual failure time for fleet with time censor} = S_c' \times k, \tag{7}$$

$$\text{Actual failure time for fleet without time censor} = S_w \times k, \tag{8}$$

and

$$ATNF = \text{Actual number of failure with/without censoring} \times k$$

5 CASE STUDY: AIRCRAFT'S RADAR TRANSMITTER UNIT

We studied a (repairable) radar transmitter unit. This transmitter was the part of the main surveillance radar (PS-37) of the AJ 37 strike aircraft. The data were right-hand censored by two processes: failure and discard. The study considers 83 repairable units. Figure 1 displays the transmitter repair data of 50 units, separately. Each line in the figure shows the failure history of a component and each bullet point shows the aircraft unit's age in hours when a transmitter was repaired. For example, Transmitter S/N 40 was repaired at 840.72, 884.18, and 932.74 hours, and was observed for 2186.47 hours. The latest age is called the unit's "censoring age."

The successive repair pattern of 13 units is plotted simultaneously in Figure 2.

As described in Section 2, equation 1 is used to estimate the MCF. Figures 3 and 4 show the MCF

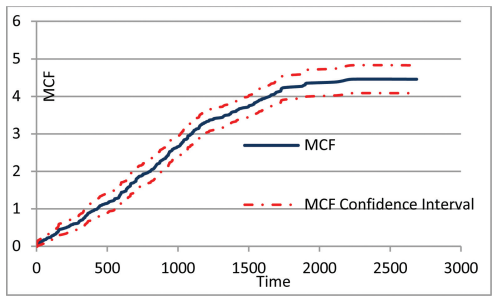

Figure 3. MCF plot of the units within the fleet.

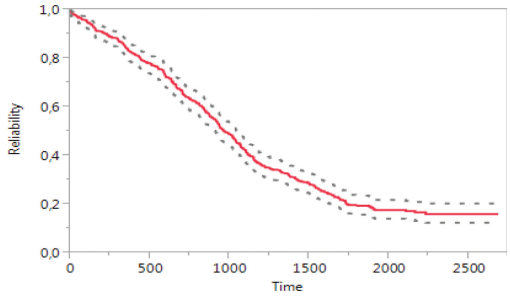

Figure 4. Reliability of fleet-level failure vs time.

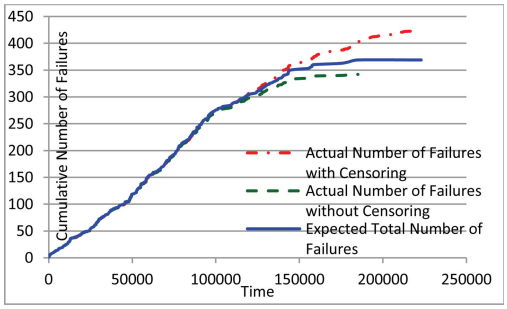

Figure 5. Actual total number of failure and ETNF for all unit.

and reliability plot, respectively, with a two-sided, 95% confidence bound.

5.1 *Non-parametric failure behavior ETNF vs the proposed model*

In addition, we calculate the Expected Total Number of Failures (ETNF) for all components and the relation of MCF with proposed model is depicted in Figure 5, simultaneously. We observe that the behavior of both curves are mostly the same until 125,000 operating hours, after which time the effects of age censoring appear.

To better understand the behavior of the above categories and to check the validity of the fleet data aggregation for estimatation of the number of failures, we select three random sample data from the data set and apply the same procedure as discussed earlier. The first random data consists of 26 random units and the second and third consist of 25 and 21 random units, respectively. The behavior of ETNF along with the actual total operational time (with/without censoring age) are plotted in Figures 6, 7, and 8, respectively. Results show similar behavior as in the first case (for analysis of all components, see Fig. 5).

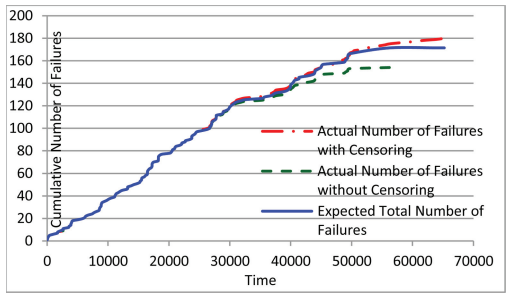

Figure 6. Actual number of failures and ETNF estimate for 26 random components.

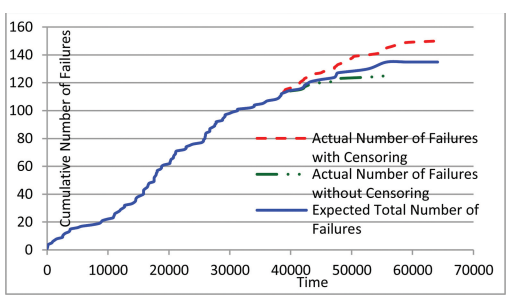

Figure 7. Actual number of failures and ETNF estimate for 25 random components.

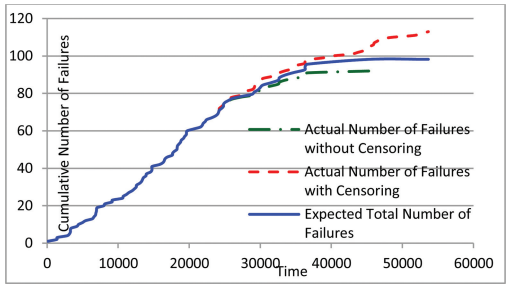

Figure 8. Actual number of failures and ETNF estimate for 21 random components.

5.2 *Fitting the parametric model to the MCF*

Here, we discuss the fitting of different models to the MCF data from our case study. We try to fit the power law process, log-linear process, and homogeneous poisson process to the MCF curve. Parameter estimations of the models are given in Table 1.

In addition, Figure 9 shows the goodness of fit of each model, separately. Also, we plot two-sided confidence levels at a significance level of 95% for our case study. The width of the confidence interval

Table 1. Parameter estimations of PLP, LLP, and HPP with censoring age data.

Model	Parameter	Estimate	Std error
Power law	θ	361,344	40,1399
	β	0,8466	0,04514
Log-linear	α	–5,7004	0,09406
	β	–0,0005	9,19e^{-5}
HPP	α	–6,1517	0,05404

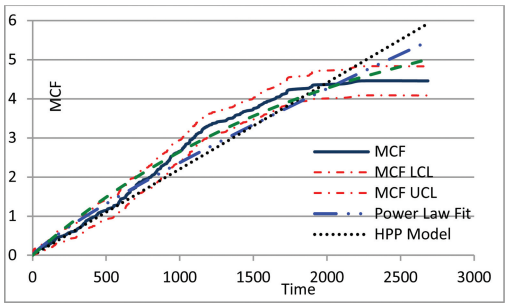

Figure 9. Goodness of fit of the power law, log-linear, and HPP.

after 2000 hours increases because several components are censored and will increases by increasing the numbers of censored units.

5.3 *Model evaluation*

Performance analysis of the proposed model is done using the four common criteria defined below (Kapur et al., 2010).

– The ***Bias*** is defined as

$$Bias = \sum_{i=1}^{k} \frac{(\hat{m}(t_i) - y_i)}{k} \tag{9}$$

The difference between the observed and predicted number of failures at any instant in time is known as PE_i (prediction error). The average of PE's is known as bias. The lower the value of Bias, the better the goodness of fit.

– The ***Variation*** is defined as:

$$Variation = \sqrt{\frac{\sum_{i=1}^{k} (PE_i - Bias)^2}{k-1}} \tag{10}$$

The average of the prediction errors is called the prediction Bias, and its standard deviation is often used as a measure of prediction variation.

– The Root Mean Square Prediction Error (RMSPE) is defined as

$$RMSPE = \sqrt{Variation^2 + Bias^2} \tag{11}$$

RMSPE is a measure of how closely the model predicts the observation.

– The Mean Square Error (MSE) is defined as

The difference between the expected values $\hat{m}(t_i)$ and the observed data y_i is measured by MSE as follows:

$$MSE = \sum_{i=1}^{k} \frac{(\hat{m}(t_i) - y_i)^2}{k} \tag{12}$$

where k is the number of observations. Low MSE indicates less fitting errors and, thus, better goodness of fit.

Table 3 show the values of MSE, Variation, RMSPE, and Bias for the power law, log-linear, and HPP models, for both censored and non-censored data sets. As the results show, the log-linear model has better comparison values than PLP and HPP for the censored data set.

However, as is evident in Figure 9, the curves associated with the proposed models do not fit properly to the MCF curve. This is due to the censoring ages at the end of the MCF curves, which have falsified effects on parameter estimation of the models. Therefore, the time censors in the data sets have been converted to failure censored, to protect against false estimation, see Table 3 (Without Censored Data Set). As shown in that table, the log-linear model fits the MCF better than the PLP and HPP models; however, the difference between them is not significant. For simplicity, we therefore suggest use of the HPP model. It may noted that the value of the shape parameter of the power law tends to 1, see Tables 2 and 3.

Figure 10 shows the goodness of fit of the log linear, PLP, and HPP models with the MCF. As is evident, the associated models provide more accuate estimation compared to the models with censored age data.

Table 2. Parameter estimation of models with failure censoring.

Model	Parameter	Estimate	Std error
Power law	θ	398.56839	39.0811
	β	0.966112	0.057858
Log-linear	α	–5.943227	0.112218
	β	–0.000124	0.000135
HPP	α	–6.025952	0.062017

Table 3. Best fit value.

	PLP	Log-linear	HPP
With censored data set			
MSE	0.0874	0.048116	0.18411
Variation	0.295631	0.219341	0.42906
RMSPE	0.295218	0.219076	0.42848
Bias	0.087655	0.048248	0.18462
Without censored data set			
MSE	0.01916	0.016207	0.02058
Variation	0.00865	0.007932	0.00881
RMSPE	0.01139	0.015056	0.02927
Bias	0.00741	–0.0128	0.02792

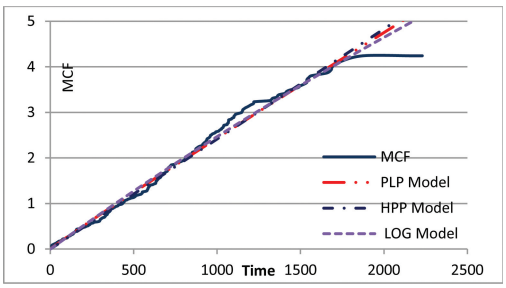

Figure 10. Goodness of fit of the power law, log-linear, and HPP (without the censored data set).

6 DISCUSSION AND CONCLUSION

In this paper, we have introduced an approach to compute the cumulative number of failures at fleet level when the recurrent failure events of units within the fleet are chronologically ordered. The proposed model is examined with three random samples. It is observed that in all three samples, the actual total number of failures (estimated by the proposed model) are slightly higher than the expected total number of failures (using the MCF). It is also observed that when the data set is non-censored, the ATNF for all three cases is slightly lower than the ETNF. In addition, the plots show that until around 125,000 fleet-wise operation hours, the ETNF and ATNF approach generates the same results for both censored and non-censored data sets. Therefore, the results obtained by the ATNF of a mature fleet can be used to estimate the number of failures for a new fleet, when the fleet is operated under approximately the same conditions.

In addition, to enhance the prediction power of the MCF, parametric models, such as the power law, log-linear, and homogeneous poisson process, are used to fit a curve on the MCF based on time-censored and failure-censored data. The results show that for both cases the log linear model provides the better fit to the MCF curve.

Learning from failures: The case of Deepwater Horizon disaster

A.W. Labib
University of Portsmouth, UK

ABSTRACT: In this work, it is argued that learning from failures and safety competence should be an important part of the curriculum of engineering and management students. The case of Deepwater Horizon will be used to illustrate how to learn about learning from failures using multi-models inspired by reliability and risk analysis in order to investigate disasters. This type of analysis can offer richness to our understanding of the root causes and provide insight into policy making and support decisions for resource allocations for prevention of such disasters. The concept of learning and unlearning from failures is relevant to the reliability and safety community.

1 INTRODUCTION—CASE STUDY DEEPWATER HORIZON

Authoritative in-depth description of the Deepwater Horizon oil spill can be found in the Deepwater Horizon Study Group Report (DHSG, 2011), the BP Commission Report (2011) and the USDOI Report (2010).

While it can be argued that this section—which provides a summarised yet extensive description of the accident and the background to it—could have been made much shorter by referring to the abundant information in this literature, it is suggested that a primary data collection would be of lower quality because with the passage of time, memories would have faded and key personnel dispersed. Therefore a secondary data analysis (a proven and widely-used research method) has been used for structuring the problem. This also gives the possibility of triangulating sources—and the analysis can be easily checked by other researchers.

Students were briefed regarding the background to the disaster (Section 1.1 below). The technical cause of the failure (Section 1.2) and the consequences and their severity (Section 1.3). They were then divided into three groups, each of which was required to use reliability engineering techniques to analyse the failure and make recommendations based on the analytic tools that were used.

1.1 *Background to the disaster*

On 20 April 2010 a massive explosion destroyed the Deepwater Horizon drilling rig in the northern Gulf of Mexico, followed by the leakage of millions of barrels of oil. The drilling rig (see Fig. 1), which was owned and operated by Transocean, had resumed the drilling of the Macondo well in the sea floor in the Gulf of Mexico, which at this point was at a depth of 8,000 ft.

The drilling operation, which had been resumed on 6th February 2010, incorporated a Blowout Preventer (BOP) that consisted of hydraulic valves designed to regulate the pressure of the oil and gases released from the well simultaneously with the drilling mud and sea water that is introduced into the well. The function of the BOP is to seal off a well that is being worked upon or drilled over, and this can happen during well interventions or drilling if there is an over pressure that threaten the proper functioning of the rig. During the drilling

Figure 1. The Deepwater Horizon drilling rig in operation (Source: Rigzone, How do Semisubmersibles Work?, Accessed November 23, 2010). (http://www.rigzone.com/training/insight.asp?insight_id=338&c_id=24).

stage the pressure increased, due to two factors: the mud and sea water that were introduced into the well and the pressure that was produced by oil and gas coming from the well bottom. Figure 2 shows the components of the blowout preventer.

Sea water and drilling mud were injected into the well to control the pressure. However, when the well pressure overcame the pressure of the mud and the sea water, the mud, accompanied by hydrocarbon gas, started to overflow on to the rig surface. Although it was controlled and diverted to the mud and gas separator, the gas source was unknown. Investigations revealed that hydrocarbon was being released through the poorly designed cement barrier, which was cast in order to isolate the well. The released gas mixed with mud, and at this stage the hydrocarbon, produced high pressure and damaged the gasket inside the blowout preventer. As a consequence, a larger quantity of gas, oil and mud flowed up to the rig surface. Minutes later, the first explosion occurred and damaged the cables that connect the control room and the blowout preventer. As a result, the blowout was completely isolated and uncontrollable. Over time, the huge amount of hydrocarbon entered the still functioning engine room which provided the ignition source of a second, massive explosion.

1.2 *Technical cause of the failure*

Investigations indicated that there were many reasons for the disaster. However, whatever these were, the consequences were disastrous. The causes can be classified into several categories as outlined below (DHSG, 2011).

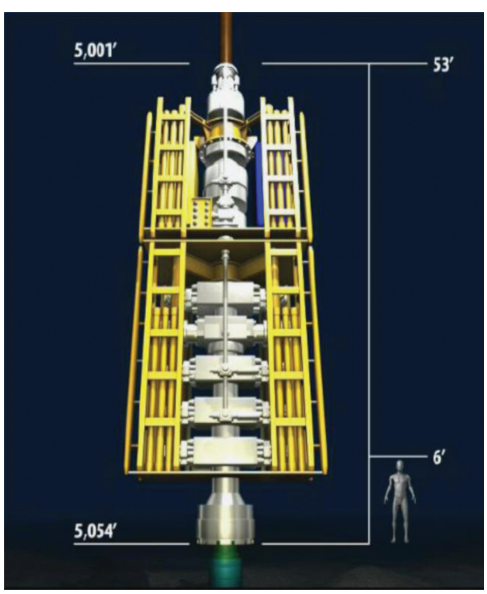

Figure 2. Blowout preventer (DHSG, 2011).

1.2.1 *Poor design of cement barrier*

It was believed that the main cause of the explosion was the leakage of hydrocarbon from the bottom of the well to the drilling tower, which resulted in the leakage of gas into the engine room. Investigators succeeded in analysing the scenario. From the beginning, the cement barrier that was used to prevent the gases from getting into the well was not successfully designed. In addition, it was not tested in order to see whether it could sustain the pressure. As a consequence, hydrocarbon was released through the cement barrier into the well.

1.2.2 *Mechanical failure of the blowout preventer*

The Blowout Preventer (BOP) is a mechanical arrangement that consists of different parts which work as valves to regulate the well pressure and prevent oil and gas from reaching the rig surface. In this case, this equipment seriously failed. The high pressure hydrocarbon that was released through the cement layer damaged the gasket inside the BOP. As a result, the well pressure became uncontrollable. This resulted in the release of large amounts of oil and gas up to the rig surface. Mud and gas separators ventilate the hydrocarbon on to the rig surface. However, the ventilated hydrocarbon gas entered the power generator room, which provided the ignition source. Furthermore, the fire safety and gas system, which is designed to prevent fire and gas mixing, was not working or was incapable of overcoming the problem. Therefore, the explosion occurred.

1.2.3 *Damage of control cables*

There were two explosions ten seconds apart. The first damaged the control cables which connected the BOP with the control room, causing the BOP to become out of control. Consequently there were no signals between the control room and the blowout preventer.

1.2.4 *Fire and gas system*

There was a safety system, to prevent fire. In oil exploration operations, frequent fire accidents are expected. However, in the Deepwater Horizon case, the system was not working, which reflected the poor maintenance of the safety systems.

1.3 *Consequences and severity*

1.3.1 *Fatalities and injuries*

At the time of the accident there were 126 personnel on the Deepwater rig, and most of them did not realise that a serious problem had occurred because

the safety system alarms were not functioning. They were subsequently instructed to evacuate the rig as early as possible. During that time there was chaos on the bridge because the shift crew members were still trying to understand what was happening. In addition, emergency plan procedures were not clear to the shift crew. However, many of them were preparing to jump into the sea and others were waiting for the lifeboats to be launched. But only two lifeboats were ready and they were partially full. Unfortunately, evacuation routes were blocked because of the explosion and the atmosphere was saturated with large amounts of carbon dioxide as the ventilation systems failed. Near the rig, there was a supply ship, the Damon Bankston. It was called for help and, due to its fast response, the people who jumped into the sea were rescued first and the injured were airlifted to the nearest hospital. The consequences were 11 fatalities and 15 injuries (DHSG, 2011).

1.3.2 *Environmental impact*

It is undeniable that the environmental impact of the disaster was catastrophic. The oil spill lasted for about 87 days before it was stopped. An independent analysis indicated that the total spilled oil was around 185 million gallons plus another 33.8 million gallons that were captured by BP. As a result, hundreds of miles of shoreline were oiled and large areas of the sea were closed to fishermen. Moreover, wildlife was affected by the oil spill; thousands of birds, fish, turtles and marine mammals were killed.

2 ANALYSIS OF 1ST GROUP OF STUDENTS

The disaster happened for various reasons, some of them technical, some organisational, some financial and yet there were problems of safety-related design.

2.1 *The technical reasons*

1. The cement barrier was incapable of preventing hydrocarbon gas from entering the well. Thus, the gas mixed with the drilling mud and was released under high pressure on to the rig surface.
2. The blowout preventer failed to isolate the well which in turn allowed hydrocarbon and oil to seep on to the rig surface.
3. The first explosion severed the control cables between the blowout preventer and control room. Consequently, the blowout preventer was out of control.
4. The fire and gas system broke down, so it could not prevent the hydrocarbon ignition.

2.2 *The design and safety reasons*

1. The well was cemented before the laboratory test results were provided to BP. Halliburton (the contractor who was responsible for testing the cement layer design) reported to BP that the well cement barrier was not effectively designed and that it was probable that a serious gas flow could occur.
2. The design of the gas and mud separator was poor. That is to say, when hydrocarbon was separated from the mud, it had not been burned or safely disposed of. It was released into the engine room where its ignition led to the massive explosion.
3. The blowout preventer was critical equipment which was used to isolate the well and regulate the oil and gas pressure. As such it should have been redundantly designed. To be more precise, there should have been a redundant blowout preventer connected in series. This would have reduced the probability of oil and gas leakage to the rig surface.
4. The design of the control room was poor. That is to say, influx of the hydrocarbon was not recognised until it reached the riser. The control room systems were either outdated or failed.
5. Safety system alarms were suspended (for some unknown reason), so most personnel did not realise what was happening and that the situation required evacuation.
6. The safety system had suffered various failures in the past. However, no actions had been taken to correct them.
7. There were only two evacuation boats. In the absence of evacuation procedures most of the workers jumped into the sea.

2.3 *Financial and organisational factors*

1. In an attempt to cut costs and increase profits BP had been cutting maintenance budgets during the previous few years. This led to inefficient maintenance programmes and a backlog of deferred corrective work, especially on critical safety items.
2. Within the BP group excessive changing of leadership positions was widespread, generating problems with work control and long term planning.
3. Financial and time pressure was one of the main reasons for the disaster. The changing of the drilling rig took a long time and thus put workers under pressure. In addition, managers were under financial pressure as the drilling process could have taken longer than planned and the company would have been forced to pay a penalty for any overrun.

2.4 *Fault Tree Analysis (FTA)*

FTA is a reliability analysis technique. Through FTA, basic events that led to the disaster can be explored. Figure 3 illustrates all the probable causes of the disaster.

From the diagram it can be concluded that the basic causes are as follows:

1. The fire and gas system failed to detect the gas leakage, either because it failed or was overloaded.
2. The blowout preventer failed to isolate the well for various possible reasons:
   - It was uncontrollable because the control cables were severed.
   - The operator was incompetent.
   - The design of the control panel was poor.
   - The pressure regulation valve failed to close.
3. The shoe track failed to isolate the well because it was badly designed or damaged.
4. The cement barrier was incapable of isolating the well for various possible reasons:
   - The design was not accurately tested in the laboratory.
   - The cementing process was inefficient.

The barrier itself was damaged by the high pressure of hydrocarbon.

Having analysed the likely disaster causes, the next step is to evaluate the reliability of the whole system by applying the Reliability Block Diagram technique to an investigation of the possible design modifications that could enhance reliability.

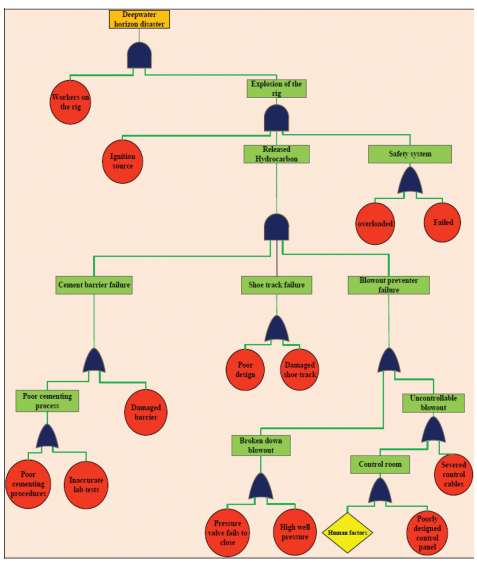

Figure 3. The Deepwater Horizon disaster fault tree analysis.

2.5 *Reliability Block Diagram (RBD)*

RBD is the next reliability assessment step following the FTA. It assesses the reliability of a system. Furthermore, designers can learn from the mistakes that might be the reasons for the disaster. Figure 4 shows, for the Deepwater Horizon case, the basic causes and their interdependencies.

2.6 *Recommendations and reliability improvement*

Technical recommendations:

2.6.1 *Blowout preventer*

- Cover the control cables so that they can be protected against damage.
- Install a redundant blowout preventer, which will increase the system reliability.
- Ensure that the BOP operator is competent.

2.6.2 *Cement barrier*

- Cementing procedures need to be revised and assessed.
- Carry out accurate experimental work to ensure the reliability of the cement barrier.
- Study the possibility of a cement barrier replacement e.g. using a metallic barrier.

2.6.3 *Shoe track*

- Needs to be redesigned and assessed.

2.6.4 *Fire and gas system*

- Replace the old system with a high capability one.
- Install a safety system that can give an indication of a high concentration of gas.

Management and financial recommendations

- Improve skills of personnel, especially for critical tasks.
- Focus on work planning and allocate enough time for work achievement.

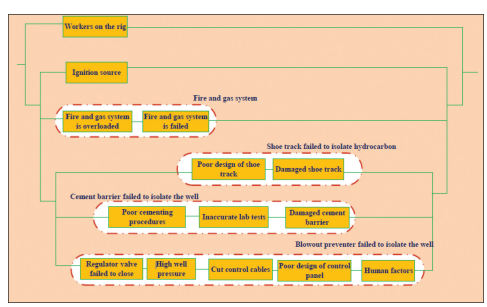

Figure 4. Reliability block diagram of Deepwater Horizon disaster.

– Allocate maintenance budget sufficient for reliability enhancement.
– Focus on safety procedures.
– Review emergency evacuation arrangements.

3 ANALYSIS OF 2ND GROUP OF STUDENTS

3.1 *Summary of the technical cause of the disaster*

– Cement-casing barrier failed to isolate.
– Incorrect interpretation of negative-pressure test.
– Fire and gas system did not prevent release of gas and its ignition.
– BOP emergency response mode failed to seal.

These technical causes are outlined in Figure 5. The resulting Fault Tree, Reliability Block Diagram and Failure Mode and Effect Analyses are illustrated in Figures 6, 7 and 8.

3.2 *Lessons learned*

– Human: Best practice and heightened vigilance in all steps from design to any variations during drilling are essential.
– Use better technology: Independent BOP activation control (e,g, audio-transmission), either from onshore or from standby vessels, is desirable.
– Installation: Ensure equipment and materials (e.g. cement) are used correctly.
– Re-design: Improve BOP so that it can show its real-time conditions.
– Data transmission: Transmission of data onshore so that situation can be further monitored.
– Contingency: Back-up Blind Shear Ram (BSR), i.e. introduce redundancy.

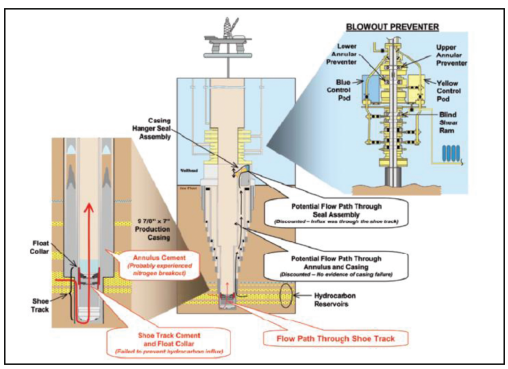

Figure 5. Technical causes of the failure (adapted from DHSG, 2011).

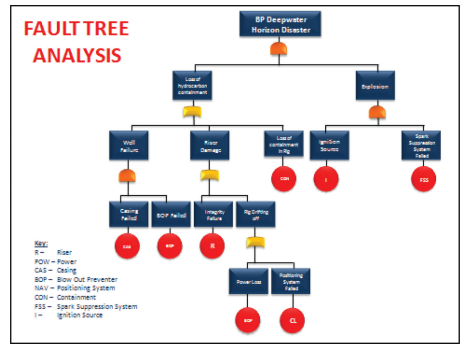

Figure 6. Fault tree analysis.

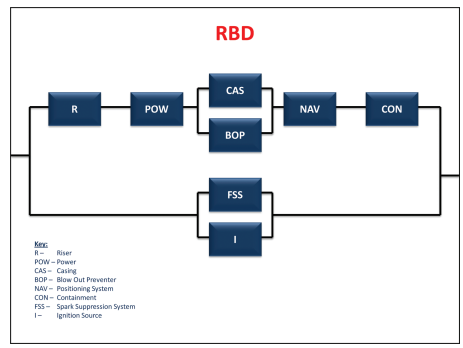

Figure 7. The reliability block diagram of Deepwater Horizon.

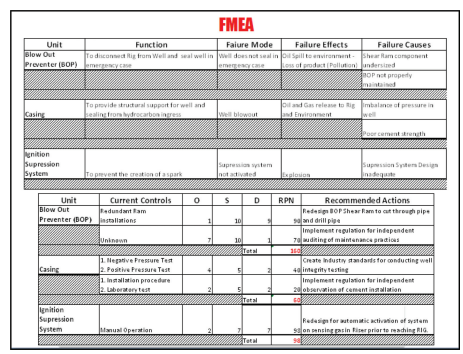

Figure 8. FMEA model of Deepwater Horizon.

4 ANALYSIS OF 3RD GROUP OF STUDENTS

4.1 *Technical cause of the disaster*

– Design and engineering flaws
  – BOP poor design had been indicated previously: (failed in 2006, 50% of usage).

  - Incorrect cement composition: use of nitrite and other additives reduces the strength of the required composition.
- Poor communication
  - Lack of effective communication Between Parties (BP, Halliburton and Transocean).
- Poor management decisions
  - Deviation from design specification (only 6 centralizers used rather than the recommended 21).
  - No dedicated BP representative.
- Mechanical failure
  - BOP failure (of battery, blind shear ram and emergency disconnect system).
- Operational implementation
  - Poor judgment of pressure reading (drill line reads 1400psi and kill line reads 0 psi) (BP and Transocean personnel could not have analyzed and interpreted pressure reading, thinking it false).
  - No action was taken due to lack of investigation of pressure reading.
  - Well integrity not established.

Figure 9 shows the barriers that were breached and subsequently led to the disaster. Figure 10 show the equivalent FTA. Figure 11 shows the related RBD with its estimated probabilities.

Not that estimated probabilities in Figure 11 are guesses based on the author's judgment. Based on Figure 11, one can then estimate overall (un)reliability, viz:

Reliability calculation:

$$\text{Line 1: } 0.5 \times 1 - (1 - 0.4925)^2 = 0.2442$$
$$\text{Line 2: } 0.2425 = 0.2425$$
$$\text{Line 3: } 0.985 \times 0.2925 = 0.288$$
$$\text{Line 4: } 1 - (1 - 0.5)^3 = 0.8768$$
$$\text{Line 5: } 1 - (1 - 0.4851)^2 = 0.7348$$
$$R = 1 - (1 - 0.2442)(1 - 0.2425)(1 - 0.288)(1 - 0.8768)(1 - 0.7348)$$
$$R = 0.986$$

Therefore: Unreliability

$$U = 1 - 0.986$$
$$U = 0.0133.$$

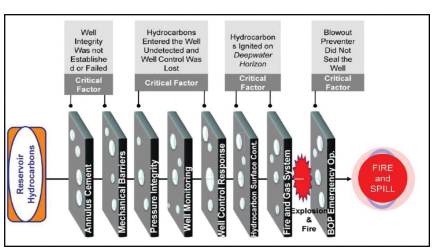

Figure 9. Barriers for Deepwater Horizon (adapted from DHSG, 2011).

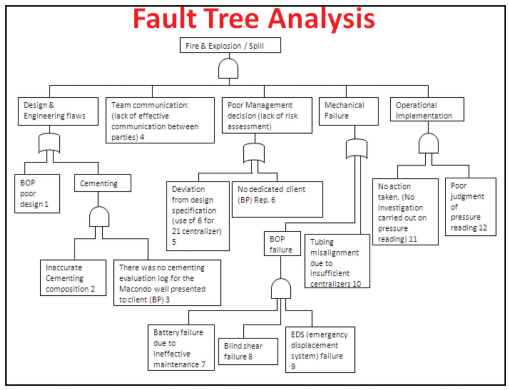

Figure 10. FTA for Deepwater Horizon.

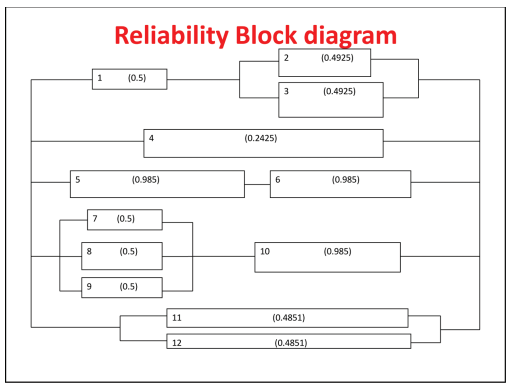

Figure 11. RBD for Deepwater Horizon.

4.2 *Lessons learned*

There was evidence of the following deficiencies in the management of the operation:

- Communication gap between parties.
- Non-compliance with design specification and procedures.
- Lack of peer review.
- Ineffective process safety management.
- Lack of monitoring and supervising operational team, from client to contractors.
- Disregard for team members' judgment.
- Insufficient organizational cultural change (from focus on cost saving to focus on ensuring safety).

Improvements needed:

- Full compliance to design specification and requirements (adequately centralized).
- More advanced BOP design.
- More effective communication.

– Establishment of on-going risk assessment procedures.
– Appointment of dedicated client representative.

5 FEEDBACK AND GENERIC LESSONS

Here the tutor (the author of the current work) offered feedback to the three student groups. This was intended to provide more insight into the accident—as an incident, as a company and as a culture—hence addressing both specific and wider generic lessons.

Each group produced a slightly different mental model, although each was exposed to the same narrative. The main differences were in the level of detail each group went into with respect to the FTA, and its use of qualitative analysis (the strength of Group 1) as opposed to its emphasis on quantitative modelling using FMEA (the strength of Group 2) and use of reliability calculations (the strength of Group 3). Nevertheless, on the whole, there were more agreements than otherwise between the findings of the groups.

The students were then directed to read a well balanced review of quantitative versus qualitative analysis of risk (Apostolakis 2004), and a good account of possible approaches for assessing and managing risks from extreme events (Bier et al. 1999).

It was also noticed that the RBDs of all three groups had an AND-gate at the top which signifying a parallel structure. As mentioned earlier, this implies the existence of a set of barriers that were all insufficient to prevent the disaster (as illustrated in the Swiss cheese model proposed by Reason (1997)).

As regards to specific regulatory lessons, the American regulatory agency of the industry—Minerals Management Service (MMS) had dual roles which can be seen as conflicting. On the one hand it had a role in promoting oil and gas leasing and collecting revenues, while on the other hand it acted as regulator and enforcer on the other (Flouron 2011). Since the accident the MMS dual functions have been separated.

In terms of BP as a company and culture the report by the Deepwater Horizon Study Group (DHSG 2011) conclude that this disaster also has eerie similarities to the BP Texas City refinery disaster as outlined in the BP Texas City report (2007). These similarities include:

a. multiple system operator malfunctions during a critical period in operations;
b. not following required or accepted operations guidelines (so-called "casual compliance");
c. neglected maintenance;
d. instrumentation that either did not work properly or whose data interpretation gave *false positives*;
e. inappropriate assessment and management of operations risks;
f. multiple operations conducted at critical times with unanticipated interactions;
g. inadequate communication between members of the operations groups;
h. unawareness of risks;
i. diversion of attention at critical times;
j. a culture with incentives that provided increases in productivity without commensurate increases in protection;
k. inappropriate cost and corner cutting;
l. lack of appropriate selection and training of personnel;
m. improper management of change (as outlined by the Baker Panel 2007 and Hopkins 2009).

The DHSG (2011) report also suggested that in both cases—Texas City and the Deepwater—meetings were held with operations personnel at the same time and place as the initial failures were developing. These meetings were intended to congratulate the operating crews and organizations for their excellent records for *worker safety*. Both of these disasters have served—as many others have served—to clearly show there are important differences between *worker safety* and *system safety*. One does not assure the other.

The DHSG (2011) report contains four strategic findings. Firstly, it warns about the apparent under-estimation of the hazard caused by the 'next generation' series of oil and gas exploration in the ultra-deep waters of the northern Gulf of Mexico. Secondly, it warns that the consequences of major offshore oil and gas system failures can be several orders of magnitude greater than those of previous generations of these activities, and that major developments are needed to address the consequences of major failures. Reliable systems are needed to enable effective and reliable containment and recovery of large releases of hydrocarbons in the marine environment. Thirdly, it suggests that strategies related to non-renewables as an energy source need to be re-examined. Fourthly, it encourages collaborative efforts in benchmarking best practice in safety.

It is clear from the analysis that the Deepwater Horizon operation had many lines of defence (safety barriers) that were breached. This view is supported by research on the Texas City refinery disaster report (Holmstrom et al. 2005) which identified several deficiencies in observability and diagnosability of the condition of safety barriers in the refinery's isomerisation unit.

Since safety barrier problems were common to both accidents, and both accidents are attributed to BP, students were then provided with some theory on safety barriers as regards their definition,

classification and performance (Sklet 2006 and Svenson 1991). For example, according to Svenson a safety barrier represents a function (and not for example an object) which can arrest the execution of the accident so that the next event in the accident chain is never realized, while a barrier system is maintains the barrier function.

Also as feedback, the students were exposed to some related industrial standards that address reduction of risk through safety barriers. For example, with respect to the concepts of risk prevention, control and mitigation, ISO:13702 (1991), a standard for the oil & gas industry) states that *prevention* means reduction of the likelihood of a hazardous event, *control* means limiting the extent and/or duration of a hazardous event to prevent escalation, while *mitigation* means reduction of the effects of a hazardous event. Hence, a barrier function is a one planned to prevent, control, or mitigate undesired events or accidents (Sklet 2006).

In another development regarding barriers related to software systems, Leveson (1995) distinguished between three types of barrier function: lockout, lockin and interlock. A lockout "prevents a dangerous event from occurring or prevents someone or something from entering a dangerous area or state", a lockin is "something that maintains a condition or preserves a system state", while an interlock serves "to enforce correct sequencing or to isolate two events in time".

As outlined by the Department of Environment (DOE, 1999), when analysing barriers in an accident investigation, the following topics need to be addressed:

1. barriers that were in place, and how they performed,
2. barriers that were in place but not used, and
3. barriers that were not in place but were required.

It is important that after their analysis of the deepwater event, students be made aware of the above theories regarding safety barriers. In this way they can better appreciate the relevance of these concepts.

The representation of nuclear power in cinema: The contribution of a filmic analysis to understanding the public debate

A. Portelli & C. Martin

ESAIP, Grasse, France

F. Guarnieri
CRC—MINES-ParisTech, Sophia Antipolis, France

ABSTRACT: Representations of the nuclear industry in European countries play a determining role in the public debate and the development of energy policies. Cinematic fiction as a media object contributes to our understanding of social reality and also exercises a major influence on public opinion, because of its ability to "colonize" awareness. The risk of nuclear conflict and the effects of radiation have inspired many filmmakers. However, there are far fewer films dedicated to the civilian use of nuclear power. Nevertheless, some notable works make it possible to investigate the topic through a focus on the relationship of man to their work in the sector, in particular the challenges of subcontracting maintenance activities, which is represented in terms of modern slavery.

The first part of this article outlines the methodology used to analyse how civilian nuclear power is represented in film. The second part puts the methodology into perspective and shows how workers in the sector are represented in a French film. Finally, the third part shows how this representation fits into the nuclear debate in France.

1 INTRODUCTION

Social representations encompasses concepts, beliefs, myths, objects or classes of individuals that appear as "shared cognitive schema that are developed by a group that allow its members to think, to represent the surrounding world and to orient and organise behaviour, often by prescribing or forbidding certain objects or practices" (Mannoni, 1998: 4). Not only can they represent a serious challenge, they can also be at the centre of controversy, such as that concerning nuclear technology (Martin *et al*., 2013). The representations that feed the public debate on nuclear power can thus have a significant impact on the development of energy policy. They can be examined through a wide variety of sources, such as photography, novels, newspaper articles and cartoons, advertising, televised debates, documentaries or cinematic fiction.

The theme of the radioactivity was initially addressed by filmmakers a few years before the Second World War. Many films were made, inspired by the destruction of Hiroshima and Nagasaki, and the subsequent tensions between the two superpowers during the Cold War. These films reflected the anxieties of the population, such as the risk of nuclear war, the destruction of humanity or mutations due to radiation. Representations of the nuclear apocalypse, which have been studied by researchers for many years (Puiseux, 1987) have fuelled the imagination of audiences and influenced their perception of nuclear technology.

However, there are far fewer films dedicated to civilian use of nuclear power. Nevertheless, a few works stand out, such as *The China Syndrome* (Bridges, 1979), the short film *Mont Fuji in Red* taken from *Dreams* (Kurosawa, 1990), *Land of Oblivion* (Boganim, 2012), *The Land of Hope* (Zion, 2012) and *Grand Central* (Zlotowski, 2013); the latter was shown at the Cannes Film Festival in 2013 in the *Un Certain Regard* category. This French film evokes, in the context of a romance, the relationship between a man and his work in the nuclear power industry; it specifically addresses the challenges of subcontracting, which is represented in terms of modern-day slavery (Fig. 1). Subcontractors intervene during scheduled power outages in order to undertake maintenance operations that are not carried out by the operator's employees.

The aim of our research is therefore to show how the film illustrates the power relationships that feed the debate on the nuclear industry and its extremely widespread practice of subcontracting in the sector. The first part of the article presents the methodology used to analyse the representations of nuclear power in film. The second part puts

Gary, the main character in *Grand Central*, has not completed his training as a boilermaker and has held down a series of temporary jobs, before becoming a subcontractor in the nuclear sector. The work is demanding and dangerous. The protagonist is integrated into a team of workers and has a secret relationship with Karole, the partner of his colleague Toni. He is slowly contaminated, by both love and radiation.

Figure 1. Summary of Grand Central.

the methodology into perspective and shows how the sector is represented in the film *Grand Central*. Finally, the third part illustrates how this representation fits into the public debate on nuclear energy in France.

2 ANALYSIS OF CINEMATIC REPRESENTATIONS

The issue of cinematic representations lies at the crossroads of filmic analysis and the social sciences. Our methodology is therefore the result of a (delicate) compromise between two disciplines that do not share the same background. Consequently, we must define the status of the filmic object. In the next step we demonstrate the relevance of the monographic approach to the study of the representation of civilian nuclear power, and we present our methodological framework.

2.1 *The status of the filmic object*

The question we seek to answer implies that the film is seen as a vector of representations that reflect the social reality which it forms part of. The researcher must therefore examine how the film restructures society in the form of entertainment, where the symbolism refers to the time it was made (Vanoye *et al*., 2001). Fiction, depending on its viewpoint, aligns itself with certain articulated and unarticulated practices and values (Ferro, 1993), which reflect a reconstructed world view. It is this ability to reinvent reality (rather than simply duplicate it) that enables the filmic object to become part of the development of social processes and influence, to a greater or lesser extent, the opinions and behaviour of the general public (Delage *et al*., 2004).

This approach requires a comparison of what is learned from the filmic analysis with its external sources. The first focuses on the description and interpretation of the fictional narrative and its audio-visual dimension, in which the analyst must remember that cinema is a collective art. In this context, the question of exactly who is the author of a film has given rise to an abundant literature, which shows that it is not the director alone. On the contrary, the film's author is considered as a "virtual meeting room" a "speaker" or the "subject of the filmic narrative" (Aumont *et al*., 2002: 13–14).

The cinema is also an industry, subject to economic and cultural considerations that affect production. A filmic analysis alone is therefore insufficient and must be supplemented by an external analysis that integrates the work into its production context. It is only with this condition in mind that the researcher can succeed in identifying the anchor points that connect the work of fiction to its place in social space-time.

The film is therefore defined as an object that is inseparable from the society that produces and watches it. Researchers can approach their work by focusing on significant sequences, or establish sets of themes. This choice not only depends on the research question; it is also determined by how the film itself is composed.

2.2 *The monographic analysis*

The corpus of films concerning the nuclear industry corpus consists of two sets. The first includes works of fiction where the part of the action takes place in a power station (*The China Syndrome*, *Grand Central*). The installation forms part of the scenery; work situations are recreated and the balance of power between the operator and workers is explored. The second set includes films that address the issue of nuclear power but do not take place inside a plant, which may be confined to the background (*Mount Fuji in Red, Land of Oblivion*, *The Land of Hope*). The operational and organizational dimension is neglected in favour of a description of the consequences of a nuclear disaster on man and the environment.

A study of the themes that are explored in these two sets makes it possible to put into perspective the representations they convey—the interior of the installation, the operator, the nuclear risk, etc. However this poses a significant problem for researchers: the corpus, at a national level, is insufficient to carry out an analysis. Given this situation, a thematic study must compare films from different countries and different eras. For example, it would lead to a comparison of an American film from 1979 (*The China Syndrome*) and a French film from 2013 (*Grand Central*). Under these conditions, it becomes difficult to contextualize representations, as they refer to different cultural objects.

On the other hand, the monograph invites the researcher to focus their efforts on a single film, which resolves contextual problems. Specifically, we chose *Grand Central* for two main reasons. It is the first French film to focus so closely on workers

in the nuclear sector, and second, its narrative is clearly centred on the relationship between the operator and subcontractors, which feeds the public debate on the sector. This work of fiction occupies an important place in the history of representations of the nuclear industry and clearly merits further analysis.

2.3 *Internal and external analysis*

For the internal analysis, the film must be considered from various angles, which correspond to the decomposition of its content. An internal analysis "does not consider the object (the film) in its entirety, but seeks to identify the various constituent components in order to identify organizational systems" (Journot, 2002: 6). The analysis begins by identifying the central plot themes, before dividing the film into sequences and describing the imagery and the soundtrack. The film cannot be studied in the same way as a novel as there are technical considerations which the analyst must identify and interpret. The objective is to formulate an explanation of the film, in other words to arrive at "an understanding of some of its *raisons d'être*" (Aumont *et al*., 2002: 6).

A sequence is a "series of scenes (or single scenes) that make up an individual or distinct piece of dramatic action" (Pinel, 2005: 365). *Grand Central* can be divided into 131 sequences. Most of them are diurnal (89) and filmed indoors (78). Our analysis is focused on sequences that address the nuclear industry (69). They concern segments where the work is mentioned but the installation does not appear onscreen, segments where the exterior of the plant is shown, and those where the action takes place in the facility. This brief description immediately highlights the importance of the relationship between the worker and the physical space in the film's narrative.

The external analysis takes a different point of view and focuses on the inspiration for the film—in terms of writing and filming—as well as sources generated by the film. The press pack provides valuable information about the project's genealogy, the documentation used in writing the script, shooting locations, the role of technicians, etc. However, as this is a communication tool used to promote the work the information it contains must be used with caution.

An evaluation of the film's reviews indicates how well it was received on theatrical release. One critical review describes the work as not only meeting "certain aesthetic criteria" (Journot, 2002: 30), but also as a system of representations around which a social consensus is formed. Consequently, this critique reveals certain connections between the film and public opinion and the ideas conveyed on the topic.

These connections are fed by multiple types of media. With respect to *Grand Central*, the post-Fukushima environment increased television and radio reporting of subcontracting. Similarly, newspaper articles addressed the issue of workers in the nuclear sector. An examination of these sources therefore serves, on the one hand, to contextualise the film, and on the other to determine how it fits into public debate on the sector.

These methodological details highlight the difficulty of linking internal and external analyses. Academic research can quickly lead to an overly mechanical cultural interpretation. In order to avoid this pitfall, external influences at the time when the sequences were filmed must be taken into account. The contextual analysis should not be seen as an alternative to the filmic analysis, but rather its endpoint.

The approach rests on a delicate balance between the two forms of analysis, which mean that the film is sufficiently contextualized but the key elements that are essential in order to understand it are not lost (Marie, 1992). Researchers are therefore limited to a form of internal-external compromise, and must be careful to avoid overly rigid causal links as "any hypotheses that are derived from a text remain hypothetical" (Jullier, 2013: 160). This suggestion is particularly applicable to the study of *Grand Central*, due to the complex relationships that link it to the debate on nuclear power.

3 THE IMAGE OF NUCLEAR POWER IN *GRAND CENTRAL*

This second section uses the methodology described above to examine how nuclear power is represented in *Grand Central*. First, it outlines the inspiration for the film, before showing how the plant, the work and subcontractors are presented.

3.1 *The film's inspiration*

The film's director Rebecca Zlotowski said in an interview that the concept for the film came from her co-writer Gaëlle Macé, who had read *La Centrale* (Filhol, 2010), which is a novel about subcontractors in the nuclear industry. Zlotowski became interested in a story that she considered to have "significant documentary rigour" and that was about "a completely fictional community". A former subcontractor and author of an essay on decontamination work (Debout, 2010) was hired as an adviser and participated at all stages of the making of the film. These details, extracted from the press pack, lend credit to the film and had a certain influence on its critical reception.

The director states she did not conceive of Grand Central as either pro- or anti-nuclear, "My film is political, it is not militant. (...) The description that I present leads to an observation and this observation may lead to further thought. But in no case was this critical reflection the inspiration for the story. (...) To describe this world, this marginalised community of social outcasts, who can be sacrificed, is a political process" (Nouchi, 2013). Although the argument is legitimate, the distinction between "politics" and "militancy" remains unclear. Zlotowski's attempt to clarify the question only emphasizes the ambiguity. The Fukushima accident, which occurred during the writing of the screenplay, had a determinant impact on the authors, "Dozens of articles were published in the press documenting the daily lives of nuclear workers who were sacrificed there, as in France, and this tragic coincidence made us sure that there was a good reason to write the script" (Press pack, 2013). The director therefore creates a link between the working conditions of subcontractors and nuclear disaster. However, this link is often repeated in the public debate to question the safety of facilities, and can become an argument in favour of a potential withdrawal from nuclear power. If *Grand Central*'s narrative is seen in the same vein as antinuclear activism, the film becomes very much a "political" object, although not in the sense that the director intended. The film's purported neutrality in the debate does not seem to hold true. The sequence analysis, in turn, tends to confirm this premise.

3.2 *The nuclear sector in images*

The representation of workers situates them in an imaginary space where the facility resembles a sacred place. Its cooling towers add to the aesthetic qualities and make us think of the bell towers of a cathedral, containing a mysterious power. They appear repeatedly, either in the background as visual elements of the landscape or as inserts, where they dominate the scene. These images represent the "nuclear brand", as the narrator says in the novel (Filhol, 2010: 25). The sacredness of the plant is again suggested when the main character first discovers the Cruas facility. The scene is shot from inside the plant. The door opens and the team leader enters first. He is followed by the others, while the door rumbles closed, as if the characters were entering an inner sanctum. The locker room is like a sacristy, where subcontractors get changed before entering the reactor to commune with the atom. The blue light emanating from the reactor's "choir" clearly represents the symbolism of this space where the profane are not allowed to enter—only the most experienced subcontractor is allowed to approach it. The sacred note, which is reflected in both the architecture and work processes (Bergé, 2010), therefore finds its place in the collective imagination related to the history of nuclear energy, which emerged from the development of the first French nuclear power centres (Hecht, 2004).

Subcontractors are proud to work in the sector. They value their profession, which requires motivation, concentration and a high level of precision. The team leader explains that the work is demanding, "If you do it, you do it well. You must be good, you must be capable". The film therefore portrays the characters as unsung heroes who are working for the public good. One of them makes it clear, "We bring light to the people!"

The industry's profit imperatives severely test worker's motivation and tend to the dehumanization of the job. A rapid recruitment process, a few days of training in radioprotection and a routine medical visit are the main character's introduction to the world of subcontracting. These steps are treated as mere formalities, and hiring procedures are immediately discredited. This representation also features in the novel, which compares the training of subcontractors to the training of young recruits in the Great War, "I was the one that trained the back of the front, lectures on theory, then ten days practice in the school yard, ten days made eight at the height of the offensive when we accelerated the training of recruits so that they were available as quickly as possible—after all, what was the point of investing any more time and money in people we knew would have a short career?" (Filhol, 2010: 18).

The film therefore treats the work of subcontractors as a struggle against radiation exposure. Their interventions are compared to a battle with a "colourless, odourless, invisible" enemy. In one sequence, workers wait in silence for the moment when they can enter the red zone. The team leader gives the signal and puts on his mask, quickly followed by the others. Time is suspended and the subcontractors seem to be preparing to mount an assault, as if in a war film.

Animal metaphors express the real danger of this confrontation. The protagonist rides a mechanical bull; in the same way workers try to tame the atom. The crocodile, seen during a visit to the zoo is as devious as radiation. It can sit still for hours in order to improve its chances of surprising its prey.

The films imagery highlights the solidarity between men who must face the risk of contamination. The team leader encourages the social relationships based on the value of sharing. He severely chastises the main character when he drinks all the water in the communal bottle. The team leader takes collective and equal responsibility for any mistakes, "Here it is nobody's fault, it's everyone's fault!" Subcontractors feel that

they belong to the same world, which is characterized by working and living conditions that seem to come from a bygone era. This class consciousness was highlighted by *Grand Central*'s technical advisor, who thinks that subcontractors are part of a large family, "They find themselves living in the same places: camping sites, hostels. They share the same worries about lack of security, separation from their families, the same risks, the same doubts, which brings them even closer together" (Press pack, 2013). In effect, the characters live in their own world, on the outskirts of the plant in cramped and uncomfortable mobile homes. Promiscuity cannot be avoided and the community likes to gather in the evening or for picnics in the countryside.

These very tight social relationships help the nuclear sector lumpenproletariat to endure the operator's domination. The film represents the relationship between the workers and the organization in a particularly distinctive dialectic: one car park is reserved for the "aristocrats" (employees of the operator) and another is for the "galley slaves" (the subcontractors). The team leader stipulates the privileges granted to the most important workers: lower exposure to radiation, better wages, a coffee machine, free electricity. The camera follows the characters as they leave the plant and head to their cars. The car park for the operator's employees remains off-screen, as if it is a place that is off-limits to subcontractors.

Domination is also takes the form of a sequence about decontamination. A female subcontractor is shot from behind, standing naked. Her face is not shown, which emphasises the anonymous nature of the operation, and she is cleaned with a water jet, which immediately suggests a prison environment. Radiation detectors indicate that young woman's hair is contaminated. She turns her head twice towards the radiation protection officers that stand round her. They decide to shave her head. Handfuls of hair are shown falling onto her legs. A close-up then shows the character's face; she is crying. The officer, who is partially out of the shot, carelessly shaves the woman's head. The physical assault evokes the idea of the concentration camp and the depersonalisation of workers.

A reduction in long-term outages increases not only tensions between the subcontractors, but also the accident rate. An intervention goes wrong and the main character is contaminated. During the medical examination, the doctor tells him that he must now work in the green zone. If he receives further exposure to radiation he will either be made unemployed for technical reasons, or sent to another site. The subcontractor refuses to accept the second option. The sequence continues silently as follows: the protagonist goes to the green zone and puts on his helmet. He then appears in the locker room, checking his dosimeter. The doctor (off camera) announces that he is now "suspended". In the film the operator is shown to fail to take responsibility for the health risks that the worker is exposed to and gets rid of him as soon as he becomes useless. The following sequence alternates between the young man and his lover, each in their respective locker rooms. The subcontractor asks, "What if I want to stay?" He does not receive any response. This decision on the part of the director lends a particular meaning to the sequence. The character approaches a stack of cylinders and hides his dosimeter, before recovering it at the end of the day. Consequently, the doctor's failure to answer can be interpreted as an incentive to circumvent regulations and behave irresponsibly, in contravention of any professional ethics.

The film therefore emphasizes the precarious situation of the subcontractor and the master-servant relationship between him and the operator. The latter takes advantage of the worker's lack of qualifications, deliberately puts his health at risk and does not acknowledge his contribution in any way. The characters' working and living conditions lead to individual and collective dramas: one worker becomes sterile, the team leader separates from his wife and no longer sees his children, some are contaminated, while the group gradually disintegrates. This representation of workers demonstrates the challenges of the debate on subcontracting, which itself is a controversy that is intrinsically linked to the development of nuclear technology (Boudia, 2007).

4 THE ROLE OF CINEMA IN PUBLIC DEBATE ON NUCLEAR POWER

This final section discusses how the narrative of *Grand Central* fits into public debate on the sector. An analysis of its critical reviews makes it possible to determine, aside from its aesthetic value, how credible the representation of nuclear power is. The reaction of the press, as much as the film itself, forms part of a broader network of representations of civilian nuclear power. Consequently, it appears to be difficult to challenge the narrative of *Grand Central*, as it seems off-limits for sociological, scientific and moral reasons. Nevertheless, there are other ways to view subcontractors and their relationships with operators.

4.1 *The critical reception of Grand Central*

The film received many positive reviews, both in the press and in specialised journals. These highlighted its intelligence and realism (Mandelbaum, 2103), its coherent aesthetic choices (Narbonne, 2013), the script's rigor (Ferenczi, 2013) and the actors'

talent (Raspiengeas, 2013). There were only a few unfavourable reviews, which focussed on the schematic plot, and suggested that the film was a half-incarnated "world of ideas" (Ferenczi & Strauss, 2013; Gester, 2013). While the harshest critics judged the narrative to be unconvincing, none questioned the way the industry was represented.

The plant is associated with several levels of symbolism. It is compared with a "nuclear hell" (Sotinel, 2013; Narbonne, 2013), an "evil stomach" or a "toxic bath" (Kaganski, 2013) in which workers are immersed. The reactors are seen as "modern mines" (*Le Parisien*, 2013) and the atmosphere of the facility is described as "prisonlike" (Delcroix, 2013). Such terminology dramatizes the workspace, which becomes a place of suffering and alienation for workers who are "dogsbodies" (Ferenczi, 2013).

The precarious situation of the characters caught the critics attention, who used very strong language. Subcontractors were described as outcasts, the underclass, the walking dead. They are a shadow proletariat, a small tribe of untouchables who live in a world without hope. Workers are represented as convicts, "In their own way, they spend their time breaking stones waiting for their release from prison. They wear their dosimonitors like chains, to calculate their degree of irradiation" (Delcroix, 2013). The representation of nuclear sector workers is said to be all the more fascinating as it is far removed from "the neat official image of engineers and highly qualified technicians that is so often conveyed" (Lacomme, 2013).

As one, critics noted the documentary nature of the film. The scenes showing the apprenticeship seem "larger than life" (Ferenzi, 2103). The narrative "places each protagonist and situation in a specific professional context, indicative of current socio-economic reality" (De Bruyn, 2013). This almost documentary-like immersion demonstrates to the pubic "the reality" of workers in the nuclear sector (Bernheim, 2013).

These analyses are interesting for several reasons. First they make it possible to identify the points where the fictional story corresponds to other representations of nuclear power. Comments about the film find similarities with the pessimism of Emile Zola's novel Germinal, to describe a new form of servitude through work.

Moreover, by giving the film documentary value, critics crystallize representations on the precarious nature of subcontracting in the nuclear power sector.

4.2 *Contextualization of the film in the public debate*

The debate on nuclear energy concerns questions about its impact on public health and the environment, lack of transparency and democratic dialogue, the safety of installations, the risk of proliferation, waste management, profitability and the cost of dismantling (Barré *et al*., 2013). The Fukushima accident revived media interest in safety issues in France, which was closely linked to the debate on subcontracting. The real nature of the power relationships between operating companies and subcontractors are understood by researchers (Thébaud-Mony, 2000). Furthermore, the idea of the subordinate subcontractor is not specific to the nuclear sector, and authors have examined the risks of subcontracting in other sectors (Mayhew & Quinlan, 1997).

The reasons for the use of subcontractors are at the heart of the controversy and are frequently cited by the media. The most common argument is without doubt the profitability imperative, which forces the operator to limit the duration of power outages and to use a cascade of subcontractors (Fayner, 2012). The outsourcing of health risks is a secondary argument: the health of workers is not given much weight and they are not under medical supervision, while the nuclear lobby refuses to recognize occupational cancers linked to ionizing radiation (Nicolas, 2013).

Another problem is the transmission of knowledge. This knowledge is lost as workers retire and subcontractors must train themselves on the job. The loss of continuity increases the potential for an accident, as "nothing can replace the memory and experience of workers who knew the installation" (Thébaud-Mony in Pascariello, 2011).

Finally, the acceleration in the pace of work due to the optimization of long-term outages (Gérard, 2011), increased levels of stress, the arduous nature of the work (Weiler, 2010) and loss of skills (Auffray, 2011) are seen as factors that threaten the safety of the facility and personnel. The narrative of *Grand Central* is consistent with this system of representations. Consequently, the film reflects the popular image of the sector presented in the media, which leaves little room for an alternative narrative.

4.3 *Factors that discourage discussion*

The visible part of a society consists of both the images producers broadcast and what audiences expect to see (Sorlin, 1977). In the context of our analysis, the subcontractor is only observed (and observable) in terms of insecurity and danger. Why is it therefore so difficult to develop an alternative representation and to criticize the film's medium? First, we must reformulate how modern society thinks about subcontracting. The transition to modernity is defined by a loss of confidence in technology and expertise. This discredit leads the

population to feel vulnerable, a sentiment that is amplified by the globalization of risks and the hypermediatisation of technological accidents. Consequently, the idea that science enables social progress has been called into question since the mid-1960s. It was in this context that civilian nuclear power became uncoupled from the idea of progress (Topçu, 2006). Since then, its detractors have associated it with counter-productivity at all levels. The nuclear disasters at Three Mile Island, Chernobyl and Fukushima crystallized this representation in the media, which structures the dissemination of information and influences civil society. However, this is only possible so long as the media makes clear its independence from the official line. This configuration of the public space, where the idea of a "nucleocracy" (a term coined to describe a mode of techno-political governance that combines various actors and pressure groups) has naturally tended to discredit arguments about power. Therefore, the media is obliged to criticise the nuclear sector in order to demonstrate its independence and usefulness.

The issue of subcontracting also highlights a problem linked to the accessibility of sources. The subject has received little attention from academics because of security issues related to nuclear energy and a lack of interest from social scientists in blue-collar workers. "In these conditions where it is difficult to access the situation on the ground, it is not surprising that journalists' treatment of the nuclear industry is confined to current concerns in all forms of televised news" (Fournier, 2012). This situation clearly limits the diversity of viewpoints.

One last factor explains the difficulty of criticizing the image of the subcontractor presented in *Grand Central*. The link that is made between work and social distress is what could be termed an "untouchable" representation. Developed societies are uncomfortable when faced with poverty, which is approached with great caution by the media. Calling into question the film's narrative could therefore be seen as an unacceptable attempt to justify the exploitation of the weak by the strong.

However, there are other potential representations that do not diminish the dignity of workers in the nuclear sector. In fact, the subcontractors depicted in *Grand Central* do not seem to be representative of this type of worker. While the film's bias helps to nourish the image of nuclear power in the popular imagination, it does not acknowledge the professionalism of subcontractors. It is clear that there is a part of the labour force in the nuclear sector that leads a precarious existence, and questions can be asked about why operators find it necessary to subcontract 80% of maintenance activities. However, the debate cannot be simply reduced to calling 20,000 subcontractors nomadic workers who are overexposed to radiation for the sake of economic efficiency. Subcontracting activities are many and varied, and while the lives of some workers are made precarious due to the nature of the contracts between operators and subcontracting companies (the social conflicts experienced by plants are witness to this), a large majority of subcontractors are employed in stable, long-term contracts.

The film does not mention the role of trade unions in the organization of nuclear industry workers. On the one hand, many workers are confident of their abilities and their professional identity, while on the other hand the distinction between employees of the operator and subcontractors is not entirely clear. Proof of this fact is found in real life, in the joint unionisation of the employees of the operator and subcontractors at the Cruas plant—precisely where the film's action is supposed to have taken place. Teams work together and the operator's employees are highly dependent on the skills of subcontractors. For example during delicate and complex cleaning and dismantling operations, contractors are clearly the experts and owners of the know-how. Such situations provide a less schematic image of subcontracting and open up perspectives that are more in line with the reality on the ground.

5 CONCLUSION

The presentation of the nuclear sector in *Grand Central* has attracted the attention of social scientists. The views presented in the film are indicative of current challenges in the public debate. They translate, starting with the description of subcontractors, concerns about working conditions in the sector and the security of French nuclear power plants. It is clearly essential, in the context of the post-Fukushima public debate, to examine the daily lives of subcontractors and once again question the human cost of energy. In this respect, Zlotowski's film contributes to the debate and provides a skilful look at aspects of the sector that are unknown to the general public.

In contrast, the relations between subcontractors and operators must also be analysed (and consequently be represented) in terms of joint operations. Interactions between subcontractors and operators are not based on simple dependency relations, but on strategies that lead to alliances (Martin *et al.*, 2012). This shows that it is necessary to investigate, rethink and eventually make visible the entire set of power struggles and relationships.

K. Kirytopoulos
School of Natural and Built Environments, Barbara Hardy Institute, University of South Australia, Adelaide, Australia

ABSTRACT: This paper's goal is to assist in road tunnel safety, providing a set of educational scenarios that incorporate the best practices regarding the use of unidirectional road tunnels. The scenarios point out the basic guidelines of driving behaviour that a tunnel user should maintain and the proper responses of the user in case of an incident. Ten UML diagrams were constructed, in order to depict the basic interactions of the tunnel user within the environment of a road tunnel.

1 INTRODUCTION

Road tunnels are a critical part of the transportation infrastructure because their use is beneficial to almost every national and international highway. The fact that they facilitate highway communication and trade, combined with the decreasing construction cost, which is the outcome of the evolution of the construction technology, has led to the increased use of road tunnels in Europe in the last years.

However, increased use of road tunnels is raising safety concerns. Accidents in road tunnels may result in severe damages to the transportation network and in the loss of human lives. Taking into account the major road tunnel accidents that took place towards the end of the twentieth century there is an on-going effort to improve safety conditions (Kirytopoulos et al., 2010).

In most countries, there are increased safety measures regarding the construction and the operation of road tunnels. Establishing new technical standards that implement more advanced technology and improving the emergency facilities are the most common measures to ensure higher levels of safety in road tunnels.

Despite the efforts made, there still remains the issue of the drivers' behaviour when they have to use a road tunnel, especially when critical conditions exist. Recent studies have shown that there is lack of education among drivers when it comes to road tunnels (PIARC, 2011). The issue is mainly addressed to by professional organizations, while scientific literature is scarce.

Human factor being pivotal to the outcome of an emergency situation, the issue of tunnel users' education demands more attention (Tesson, 2009; PIARC, 2008). The better a tunnel user is informed, the more are the chances to reduce the possibility of an accident, as well as to mitigate the consequences, if the accident eventually occurs.

For the purpose of this study a total of ten educational scenarios were constructed and three of those are presented in this paper. The scenarios were modelled in order to facilitate the development of an educational software application, which is the long term goal of this research.

2 EDUCATING USERS IN ROAD TUNNEL SAFETY

2.1 *Tunnel users*

The need for increasing the effort on educating tunnel users became a central issue of tunnel safety, because a series of events revealed that their behaviour inside road tunnels did not match the expected, as determined by international organizations (Tesson et al., 2012).

Bringing tunnel users' education up to the desired standards is not an easy task. Several attempts have been made in order to study the behaviour of drivers when they are using a road tunnel, and the results show that drivers adopt a negative perception of tunnels. Drivers tend to feel anxious and uncomfortable, a fact that is mainly caused by the confined space but can also be attributed to the drivers being unfamiliar with the road tunnels' environment (Amundsen, 1994; Serrano & Blennemann, 1992; Arias et al., 2008).

The most important part of the education that tunnel users should receive is pointing out the main

differences between road tunnels and open highways and the expected behaviour on their part.

The role of the tunnel operator is a critical factor that many tunnel users do not take into account. The tunnel users should be informed that many of the tunnels' safety systems and signs are controlled by an operator, and they should at any time follow the operator's instructions. When information or instruction are being provided through the tunnel's radio frequency, the tunnel's loudspeakers or there is a change in traffic lights, variable speed limit signs or the tunnel's closure system, the tunnel users should respond without hesitation (Papaioannou & Georgiou, 2003).

Many tunnel users are not informed about the road tunnels infrastructure and equipment. One of the major issues of the tunnel users' education is to make it clear that when driving through a road tunnel the user should pay attention to the location of emergency equipment, emergency exits, emergency phones and emergency stop areas. This behaviour might become extremely important when a tunnel user is involved in a critical incident, because at that point there might not be enough time to locate the necessary equipment. It should be pointed out that all the safety equipment and infrastructure of a road tunnel is highlighted with the corresponding signs (PIARC, 2011; Tesson, 2009).

Furthermore, tunnel users often seem to be unfamiliar with basic traffic rules inside a tunnel. Avoiding U-turns and reverse movement, switching on the headlights and taking off their sunglasses, are some of the most important rules that drivers do not comply with.

The most important issue of tunnel safety is the development of fire inside a road tunnel. Unfortunately, this is one of the most difficult issues to educate tunnel users on. The series of actions when encountering fire in a road tunnel should consist to instructing tunnel users to guide themselves to safety as soon as possible using an emergency exit. There are also several useful actions that a tunnel user should perform in order to assist the operator in case of fire. It would be useful to report the fire to the tunnel operator and enable the tunnel's fire alarm as soon as possible. It would also be critical to try and extinguish the fire if it is possible. These actions should only be performed if the tunnel user is well prepared to manage the fire and only if the fire is at a starting stage (Carvel & Beard, 2005; Gandit et al., 2009; PIARC & ITA, 2004). It should be taken into account that the impact of the psychological factor on the reactions of the tunnel users is pivotal. Although human reaction in stressful situations is uncertain, it is considered that being educated on safety issues, tunnel users can improve their reactions when an unexpected incident occurs (Canter, 1980; Papaioannou & Georgiou, 2003; Reisser-Weston, 1996).

2.2 *Educational scenarios*

With the aim of achieving better results regarding the education of tunnel users, it is essential to provide a theoretical structure of the educational process. Creating an educational scenario requires the specification of the conditions and the activities that have to be performed to enable the learners to acquire the desired knowledge (Koper & Olivier, 2003; Lejeune & Pernin, 2004). The aim of this research is to produce an online educational tool for the education of the users of uni-directional tunnels. The structure of this tool will be based on educational scenarios that incorporate the basic guidelines for proper behaviour inside a road tunnel, as they derive by the existing literature and the existing researches of professional organizations.

In order to create a proper educational scenario, various aspects of the educational process should be taken into account. At first it is essential to determine the main aim of the educational process, along with the set of relevant information. An important part of the educational scenario is the assignment of roles. The role is characterised by the requirements that each participant has to comply with throughout the process, and the set of actions that should be performed. Two other factors that should be taken into account are the stages of the process and the environment in which it takes place. The distinction between the stages of the educational scenario is critical in the manner that as the process advances there are changes on the main scenario, and during the latter stages of the educational process more complicated issues have to be addressed. Describing the educational environment, means providing information on the conditions under which the educational process takes place, and determining the use of educational aids. In some cases, usually when the educational process is interactive, special guidelines are provided to the participants determining the way they should react on specific circumstances. These guidelines should also be part of the educational scenario (Koper, 2005).

Determining and designing the environment in which the educational activities take place is a complex task. In order to support this task the use of modelling languages is proposed. Modelling languages provide the notations that enable the designers to overcome the complexity of educational scenario design and create a visual model of the described process. The use of modelling languages for educational scenarios is gaining more attention in the last few years because of the increasing use

of e-learning and other forms of computer aided education (Derntl & Hummel, 2005).

3 RESEARCH METHOD

In order to create and model the educational scenarios and develop the corresponding diagrams, it was necessary conduct a scientific literature review, as well as explore professional organizations' relevant research. Doing this revealed the basic information about the good practices of unidirectional road tunnel users. This is how the basic aspects of the scenarios were determined.

Furthermore, there was the need to research the field of educational design, for the purpose of acquiring valid information about the structure and the components of an educational scenario. Based on the literature on educational design, it proved to be essential to model the educational scenarios using a standardised modelling language.

The language that was used is UML (Unified Modelling Language), a standardised general purpose, object oriented modelling language. Using UML provided the ability of reviewing the scenarios, to emphasizing on specific elements and components, and focusing on different aspects of the scenarios according to the needs. Taking into account that UML was primarily designed for use in the fields of software engineering, the research aim of creating the design of an educational software application is facilitated (Fowler, 2004; Rumbaugh et al., 1999).

4 EDUCATIONAL SCENARIOS FOR INCREASING SAFETY OF ROAD TUNNEL USERS

In order to describe the basic guidelines that a road tunnel user should follow, a series of scenarios were constructed and represented in the respective UML diagrams. The scenarios provide a description of the proposed course of action when the tunnel user is presented with specific events inside a road tunnel. The scenarios are summarized in ten use cases (Fig. 1):

- Approaching a road tunnel.
- Driving through a road tunnel.
- Immobilising the tunnel user's vehicle.
- Vehicle malfunction or collision.
- Communication with Tunnel Operator.
- Emergency exit.
- Managing fire in tunnel user's vehicle.
- Managing fire in another vehicle.

Due to space limitation, only the sequence diagrams of the "Driving through a road tunnel",

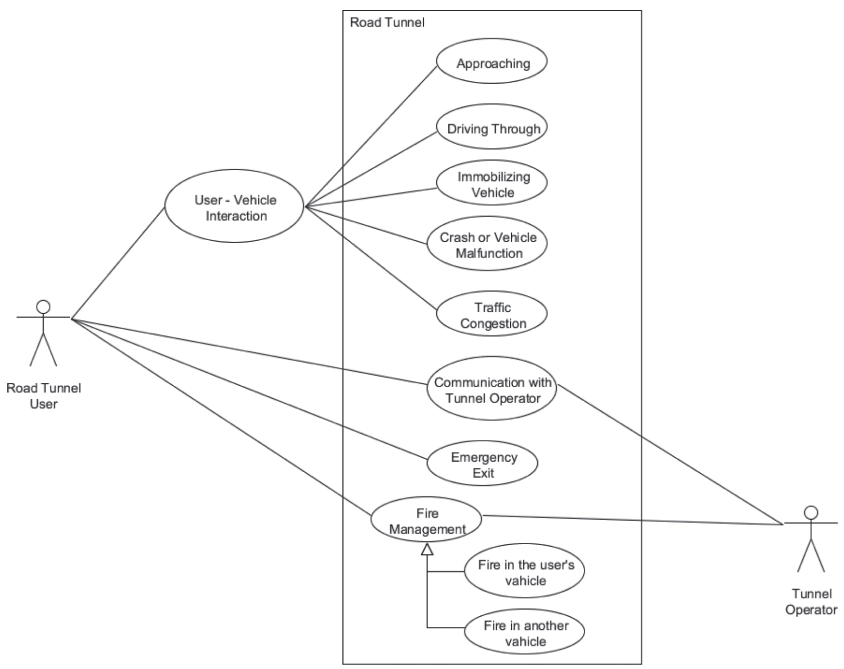

Figure 1. Use case diagram of the tunnel user's interactions.

"Emergency exit" and "Communication with Tunnel Operator" use cases are presented here.

In these use cases the actors are the tunnel user and the tunnel operator. Tunnel user interacts with the use cases either directly or through the interaction of the vehicle, while tunnel operator is in all cases directly interacting. The main focus of the study being the tunnel user, the role of the tunnel operator is secondary and only the interacions of the communication among the operator and the user are depicted.

4.1 *Driving through a road tunnel*

This use case depicts the series of actions that a tunnel user is expected to perform, after entering a road tunnel and until exiting. The sequence diagram developed (Fig. 2) describes

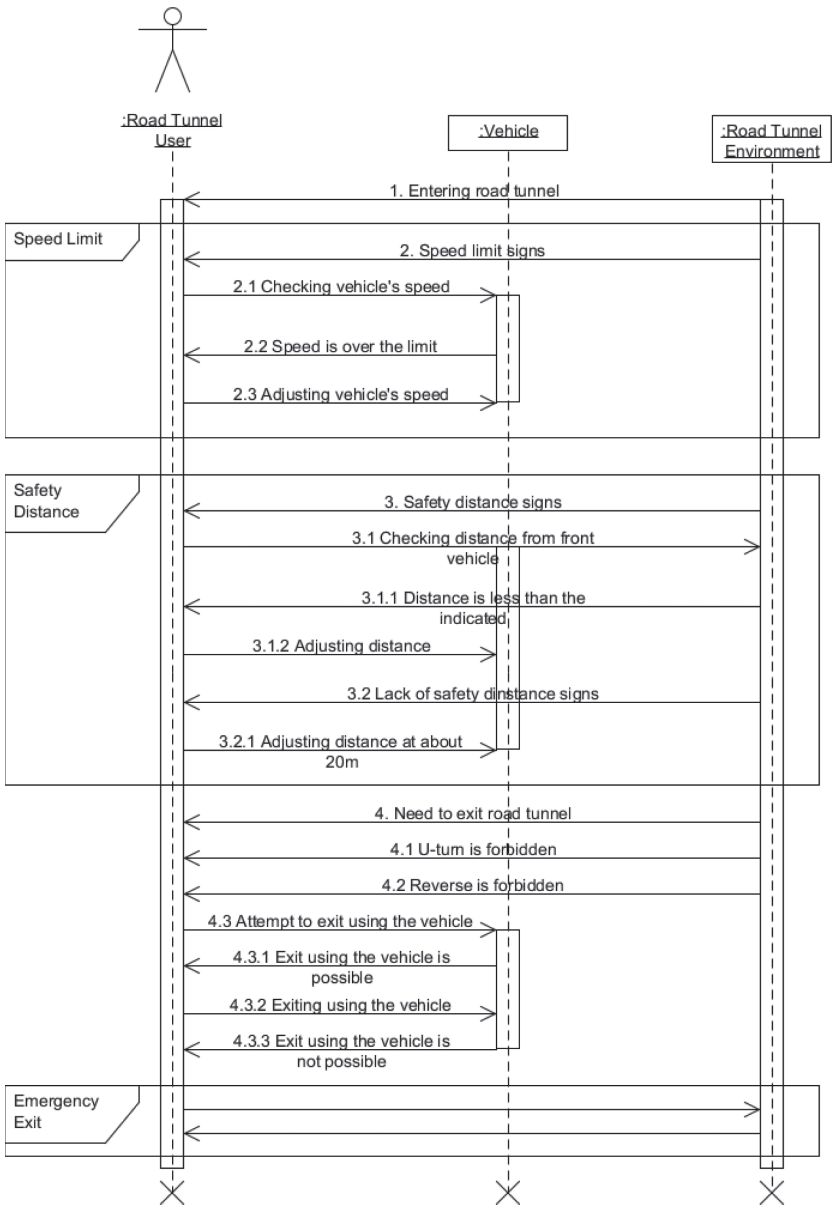

Figure 2. Sequence diagram of "Driving through" use case.

the expected actions, both in normal and critical conditions.

When a tunnel user enters the road tunnel, the priority is to maintain the vehicles speed, under the speed limit that is applied inside the road tunnel. The tunnel user should notice the speed limit signs and make sure that the vehicle's speed is not exceeding this limit. If the limit is indeed exceeded, then the vehicle should be slowed down to the desired speed, making sure that there will not be an abrupt change of the vehicle's speed that could endanger the tunnel users' safety.

The second point of interest is the maintained distance to the preceding vehicle. In road tunnels there might be limitations on the distance between moving vehicles, different than those on a freeway. Tunnel user should notice the corresponding traffic signs, and adjust the distance to at least match the indicated. Even if there are no signs concerning safety distance or the driver fails to locate them, the distance between two vehicles should not be less than twenty meters.

When the need to exit the road tunnel occurs, tunnel users should first attempt to exit using the vehicle. If this is not possible, the tunnel user should leave the vehicle and move to an emergency exit on foot. In all cases tunnel users should keep in mind that U-turns as well as moving in reverse should not be attempted inside a uni-direction road tunnel.

4.2 *Emergency exit*

In the case that the need to immediately exit the tunnel arises, the tunnel user and the tunnel operator are expected to act in a specific manner. The actions they should perform are described by the "Emergency exit" use case (Fig. 3).

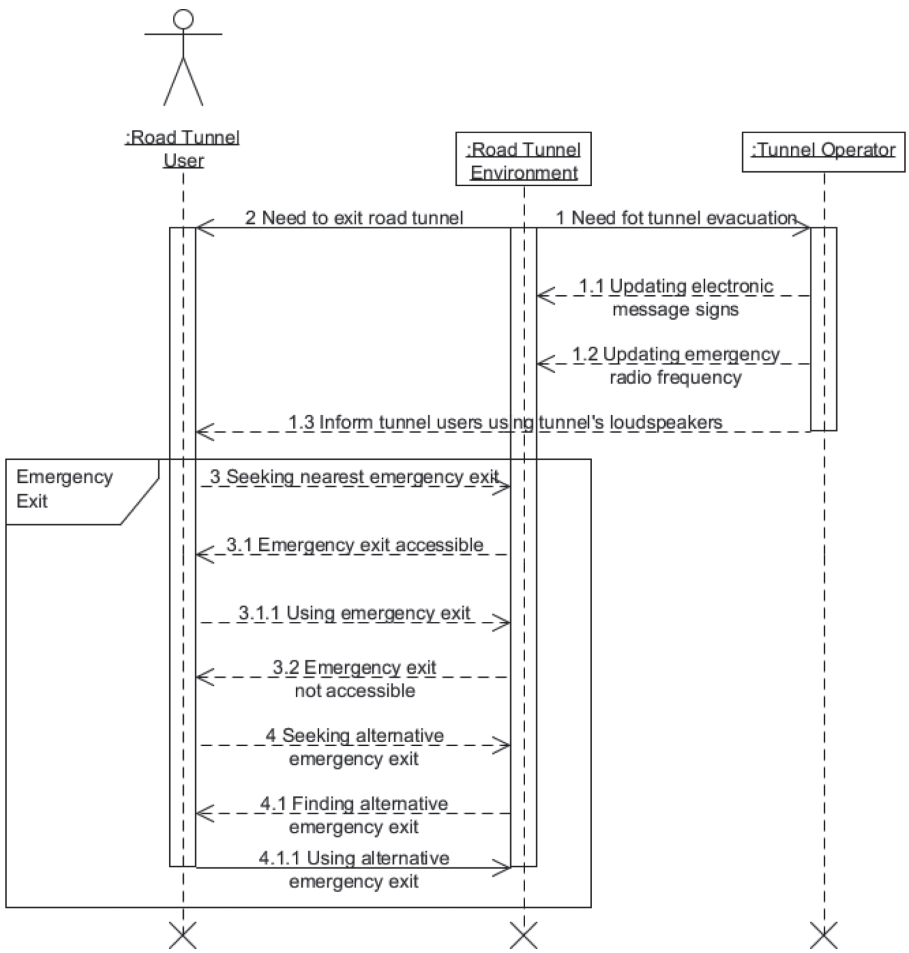

Figure 3. Sequence diagram of "Emergency exit" use case.

When the tunnel operator, based on the situation inside the tunnel, decides that there is the need to evacuate the tunnel, the primary priority is to notify the tunnel users. To achieve that, the tunnel's infrastructure should be used. The messages that are displayed on the electronic message sings and the emergency radio frequency should be updated in accordance to the situation and the tunnel's loudspeakers should provide information and directions to the tunnel users.

As soon as the tunnel user perceives the need to evacuate, the proper reaction is to seek for the nearest emergency exit and use it, if it is accessible. Otherwise, seeking for an accessible emergency

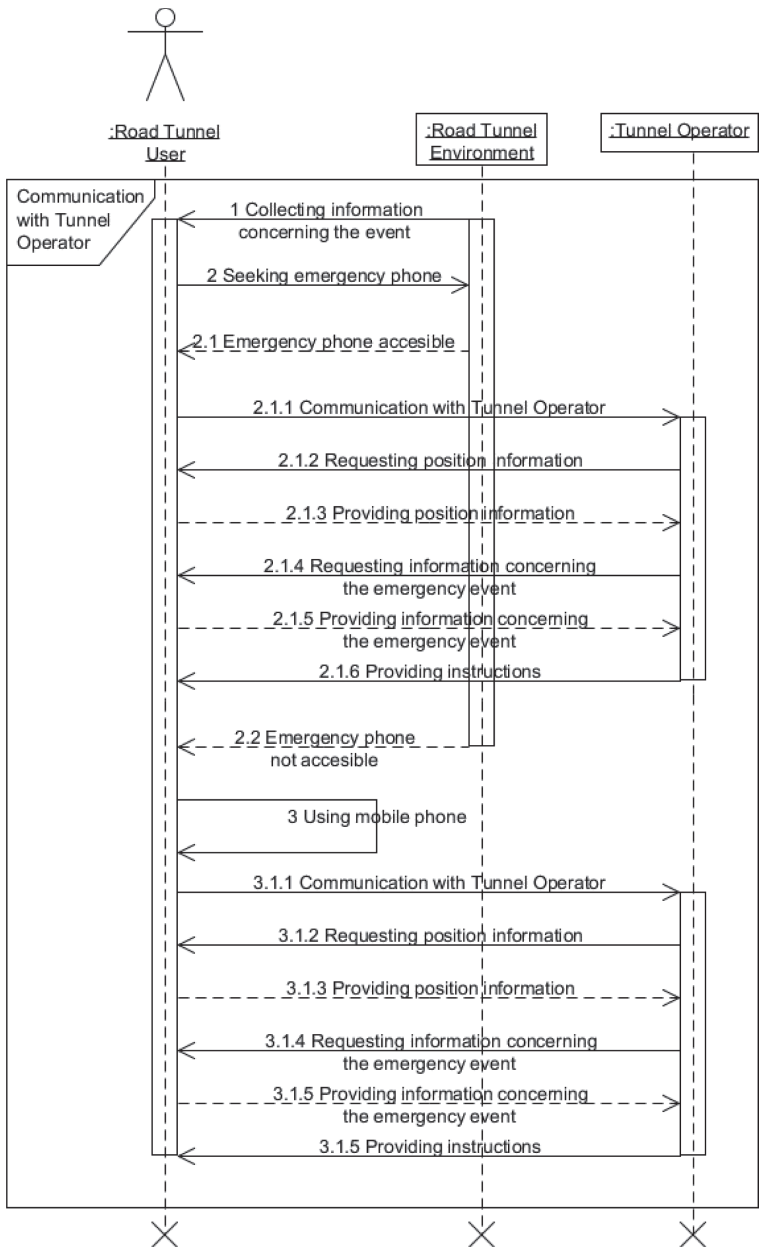

Figure 4. Sequence diagram of "Communication with tunnel operator" use case.

exit, while moving away from danger, is the proper reaction.

4.3 *Communication with tunnel operator*

When a tunnel user observes any irregularity inside a road tunnel, it is necessary to inform the tunnel operator of the situation. For this action to be helpful, there are specific requirements and priorities that the tunnel user should follow. The sequence diagram that describes the use case of "communication with tunnel operator" (Fig. 4), is presenting the course of actions that comply with those requirements.

Before communicating with the tunnel operator, the tunnel user should be prepared by gathering information about the event that needs to be reported. Being able to describe the exact position of the event, the existence of fire or injured people and the involvement of vehicles carrying dangerous goods is significant when reporting an incident.

The tunnel user should use the closest accessible emergency phone and only if this is not an option a mobile phone should be used.

Regardless of the means of communication used, after the tunnel user provides the operator with all the details that are need, the tunnel operator will instruct the user for the appropriate response to that specific situation.

5 CONCLUSIONS

5.1 *Practical implications*

When it comes to road tunnel safety, the human factor is critical. The course of actions that a tunnel user will chose to follow under normal condition may make the difference between avoiding an accident and provoking one. In the same manner the tunnel users' reactions under critical conditions can determine the outcome of the situation. Proper education of drivers for the use of road tunnels is pivotal to their reactions and has a great impact on the safety of themselves and the other users of the tunnel.

For the purpose of minimising the hazards that are results of erroneous human behaviour, a structured educational process is necessary. Although it is known that the human factor is unpredictable in critical situations, the probability of a proper reaction increases if the tunnel users have received better education and training. Throughout the education and training process, tunnel users should familiarise themselves with an otherwise strange environment (i.e. the road tunnel). Apart from basic rules and guidelines, the tunnel user should be able to react in a proper manner even in more complicated circumstances. Recognising the circumstances under which a reaction is called for and being able to remain patient under critical conditions is one of the main goals of the tunnel user's education.

The educational scenarios that were developed as part of this research address this issue. Providing tunnel users with information about events that might occur inside a unidirectional road tunnel and the good practices when confronting such events is of key importance to their education. By being able to identify which course of actions is needed in any incident that might take place inside a road tunnel, a well-trained user will be able to respond safely an also be an example for other users to follow.

In practice, these scenarios can be the base of a complete educational process and assist in the effort of increasing tunnel safety by improving the users' reactions.

5.2 *Further research*

Constructing and modelling educational scenarios that describe the proper behaviour and actions of a tunnel user, is the first step of creating an educational software application. These scenarios will be incorporated into the application, where the user will be asked to follow the provided instructions while interacting with a road tunnel environment. The scenarios will be tested on groups of drivers in order to provide feedback for the improvement and expansion of the educational tool.

Other aspects of further research include the effort to model the physical and environmental processes inside road tunnels with the aim of facilitating the decision making process in emergency situations. The application of these models may result in an online tool for mobile phones that will receive information from the tunnel users and the tunnel environment. This information can then be used as input for the operating centre's decision making system, and allow the operator to guide tunnel users to safety, through an interactive process.

ACKNOWLEDGEMENTS

This research has been co-financed by the European Union and Greek national funds through the Operational Program "Competitiveness and Entrepreneurship" of the National Strategic Reference Framework—Research Funding Program: Support of SME clusters for Research & Technological Development activities.

This research has been undertaken by the companies SIEBEN, Mediacape and SYNERGEIA with the National Technical University of Athens as a scientific consultant-subcontractor.

ABSTRACT: The safety conditions regarding an emergency evacuation of the building of the Faculty of Letters, University of Lisbon, were investigated. Some traps inside the building were found and thus a group of researchers created their own emergency plan. The plan includes escape routes and a meeting point outside of the building. The goals of this experience were to test the emergency plan by conducting a pilot-evacuation exercise and also to analyze the behavior of the participants. In fact, this was the first time such an emergency evacuation exercise was performed at the Lisbon University main campus. The findings of this study raise some questions that may have policy implications: how to communicate the risk and how to include participation in planning escape; is hazard prevention education and training important for people awareness; are risks awareness a priority of public institutions.

1 INTRODUCTION

Recent experiences related to disasters around the world have caused a significant number of casualties, as well as millions of costs in damage. As a consequence, the general population and stakeholders are more aware of the safety procedures and the importance of regular practice of emergency drills in urban areas, including neighborhoods, public buildings and facilities. Even in academic literature, some studies focus on the practical ways that common building users can deal with fires and other hazards (Ramachandran, 1990).

In recent years, a new dimension to emergency preparedness emerged to ensure rapid and safe evacuation of occupants of buildings in the event of a fire: human behavior. The success of fire safety measures depends to a great extent on the behavior of building occupants who are under stress at the time of a fire (Ramachandran, 1990). Moreover, crisis management researchers have becoming more proactive in assessing the safety conditions of their academic institutions by developing and enhancing their disaster response plans (Beggan, 2011). In addition, a study showed that schools that had a disaster plan were more prepared for earthquakes than those that did not have a disaster plan (Ocal, 2011), thus showing the importance of having one. Moreover, the analysis of the survivors' accounts of the 2011 Tohoku Tsunami (Santos & Queirós, 2013) showed that knowledge about emergency plans combined with regular drills and evacuation exercises prepared many people to evacuate safely during the tsunami.

For the above reasons, the authors investigated the safety conditions of the Faculty of Letters building of the University of Lisbon (FLUL), Portugal, located at the main university campus. The authors noticed a chilling reality about the exit doors: most of the doors of the basement are permanently closed, as shown in Figure 1a, b. Although this is a security measure, the locked basement doors do not ensure the safe and quick evacuation of the building in emergencies. In addition, the building itself has several traps. Figure 1c shows a door locked with a chain, which allows access to an interior garden but no possible path to the exterior of the building. Constant building modifications, which include the creation of narrow corridors and the division of wide rooms into smaller ones, full until the roof with books and research objects, also make emergency evacuations from the building challenging.

Therefore, FLUL community should be aware of these aspects of the building, which are a threat and should practice emergency evacuation procedures.

Portuguese Law has several national regulations related to the fire and earthquake safety for educational buildings (ME, 2003, SNBPC-CML, 2005).

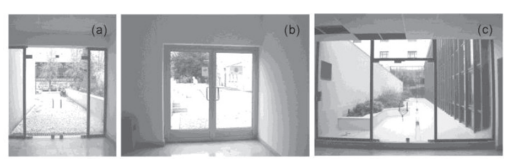

Figure 1. Photos of the exit doors in the basement of the FLUL taken on December 30, 2011: (a) and (b) are permanently locked; (c) is closed with a chain.

Under Portuguese Law, public buildings must have an emergency plan, which in the case of FLUL complies with all of safety guidelines. However, the authors have never had access to or knowledge about such an emergency plan for the FLUL building. The authors have also investigated past events that might have occurred in the building, but did not find records of any previous incident such as a fire, gas leak, or any other type of hazard endangering the building users.

Thus, the members of the Research Group on Environmental Hazard and Risk Assessment and Management (RISKam) decided to create their own emergency plan that includes escape routes and an emergency evacuation meeting point outside of the FLUL building. Thus, the objectives of the study are to test the emergency plan by conducting an evacuation exercise and to observe and discuss the human behavior of the usual occupants of the building during the pilot evacuation exercise.

This was the first time that an emergency evacuation study was conducted at the FLUL building. In fact, it was the first time such an emergency evacuation exercise was performed at the Lisbon University campus. The trigger event of this evacuation exercise was a hypothetical earthquake; also a basic training on how to safely evacuate the building was tested. Portugal is not a country prone to earthquakes. Nevertheless, the concern about earthquakes is related to the fact that in the past there were severe damage and fatalities due to earthquakes (ANPC, 2010).

In several other countries, the impact of extreme weather events motivates a variety of strategies for pre-disaster preparedness (Greenough et al., 2001). An example of the consequences of harsh weather conditions during an emergency evacuation was observed with the 2011 Tohoku Tsunami. The first author participated in the 2012 UNESCO Technical Field Trip to the areas affected by the 2011 Tohoku Tsunami. When the group was visiting Onagawa, it was snowing and it was about 1ºC outside. It was cold, and the weather conditions were similar to the day of the disaster. Because it was snowing on March 11, 2011, some people did not feel the urgency to evacuate, which is one of the many reasons that some people did not evacuate in time to escape the tsunami (Santos, 2011). As a consequence, weather conditions should be taken into consideration when an outdoors exercise is organized.

2 WHY CONDUCT DRILLS?

The increased interest in the study of risk mitigation is due in large measure to the rise of the "risk society", a recent societal and ideological reflexive context (Queirós & Henriques, 2009). However, this concern has resulted in a variety of scientific efforts to determine objective risk (hazard and quantification of human exposure to these hazards) rather than to actually study how risks are assessed and integrated into the practices of everyday life. A good knowledge of human perceptions and actions in response to risks is essential to the implementation of preventive and mitigation measures for increasing the safety level of the population. Buildings contain a variety of people, some who will be able to escape in most circumstances, some who will have extreme difficulty, and some who will not attempt to escape, and others will take the risk of fighting the hazard (Ramachandran, 1990). These facets of behavior were confirmed by the accounts of survivors of the 2011 Tohoku Tsunami (Murakami et al., 2012; Santos & Queirós, 2013). Behavior during an emergency is influenced by psychological, physiological and circumstantial factors (Ramachandran, 1990); it can also be influenced by the severity of threat posed by the hazard, the design of the building in which an emergency takes place, and the protective devices installed in the building. In addition, previous involvement in hazard incidents is also important in the risk perception (Queirós et al., 2007; Momani & Salmi, 2012). The role of risk perception in shaping people's behavior in the face of hazards has long been debated in the disaster research. Slovic's (1987) analysis for years explain that people tend to be intolerant of risks that they perceive as being uncontrollable, having catastrophic potential or bearing an inequitable distribution of risks and benefits. In its view assessments of risk can be more accepting of the role of emotions and cognition in people conceptions of danger, thus it is relevant to aid decision-makers by improving interaction with the public, by better directing educational efforts.

Several studies have been focusing on evacuation procedures based on simulations and models (Xudong et al., 2009). However, the best approach to test such models is to conduct drills and evacuation exercises (Kobes et al., 2010). Considering that regular building users are not safety professionals (like fire-fighters, civil protection agents or first aid experts), practice is the key for a successful emergency evacuation. In fact, the only way people have to practice emergency evacuations and be able to learn about safety procedures is handling with drills and evacuation exercises. For this reason, drills across Japan are made on a persistent basis. For example, Japanese drills are conducted annually on September 1 to mark the anniversary of the 1923 Great Kanto Earthquake (NHK World, 2011, 2012). Furthermore, evacuation drills help

to develop "muscle memory" (Dengler et al., 2011) in individuals to prepare themselves to appropriate responses to the natural warning signals of local tsunamis. Evacuation drills also provide an opportunity to test evacuation routes, and to provide input to officials and stakeholders for improving evacuation models. While drills are organized on regular schedules in Japan, in Portugal the number of evacuation exercises and drills are rare.

3 METHODOLOGY

After investigating about evacuation procedures on public buildings (Rodriguez et al., 2006; ISDR, 2007; Oreta, 2009; Machado, 2011; Penuel & Statler, 2011; Wisner et al., 2012; Handmer & Dovers, 2013) the authors decided to elaborate an evacuation plan. The most challenging part was to choose which path to follow as some offices have only one exit door, while other offices have at least two options of path leading to the street. Therefore, the criterion was to leave the building by using the shortest path, away from windows or narrow corridors. The plan determined indoors evacuation routes according to the location of the offices in the FLUL, and defined the place for the evacuation meeting point outside of the FLUL building. The evacuation plan was executed based on the authors' experience in collaboration with a highly skilled teacher of emergency plans for schools (see Machado, 2011).

In order to test the emergency plan, a pilot-evacuation exercise was organized. The participants agreed in advance that the exercise would start at 16:00 Lisbon Time (16:00 UTC) on March 21, 2012, with a situation of calm and nice weather. The participants had synchronized watches and were on their desks. At 16:00 all participants left their offices by following the evacuation route indicated on the emergency plan to the designated meeting point, outside the FLUL building. Those who were sharing the same office walked in order, others walked alone.

When the participants reached the meeting point, they answered the questionnaire shown in Figure 2, which was prepared by the authors. The participants did not know anything about the contents of the questionnaire until it was administered to ensure that participants would not prepare answers in advance. Some questions given in questionnaire seem to be to some extent naïve (for ex. 2.6, 3.1, 3.5). However, since this was the first time that such an approach was undertaken at the university campus, it was the authors' intention to ask even the most basic and obvious questions to test human ability to sense signs and codes present in the environment related with safety measures.

1. Personal Information
1.1 Sex
1.2 Age
1.3 Classify your motivation to this exercise.
1.4 Classify your health.
1.5 Have you ever participated in a drill?
1.6 Have you ever used a fire extinguisher (drill/real situation)?
1.7 Have you ever participated in a Civil Protection course/workshop?
1.8 Write the following phone numbers:
National Emergency Number/INEM _____
Nearest Fire department _____
Nearest police station _____
Building security _____

2. Drill
2.1 How long did you take to reach the meeting point?
2.2 Did you follow the path initially established?
2.3 During the evacuation did you noticed any exit sign?
If you answered *yes* to question 2.3, go to question 2.4. Otherwise, go to question 2.5.
2.4 Did your path coincide with the observed signs? 2.5 During the evacuation did you see any fire extinguisher?
2.6 During the evacuation did you see any emergency buttons?

3. Evaluation
3.1 Now that you finish the drill, do you feel safer in the building?
3.2 Now that you finish the drill, do you feel more prepared to deal with an emergency situation?
3.3 Now that you finish the drill, do you think the initial emergency plan is adequate?
3.4 Now that you finish the drill, do you recommend that others did it also?
3.5 Would you like to participate in future drills?
If you answered *yes* to question 3.5, go to question 3.6. Otherwise, go to question 3.7.
3.6 What kind of situations would you like to practice?
3.7 Comments and suggestions.

Figure 2. Questionnaire answered by the participants of the evacuation exercise.

Also, to understand if the experience of the exercise provides more self-awareness of how individuals think about and respond to risk (Slovic, 1987).

4 RESULTS

The answers given by the participants to the questionnaire were treated as descriptive statistics. The study population was a sample of sixteen participants who are professors, researchers and PhD students.

The questionnaire's results are shown in Figure 3. The responses to question 1.1 indicate there was a balanced distribution of genders (50% male and 50% female). The average age was 34 years, ranging from 25 (minimum) to 56 (maximum) years old. The most frequent value of ages was 37 years old; 44% of participants in the exercise were in the age range between 30–40 years (44%), and the standard deviation for the ages of the respondents is about 9 years. For 94% of the respondents, the motivation for participation (question 1.3) in the evacuation exercise was high or very high, corresponding to 15 people; only one person answered sufficiently motivated. Regarding the health status of the participants, not all of the participants felt healthy

Question	%
1. Personal Information	
1.1 Sex:	
Male	50
Female	50
1.2 Age:	
Age group 20-30	31.25
Age group 30-40	37.5
Age group 40-50	12.5
Age group 50-60	12.5
No reply	6.25
1.3 Motivation:	
High or very high	93.75
Sufficient	6.25
1.4 Health	
very healthy	31.25
Healthy	56.25
Sufficient	6.25
sick	6.25
1.5 Participation in a drill:	
Yes	25
No	75
1.6 Use of fire extinguisher:	
Yes	12.5
No	87.5
1.7 Participation in course on civil protection:	
Yes	6.25
No	93.75
1.8 Knowledge of emergency phone numbers:	
INEM	100
Others	6.25
2. Drill	
2.1 Evacuation time (minutes):	
3:00-3:30	6.25
3:30-4:00	12.5
4:00-4:30	81.25

Question	%
2.2 Followed the route initially established:	
Yes	100
2.3 Observation of emergency signs:	
No	100
2.5 Observation of fire extinguishers:	
Yes	37.5
No	62.5
2.6 Observation of emergency buttons:	
No	100
3. Evaluation	
3.1 Feel safer after this exercise:	
Yes	25
No	75
3.2 Feel better prepared to act in an emergency situation:	
Yes	81.25
No	18.75
3.3 Initial emergency plan adequate:	
Yes	62.5
No	37.5
3.4 Repetition of the exercise:	
Yes	100
3.5 recommendation that the exercise could be extended to other building users:	
Yes	100
3.6 Situations to practice:	
simple evacuation exercise	37.5
Fire	93.75
Flood	37.5
Gas leak	68.75
Earthquake	50
Other (landslide)	6.25

Figure 3. Results of the questionnaire.

(12.5%). Through their responses to questions 1.5, 1.6 and 1.7, most of the participants revealed that they did not take part of an exercise of this nature (75%). 87% have never used a fire extinguisher, and 94% have never attended a course on civil protection. Question 1.8 was related to emergency phones. Everyone knew the National.

Emergency Number, but nobody was aware of the telephone numbers of the nearest police station and the fire station. Only one participant knew the FLUL building security number.

The results of the Group 2 questions of the questionnaire are as follows: the average evacuation time (question 2.1) was 4′6″. The standard deviation of evacuation was 16″. Only one person left the building in less than 3′ 30″; 2 people took between 3′30″ and 4′ to leave the building, and 81% of the participants took more than 4' to evacuate. All participants followed the route initially established (question 2.2), and nobody noticed the emergency signs and buttons along the building (questions 2.3 and 2.6, respectively). However, 38% observed the fire extinguishers.

In the evaluation of the evacuation exercise (the Group 3 questions of the questionnaire), participants stated they did not feel safer after this exercise (75%), but a majority experienced a feeling of being better prepared to act in an emergency situation, corresponding to 81%. However, a significant percentage of the participants (62%) stated that the initial emergency plan "was adequate". All the participants recommend that the exercise could be extended to other building users. Also, all participants enjoyed the exercise. About 94% of the participants would like to conduct a fire drill.

5 DISCUSSION

Immediately after the pilot evacuation exercise, an indoor inspection was conducted at the FLUL building, and all distances used by the participants were measured (both inside and outside the building) till the meeting point. Figure 4 shows some of the emergency signs and equipment that are spread throughout the building. The inspection shows the FLUL building is very well equipped with all of the necessary emergency signs. All photos shown in Figure 4 were taken in areas where the exercise participants walk every day, several times a day. All the exit signs are located more than 2 m

Figure 4. Emergency signs and equipment: (a) and (b) at floor 1; (c) and (d) floor 0, (e) and (f) basement.

from the floor. However, a recent study shows that low-placed exit signs, rather than high placed signs, appear to have a positive influence on the use of the nearest fire exit (Kobes et al., 2010).

The pilot evacuation exercise shows the weaknesses in the preparation of FLUL building users during an emergency evacuation. The most significant results indicate that 100% of the participants did not see any emergency buttons (question 2.6). Initially, this question looked somehow naïve. However, this paper shows the importance of these types of evacuation exercises because the users did not noticed the existence of the emergency buttons. Although the indoor inspection shows the building is well equipped with emergency buttons, they are useless (Fig. 4c, d, e) if users do not know about the existence of these buttons; also 100% of the participants did not realize any exit signs, showing they were not aware of the signs and equipment. An example is the exit sign at the right hand side of a door that most of participants use every day, several times a day (Fig. 4a). Furthermore, the indoor inspection revealed that in some parts of the evacuation path chosen in the exercise was in the opposite direction of the exit signs. Figure 4a show the exit sign pointing to the left (conducting the users to the main exit door which is located about 390 m from the sign), while the nearest exit to the exterior of the FLUL building is located on the right (at about 50 m distance). 81% of the participants took more than 4' to evacuate. Therefore, for future emergency plans, the estimated evacuation time should be 4'30''. Those participants who used the shorted path (about 230 m) took an average velocity of 0.94 m/s, which is in agreement with the average velocity of 0.9–1.0 m/s, measured by Kobes et al. (2010). However, those participants who took the longest path (about 970 m) had an average velocity of more than 5 m/s. This shows that these last participants evacuated the building running, instead of walking. Therefore, the 2012 pilot-evacuation exercise at the FLUL confirms that more evacuation exercises are essential to avoid future panic, mishaps and human errors, as point out by Woodcok & Au (2013).

Initially, question 3.1 seems too obvious; however, 75% of the participants stated they did not feel safer after this exercise as they realized that they are unprepared to risk situations. On the other hand, question 3.2 shows a majority—corresponding to 81%—that experienced a feeling of being better prepared to act in an emergency situation. A significant number of the participants (62%) stated that the initial emergency plan "was adequate" (Fig. 3). However, the plan needs to be improved. These results show the participants may have been confused by the exercise and therefore need to practice evacuations more often. Finally, the participants were highly motivated to learn about proper emergency evacuation procedures. They would like to continue the emergency preparedness drills and evacuation exercises. They also indicated that would recommend emergency preparedness to others. These findings show that although the evacuation exercises are not incorporated in the university campus practices, the participants understood the importance to continue with these kinds of safety activities.

One of the purposes of the questionnaire was to study the human behavior in an emergency evacuation, and more specifically, to study the perception and the degree of internalization of the concept of risk by the users of the FLUL building. Through this study, the authors tried to ascertain the extent to which the idea of risk is not fully incorporated by the participants (Queirós & Henriques, 2009). After conducting the evacuation exercise, the authors can assert that there is an insufficient internalization of "being at risk" through the preparedness of the users of the building during the evacuation. Moreover, the existence of the correct emergency signs and equipment it is not enough to raise awareness to the buildings' users. Thus, the importance of the evacuation exercises to allow a more practical dissemination of information to the general users (Capel, 1973).

In traditional scientific thought, one cannot generalize on the basis of a single case (Flyvbjerg, 2006), and a case study cannot contribute to scientific development; nevertheless, the author states that this is not completely true because *one can often generalize on the basis of a single case and the case study may be central to scientific development via generalization as a supplement or as an alternative to other methods. However, formal generalization is overvalued as a source of scientific development, whereas "the force of example" is underestimated.* Deferring to conventional wisdom, because of the small size of the group that participated in the exercise and since the evacuation exercise was a single case study, the authors are cautious about generalizing the results. Still, having in mind Flyvbjerg reasons in mind, with the results achieved with this pilot evacuation exercise, the authors are convinced that this kind of research is also essential for the development of social science because this contributes to the understanding of the degree to which certain phenomena are present in a given group. Nevertheless, questionnaires are important tools to assess participant experiences (Ocal, 2011; Murakami et al., 2012), even with a small number of participants.

On the other hand, the initial traps found at the exit doors (Fig. 1) demonstrate that security measures continue to be a barrier to the safe and quick evacuation of the building in an emergency

situation. In addition, there is no exit sign in the vicinity of the doors shown in Figure 1. In fact, Figure 5 shows the emergency plan placed about 1.7 m from the ground floor, near the door shown in Figure 1a. The instructions are difficult to read, and most users are not aware of the sign. Nevertheless, a closer look reveals that the information on the board shows that the exit door shown in Figure 1a is indeed a "regular exit path to the exterior"; however, this door is permanently closed, without any alternative quick escape route nearby. In addition, no emergency plan or sign was found near the door shown in Figure 1b. These situations already have been reported to the safety management staff of the FLUL buildings and are being studied. Regarding earthquakes and fires other safety improvements are already underway such as training courses for the staff as well as measures to improve the emergency plan. However, for potential terrorist attacks the problem of evacuation is more difficult and the evacuation exercises should be supervised by external security experts, and also military and police forces.

The findings of this study have implications for risk prevention education and training on the university campus. For the foregoing reasons, drills and more emergency preparedness training should be extended to all FLUL users. Drills ought to be extended to all of the Lisbon University campuses. In addition, future drills and evacuation plans should be more complex, by informing instructions and cooperating with the rescue units. As Slovic (1987) states risk preparedness, risk management and risk communication efforts may not result in better outcomes unless they are structured as a two way process involving both building users and experts on risk assessment and management.

Finally, the findings of this pilot exercise raise some questions with policy implications: how to communicate the risk and how to include participation in planning "escape routes" in public (University) buildings. Hazard prevention education and training are important measures for people's awareness and preparedness, thus risks perceptions and acquaintance on human behavior in emergency situations should be a priority in higher education institutions.

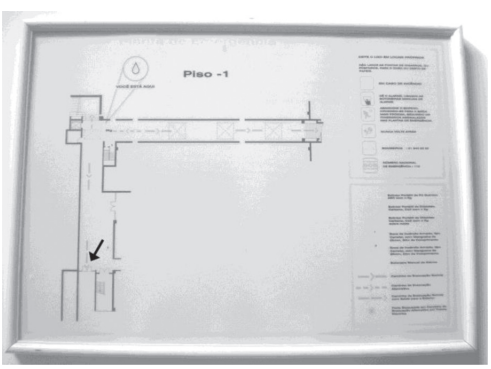

Figure 5. Emergency plan found in the interior of the FLUL building. The arrow indicates the emergency door to the exterior of the FLUL building that is locked.

A safety analysis via minimal path sets detection for object-oriented models

C. Schallert
German Aerospace Centre, Institute of System Dynamics and Control, Wessling, Germany

ABSTRACT: Safety is of prime importance for aircraft and must be considered from the beginning of the design process. Conducting a safety analysis involves considerable effort, particularly if traditional methods, such as manual fault tree analysis, are used. This may explain why analyses are performed usually only once or twice during an entire aircraft development. Furthermore, traditional methods are hardly linked to other tools for system conceptual design.

In the field of modelling and simulation, multi-domain object-oriented languages are increasingly adopted. They enable an intuitive way of modelling, since objects and their interconnections correspond with real components. Thus, large-scale system models can be created and simulated efficiently.

A new method is developed that integrates safety analysis with multi-domain object-oriented modelling. This is the contribution aimed by this paper. In essence, the proposed method automatically detects the minimal path sets of a technical system.

1 INTRODUCTION

This paper describes a method for automated safety analysis of a technical system that is represented as a multi-domain object-oriented model. The proposed method automatically detects the minimal path sets of the modelled system. Then, the probability of system operation or failure is computed from the minimal path sets using component failure rates.

Object-oriented modelling based on differential algebraic equations offers large expressive power for establishing multi-disciplinary engineering tools. In addition, the structure of an Object-Oriented Model (OOM) resembles the functional paths that cause a technical system to operate. This property is exploited by the minimal path sets detection method.

Fault modelling is introduced in addition to the common modelling of normal operation. This forms a basis for the proposed method that belongs to the class of state space simulations. In this context, the state space denotes the set of all possible combinations of intact and failed components of a system. Search algorithms from graph theory are adopted to narrow down the state space, thus preventing unfeasibility of the method due to an exponential increase of the number of combinations and thus simulations to be performed.

The developed modelling approach is not exclusively dedicated to safety analysis. It rather serves several purposes, such as system performance or parameter studies, as usually is the motivation for physical modelling and simulation.

This paper is organised as follows: Section 2 recaps the basics of OOM, describes the selected modelling approach and establishes an example model of a safety relevant aircraft system. Section 3 describes the minimal path sets detection and exemplifies the method by means of the established system model. Section 4 concludes the paper.

2 MULTI-DOMAIN OBJECT-ORIENTED MODELLING OF SAFETY RELEVANT AIRCRAFT SYSTEMS

2.1 *Multi-domain object-oriented modelling*

This section briefly recaps the basic principles of the modelling approach.

The idea of multi-domain object-oriented modelling was formulated by Elmqvist (1978), who proposed a language called Dymola (Dynamic Modelling Language). In object-oriented modelling, objects, their boundaries and interconnections correspond with real existing equipment. Physical equations have to be established or understood only for each object. By connecting objects with each other, further model equations are introduced.

A translator then automatically transforms the model equations into a simulation ready runtime model. This approach has a couple of advantages over block diagrams (e.g., Simulink), as explained by the two corresponding model implementations of a small electronic circuit shown in Figure 1.

As Figure 1 shows, the OOM (a) retains the physical structure of the circuit, whereas the block diagram (b) does not. The OOM is changed intuitively by removing or adding components and connecting them with other components. Different physical domains can be combined in a single model.

The circuit model includes, among others, a resistor, capacitor and inductor. Such component models are available from standard libraries. The model equations are $v = R \cdot i$, $i = C \cdot der(v)$ and $v = L \cdot der(i)$, respectively, where $der(\,)$ denotes the time derivative. Each component has two electric pin interfaces (filled and non-filled blue squares in Figure 1a) that include the voltage v as a potential and current i as a flow variable. Model equations are introduced for connected component (object) interfaces as follows: The potential is the same, whereas the sum of flow equals zero according to Kirchhoff's node rule. For example, in case of the circuit model shown by Figure 1a): $v_1 = v_3 = v_7$ and $i_1 + i_3 + i_7 = 0$.

The system model described in section 2.3 also covers the mechanical (M) and hydraulic (H)

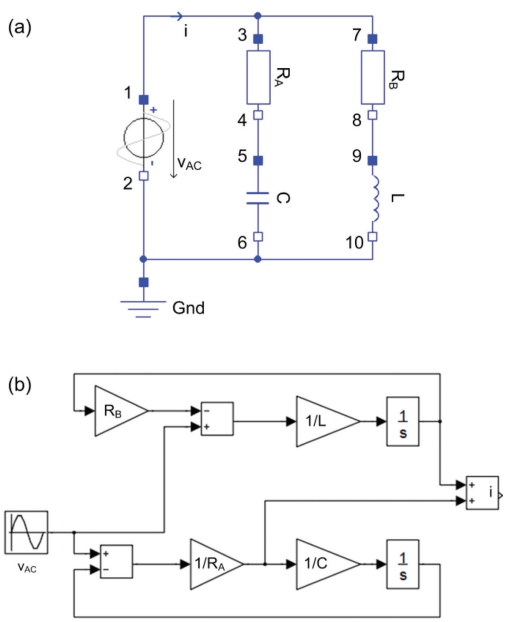

Figure 1. Small electronic circuit (a) and its block diagram representation (b). Taken from The Modelica Association (2000).

Table 1. Model interfaces, icons and domain (dom) identifiers.

connector	potential	flow	icon	dom
electric pin	voltage v	current i	■ □	E
translational flange	position s	force f	■ □	M
rotational flange	angle φ	torque τ	● ○	M
hydraulic port	pressure p	flow rate q	■ □	H

Boolean signal	dto.		▶ ▷	S

domains, as well as real and Boolean signals (S). Table 1 summarises the according interface definitions and icons. These appear in Figures 1 (a), 3, 4 and 5.

Thus, an OOM consists of the equations of each object and of those imposed by the connections between them. By symbolic processing, this set of equations is translated into a simulation runtime model of the differential algebraic (DAE) form

$$\begin{aligned} \dot{\boldsymbol{x}}(t) &= \boldsymbol{A} \cdot \boldsymbol{x}(t) + \boldsymbol{B} \cdot \boldsymbol{u}(t) \\ \boldsymbol{y}(t) &= \boldsymbol{C} \cdot \boldsymbol{x}(t) + \boldsymbol{D} \cdot \boldsymbol{u}(t) \end{aligned} \tag{1}$$

2.2 *Modelling additions for safety analysis*

2.2.1 *Modelling and simulation of failures*

The proposed safety analysis method is based on simulation of failures. Component models that only reflect normal operation have to be enhanced accordingly. At system level, control or reconfiguration logics have to be implemented that define how a system reacts to the occurrence of failures. The pursued modelling approach is structure invariant, i.e. the DAE structure (equation 1) remains always the same. Failures are represented by model parameter (values in matrices $\boldsymbol{A}$, $\boldsymbol{B}$) changes.

Elmqvist et al. (2014) propose and Bouissou et al. (2014) use a structure variant approach that is even more flexible for the modelling of failures. Future work will combine this approach with the minimal path sets detection method described in this paper.

In general, the concept of minimal path sets distinguishes only between operation and failure. Thus, the proposed detection method addresses two states (intact, failed) at component and at system level.

2.2.2 *Indication of system status*

Safety assessment requires the analyst to define criteria that distinguish normal operation from failure of a system. The analysis method proposed by this paper requires implementing these criteria in a system model, such that an output signal indicating the system status is computed. A system model is simulated by the analysis method for various combinations of intact and failed components, and

the resulting system status (operation or failure) is correlated with the respective component states.

2.2.3 *Insertion of component failure rates*

Failure rates λ are stored in each component model that is enhanced with failures. Constant failure rates (exponentially distributed lifetimes) are assumed per default. Since the stress level of a component is known in the simulation, its failure rate can be adapted accordingly. Failure rates are used to compute probability of system operation $R_{sys}(t)$ or failure $F_{sys}(t)$ from the detected minimal path sets.

2.3 *Stabiliser trim system model*

This section describes the multi-domain object-oriented model of a stabiliser trim control and actuation system. This model of a safety relevant aircraft system is based on generally available information (Airbus Training, Boeing B737 NG, Persson et al. 2001). It is established for exemplification of the automated minimal path sets detection method.

2.3.1 *System description*

Longitudinal control of an aircraft is achieved by elevators and a horizontal stabiliser surface. The latter is positioned by a stabiliser trim control and actuation system. A main part of this system is a ballscrew actuator that is equipped with two hydraulic motors to rotate the ballscrew through a reduction gear. If the stabiliser is not moved, it is held in place by the actuator. To this end, an electro-mechanical, power-off engaged brake (POB) is mounted to each motor shaft. The brakes are engaged if the associated motor is shut off or if the system has to be stopped after a failure is detected.

The pilots operate the system via pairs of trim switches that are mounted to each control wheel (or centre pedestal). The trim switches are spring-loaded to the neutral position. To command trimming, the two switches of a pair have to be pushed up or down simultaneously. This causes the active system channel to release the associated brake and energise a hydraulic valve to direct fluid to the motor. The actuator moves the stabiliser until the trim switches are released, the end of the stroke is reached, or a fault is detected. The system is monitored for faults, such as loss of hydraulic pressure, valve or motor failure, by comparing the sensed motor speed and stabiliser motion rate with the actual trim command.

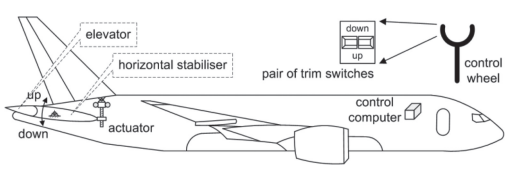

Figure 2. Stabiliser trim control and actuation system.

The minimal path sets detection method reveals those conditions that cause a system to operate. The example system is considered operational if it moves the stabiliser surface according to the actual command and holds it in place if no command is present.

2.3.2 *Component modelling*

The modelling of the stabiliser trim system includes one-dimensional mechanics with elasticity, damping, inertia and friction; hydraulics with bulk modulus, fluid density, turbulent and laminar flow; and resistive electrics. One of the developed component models is explained below.

A spur (reduction) gear is essentially described by the ratio of input and output torques and angles:

$$0 = I_{SG} \cdot \tau_a + \tau_b, \qquad \varphi_a = I_{SG} \cdot \varphi_b \tag{2}$$

The "IdealGear" element introduces these equations to the spur gear model. The "Disconnect" and "Jam" elements are rotational spring-dampers described by:

$$\tau = c \cdot \varphi_{rel} + d \cdot \dot{\varphi}_{rel}, \qquad \tau = \tau_b = -\tau_a,$$
$$\varphi_{rel} = \varphi_b - \varphi_a \tag{3}$$

They are used to represent failures of the spur gear. To this end, the spring and damping coefficients (c and d) are varied as indicated by Table 2. In equations 2 and 3, indices a and b denote the rotational flanges of the spur gear and of the spring-damper elements (shown in Figure 3), respectively.

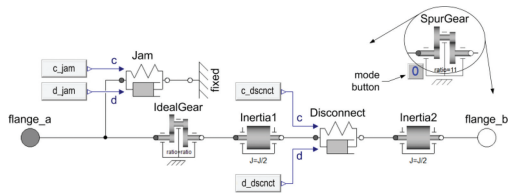

Figure 3. Spur gear model including disconnection and jam.

Table 2. Modelling of spur gear failures by variation of spring and damping coefficients. [c] = *Nm/rad*, [d] = *Nms/rad*

	Mode	C_{dscnct}	d_{dscnct}	d_{jam}
Normal operation	0	10^4	10^4	d_{G-drag}
Disconnection	1	0	0	d_{G-drag}
Jam	2	10^4	10^4	10^4

In normal operation, the "Disconnect" element is quasi-rigid. It is literally broken to represent a disconnection of the spur gear. A jam is modelled by a quasi-rigid connection to the "fixed" element. The coefficient values implicate small relative rotations in the order of $\varphi_{rel} = 10^{-3}$ *rad* for a transferred torque of $10Nm$, which is negligible for the present application. The coefficients have to be adapted for applications of different scale. The "Jam" element also reflects the friction of the intact spur gear, e.g. by $d_{G-drag} = 2 \cdot 10^{-4}$ *Nms/rad*.

Normal operation (*mode* = 0) or disconnection (*mode* = 1) of the spur gear are considered for the detection of minimal path sets.

2.3.3 *System model*

Figure 4 shows an image of the developed stabiliser trim control and actuation system model. It contains two instances of the drive channel model depicted by Figure 5. Each channel consists of a control computer, a hydraulic valve, motor and brake (POB) that are electrically activated. The channels are connected to different electric (DC1, 2) and hydraulic (Pressure1, 2) sources. Each computer is connected to the trim switches (Up1, 2 and Down1, 2), and to the other channel computer for coordination of active or stand-by status. The model interface and connection types are as defined in Table 1.

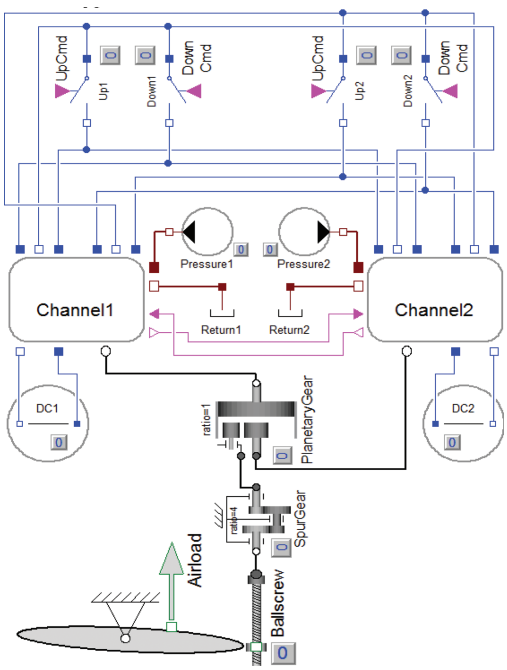

Figure 4. Stabiliser trim control and actuation system model.

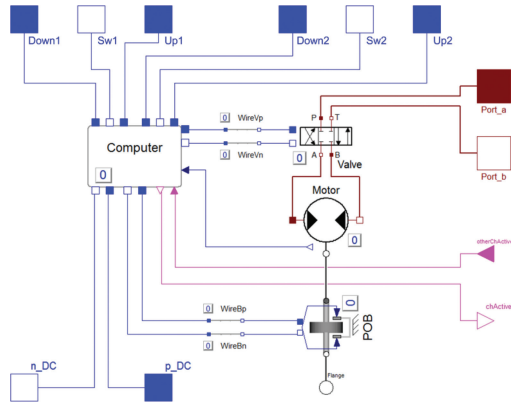

Figure 5. Model of a drive channel of the stabiliser trim system.

As explained in section 2.2.2, a system status output (not shown in the images) is computed for use by the minimal path sets detection (section 3). This output indicates if the system operates normally or if it fails (no motion or uncommanded motion). To this end, the actual motion rate of the stabiliser surface is compared with the command (trim switch inputs).

3 DETECTION OF MINIMAL PATH SETS

This section describes the proposed method for automated detection of the minimal path sets of a technical system. It is based on the idea that the related object-oriented model structure resembles the functional paths that cause the system to operate.

After detection of the minimal path sets, probabilities of system operation $R_{sys}(t)$ or failure $F_{sys}(t)$ are computed from failure rates (section 2.2.3) using the method described by Heidtmann (1989).

3.1 *Definitions*

A *path set* is a set of intact components that causes a system to operate. A *path set* is *minimal* if it contains only as many intact components as are necessary for the system to operate.

A *path* is a sequence of consecutive nodes in a graph, where each two successive nodes are connected via an edge.

A *union* (denoted by ∪) of a collection of *paths* consists of all nodes in the collection of *paths*.

3.2 *Properties of minimal path sets in an object-oriented model*

The structure of an OOM is regarded as a graph. Nodes and edges of the graph represent

components (objects) and connections between them. Nodes that include failure behaviour are indicated by filled circles in Figures 6, 7 (b), 8, 10–15. Non-filled circles indicate nodes that are always intact. Non-filled squares indicate auxiliary nodes.

In such a graph, minimal path sets are not just simple s-t paths. An s-t path connects two nodes "s" and "t" of a graph through an unbranched, open walk:

Minimal path sets are sometimes unbranched, just as s-t paths are. In general, however, a minimal path set includes junctions or circles, as Figure 7 indicates for a part of the stabiliser trim

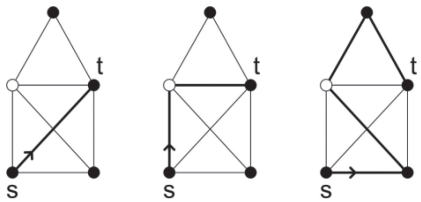

Figure 6. Several s-t paths in a graph.

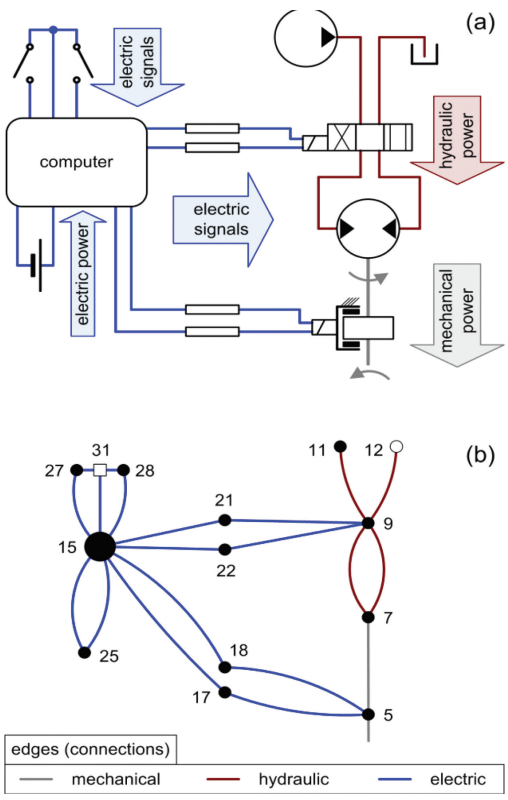

Figure 7. Exchange of power, material and signals across the edges in a coherent set of nodes—Part of OOM of stabiliser trim system (a) and corresponding graph (b).

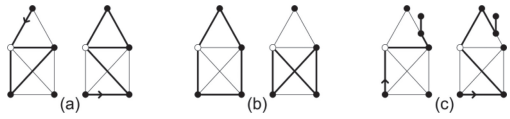

Figure 8. Ties (a), circles (b) and open walks (c) in a graph.

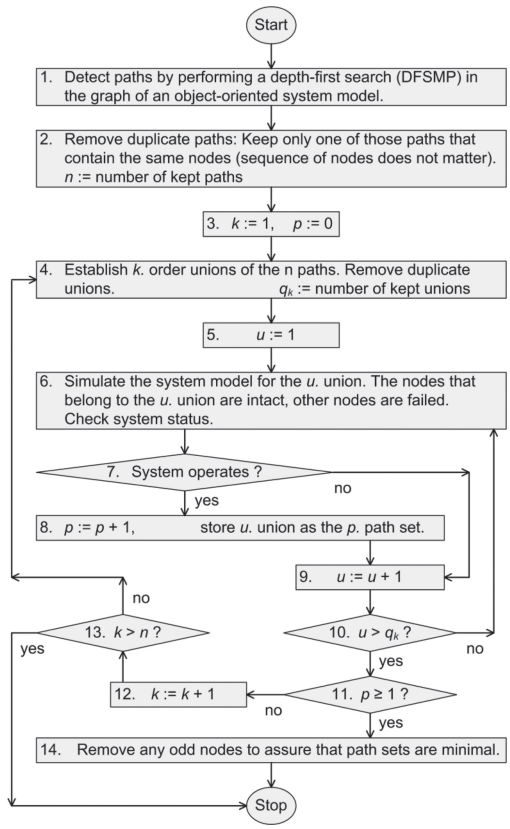

Figure 9. Flow chart of a minimal path sets detection method.

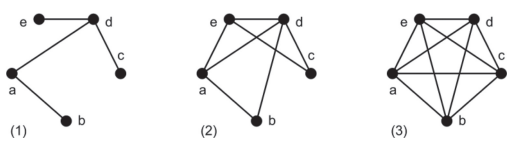

Figure 10. Three graphs of different density.

system model graph. The electric connections between the computer (15), valve (9) and brake (5) introduce such junctions. (The numbering of nodes is consistent with Figures 11–14 and section 3.4.) Since there is more than one junction, circles exist in the graph.

A minimal path set consists of one or more nodes. Power, material or signals are exchanged between neighboured nodes across the connections (edges) between them, as depicted in Figure 7. This causes a technical system to operate. Only neighboured nodes, i.e. coherent sets of nodes, can perform this exchange and render a system operational.

3.3 *Detection method*

The proposed detection method belongs to the class of state space simulations. At first, the system model graph is evaluated to find candidates of minimal path sets. This is achieved by an adapted depth-first search algorithm and establishing of unions of the found paths. Then, the system model is simulated only for the candidates to detect the actual minimal path sets. Figure 9 shows a flow chart of the detection method. Without the prior evaluation of the model graph, the number of simulations would be 2^{nr}, nr being the number of system components.

3.3.1 *An adapted depth-first search*

Due to the described properties of minimal path sets, it is meaningful to use a Depth-First Search (DFS) for detection. This algorithm is known from many references, such as Krumke et al. (2012). It finds sets of consecutive nodes (paths) in a graph. In doing so, it commences at a start node and progresses into depth with one of the neighbours of each visited node. For the purpose of detecting minimal path sets, the algorithm is adapted (→ DFSMP) with a definition of the target nodes. It finds the following types of path:

a. Ties. A tie is a path that ends at a node already contained in the path.
b. Circles. A circle is a special case of a tie.
c. Open walks. An open walk ends at a node that only has one neighbour.

3.3.2 *Unions of paths*

The DFSMP is capable of finding minimal path sets that include a junction or circle. Still, a minimal path set might not be detected if the start node is unfavourably selected, or if more than one junction or circle occur. To accommodate for such formations (present in Figure 7), unions of paths are established. This corresponds with step 4 of Figure 9.

The maximum number of unions is denoted by the binomial

$$\binom{n}{k} = C(n,k) = \frac{n!}{k!\cdot(n-k)!} \tag{4}$$

where n is the number of all paths and k is the number of paths to be merged in a union. The actual number of unions q_k is much lower, dependent on the density d of the graph. d is generally defined, e.g. by Roberts et al. (2007), as

$$d(N,E) = \frac{2\cdot E}{N\cdot(N-1)} \tag{5}$$

For the three graphs depicted in Figure 10, each having $N = 5$ nodes, the number of edges E, density and number of paths n are listed in Table 3. The paths are established starting from node "a" according to the rules defined in section 3.3.1. Since the sequence of nodes in a path or union does not matter, duplicates are removed. n paths or, respectively, q_k unions are kept as summarised in Table 4.

For the complete graph ($d = 1$), q_k is much lower than the corresponding binomial. The reason is that the paths are longer, the higher the density of the graph is. The longer the paths are, the more they cover the graph. Unions of long paths cover

Table 3. Number of edges, density, and number of paths.

Graph	E	d	n
(1)	4	0.4	3
(2)	7	0.7	5
(3)	10	1	11

Table 4. Binomial (n in rows, k in columns) and actual number of unions q_k for the three graphs.

$C(n, k)$	2	3	4	5	q_k	2	3	4	5
3	3	1			3	3	1		
5	10	10	5	1	5	3	2	1	1
11	55	165	330	462	11	5	5	5	1

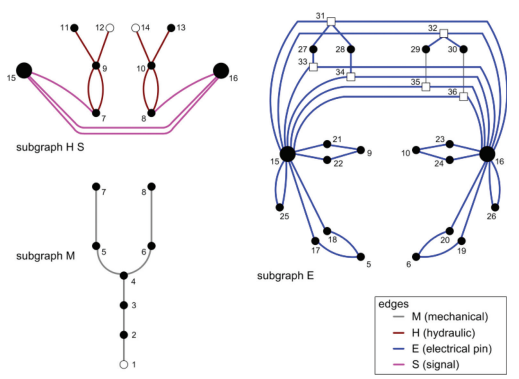

Figure 11. Subgraphs of stabiliser trim system model.

the graph even more, so the number of different unions q_k is relatively low. For a low-density graph, the paths are relatively short, so relatively more different unions (compared to the binomial) occur.

3.3.3 *Removal of odd nodes*

In some cases, the detected path sets are not minimal. This means that more (odd) nodes are contained in a path set than are necessary to cause the system to operate. A path set is minimal only if a failure of any of its nodes (components) causes system failure.

Thus, a check is introduced at the end of the detection method (step 14 in Figure 9): Tracing and removal of odd nodes.

Essentially, the check proceeds by simulating the system model for each path set such that one of its nodes fails, one by one, while the others are intact. If the system still operates, then the respective path set is stored without the failed node. This is repeated until no odd nodes are detected in any path set anymore. Since it is basic trial-and-error, without any evaluation of the model graph, this check is used only to assure that the path sets are minimal by removing a small number of odd nodes, if necessary.

3.3.4 *Separation of physical domains*

The number of paths n in a graph increases strongly with the number of its nodes N and density d, the phenomenon known as combinatorial explosion. This is clarified by an estimation of the number z of s-t paths proposed by Roberts et al. (2007) for graphs of a density $d \in [0.1; 0.9]$. (The DFSMP detects three different kinds of paths. However, estimations exist only of the number of s-t paths.)

$z(N,d) \approx K(N) \cdot d^{N-1+\delta(N,d)}$ where

$$K(N) = \sum_{k=0}^{N-2} \frac{(N-2)!}{k!}, \qquad \delta(N,d) = \frac{3.32}{N} - \frac{5.16}{d \cdot N} \qquad (6)$$

It is proposed to mitigate the growth phenomenon by splitting up the model graph at the boundaries of the physical domains. These are identified by the different types of model interfaces (listed in Table 1). Thus, a model graph split-up algorithm is created that recognises these interface attributes.

Smaller subgraphs are established that are evaluated one by one according to the flow chart of Figure 9. (Due to splitting up the model graph, some additions to the algorithm are needed, as Schallert (2014) describes.) Figure 11 shows the subgraphs established for the stabiliser trim system model. Table 5 lists some of the properties of the model graph before split-up (all-up) and of the subgraphs. n are the actual numbers of paths found in a (sub-)graph.

Table 5. Number of nodes, edges, density, estimated number of s-t paths and actual number of paths in (sub-) graphs.

Subgraph	N	E	d	z	n
all-up	36	54	0.086	1766	1932
M	8	7	0.25	2.4	3
H S	10	9	0.2	2.09	4
E	26	38	0.117	244	91

3.4 *Course of minimal path sets detection algorithm for the stabiliser trim system model*

The minimal path sets detection algorithm is exemplified by means of the stabiliser trim system model.

Subgraph M is evaluated first, starting from node 2 (ballscrew in Figure 4). Figure 12 shows this stage of the algorithm. The DFSMP finds three paths (parentheses indicate nodes that are always intact):

$path_1 = \{2, (1)\}$; $path_2 = \{2, 3, 4, 5, 7\}$;
$path_3 = \{2, 3, 4, 6, 8\}$

The three paths are tested by simulation of the system model (steps 6. - 10. in Figure 9). At the same time, all nodes covered by the shaded area are intact. The result of this first iteration is that the system does not operate for any of the three paths.

Thus, steps 6. - 10. are repeated for $k = 2$, which reveals that the system operates for the union {2, 3, 4, 5, 6, 7, 8}. The removal of odd nodes (step 14. in Figure 9) leads to storing the two, yet incomplete minimal path sets

$MP_1 = \{2, 3, 4, 5, 6, 7\}$; $MP_2 = \{2, 3, 4, 5, 6, 8\}$

These are indicated by the green nodes in Figure 13. After this, the evaluation of subgraph M ends.

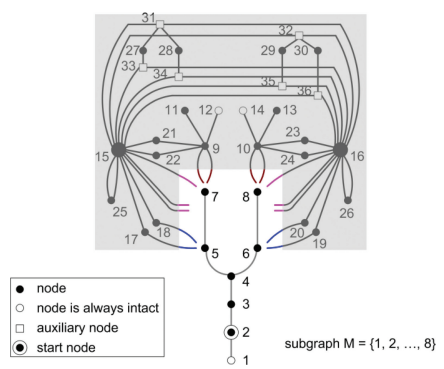

Figure 12. Evaluation of mechanical domain subgraph.

The algorithm continues by evaluating subgraph H S for each of the two incomplete minimal path sets. For MP_1, the DFSMP starts from node 7 (as shown by Figure 13) and finds four paths:

$path_1$ = {7, 9, 11}; $path_2$ = {7, 15, 16, 8, 10, (14)}

$path_3$ = {7, 9, (12)}; $path_4$ = {7, 15, 16, 8, 10, 13}

Next, the paths are tested by simulating the system model (steps 6. - 10. in Figure 9 for k = 1).

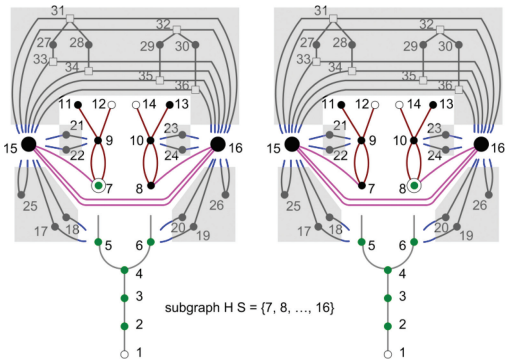

Figure 13. Hydraulic and signal domains subgraph evaluation.

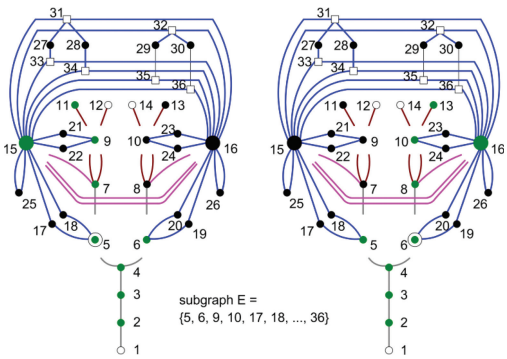

Figure 14. Evaluation of electrical domain subgraph.

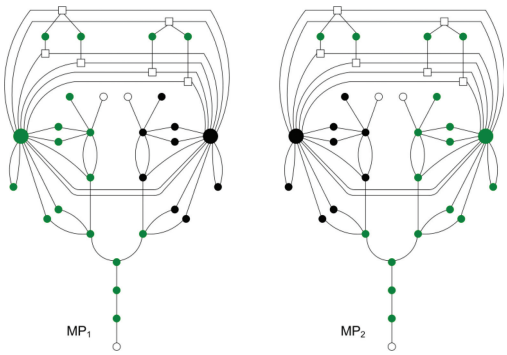

Figure 15. Minimal path set of stabiliser trim system.

In doing so, those nodes are intact that belong to $MP_1 \cup path_j$, $\forall j \in \{1, 2, 3, 4\}$ respectively. Also, all nodes covered by the shaded area are intact. The system does not operate. The next iteration (k = 2) reveals that the system operates for the union $MP_1 \cup path_1 \cup path_2$. The removal of odd nodes leads to storing MP_1 = {2, 3, 4, 5, 6, 7, 9, 11, 15}.

The algorithm proceeds accordingly for the second minimal path set (DFSMP starts from node 8). After the evaluation of subgraph H S is complete, it is stored as MP_2 = {2, 3, 4, 5, 6, 8, 10, 13, 16}. The two minimal path sets developed so far are indicated by the green nodes in Figure 14.

Next, the algorithm evaluates subgraph E to complete the two minimal path sets. For MP_1, the DFSMP starts from node 5 and find 91 paths. Three of them are:

$path_1$ = {5,17,15,25}; $path_2$ = {5, 18, 15, 21, 9, 22};

$path_3$ = {5, 17, 15, (33), 27, (31), 28, (34), 16, (36), 30, (32), 29, (35)}

The loop (steps 6. - 10. in Figure 9) of testing paths and unions by simulating the system model is repeated up to k = 3. Then, the system operates for the union $MP_1 \cup path_1 \cup path_2 \cup path_3$. Odd nodes are removed, and the minimal path set is stored as MP_1 = {2, 3, 4, 5, 6, 7, 9, 11, 15, 17, 18, 21, 22, 25, 27, 28, 29, 30}.

For k = 2, $C(91, 2)$ = 4095 unions were established of which a number of q_k = 634 remained after removal of duplicates. For k = 3, $C(91, 3)$ = 121485 unions were established of which a number of q_k = 1279 remained. As explained, the model is simulated only for the respective q_k unions.

Next, the second minimal path set is completed by starting a DFSMP from node 6. The loop of testing paths and unions in the simulation is run through up to k = 3 with similar computing effort. The result is MP_2 = {2, 3, 4, 5, 6, 8, 10, 13, 16, 19, 20, 23, 24, 26, 27, 28, 29, 30}. Both complete minimal path sets are indicated by the green nodes in Figure 15.

The total number of system model simulations performed is 4129. Most of them are caused by step 6., and a few are due to step 14. of the minimal path sets detection algorithm depicted by Figure 9. If the model graph was not split up (row 1 in Table 5), this would cause a total of > 615000 simulations, which is unfeasible. Without any evaluation of the model graph, the number would even be $2^{27} = 1.34 \cdot 10^8$ due to the system comprising 27 components (nodes) that include failure behaviour.

4 CONCLUSIONS

This paper described and exemplified a method for minimal path sets detection of a technical

system that is represented by a multi-domain object-oriented model. The method is the core of an automatic safety analysis that can be performed throughout the design process of the system, thus keeping the analysis consistent with design iterations. It is meaningful to apply the method if multi-domain object-oriented modelling is used already in systems engineering. The proposed method enhances the scope of application of a system model while permitting all other simulation studies that originally motivated development of the model to be conducted.

The method belongs to the class of state space simulations. A search algorithm from graph theory is adapted to evaluate the object structure of the model, which prevents exponential growth of the state space and thus unfeasibility of the method.

Further detail of the proposed method, estimation of computing effort, as well as modelling and analysis examples are described by Schallert (2014).

It must be beared in mind that all model-based analysis methods capture only those phenomena that are covered in the modelling approach. Then again, the automation ensures that all relevant failure conditions (at least in so far as modelled) are considered, whereas a manually conducted analysis might be errorneous or incomplete.

ABSTRACT: In recent years the world observed great interest in air transport, which consequently leads to an increase in air traffic. Growing technology forces on air transport to meet the requirements of safety and economics of transport.

That is why it becomes important problem of mathematical modeling of the high degree of precision mapping of actual flights a mathematical model in the form of artificial neural network. In order to obtain a very good accuracy of mapping the actual flight, the studies have used actual data, whose source was the on-board recorder operating the flight.

During the analysis examined data from more than a dozen flights made EMB—170 aircraft on the same route but in different weather conditions. The results were analyzed in terms of qualitative and quantitative evaluation on the quality of the mapping by comparing the results obtained using the model developed with the results obtained from the recorder. Mapping the landing phase of an aircraft by means of an artificial neural network gives positive results.

Model developed based on actual data from on-board flight data recorder, can be used to create a simulation model used in the study of air traffic and to create flight crew training simulators.

1 INTRODUCTION

In the last century, have been increasing interest in air transport, which leads to increased air traffic. Constantly evolving technology forces air transport to meet the requirements of security and transport economics.

Then it becomes essential problem of mathematical modeling of the high degree of precision mapping of actual flights by mathematical model in the form of artificial neural network.

In order to obtain a very good accuracy of mapping the actual flight, studies have used actual data, which originated in the on-board recorder operating the flight.

2 LANDING PHASE

In the literature [5], is described as a landing operation of the aircraft transitions from flight to ground operations. This should be carried out into the wind. This helps reduce the ground speed, shorten the landing run and avoid lateral drift [3].

Landing is the last stage of the flight, which consists in bringing the aircraft to the airport. Approaching the landing is the most complex stage of the aircraft's flight, called Critical phases of flight [1].

At this stage, the aircraft approaches the surface of the earth, and the flight is at a variable height and in variable—speed wind [4].

During the landing phase is distinguished by the following steps: final approach to landing, supply, alignment, endurance, touchdown and roll (Fig. 1).

At presented below figure shows the change in position (value) parameters were determined by which individual segments. The main factors affecting the course of the flight phase include: chassis, flaps position and speed of the aircraft.

For the landing maneuver the aircraft pilot gives a configuration, through a series of operations at specific stages of the flight. Each airport has a personalized procedure for landing on the runway.

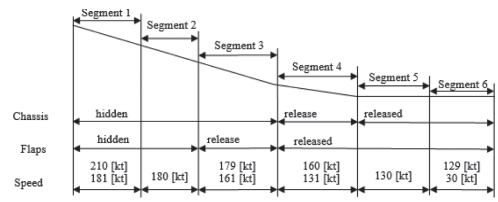

Figure 1. Schematic landing phase of aircraft [own elaboration].

During the study utilized the data from the EMB 170 aircraft landing on the road 11 (RWY 11) at the Chopin airport in Warsaw.

3 FLIGHT DATA RECORDER

Flight recorders are devices that are designed to save and protect the information from the course of the flight, the main parameters include [6]:

- Flight parameters (ex. position, time, attitude, pressure altitude, arte of climb, heading, true air speed, distance above surface),
- Parameters of the drive unit,
- The location of the controls by air,
- The status of individual devices and systems,
- Background sound in the aircraft, including radio communication and internal communications,
- Image from cameras onboard instruments working.

The sources of information for the recorder are:

- On-board systems,
- Transmitters angular displacements,
- Linear encoders,
- Transmitters motion (spatial position, angular velocity, acceleration),
- Transmitters parameters of the environment surrounding the aircraft (the atmosphere).

Most information is processed in block acquisitions. To the recorder provided the following signals:

- Analog,
- Digital transmitted by interfaces (Bus),
- Binary.

Recorders qualifies for flight control objective, making it a priority element having an impact on raising the level of flight safety and prevention of air accidents. They are used, among others, to control the remote piloting techniques.

Thanks to new technologies, the information obtained from the "black boxes" have enabled flight animation, and their simulation, which enables the efficient training of the flight crew. Thus it can be seen that the objective measures of flight control are crucial in the training of pilots.

Recorders on aircraft appeared from the very beginning. Brothers Wilbur and Orville Wright documented its first flight recording engine speed, the distance traveled and the time of flight. The first flight across the Atlantic made by Charles Lindberg in 1927 was registered by the barograph.

The Flight Data Recorder (FDR) has been around for more than 70 years. The first unit was invented in 1939 and slowly developed into a useable flight unit in the late 1940s. It wasn't until 1954 that the Cockpit Voice Recorder (CVR) was invented.

The first FDR systems were rather simplistic because they were entirely electro-mechanical units which utilized specific foil as the recording media which motored between spools, and had five styluses that scratched readings for altitude, heading, vertical accelerations, airspeed and time on one-side of the foil. Soon this system was enhanced by adding three more styluses on the opposite side of the foil, thus adding roll, pitch, and flap information.

The literature distinguishes four basic classification recorders [6]:

1. Flight data recorders FDR (Flight Data Recorder):
   - Catastrophic,
   - Consumables.
2. Special recorders.
3. Image DVR (Digital Video Recorder).
4. Sound CVR (Cocpit Voice Recorder).

With the arrival of the Solid State, the Digital Flight Data Recorder—both the survivability and reliability of this valuable monitoring system leapt, thanks to the elimination of tapes, drive motors, drive belts, and all other moving parts that were necessary with all previous versions. So that they become more popular and used in commercial aircraft.[2]

During the study were used data from flight data recorder FDR.

4 MODELING PROCESS

For the analysis of the landing phase of an aircraft based on data obtained the actual flight recorders. All flights were performed during similar meteorological conditions.

Data obtained from the recorder board included:

CAS - Calibrated Airspeed,

GSPED - Ground Speed - speed relative to the earth's surface,

LAT - Latitude,

LONG - Longitude,

LOACC - Long Acceleration,

MHEAD - Magnetic Heading,

N1 - N1 Engine,

Pitch - Pitch Attitude—the horizontal position,

PRALT - Pressure Altitude,

RALT - Radio Altitude—the height of the radio,

VACC - Normal Acceleration,

AGSW - Air/Ground Sensor—position indicator ground/air,

AT - Auto Throttle Engaged—sensor readings of the recording: the location on the ground or in the air, moments when the crew are broadcast radio messages, signaling the inclusion of auto throttle,

FLAPS - Flaps Position Angle,

GW - Gross Weight—the total weight of the aircraft [kg],

LGPOS_L - Left Main Landing Gear Position—position of the chassis,

TAT - Total Air Temperature,

WND_DIR - Wind Direction,

WND_SPD - Wind Speed,

local time.

The first step was the selection of the data in terms specify only those that described the landing phase, on the basis of the above data.

Then had to extract individual segment of the test flight phase, as presented in Figure 1.

Another important activity for the analysis was conducted of data normalization. The values were normalized according to the formulas presented below:

- mapped parameter flight (flight speed):

$$\overline{y}_i = \frac{y_i - y_{min}}{\Delta y} \tag{1}$$

where:

- i—measurement number,
- $\Delta y = y_{max} - y_{min}$

- mapped flight parameter (time):

$$\overline{t}_l = \frac{t_i - t_{\min}}{\Delta t} \tag{2}$$

where:

- $\Delta t = t_{max} - t_{min}$

If $y_i = y_{min}$ then $\overline{y}_l = \frac{0}{\Delta y} = 0$

If $y_i = y_{max}$ then $\overline{y}_l = 1$.

In this way, the prepared data are implemented to the artificial neural network.

5 OPERATION MODEL

The prototype of all the neural network is the human brain. The neural network is substantially simplified model of the brain. It consists of a large number (several hundred to several thousand) information processing elements, called neurons.

Neurons are linked in a network with connection parameters (weights) modified during the so-called learning process. Topology of connections and their parameters are the program activities of the network, and the signals appearing at its output in response to the output signals are solutions against her tasks.

Most recently built and used in a neural network has a layered structure, during the learning process divided into the following layers:

- the input,
- output,
- hidden layer [7–10].

The paper input signals are stored in vector form (Fig. 2):

$$X^T = [t, s, V_{i-2}, V_{i-1}] \tag{3}$$

where:

- t - time [s],
- s - segment [-],
- V_{i-2} - the speed at the moment of i- 2 [kt]
- V_{i-1} - the speed at the moment of i- 1 [kt].

The output of the airspeed at the time (i) (vi).

In the presented neural network is used neuron as in Figure 3.

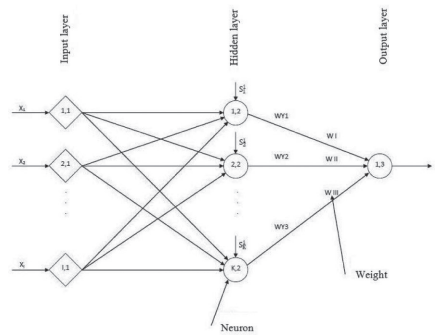

Figure 2. Schematic of a multilayer neural network [own elaboration].

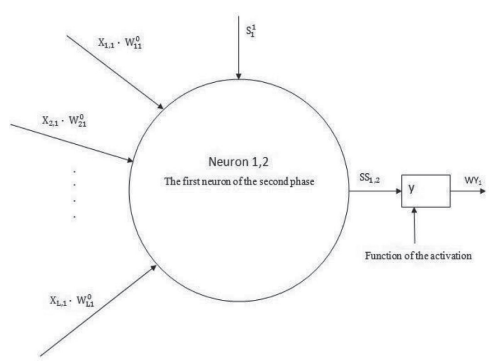

Figure 3. Neuron used in the modeling of neural networks. Function of the activation [own elaboration].

As presented above neuron output of the first neuron is the sum of the input x_{11}, x_{21}, ..., x_{L1}, multiplied by the weight wo_{11}, wo_{21}, ..., wo_{L1} and constant s_{11}.

The output signal $ss_{1,2}$ has the form:

$$SS_{1,2} = x_1(1,1) \cdot w_1(1,1) + s_1^1 \tag{4}$$

where:

$X_1=[x_{1l}, \ldots, x_{Ll}]$;
$W_1=[w^0_{11}, \ldots, w^0_{L1}]$.

Furthermore, the activation function was used in the form of:

$$y = \frac{1}{1+\exp(-2y_w)} \tag{5}$$

The essence of the development of the ANN is to determine the weights and fixed using the results of the registration board flights. For the algorithm used to create the torque back propagation method, in which the variables are constant learning α and η momentum.

Assessment of the accuracy of the mapping is determined by the sum of squared differences between the model and the real object and the number of positive events. The next step is to test the accuracy of the determination or the network compared input and output signals from the network [7].

6 RESULTS

In tests, examined data from more than a dozen flights EMB 170 aircraft. The research shows that the structure of the network, which accurately reproduces the landing phase of an aircraft EMB-170 is a network with four inputs, two hidden layers respectively five and four neurons and one output (4541).

Table 1 lists the results obtained by assessing the accuracy of the mapping model in an artificial network of the actual speed during the landing phase of flight of the EMB 170 aircraft.

The results are shown for different neural network structures. The number of neurons the input and output layer is always the same, respectively 4 and 1, and the change in the number of hidden layers and the number of them occurring in neurons.

The presented network structures shows that the EMB-170 aircraft network with structure 4541 (4 inputs, 1 output and 2 hidden layers with 5 and 4 neurons) generates the lowest value of χ2, which means that the selected structures is this best matches the actual flight. The number of events for the presented flight was 190, as can be seen all the tested structure gave 100% the number of positive events.

Also checked the extent to which a change in the momentum η and constant learning α affects the accuracy of the mapping.

The results obtained clearly define the impact of a constant learning and the momentum mapping accuracy landing speed by ANN.

The following graph shows the results. Figure 4 shows a comparison of the speed of the aircraft with registration and on-board artificial neural network for the EMB 170 aircraft.

V_{lot} course presents the actual speed of the on-board flight recorder, V_{SSN-D} velocities of the ANN with the best degree of mapping and V_{SSN-Z} the speed of the SSN of the worst degree of mapping the actual flight.

From the obtained results it can be concluded that, for the EMB 170 aircraft in the initial landing phase, the neural network very well reproduces the speed of the aircraft. In the final step results in inferior image.

Table 1. Rating accuracy of mapping the actual landing phase by SSN with different structures.

No	No of neurons in the hidden layer		No of positive events [%]	χ^2av
1	2	0	100	$0{,}51060 \cdot 10^{-3}$
2	3	0	100	$0{,}41722 \cdot 10^{-3}$
3	4	0	100	$0{,}29450 \cdot 10^{-3}$
4	5	0	100	$0{,}41122 \cdot 10^{-3}$
5	6	0	100	$0{,}44352 \cdot 10^{-3}$
6	2	2	100	$0{,}53347 \cdot 10^{-3}$

7 CONCLUSIONS

During the analysis examined data from more than a dozen flights made EMB-170 aircraft on the same route but in different weather conditions. The results were analyzed in terms of qualitative and quantitative evaluation on the quality of the mapping by comparing the results obtained using the model developed with the results obtained from the recorder. Mapping the landing phase of an aircraft by means of an artificial neural network gives positive results.

Yes developed models can be used to create simulation models used to study air traffic, as well as training simulators. Unfortunately drawback of this method is time-consuming very large data associated with the preparation and testing of the network.

ABSTRACT: Runway overrun is one of the main accident types in airline operations. Nevertheless, due to the high safety levels in the aviation industry, the probability of a runway overrun is small. This motivates the use of structural reliability concepts to estimate this probability. We apply the physically-based model for the landing process of Drees and Holzapfel (2012) in combination with a probabilistic model of the input parameters. Subset simulation is used to estimate the probability of runway overrun for different runway conditions. We also carry out a sensitivity analysis to estimate the influence of each input random variable on the probability of an overrun. Importance measures and parameter sensitivities are estimated based on the samples from subset simulation and concepts of the First-Order Reliability Method (FORM).

1 INTRODUCTION

The airlines organized in the International Air Transport Association (IATA) carried about 3.6 billion passengers in 2012. Among these, 414 where killed in an aviation accident (IATA, 2013). Of the many accident types, runway excursion is the most common one. There are several types of runway excursions; one of the most critical one is runway overrun (RWO) of a landing aircraft, which is investigated in this paper.

The high safety requirements within the civil aviation industry make a quantitative estimation of the probability of a runway excursion important. However, the already high reliability standards within the industry hinder an estimation of accident probabilities with purely statistical methods. In particular, it is difficult to investigate the effect of individual factors on the probability of specific accidents. This motivates the use of structural reliability concepts. This is demonstrated in this paper, where we estimate the probability of runway overrun using a previously proposed physically-based model for the landing process (Drees and Holzapfel, 2012).

A few authors proposed RWO models based on regression e.g. (Kirkland, 2001, Hall et al., 2008, Ayres Jr. et al., 2011). However, to the best of our knowledge, structural reliability methods in combination with a physically-based model have not been applied previously.

In the next section a short outline to structural reliability in general and subset simulation in particular is given. This is followed by a summary of the RWO model and the related probabilistic model. Thereafter, the results of the reliability analysis are presented for different runway conditions. The influence of the individual input random variables on the probability of a RWO is investigated through different importance and sensitivity measures. In this context, FORM is shortly explained, as some of its theory is applied. The paper concludes with a discussion of the results.

2 STRUCTURAL RELIABILITY

In reliability analysis, $\mathbf{X}$ denotes a vector of random variables that are the input to a model; $\mathbf{X}$ has the joint probability density function $f(\mathrm{X})$. The response of the physical model as a function of $\mathbf{X}$ is described by means of Limit State Functions (LSF) $g(\mathbf{X})$. For RWO, $g(\mathbf{X})$ corresponds to the stop margin of the aircraft, i.e. the length of the runway minus the operational landing distance (the distance actually needed to stop the aircraft). A runway overrun corresponds to the event $g(\boldsymbol{X}) \leq 0$ and its probability can be written as:

$$\Pr(RWO) = \int_{g(\mathbf{X})\leq 0} f(\mathbf{X}) d\mathbf{X} \tag{1}$$

This type of problem is well known within the field of structural reliability, which is concerned with estimating probabilities of failure of engineering structures (Rackwitz, 2001). As the integral in Equation (1) can in general not be calculated analytically, a number of methods for efficiently solving this kind of problems have been developed in the field of structural reliability. The most prominent among these are the first—and second-order reliability methods (FORM and SORM) e.g. (Der Kiureghian, 2005), the standard Monte Carlo Simulation (MCS), and advanced sampling methods like importance sampling or subset simulation (SuS) (Au and Beck, 2001).

Both FORM and SORM rely on finding the Most Likely Failure Point (MLFP), i.e. the most likely realization of $\mathbf{X}$ that leads to failure, here RWO. These methods are based on optimization for finding the MLFP. This may be critical if the method is to be applied for the computation of the probability of RWO in near-real time. For this reason, we apply SuS, which is still relatively efficient, but does not necessitate optimization.

2.1 *Subset simulation (SuS)*

The classical MCS approach provides an unbiased estimate $\hat{P}_F$ of Equation (1) by generating n_S samples from the joint distribution $f(\mathbf{X})$ and evaluating $g(\mathbf{X})$ for each of the samples. The estimated probability of failure is then:

$$\hat{P}_F = \frac{1}{n_S}\sum_{i=1}^{n_S} I_{g(\mathbf{X}_i)\le 0}(\mathbf{X}_i) \tag{2}$$

where $I_{g(\mathbf{Xi})\le 0}(\mathbf{X_i})$ is an indicator function, which is 1 for $\mathbf{g}(\mathbf{X_i}) \le 0$ and 0 otherwise. This MCS approach becomes computationally unfeasible for small probabilities of failure. For a desired coefficient of variation of the estimate $\delta_{\hat{P}_F}$ the required number of samples is:

$$n_S = \frac{1-\Pr(F)}{\delta^2_{\hat{P}_F}\Pr(F)} \tag{3}$$

For a small probability of failure of $\Pr(F) = 10^{-8}$ and a desired coefficient of variation of $\delta_{\hat{P}_F} = 0.1$ approximately 10^{10} LSF evaluations would be necessary. SuS proposed by (Au and Beck, 2001) overcomes this problem by expressing the failure event F as a sequence of nested events F_i.

$$F_1 \subset F_2 \subset \cdots \subset F_n = F$$

With these nested events the probability of failure can be rewritten as:

$$\Pr(F) = \Pr(F_1)\prod_{i=2}^{n}\Pr(F_i|F_{i-1}) \tag{4}$$

The probability of the first intermediate event, $\Pr(F_1)$, is not conditional on a previous intermediate event and can therefore be estimated with a standard MCS. All other probabilities $\Pr(F_i|F_{i-1})$ in Equation (4) are conditional on a previous intermediate event, these conditional probabilities are estimated using Markov Chain Monte Carlo (MCMC) simulation procedures. In Figure 1 the MCMC approach is schematically shown for estimating $\Pr(F_2|F_1)$. The grey points represent the samples generated from $f(\mathbf{X})$ in the initial MCS step. Those samples $\mathbf{X}_i$, which are above the LSF (shown here as a black line) are said to be in the failure domain F_1, i.e. for them $\mathbf{X}_i \in F_1$. From each of those m intermediate failure samples, a Markov Chain of length n_S/m is generated (black samples). In these chains a new candidate state is generated conditional on the previous state of the chain. Furthermore if the newly generated candidate state $\mathbf{X}'$ fulfills the condition $\mathbf{X}' \in F_1$ it becomes the new state of the chain otherwise the previous state is repeated. SuS is performed in the uncorrelated standard normal space (U-Space). The component wise Metropolis Hastings algorithm, which was proposed by (Au and Beck, 2001) as a MCMC algorithm for SuS makes use of this by generating the candidate states independently for each dimension. The performance of SuS thus becomes independent of the number of dimensions of the problem.

In this paper we apply a MCMC algorithm proposed by (Papaioannou et al., 2014) for use in SuS. Like the algorithm of (Au and Beck, 2001) this algorithm works in a component-wise fashion and its performance is therefore also independent of the dimensionality of the problem. However, the generation of the pre-candidate states is done, such that every pre-candidate state is accepted.

Typically the intermediate failure events F_i are chosen adaptively, such that $\Pr(F_1) = \Pr(F_2|F_1) = \cdots = \Pr(F_{n-1}|F_{n-2}) = p_0$. Often a value of 0.1 is chosen for p_0. The final failure event $F_n = F$ is fixed and therefore its conditional probability cannot be chosen a priori. Equation (4) is then:

$$\Pr(F) = p_0^{\,n-1}\Pr(F \mid F_{n-1}) \tag{5}$$

As SuS is applied in U-space the random variables $\mathbf{X}$ have to be transformed to U-space. Typically the Nataf or the Rosenblatt transformations are applied for this purpose (Hohenbichler and Rackwitz, 1981). In the problem at hand one of the random variables is defined conditional on other random variables. For that reason the Rosenblatt

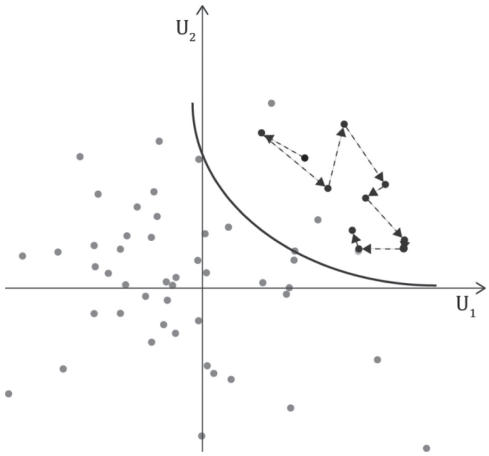

Figure 1. Generation of samples conditional on a first intermediate failure event. The new samples (black) are sampled starting from a seed sample using a MCMC algorithm. The grey samples were obtained by MCS in a previous step.

transformation appears to be suitable. This transformation is based on expressing the distribution of every random variable conditional on the previous random variables.

3 PHYSICAL MODEL OF RUNWAY OVERRUN (RWO)

In this section, we *briefly* present the applied RWO model. For a more detailed description, the reader is referred to the original paper by (Drees and Holzapfel, 2012). The RWO event can be defined as the operational landing distance exceeding the runway length (Fig. 2). The LSF can therefore be written as:

$$g(\mathbf{X}) = \textit{Stop margin}\ (\mathbf{X})$$

The stop margin is the deterministic runway length minus the operational landing distance, which depends on a number of factors that are modeled as random variables. The model is derived from the equations of motion. The acceleration of the aircraft in x-direction is:

$$\dot{V} = \frac{1}{m}[T - D - mg \cdot \sin\gamma - \mu_F(mg \cdot \cos\gamma - L)] \quad (6)$$

where m is the mass of the aircraft, T is the propulsion force from the aircraft engines and D is the aerodynamic drag. The term $mg \cdot \sin\gamma$—with g being the constant of gravitation and γ the flight path angle—represents the contribution of the runway slope to the acceleration. Finally, the last term describes the influence of the friction and brake forces. L denotes the aerodynamic lift and μ_F the friction coefficient, which depends on the runway condition, on the brake force and on the velocity of the aircraft.

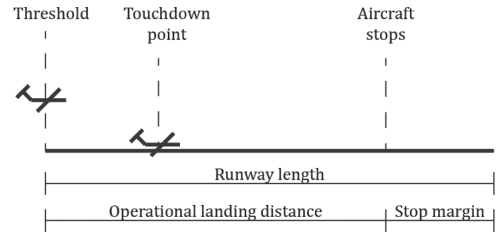

Figure 2. Definitions.

The drag force can be written as:

$$D = \frac{\rho}{2}(V_K - V_W)^2 S \cdot C_D \quad (7)$$

and the lift force as:

$$L = \frac{\rho}{2}(V_K - V_W)^2 S \cdot C_L \quad (8)$$

ρ is the air density, V_K is the speed of the aircraft and V_W the speed of the surrounding air, such that $V_K - V_W$ is the speed of the aircraft relative to the wind speed. Furthermore, S is the reference area of the wings and C_D respectively C_L are the drag and the lift coefficients.

Integrating equation (6) twice with respect to time will yield the operational landing distance. For practical reasons the operational landing distance is split in three parts. First the touchdown distance, which is directly modeled as a random variable; second the distance from the touchdown point to the point where the pilot deactivates the auto-brake system, which, in addition to the environmental and technical factors, depends on a number of human factors, e.g. the point in time until the pilot starts braking and the point in time when the spoiler is deployed. The third part is the distance the aircraft travels from the point of auto-brake deactivation to the final stopping position. During a normal landing, the aircraft will not stop completely on the runway but exit the runway with slow velocity to the taxiways. However, it is assumed that in the case of a critical landing, which is likely to result in a RWO, this distance is traveled with maximum deceleration efforts i.e. maximal braking forces.

Table 1. Random variables of the physical model. The pressure is the air pressure adjusted to the sea level. Approach speed deviation is the deviation from the target approach speed. The mean value of the touchdown point depends on the calculated required landing distance, which again is a function among others of the headwind, the landing weight and the temperature. Abbreviations: weibull distribution (WBL), normal distribution (N) and generalized extreme value distribution (GEV).

Random variable	Distribution model	Mean	Std. dev.
Landing weight [t]	WBL (60.0,44.3)	59.3	1.69
Head wind [kts]	N (5.4,5.8)	5.4	5.8

Pressure [hPa]	N (1016,8.1)	1016	8.1
Appr. speed dev. [kts]	GEV (–0.20,4.0,3.0)	4.7	4.2
Rev. deployment [s]	Gamma (9.0,0,55)	5.0	1.7
Start braking [s]	GEV (0.15,3.9,10.2)	13.1	6.4
Splr. Deployment [s]	GEV (0.11,0.89,3.7)	4.3	1.3

3.1 *Technical and human factors*

The quantities in the differential Equation (6) are influenced by environmental factors on the one hand, and technical as well as human factors on the other hand. The technical aspects are captured in the RWO model by allowing certain technical components like the spoiler, the auto-brake system or the engines to be either operative or inoperative with a certain probability. The brake system can be operative, inoperative or degraded. In the scope of this paper we do not consider any technical failures, thus all components are considered to be fully operative. Furthermore, we assumed the flaps and slats to be in configuration full, which is used in 96% of approaches (Drees and Holzapfel, 2012).

The friction coefficient between the tire and the runway μ_F is a major factor influencing the deceleration of the aircraft. This friction coefficient is mainly determined by the runway condition; we differ between a dry and a wet runway in our calculations.

The auto-brake system automatically applies a brake pressure when the landing gear touches ground. The magnitude of the applied pressure depends on the setting of the auto-brake system. For the scope of this paper, we compute RWO probabilities for the auto-brake settings set to medium.

In operational aviation, the times after touchdown at which the spoiler and thrust reversers are deployed and the times at which the braking starts and ends can be obtained from operational data. On the basis of this measured data, distribution models are selected. These models are summarized in. Another factor, whose variability is influenced mainly by human actions, is the touchdown point. A normal distribution, with fixed standard deviation and a mean value (μ_{TDP}) that is a function of the environmental conditions is used for this. It was found from flight operation data that pilots change their touchdown behavior according to the required landing distance estimate, which they calculate during the approach. The required landing distance is thereby calculated from aircraft and runway specific characteristics as well as from the flap setting, the head wind, the temperature and the landing weight.

4 PROBABILITY OF A RWO

As a case study, we calculate the RWO probabilities for an aircraft of type Airbus A320 landing on runway EDDM 26 L at the Munich airport (MUC). The runway is 4000 m long with a concrete surface. We apply subset simulation using the MCMC algorithm proposed in (Papaioannou et al., 2014). The inter-sample correlation is initially chosen as 0.8. The intermediate thresholds were chosen adaptively, such that at each simulation level 10% of the samples would lie in the intermediate failure region. At each of the simulation levels, 1000 samples were generated such that considering the presented results in Table 2 7000 respectively 8000 LSF evaluations were necessary for each simulation run.

The resulting probabilities are in the same order of magnitude for the different runway conditions.

The fact that the RWO probabilities are smaller for a wet runway than for a dry one may be counterintuitive, as a wet runway reduces the friction between the tire and the runway and thus also the effectiveness of the braking procedure.

The explanation for this result is that the pilots calculate the required landing distance according to an approximate formula when approaching an airport and adapt their landing behavior to the

Table 2. Simulation results for different runway conditions (dry and wet). For each simulation 1000 samples were used per simulation level.

Runway condition	$P_r(RWO)$
Dry	1.06E – 7
Wet	7.03E – 8

result. In the model this is accounted for through the mean value of the touchdown point. The inferior grip of the tires is therefore compensated or even overcompensated by an adapted touchdown behavior, at least according to the model.

5 SENSITIVITY ANALYSIS

We conduct a sensitivity analysis to find the influence of the individual random variables on the probability of a RWO. First importance measures based on FORM are calculated. For the most important random variables, parameter sensitivities are then calculated based on the samples from subset simulation. In the following the concepts of FORM, which are of major importance for our purpose are introduced. For a deeper introduction the reader is again referred to the literature e.g. (Der Kiureghian, 2005, Ditlevsen and Madsen, 2007). In a later section parameter sensitivities are calculated using the samples from SuS.

5.1 *Importance measures with FORM*

FORM gives an approximation of Equation (1) by substituting the LSF in U-space with a linear surrogate model $g_L(\mathbf{u})$. The linearization of the LSF is done in the design point i.e. the most likely failure point $\mathbf{u}^*$ in U-space. The probability of failure Pr(F) can then be approximated through the probability of failure corresponding to the linear surrogate model. With Φ being the standard normal CDF and β_{FORM} the reliability index Pr(F) can be approximated as:

$$\hat{P}_F = \Phi(-\beta_{FORM}) \tag{9}$$

With the reliability index being defined as:

$$\beta_{FORM} = |\mathbf{u}^*| \tag{10}$$

The task of calculating the probability of failure reduces thus to finding the design point $\mathbf{u}^*$. In general the convergence of the optimization algorithms, applied to find $\mathbf{u}^*$ is the bottleneck in FORM analysis.

A useful byproduct of the FORM analysis is the normal vector of the linear approximation of the LSF $\boldsymbol{\alpha}$ (Der Kiureghian, 2005). The elements of this vector can be interpreted as importance measures of the standard normal random variables U_i (Figure 1):

$$\alpha_i = \frac{u_i^*}{\beta_{FORM}} \tag{11}$$

If a random variable U_i is the only one influencing $\hat{P}_F$ its corresponding α_i will have an absolute value of 1. If on the other hand U_i has no influence on $\hat{P}_F$ its α_i is 0. We can further distinguish between random variables of load type, which have a positive α_i and those, which are of capacity type that correspond to a negative α_i.

If the random variables in $\mathbf{X}$ are independent the importance measures $\boldsymbol{\alpha}$ of the transformed variables $\mathbf{U}$ are readily valid also in the original space otherwise a transformation as described in (Der Kiureghian, 2005) needs to be applied.

In the scope of this paper the FORM importance measures are determined for a linear LSF fitted to sample points as proposed in (Melchers and Ahammed, 2004). Thus the optimization usually necessary for FORM, which is a bottleneck especially in near-real time applications, is circumvented. Fitting a linear hyper-plane to a set of points is a robust way to estimate the design point according to (Melchers and Ahammed, 2004). As the linear LSF $g_L(\mathbf{u})$ should approximate the actual LSF as accurately as possible mainly in the proximity of the design point/limit state surface it is suggested to only use those sample points $\mathbf{u}$, for which $g_L(\mathbf{u}) \approx 0$ or $g_L(\mathbf{u}) \leq 0$.

The sensitivity analysis is done in this paper for a dry runway. A simulation run with 1000 samples per simulation level was done to this end and the samples from the last simulation step were used to fit the linear LSF with the method of least squares.

In Table 3 the FORM importance measures for the problem at hand are summarized. The numbers in brackets give the values for a linear LSF that was fitted to sample points from a different simulation run.

'Head wind', 'Start braking', 'Touchdown point', Approach speed deviation' and 'Landing weight' appear to be the random variable, having the most influence. All of them are of load type except head wind, which is of capacity type meaning that a large head wind velocity reduces the probability of a RWO.

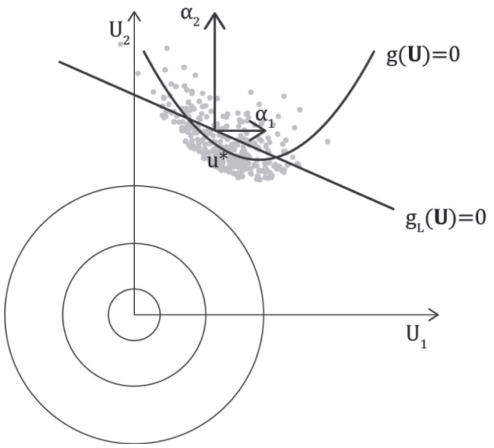

Figure 3. Importance measures α of linear LSF approximation fitted to samples from a SuS run.

Table 3. FORM importance measures for the dry runway conditions and a flap setting medium.

Random variable	FORM	Measures
Landing weight [t]	0.116	(0.138)
Head wind [kts]	–0.693	(–0.663)
Temperature [°C]	0.020	(0.010)
Pressure [hPa]	0.010	(0.002)
Appr. speed dev. [kts]	0.202	(0.179)
Rev. deployment [s]	0.037	(0.042)
Start braking [s]	0.650	(0.680)
Splr. Deployment [s]	0.019	(–0.013)
End braking [s]	0.004	(0.013)
Touchdown point [m]	0.204	(0.213)

From Table 3 it becomes obvious that the linear LSF depends on the points used for fitting. However the results show that the measures for the variables with a large influence (i.e. > |0.1|) are fairly similar in both runs while the variables that have only a minor influence are in one case even of different type (i.e. load or capacity) in the two runs.

Although the 'Touchdown point' is one of the main influencing factors according to the FORM measures one may expect it to have an even larger influence. The reason for that is, that it was modeled as a function with fairly low variability and a mean, which is shifted according to the outcome of other random variables.

In general it should be noted that the FORM importance measures in Table 3 are dependent on the distributions of the random variables. For example from the fact that the pressure appears to have only a minor influence in the case study at hand it cannot be concluded that the pressure may not be an important factor if one considers different airports, where some of them are located at high altitudes.

5.2 *Sensitivity measures*

For the random variables, which were found to be important according to the FORM importance measures, parameter sensitivities are calculated. We calculate sensitivities of the probability of failure with respect to the parameters of $f(\mathbf{X})$, $\boldsymbol{\theta}$. These sensitivities can be defined as:

$$\frac{\partial \hat{P}_F}{\partial \theta_i} = \int_{g(\mathbf{X})\leq 0} \frac{\partial f_{\mathbf{X}}(\mathbf{X},\boldsymbol{\theta})}{\partial \boldsymbol{\theta}_i} d\mathbf{X} \tag{12}$$

where $f_{\mathbf{X}}(\mathbf{X}, \boldsymbol{\theta})$ is the probability density function of X with the parameters $\boldsymbol{\theta}$. $\boldsymbol{\theta}_i$ denotes the parameter with respect to which the sensitivity is calculated. In the scope of this paper we consider sensitivities with respect to the means μ_i and standard deviations σ_i of the random variables X_i.

Based on the calculated FORM approximation of the LSF, sensitivities of the form $\partial \Pr(F)/\partial \boldsymbol{\theta}$ can be calculated as described in (Der Kiureghian, 2005). These approximate sensitivities can be calculated based on a design point, which was obtained using an optimization algorithm. In a near real-time context, where convergence of the optimization algorithms may be critical this can be done also based on a linear LSF fitted to samples, as already described. Here we calculate the sensitivities with respect to the mean values μ_i and standard deviations σ_i directly from the samples obtained from SuS. The parameter sensitivities can be written as:

$$\frac{\partial \hat{P}_F}{\partial \theta} = \sum_{i=1}^{n} \frac{\hat{P}_F}{P_i} \frac{\partial P_i}{\partial \theta} \tag{13}$$

where P_i are the (un)conditional failure probabilities corresponding to the intermediate failure events i.e. $P_1 = \Pr(F_1)$ and $P_i = \Pr(F_i|F_{i-1})$ for $i > 1$. The derivative of the intermediate failure probabilities can be estimated using the samples obtained in subset simulation (Song et al., 2009):

$$\frac{\partial P_i}{\partial \theta} \approx \frac{1}{N} \sum_{k=1}^{N} \left[I_{F_i}(\mathbf{X}_k) \left(\frac{1}{f_{\mathbf{X}}(\mathbf{X}_k)} \frac{\partial f_{\mathbf{X}}(\mathbf{X}_k)}{\partial \theta} - \sum_{j=1}^{i-1} \frac{1}{P_i} \frac{\partial P_j}{\partial \theta} \right) \right] \tag{14}$$

where $I_{F_i}(\mathbf{X}_k)$ denotes the indicator function, which is 1 if $\mathbf{X}_k \in F_i$ and 0 otherwise.

Table 4. Elasticities of $\hat{P}_F$ with respect to μ_i and σ_i, calculated following Equation (13) and (15).

Random variable	$(\mu_i/\hat{P}_F)(\partial\hat{P}_F/\partial\mu_i)$	$(\sigma_i/\hat{P}_F)(\partial\hat{P}_F/\partial\sigma_i)$
Landing weight [t]	53,4	1.4
Head wind [kts]	–3.2	10.6
Appr. speed dev. [kts]	0.8	0.04
Start breaking [s]	1.1	56.0
Touchdown point [m]	–	1.0

In Table 4 the elasticities $\varepsilon_{\hat{P}_F,\theta}$ are shown for the five most important random variables according to the FORM importance measures from Table 3. Elasticities are defined as:

$$\varepsilon_{\hat{P}_F,\theta} = \frac{\theta}{\hat{P}_F}\frac{\partial\hat{P}_F}{\partial\theta} \tag{15}$$

They describe the relative change of probability of failure due to a relative change in the parameter θ and are in general easier to interpret than sensitivities.

6 CONCLUDING REMARKS

Structural reliability methods have been applied to estimate runway-overrun probabilities and were shown to be suitable for this purpose. In particular, the calculated sensitivities and FORM importance measures support the interpretation and further development of the model. With the help of the FORM importance measures, one can simplify the model by modeling the quantities of minor importance deterministically. We have found that the parameters 'Temperature', 'Pressure', 'Reverser deployment', 'Spoiler deployment' and 'End breaking' may be modeled deterministically without inducing a large error. This does, however, not imply that the influence of these quantities is small. It can only be concluded that the uncertainty associated with the quantity is not significant. The parameter sensitivities were in this paper calculated based on the samples obtained with subset simulation. These parameter sensitivities describe the effect of a change of the mean or standard deviation on the probability of failure. We presented the parameter sensitivities in the form of elasticities, which are typically easier to interpret. From the results it can be seen that the variables, which are of main importance according to the FORM importance measures, are the most sensitive ones with respect to a change in the standard deviation (i.e. the variability).

A physically-based RWO model in combination with robust methods for reliability analysis could be applied in real time or near-real time risk assessment. A possible scenario would be an aircraft approaching an airport and getting gradually better information on uncertain factors like landing weight, head wind at the destination airport etc. Based on the calculated RWO probabilities a pilot could decide on whether it is save to land at the destination airport or to approach an alternate airport.

A meta model framework for risk analysis, diagnosis and simulation

H. Kanj & J.-M. Flaus
Université Grenoble Alpes, G-SCOP, Grenoble, France
CNRS, G-SCOP, Grenoble, France

ABSTRACT: This document represents an overview of the Function Interaction Structure (FIS) modeling, where the goal is to represent a system and the risk analysis that is made, and to obtain a simulation model from the risk analysis. This model is able to show the results of risk analysis. This model is supplemented by information on its behavior, in order to generate the dynamic model in degraded mode. Our proposed meta model is also used to analyze the risk associated with a system such as: evacuation system, transport of dangerous goods, ...

1 INTRODUCTION

The goal of risk analysis is to identify events that may have one or several undesirable consequences on a system, and to assess the likelihood and severity of these consequences. A lot of methods can be used to conduct risk analysis (Flaus, 2013a) such as Preliminary Hazard Analysis (PHA) and Failure Mode Effects Analysis (FMEA) (Papadopoulos et al., 2004). In most of these methods, the obtained information may be used to build a risk model. The next step after risk analysis is to study the behavior of the system, when the undesirable events occur, in order to evaluate its performance in degraded conditions, and its robustness or resilience. An approach to allow integrated risk analysis and simulation has been proposed for business process management (Tjoa et al., 2011).

The aim of this paper is to present a meta model, suitable to socio-technical systems. This model allows describing the system to analyze, the result of the risk analysis, and the required aspects of dynamical system behavior, in order to automatically perform simulation under degraded conditions. The model is an extension of the FIS model presented in (Flaus, 2011, Negrichi et al., 2012). The meta model may also be used for fault diagnosis, as it can be used to generate redundancy relation and to perform root cause search (Flaus et al., 2011).

The remainder of this paper is organized as follows. Section 2 represents the first part of the FIS model, defines the architecture of the analyzed system, and describes the characteristics the system and the material entities used. This is the basic view. Section 3 represents the second part of the FIS model. It is built when we realize the risk analysis (Karagiannis et al., 2010). Section 4 displays the last part of the FIS model. It is assembled when we describe the behavior of the system in normal or degraded mode. An illustration of this method on transporting hazardous material by road is presented and discussed in Section 5. Finally, Section 6 concludes this paper.

2 SYSFIS VIEW

This part describes the structure of the equipment or the analyzed object, in a relatively simple manner by showing the various systems interactions, and specifying, if necessary their functions and the material components (human, technical or informational) that compose them (see Figure 1). This part also allows describing the links between these elements. The purpose of this view is to provide a frame structure for the dysfunctional or for behavioral view (Flaus, 2008).

2.1 *Elements of the model*

The basic element of the representation is the *process* or *system*, composed of functions, physical

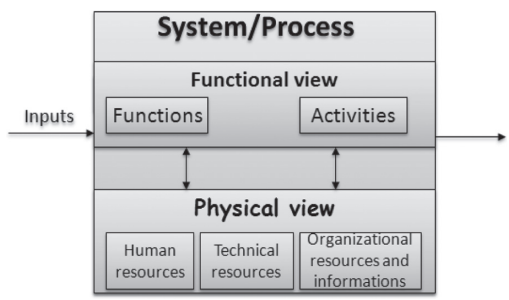

Figure 1. SysFis model.

resources and input/output ports. A process or system is seen as an organized set of activities that uses resources (personnel, device, equipment andmachinery, raw material and information) to transform inputs into output elements. Each process or system is described internally by:

- The *Structural Elements* (SE), known as *resources* or *entities*, which consist of hardware (machinery and materials), informational, human and organizational activities to conduct the process activities. We distinguish machines, materials and processed parts, human actors, methods represented by procedures, software, The physical context characterized by variables such as temperature, the concentration of various products, the noise level ...
- The *Functional Elements* (FE), called *functions* or *system activities*, are defined as the role played by a set of resources in terms of purpose. It is a kind of dematerialization of a set of entities specifying what the system can do. This represents a specification of the system behavior. A function can be active or not active at a given time. Its behavior is characterized by a set of variables, and eventually by a performance model describing the temporal evolution.

It is possible to define for each system a structural element and a main functional components. A system is decomposed of subsystems, which themselves can be described by structural elements and/or functional components.

The advantages of this model for risk analysis are:

- on the one hand: it allows a description of the installation or the object analyzed, in an organized and hierarchical way. This description may be systemic, functional or structural where the different parts of the model are managed simultaneously.
- and on the other hand, it helps at the identification of risks, based on the category of the different elements of the model. For example, a risk of explosion types can be identified for the element "gas pressure".

Note: When modeling a complex reality, it is necessary to decompose it in several systems, and eventually subsystems.

2.2 *Links between model elements*

Relationships may be defined between the structural and functional elements of the model (Figure 2). To perform a function or activity:

- a number of incoming items may be necessary, they are consumed or brought using information, there are inputs for the function. This is the case of a raw material, a part to be assembled or a sensor;
- other elements are generated where there state is modified, resources are then "outputs" for the function. This is the case of a material produced from an assembled or machined object;
- finally, some *structural elements* may be used, they are "supports" for the function. For example, this is the case of a machine or an operator used to perform a function.

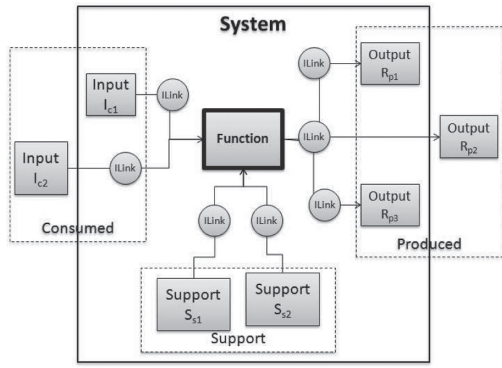

Figure 2. Relations.

When the links are given at the systems level, they represent a broader point of view, because they do not detail the relationships within a system. Links between elements of the model may contain information, such as coefficients or properties.

Remark *Resources include both items that are processed, items products and components used for processing. The terminology used in the context of flow simulation, is to call entity, produced and consumed resources and resources, used ressources.*

2.3 *Details of model elements*

Before describing in detail the elements of the model, we may define:

- A *variable*, which corresponds to a magnitude that can be represented by an integer, a real, ...
- An *attribute*, that can describe any property given by: $a =< name, value >$, where value is any value representable by a structured string character following the ECMA-404 JSON Data Interchange Standard syntax.

A *variable* can be used to evaluate system behavior, values are the possible values of a state variable of a hybrid dynamical system. An *attribute* is of a different nature. Its aim is to represent one of the properties of a meta element. Its values can be generally represented by an object, the chosen format is JSON.

Formally, a structural view of a model is defined by $M =< S, L >$ where:

- S is a set of systems, $S = \{s_i \mid 0 \le i \le n\}$ with $s =< F(s), R(s), Sub(s), V(s), A(s) >$ is a system defined by a set of functions F, a set of resources R, a set of subsystems Sub, a set of variables $V(s)$ and a set of attributes $A(s)$.
- L is a set of links defined as follows $L =< me_s, me_t, nature, A(l), nature, direction, M_s \times M_t >$

A model element, me may be a system, a functional element or a structural element. The set of model elements connected to a model element is denoted by $N_s(me)$.

Remark *The function $O(x)$ defines the owner(s) of x. This function is denied for variables $O(v)$, attributes$O(a)$, functions, structural element $O(r)$, ...*

3 DYSFIS VIEW

3.1 *Elements of the model*

The dysfunctional view (Figure 3) is used to describe the risk analysis or malfunction. This analysis consists in identifying, for each element of a system, states in which this element may cause a damage, or might be unable to answer correctly with the expected level of performance. The principle of this analysis with the view DysFis is as follows:

- each fact that may occur is represented by an event;
- the nature of the fact is described by the type of events: there are such events characterizing hazards, failure modes or deviations of variables;
- each event is associated with the element of the model view SysFIS to which is related. For example, a failure mode can be associated with a given resource;
- the causal links between events can describe the sequence of malfunctions. It is possible to associate properties to these links and barriers that affect the propagation.

The list of event types proposed by the model is the following: events representing the degraded dangerous phenomena (*dp*), events representing the failure modes (*fm*), events representing the deviations of variables (*vdev*), events representing degradation events (*dam*), intermediate events (*gen*), events characterizing the hazardous situations (*hs*), central unwanted events characterizing the loss of control (*uce*).

Each event is associated with a Boolean value. For a model element, the OK mode is defined as true if no event model dysfunction is true.

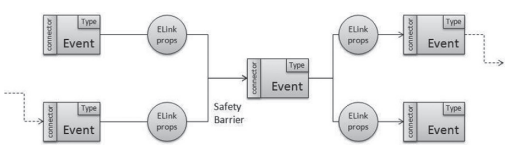

Figure 3. Events graph.

3.2 *Links between model elements*

Events are related to each other by links representing causal relationships: the causes of an event are connected to the input of the resulting event. Different types of connectors exist, such as AND and OR connectors. Links between events may occur with a certain probability, in particular an influence coefficient. Each link may relate to the input or the output of an event a barrier characterized by a reduction coefficient of the likelihood or severity.

The events are connected depending on the causal links. The model allows then to generate the fault tree relating to an event. Furthermore, the links between events can be weighted and it is possible to associate them with security gates.

3.3 *Details of model elements*

Figure 4 illustrates the relationship between the views SysFis and DysFis: events are associated with different elements. Links between the elements of SysFis model can guide the analysis of the propagation of dysfunctions for causal links between events.

Formally, the dysfunctional view is defined by a set of events $E = \{e_i\}$, and a graph G. The events are defined as

$$e =< N, P(e), S(e), O(e), g, \mu, \nu, A(e), V(e) >$$

where

- N is the set of the nature of events. Most often, $N \subset \{dp, fm, vdev, hs, uce, dam, gen\}$;

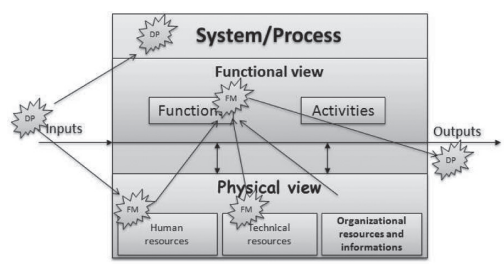

Figure 4. Links between system element, function, resources and events.

- $P(e)$ and $S(e)$ are sets of predecessors and successors of the event;
- $O(e)$ is the owner of event;
- $g_i(e)$ is the input gate;
- μ is a function that defines the likelihood of the event, and v is the severity of the event.

The event graph G is defined with the sets $P(e)$ and $S(e)$ for each event; $\rho(e_i,e_j)$ is a partially defined function which describes a weight related to the edge between two events; $M(e_i,e_j)$ a partially defined function which associates modifiers to the relation between e_i and e_j. An example of modifier is a safety barrier. The failure mode of a model element is denoted by $fmode_i$ (failuremode). The normal of a model element is defined as:

$$ok = \bigwedge_i \neg dfmode_i$$

4 SIMFIS VIEW

The SimFis view describes the dynamic behavior of the system. It is not necessary to construct this view to perform a simple risk analysis or even to build a fault tree or node bow tie diagram. However, when we have this view, it is possible to simulate the operation of the system, including degraded mode. In addition, some elements of this view can be exploited for diagnostic or prognostic (Flaus, 2013b, Giap et al., 2009).

The behavior is described by several complementary aspects. Each model element (*System*, *Functional element* or *Structural element*), which is desired to describe the evolution, has one or more behavior modes. Usually, at least one mode of behavior is defined for the *OK* mode of, and a mode of behavior is associated with each failure mode that could be interesting to simulate. A model element may be active or inactive, which means that it is not used in a given configuration.

At each mode of behavior is associated with one or more activities, which can be of the following types:

- a simple modification activity of the informational state, described by a mathematical relationship and an execution duration (may be null);
- an activity of transformation element, which can be seen as an entity processor (Figure 5) and used to represent the flow diagrams of processing: a *System*, a *Functional element* or a *Structural element* can be seen as a processor which transforms into output, member elements, or that performs actions on elements. A processor can be active or not;
- a macro-type activity described by a diagram of subset of BPMN Type (Figure 6).

When an element becomes active for a given mode, the corresponding activities to this mode become active and can describe the behavior of this element. When it changes its operation mode, i.e from a normal mode OK to a dysfunctional mode DM1, the current activity is interrupted and the dynamic behavior changes. More precisely, a simple activity is defined by $a =< name, x \leftarrow f_a(x), \delta >$ where x is a vector of variables defined in the model element or the set of model elements via a structural link english $N_s(me)$, and δ is a positive integer representing the time english $t = \delta.T_s$.

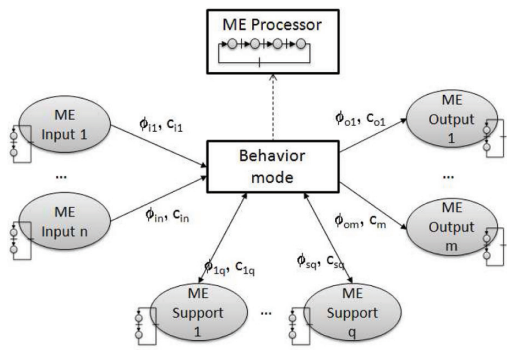

Figure 5. Process.

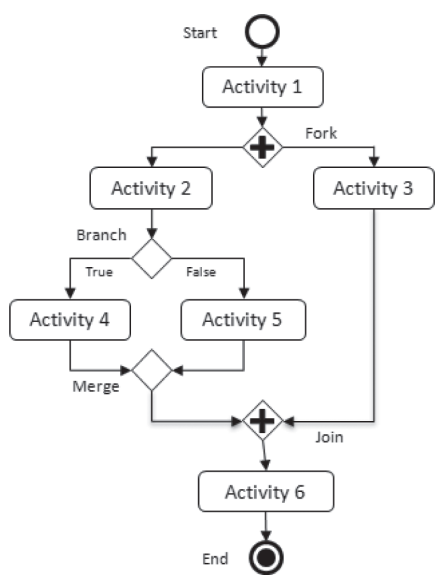

Figure 6. Activity diagram.

A transformation activity is defined by:

- a transformation relation defined as follow:

$$\sum n_i me_i \mid \varphi_i .. \rightarrow \overset{n_s me_s \mid \varphi_s}{\longrightarrow} \sum n_o me_o \mid \varphi_o \{m_i\}$$

where me_i is an input model element, required in number n_i and which must satisfy the condition φ , which a logical relation expressed with respect to the variables, the attributes and the events available in the scope. me_o is an output and me_s is a model element representing a support;
- a positive integer duration δ representing the time english $t = \delta.T_s$, and/or a set of final conditions;
- a priority p;
- a set of input actions defined as mathematical relation on variables in the scope $\{me\} \cup N_s(me)$.

$$x_c(k) \leftarrow f_{input}(x_c(k)) \cup \{m_i\};$$

- a set of output actions defined in a similar way

$$x_c(k) \leftarrow f_{ourtput}(x_c(k)) \cup \{m_i\};$$

- a set of evolution equations, computed at each sampling time

$$x_c(k+1) = f(x_c(k)) \cup \{m_i\}.$$

This set of elements allows to model the system behavior as follows:

1. A model element, when it is active, evolves according to the diagram in Figure 7:
   (a) block 1 is activated: this step consists of searching input elements satisfying the conditions in adequate numbers. If all items are not available, the block 1 is still active;
   (b) else, block 2 becomes active. The input actions are performed;
   (c) block 3 becomes active and evolution calculation is performed, if the equations are defined;
   (d) while the execution time mode is less then max time and the final condition is false, the block will be executed;
   (e) the final actions are executed, the inputs are destroyed and the support and outputs are released.

Remark • *An operating mode can be defined for each phase of life in OK mode, phases of life taking values in the set OM : Normal Operating Mode, DW : Shutdown, MA : Maintenance, UP : Startup, DW : Shutdown;*

- *model elements have a variable defining the number of modes of behavior that use and an attribute defining the max number (generally 1);*
- *the dynamic model is only valid for a given mode. In this mode, the connection variables are carried out during the activation step, and they are disconnected during the desactivation phase.*

Remark. *Changing the functional mode for an transforming activity type. When a change mode occurs, if the transformation relationship is not valid for this mode, this one is interrupted and the elements being processed (inputs and outputs) are destroyed. If we desire specifying a simple abnormal transformation of inputs, it is sufficient to define the activity as being valid for this mode, and to specify in the dysfunctional model, that the defects of the support element or the defects associated with the function behavior pattern, lead to a output default. For example, a default in a machine may product a defective part, while maintaining the same behavior in terms of machining.*

4.1 *Use for the simulation and diagnosis*

The proposed meta model may be used to structure the risk analysis, and to allow the exploitation of the obtained information for system simulation and diagnosis (Chittaro and Ranon, 2004). For space reasons, we can not give details here. A simulation approach which uses the transformation of the FIS meta model into High level Petri net may be found in (Negrichi et al., 2012).

5 EXAMPLE OF APPLICATION

In this section, we will illustrate the behavior of the system for transporting hazardous materials by road. This system consists of five functions: *Loading* of hazardous materials in a truck; *Moving* of the truck along a given route; *Waiting* for the truck at various points: parking, waiting for unloading at customer or waiting for loading at supplier; truck *Unloading* at customer; *Storage* at customer or supplier. We will detail the *Loading* function. We will construct the structural, the dysfunctional and the evolution views. This function presents the *Loading* of hazardous materials (which is simulated in the form of blocks) in a truck. To achieve such a load, many entry attributes are required such as a deposit, a machine, a worker and a truck, and it needs as attributes outputs: a deposit, truck and materials. The deposit and materials are seen as modified resources. *Loading* will decrease the amount of materials contained in the deposit and will change the positions of contents. Deposit, truck, workman are seen as supports for the *Loading* function, they are reserved prior to

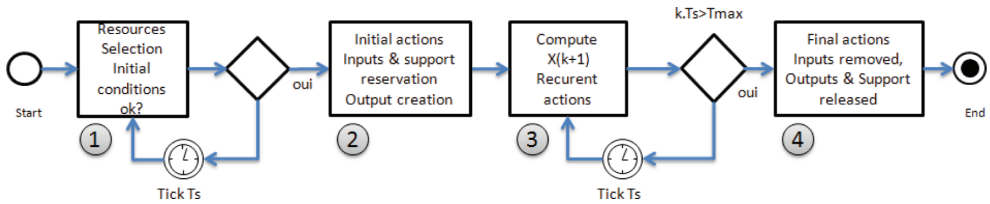

Figure 7. Activity diagram.

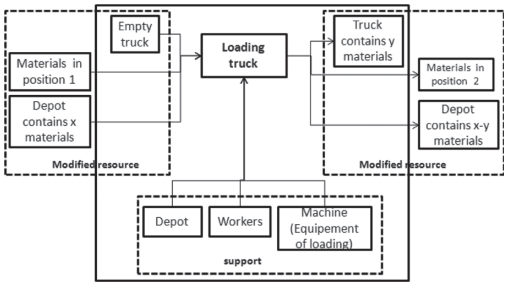

Figure 8. Relations for Loading.

loading and released at the end. Figure 8 shows relations of *Loading* describing before.

To have a good load, we should take note about time loading and the quality of loaded products, and eliminate any incompatibilities of products in the same expedition. A *Load* failure may come from four cases (Flaus and Granddamas, 2002) (Wirth et al., 1996):

- delay of loading (unavailability of a deposit, truck, worker or machine);
- delay during loading (in case of unavailability of the machine, materials can be loaded manually but it may take much time);
- a collision during loading which can affect the quality of contents;
- and finally a bad loading represented by an expedition of incompatible two products in the same truck.

Figure 9 shows the various failure modes of loading describing a Fault tree (Karagiannis et al., 2010).

Table 1 illustrates the evolution mode of each situations. Our simulation allows the system to evolve the basic events (basic events Fault tree), and it describes the failure mode of the function. This failure mode helps to obtain the behavior mode related to each failure (Table 1), where each Fault tree (Delay during loading, delay of loading, bad loading and Accident) is carried by a behavior mode evaluating the level of risk related to each situation.

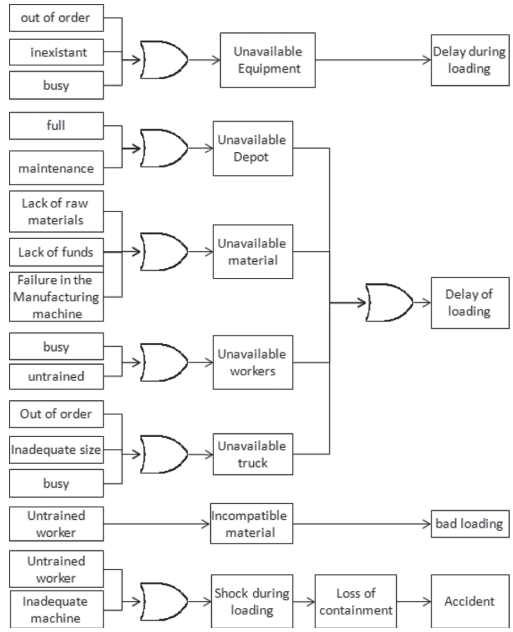

Figure 9. Fault tree for loading.

6 CONCLUSION

In this paper, we have presented a method for risk analysis including a specification of the general process and her functions. For each function, we have precised the inputs, the outputs, the required resources, a dysfunctional model, and a model of evolution. The main interest of this meta model is that it allows the representation of risk analysis and dynamical behavior in a coherent manner, which can be used to perform various related tasks: risk evaluation, diagnosis, simulation under degraded conditions, prognostics ...This was illustrated through an example of loading hazardous materials in a truck. One of our future goals is to to simulate several times a complex phenomenon of transportation of dangerous goods, by using multi-agent based simulation and to generate randomly risks via the Monte Carlo simulation.

Table 1. Evolution mode of load function.

Model element	Behavior mode	Related fault tree event	Equations
Loading	Normal		$T = f(q,d) = \frac{q}{d}$ where T is the loading time, q is the quantity to be loaded, and d is the loading flow;
Loading	Abnormal1	Delay of loading	$T = f(q,d) = \frac{q}{d} + T_1$ where $T1$ time of unavailability of machine, workers, depot, material or truck;
Loading	Abnormal2	Delay during loading	$T = f(q_1,d_1) = \frac{q_1}{d_1 \times n}$ where q_1 is the quantity to be loaded, d_1 is the loading flow for one workers, and n is the number of workers;
Loading	Abnormal3	Bad loading	$\frac{\Delta T}{\Delta t} = F(T,c_a,c_b)$ where c_a is the concentration of product A, c_b is the concentration of product B, and T is the environmental temperature;
Loading	Abnormal4	Accident	$D = f(M,t)$ where M is the material to be loaded, and t is the temperature.

Proposing a multi-layer modeling framework for complex infrastructure systems

C. Nan & G. Sansavini
Reliability and Risk Engineering Group, ETH Zürich, Switzerland

ABSTRACT: The heterogeneity and tight coupling of modern infrastructure systems makes a tractable description of their emergent behaviors a challenging task. Classic analytical methods lack the capability to provide sufficient insights into system behaviors and fully capture the complexity of these systems. In this paper, a multi-layer modeling framework is proposed, targeting toward an in-depth understanding and holistic analysis of infrastructure systems. Within this framework, an infrastructure system is viewed as three interrelated subsystems in corresponding layers, i.e., System Under Control (SUC), Operational Control System (OCS), and Social System (SS). Subsystem 1-SUC (layer 1) and subsystem 2-OCS represent the technical parts of infrastructure systems. In general, the SUC is a time-based, while the OCS is an event-driven and service-oriented. Subsystem 3-SS (layer 3) represents the non-technical part of infrastructure systems, which is generally related to social factors that intend to have influences on the overall system performance. In order to demonstrate the capability the proposed modeling framework, a feasibility experiment is developed using Swiss electricity supply system as an exemplary system.

1 INTRODUCTION

The welfare and security of each nation rely on a continuous flow of essential goods (e.g., energy, food, water, data) and services (e.g., banking, health care, public administration). Infrastructure systems are those systems so vital to any country that their incapacity or destruction would have a debilitating impact on the health, safety, security, economics and social well-being, including the effective functioning of governments (Kröger and Zio, 2011). Infrastructure systems have always been "complicated", but in recent years, they have witnessed growing integration and interconnectedness, which have turned them into complex systems (Eusgeld et al., 2009, Kröger, 2008). According to its definition, inherent characteristics of a complex system include having a large number of dimensions, nonlinear and adaptive behaviors, strong internal and external interactions, uncertain rules of interaction among its components (may change over time time), etc (Kröger and Nan, 2014). Besides inherent complexities of these systems, one important aspect is their interconnections, which made them grow into a so-called "Systems-of-Systems" (SoS). These unforeseen interdependencies could become an important factor providing the tolerance to attacks and failures if well managed (positive impact). For instance, technical failures such as abnormal disconnection of a transmission line (a component of electricity power supply system) can be detected by devices remotely installed at substation and corresponding alarm can be transmitted to a control centre via services provided by coupled telecommunication systems in order to prevent further failure propagations. However, on another side, these interdependencies might also be a source of threat generating new uncertain risks, especially the risk of cascading failures, which made them more vulnerable (negative impact). For instance, a failure within one infrastructure system or loss of its continuous service may be damaging enough to society and economy, while cascading across system-boundaries has the potential for multi-infrastructural collapse and unprecedented consequences (e.g., the August 14, 2003 blackout in North America affected 50 million people and led to 3 billion USD insurance claims).

Modern societies have become embedded in an increasingly dense and intricate web of interconnected infrastructure systems (Vespignani, 2010). Addressing the significance of infrastructure systems is a challenge due to the complexity and perpetual nature of these systems, the lack of sufficient information clearly characterizing failure propagations, and the lack of modelling/simulation tools by which their interactions can be comprehensively analysed. All this makes clear that it is vital to develop an over-arching and cross disciplinary vision of integrated risk management, e.g., horizontal approach using the advanced modelling and simulation techniques.

2 RESEARCH STREAMS AND PROPOSED FRAMEWORK

2.1 *Available methods and approaches*

Research work related to modeling infrastructure systems is still at an early stage and is challenged by their inherent characteristics, e.g., dynamic/nonlinear behaviors, intricate rules of interactions as the results of their openness and high degree of interconnectedness (Griot, 2010, Pederson et al., 2006). Developing a comprehensive modeling framework with the capabilities of achieving a closer representation of behaviors of these systems and gaining insights into interactions within and among them seems promising and is vital for improving our understanding and identifying means to design, maintain, and protect SoS in the long run. Currently a broad scale of modeling approaches/techniques have been developed and applied, e.g., Input-output Inoperability Modeling (IIM), Complex Network Theory (CNT), Agent-based Modeling (ABM), System Dynamic (SD), PetriNet(PN)-based, Bayesian Network (BN), etc (see (Zio and Sansavini, 2011b) and (Ouyang, 2014) for more details about these approaches). The capability and applicability of these approaches in terms of analyzing infrastructure system behaviors vary. Each of these approaches can be used to deal with a specific topic and has the ability to represent characteristic properties of a type of infrastructure system, e.g. physical, social, informational, or cyber. Some approaches are only capable of analyzing infrastructure systems at the structure/topology level, e.g., CNT approach, while some approaches are capable of capturing and analyzing dynamic behaviors of studied systems at the functional level, e.g., ABM approach.

2.2 *Proposing a multi-layer modeling framework*

Modern infrastructure systems, e.g., power supply, telecommunication, and rail transport systems, are all large-scale, complex, highly integrated and particularly interconnected. The operators of these systems must continuously monitor and control them to ensure their proper operation (Igure et al., 2006). These industrial monitor and control functions are generally implemented using an operational control system, e.g., Supervisory Control and Data Acquisition (SCADA) system. The fundamental purpose of this type of systems is to allow a user (operator) to collect data from one or more remote facilities and send control instructions back to those facilities (Boyer, 2004). Moreover, the primary focus of modeling/simulating an infrastructure system has been on technical part, almost ignoring non-technical parts, e.g., organizational factors, human factors, etc (Ferscha et al., 2011, Baxter and Sommerville, 2011). A number of studies have shown that human and organizational factors are major causes for accidents occurred in electric power, railway, aviation and maritime infrastructure sectors (Johnson and Holloway, 2007, Kröger and Nan, 2014, Wreathall et al., 2003), highlighting the importance of these factors.

In practice, there is still no a "one-fits-all" approach for analyzing the full spectrum of characteristics and dimensions of a SoS. The lack of coherent modeling approaches hinders the possibilities of analyzing/assessing dynamic system behaviors comprehensively in a heterogeneous network of interdependent infrastructure systems. Therefore, there is a need to develop a comprehensive modeling framework with the capabilities of achieving a closer representation of their behaviors. The framework should also be capable of considering social factors in order to better understand how these factors affect the performance of infrastructure systems. Furthermore, modeling entire infrastructure system as a whole is usually impractical (Ring, 2012, Bloomfield et al., 2009, Filippini and Silva, 2012). Choosing relevant subsystems and modeling them efficiently for the intended purposes seem more promising. For each subsystem, appropriate modeling approaches/methods can be determined to fully represent its behavior and functionalities. Based on this concept, a multi-layer modeling framework is proposed. Within this framework, infrastructure systems are viewed as three interrelated subsystems in corresponding layers, i.e., System Under Control (SUC), Operational Control System (OCS), and Social System (SS).

Subsystem 1-SUC (layer 1) represents the technical part of infrastructure systems, which is generally time-based. In order to fully model this type of systems, both functionality (physical laws) and structure (topology) need to be considered. Therefore, the approaches of ABM and CNT seem promising. Subsystem 2-OCS (layer 2) also represents the technical part of infrastructure systems, which is generally event-driven and service-oriented. The major responsibility of this type of systems is to control and monitor corresponding SUC. The developed model needs to be able to process messages among components efficiently and to represent the functionality of the system. Compared to all the approaches introduced above, the approach of ABM seems more promising. Subsystem 3-SS (layer 3) represents the non-technical part of infrastructure systems, which is generally related to social factors that have influences on the overall system performance. The developed model needs to be able to evaluate and quantify the effects of social factors such as human

performance, organizational behaviors, etc. For example, the approach of HRA (Human Reliability Analysis) seems promising for the evaluation of human performance.

2.3 *Modeling the layers of a complex infrastructure system*

The key idea of the proposed multi-layer modeling framework is to develop different types of modeling approaches for each subsystem, to search solutions to integrate these approaches and finally to be able to represent behaviors of the studied system including interconnections among components in different layers. In this section, the framework will be further introduced and explained in detail, using the Swiss Electricity Power Supply System (EPSS) as an exemplary system to demonstrate its feasibility and applicability.

2.4 *Representing EPSS by multi-layer modeling framework*

The three subsystems of the EPSS are:

- **Subsystem 1-SUC:** electricity transmission network is used as an exemplary system of the SUC within the EPSS, which is controlled and monitored by a SCADA system. Components of this system include transmission lines, generators, busbars, etc (see (Brand et al., 2003) for more detail).
- **Subsystem 2-OCS:** a SCADA system is used as an exemplary system of the OCS within the EPSS. Components of this system include (1) field instrumentation and control devices, i.e. FIDs and FCDs respectively (sensors and actuators), (2) Remote Terminal Unit (RTU), a standard stand-alone data acquisition and control unit with the capabilities of acquiring data from monitored processes, transferring data back to the control centre, and controlling locally installed equipment, (3) Communication Unit (CU), providing a pathway for communications between a control centre and RTUs, and (4) Master Terminal Unit (MTU), which is the "host computer" issuing commands, collecting data, storing information, and interacting with operator(s) (see (Boyer, 2004) for more details).
- **Subsystem 3-SS:** the human operators in the control center of the SCADA system is used as an exemplary element of SS within the EPSS. It should be noted that in this paper only human performance is considered and other social factors such as organizational behavior are ignored. Generally, their responsibilities include monitoring/processing generated alarms, switching off components located at remote substations, sending commands to remote substations, etc. Although these responsibilities are mainly related to system functionalities of monitoring and remote control and may not appear to have significant impacts on system performance, examining the reliability of the human operator remains crucial.

Figure 1 shows a simplified multi-layer representation of the EPSS with various interacting subsystems and associated components: parallel planes represent different subsystems in corresponding layers while nodes represent various components together with some of interconnections among them. The elements of the various layers depend on each other, depicted by various horizontal (inside a layer) and vertical (between layers) links. These links demonstrate (inter)links among components of different layers and a failure of a component may cascade to other layers and impacts functionality of the infrastructure system.

2.5 *Modeling SUC and OCS*

Several modeling approaches have been briefly introduced in Section 2.1. Among these approaches, the CNT and ABM turned out to be promising for modeling infrastructure systems, especially their technical parts. Both approaches intend to represent a whole system by dividing it into many smaller interacting entities, i.e. nodes (CNT) or agents (ABM). Within the CNT, the SoS is mapped into a graph G(V,E) composed by a set of nodes V and the set of connections E between them. Each node (or vertex) represents an element of the system, while a link (or edge) represents the relation between corresponding elements. A number of

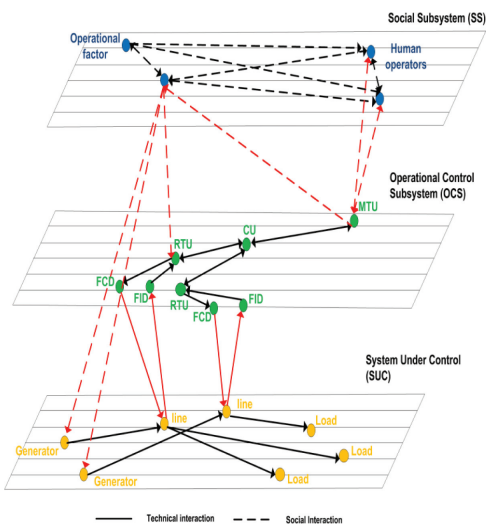

Figure 1. Representing EPSS in three subsystems (layers).

modeling efforts have been made to adopt this approach for the development of infrastructure system models demonstrating its capability of modeling relation established through connections among technical components (Crucitti et al., 2004, Bompard et al., 2009, Duenas-Osorio and Vemuru, 2009, Zio and Sansavini, 2011a). This approach is based on the network model mapping physical configuration of the components of infrastructure systems and their physical interconnections. However, it lacks the ability to capture uncertain and dynamic characteristics of infrastructure systems, which can be overcome by replacing nodes/links with agents in the ABM approach.

Using the ABM approach, each agent is capable of modifying its internal data, behaviors and adapts itself to environmental changes. ABM can be regarded as a bottom-up approach and each component can be modeled as an agent; different agents interact with each other directly or indirectly (Schläpfer et al., 2008, Sanford Bernhardt and Mcneil, 2008, Chappin and Dijkema, 2008). Compared to CNT, ABM is able to provide an integrated environment where a more comprehensive analysis of dynamic system behaviors can be performed by "looking-into" the component level of studied systems. Motivated by the advantages of this approach, a two-layer agent-based modeling approach (Fig. 2) has been developed and applied for the purpose of the vulnerability assessment of the electric power system (Schläpfer et al., 2008). Within this approach, the lower layer represents the separate modeling of the physical components by means of conventional, deterministic techniques such as power flow calculations, whereas the upper layer represents the abstraction of the electric power system with all its components as individual agents.

The SCADA system (an example of OCS) is event-driven and service-oriented. Normally it is used to monitor and control very large industrial process facilities such as electricity transmission

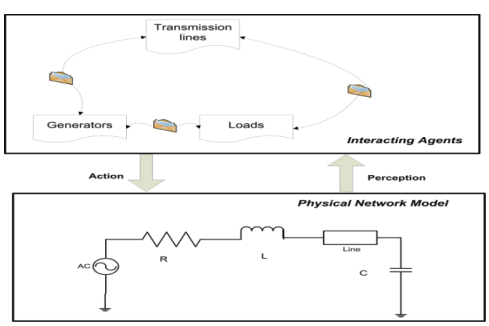

Figure 2. Two-layer agent-based modeling approach (illustration using SUC of EPSS as an example).

facilities and oil and gas production facilities (Boyer, 2004). In general, it comprises remotely located field level devices, which are connected to a control center through a variety of communication devices. Modeling a SCADA system is not just a challenge from a theoretical point of view but of great practical importance (Balducelli et al., 2007) (Bobbio et al., 2010). It is not applicable to use graph-based (e.g., CNT) or analytical (e.g., IIM) approaches. Motivated by the results of applying two-layer agent-based modeling approach to model the SUC, a failure-oriented two-layer agent-based modeling approach is also developed to model the SCADA system. Compared to the approach applied for modeling the SUC, device modes are introduced as parts of agent development. Within this approach, the "agent state" is defined as a location of control with a particular set of reactions to conditions and/or events of its related agent, while the "device mode" is defined as the hardware status of corresponding simulated hardware devices. The transition of various device modes can affect corresponding agent state. It should be noted that this type of approach mainly focuses on the negative effects due to technical failure of components (see (Nan and Eusgeld, 2011b) for more details).

2.6 *Modeling SS*

Social factors play an important role in the operations of infrastructure systems. The lack of careful consideration of influences of these "non-technical" parts of infrastructure systems often results in poor system performance and high costs. Their roles and impacts need to be strengthened by developing advanced approaches that take these factors into consideration and focus more on the ways to analyse their effects efficiently in varying contexts. Over the years, many HRA methods have been widely developed and improved in order to provide a more applicable way to assess these factors, especially human performance. However, these methods are challenged by their inherent limitations, e.g., the lack of objectivity, inability to take other social factors (e.g., organizational/political factors) and contexts (e.g., emotion, learning ability, and experience) into consideration. Furthermore, most of these works are based on the implementation of classical analytical approaches and seem not sufficient to represent the complexity of social factors, which is the most critical shortcoming compared to research works focused on technical parts of infrastructure systems. The full mapping of the complexity of infrastructure systems depends on the continued development/improvement of social factor models. Motivated by these challenges, a hierarchy modeling approach to model the SS is proposed, illustrated in Figure 3. Within this model, it is assumed that the

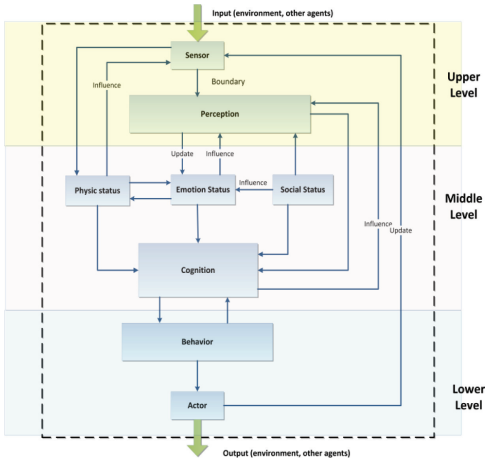

Figure 3. The structure of the proposed hierarchy modeling approach.

human factor is the key factor and all other factors such as organizational behaviors and cultures eventually have influences on it.

The model consists of three levels. The upper level includes the components sensor and perception, which can be regarded as the input of the model. The information such as interactions with other agents, influence of environment, predefined goals, is first processed by the sensor component. After that, the information will be further interpreted by the perception component. For example, if an alarm is received by the operators in the control room, it needs to be first received by the sensor and then interpreted by the perception in order to extract more detailed information, such as the severity of the alarm, etc. The middle level includes four components: physic status, emotion status, social status and cognition. These components contain parameters, state variables, states, rules, which can be used to determine states and behaviors of the human agent. The social status is one of most important components for determining the behavior and state of the agent. Similar to the physic and emotion status, this component also includes different internal states. The interaction among agents, which is mainly represented in this component, potentially can be used to model/represent trusts between agents. The influences of other social factors such as organizational factor can be included in the three status components. The lower level includes the components of behavior and actor, which can be regarded as the output of the model. The order of executing agent action/behavior is determined by the component behavior, while the execution is carried out by the component actor. The information that has influence potentially on other agents/objects will be sent out by the component actor.

2.7 *Experimental simulation platform*

All the developed models (three subsystems) are integrated in an HLA (High Level Architecture)-compliant experimental simulation platform. The platform consists of four components: the SUC model, the SCADA and SS model, the RTI (Run Time Infrastructure) server, and the simulation monitor. RTI is the core element of the HLA standard providing common services (e.g., joining into and resigning from the federation, specification of interfaces, etc) to all the participating components (models). These components are connected over a Local Area Network (LAN). The RTI server acts as the center of the experimental platform and is responsible for synchronizing the simulation and routing communications among all components. The RTI server interacts with each model through corresponding local RTI interface. The simulation monitor is a real-time tool, through which the simulation of three models can be observed. The standard of HLA 1516 (IEEE, 2000) is used to implement this platform (see (Nan and Eusgeld, 2011a) for more details about this platform).

3 CASE STUDY

Electric power systems are among the most prominent representatives of infrastructure systems and the need for their reliable and resilient performance during disruptive events is essential (Zio and Sansavini, 2013, Bilis et al., 2013). In this section, the Swiss EPSS is selected as an exemplary system to demonstrate the feasibility and applicability of the proposed modeling framework. It is assumed that this system is a stand-alone and the energy exchange with the neighboring countries is regarded as independent positive and negative power injections at the respective boundary substations.

The modeling approaches proposed for each subsystem (i.e. SUC, OCS, and SS), introduced in section 3, have been further applied to model the exemplary system. Based on the two-layer modeling approach, an agent-based model is developed to represent the SUC within the EPSS using the software Anylogic 5.5. In total, 585 agents are created to represent its components, i.e., transmission lines, generators, busbars, and loads. The SCADA system within the EPSS is modeled by applying the proposed failure-oriented two-layer modeling approach using the software Anylogic 6.6. In total, 587 agents are created to represent its components, i.e., FCDs, FIDs, and RTUs (see (Nan et al., 2013) for more details about SCADA model). Based on the hierarchy modeling

approach, an agent-based model is developed to model the SS of the EPSS using the software Anylogic 6.6. The focus of this model is mainly related to the evaluation of the performance of human operators (examples of human factors), therefore, the effects of other social factors (e.g., organizational factor) are ignored. The second generation HRA (Human Reliability Analysis) method CREAM (Cognitive Reliability Error Analysis Method) is applied to implement the perception component of the SS model (see (Hollnagel, 1998) for more details about CREAM). Using this method, Performance Shaping Factors (PSFs) can be assessed dynamically based on current simulation environment, e.g., time of day, simultaneous goals, etc, and corresponding Human Error Probability (HEP) ([0,1]) will then be calculated. The lower HEP value indicates better performance. To decide whether or not there is an error by human operators, it is necessary to set a threshold value (HEP_A) representing the maximum acceptable HEP value. If a calculated HEP is more than HEP_A, then it is assumed that a human error occurs (the human is not successful). The higher HEP_A indicates fewer changes of human errors (see (Nan and Kröger, 2014) for more details).

In order to demonstrate the applicability of the proposed modeling framework, a feasibility experiment has been designed and developed. The purpose of this experiment is to study the capability of the proposed modeling framework as an approach to represent behaviors of infrastructure systems in a comprehensive way. In this experiment, it is assumed that a certain number of components of the EPSS fail to function at same time, i.e. the related failure modes are triggered simultaneously. Among all the failure modes that have been considered for the EPSS, the SCADA FRH (Failure to run (too high)) is selected to be triggered due to its significant negative effects to the performance of whole system (see (Nan et al., 2013) for more details). The FRH failure mode can be described as the failure of a FID (Field Instrumentation Device) to indicate the actual value of its monitored variable and indicates a larger than actual value. The causes could be personnel performance error during maintenance and other activities, insufficient attention to the aging of piece parts of FID, etc. For example, personnel apply outdated procedures for adjusting FIDs, mistakes during calibrating setpoint values, or erroneously not accounting for technical modifications of the field when calculating setpoint values. In this experiment, it is assumed that the number of FID devices that are in FRH failure modes is 30. The reason to set the number of failed FIDs as 30 is based on several trial tests before starting the experiment. Results obtained from these tests show that likelihood of the occurring of cascading failures after failures of 30 FIDs becomes high. To evaluate the performance of the three subsystems, following MOPs (measurement of performance) are developed.

$$\mathrm{MOP}_{\mathrm{SUC}} = \frac{\text{Number of available transmission lines}}{\text{Number of total transmission lines}} \in [0,1]$$

$$\mathrm{MOP}_{\mathrm{SCADA}} = \frac{\text{Number of available RTU devices}}{\text{Number of total RTU devices}} \in [0,1]$$

$$\mathrm{MOP}_{\mathrm{SS}} = \mathrm{HEP}(\text{Human Error Probability})$$

Figure 4 shows the MOPs of those three subsystems during the experiment. The simulation starts at the $t = 0$ h, which is the time used by the simulation platform to synchronize the communication among platform components. The failure modes of corresponding FIDs are triggered at time 3 h, meaning that the calibration value of the FID devices is modified to a larger value. Therefore, the lines monitored by these FIDs become overloaded although they should not. Normally, whenever a transmission line is overloaded, an overload alarm will be generated and sent to the operator in the control centre (MTU) by the RTU of the SCADA system. If, after a certain period, the operator fails to react to the overload alarm, then the protection devices such as disconnectors (an example of FCD) will automatically disconnect the overloaded transmission lines to minimize the negative consequence of the problem. As shown in Figure 4, MOP_{SS} increases (from 0 to 0.036), indicating that the likelihood of the operators in control room making errors also increases. This might be caused by the sudden increase of the number of alarms received in the control center. Due to the assumed poor performance of the operators (in this experiment, it is assumed that the HEP_A equals to 0.03), the overload alarms can not be handled appropriately and transmission lines start to be disconnected. The MOP_{SUC} starts to drop at time 3.3 h, meaning that the number of disconnected transmission lines increases. As a consequence, the

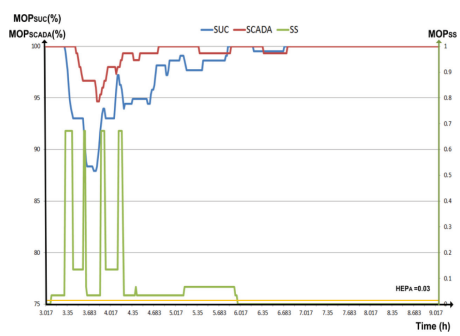

Figure 4. The performance of three subsystems measured by appropriate MOPs ($HEP_A = 0.03$).

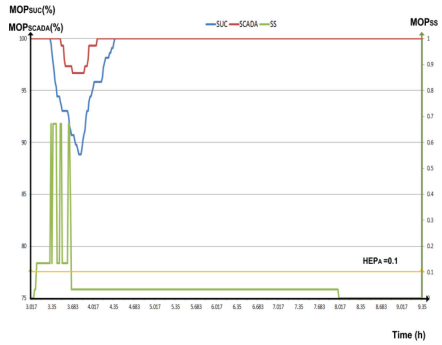

Figure 5. The performance of three subsystems measured by appropriate MOPs ($HEP_A = 0.1$).

MOP_{SCADA} value drops after a certain period. In total, 48 overload alarms are triggered, 30 of which are caused by the triggering of the FRH failure modes of initially selected FID devices (the size of the disconnection cascade is 18 FID devices).

Figure 5 shows simulation results when HEP_A is set to 0.1 (i.e. human performance is improved). As seen from this figure, after triggering initial disruptive events, both MOP_{SUC} and MOP_{SCADA} drop due to human performance errors ($HEP = 0.672$), which is similar to the previous test. However, in this case, it takes less time for the MOP value of both systems to reach 100% due to the improvement of human performance ($HEP_A = 0.1$), although the triggering of overload alarms continues (MOP_{SS} returns to zero after time 8 h).

The results from the feasibility experiment demonstrate how three subsystems interact with each other. The failures are initially triggered in components (FIDs) of the SCADA system, which causes the overloads of transmission lines. Due to sudden increase of the number of overload alarms, the operator might become overwhelmed and the MOP_{SS} rises, increasing the possibility that the human operators can make a mistake. As the consequence, transmission lines start to be disconnected, increasing the number of impacted components of the SCADA system (more RTUs start to lose power). In this experiment, the importance of human operators is also demonstrated. If the human operator is able to respond to overload alarms adequately and send commands to corresponding RTUs for further corrective functions, failures might not propagate and negative consequences can be significantly minimized.

4 CONCLUSIONS

In recent years, infrastructure systems have become increasingly intricate and interdependent, which have dramatically increased their overall complexity, turning them to so-called "systems-of-systems" and causing the emergence of unpredictable behaviors and negative impacts. Our society should face the fact that these systems will continue to become more integrated and their behaviors may become more complex. Understanding and characterizing them is a real challenge; research in this area is still at an early stage. It is essential to get a clearer understanding of their cascading behaviors by applying appropriate techniques. Consequently, modeling/simulating those systems will remain as a field of active research. Although progress has been made in advanced modeling and simulation, more efforts are needed to further improve the methods/tools, to validate them and to scale them up to the level of SoS.

This paper proposes a multi-layer modeling framework in order to achieve a closer representation of system behaviors and getting in-depth insights of infrastructure systems. The framework is mainly focused on the engineered infrastructure systems. Within this framework, each infrastructure system is viewed as three interrelated subsystems in corresponding layers, i.e., System Under Control (SUC), Operational Control System (OCS), and Social System (SS). The proposed modeling framework provides a more efficient and comprehensive way to analyze behaviors of infrastructure systems. For each subsystem, appropriate modeling approaches and methods can be determined which fully utilize advantages of each approach and optimize the performance of the overall simulation. Furthermore, not only technical parts of infrastructure systems, non-technical parts (i.e. social factors) are also considered by the framework.

The first results from the application seem promising, demonstrating the feasibility of the proposed framework, not just due to its capability for representing the complexity of infrastructure systems, but also its modeling flexibility and adaptability. They demonstrate how the three subsystems interlink with each other. For example, the operator performance degrades when a burst of false overload alarms occur due to faulty calibration of sensors and its impact on the overall system performance. Currently, more experiments are under development such as the experiment targeting the analysis of behaviors of socio-technical systems and the experiment to evaluate the resilience related behaviors of infrastructure systems.

ABSTRACT: Challenges to the modeling and simulation of engineered Critical Infrastructures (CI) lie in the multiple levels of interdependencies and lack of fixed boundaries, in the diversity of the underlying physics of the provided service, in the coexistence of multiple time scales, and in the level of resolution required to fulfill the objectives of the analysis. Such challenges impact the selection of the most suitable modeling approach or integration of different approaches for the reliability and vulnerability analysis of CI. This paper suggests a framework for selecting the hybrid modeling and simulation approach which is more suitable to analyze specific types of CI. The focus steps consider the system characteristics, e.g. interdependencies between CI, identification of the host system, and the objectives of system analysis. The framework is exemplified with reference to CI of different types.

1 INTRODUCTION

Decades of massive system integration and scarce investments have caused large-scale/wide-area technical networks, such as engineered Critical Infrastructures (CI), to become increasingly interdependent on each other and to operate in the proximity of system limits. Emerging "Systems-of-Systems" (SoS) have shown the emergence of unprecedented complex behaviors with negative impacts, e.g. vulnerability to cascading failures with widespread consequences. Understanding and characterizing such complex systems is vital for thorough reliability and vulnerability analysis and for capturing emergent behaviors and failure cascades, especially when strong interdependencies exist.

Research on this topic is characterized by two key aspects: *i*) it is not feasible to build lab-scale experimental setups to reproduce systemic failures (i.e., involving the entire system) of large-scale technical networks; *ii*) empirical observations of systemic failures in large-scale technical networks are available but sparse because these systems are designed and operated to minimize such occurrences. Therefore, we have to resort to models and simulations which can capture the system behavior and reproduce the consequences of the disruptive event, taking advantage of the few empirical observations of events in CI (Luiijf et al., 2009). The challenge is the development of adequate modeling/simulation approaches capable to represent characteristics and underlying physics specific to different types of infrastructures with high fidelity. These approaches must be balanced; on the one hand, avoid the danger of creating artifacts which postulates systemic hazards which do not occur in real-world infrastructures, while on the other hand, oversimplification may fail in capturing the actual system behavior and misrepresent or underestimate potential severe consequences at the system level.

The modeling and simulation of CI and SoS is challenged by the key characteristics of these systems: *i*) coexistence of multiple time scales, from infrastructure evolution to real-time contingencies; *ii*) multiple levels of interdependencies and lack of fixed boundaries, i.e. CIs are made of multiple layers (management, information & control, energy, physical infrastructure); *iii*) broad spectrum of hazards and threats; *iv*) different types of physical flows, i.e. mass, information, power,

vehicles. An additional challenge lies in the level of resolution required to fulfill the objectives of the analysis, which guides the level of abstraction and aggregation in the models and simulations.

Currently, a broad scale of modeling approaches has been developed and applied and two main directions have been followed, namely, knowledge-based and model-based approaches. Knowledge-based approaches are based on empirical investigations and brainstorming aimed at analyzing past events to improve the understanding of the dimensions and types of interdependencies in CI. Model-based approaches aim at analyzing interdependent infrastructure systems comprehensively by using advanced modeling/simulation techniques, capable of providing both quantitative and qualitative information. A variety of models have been applied, e.g. Input-output Inoperability Modeling (IIM), Complex Network (CN) Theory, Agent-Based Modeling (ABM), System Dynamic (SD), Petri Nets (PN), Bayesian Networks (BN) and Dynamic Control System Theory (DCST).

These modeling approaches vary in their applicability and capability of analyzing behaviors of CI. The most suitable approach or integration of different approaches (a hybrid modeling and simulation approach) must be identified in connection to specific system characteristics and objectives of system analysis.

This paper proposes a framework for selecting the hybrid modeling and simulation approach which is more suitable to the analysis of a specific type of SoS, and which can be integrated into existing frameworks for the vulnerability analysis of CI (Kröger and Zio 2011). The focus steps will consider the system characteristics, e.g. interdependencies between infrastructures, identification of the host systems, and the objectives of system analysis. Taking advantage on the literature about existing approaches to the model of CI (Satumtira and Dueñas-Osorio 2010; Kröger and Nan 2014), the framework is exemplified with reference to infrastructures of different types, i.e. energy supply (electricity, gas), information and communication and transport (rail, road).

2 CONCEPTUAL FRAMEWORKS FOR VULNERABILITY ASSESSMENT

A conceptual framework for vulnerability analysis of CI was proposed in Kröger and Zio (2011) to bring all system aspects and attributes together and to take advantage of the diverse capabilities of the available model and simulation approaches. Vulnerability analysis address several system issues: the end states of interest for the given systems; the boundary definition; the threats and hazards of relevance and the susceptibility of the system; the resulting cascades; system interdependencies and their impact; the uncertainties involved; the obvious and non-obvious ("hidden") vulnerabilities to be reduced and managed.

The conceptual framework for vulnerability analysis follows a stepwise, problem-driven approach tailored to the needs of the analysis, and distinguishes five steps, several decision points and feedback loops (Figure 1).

The first step, the preparatory phase, integrates the task framing and definitions (step 1.1) into the process of familiarization with the system. It is also important to decide on the spectrum of hazards and threats to be included into the analysis. Furthermore, it is necessary to deeply understand failure models and effects on each of the components of the CI. For a more effective screening of the system vulnerability some reasonable simplifications should be made. These assumptions need re-visiting in a later phase of the assessment (step 3.2). After key information is collected and pre-assessment is done, the knowledge base should be checked with respect to the availability of methods suitable for the defined tasks.

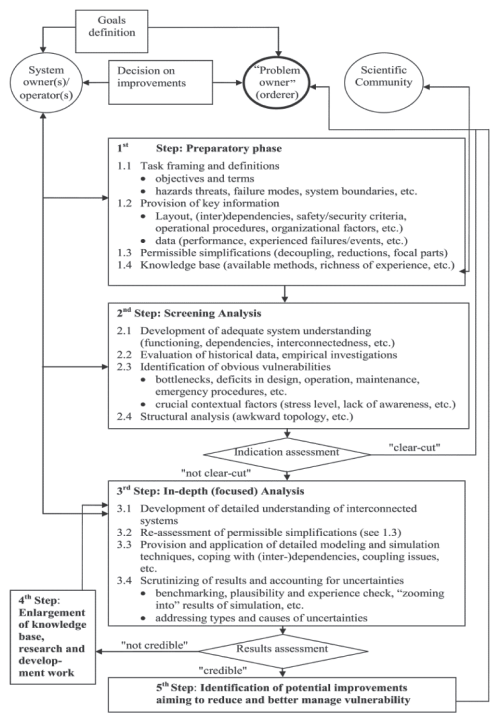

Figure 1. Conceptual framework for the vulnerability analysis of interconnected infrastructures (Kröger and Zio 2011).

The purpose and goals of the analysis affects the degree of detail, e.g. the assessment of interdependencies and cascading failures, or the width of system boundaries. It is assumed that the vulnerability analysis should evolve in two steps where appropriate. A screening-type of analysis might be efficient and sufficient to identify eye-catching, obvious weak points, e.g., awkward topology, spatial proximity of interconnected systems or bottlenecks, and further actions should focus on eliminating or reducing them. The screening analysis could also prepare the ground for and give steer to the in-depth analysis which may turn out necessary. The screening analysis leads off with development of adequate system understanding; we assume that information provided from system owners/operators (step 1.2) allows for general understanding of main functionalities, states of relevance, interfaces, interdependencies. In this phase, the main emphasis is placed on experts' opinions, brainstorming, etc., rather than on application of detailed models. If the results and insights gained by screening analysis are not satisfying (not "clear-cut") and major hidden vulnerabilities are still feared, a more sophisticated in-depth analysis (step 3) has to be launched. To achieve a higher degree of accuracy in the vulnerability evaluation, system understanding has to be further developed on the basis of additional information about the system and its operating environment. Special attention should be placed on interdependencies within or among systems. The re-assessment of simplifications made earlier may call for more sophisticated methods of analysis, e.g., following a system or even a system-of-systems approach, and integrating a comprehensive spectrum of different phenomena. While full validation and verification of models and methods, as well as of results, seem infeasible, benchmarking against other similar analyses, plausibility checks and checks against experienced events, if available, may help to support the credibility of the vulnerability assessment and build confidence in the decision making which follows.

System improvements (step 5) may be proposed to further reduce and better manage vulnerabilities by all means of provisions.

3 APPROACHES FOR INTERDEPENDENCY ANALYSIS

Applied modeling/simulations approaches, have different viewpoints, e.g., functional or structural, different levels of abstraction, different focus, objectives and metrics, different degrees of maturity and are based on different levels of available information and knowledge. None of the available methods alone is capable to address and tackle the variety of issues of vulnerability assessment including the impact of interdependencies. It is commonly agreed that a universal, all-encompassing approach or model which accounts for all issues does not exist. In recent years, two main directions can be distinguished, i.e., knowledge-based and model-based approaches.

3.1 *Knowledge-based approaches*

Knowledge-based approaches, e.g., empirical investigations or brainstorming, intend to use data collected by interviewing experts and/or analyzing past events to acquire information and improve the understanding of the dimensions and types of interdependencies (Zimmerman 2004; Luiijf et al., 2009). This approach is straightforward and easy to understand. It is capable of providing a qualitative assessment on the severity of interdependencies and can be considered as an efficient screening method. However, it is a purely data-driven approach, meaning that the accuracy of results depends on the quality and the interpretation of the collected information.

3.2 *Model-based approaches*

Various advanced modeling approaches are available and have been applied, e.g., Input-output Inoperability Modeling (IIM), Complex Network (CN) Theory, PetriNet (PN)-based modeling, Agent-Based Modeling (ABM), System Dynamic (SD), Bayesian Network (BN), Dynamic Control System Theory (DCST).

The IIM approach captures interdependencies among infrastructure systems via mathematical models. This approach is originally a framework for studying the equilibrium behavior of an economy by describing the degree of interconnectedness among various economic sectors. It assumes that each system can be modeled as an atomic entity whose level of operability depends on other systems and propagation between them can be described mathematically based on the basic Leontief high order mathematical model. The IIM approach is capable of analyzing cascading failures and providing a mechanism for dependency measurement (Haimes et al., 2005).

The PN-based approach is a mathematical modeling language for the description of distributed systems which has also been used to represent/assess interdependencies among infrastructure systems. In this approach, components (subsystems) of infrastructure systems and their states are modeled using basic PN elements such as places, transitions, etc. This approach alone has difficulties representing infrastructure systems quantitatively

and needs to be combined with other methods (Klein et al., 2007).

Fundamental elements of the CN theory approach are originally formed by graph theory. It captures the coupling among systems as a set of nodes connected by a set of links and by this characterizing their topology. A number of modeling efforts have been made to adopt this approach for the development of infrastructure system models and interdependency-related assessments, demonstrating its capability of representing relationships established through connections among system components (Eusgeld et al., 2009; Buldyrev 2010). The CN theory approach is based on the network model mapping physical configuration of the components (elements) of studied infrastructure systems and their (physical or logical) interconnections. The analysis of the topological properties of the network is able to reveal useful information about the structural properties, topological vulnerability, and the level of functionality demanded for its components. However, this approach lacks the ability to capture uncertain and dynamic characteristics of infrastructure systems and system properties when dynamical processes, acting on the network, occur. For instance, the underlying physics of voltage collapse or frequency instability in electric power grids is overlooked by CN theory models.

In ABM approach, each agent is characterized by internal data, its behavior and environment, and adapts itself to environmental changes (Eusgeld et al., 2009). An agent can be used to model both a technical component (e.g., a transmission line), and a non-technical component (e.g., a human operator). The rules of behaviors of each agent are represented by using Finite State Machines (FSMs) and include both deterministic and stochastic time-dependent, discrete events. The ABM approach achieves a closer representation of system behaviors by integrating the spectrum of different phenomena that may occur, e.g., generating a multitude of representative stochastic, time-dependent event chains. However, this approach demands a large number of parameters defined for each agent, requiring thorough knowledge of the studied systems.

SD is a mathematical modeling technique for framing, understanding, and managing complex feedback systems. Stocks, flows, and feedbacks are central concepts of this approach, which are used to describe the system behaviors. The approach assumes that the behaviors of infrastructure systems are the results of interrelationships among various system variables (Min et al., 2007). It is possible to use this approach to perform CI interdependency analysis by representing a system or a system component as a node and an influence among systems or components as a link. In general, SD based models developed for CI interdependency study intend to explore system behaviors by studying high-level services provided by each infrastructure system. Differential equations are developed to evaluate relationships between different nodes. SD is capable of modeling the interdependencies among CIs only a relatively abstract level, and lacks modeling flexibility, e.g. probabilistic relationships are not modeled.

BN is a probabilistic approach that can be used for modeling behaviors of a system, based on observed stochastic events. A BN is a model representing the interactions among components in a system from a probabilistic perspective (Di Giorgio & Liberati 2011). One of major disadvantages of this approach is its difficulty of taking time into account. Therefore, an improved approach, Dynamic Bayesian Network (DBN), has been developed. In order to analyze CI interdependencies, the general BN and DBN represent system components as variables and interactions between variables as directed probabilistic links. BN or even DBN approach is not suitable to analyze dynamic, often non-linear, behaviors of infrastructure systems.

DCST (Casalicchio et al., 2011) can be applied to assess the interdependencies using transfer functions and corresponding frequency responses. Each studied infrastructure needs to be assumed as a linear time invariant dynamic system. The input/output relationship among components or infrastructure systems can be represented and quantified by transfer functions. Based on the overall transfer function and its corresponding frequency responses, the stability of interdependencies between infrastructures can be evaluated using Bode and Nyquist diagrams. In DCST, all the links between components and infrastructures are determined during the transfer function development. Therefore, hidden vulnerabilities caused by interdependencies cannot be captured.

4 HYBRID MODELING AND SIMULATION APPROACH

Due to inherent complexity of interdependencies among infrastructure systems, there is still no "silver-bullet" approach. The knowledge-based approaches are straightforward and easy to understand, while the model-based approaches are more comprehensive and promise to gain a deeper understanding of behaviors of studied systems. The level of this "deeper understanding" also varies: some approaches are only capable of analyzing the structure/topology level, which can be considered as appropriate approaches for the screening

analysis, e.g., CN theory, PN and BN modeling approaches, while some approaches are capable of capturing and analyzing dynamic behaviors of studied systems, e.g., ABM and IIM approach.

Therefore, it has proven necessary to integrate different types of modeling approaches into one simulation tool in order to fully utilize advantages of each approach and to optimize the efficiency of the overall simulation. One of the key challenges for developing such type of simulation tool is the required ability to create multiple-domain models, e.g., discrete and continuous time models, time-based and frequency-based models, and to effectively exchange data among them (Bloomfield et al., 2009). One solution for meeting these challenges and handling these technical difficulties is to distribute different simulation components by adopting the concept of modular design. The overall simulation platform can be divided into different simulation modules and distributed across one simulation platform.

This hybrid modeling/simulation approach intends to integrate different modeling and simulation techniques for the analysis of interdependent infrastructures (Rome et al., 2014). Different simulation components are developed interacting with each other over a real-time simulation platform. Each distributed component represents specific system characteristics by the appropriate modeling approaches. The information and control commands exchanged among simulation components are interpreted and processed over the network connection, allowing quick assembly of independently developed components without full knowledge of their peer simulation components.

Integrated hybrid simulation approaches provide a high-fidelity representation of the infrastructure under analysis. They are very expedient to run scenarios and case studies. On the other hand, it is difficult to draw general conclusions regarding system operations and management based on their application because they rely on the tuning of many parameters which have competing effects on the system behavior. As a countermeasure to that, reduced-order models can be developed and validated based on the results of high-fidelity simulation and used as a surrogate approximated model in the hybrid modeling/simulation approach. The use of reduced-order model alleviates the computational burden of the distributed simulation and enables general insights on system behavior.

4.1 *Objectives of the analysis*

The hybrid modeling and simulation approach may be aimed at the quantification of different objectives, which has an impact on the selection of the most suitable combination of approaches:

- Reliability: the probability that the system is operational or that it meets the target performance throughout the mission time.
- Vulnerability: specific components of the system subjected to expected adverse events whose occurrence causes loss in functionality of the system (Linkov et al., 2014). Vulnerability analysis helps the system prepare and plan for adverse events.
- Resilience: the ability to prepare and plan for, absorb, recover from, and more successfully adapt to adverse events (Linkov et al., 2014). Resilience management further integrates temporal patterns of the capacity of a system to absorb and recover from adverse events, then adapt.
- Optimization of system planning (design phase).
- Optimization of operations.

Any of the modeling/simulation approach can be used in the reliability analysis when the stochastic nature of the system components is represented and when the target system state is identified and assessed. Vulnerability analysis and system planning rely on the characterization of system functionality; hybridization of CN theory, SD, DS, IIM and ABM approaches is suitable in this step. Resilience analysis and optimization of the operations require modeling time-dynamics, transitions between discrete states, adaptation and recovery in the systems; hybridization of CN theory, IIM and ABM approaches is suitable in this step.

4.2 *Identification of the host system*

The quantification of system performance in presence of interdependent networks may vary depending on the presence of clear host system. It is sometimes not clear whether there is one system (host system) which profits from the services of a dedicated network (dedicated guest/support system), in which the system under control and the control system can be clearly distinguished, or whether interdependent infrastructures are at an equal level. In the first case, the system performance level should characterize the host system, while in the second case, the different performance levels of the interdependent networks have to be considered.

Example of host system and dedicated support system is a power distribution network monitored and controlled by a dedicated SCADA; on the other hand, a power distribution network and a monitoring and controlling communication infrastructure, e.g. the public IP network, are examples of two comparable systems. By the same token, the functionality of the power distribution network

may have an impact on the urban freshwater supply (host system), while the contrary may not be true.

The proposed models should be built through a process by which a system consisting of a network requiring the input of another network for normal or exceptional operations is represented by the two networks, where the first network is the behaving net and the second is the auxiliary net.

4.3 *System behavior*

The selection of the approaches to integrate in modeling interdependent infrastructures must be tuned on the required ability to capture specific system features and behaviors:

1. Structure/topology level, abstract level vs. dynamic behavior at the functional level. Among all approaches, IIM is the least adaptable in mapping the system structure because it describes the system through a lumped operability value. CN theory, SD, DCST and ABM can capture time dynamics in the system. Among them, CN theory requires a certain level of abstraction of system functionality and is less capable of integrating physical laws.
2. Intensity and system performance levels. PN and BN can assess the probability that a system operates at a given performance level but cannot adapt to varying performance levels.
3. Cascading failures. As in 2), PN and BN are not suitable for this task.
4. Specific characteristics of a type of infrastructure system, e.g. physical, social, informational, or cyber. SD, DCST and ABM can integrate physical laws and model different infrastructure characteristics.

4.4 *Interdependency characteristics*

The selection of the approaches to integrate in modeling interdependent infrastructures must be tuned on the required ability to capture specific characteristics of the interdependencies:

1. Dynamics, time delays and failure repair rates (event-driven interdependencies). ABM can include event-driven processes in the interdependency modeling. SD and DCST also model dynamics taking place through the interdependencies using analytical functions, but do not capture event-driven processes. PN and BN can account for probabilistic dependencies (transition rates).
2. Explicitly model of the independencies vs. simulating the behavior of the CI interconnected within the SoS and assess the strength of interdependencies as an emerging system property. The former is a top-down model which assumes the existence of interdependencies. The latter is bottom-up system description which maps the functional relations among components in different systems. ABM can be regarded as the bottom-up approach; CN, SD, and DCST can represent system functionality as bottom-up approaches; PN, BN and IIM require the identification of system dependencies and are top-down approaches.
3. Local physical/logical/functional interdependencies among system components vs. macroeconomic sector interdependencies based on expert knowledge. IIM is not suitable to model interdependencies at the atomic component level.

Table 1 offers an overview of the capabilities of different approaches to capture specific characteristics of the interdependencies.

5 APPLICATION TO CRITICAL INFRASTRUCTURES

For different CI, we suggest the approaches which seem to be more promising for their use in hybrid integrated modeling and simulation approaches.

5.1 *Energy supply (electricity, gas)*

Power supply systems have been modeled using CN theory (Bompard et al., 2009; Hernandez-Fajardo

Table 1. Capabilities of different approaches to capture specific system features and behaviors and interdependencies characteristics. √ and × indicate capable and incapable approaches, respectively.

			Structure	Component level	Functional links (delays, repair)	Non linear, time dynamics of system behavior	Integrate physical laws	Bottom-up modeling of interdependencies	Cascade representation	Reliability analysis	Vulnerability analysis & System planning	Resilience analysis & Operations optimization
Knowledge -based	Empirical Investigation, Brain Storming		x	√	x	x	x	x	x	x	x	x
Model-based	Graph Theory	CN	√	√	x	√	x	√	√	√	√	√
	Probabilistic	PN	√	√	x	x	x	x	x	√	x	x
		BN	√	√	x	x	x	x	x	√	x	x
	Dynamic System Theory based	SD	√	√ (abstract)	√	√	√	√ (abstract)	√ (abstract)	√	√	x
		DCST	√	√ (abstract)	√	√	√	√ (abstract)	√ (abstract)	√	√	x
	Mathematic	IIM	x	x	√	x	√	x (abstract)	√ (abstract)	√	√	√
	Object Oriented	ABM	√	√	√	√	√	√	√	√	√	√

& Dueñas-Osorio 2013; Schneider et al., 2011). Thanks to their level of abstraction, CN models have relatively few parameters and their behavior can be explored somewhat comprehensively. General considerations and behaviors can be easily inferred. By contrast, physical models of real systems can have many parameters which are even difficult to measure in the real infrastructure. Thus, the interesting behavior of the CN models, i.e. power law distributions of cascade size, optimal interconnectivity and systemic risk, has served as hypotheses to test and refine in more realistic models (D'Souza et al., 2014). On the other hand, CN topological approaches do not seem to correctly model and represent the power grid (Eusgeld et al., 2009; Hines et al., 2010) because they model failure propagation in power grids as an epidemic spreading with local propagation effects. In fact, the failure of a component in the power grid causes an almost instantaneous rerouting of the power flow following Kirchhoff laws with distant non-local effects.

Physic-based models embedding power flow equations complement the information on the topological structure of the system with physical parameter and represent non-local cascading effects. Physic-based models are used in the energy hub concept (Geidl & Andersson 2007). Energy hubs are considered as interconnection points among energy-carrier networks (electricity, gas and heat) which are modeled within a power flow approach. In contrast to CN and network flow models (Quelhas et al., 2007), power flow models incorporate constitutional physical laws, such as the relation between voltage and current, pressure and flow, etc. These relations are system specific and have to be adapted to represent the individual types of energy flows.

Thanks to the great computer power available nowadays, CN theory models are outperformed by reduced-order physical models, e.g. DC power flow in power grids. Nonetheless, power-flow models alone lack the capability of capturing time-varying interdependencies and discrete processes, e.g. cascading failures, therefore, it is advisable to integrate them into approaches such as ABM to represent discrete event-driven processes (Schläpfer et al., 2008; Nan et al., 2013).

Nonetheless, when the boundaries of the analyzed CI are pushed forward to embrace the continental scale, e.g. in Carvalho et al., (2014) for the gas supply network, CN approaches may be only solution for a feasible analysis.

5.2 *Information and communication*

High-fidelity simulation of communication networks based on ABM is employed for the analysis of network problems and validation of models of communication networks (Riley et al., 2004). These high-fidelity simulations require high computational demand, which can be overcome either by distributing the simulation across multiple networked processors, which results in faster simulation, or by setting up the distributed simulation as a federation of several simulators, which allows simulating larger networks.

Simulators for such discrete-event systems have the capability of accommodating physical processes in communication networks, i.e. MAC addresses, but they may fail in integrating with other models for interdependent infrastructures due to their computational burden which hinders their interfacing.

Interdependencies between communication networks and other infrastructures can be assessed by analytical approaches based on DCST (Casalicchio et al., 2011). Transfer functions of the system and its components are defined and characterized to couple them and interdependent infrastructures. In order to create high-fidelity DCST models, ABM simulation of the communication networks must be used to validate the analytical models before their inclusion in a hybrid model/simulation approach for interdependent infrastructures.

5.3 *Transport (rail, road)*

The ABM approach is employed in the modeling of car traffic because it is able to capture individual drivers' preferences (Galus et al., 2012). In particular for electric car mobility, ABM takes advantage of high resolution road network maps and allows for an accurate mapping between the transportation network and the electricity infrastructure. However, in order to evaluate interdependencies between road and electricity network, detailed data on the electric equipment, drivers' behavior, and power demand are needed.

When such detailed data are missing or when the knowledge of individual driver's behavior is not needed, the transportation infrastructure and vehicle traffic can be modeled using CN and network flow model (Lee et al., 2007). PN have been employed when the objective of the analysis is the estimation of delays in the rail system (Trantopoulos 2011).

ABM was also proposed to assess the impact of electric blackout on the railway infrastructure, and the interdependencies between the latter and alternative transportation networks through the customers' behavior (Balducelli et al., 2005).

SD is suggested to assess the impact of the railway infrastructure on the stability of the electric infrastructure (Genge et al., 2013).

Table 2 summarizes the suggestions of specific modeling and simulation approaches for their use

Table 2. Suggestions of specific modeling and simulation approaches for their use in the hybrid modeling/simulation approach which encompasses multiple interdependent CI.

	Electricity	Gas	ICT	Rail	Road
Electricity		ABM + physical CN (network flow)	DCST ABM BN	ABM	SD
Gas	ABM + physical				
ICT	ABM DCST				
Rail	SD				ABM
Road	ABM				

in hybrid modeling/simulation approaches which encompass multiple interdependent CI. Each cell (*i*, *j*) of Table 2 contains the approaches that are suggested when we want to assess the impact of the infrastructure *i* on infrastructure *j*. Interdependencies between the electric infrastructure and other infrastructures are better understood as it appears from the first row and column which are fully populated. The electric infrastructure is indeed the major coupling point between the other multi-energy energy networks and infrastructures.

On the other hand, empty cells identify interdependencies between infrastructures that are not well understood or for which data are scarce. When this is the case, approaches that model the entire infrastructure as an individual element, i.e. IIM, SD and DCST, can be tailored on the basis of economic data, empirical observations and expert judgment. As an example, IIM can be used to model the infrastructure as a whole entity and the magnitude of the interdependencies can be approximated by the flow of value between them.

6 CONCLUSIONS

This paper proposes a framework for selecting the hybrid modeling and simulation approach which is more suitable to the analysis of a specific type of SoS, and which can be integrated into existing frameworks for the vulnerability analysis of CI. Although the selection is CI-specific, general conclusions can be drawn.

Approaches that can embed physical laws are promising, i.e. ABM has capability of representing the complexity of CI through bottom-up modeling of its elements and does not explicitly assume interdependencies. ABM can be integrated with many other modeling/simulation techniques including physical laws and can be applied to reliability, vulnerability and resilience analysis, as well as to CI planning and operations optimization.

The selection of hybrid approaches strongly depends on the required level of the detail of the analysis, on the granularity in system representation and on data availability. Nonetheless, there are approaches that are outperformed irrespective of the required level of detail. In the electricity infrastructure, DC power flow is a valid alternative to CN theory.

Reduced-order models, i.e. CN, SD and DSCT, can enhance the feasibility of hybrid modeling and simulation approaches but the adherence to real system behavior must be validated by high-fidelity simulations.

Time dependent gas transmission network probabilistic simulator: Focus on storage discharge modeling

V. Kopustinskas & P. Praks
European Commission, DG Joint Research Centre, Institute for Energy and Transport
Energy Security Unit, Ispra, VA, Italy

ABSTRACT: The overall aim of the ProGasNet (Probabilistic Gas Network Simulator) project is to develop the European gas transmission network probabilistic model capable to analyse reliability and risk aspects of the network under normal load and extreme crisis situations. The paper presents extension of the existing probabilistic Monte-Carlo based gas network model of 1-day to longer periods of up to 30 days when storage supply might be important to overcome crisis or network equipment failures. The study test case represents a country transmission network model and impact of storage supply under various crisis situations is presented and various network management options are discussed.

1 INTRODUCTION

Recent gas supply crisis in Europe (Russian-Ukrainian gas disputes in 2006, 2008, 2009; Libyan crisis in 2011) affected many consumers and challenged security of gas supply to Europe. The gas dispute in January 2009 between Russia and Ukraine resulted in gas supply disruptions to many EU countries. This event stimulated to look at security of gas supply issue from political, technological and research perspectives. The EU Regulation (2010) which appeared after the 2009 crisis highlights importance of security of gas supply in Europe and proposes a number of measures by improving network resilience and encouraging EU countries to cooperate more by sharing infrastructure and building interconnections.

The overall aim of the ProGasNet (Probabilistic Gas Network Simulator) project is to develop the European gas transmission network probabilistic model capable to analyse reliability and risk aspects of the network under normal load and extreme crisis situations. The paper presents extension from 1-day simulation model (Praks & Kopustinskas, 2014) to longer periods of up to 30 days when storage supply might have an important role to overcome crisis situations.

Computational studies of energy networks and infrastructures are increasingly important in the current world of challenging crisis and disruptions. Risk, reliability, vulnerability, resilience issues in various networks have been analysed by many researchers (Ball et al., 1992; Johansson et al., 2013). The most recent focus is however on security of supply aspects in the infrastructure networks (E. Zio et al., 2012).

Reliability analysis of energy infrastructure networks present a number of challenges as many network analysis algorithms (optimal distribution of capacity, rerouting of flows etc.) originally developed for telecommunication networks are not directly applicable. The main reason for this is physical properties of energy transport when the flows can be exchanged from the nearest source and do not necessarily need to be transport through the whole network as is the case in case of information transmission.

2 METHODOLOGY

The gas transmission network model is based on maximum flow algorithm well known in graph theory (Deo, 2008). The algorithm was modified to reflect gas transport property to have lower pressure at the points far from the supply source. This means that in case of disruption and lack of gas in the network, consumers that are closer to the source have better chances to be served rather than those that are located far away. Therefore, the maximum flow algorithm was modified to distribute gas first to the consuming nodes close to the supply source and distance from the nearest source was used as a priority criteria.

Let f represent the amount of flow in the network from node 1, called the source, to node m, called the sink. With each arc (i, j) a non-negative flow is associated having an upper bound of u_{ij}. Then

the maximal flow problem may be mathematically formulated as an optimization problem with constrains:

Maximize f subject to

$$\sum_{j=1}^{m} x_{ij} - \sum_{k=1}^{m} x_{ki} = \begin{cases} f & if\ i = 1 \\ 0 & if\ i \neq 1\ or\ m \\ -f & if\ i = m \end{cases} \qquad (1)$$
$$x_{ij} \leq u_{ij},\ i, j = 1,\ldots,m$$
$$x_{ij} \geq 0, \quad i, j = 1,\ldots,m,$$

where the sums and inequalities are taken over existing arcs in the network. Here the symbol x_{ij} represents the flow from node i to node j. This is called the node-arc formulation of the MF problem since the constraint matrix is a node-arc incidence matrix (Bazaraa, 2010).

The aim of this optimization problem (1) is to masximize the value of f which represents the amount of flow passing from the source node to the sink node. The first constrain represents a conservation of flows: the sum of the flows entering a node must equal the sum of the flows exiting a node, except for the source node and the sink node. The second constrain represents capacity: the flow of an edge is non-negative and cannot exceed its capacity.

The optimization problem of the MF problem can be solved by various approaches, for example by linear programming or by Ford–Fulkerson algorithm, which finds directed paths from the source node to the sink node with available capacity on edges in this path. In the algorithm, this path-searching process is repeated until no additional flow can be added to this directed path. The algorithm uses the concept of so called residual networks (Ahuja et al., 1988), which represents the maximum additional flow that can be sent from any node i to any node j using the arcs (i, j) and (j, i).

The case of multiple sources and sinks, involving several source nodes $s_1, s_2, \ldots, s_k$ and several sink nodes $t_1, t_2, \ldots, t_r$, and where the flow from any source can be sent to any sink, it is known as Multiple Sources and Sinks problem, and can be straightforwardly converted into a one-source and one-sink problem by introducing a supersource s (virtual source node) with edges (of unlimited capacity) directed from this supersourse s to all source nodes $s_1, s_2, \ldots, s_k$. Furthermore, a supersink node t (virtual source node) is introduced with edges (also of unlimited capacity) directed from all sink nodes $t_1, t_2, \ldots, t_r$ to t. Then the problem of maximizing the total value of the flow from all sources is then the same as that of maximizing the value of the flow from s to t.

In order to concurrently model both reliability and capacity constraints of the gas transmission network, stochastic network representation is used, where each node and edge of the flow network can randomly fail, according to a predefined probabilistic model. The component failures in the network are modelled by the Monte-Carlo simulation technique.

The algorithm has these inputs:

- The capacity matrix C that provides information about capacity constraints of the network elements including input source nodes, demand nodes and information about connected pipeline capacities;
- The length matrix L that provides information about length of the edges between nodes. This matrix is used to generate pipeline failures in the network;
- Component failure probabilities and failure consequences to the network operation;
- Supply and demand data for each node in the network.

The output of the algorithm is an optimal flow matrix F satisfying for each Monte-Carlo step the relation (1) and the distance based supply pattern, in which the nodes closer to the source are served first. In order to correctly model the priority supply pattern based on the distance from the source node for the case of tasks with multiple sources and sinks, additional conditions has to be introduced. For a task with multiple sources, the links between the virtual source node s and the source nodes $s_1, s_2, \ldots, s_k$ are assumed to be unidirectional. It also means that the virtual source node cannot be reached from source nodes. This condition is expressed in the length matrix by adding further constrains: infinite distance. The same is valid in case of multiple sinks.

At the initial stage of the computational process, for each Monte Carlo simulation run, network configuration is generated by using failure probability matrix P. This step defines which network components are operating and which are failed. The total failure of the network element causes the component inaccessibility, which can be coded in the algorithm by an infinity distance penalty. The length matrix must be updated accordingly. The algorithm can be also used for modelling the partial failure of a multi-state component, which can be expressed by a partial reduction of the component capacity. In the next step distance vector is computed. It contains the distance of the shortest paths between the virtual source node and all remaining non-virtual nodes. For this purpose, Matlab tool Bctnet (Rubinov and Sporns, 2010) based on Dijkstra's algorithm was used. Contrary to the classical Dijkstra's algorithm, it is not necessary to compute the full distance matrix, as only the distance from the virtual source node is used

in the developed algorithm. The distance vector is used to prioritise the supply in case of lack of available gas in the network due to disruption scenarios or component failures. At the last step flow matrix F of the Maximum flow algorithm is computed. The aim is to maximize the flow from the virtual source node 1 to the virtual sink node t, according to given constrains by using Ford–Fulkerson algorithm. The resulting flow matrix F is ready for further exploration by statistical methods in order to estimate lack of gas probability and determine the weakest nodes in the network.

3 TEST CASE

Figure 1 shows topology of the test case gas transmission network. It is based on a real country network topology and data, however geographical locations are not displayed.

Table 1 shows types of nodes used in the test network. The virtual supersource node 1, virtual supersink sink node 47 and other virtual nodes (used for computational purposes only) are not shown in the Table 1. The test case network contains major elements of the gas transmission network. The network is supplied by pipelines and no LNG terminal is available. Table 2 shows maximum capacities of input supply nodes in millions of cubic meters (mcm) per day. It should be noted that maximum shown UGS supply capacity decreases with time.

The total maximum supply capacity is 24.7 mcm per day. The total network demand (Node 47) is 16.8 mcm/d, so the network has certain degree of spare capacity to compensate supply disruptions.

The probability failure matrix P is based on the following annual failure rates:

- Compressor Station (CS) failure: 2.5E-01/yr;
- UnderGround Storage (UGS) failure: 2.5E-01/yr,
- Pipeline failure: 3.5E-05 /km/yr.

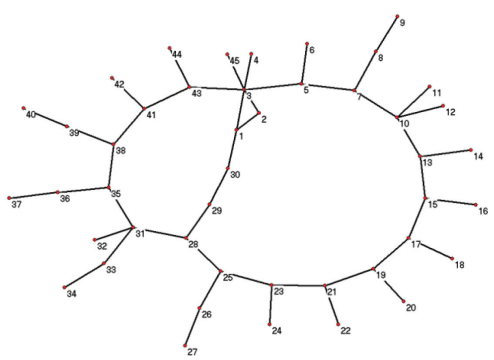

Figure 1. Topological layout of the test case network.

Table 1. Types of network nodes: CS—Compressor station; UGS—underground storage; D—demand nodes (millions of cubic meters per day).

Node type	Node no.	Demand, mcm/day	Node type	Node no.	Demand, mcm/day
CS	2	0	D	24	0.022
CS	3	0	D	26	6.319

D	16	2.109	D	42	0.6
D	18	1.158	D	44	0.258
D	20	0.089	D	45	0.072
D	22	0.532			

Table 2. Maximum supply capacity.

Node	Capacity, mcm/day
1->2	19.2
1->30	4.3
1->3	1.2

The CS failure rate was computed using a typical model of CS station and industrial reliability data. The UGS failure is modelled assuming the same probability of failure as a compressor station which is an assumption due to lack of reliable data. The pipeline failure rate was taken from EGIG (2011) incident database and assuming that rupture occurs 10 less frequently as incident.

As a consequence due to a CS failure, capacity reduction by 20% of the inlet pipelines and also the outlet pipelines until the next connection node is assumed. This assumption is based on physical flow models, however is not accurate in all cases and also multiple CS failures will have more severe effects on the network operation. Further research is planned in order to estimate the effect of CS failures more accurately.

4 STORAGE DISCHARGE MODELING

A number of studies have already been completed by using probabilistic gas network model (Praks & Kopustinskas, 2014) for 1-day duration. The present study case includes storage facility and 1-day model cannot capture the effect of reduced

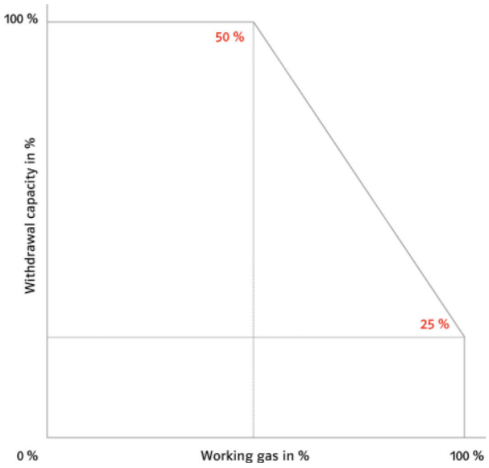

Figure 2. Typical storage withdrawal curve.

Table 3. Time steps and possible duration at lower discharge levels.

Time step	Duration, days	Discharge, mcm/d
1	15	4.3
2	45	3.0–4.2
3	40	2.0–3.0
4	40	1.0–2.0
5	–	0

flow from storages if disruption continues for a long period. The model was extended to be able to model disruptions in a time dependent manner for many days.

Figure 2 shows typical storage withdrawal pattern. In fact, maximum withdrawal capacity (Node 30 in Table 2) can be maintained only until 50% of the total storage capacity is reached and then linearly decreases. The minimum discharge capacity is about 25% of the maximum discharge capacity.

Assuming 70% level of the UGS in the present case study at the moment of disruption, maximum discharge level can be maintained for 15 days. Duration for lower supply levels are shown in Table 3. The model simulations in a time-dependent manner can be performed for each day, however due to memory limitations, 4 time steps were used, assuming minimum flow available. Time step 5 was also used reflecting empty storage situation.

5 DISRUPTION SCENARIOS

The probabilistic model takes into account internal component failures: pipelines, compressor stations and other facilities (storages, LNG terminals if present). However, external import supply by pipeline is not probabilistically modeled because of a number of reasons:

– Lack of upstream pipeline system model;
– Difficult to estimate numerically possible political/social origin of the disruption (e.g., Libyan war or Russian-Ukraine gas dispute);

The focus of the current study is on storage importance to address supply crisis, therefore only 3 scenarios were analysed in detail:

Scenario A: all facilities and input sources operate as expected;

Scenario B: storage facility is unavailable.

The storage discharge is modeled in Scenario A with 4 time steps (see Table 3).

The model results are obtained by running 1 million Monte Carlo simulations.

6 MODELING RESULTS

The modeling results for 1-day are shown in Table 4 (Scenario A) and Table 5 (Scenario B). The time-dependent storage discharge effects are modeled by additional simulations and results are reported

below in this section. By interpreting the results, the following model features should be considered:

- Failures are simulated on annual basis;
- No more failures nor repairs can occur during time-dependent phase of the simulation;
- Demands are assumed to be maximum peak demands throughout the year.

Under scenario A the overall network reliability is good enough, as probability to supply less than required maximum demand (D) is 1.1E-01 per year and probability to supply less than 80% of demand is only 8.8E-04 per year, see Figure 3 for details. Looking at the specific locations, Node 22 seems to be the weakest point of the network but its demand is low. Probability to supply less than demanded volume is 1.1E-01 per year, in fact very close to overall network non-supply probability. The other nodes with the highest probability of non-supply are 20, 24,26 and 27, but their corresponding probability is much lower: 1.6E-02 per year of having less than demanded gas. In case of Node 26 (high demand node) the probability to have no gas at all is very low: 2E-04 per year, and less than 50% of maximum demand: 2.7E-04 per year. The model allows quantification of the obvious advantage of ring gas network structure against the tree structure (Praks & Kopustinskas, 2014). Other network nodes have lower non-supply probabilities and indicate relatively reliable supply situation.

Under Scenario B (UGS is not available) the network is affected, but at rather moderate levels in terms of severity. Nodes 22 remains the weakest link (complete annual loss of supply probability is 4.368E-01) and Nodes 20, 24, 26 and 27 are second weakest points (complete annual loss of supply probability is 6.4E-02) of the network as they are geographically situated far from the single supply source. However, Node 26 (high demand node) supply situation is much better compared to other weakest points as its complete loss of supply probability differs significantly (6.4E-04 per year). The total network probability of supply less than demanded is 4.374E-01 per year and Node 22 is the major contributor to this probability. Probability to have less than 50% of demanded gas in the network is significantly lower: 6.4E-04 per year. Figure 4 provides more details on CDF of the total loss of supply probability.

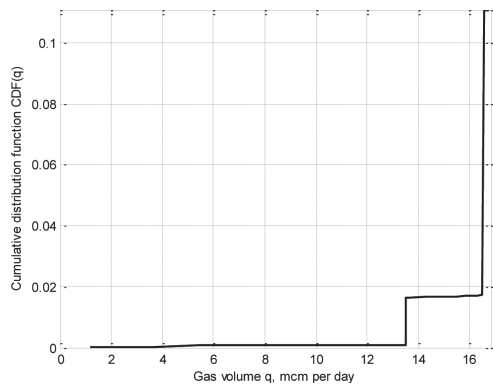

Figure 3. Cumulative distribution function of the total network supply under scenario A.

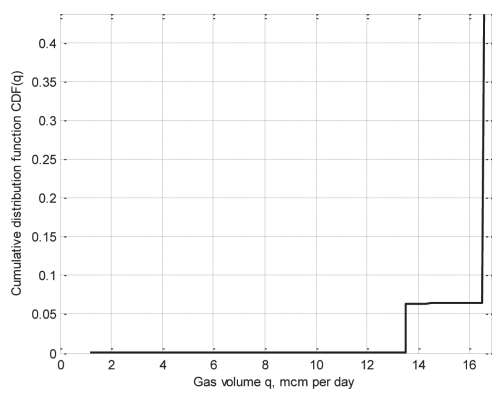

Figure 4. Cumulative distribution function of the total network supply under scenario B.

The next set of computations was performed for different time steps as presented in Table 3. The results show the effect of storage discharge volumes available for the consumers, see Table 6.

Figure 5 shows CDF at different time steps and the effect of storage supply can be quantified. Computations were performed for different supply levels at the main pipeline connection (Node 2), having maximum capacity of 19.2 mcm per day (Table 2). The following hypothetical supply capacity of Node 2 was analysed:

15 mcm per day (Figure 6);

13 mcm per day (Figure 7);

10 mcm per day (Figure 8).

The effect of storage supply is well visible in these CDF plots and can be quantified. For example, when full input capacity is available, probability to get less than 80% of demanded gas is rather low and is estimated to be 1.2E-03 per year even if storage is unavailable (Table 6). However, if Node 32 supply capacity is reduced to 10 mcm per day (almost 50% reduction) then probability to get less than 66% of the demanded gas reaches one at time step 3 (after 60 days). The results are available for each node, however they are most interesting at the total network level.

Using the probabilistic network model, many hypothetical scenarios can be tested in order to

Table 6. Estimated probabilities of the total available gas in the network at different Time steps (Ts).

Ts	P(X = 0)	P(X < 0.5D)	P(X < 0.8D)	P(X < D)
